Feedforward Design for a Mechanical System with Marginally Stable Inverse

Peter Nauclér * Torsten Söderström *

* Department of Information Technology, Uppsala University, P.O. Box 337, SE-751 05 Uppsala, Sweden.

Abstract: This paper considers feedforward control of a system which is described by transfer functions with marginally stable inverses. We present three different feedforward control strategies. Two of them rely on an ‘ideal’ design which is derived in the noise-free case, whereas the third is based on Wiener filtering theory. The control strategies are compared and evaluated for different signal models and in the presence of measurement noise. We show that the performance can be substantially improved by using the (optimal) Wiener feedforward controller.

Keywords: feedforward control, Wiener filters, wave guides, vibration control, polynomial methods

1. INTRODUCTION

When some disturbances that enters a system are measurable it is often advantageous to apply feedforward control. In ideal cases, the effect of these disturbances can then be totally eliminated before they reach the output. However, for this to happen a perfect model of the system is needed and the ideal feedforward controller may turn out to be unstable or noncausal and therefore has to be approximated.

In this paper we consider the problem of feedforward control for systems with marginally stable inverses. This is problematic since the poles of the inverses cannot be mirrored into the stable region. Especially, we illustrate a general Wiener feedforward technique by use of a specific example. We assume perfect models but noisy data, which is a way to robustify the design.

2. BACKGROUND

Systems with marginally stable inverses appear when modeling propagation of mechanical waves and sound. Also, positive real transfer functions between collocated actuators/sensors of undamped vibrating beams are marginally stable and have marginally stable inverses. This fact is a consequence of the positive realness, which implies that the poles and zeros are interlacing along the imaginary axis [Preumont, 2002].

For systems with marginally stable inverses, the control problem is challenging since the controller is required to have very high gain at certain frequencies. In particular, sensor noise may be amplified and it fundamentally limits the performance of feedforward control.

Here, we consider an example of feedforward control for extensional (longitudinal) waves in a bar, as shown in Figure 1. At two sections, the bar is equipped with strain gauge pairs. These gauges are arranged to measure only extensional waves. Also, along a segment of the bar, a pair of piezo-electric actuators, electrically and mechanically in parallel, are attached. The idea with this configuration of bar, sensors and actuator is to apply feedforward control so that waves traveling from the sensors towards the first bar-actuator interface will be fully reflected while waves traveling in the opposite direction, towards the second bar/specimen interface, will be transmitted undisturbed.

Therefore, waves traveling from the sensors towards the first bar/actuator interface will be considered measurable disturbances which are to be suppressed through feedforward control.

The concept of such a device was originally introduced in Nauclér et al. [2007] and referred to as a ‘mechanical wave diode’. For example, two such devices could be arranged to isolate a region from incoming disturbances. Furthermore, if disturbances arise within this region, they are transmitted out of the region without exciting the control system. The contribution of this paper lies in more general control strategies compared to the one reported in Nauclér et al. [2007]. Especially, an approach based on Wiener smoothing is shown to have superior performance.

2.1 Notation

The following notational conventions are used in this paper.
\[ T \] sampling period
\[ \tau \] time delay (in samples)
\[ q^{-1} \] backward shift operator, \( q^{-1}y(t) = y(t-T) \)
\[ nP \] degree of polynomial \( P \)
\[ P = P(q^{-1})p_0 + p_1q^{-1} + \cdots + p_nq^{-nP} \]
\[ P^* = p_0 + p_1q + \cdots + p_nq^nP \text{ (reciprocal poly.)} \]
\[ x \] scalar
\[ X \] vector
\[ \mathbf{X} \] matrix

When appropriate, the complex variable \( z \) is substituted for the forward shift operator \( q \). The polynomial arguments \( q^{-1}, z^{-1} \) are sometimes omitted in order to simplify the notation. The zeros of the polynomial \( P(z^{-1}) \) are the solutions to \( z^nP(z^{-1}) = 0 \).

