Abstract: This paper presents the application of a generalized super-twisting algorithm to estimate a critical variable needed for implementing real time optimization feedback controllers in a certain class of bioreactors. A bank of redundant super-twisting observers designed for equivalent systems under a state transformation is used. The procedure is motivated by the fed-batch cultivation of a strain of E. coli that has overflow metabolism, where a useful variable to estimate is the difference between two reaction rates. The results show the applicability of the procedure and illustrates some compromises between the accuracy and the measurement noise.

Keywords: Biotechnology; observers; super-twisting algorithm; fermentation processes; parameter estimation; variable-structure systems.

1. INTRODUCTION

Under fed-batch growth, the catabolism of certain strains of E. coli has a limited energy production for cell growth and division originating from a limited capacity to oxidize the main substrate, usually glucose. The excess part of this nutrient then can follow another metabolic pathway more commonly known as fermentation, producing a by-product which is generally a growth inhibitor, e.g. acetate. This is called overflow metabolism (Crabtree, 1929) and there exist validated mathematical descriptions of the phenomenon (Rocha, 2003).

The mathematical model considered here is a simplification of the one presented by Dewasme et al. (2011) and it involves only the biomass \(X\), the substrate \(S\), the dissolved oxygen \(O\) and CO\(_2\) \(C\) concentrations:

\[
\frac{\dot{\xi}}{\xi} = K_r \rho X - \xi u + f, \quad \xi(0) = \xi_0,
\]

where \(\xi = [X, O, C, S]^T\) is the state vector, \(K \in \mathbb{R}^{4 \times 2}\) contains the pseudo-stoichiometric coefficients, \(u = Q_{\text{INT}}/V\) is the dilution rate, and \(f = [0, f_{\text{OTR}}, -f_{\text{CTR}}, S_n u]^T\) is the vector of gas and mass flow rates in and out of the reactor; \(f_{\text{OTR}}\) and \(f_{\text{CTR}}\) are the oxygen and CO\(_2\) transfer rates, respectively, while \(S_n\) is the inflow substrate.

concentration. The by-product (acetate) is not included in this model and thus the specific reaction rate vector is only given by \(\rho = [r_1, r_2]^T\), where \(r_1\) is the respiration rate and \(r_2\) is the fermentation rate:

\[
r_1 = \min (r_S, r^*_S), \quad r_2 = \max (0, r_S - r^*_S). \quad (2)
\]

These definitions of the rates lead to either a respirative regime, when \(S(t) < S^*\), or a respiro-fermentative regime when \(S(t) > S^*\). Substrate (glucose) is consumed in any case with rate \(r_S\), which follows a Monod model,

\[
r_S = \mu_S \left( \frac{S}{S + K_S} \right). \quad (3)
\]

Although it is not modeled here, acetate is produced in respiro-fermentative regime, but only slowly consumed in respirative regime. This by-product is inhibitory for biomass growth, as its accumulation decreases the critical consumption rate \(r^*_S\) as follows:

\[
r^*_S = \mu^*_S \left( \frac{O}{O + K_O} \right) \left( \frac{K_{IP}}{K_{IP} + P(t)} \right), \quad (4)
\]

where \(\mu^*_S\), \(K_O\), and \(K_{IP}\) are constants and \(P(t)\) is the product (acetate) concentration. The best strategy for enhancing biomass production without accumulating acetate is thus to operate in the boundary between regimes, i.e. maintaining \(S(t)\) at the critical value \(S^*\), where \(r_S(S^*) = r^*_S\). However, \(S^*\) is not a priori known and furthermore it may change (decrease) slowly during the fed-batch cultivation if acetate accumulates.

For this reason real-time optimization (RTO) schemes have been proposed by Dewasme et al. (2011) and Vargas et al. (2012), which use a virtual output that is a linear combination of the two reaction rates in the process. Other schemes also assume the measurement of this output (Santos et al., 2012). This output is given by
\[ y = r_1 - r_2 = \gamma^T \rho \quad \gamma = [1, -1]^T. \]  
(5)

As a function of \( S \), this output reaches a maximum whenever \( S = S^* \); then \( y = r_2^* \). The controllers proposed manipulate the dilution rate \( u \) to keep \( y(t) \) near its optimum value at \( r_2^* \).

