Abstract: Based on the Unscented Kalman Filter (UKF), the nonlinear filter is presented for parameter estimation in linear system with correlated noise where the unknown parameters are estimated as a part of an enlarged state vector. To avoid the computational burden in determining the state estimates when only the parameter estimates are required, a new form of UKF, where the state consists only of the parameters to be estimated, is proposed. The algorithm is based on the inclusion of the computed residuals in the observation matrix of a state representation of the system. Convergence properties of the proposed algorithm are analyzed and ensured. The algorithm is verified by using Matlab simulations on the vehicle navigation systems with aided GPS.

1. INTRODUCTION

The problem of parameter estimation is stochastic linear dynamic systems has been researched considerable because of its importance in model building and control theory (Astrom et al., 1971; Granados et al., 1998; James et al., 2000; Chin-Lang Tsai et al., 2006). It is well known that the general case of correlated noise leads to a nonlinear estimation problem. A number of methods have been proposed, most of which base on the Extended Kalman Filter (EKF) (Jazwinski, 1970; Astrom et al., 1971). A variant of method will be discussed in this paper.

The approach to parameter estimation in linear systems can be summarized as follows. To estimate the unknown parameters of a linear system, the parameters are appended to the state variables, and a state estimator for the enlarged system is then used to obtain joint estimates of both the original system state and the system parameters. However, since the enlarged system is nonlinear (Astrom et al., 1971), to make the computation of the estimates feasible, the unscented kalman filter (UKF) (Julier et al., 1995), which aims at the nonlinear system directly (Julier, 2000; Julier et al., 2000; Lefebvre et al., 2002; Julier et al., 2004), is proposed.

Although the UKF approach to parameter estimation has a strong intuitive appeal and offers the possibility(Julier et al., 1997a; Julier et al., 1997b; Julier et al., 1997c; Wan et al., 2000), it suffers from many disadvantages (Pan Quan et al., 2005). The computational burden of estimating the enlarged state and magnified by the necessity for Unscented Transform (UT) at each step may have divergence problems, and although filter divergence can be avoided in modified algorithms, the modifications require additional computing time.

The contribution of this paper rests in the development of the UKF for parameter estimation. This is achieved by modeling the system, whose parameters are to be estimated, by state equations where the state consists of the system and noise parameters, while the corresponding inputs, outputs, and computed residuals are collected in the observation matrix of the state equations. This results again in a nonlinear system, and the UKF state estimator directly gives, in this case, the parameter estimates only. To study the convergence properties of the algorithm, some techniques based on the associated differential equation (Ljung, 1977; Ljung, 1979; Xionga et al., 2006) are used. It is shown that the UKF can achieve the convergence properties.

The paper is structured as follows. Section II contains the outline of the problem and gives the UKF equations. In Section III, the parameter estimation algorithm is developed, and the related convergence results are obtained in Section IV. The algorithm is verified by using Matlab simulations on the vehicle navigation systems with aided GPS (Nebot, 1998) and the results show the effectiveness of the algorithm.

2. PRELIMINARIES

Consider the state representation of a multivariable system

\[ \begin{align*}
    x(t+1) &= A_t x(t) + B_t u(t) + v(t) \\
    y(t) &= C_t x(t) + w(t)
\end{align*} \]

where \( u(t) \), \( y(t) \), and \( x(t) \) are the input, output, and state vector of dimensions \( n_u \), \( n_y \), and \( n_x \), respectively, and \( \{v(t)\} \), \( \{w(t)\} \) are sequences of independent random vectors with zero mean and the covariance.

\[ E\left[ \begin{bmatrix} v(t) \\ w(t) \end{bmatrix} \begin{bmatrix} v^T(t) \\ w^T(t) \end{bmatrix} \right] = \begin{bmatrix} O & S \\ S^T & R \end{bmatrix} \delta_t, \quad \delta_t = 1, \delta_t = 0 \quad (t \neq j) \quad (2) \]
Also, the initial state $x(0)$, assumed to be a random vector with zero mean and a covariance $\Sigma(0)$ is considered independent of $[v(t)], [w(t)]$ for $t > 0$, and the matrices in (1) and (2) are time invariant.