### 3. SYSTEM MODELING

In Figure 1, \( A, E \) and \( \rho \) denote cross-sectional area, Young’s modulus and density, respectively. These quantities differ for different sections of the bar. For given properties of the bar and actuator materials, the cross-sectional areas \( A_1 \) and \( A_2 \) are assumed to be chosen so that impedance matching is achieved. Therefore, the waves \( \bar{v} \) and \( v \) traveling back and forth in the structure are transmitted undisturbed through the actuator region if no control action is applied. The wave motion in the bar can be expressed in terms of the Fourier transform of the normal force as

\[ N(\xi, \omega) = V(\omega)e^{-i\omega \xi} + \bar{V}(\omega)e^{-i\omega \xi} \quad (1) \]

where \( \xi \) is a transformed axial coordinate with dimension of time \( [\text{Nauclér et al., 2007}] \). \( V(\omega) \) and \( \bar{V}(\omega) \) are the Fourier transforms of \( v(t) \) and \( \bar{v}(t) \), respectively. In the time domain, (1) means that waves propagate through the bar without damping and that superposition holds.

In [Nauclér et al., 2007], we extensively describe the electromechanical modeling of the wave diode system. Here, we will briefly review the final modeling in discrete time, where it is assumed that the time delays \( t_a, t_m \) and \( t_c \) are integer multiples of the sampling interval \( T \). We label these multiples as \( \tau_a, \tau_m \) and \( \tau_c \), respectively, so that \( t_a = \tau_aT \), etc. This means that we can use the backward shift operator \( q^{-1} \) so that, e.g., \( q^{-\tau_a}n(t) = n(t - \tau_aT) = n(t - t_a) \).

Generally, the waves represented by \( v \) and \( \bar{v} \) overlap in the time domain. Therefore, the disturbance \( v \) cannot be measured directly. However, the waves traveling back and forth in the bar can be separated if \( n_1 \) and \( n_2 \) are measured strains at two different bar sections \( \xi_1 = -t_m \) and \( \xi_2 = t_m \) as in Figure 1 [Lundberg and Henchoz, 1977]. The \( \bar{v} \) component carried by \( n_1 \) and \( n_2 \) can be removed by the filtering operation

\[ n_a(t) = q^{-\tau_a}n_1(t) - q^{-3\tau_m}n_2(t). \quad (2) \]

The fact that \( \bar{v} \) is indeed filtered out can be seen by equating (2) while assuming noisy measurements,

\[ n_o(t) = q^{-\tau_a}[q^{-\tau_m}v(t) + q^{-3\tau_m}\bar{v}(t) + w_1(t)] - q^{-3\tau_m}[q^{-\tau_a}v(t) + q^{-\tau_m}\bar{v}(t) + w_2(t)] \]

\[ = B_1(q^{-1})v(t) + w(t) \quad (3) \]

with

\[ B_1 = 1 - q^{-4\tau_m} \]

\[ w(t) = q^{-\tau_m}w_1(t) - q^{-3\tau_m}w_2(t). \quad (4) \]

Fig. 2. Block diagram of the wave diode system. \( B_1 \) and \( B_2 \) are polynomials with all zeros on the unit circle.

Here, \( w(t) \) is the assembled effect of the two noise sources \( w_1 \) and \( w_2 \). Equation (3) follows from the wave equation (1) and how \( n_1 \) and \( n_2 \) are defined in Figure 1. In the sequel, \( n_o \) is treated as a ‘virtual’ measured signal that only depends on \( v \) and \( w \), and not on \( \bar{v} \). This signal is used as input signal to the feedforward controller. The output from the controller \( u(t) \) is fed to the actuator. It has the input-output relation

\[ y^{(c)}(t) = B_2(q^{-1})u(t) \]