The problem is that this output cannot be measured directly. Dewasme et al. (2011) propose an algebraic approach to estimate it under the assumption of quasi-steady-state, perfect knowledge of the matrix \( K \), and measurement or knowledge of all the signals in \( f(t) \), but this approach has three disadvantages: (i) it will not work during transients, (ii) it is based on the inversion of a \( 3 \times 3 \) submatrix of \( K \), so it is very sensitive to the exactness of the model, and (iii) it estimates the quantity \( (r_1 - r_2)X \), so it will also become sensitive to the noise present in \( X(t) \) if we insist on estimating \( y = r_1 - r_2 \).

This work presents instead the use of a bank of redundant super-twisting observers to robustly estimate \( y(t) \), using only the on-line measurements of \( X \), \( O \), and \( C \) (using probes), as well as \( f_{\text{OTR}} \) and \( f_{\text{CTR}} \) (using a gas analyzer). Measurement of \( S \) is not needed, nor the knowledge of \( S_0 \). Knowledge of the matrix \( K \) is assumed, but if this is not possible, the methodology can be used to build an estimate of its underlying structure, given recorded data.

2. STATE TRANSFORMATION

Let us assume that \( n > m \) in the matrix \( K \in \mathbb{R}^{n \times m} \) of system (1) and rank(\( K \)) = \( m \). Consider \( p \geq 1 \) solutions \( a_j, j = 1, \ldots, p \) to the following linear equation:

\[ K^T a_j = \gamma. \]  
(6)

Then we can build the matrix

\[ A^T = [a_1 \; a_2 \; \cdots \; a_p] \in \mathbb{R}^{n \times p}. \]  
(7)

Note that each column of the matrix \( K^T A^T \) is equal to the vector \( \gamma \) and therefore each element of the vector \( A^T K \) becomes \( y = \gamma^T \rho \). Define a state transformation

\[ \zeta = A \xi, \]  
(8)

such that \( \dot{\zeta} = A^T \xi = A^T K \rho X - A^T \xi u + A^T f \) and thus system (1) becomes

\[ \dot{\zeta} = l_p y X - \zeta u + A^T f, \]  
(9)

\[ \zeta(0) = A \zeta_0. \]  
(10)

System (9) is not diffeomorphic to system (1), because the transformation (8) is not injective, since \( A \) is always rank deficient, even if \( p \geq n \). We use the system (9) to design a bank of \( p \) observers to build several estimates of the same signal, namely \( \hat{y}(t) \). The redundancy in the estimations will prove to be beneficial.

3. BANK OF SUPER-TWISTING OBSERVERS

We want to estimate \( y \) and we may assume that we can measure \( \zeta \), either because the whole state \( \xi \) is available or because we managed to choose \( A \) such that \( \zeta = A \xi \) can be built with the available measured states (the corresponding entries in each \( A_j^T \) are zero for the unmeasured states).

Let us now choose some \( \zeta_j, j \in \{1, \ldots, p\} \) and assume that the dynamics of \( y \) may be unknown, but \( \hat{y} \) is bounded, so we can artificially consider \( y \) as an unmeasured state and propose that

\[ \dot{\zeta}_j = y X - \zeta_j u + a_j^T f \]  
(11)

\[ \hat{y} = \delta_{y_j} \quad \delta_{y_j}(t) \in [\Delta, \Delta]. \]  
(12)

To estimate \( y \) we can use a variation of the generalized super-twisting observer (Moreno, 2011) that considers the explicit contribution of the biomass, as follows:

\[ \dot{\hat{y}}_j = -\ell_1 \phi_1(\hat{y}_j) + \bar{y}_j X - \zeta_j u + a_j^T f, \]  
(13)

\[ \hat{y}_j(0) = a_j^T \xi_0, \quad \bar{y}_j(0) = \delta_{y_0}, \]  
(14)

where \( \hat{y}_j = \hat{\zeta}_j - \zeta_j \) is the observation error. The observer gains are \( \ell_1 \) and \( \ell_2 \), and

\[ \phi_1(x) = \mu_1 |x| p_1 \text{sign}(x) + \mu_2 |x| p_2 \text{sign}(x), \]  
(15)

\[ \phi_2(x) = \mu_2 |x| p_2 - 1 \text{sign}(x) + \mu_1 |x| p_1 + p_2 \text{sign}(x) + \mu_1 |x| p_2 - 1 \text{sign}(x) = \phi'_1(x) + \phi'_2(x), \]  
(16)

where \( \frac{1}{p_1} \leq p_1 < 1 \leq p_2 \) and \( \mu_1, \mu_2 \geq 0 \) are design parameters. The dynamics of the observation error are given by:

\[ \dot{\hat{y}}_j = -\ell_1 \phi_1(\hat{y}_j) + \bar{y}_j X - \zeta_j \]  
(17)

\[ \hat{y}_j(0) = a_j^T (0) \]  
(18)

