Abstract: A control design approach for the autonomous crosswind flight of tethered wings, to be used in airborne wind energy systems, is described. The proposed technique aims to learn the behavior of a human pilot, by exploiting a finite number of data collected during manual operation of the system, hence avoiding the need for an explicit model of the system dynamics. Along with the design technique, experimental data showing its successful application are presented.

1. INTRODUCTION

Airborne wind energy technologies aim to produce power exploiting the aerodynamic forces generated by a wing tethered to the ground, hence realizing a wind generator capable of reaching higher altitudes with respect to the current wind turbines, see e.g. Ahrens et al. (2013); Fagiano and Milanese (2012) for details. In particular, the lift force developed by the wing is large enough to sustain its weight and that of the tethers, and to produce power. In the configuration considered in this work, such a power is extracted at ground level by executing a two-phase (“pumping”) cycle consisting of reeling-out the lines under large traction forces and subsequently reeling-in under low forces, thus realizing a positive net energy balance. The automatic control of the wing is a key aspect of this technology, since the optimal trajectories that the wing should fly are unstable in open loop and the system is subject to external disturbances like wind turbulence. In particular, one of the main control tasks is to make the wing fly along figure-of-eight patterns in the so-called crosswind conditions, i.e. roughly perpendicularly to the wind. This problem has been addressed by several researchers in the last years, leading to a number of contributions, Canale et al. (2007); Williams et al. (2008); Baayen and Ockels (2012); Houska and Diehl (2007); Ilzhöfer et al. (2007); Fagiano et al. (2013a,b); Canale et al. (2010); Fagiano et al. (2010). Most of these techniques employ a standard two-phase approach where a dynamical model of the system is firstly derived and then a feedback controller is designed on the basis of such a model. One of the main potential difficulties in such approaches is that the derivation of a dynamical model suited for control design might be not easy, due to the mentioned open-loop instability and the presence of disturbances which make the use of model identification techniques hard. In this paper, we show how this control problem can be tackled effectively with a direct technique, i.e. an approach that aims to design a feedback controller directly from measured data, without the need for an explicit model of the system’s dynamics. In particular, we present an approach to learn the behavior of a human operator (or more in general of an existing, unknown feedback controller) using a finite number of data collected in an initial experiment. We present a theoretical analysis showing that the approach provides stability guarantees as the number of employed data-points increases, and we present the successful experimental application of the approach on a small-scale prototype built at the University of California, Santa Barbara.

2. SYSTEM DESCRIPTION

We consider a flexible wing connected by three lines to a ground unit (GU), as shown in Fig. 1. The wing’s trajectory evolves downwind with respect to the GU. For simplicity, we assume that the nominal wind direction (i.e. neglecting turbulence and small, zero-mean deviations) is aligned with the longitudinal symmetry axis of the GU, denoted by X. The latter, together with the Z axis being perpendicular to the ground and pointing upwards and with the Y axis to complete a right-handed system, forms the inertial frame \( G \equiv (X,Y,Z) \), centered at the GU (see Fig. 2). By considering a fixed length of the lines, denoted by \( r \), the wing’s trajectory is confined on a quarter sphere, commonly named “wind window”, see Fig. 2 (dashed lines).

The wing’s position \( p(t) \) can be expressed in the inertial frame \( G \) by using the spherical coordinates \( \theta(t), \phi(t) \) (see Fig. 2), where \( t \) is the continuous time variable. We also consider a non-inertial coordinate system, \( L \equiv (L_N, L_E, L_D) \), centered at the wing’s position (depicted in Fig. 2). The \( L_N \) axis, or local north, is tangent to the sphere of radius \( r \), on which the wing’s trajectory evolves, and points towards its zenith. The \( L_D \) axis, called local down, points the center of the sphere (i.e. the GU), hence it is perpendicular to the tangent plane to the sphere at the wing’s location. The \( L_E \) axis, named local east, forms a right-handed system and spans the tangent plane together with \( L_N \). The system \( L \) is a function of the wing’s position only, see Fagiano et al. (2013b) for a complete derivation. The wing velocity vector can be expressed in the \( L \) frame as