which is derived in [Jansson and Lundberg, 2007] and modified to discrete time in [Nauclér et al., 2007]. The signal \( y^{(c)} \) denotes the part of the output signal \( y \) that is deduced from the control action. The part of the output that originates from the disturbance transmission in the bar, \( y^{(t)} \), is a pure time delay of \( v \),

\[ y^{(t)}(t) = q^{-(\tau_c + \tau_a)}v(t), \quad (5) \]

according to (1) and the bar configuration in Figure 1, where \( y(t) = y^{(c)}(t) + y^{(t)}(t) \) is defined at the 2nd interface. Finally, we model the time delay that occurs in the feedforward link due to hardware limitations etc. In order to prevent a need for signal prediction in the feedforward filter, this time delay is not allowed to be larger than the disturbance transmission delay, which is \( (\tau_c + \tau_a)T \), see (5). Therefore, these time delays are put in relation and the control loop delay is modeled as \( (\tau_c + \tau_m - m)T \), with \( m \geq 0 \).

By use of the relations introduced so far the system can be schematically realized as shown in Figure 2, with the single input \( v(t) \) and single noise source \( w(t) \). The measured signals \( n_1 \) and \( n_2 \) are ‘hidden’ in \( n_o \) as described by (2)–(4). The expressions for the output signal and control signal as functions of the disturbance and measurement noise can then be written as

\[ y(t) = [1 + q^mB_2FB_1]q^{-(\tau_c + \tau_a)}v(t) \]

\[ + B_2Fq^{-(\tau_c + \tau_m - m)}w(t) \quad (6) \]

\[ u(t) = q^mFB_1q^{-(\tau_c + \tau_a)}v(t) + Fq^{-(\tau_c + \tau_m - m)}w(t) \quad (7) \]

where \( B_1 \) and \( B_2 \) have marginally stable inverses.

The following values of the system parameters are chosen for illustrations and numerical examples:

\[ T = 5 \mu s, \quad \{\tau_a, \tau_m, \tau_c\} = \{2, 8, 200\}. \]

These values coincide with the ones employed in [Nauclér et al., 2007].

\[ 2271 \]
3.1 Signal Modeling

The disturbance \( v(t) \) and the measurement noise \( w(t) \) are modeled as ARMA processes,

\[
v(t) = C(q^{-1}) \hat{v}(t) \quad w(t) = M(q^{-1}) \hat{w}(t)
\]

with driving noise variances \( \lambda_2 \) and \( \lambda_2 \), respectively. It is assumed that \( v(t) \) and \( w(t) \) are mutually independent.

These models are quite general. One can employ ARMA models for modeling of stochastic signals as well as deterministic-like signals, such as steps, pulses etc. as discussed in Ljung [1999] and Nauclér et al. [2007]. In this paper we will treat two cases for numerical examples,

**Case (i)** \( C = 1 \quad M = 1 \quad C = 0.1 \quad M = 0.5 \)

**Case (ii)** \( D = 1 \quad N = 1 \quad D = 1 - 0.9q^{-1} \quad N = 1 - 0.5q^{-1} \).

The first case treats disturbance and measurement noise with constant spectra, whereas the second case treats a disturbance of low frequency content and a noise source with a relatively broader bandwidth.

3.2 Ideal Feedforward Controller

The ideal feedforward filter, as derived in Nauclér et al. [2007] is

\[
F(q^{-1}) = \frac{q^{-m}}{B_0 B_2} = \frac{-2q^{-m}}{(1 - q^{-2\tau_2})(1 - q^{-2\tau_1})}, \quad (8)
\]

which performs perfectly in the noise-free case, yielding \( y(t) = 0 \), see (6). However, if measurement noise is present the output variance will grow linearly with time. This is due to that the poles of (8) are located on the unit circle, and the measurement noise will contribute to the output as a random walk process after passing (8). The same problem is apparent for the control signal, \( u(t) \). Therefore, the ideal design needs to modified to be useful in a realistic scenario where measurement noise is present.