We shall now consider the case where the matrices in (1) and (2) are unknown and to be estimated from the input-output measurements $[u(t), y(t)]$, $t = 0, 1, \ldots$. For this purpose, we shall establish a model of (1):

$$
\begin{align*}
\dot{x}(t+1) &= A(\theta) x(t) + B(\theta) u(t) + v(t) \\
y(t) &= C(\theta) x(t) + w(t)
\end{align*}
$$

where

$$
E\left[ \left( \begin{array}{c} w(t) \\ v(t) \end{array} \right) \left( \begin{array}{c} f(j) \\ v^2(j) \end{array} \right) \right] = S_{ij} = \begin{cases} Q & j = 1, \delta_j = 1 \\
R & j = i, \delta_j = 0 \end{cases} (i \neq j)
$$

$$
E(x(0)) = 0, E(x(0)x^T(0)) = \Sigma(0)
$$

In this model, the unknown matrices are represented as some differentiable functions of a parameter vector $\theta$ which will be estimated by using the UKF approach. First, form an enlarged state vector by appending the parameter vector $\theta = \theta(t)$ to the state

$$
z(t) = [x(t) \ \theta(t)]^T
$$

The resulting state equations are nonlinear:

$$
\begin{align*}
z(t+1) &= f(z(t), u(t)) + v(t) \\
y(t) &= g(z(t), w(t))
\end{align*}
$$

where

$$
\begin{align*}
f(z(t), u(t)) &= \begin{bmatrix} A(\theta) x(t) + B(\theta) u(t) \\ C(\theta) x(t) \end{bmatrix} \\
g(z(t), w(t)) &= \begin{bmatrix} C(\theta) x(t) \end{bmatrix}
\end{align*}
$$

The required parameter estimates are now obtained by applying the UKF to (6) which gives

The n-dimensional random variable $z(t)$ with mean $\bar{z}(t)$ and covariance $P(t)$ can be approximated by sigma points $\xi(t)$ selected from the columns of $\bar{z}(t)\pm(\alpha\sqrt{L}P(t)^{1/2})$, $i = 0, \ldots, 2L$. The opposite weight $a_i$ is $a_0 = 1-(L+1)\alpha^2$, $a_i = 1/2L\alpha^2$ ($i = 1, 2, \ldots, 2L$).

The predicted mean and covariance are computed as

$$
\bar{z}(t+1) = \sum_{i=0}^{2L} a_i \xi_i(t+1) \\
P(t+1) = \sum_{i=0}^{2L} a_i (\xi_i(t+1) - \bar{z}(t+1))(\xi_i(t+1) - \bar{z}(t+1))^T
$$

Then the measurement update can be performed with the equations as follows.

$$
\begin{align*}
\dot{x}'(t+1) &= g(\xi(t+1)) \\
\dot{y}'(t+1) &= \sum_{i=0}^{2L} a_i \xi_i(t+1) y_i(t+1) \\
P'_{x}(t+1) &= \sum_{i=0}^{2L} a_i (\xi_i(t+1) - \bar{z}(t+1))(\xi_i(t+1) - \bar{z}(t+1))^T \\
P'_{y}(t+1) &= \sum_{i=0}^{2L} a_i (\xi_i(t+1) - \bar{z}(t+1))(\xi_i(t+1) - \bar{z}(t+1))^T \\
P'(t+1) &= K'(t+1)P'(t+1)K'(t+1)^T + R
\end{align*}
$$

$$
K'(t+1) = \sum_{i=0}^{2L} a_i (\xi_i(t+1) - \bar{z}(t+1))(\xi_i(t+1) - \bar{z}(t+1))^T
$$

$$
\bar{z}(t) = \bar{z}(t) + K'(t)(y(t) - \bar{y}')
$$

$$
P'(t+1) = \sum_{i=0}^{2L} a_i (\xi_i(t+1) - \bar{z}(t+1))(\xi_i(t+1) - \bar{z}(t+1))^T + R
$$

$$
P'(t+1) = P'(t+1) + K'(t+1)P'(t+1)K'(t+1)^T
$$

The algorithm may lead to divergence and bias problems. Therefore, it would be of interest to investigate an alternative representation to (1) which should not give rise to the need for the selection of the covariance matrices (4) when there is no priori information about their structure available; the representation should have fewer parameters and should obviate the necessity for the state estimation where only the parameter estimates are required. At the same time, we would like to keep the structure of the Kalman filter estimator because of its advantageous minimum variance formulation of the estimation problem. A representation of (1) having all the above features will be discussed in the next section and will form a basis for the proposed estimation algorithm.