This almost has the form of the generalized super-twisting algorithm, except for the growing influence of \( X(t) \) in the first state estimation. Using Lasappunov arguments similar to those presented by (Moreno, 2011), we can show that gains \( \ell_1 \) and \( \ell_2 \) can be found such that the origin of this system is asymptotically stable. A sketch of the proof of this claim is shown in the Appendix.

Choosing \( \mu_1 = 0, \mu_2 > 0 \) and \( p_2 = 1 \) leads to a linear high gain observer, while choosing \( \mu_1 > 0, \mu_2 = 0 \) and \( p_1 = \frac{1}{2} \) leads to the classical super-twisting algorithm (Moreno, 2011). In fact, following the proof therein, it is possible to show that if \( p_1 = \frac{1}{2} \) and \( p_2 > 1 \), then the origin of (17)-(18) is uniformly and exactly stable, converging in finite-time, even despite a persisting, but bounded perturbation \( \delta_{y}(t) \).

De Battista et al. (2012) and Moreno and Guzmán (2011) also consider explicitly the bilinear term \( y \dot{X} \), but in both cases the correction term in the dynamics of \( \hat{y} \) includes somehow \( X(t) \). This makes these approaches very sensitive to the noise that may be present in \( X \). If we know that \( y \) is not influenced by \( X \), it does not make sense to make the gain in the correction term depend on this variable.

Using the estimated common \( \hat{y}_j \) we could also construct the following exponential observers for the other states in \( \zeta \), i.e. for each \( i = 1, \ldots, (j - 1), (j + 1), \ldots, p \) we propose

\[ \dot{\tilde{\zeta}}_i = -\beta \tilde{\zeta}_i + \bar{y}_i X - \zeta_i u + a_i^T f, \]  
(19)

\[ \tilde{\zeta}_i(0) = a_i^T \xi_0, \]  
(19)

where \( \tilde{\zeta}_i = \tilde{\zeta}_i - \zeta_i \) and \( \beta > 0 \) is an additional gain. Upon convergence of \( \hat{y}_j \), the error dynamics are \( \dot{\zeta}_i \approx -\beta \zeta_i \) and thus \( \zeta_i \rightarrow 0 \) exponentially. Later we will see that this is really not so useful.

In the same way that we have chosen some \( \zeta_j \), we could build a bank of similar observers for each \( j = \{1, \ldots, p\} \). Each one will provide an estimate \( \hat{y}_j(t) \) of the same \( y(t) \) and we can use this redundancy to tune the observer, as will be discussed later.
4. CHOICE OF THE TRANSFORMATION MATRIX

Each transformed state $\zeta_j$ is a linear combination of the states in $\xi$ via $\zeta_j = A^T \xi$, with $a_j$ a solution to $K^T a = \gamma$. In this section we present a methodology to choose the $a_j$ such that all transformed states are built giving approximately the same weight to each $\zeta_j$ involved. Given the rank assumption on $K$, a solution to system (6) is given by

$$a_j = a_0 + N_K b_j,$$

where $N_K \in \mathbb{R}^{n \times (n-m)}$ is a matrix whose columns form a basis for the nullspace of $K^T$ and $b_j \in \mathbb{R}^{n-m}$ can be any vector. The vector $a_0$ is any solution to the linear equation (6), but let us consider the least norm solution:

$$a_0 = (K^T)^+ \gamma = V_K \Sigma_K^{-1} U_K^T \gamma,$$

where $(K^T)^+$ is the pseudoinverse of $K^T$, which has been calculated using a singular value decomposition (SVD):

$$K^T = U_K \Sigma_K V_K^T,$$

where $U_K \in \mathbb{R}^{n \times m}$, $V_K \in \mathbb{R}^{m \times n}$, and $\Sigma_K$ is a diagonal matrix with the singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_m$. Note that the columns of $N_K$ form a basis for the nullspace of $K^T$; since $[V_K N_K]$ is orthogonal, then $K^T N_K = (U_K \Sigma_K V_K^T) N_K = 0$.