4. FEEDFORWARD DESIGN

In this section three different ways of designing asymptotically stable feedforward filters are presented. The first two techniques utilize the structure of the ideal design and are therefore referred to as 'fixed feedforward structures'. The third feedforward design is instead based on Wiener filtering techniques.

The first approach was originally introduced and analyzed in Nauclér et al. [2007], whereas the other two are novel for this paper.

4.1 Fixed Feedforward Structures

The two fixed feedforward approaches are both based on modifying the ideal design (8) by moving its poles towards the origin to make the filter asymptotically stable. The modification is

\[
F(q^{-1}) = \frac{-2q^{-m}}{(1 - r_1 q^{-2\tau_1})(1 - r_2 q^{-2\tau_2})},
\]

where \( r_1 \) and \( r_2 \) are real numbers in the interval \([0, 1)\).

These parameters are design variables that can be adjusted to for example minimize some cost function. The criteria we utilize are based on computing the variances of \( y(t) \) and \( u(t) \). In order to perform this it is useful to first realize the system in state-space form. Such a realization has the structure

\[
x(t + T) = \Phi(r_1, r_2) x(t) + \Gamma \begin{bmatrix} \hat{v}(t) \\ \hat{w}(t) \end{bmatrix} \quad (9)
\]

where the dependence of \( r_1, r_2 \) on \( \Phi \) is stressed. The state-space realization can be obtained using e.g. some kind of canonical form. Of course, (9) will also depend on the signal models for \( v(t) \) and \( w(t) \).

The, the output variance and the control signal variance can be computed as Söderström [2002]

\[
E \begin{bmatrix} y^2(t) \\ y(t) u(t) \\ y(t) \hat{w}(t) \\ \hat{w}^2(t) \end{bmatrix} = \text{HPH}^T
\]

where \( P \) is the covariance matrix of the state vector \( x \), which is computed by solving the Lyapunov equation

\[
P = \Phi P \Phi^T + \Gamma \begin{bmatrix} \lambda_2^2(t) & 0 \\ 0 & \lambda_2^2(t) \end{bmatrix} \Gamma^T. \quad (10)
\]

In (10) the assumption that \( v(t) \) and \( w(t) \) are mutually independent is utilized. This procedure of variance computation will also be useful in Section 5, where the different control strategies are evaluated.

4.2 Fixed one-DOF Design

In the first approach for feedforward design, all poles of the feedforward filter are constrained to be placed at the same distance to the origin. This is achieved by minimization of the criterion

\[
J_1 = Ey^2(t) \quad \text{s.t.} \quad r_2 = r_1^{\tau_m/2\tau_m}. \quad (11)
\]

Due to the coupling between \( r_1 \) and \( r_2 \) this filter has only one degree of freedom (DOF) and is therefore referred to as a fixed one-DOF structure. The constraint to place all poles on the same circle is one way to make the feedforward filter asymptotically stable. If \( r_1 \) and \( r_2 \) are treated as independent design variables it turns out that \( Ey^2(t) \) will decrease as \( r_2 \) approaches 1. However, the output variance is not defined for \( r_2 = 1 \), since this would cancel common poles and zeros on the unit circle, c.f. (6). In addition, \( r_2 = 1 \) would cause \( u(t) \) to be a random walk process with a variance that grows unbounded.

The minimum point of (11) is found in a numerical search procedure. The equation (10) is repeatedly solved for different values of \( r_1 \) and \( r_2 \). Due to the coupling between the two parameters the optimization is carried out in one dimension.