### 3. THE ALGORITHM

Since in parameter estimation only the input-output properties of a system are of interest, we shall now start with the parameter parsimonious vector difference equation (VDE) representation of a multivariable linear system. We shall use the form

$$
A(q^{-1})y(t) = B(q^{-1})u(t) + C(q^{-1})w(t)
$$

where $q^{-1}$ is the backward shift operator.

$$
A(q^{-1}) = 1 + A_1 q^{-1} + \ldots + A_n q^{-n}
$$

$$
B(q^{-1}) = B_0 q^{n-1} + \ldots + B_{n-1} q
$$

$$
C(q^{-1}) = C_0 q^{n-1} + \ldots + C_n q^{-n}
$$

where the coefficients $A, C$ are $n \times n$ matrices, whereas the coefficients $B$ are $n \times n$ matrices. The sequence $[e(t)]$ is assumed to consist of independent random vectors of dimension $n$, having zero mean and a covariance

$$
E(e(t)e^T(t)) = \Sigma
$$

Although it is possible to obtain under some assumptions the representation (8) from the state form (1) and vice versa, in the sequel we shall assume that the data $[u(t), y(t)], t = 0, 1, \ldots$ have been generated by (8), which is an important form in its own right, and we shall formulate the problem as the estimation of the parameters in (9) and (10) from the given input-output data.

To develop the estimation algorithm, first write the system (8) in the form

$$
y'(t) = \psi_e(t) \theta_e + e(t)
$$

with

$$
\psi_e(t) = \begin{bmatrix} \eta_1(t) & 0 & 0 & 0 \\
0 & \eta_2(t) & \ldots & 0 \\
0 & 0 & \ldots & \eta_n(t) \end{bmatrix}
$$

an $n \times n_{\theta_e}$ matrix.

$$
\theta_e = [\theta_1^T \ \theta_2^T \ \ldots \ \theta_n^T]^T
$$

where

$$
\eta_i(t) = (y(t-1)^T, \ldots, y(t-n_i)^T, u(t-1)^T, \ldots, u(t-n_i)^T, e_1(t-1)^T, \ldots, e_{n_i-1}(t-1)^T)
$$

$$
\theta_i = \text{ith row of } \theta_1 \ \theta_2 \ \ldots \ \theta_n \ \Sigma
$$

If (11) is now formally considered to be the observation equation of a state representation of system (8) with the state defied as the (constant) parameter vector $\theta_e(t)$, we obtain a particular form of state equations for (8):

$$
\theta_e(t+1) = \theta_e(t) + \gamma'(t) + e(t)
$$

$$
y'(t) = \psi_e(t) \theta_e(t) + e(t)
$$
For parameter estimation purposes, we also need a model of (15) based on parameter value \( \theta(t) \):

\[
\theta(t+1) = \theta(t) + \nabla \psi(\theta(t) + e(t))
\]

(16)

where, in analogy with (11)-(14),

\[
\Psi(t) = \begin{bmatrix}
0 & 0 & 0 \\
0 & \Psi(t) & \cdots \\
0 & 0 & \Psi(t)
\end{bmatrix}
\]

(17)

is a matrix of dimension \( n_t \times n_t \).

\[
\theta(t) = [\sigma_1(t), \sigma_2(t), \ldots, \sigma_{n_t}(t)]^T
\]

(18)

where \( \sigma_i(t) \) are the random vectors \( \sigma(t-1), \ldots, \sigma(t-n_t) \) in \( \Psi(t) \) are unknown, these quantities are replaced in the observation matrix \( \psi(t) \) in (16) by the computed residuals \( \epsilon(t-1), \ldots, \epsilon(t-n_t) \) as shown in (19), which makes (16) a usable model. The matrix \( \psi(t) \) now depends on \( \theta(t) \), and the representation (16) is nonlinear so the UKF must be used. Note that the sequence \( \{\epsilon(t)\} \) is not white, but becomes white as \( \theta(t) \rightarrow \theta_0 \).

From the conversion of a parameter estimation problem into an UKF problem, we shall also derive some additional benefits. The available information about the statistical properties of the parameters to be estimated can be readily incorporated into the algorithm as has already been discussed, and the minimum variance Kalman filtering approach leads us to expect that lower variance of the parameter estimates can be obtained then from a number of other approaches available. Also, by a natural extension of the algorithm, it will be possible to estimate parameters which are Gauss-Markov random processes. What is left now is to apply the UKF algorithm to the state equation model (16). To make use of the minimum variance formulation of the Kalman filter, an estimator for the covariance \( \Lambda_t \) will be coupled with the filter equations. The resulting algorithm is particularly simple:

The n-dimensional random variable \( \theta(t) \) with mean \( \hat{\theta}(t) \) and covariance \( P(\theta(t)) \) can be approximated by sigma points \( \chi(t) \) selected from the columns of \( \hat{\theta}(t) \pm (a \Lambda(t) P(\theta(t))^T) \), \( i = 0, \ldots, 2L \). The opposite weight \( \alpha_i \) is \( \alpha(0) = 1 - L^2, \alpha(i) = 2L^2 \), \( i = 1, 2, \ldots, 2L \).