In order to give the same weight to each $\xi_i$ when defining the transformed states $\zeta_j$, we can design $A$ such that its SVD has equal singular values, leading to a matrix $A^T$ with unity condition number. Notice that (20) implies that

$$A^T = a_0^T + N_K B^T,$$

$$B^T = [b_1 b_2 \cdots b_p] \in \mathbb{R}^{(n-m) \times p}.$$

If we define $u_0 = \frac{1}{\|a_0\|} a_0$ and $v_0 = \frac{1}{\|b\|} b$, we can write

$$a_0^T = u_0 \sigma_0 v_0^T \text{ with } \sigma_0 = \sqrt{\|a_0\|}.$$ By the choice (21) of $a_0$ we have that $N_K^2 a_0 = 0$ by the orthogonality of $[V_K N_K]$. This implies that $[u_0 N_K]$ is an orthonormal matrix, so now define $\Sigma_0 = \sigma_0 I_{n-m}$ and consider the decomposition

$$A^T = u_0 \sigma_0 v_0^T + N_K \Sigma_0 L^T = [u_0 N_K] \left[ \begin{array}{cc} \sigma_0 & 0 \\ 0 & \Sigma_0 \end{array} \right] [v_0 B]^T,$$

where $B$ is an orthonormal matrix such that its columns are also orthogonal to $v_0$. Then this decomposition qualifies as an SVD of $A^T$ and $B$ can be found by choosing some full rank matrix $M \in \mathbb{R}^{p \times (n-m)}$ and performing a Gram-Schmidt orthogonalization of the matrix $[v_0 M]$ with respect to its columns, but care should be taken in the choice of $M$ so that $A^T$ does not have repeated columns.

5. ESTIMATION OF $K$

So far, we have provided a method to design a bank of super-twisting observers, each one estimating the same second state, namely $y(t)$, using measurements of the several $\zeta_j(t)$; see (13)–(14). Since each $\zeta_j$ depends ultimately on $K$, we should therefore expect the estimates $\hat{y}_j$ to be basically the same if $K$ is correct. If instead of the true $K$ we use $\hat{K} = K + \hat{K}$ with $\hat{K} \neq 0$ for the design and implementation of the bank of observers, differences between the estimates $\hat{y}_j(t)$ are expected. However, we show now that we can use the redundancy for eliminating the bias between these estimations.

Solving $\hat{K}^T \hat{a}_j = \gamma$ and using the transformations $\zeta_j = \hat{a}_j^T \xi_j$, $j = 1, \ldots, p$, leads to a system with

$$\hat{\zeta}_j = yX - \hat{a}_j^T \hat{K} \rho X - \zeta_j u + \hat{a}_j^T f.$$ (25)

There is now a perturbation term $\hat{a}_j^T \hat{K} \rho X$ and we get the error system

$$\hat{\zeta}_j = -\epsilon_1 \phi_1(\hat{\zeta}_j) + \hat{y}_j X + \hat{a}_j^T \hat{K} \rho X, \quad \hat{\zeta}_j = \hat{\zeta}_j - \zeta_j$$ (26)

$$\hat{y}_j = -\epsilon_2 \phi_2(\hat{\zeta}_j) + \delta_y(t), \quad \hat{y}_j = \hat{y}_j - y.$$ (27)

Because of the nonvanishing perturbation $\hat{a}_j^T \hat{K} \rho X$, the super-twisting algorithm will lead to practical stability in the sense that $\hat{\zeta}_j$ and (more importantly) $\hat{y}_j$ will now only converge to a neighborhood of the origin.

Consider the case when $\rho(t) = \bar{\rho}$ is constant. Practical application of the super-twisting observer in this case shows that after some finite convergence time the region to which error trajectories converge is such that

$$|\hat{\zeta}_j(t)| \leq \epsilon_0 \gamma, \quad |\hat{y}_j(t) - y_j| \leq \epsilon_y,$$ (28)

with $\epsilon_0$ and $\epsilon_y$ very small, i.e. the error $\hat{\zeta}_j$ converges to almost zero, while $\hat{y}_j$ converges to some constant value $\bar{y}_j$ (in a practical sense). Since $\epsilon_0$ is small, then assuming that $\hat{\zeta}_j$ remains practically constant after convergence (in finite time) we can find a practical steady state by setting $\hat{\zeta}_j = 0$ in (26). Since $\phi_1(\epsilon_0) = 0$ this leads to

$$\hat{y}_j(t) = \hat{y}_j = -\hat{a}_j^T \hat{K} \bar{\rho}.$$ (29)