In Figure 3(a) the result of such a procedure is shown for case (i). For purpose of illustration the output signal is decomposed in a signal part and a noise part (c.f. (6)),

\[
y(t) = y_s(t) + y_u(t),
\]

and their respective variances as functions of \( r_1 \) are shown in the figure. It portrays the tradeoff between disturbance rejection and measurement noise sensitivity. The variance of the signal part decreases as \( r_1 \) approaches 1, while at the same time the variance of the noise part rapidly increases.
Variance of the cost function $J_3$. The structure in (12) appears when formulating the Wiener problem by using the completing criterion to minimize. Such a cost function is expressed as

$$J_3 = E y^2(t) + \rho E u^2(t),$$

where $\rho > 0$. The amount of penalty on the control signal grows as $r_2$ decreases. The optimization procedure is carried out in a similar fashion as for the one-DOF structure. The difference is that also $J_3$ is employed for each new set of $\{r_1, r_2\}$ and that the optimization is carried out in two dimensions, since the parameters are treated as independent design variables. Therefore, the obtained feedforward filter is referred to as a fixed two-DOF structure.

For case (i), a contour plot of the cost function is shown in Figure 3(b). Here, $\rho = 10^{-3}$ and SNR = 20 dB are chosen. The value of the cost function for different level curves are shown in the plot and the minimum point is obtained for $r_1 = 0.904$ and $r_2 = 0.941$.

For both of the two fix feedforward structures the optimum values of $r_1$ and $r_2$ will depend on the SNR. For high noise levels, their values will decrease to diminish the effect of the noise and vice versa.

4.4 Design based on Wiener Filter Theory

The Wiener filter procedure is different from the other two design principles in the sense that no prior feedforward structure is utilized. The Wiener filter is designed to optimally minimize the cost function

$$J_3 = E y^2(t) + \rho E u^2(t),$$

where $m \geq 0$ is used as a fixed lag smoothing parameter to possibly improve the performance of the feedforward filter.

Wiener filters are usually designed to recover some desired signal from noisy measurements. The classical approach to realize such a filter is to utilize the statistical relation between the desired signal and the measured signal by employing the Wiener-Hopf equations [Hayes, 1996]. Other methods include variational arguments and the completing the squares approach [Ahlen and Sternad, 1994]. For the wave diode system, the difficulty is that it is not possible to pose a Wiener problem in a usual way. One cannot find two correlating signals that can be used to produce an asymptotically stable feedforward filter.

Instead, the cost function is evaluated using frequency domain relations and we notice that the obtained structure can be utilized to produce a Wiener solution for the feedforward filter. Expressing the output variance and control signal variance by use of Parseval’s relation yields

$$E y^2(t + m) = \frac{1}{2\pi} \int_{|z|=1} (1 + z^m B_2 F B_1) (1 + z^m B_2 F B_1)^* \Phi_v \frac{dz}{z} + \frac{1}{2\pi} \int_{|z|=1} B_2 B_2^* F^* \Phi_w \frac{dz}{z}$$

$$E u^2(t + m) = \frac{1}{2\pi} \int_{|z|=1} F F^* B_1^* \Phi_v \frac{dz}{z} + \frac{1}{2\pi} \int_{|z|=1} F^* \Phi_w \frac{dz}{z}$$

and the cost function is readily evaluated,

$$J_3 = \frac{1}{2\pi} \int_{|z|=1} \left( \Phi_v + F z^m B_2 B_2^* \Phi_v + B_1^* B_2^* z^{-m} \Phi_v F^* + F^* [B_2 B_2^* B_1^* \Phi_v + B_2^* B_2^* \Phi_w + \rho (B_1 B_1^* \Phi_v + \Phi_w))] F^* \right) \frac{dz}{z}$$

$$\triangleq \frac{1}{2\pi} \int_{|z|=1} \left( \Phi_v - F \Phi_{vz} - \Phi_{vz} F^* + F^* \Phi_{vz} \right) \frac{dz}{z}$$

(12)

In (12), the spectra $\Phi_v$ and $\Phi_{vz}$ are defined as

$$\Phi_v = B_2 B_2^* B_2^* \Phi_v + B_2 B_2^* \Phi_w + \rho (B_1 B_1^* \Phi_v + \Phi_w)$$

$$\Phi_{vz} = F^* \Phi_{vz} = (B_2 B_2^* \Phi_v + \Phi_w) (B_2 B_2^* + \rho)$$

(13)