The predicted mean and covariance are computed as

\[
\hat{\theta}(t+1) = \sum_{i=0}^{2L} \alpha_i \chi(t) \]

(20)

\[
P^{\theta}(t+1) = \sum_{i=0}^{2L} \alpha_i \chi(t) \hat{\theta}(t+1) + \alpha_i (\chi(t) - \hat{\theta}(t+1))^T
\]

(21)

Then the measurement update can be performed with the equations as follows.

\[
\Psi(t) + \sum_{i=0}^{2L} \alpha_i \chi(t)^T \epsilon(t+1) (\chi(t) - \hat{\theta}(t+1)) = \sum_{i=0}^{2L} \alpha_i (\chi(t) - \hat{\theta}(t+1) \epsilon(t+1))
\]

(22)

\[
P^{\theta}(t+1) = \sum_{i=0}^{2L} \alpha_i (\chi(t)^T \epsilon(t+1) (\chi(t) - \hat{\theta}(t+1) \epsilon(t+1))^T + \lambda(t+1))
\]

(23)

\[
P^{\theta}(t+1) = \sum_{i=0}^{2L} \alpha_i (\chi(t)^T \epsilon(t+1) (\chi(t) - \hat{\theta}(t+1) \epsilon(t+1))^T)
\]

(24)

\[
K^{\theta}(t+1) = N^{\theta}(t+1) P^{\theta}(t+1)
\]

(25)

where, in analogy with (27), \( \lambda(t+1) \) denotes an estimate of \( \Lambda \) based on \( t+1 \) data pairs \( \{\epsilon(t), \theta(t)\}, \) \( j = 0, 1, \ldots, L \), and the resulting formula (28) is obtained by rewriting its off-line version.

To avoid some numerical problems which may arise if the matrix \( P^{\theta}(t+1) \) becomes singular, (21) is sometimes replaced by

\[
P^{\theta}(t+1) = \sum_{i=0}^{2L} \alpha_i \chi(t)^T (\chi(t) - \hat{\theta}(t+1)) + \Delta Q
\]

(26)

where, \( \Delta Q \) is an extra positive definite matrix introduced in the calculated covariance matrix as a slight modification of the UKF so that the stability will be improved.

**Remark 1.** To ensure the convergence of UKF, the matrices \( P^{\theta}(t+1) \) need to be positive definite. From (27), as \( P^{\theta}(t+1) \) and \( -K^{\theta}(t+1) P^{\theta}(t+1) K^{\theta}(t+1)^T \) may not be positive definite matrices, extra additive matrix \( \Delta Q \) in (30) should be introduced as a modification to the UKF so that \( P^{\theta}(t+1) \geq 0 \) will be satisfied. Obviously, if \( \Delta Q \) is sufficiently large, \( P^{\theta}(t+1) \) can always be positive definite. This means that the UKF can tolerate high order error introduced during the UT by enlarging the noise covariance matrix.

### 4. CONVERGENCE ANALYSIS

In this section, a simple approach to convergence of the algorithm (20)-(30) is given.

Expanding \( \theta(t) \) in (16) by a Taylor series about \( \theta = \hat{\theta}(t) \),

\[
G(t) = \frac{\partial \varphi}{\partial \theta} \theta(t) \bigg|_{\theta(t)} = \frac{\partial \varphi}{\partial \theta} \bigg|_{\theta(t)}
\]

(31)

Substituting (31) into (16) yields an approximate equality.

\[
y^{\theta}(t) = G(t) \hat{\theta}(t) + e(t)
\]

(32)

In (32), it is evident that there always exist residuals of error prediction \( \hat{\theta}(t+1) \). In order to take these residuals into account and obtain a more exact equality, an unknown instrumental diagonal matrix \( \Lambda = \text{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n) \) is introduced, so that

\[
y^{\theta}(t) = G(t) \theta(t) + e(t)
\]

(33)

To prove the convergence of the algorithm (20)-(30), a method of analysis based on an associated deterministic differential equation (Ljung, 1977) will be used. To be able to apply the analysis, we shall assume in the following that the input \( u(t) \) is a weakly stationary process with rational spectral density and that all absolute moments of the sequences \( \{\epsilon(t)\} \), \( \{\eta(t)\} \) are bounded, and we shall also require that the system (8) and the equation generating \( \epsilon(t) \) in (29) be stable.

