Background. Although techniques for off-pump coronary artery bypass grafting (CABG) are continually being refined, angiographic follow-up studies have indicated a higher rate of anastomoses-related stenoses than expected after traditional on-pump CABG. This study was performed to evaluate the use of intraoperative epicardial color Doppler ultrasound to quality-assess left internal mammary artery (LIMA) to left anterior descending coronary artery (LAD) anastomoses performed on the beating heart.

Methods. Twenty-four LIMA-to-LAD anastomoses were evaluated with real-time epicardial ultrasound imaging using an ultrasound transducer positioned between the paddles of the stabilizer during off-pump procedures. The length of the anastomosis (D_A), diameters of LIMA (D_M), LAD at the toe of the anastomosis (D_1), and 5 mm distally to the anastomosis (D_2) were measured, and the ratios between these variables were calculated. The flow velocity through the anastomoses was visualized by color Doppler coding, and flow was assessed with transit-time flowmetry.

Results. The epicardial color Doppler ultrasound allowed accurate assessment of the anastomoses. Twenty-three (96%) of the primary anastomoses were confirmed as patent. Mean ratios of D_1/D_2, D_A/D_2, and D_M/D_2 were 0.89 ± 0.13, 3.01 ± 1.04 and 1.32 ± 0.32, respectively. One anastomosis had a stenosis more than 50% detected by color Doppler ultrasound. After surgical revision, transit-time flow increased from 22 to 40 mL/min.

Conclusions. Intraoperative color Doppler ultrasound allowed adequate imaging for quality assessment of LIMA-to-LAD anastomoses performed on the beating heart. One anastomosis was revised due to a technical error detected by epicardial color Doppler imaging. Epicardial ultrasound scanning is a valuable tool for intraoperative assessment of LIMA-to-LAD anastomoses during off-pump coronary surgery.

preoperative angiograms. Furthermore, ultrasound imaging allowed evaluation of the morphology of the anastomoses and a semiquantitative assessment of the flow velocity at the anastomotic site [8].

Based on our previous positive experience with on-pump CABG, we decided to test the device during OPCAB procedures. The present study was designed to establish a valid method of intraoperative quality-assessment of left internal mammary artery (LIMA) to left anterior descending artery (LAD) anastomoses with epicardial color Doppler ultrasound during off-pump surgery.

**Material and Methods**

**Patient Selection and Demographics**

Twenty-four consecutive patients (17 men and 7 women; 63.1 ± 8.0 years) scheduled for elective off-pump CABG were included. Their clinical characteristics were stable angina (CCS class II: 13, CCS class III: 11), one- or two-vessel coronary disease, and mean left ventricular ejection fraction of 0.70 ± 0.10. The protocol was approved by the Regional Board of Ethics in Medical Research. Informed consent was signed before inclusion. All patients received a LIMA graft anastomosed to the LAD and 13 patients received an additional graft (1 patient had a right internal mammary artery to the right coronary artery, 1 patient had a radial artery graft to the posterior descending artery, 1 patient had a saphenous vein graft to right coronary, 3 patients received a saphenous vein graft to posterior descending artery, and 2 patients a saphenous vein graft to a diagonal branch).

**Surgical Technique**

All operations were performed by the same surgeon (R.H.). Median sternotomy was used in all cases. After full heparinization (3 mg/kg), the LIMA was harvested with its pedicle and a diluted solution of papaverine was injected intraluminally. The activated clotting time was not allowed to drift below 270 seconds. The LAD was identified and snared with a 4-0 pledgeted polypropylene suture (Prolene; Ethicon, Somerville, NJ) proximally to the incision. After 3 to 5 minutes of ischemic preconditioning, the snare was released and an epicardial stabilizer was used to immobilize the target site chosen for grafting. After the incision of LAD, an intracoronary shunt (CardioThoracic Systems, Inc, Cupertino, CA) was positioned into the vessel lumen and the coronary anastomosis was performed using a continuous 7-0 or 8-0 (Prolene) suture. The LIMA pedicle was secured with two epicardial stitches using 7-0 polypropylene on both sides. After assessment of the graft, heparin was reversed with protamine. The stabilizer was then removed.

**Epicardial Ultrasound Scanning**

After completing the LIMA-to-LAD anastomosis, with the stabilizer still in place, epicardial color Doppler scanning of the anastomosis was performed by means of a linear array 10 MHz GE Vingmed transducer (foot-print 27.3 × 9.6 mm) connected to a GE Vingmed System FiVe echocardiography unit (GE Vingmed, Horten, Norway) [8]. With sterile gel as conduction medium, the sterilized transducer was applied directly onto the epicardium between the paddles of the stabilizer (Figure 1). Real-time ultrasound images and storage of data for later analysis were obtained within approximately 10 minutes in each patient. The ultrasound images were stored as digital data for later analysis using the Echo PAC software (GE Vingmed).