The signal $z(t)$ has no physical interpretation that could be shown in e.g. Figure 2. It is rather an instrument in formulating the Wiener solution for minimization of the cost function $J_3$. The structure in (12) appears when formulating the Wiener problem by using the completing...
the squares approach [Ahlén and Sternad, 1994]. The ‘direct’ Wiener solution,
\[ F(z^{-1}) = \Phi_{vz}(z^{-1})\Phi_z^{-1}(z^{-1}), \]
is generally unrealizable since it is non-causal. The realizable Wiener filter is instead obtained by first computing an innovations representation of \( z(t) \) and then extracting the causal part \( \{\rfloor_{\star} \) of a filter [Söderström, 2002].

The innovations representation and its spectrum can be written as
\[ z(t) = H(q^{-1})e(t), \quad \Phi_z = H^*\lambda_z^2 \]
where the innovations sequence \( e \) is white with variance \( \lambda_z^2 \) and the asymptotically stable minimum phase filter \( H \) is determined by use of spectral factorization. Inserting the expressions for the spectra of \( v(t) \) and \( w(t) \) in (13) yields
\[ \left( B_1B_1^*CC^* + MM^*NN^*\lambda_w^2 \right) (B_2B_2^* + \rho) = HH^*\lambda_z^2, \]
where \( H \) must have the structure
\[ H = \frac{D}{DN}. \]
The structure of \( H \) is determined by setting the left hand side of (15) on common denominator form. The polynomial \( \beta \) has all its roots strictly inside the unit circle and can be computed by two spectral factorizations; one for each factor of (15),
\[ B_1B_1^*CC^*NN^*\lambda_v^2 + MM^*DD^*\lambda_v^2 = \beta_1\beta_1^*\lambda_1^2, \]
\[ B_2B_2^* + \rho = \beta_2\beta_2^*\lambda_2^2, \]
where \( \beta = \beta_1\beta_2 \) and \( \lambda_v^2 = \lambda_1^2\lambda_2^2 \). Then, the filter that minimizes \( J_\beta \) is [Söderström, 1992; Ahlén and Sternad, 1994]
\[ F(z^{-1}) = \left[ \Phi_{vz}\{H^*\}^{-1} - \frac{1}{\lambda_2^2} \right] + Hz^{-1} \]
\[ = -\frac{\lambda_2^2}{\lambda_2^2} \left[ B_1B_1^*z^{-m}CC^*N^* \right] \frac{DN}{\beta}. \]

The causal bracket \( \rfloor \) in (18) can be evaluated by solving a Diophantine equation [Ahlén and Sternad, 1994]. This can be seen by writing the expression as a sum of a causal and strictly anti-causal part,
\[ \frac{B_1B_2^*z^{-m}CC^*N^*}{D^*} = \left[ \frac{Q}{D} \right] + \left[ \frac{L^*}{D^*} \right] \frac{\beta}{\lambda_2^2}. \]

where \( Q \) and \( L^* \) are polynomials in \( z^{-1} \) and \( z \), respectively, of degree
\[ nQ = \max\{nC + n, nD - 1\} \]
\[ nL = \max\{nB_1 + nB_2 + nC + nN - m, n\beta\} - 1. \]

The Diophantine equation is obtained by expressing the right hand side of (19) on common denominator form (ignoring the brackets),
\[ B_1B_2^*z^{-m}CC^*N^* = \beta^*Q + zDL^*, \]
and the optimal filter is obtained using (18) and (19),
\[ F(z^{-1}) = -\lambda_2^2 \frac{Q(z^{-1})N(z^{-1})}{\beta(z^{-1})}. \]

The Diophantine equation (20) will have a unique solution due to the construction of \( Q \) and \( L^* \), as described in Ahlén and Sternad [1989].