Now consider the $p$ observers that also include the exponential observers, each one estimating the same $\zeta_j(t)$, for these other observers are given by

$$\hat{\zeta}_{j,i} = \hat{y}_j X + \hat{a}_j^T \hat{K} \rho X - \beta \hat{\zeta}_{j,i}.$$ (30)

Assume that the dynamics of $X(t)$ are much slower than those of $\hat{\zeta}_{j,i}(t)$. Since $\beta > 0$ and $\hat{K}$ is constant, exponentially $\hat{\zeta}_{j,i}(t) \rightarrow \hat{\zeta}_{j,i} X(t)$, with

$$\hat{\zeta}_{j,i} = \frac{1}{\beta} \left( \hat{y}_j + \hat{a}_i^T \hat{K} \bar{\rho} \right) = \frac{1}{\beta} \left( \hat{y}_j - \bar{y}_i \right),$$ (31)

where we have used the equality in (29). Note that $\hat{\zeta}_{j,i} = -\hat{\zeta}_{j,i}$ and in fact we gain no more information by using the additional exponential observers, but nevertheless they could provide some additional robustness to the identification method explained below.

It is clear that if $\hat{K} = 0$, the $p(p-1)/2$ steady-state errors $\hat{y}_{j,i} = \hat{y}_j - \hat{y}_i = (-\hat{a}_j^T + \hat{a}_i^T) \hat{K} \bar{\rho}$ (32) will all be zero. This leads naturally to the idea of using an a posteriori numerical optimization procedure to minimize

$$J(\hat{K}) = \sum_{j=1}^{p} \sum_{i=j+1}^{p} |\hat{y}_j - \hat{y}_i|^2 + \beta \sum_{i=1}^{p} \sum_{j=1}^{p} \hat{\zeta}_{j,i}^2.$$ (33)

or a similar criterion. In this sense, the idea is to collect data e.g. for one cultivation using an observer with some $\hat{K}$. Then, having identified a convergence time $T_c$, the numerical optimization searches for the $\hat{K}$ that minimizes (33) by simulating the implementation of the bank of observers in open loop with the collected data. The next cultivation would use $\hat{K}$ in the observer implementation.
Unfortunately, there is no unique $\hat{K}$ leading to $J = 0$. In fact, this happens for all $\hat{K}$ with the same SVD structure as the true $K$. To see this consider that $K^T = U_K \Sigma_K V_K^T$ and $\tilde{K}^T = U_K \left( \Sigma_K + \tilde{\Sigma}_K \right) V_K^T$ with $\tilde{\Sigma}_K = \text{diag}(\sigma_K)$; then

$$\tilde{K} = \tilde{K} - K = V_K \Sigma_K U_K^T.$$  \hfill (34)

Using the construction (20) of each $a_j$ and the definition (34) in (32) leads to

$$\tilde{y}_{j,i} = -(b_j - b_i)^T N_K V_K \Sigma_K U_K^T \beta = 0$$  \hfill (35)

for any $\tilde{\Sigma}_K$. This implies that there exist a family of matrices $\tilde{K}$ for which the observer implementation will lead to practically $\tilde{y}_j(t) = \tilde{y}_i(t)$ after $t \geq T_c$ for all $j \neq i$, but $\tilde{y}_j(t) \neq y(t)$.

Even though an unrestricted optimization may not be successful in finding the true value of $K$, it will find the SVD structure, and this can be used to narrow the search space. For example, if we know $K_{\text{min}}$ and $K_{\text{max}}$ such that $K_{\text{min}} < K < K_{\text{max}}$, then we can add a penalizing term in the optimization criterion (33) for $K$’s out of bounds.

6. SIMULATIONS

A more complex model than the one explained in Section 1 was used for simulation using Matlab 7.12.0.635 (R2011a). It considers the production of acetate in respiro-fermentative regime and its low consumption in respirative regime, which makes $S^*(t)$ become time-varying. A local PI controller for regulating the dissolved oxygen concentration is used. Details of this model, including the values of the parameters used, are found in (Santos et al., 2012).