The described control problem involves open-loop unstable, nonlinear and time-varying dynamics. Mathematical models for this kind of system have been derived for the design of predictive control approaches, which have been used in numerical simulations, Houska and Diehl (2007); Williams et al. (2008); Canale et al. (2010). However, in a real-world experimental setup it is not easy to employ such approaches, due to difficulty of identifying the model parameters from experimental data, the absence of accurate measurements of the wind speed at the wing’s location, finally the need to solve a nonlinear program in real-time at each time step. However, a human operator is able, after some training, to obtain the desired flying paths by issuing a suitable course of the actuator position reference \( u \), adapting to different wind conditions and counteracting the effects of turbulence and gusts: hence, a possible approach is to design a feedback controller by learning the behavior of such a human operator from experimental data. In the next section, we present a technique able to achieve this goal.

3. LEARNING A CONTROLLER FROM DATA

3.1 Problem setting

The setting we consider in this work is the following. A single-input, discrete time, nonlinear dynamical system of interest operates in closed loop with an existing controller. Both the system and the controller are not known. The system’s input variable \( w(t) \), i.e. the controller’s output, is known and it can be measured at discrete time instants \( t \in \mathbb{Z} \). Moreover, \( u \) is limited in a compact \( U = [-\bar{u}, \bar{u}] \). The system’s output variable \( y(t) \), i.e. the controller’s input, is not known a priori but the control designer can rely on sensors to acquire measurements of different “candidate” feedback variables, based on her/his intuition and experience with the physical process under study. The output \( y \) is assumed to belong to a compact set \( Y \subset \mathbb{R}^n \). After a choice of \( y(t) \) has been made, we assume that the controller is a static function of this variable:

\[
\kappa : Y \rightarrow U
\]

where \( \kappa \) is Lipschitz continuous with respect to \( y \). Moreover, we assume that a disturbance variable \( e_d(t) \) is acting

Fig. 1. Small-scale prototype built at the University of California, Santa Barbara, to study the control of tethered wings for airborne wind energy.

Fig. 2. Reference system \( G = (X,Y,Z) \), wind window (dashed lines), variables \( \theta, \phi, \) and local north, east and down \( (L_N,L_E,L_D) \) axes.

\[
\frac{d}{dt} p(t) = r \begin{pmatrix} \dot{\theta} \\ \cos(\theta)\dot{\phi} \\ 0 \end{pmatrix}, \tag{1}
\]

Finally, the velocity angle \( \gamma(t) \) of the wing is defined as:

\[
\gamma(t) = \arctan_2 \left( \cos(\theta(t))\phi, \dot{\theta} \right), \tag{2}
\]

where \( \arctan_2 \) is the four-quadrant arc-tangent function. \( \gamma(t) \) is the angle between the local north, \( L_N(t) \), and the wing velocity vector, \( v(t) \), and it provides a good description of the heading of the wing while flying on the surface of the wind window.

The two lateral lines linking the wing to the GU, named steering lines, are attached to the back tips of the wing (see Fig. 1) and they are used to influence its trajectory: a shorter left steering line with respect to the right one impresses a left turn to the wing (i.e. a counter-clockwise turn as seen from the GU), and vice-versa. In the considered prototype, a single motor, together with a linear motion system (visible in the lower-left corner of Fig. 1), is able to change the difference of length of the steering lines. In particular, a linear controller modulates the motor current in order to track a desired position of the actuators: such a position reference is the manipulated variable \( u \) and it can be set either by a human operator through an analog joystick, or by an automatic controller.

The wing is equipped with inertial onboard sensors and a radio transmitter; the receiver and other sensors are installed on the GU, including a line angle measurement system, load cells, and an anemometer. The available sensors, together with suitable filtering algorithms, provide real-time measurements of the wing’s position, velocity, and velocity angle, which can then be used for feedback control (see Fagiano et al. (2013a) for details on the filtering and sensor fusion aspects).

The aim of the control system is to obtain crosswind trajectories, i.e. flight paths that are symmetric and roughly perpendicular with respect to the \( X \) axis (i.e. the wind direction), whose shape is a that of an eight. This kind of patterns has been shown to be optimal for power generation, see e.g. Houska and Diehl (2007); Canale et al. (2010); Fagiano and Milanese (2012).