A remark regarding the choice of \( \rho \): It can be seen from (17) that \( \rho = 0 \) generates a feedforward filter with poles on the unit circle. This is due to the fact that \( \beta \) then would have a factor \( B_2 \), which leads to a feedforward filter that is only marginally stable when (21) is computed. Thus, \( \rho = 0 \) is not a permitted choice.

This design strategy is directly applicable to more general models. One needs only to modify (6) and (7) and carry out the above calculations.

5. NUMERICAL EXAMPLES

In this section the different feedforward control strategies are evaluated and compared for different SNR values. The one-DOF, two-DOF and Wiener feedforward filters are denoted \( F_1 \), \( F_2 \) and \( F_3 \), respectively. For \( F_2 \) and \( F_3 \), \( \rho = 10^{-3} \) is chosen. The Wiener feedforward filter is evaluated for pure filtering (\( m = 0 \)) and smoothing with \( m = 32 \). This value appears to yield a reasonable tradeoff between performance and time delay requirements.

The result for case (ii) is reported in Figure 4. The (a)-parts of the figure shows the normalized output variance as a function of the SNR in dB scale. The interpretation should be that the feedforward control is efficient for SNR values that yield outputs below 0 dB. If the output quantity reaches above 0 dB, the control loop amplifies the disturbance \( v(t) \) and the wave diode becomes useless.

The (b)-part of the figure depicts the normalized cost function measure \( \|E_y^2(t) + \rho E\nu^2(t)/E\nu^2(t) \). Here, the Wiener filter \( F_3 \) should give better performance than \( F_1 \) and \( F_2 \). This is due to the fact that it in some sense has the ‘truly optimal’ structure.

The two feedforward filters based on Wiener filtering yield the best performance in terms of cost function evaluation. The Wiener filter with fixed lag smoothing gives the lowest value since this filter utilizes ‘future’ data.

In terms of output variance minimization, the Wiener filters also give the best overall performance. For high SNR values the one-DOF feedforward filter \( F_1 \) gives very low output variance. It may even beat the Wiener filter structures. This is to the expense of a very high control signal variance. Notice that \( F_1 \) is not designed to take the magnitude of the control signal into account. The effect of this can be seen in Figure 4 (b) where the variance of the control signal dominates for high signal to noise ratios. Here, \( F_1 \) clearly gives a substantial performance degradation compared to the other design techniques.

The overall performance of the two-DOF filter \( F_2 \) lies somewhat in-between \( F_1 \) and \( F_3 \). It performs similar to \( F_1 \) for low to moderate SNR values. However, it lacks \( F_1 \)’s drawback of a substantial control signal variance for high SNR.

Another issue is robustness against modeling errors. In Figure 5, the case of inaccurate signal models are evaluated. The system is here operating with the signal models out under the assumption of case (i). Therefore, Figure 5 should be compared to Figure 4 since both figures reports results from identical systems. It can be seen that the performance of the feedforward filter is only slightly
A criterion with control signal penalty is introduced, which allows optimal feedforward control design based on Wiener determined model structure. In order to accomplish this, a filtering. The technique is general and can be used for values and at the same time keeping the control signal output variance can be kept low for a wide range of SNR.

6. CONCLUSIONS

In this paper, the results reported in Nauclér et al. [2007] are extended with more general types of feedforward control strategies. An apparent motivation for the work is to investigate how much can be gained by utilizing an optimal design strategy that does not presume a pre-determined model structure. In order to accomplish this, a criterion with control signal penalty is introduced, which allows optimal feedforward control design based on Wiener filtering. The technique is general and can be used for systems that contains transfer functions with marginally stable inverses. This is in contrast to the previous work that only considered output variance minimization with constraint on the pole locations for a pre-determined feedforward structure.

The conclusion is that it is worthwhile to employ the Wiener filter structure. The main achievement is that the output variance can be kept low for a wide range of SNR values and at the same time keeping the control signal variance at moderate levels.