The following input makes $S(t)$ converge to $S^*(t)$

$$u^*(t) = \frac{X(t) r^*_S(t)}{S_i - S^*(t)}.$$  \hfill (36)

Since this input is not implementable, other controllers have been proposed that will approximate it using the information from the virtual output that we are estimating (Dewasme et al., 2011; Vargas et al., 2012; Santos et al., 2012). Therefore, to test the observers we generate the data by constructing the optimal input $u^*(t)$ as in (36) and perturb it with a quasi-periodic signal $p(t)$ in order to mimic what such controllers would do:

$$u(t) = (1 + p(t)) u^*(t).$$  \hfill (37)

Since we are assuming that $S(t)$ cannot be measured and $S_i$ is not known, we eliminate the last state in $\xi$ and use only a reduced model with the first three states. Furthermore, we also assume that $O(t)$ is constant and known (it is regulated by the PI controller) and $C(t)$ remains at a very low known and constant value (the solubility of CO$_2$ is very low), so there is no need to measure them. We do measure on-line the biomass $X(t)$, as well as $f_{OTR}$ and $f_{CTR}$ and have added white measurement noise to them with standard deviations of up to 0.01 g/L for $X(t)$ and 0.015 g/L/h both for $f_{OTR}$ and $f_{CTR}$.

Figure 1 shows the results of a simulation where the dissolved oxygen $O(t)$ is regulated at 2.5 mg/L using a simple PI controller (which indirectly modifies the $f_{OTR}$ via the $k_T a$ value), while $f_{OTR}$ and $f_{CTR}$ are directly calculated from the model equations assuming steady state. Notice the typical exponential growth of $X(t)$ and the time-varying nature of the maximum $y^* = r_S^*$ and consequently of the desired setpoint at $S^*$.

In order to design the bank of observers, we need the matrix $K$, which has $n = 3$ rows and $m = 2$ columns and is given numerically by:

$$K^T = \begin{bmatrix} 0.316 & -0.339 & 0.406 \\ 0.040 & -0.472 & 0.757 \end{bmatrix}. $$  \hfill (38)

An SVD is given by the following matrices and vector:

$$U_K = \begin{bmatrix} -0.548 & -0.836 \\ -0.836 & 0.548 \end{bmatrix}, \quad \sigma_K = \begin{bmatrix} 1.054 \\ 0.255 \end{bmatrix},$$

$$V_K = \begin{bmatrix} -0.196 & -0.950 \\ 0.551 & 0.100 \\ -0.812 & 0.297 \end{bmatrix}, \quad N_K = \begin{bmatrix} 0.244 \\ 0.829 \\ 0.503 \end{bmatrix}. $$  \hfill (39)

The nullspace is of dimension 1 and the least-norm solution vector $a_0$ and thus $\sigma_0$ are given, respectively, by

$$a_0 = [5.0943 -0.3894 -1.8305]^T, \quad \sigma_0 = 7.6752. $$  \hfill (40)

The transformation matrix $A$ is built as indicated previously. In the observers the $\phi_1$ function has parameters $p_1 = 0.5, \ p_2 = 1, \ \mu_1 = 1$ and $\mu_2 = 0.2$, i.e. a classical super-twisting observer with an additional linear correction term. The simulations were made implementing a discretized version of the observers using a forward Euler approximation using a sample time of $T_s = 6$ s.

Figure 2 shows the result of a bank of $p = 7$ observers under perfect system knowledge (with $K = K$). The observer gains are $\ell_1 = 1.5, \ |\ell_2| = 0.5$ and $\beta = 20$. As expected, all observers in the bank converge to the same signal, the virtual output $y(t)$. The purple line
shows the mean $\tilde{y}(t)$ of the seven observers implemented. The top figure shows a simulation without noise in the measurement of $X$, while the bottom figure shows it when noise is present. In both cases noise is present in both $f_{\text{OTR}}$ and $f_{\text{CTR}}$. It is interesting to notice that the observer actually acts as a filter under noise in the measured state, delaying the estimation, but also damping the influence of noise coming from $f(t)$. If we increase the noise level in $X$, the delay in the estimation also increases. We can increase the observer gains to diminish the delay, especially $\ell_2$, but the noise is less damped and the estimation would become useless for implementing a controller. There is thus a clear compromise that would later have to be further studied when implementing an output-feedback controller.