The described control problem involves open-loop unstable, nonlinear and time-varying dynamics. Mathematical models for this kind of system have been derived for the design of predictive control approaches, which have been used in numerical simulations, Houska and Diehl (2007); Williams et al. (2008); Canale et al. (2010). However, in a real-world experimental setup it is not easy to employ such approaches, due to difficulty of identifying the model parameters from experimental data, the absence of accurate measurements of the wind speed at the wing’s location, finally the need to solve a nonlinear program in real-time at each time step. However, a human operator is able, after some training, to obtain the desired flying paths by issuing a suitable course of the actuator position reference \( u \), adapting to different wind conditions and counteracting the effects of turbulence and gusts: hence, a possible approach is to design a feedback controller by learning the behavior of such a human operator from experimental data. In the next section, we present a technique able to achieve this goal.

3. LEARNING A CONTROLLER FROM DATA

3.1 Problem setting

The setting we consider in this work is the following. A single-input, discrete time, nonlinear dynamical system of interest operates in closed loop with an existing controller. Both the system and the controller are not known. The system’s input variable \( w(t) \), i.e. the controller’s output, is known and it can be measured at discrete time instants \( t \in \mathbb{Z} \). Moreover, \( u \) is limited in a compact \( U = [-\bar{u}, \bar{u}] \). The system’s output variable \( y(t) \), i.e. the controller’s input, is not known a priori but the control designer can rely on sensors to acquire measurements of different “candidate” feedback variables, based on her/his intuition and experience with the physical process under study. The output \( y \) is assumed to belong to a compact set \( Y \subset \mathbb{R}^n \). After a choice of \( y(t) \) has been made, we assume that the controller is a static function of this variable:

\[
\kappa : Y \rightarrow U
\]

where \( \kappa \) is Lipschitz continuous with respect to \( y \). Moreover, we assume that a disturbance variable \( e_d(t) \) is acting
on the dynamical system. The variable \( e_s \) accounts for (a) exogenous disturbances, (b) neglected and time-varying dynamics, and (c) the approximation error induced by choosing the input of the controller to be equal to \( y \). The value of \( e_s(t) \) is also assumed to belong to a compact set \( E_s \subset \mathbb{R}^n \). We then assume that the chosen output variable evolves in time as follows:

\[
g(l+1) = f(y(l), u(l), e_s(l)) = f : Y \times U \times E_s \to Y.
\]  

(4)

where \( f \) is Lipschitz continuous with respect to \( y, u \) and \( e_s \). Lipschitz continuity of \( f \) and \( M \) imply that the closed loop system:

\[
y(l+1) = g(y(l), e_s(l)) = f(y(l), \kappa(y(t)), e_s(l))
\]  

(5)

\( g : Y \times E_s \to Y \)

is also described by a Lipschitz continuous function \( g \).

In this work, we suppose that a set of \( N \) input-output measurements is available, indicated as \( \tilde{u}(k), \tilde{g}(k), k = 0, \ldots, N-1 \), collected from the system operating in closed loop with the unknown controller \( \tilde{u} \). These data points are assumed to be affected by additive noise variables, indicated as \( e_u(t) \) and \( e_y(t) \), respectively:

\[
\tilde{u}(t) = u(t) + e_u(t)
\]  

\[
\tilde{g}(t) = y(t) + e_y(t).
\]  

(6)

Note that \( e_u(t) \) may include both measurement noise and errors arising in the application of the control law. The signals \( e_u(t) \) and \( e_y(t) \) are assumed to be bounded in \( \ell_\infty \) norm.

3.2 Learning algorithm

In this section, we present an approach to learn a controller \( \hat{\kappa} \approx \kappa \) from the available experimental data. A parametric representation is considered for this controller:

\[
\hat{\kappa}(y) = \sum_{i=1}^{M} \hat{a}_i \varphi_i(y)
\]  

(7)

where \( \varphi_i : Y \to U \) are Lipschitz continuous basis functions. The coefficients \( \hat{a}_i \in \mathbb{R} \) are identified by means of the following Algorithm 1.

Algorithm 1. Controller learning

(1) Take a set of basis functions \( \{ \varphi_i \}_{i=1}^{M} \). The choice of this set can be carried out by means of the procedure in Fagiano and Novara (2013).