The quality of the images was rated good when both the anastomosis and the distal run-off in the coronary artery could be well visualized. Images obtained from anterior-posterior and transverse planes were used to assess the quality and patency of the anastomosis. The length of the anastomosis proper (Dₐ), the diameters of LIMA (Dₐ), LAD at the toe of the anastomosis (D₁), and 5 mm distally to the anastomosis (D₂) were measured (Figure 2). D₂ was defined as the reference diameter; the ratios D₁/D₂, Dₐ/D₁, and Dₐ/D₂ were calculated to visualize the geometry of the anastomosis.

**Transit-Time Flowmetry**

Intraoperatively, before chest closure, graft flow was measured with transit-time flowmetry (Medi-Stim Butterfly Flowmeter, Oslo, Norway) using sterile gel as conduction medium [2].
Statistical Analysis

Data normally distributed were described as arithmetic mean and standard deviation (SD) was the measure of variability. Skewness test was used to test the distribution of the data. Skewed data are presented as median and range. A two-sampled Student’s t test was used to evaluate differences in normally distributed continuous data. Skewed distributed continuous data and categorical data were analyzed with the nonparametric Mann-Whitney test. Linear regression was used to evaluate the correlation between LAD flow rate and the D1/D2 ratio. A \( p \) value of less than 0.05 was considered statistically significant. Statistical analyses were performed with the NCSS program (Number Cruncher Statistical System, Kaysville, UT).

Results

No postoperative mortality or myocardial infarctions were observed. Epicardial scanning did not cause cardiac arrhythmia or hemodynamic instability in any of the patients. The transducer allowed an easy approach to the LIMA-to-LAD anastomoses.

Table 1. Measurements of the LIMA-to-LAD Anastomosis Assessed by Epicardial Ultrasound Scanning in the Anterior-Posterior Plane

No statistically significant difference was observed between D1 and D2 in the entire group. All other dimensions as well as ratios were significantly different from each other (D1 versus D2, NS; D1 versus D3, \( p < 0.001 \); D1 versus D4, \( p < 0.001 \); D2 versus D3, \( p < 0.001 \); D2 versus D4, \( p < 0.001 \); D3 versus D4, \( p < 0.001 \); D1/D2 versus D3/D2, \( p < 0.001 \); D1/D2 versus D4/D2, \( p < 0.001 \); D3/D2 versus D4/D2, \( p < 0.001 \).)

LIMA = left internal mammary artery; LAD = left anterior descending coronary artery; DA = length of the anastomosis proper; DM = diameter of left internal mammary artery.

Twenty-three (96%) anastomoses were fully patent according to color Doppler imaging (Figure 3), with median transit-time flow rate 29 mL/min and a range from 7 to 72 mL/min. Measurements of D1, D2, D3, and D4 as well as the ratios D1/D2, D3/D2, and D4/D2 are presented in Table 1. No statistically significant difference was observed between D1 and D2 in the entire group. All other dimensions and ratios were significantly different from each other (Table 1). No significant correlation was observed between LAD flow and the D1/D2 ratio (\( r^2 = 0.05, p = 0.1 \)). Nine anastomoses (38%) with D1/D2 less than 0.9 (mean 0.79 ± 0.14) had a minor intraluminal echo-dense protrusion observed at the toe.

To assess whether a decreased D1/D2 ratio could limit graft flow, we decided to compare LIMA-to-LAD flow between patients with D1/D2 ratio below the mean value (0.89) with the graft flow observed in patients with a D1/D2 above the mean value. No difference in LIMA-to-LAD flow was observed between D1/D2 more than 0.89 versus D1/D2 less than 0.89 [27 (16 to 69) mL/min versus 22 (7 to 72) mL/min, respectively; \( p = 0.57 \)]. In one anastomosis the D1/D2 ratio was 0.43, and a large echo-dense protrusion as well as an increased flow velocity were observed in the color Doppler image on longitudinal and transverse views. Despite a transit-time flow rate of 22 mL/min, the ultrasound findings were suggestive of a more than 50% stenosis at the toe of the anastomosis. Revision of the anastomosis revealed an intimal flap in the LAD. After revision, the transit-time flow rate increased to 40 mL/min.