Figure 3 shows the simulation for the same data set as above, but using $\hat{K} \neq K$. We restrict $\hat{K}$ to have elements between:

$$K_{\text{min}} = \begin{bmatrix} 0.253 & 0.036 \\ -0.424 & -0.636 \end{bmatrix}, \quad K_{\text{max}} = \begin{bmatrix} 0.380 & 0.044 \\ -0.255 & -0.306 \end{bmatrix}.$$  

The starting $\hat{K}_0$ is chosen at random within these bounds and the result of applying the bank of observers is shown on the top graph of figure 3. The same gains and observer parameters were used as before. As expected, the estimates $\hat{y}_j(t)$ are different and do not converge to the true value of $y(t)$. Using this matrix as initial estimate, we used the (unconstrained) \texttt{fminsearch} algorithm under Matlab for the numerical optimization procedure with a large penalization for matrices outside the sought range. The bottom graph of figure 3 shows the result after the optimization, with $\hat{K}_*$. All the estimates now converge to their mean $\bar{\hat{y}}(t)$, but not to the true $y(t)$. Notice, however, that the individual estimates $\hat{y}_j$, $j = 1, \ldots, 7$ are noisy, but their average has reduced this noise. The advantage of using a bank of seven observers instead of one is evident.

The SVD $\hat{K}^T = U_K \text{diag}(\hat{\sigma}_K) \hat{V}_K^T$ is given by

$$\hat{U}_K = \begin{bmatrix} -0.657 & -0.754 \\ -0.754 & 0.657 \end{bmatrix}, \quad \hat{\sigma}_K = \begin{bmatrix} 0.991 \\ 0.245 \end{bmatrix},$$

$$\hat{V}_K = \begin{bmatrix} -0.237 & -0.869 \\ -0.838 & 0.409 \end{bmatrix}, \quad \hat{K}_* = \begin{bmatrix} 0.315 & 0.037 \\ -0.371 & -0.323 \end{bmatrix}.$$  

It can be verified that the right and left singular vectors of $\hat{K}_*$ are very similar to those of the true $K$ shown in (39).

From the point of view of a RTO feedback controller such as that proposed by Vargas et al. (2012) or Dewasme et al. (2011), the bias between $\hat{y}(t)$ and $y(t)$ is not important, since these controllers use this virtual output to follow a maximum, so as long as their profiles are similar and their (local) maxima occur simultaneously (some delay is inevitable), the implementation of the controllers could be successful.

We have observed that the noise in $X(t)$ is critical. Although we still have to use it in the term $\dot{\hat{y}}X$ we can eliminate this measurement in the observer design using only the $2 \times 2$ submatrix $K_{\text{OC}}$ of $\hat{K}$ that corresponds to the dynamics of $O$ and $C$ (the last two rows of $\hat{K}$). However, we can design only one observer, with $a_{\text{OC}}^T = \gamma^T \hat{K}_{\text{OC}}^{-1}$ and whose dynamics are basically driven by the inputs from $f_{\text{OTR}}$ and $f_{\text{CTR}}$.

Having identified $\hat{K}_*$, we use it to get $\hat{K}_{\text{OC}}$ and run the resulting super-twisting observer to estimate a single $\hat{y}$. The gains in this case were manually adjusted for the same data base and the results are shown in figure 4. The delay is almost zero (previously due to the noise in $X$), but the estimate (in blue) now has the influence of the noise present in $f_{\text{OTR}}$ and $f_{\text{CTR}}$ and is not as good as before. We can reduce this by previously filtering the noise in these

---

Fig. 2. Bank of observers under perfect system knowledge, without (top) and with noise in $X$ (bottom); the true $y$ is shown green, while the mean $\bar{\hat{y}}$ of all $\hat{y}_j$ is shown purple (same observer parameters).

Fig. 3. Bank of observers with $\hat{K} \neq K$: using $\hat{K}_0$ before optimization (top) and using $\hat{K}_*$ after optimization (bottom); the true $y$ is shown green, the estimates $\hat{y}_j$ in different colors with thin lines, while their mean $\bar{\hat{y}}$ is shown purple.
signals (in purple), but then delay appears. In any case, the estimation is not as good for the RTO controller, since the maxima in the signal are not as clearly defined as in the previous case when we use explicitly the signal \( X(t) \) and a bank of redundant observers.

![Graph of y (mg/L/h) vs t (h)](image)

Fig. 4. Single observer without using \( X \); true \( y \) shown with (purple) and without (blue) filtering of the \( f_{\text{OTR}} \) and \( f_{\text{CTR}} \) signals.

7. CONCLUSION

For RTO control of certain biotechnological processes, the on-line knowledge of a signal that has a maximum at the desired operating point is needed. Using a bank of redundant super-twisting observers we have proposed a methodology to estimate this virtual output. Through simulations in a system with overflow metabolism, the convenience of this redundancy has been shown.