For analysis of the algorithm convergence, some regularity conditions similarly as in (Ljung, 1977; Ljung, 1979; Xionga et al., 2006) are recalled.

**Lemma.** Consider the differential equation given by

\[
\frac{d}{dt} \theta^{\theta}(t) = f(\theta^{\theta}(t))
\]

(34)
Let $D = \{ \vartheta|(A(\vartheta), Q) \text{ stabilizable and } (A(\vartheta), C(\vartheta)) \text{ detectable} \}$. Let $\{ \hat{\theta}(i), \hat{x}(i) \}$ be given by algorithm (20)-(30).

1) Suppose that the associated deterministic differential equation (34) has an invariant set $D_0$, with domain of attraction $\theta \in D_0$ (which will be a subset of $D$). Suppose further that $\hat{\theta}(i)$ belongs to a compact subset of $D_0$ and $\hat{x}(i)$ is bounded infinitely often with probability one. Then
\[ \hat{\theta}(i) \to D_0 \text{ with probability } 1 \text{ as } i \to \infty. \tag{35} \]

2) Suppose that $\hat{\theta}(i) \to \theta^*$ with probability greater than zero. Then $\theta^*$ must be a stable stationary point of the differential equation (34).

3) Let $\bar{D}$ be a compact subset of $D_0$ such that the trajectories of (34) that start in $\bar{D}$ do not leave $\bar{D}$. Suppose that the estimates $\hat{\theta}(i)$ are projected into $\bar{D}$ and that (34) has an invariant set $D_1 \supset \bar{D}$. Then $\hat{\theta}(i) \to D_1$ with probability $1$ as $i \to \infty$.

To apply the Lemma and the theory in (Ljung, 1977), we shall start with a derivation of an alternative expression for the Kalman gain $K(i)$ in (26). Writing (20) and (30) in terms of
\[ \Theta(i) = [D^\vartheta(i)]^{-1} \tag{36} \]
We obtain
\[ \hat{\theta}(i+1) = \hat{\theta}(i) + (\lambda + 1)(\bar{D} + \Theta(i))\left[ t \left( (t-i) - \psi(\bar{\theta}(i)) \right) \right. \tag{37} \]
\[ \Theta(i) + (1 + 1) \left[ t [K(i) - i] \left( (i + 1) - \Theta(i) \right) \right] \tag{38} \]
The associated differential equation for the algorithm (20)-(30) will now be defined in terms of processes resulting from the algorithm when the parameter estimates are kept at some constant value $\hat{\theta}(i) = \theta$, $\lambda = \lambda^*$. Then $G(i)$, $\psi(i)$, and $e(i)$ would give some $G(\theta)$, $\psi(\theta)$, and $\varepsilon(\theta)$ for large $i$. Define now the expectations
\[ f(\theta, \lambda) = \lambda E\left( G(\theta) \right) \tag{39} \]
\[ W(\theta) = E\left( \varepsilon(\theta) \varepsilon^T(\theta) \right) \tag{40} \]
The behavior of the estimates obtained from (20)-(30) can be described by the coupled differential equations
\[ d\Theta(\tau) = R^{-1}(\tau) f(\Theta(\tau), f(\tau)) d\tau \tag{41} \]
\[ dL(\tau) = W(\Theta(\tau) - \Theta(\tau)) d\tau \tag{42} \]
To comment on the significance of some of the quantities introduced in (39), the expression $f(\theta, \lambda)$ can be interpreted as the average correction to $\hat{\theta}(i+1)$ in (37) with $[1 + (t-i)]\lambda = \hat{\theta}(i)$ being the correction gain. Apparently, $P(t) \to 0$ for large $t$ if $\Theta(i)$ is bounded, but this is guaranteed by (38). The convergence properties of the algorithm (20)-(30) can now be summarized in the following result.