Comment

The present study demonstrates that epicardial color Doppler scanning with a new 10 MHz GE Vingmed transducer provides satisfactory visualization of LIMA-to-LAD anastomoses, allowing accurate measurements...
of the length of the anastomosis proper \((D_{Aa})\), diameters of LIMA \((D_{La})\), LAD at the toe of the anastomosis \((D_{Lc})\), and 5 mm distally in the downstream LAD \((D_{2})\). Furthermore, we were able to detect a stenosis in the anastomosis presenting with a normal transit-time flow pattern. Epicardial scanning did not cause cardiac arrhythmia or hemodynamic instability in any of the patients.

A patent LIMA-to-LAD graft is the single most important determinant of long-term and event-free survival and imperfect graft anastomoses have a poor long-term patency after CABG [9, 10]. Epicardial color Doppler scanning allows an accurate assessment of the LIMA-to-LAD anastomoses and provides three important pieces of information: visualization of the anastomosis and its components (LAD and LIMA); measurement of the length of the anastomosis proper as well as the diameters of the LAD downstream and the LIMA; and color Doppler assessment of blood flow velocity at the anastomotic site. The necessary measurements were obtained easily without risk of any complications, are not time consuming, and provide important information about the geometry and the flow pattern of the anastomosis.

Minor intraluminal protrusions at the toe were observed in nine of the anastomoses with a \(D_{1}/D_{2}\) ratio of less than 0.9. Incongruence or a slight bulging at the edges of the vessel walls where the graft and the LAD are joined together may explain these findings. However, no major changes in blood velocity were observed at these sites. Anastomoses may develop temporary edema, hematoma, and spasm, and some angiographic follow-up studies have suggested that some FitzGibbon B lesions seen with immediate or early postoperative angiography have spontaneously resolved at later coronary angiography [9, 11]. Transit-time flowmetry has been widely used to evaluate the quality of distal anastomoses after CABG. However, the lowest acceptable flow value in the LIMA graft has not been defined and graft revision has been advised when flow ranges from 5 to 20 mL/min [4, 12]. This wide range indicates that the mean graft flow alone is not a reliable measurement for graft assessment, unless the stenosis is more than 75% to 90% [13, 14]. The only anastomosis with a marked stenosis observed in the present study was detected by epicardial imaging in a patient with a LIMA transit-time flow rate of 22 mL/min. During surgical revision, an intimal flap at the toe of the anastomosis was detected. After revision LIMA flow increased to 40 mL/min. Intimal flap is a well-known technical failure of the anastomosis, along with thrombosis, stenosis at the heel, coronary dissection, LIMA dissection, and vessel stenosis distal to the graft [4, 15, 16]. The epicardial color Doppler scanning technique used in the present study may be considered the only method advised when any LAD lesion caused by snares or intraluminal shunts with intraoperative epicardial color Doppler scanning.

However, our patient cohort will undergo angiographic follow-up to evaluate whether stenosis at these sites develop over time.

Previous experimental and clinical studies have demonstrated that the assessment of the technical adequacy of bypass grafts may be enhanced by the use of epicardial echocardiography [5–7, 18, 19]. The main reason why epicardial echocardiography has not gained more popularity is the large size of the ultrasonic probe, allowing only the visualization of LAD, diagonals, and proximal right coronary artery [5–7, 18, 19]. Coronary branches located laterally or at the back of the heart could be scanned only during CPB because the dislocation of the heart caused hemodynamic instability. When performing OPCAB through a median sternotomy, the heart is exposed with pericardial stitches and modern stabilizers, allowing epicardial scanning of coronary vessels also on the inferior and lateral walls. In the present study we emphasized quality assessment of LIMA-to-LAD anastomosis. However, the design of the transducer allows epicardial imaging of all areas, and we plan to use it for assessing all distal anastomoses with the stabilizer still in place in future studies.

The early-generation transducers were able to provide only tissue images. In this study the color Doppler modality was obtained as a semiquantitative measure. Although color Doppler imaging may be given as an absolute velocity with the device used in our study, this measurement is still not reliable intraoperatively in a clinical setting because of difficulties in adjusting for the angle created between the transducer and the blood flow within the vessels. The latter problem points out that the technology of intraoperative color Doppler imaging in off-pump coronary surgery still needs further development, and the prognostic value of graft patency has yet to be evaluated by follow-up angiography. The introduction of this new transducer for epicardial imaging of small vessels with color Doppler features may enhance the widespread use of epicardial scanning in coronary artery surgery.

**Conclusions**

The present study demonstrated that epicardial color Doppler scanning with the new 10 MHz GE Vingmed transducer provides visualization of LIMA-to-LAD anastomoses that allows accurate measurements of the anastomosis. All these measurements are easily obtained without risk of any complications, are not time-consuming, and provide important information about the geometry and flow pattern of the anastomosis. The introduction of this new transducer for epicardial imaging of small vessels with color Doppler features may enhance the widespread use of epicardial scanning in coronary artery surgery.