Appendix A. PROOF OF CONVERGENCE

Consider the following perturbed system, which corresponds to the observation error dynamics:

\[
\begin{align*}
\dot{x}_1 &= -\ell_1 \phi_1(x_1) + a(t)x_2 + \delta_1(t,x), \\
\dot{x}_2 &= -\ell_2 \phi_2(x_1) + \delta_2(t,x),
\end{align*}
\]

where the measured signal \( a(t) \) is positive and bounded, i.e. \( a \geq a(t) \geq a > 0 \) for all \( t \), and \( \phi_1 \) and \( \phi_2 \) as in (15)-(16). The class of perturbations considered satisfy, \( |\delta_i(t,x)| < g_i(\phi_i(x_1)) \), \( g_i > 0 \), \( i \in \{1,2\} \).

Consider the transformation

\[
z = \begin{bmatrix} \phi_1(x_1) \\ x_2 \end{bmatrix} \quad \implies \quad \dot{z} = \phi'(x_1) (Az + \delta),
\]

where \( A = A_0 - LC \)

\[
A_0 = \begin{bmatrix} 0 & a(t) \\ 0 & 0 \end{bmatrix}, \quad L = \begin{bmatrix} \ell_1 \\ \ell_2 \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \delta = \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix}.
\]

Note that \( \phi'_j(x_1) = \mu_1 |x_1|^{p_1-1} + \mu_2 |x_1|^{p_2-1} \geq 0 \) for all \( x_1 \). When \( a(t) \equiv 1 \), Moreno (2011, Theorem 2) shows that \( V_Q = z^T P z \) is a strong, robust Lyapunov function for system (A.1)-(A.2) and the system will be exponentially stable (and finite-time convergent in some cases) if we can show that there exist \( P = D^T P D > 0 \), gains \( \ell_1 \) and \( \ell_2 \), \( \Theta_1 > 0 \), \( \ell_2 > 0 \), and \( \epsilon > 0 \) such that

\[
A^T P + PA + \epsilon P + R + P \Theta^{-1} P D^T P \leq 0,
\]

with

\[
R = \begin{bmatrix} \ell_1 \Theta_1^{-1} + \ell_2 \Theta_2^{-1} & 0 \\ 0 & 0 \end{bmatrix}, \quad \Theta = \begin{bmatrix} \ell_1 & 0 \\ 0 & \ell_2 \end{bmatrix}.
\]

The matrix \( B \) is either \( B = I \), \( B = [1,0]^T \), or \( B = [0,1]^T \) depending on whether \( \delta_1 \) or \( \delta_2 \) are considered or not (the definitions of \( \Theta \) and \( R \) must change accordingly).

To extend the result of (Moreno, 2011) to the case studied here, we need to satisfy the algebraic Riccati inequality (ARE) (A.5) for all \( a \leq a(t) \leq \bar{a} \). Using the Schur complement and given some value for \( a \), these ARE’s are equivalent to the matrix inequalities \( M(a) \leq 0 \):

\[
\begin{bmatrix}
A_0^T P + PA_0 - C^T D^T P - PLC + \epsilon P + R & PB \\
B^T P & -\Theta
\end{bmatrix} \leq 0,
\]

Since the family of matrices \( A_0(a) \) is a convex set with vertices at \( \bar{A}_0(a) \) and \( \underline{A}_0(a) \), so is the family \( M(a) \). We can check the simultaneous feasibility of the family of matrix inequalities by checking only the feasibility of

\[
\text{diag} \left[M(\bar{a}) \right], \ M(\underline{a}) \leq 0.
\]

Replacing the term \( \epsilon P \) with \( \epsilon \ell \) does not affect its solvability, but makes (A.7) and (A.8) a linear matrix inequality (LMI) in the unknowns \( P, \Theta, \epsilon \) and \( \Theta \), and thus we can use known efficient algorithms to solve it.

A very important aspect to notice is the guaranteed convergence for the class of perturbations defined by (A.3). These perturbations usually have to vanish at the origin, e.g. \( |\delta_1(t,0)| \leq g_1 \phi_1(0) = 0 \), but when \( p_1 = \frac{1}{2} \), then \( \phi_2(x_1) \) has a signum function and therefore we allow

\[
-\frac{g_2 \mu_2^2}{2} \leq \delta_2(t,0) \leq \frac{g_2 \mu_2^2}{2}.
\]

Hence the robustness of the approach.