**Theorem.** Consider input-output data $\{ u(t), y(t) \}$ $t = 0, 1, \ldots$ generated by a stable system (8), and its model (16) whose parameters are estimated by the algorithm (20)-(29) with (21) replaced by (30). Assume that the algorithm is equipped with a feature that guarantees stable generation of $e(t)$ in (29). (This is achieved by allowing only such parameter vector $\theta(i)$ for which $\lambda^{-1}(\vartheta(i))$ is stable.) Then the estimate $\hat{\theta}(i)$ converges with probability one to a stationary point of the function
\[ V(\theta, \lambda) = E\left( f(\theta, \lambda)^T \right) \tag{43} \]
where $\lambda$ denotes the determinant of $\Lambda$ and
\[ \tau(\theta) = C(\vartheta)^T \left( \lambda(\vartheta) \right) y(\vartheta) - C(\vartheta)^T \left( \lambda(\vartheta) - \lambda(\vartheta) \right) \]

with parameters unknown.

This model may be described by a shaping filter with process parameter $\lambda(t)$.
where, $v_\alpha(t)$ and $v_\beta(t)$ are the velocity on the directions of longitude and latitude, respectively. $x_\alpha(t)$ and $x_\beta(t)$ are the parameters of the variance of longitude and latitude, respectively. $q_{\alpha}^2$, $q_{\beta}^2$, $\sigma_{\alpha u}^2$, and $\sigma_{\beta u}^2$ are white noises.

It is obviously that in this application the observation is composed of the GPS position measurement that is corrupted with correlated noise. Then the unknown parameters $\alpha$, $\beta$ and $\gamma$ are represented as a parameter vector $\theta$ which will be estimated by using the UKF approach and form an enlarged state vector by appending the parameter vector $\theta = \theta(t)$ to the state. So we can obtain

$$\theta(t) = [\alpha \ \beta \ \gamma]^T$$

$$z(t) = [x(t) \ \theta(t)]$$

The required parameter estimates $z(t)$ and $\theta(t)$ are now obtained by applying the proposed UKF. The trajectories of the estimated parameters $x_\alpha(t)$ and $x_\beta(t)$ with EKF and UKF are depicted in Fig. 1 and Fig. 2, respectively.

Fig. 1 and Fig. 2 show the filtering results of the system with respect to the GPS position estimate $x_\alpha(t)$ and $x_\beta(t)$. The GPS observation consists almost entirely of correlated noise because the vehicle is stationary. Compare with EKF, the position estimation with UKF is substantially obtained and the position error can remain in the 100 m range on the whole. The trajectories of the estimated parameters $\alpha$, $\beta$ and $\gamma$ with EKF and UKF are compared in Fig. 3 to Fig. 5 and with the new form of EKF and UKF are compared in Fig. 6 to Fig. 8, respectively.

Fig. 1. The parameter estimation of the longitude $x_\alpha(t)$.

Fig. 2. The parameter estimation of latitude $x_\beta(t)$.

Fig. 3. The parameter $\alpha$ estimation with UKF and EKF.

Fig. 4. The parameter $\beta$ estimation with UKF and EKF.

Fig. 5. The parameter $\gamma$ estimation with UKF and EKF.

Fig. 6. $\alpha$ estimation with the new form UKF and EKF.

which are estimated by using the new proposed UKF approach. The filter also can obtain the required parameters and satisfy the anticipated values of GPS observation. And also, UKF make sure the estimation achieve the anticipated values more quickly compare with EKF. Furthermore, compare with Fig. 3 to Fig. 5, it is easy to see that the estimation achievement process to the anticipated values is expedited. Consequently, the computational burden is obviously reduced by using the new proposed UKF. From these figures, the convergence of the new proposed UKF is also verified.
The simulations on the vehicle navigation systems with aided GPS in this section verify the proposed algorithm and its performance from the view of experimentation. It is shown that the proposed algorithm has practicability to a certain extent.

6. CONCLUSIONS

Based on the nonlinear filter UKF, the algorithm is presented for linear systems with correlated noises. Firstly, the outline of the problem is presented and the UKF equations are proposed. Then the parameter estimation algorithm is developed and an extra additive matrix $\Delta Q$ is introduced to make sure the matrices $P(t+1)$ is positive define. Furthermore, the analysis of the related convergence properties of the algorithm is given. According to some standard results about the convergence of stochastic processes, it is pointed out that, the convergence of the algorithm may be ensured and do not depend on the magnitude of $\lambda$ which is an unknown instrumental diagonal matrix introduced to evaluate the error introduced by linearization. Moreover, the vehicle navigation systems with aided GPS are introduced to show the high performances of the proposed algorithm.