(2) Using the data set \( D^N \equiv \{ \tilde{u}(k), \tilde{g}(k) \}_{k=0}^{N-1} \) and the basis functions chosen at step 1), define the following quantities:

\[
\Phi = \begin{bmatrix}
\varphi_1(\tilde{g}(0)) & \cdots & \varphi_M(\tilde{g}(0)) \\
\vdots & \ddots & \vdots \\
\varphi_1(\tilde{g}(N-1)) & \cdots & \varphi_M(\tilde{g}(N-1))
\end{bmatrix} \in \mathbb{R}^{N \times M}
\]

\[
\hat{\mu} = (\hat{u}(0), \ldots, \hat{u}(N-1)) \in \mathbb{R}^{N \times 1}.
\]

(3) Using the procedure in Fagiano and Novara (2013), estimate \( \hat{\varepsilon}, \hat{\gamma}_f \) and \( \hat{\gamma}_{g,y} \) is a bound on the overall noise affecting the measurements, \( \gamma_f \) is the Lipschitz constant of \( f \) and \( \gamma_{g,y} \) is the Lipschitz constant of \( g \) w.r.t. \( y \). Choose \( \hat{\gamma}_\Delta \approx (1 - \hat{\gamma}_{g,y})/\hat{\gamma}_f \) such that \( \hat{\gamma}_\Delta < (1 - \hat{\gamma}_{g,y})/\hat{\gamma}_f \).

(4) Solve the following convex optimization problem:

\[
a^1 = \arg \min_{a \in \mathbb{R}^M} \|a\|_1
\]

subject to

\[
(a) \| \hat{\mu} - \Phi a \|_\infty \leq \hat{\varepsilon}
\]

\[
(b) \| \hat{u}(l) - \hat{u}(k) + (\Phi_k - \Phi_l) a \| \leq \gamma_\Delta \| \hat{g}(l) - \hat{g}(k) \|_\infty + 2\hat{\varepsilon}, \quad \{ l = 0, \ldots, N-1, \quad k = l + 1, \ldots, N-1 \}
\]

(8)

(5) Obtain the coefficient vector \( \hat{a} = (\hat{a}_1, \ldots, \hat{a}_M) \) from the following convex optimization problem:

\[
(\hat{a}, \hat{\gamma}_\Delta) = \arg \min_{a \in \mathbb{R}^M, \hat{\gamma}_\Delta \in \mathbb{R}^+} \hat{\gamma}_\Delta
\]

subject to

\[
(a) \| \tilde{u} - \Phi a \|_\infty \leq \hat{\varepsilon}
\]

\[
(b) \| \tilde{u}(l) - \tilde{u}(k) + (\Phi_k - \Phi_l) a \| \leq \gamma_\Delta \| \tilde{g}(l) - \tilde{g}(k) \|_\infty + 2\hat{\varepsilon}, \quad \{ l = 0, \ldots, N-1, \quad k = l + 1, \ldots, N-1 \}
\]

\[
(c) \ hat{a}_i = 0, \quad \forall i \notin \text{supp}(a^1)
\]

(9)

where \( \text{supp}(a^1) \) is the support of \( a^1 \), i.e. the set of indices at which \( a^1 \) is not null.

It can be proven that, under mild conditions, the controller \( \hat{\kappa} \) derived by this algorithm stabilizes the closed-loop system (in an input-output sense) when the number of data used for design tends to infinity.

4. EXPERIMENTAL RESULTS

4.1 Data collection and controller learning

We have considered \( \theta, \phi, \hat{\phi}, \gamma \) as candidates feedback variables, since they can be measured or estimated with good accuracy and they provide a representation of the quantities that the human operator observes when controlling the wing. In particular, we present here the results obtained by considering four different combinations of these signals to form the feedback variable \( y \), and we indicate the corresponding controllers as \( \hat{\kappa}^i, i = 1, \ldots, 4 \). Table 1 shows the choice of output vector \( y \) for these four cases. The employed sampling time is \( T_s = 0.02 \) s. Albeit also the line forces and the ground wind speed and direction are measured, we do not consider such variables for feedback control, since the human operator does not exploit this information.

We have collected experimental data from a flight session of 12 minutes, i.e. about 3.510^4 data points, where the wing was controlled by a human operator. Fig. 3 shows a typical full cycle, i.e. a single 8-shaped trajectory, in the \( \phi, \hat{\phi} \) plane, together with the related courses of \( \hat{\phi}, \hat{\theta} \), of the velocity angle \( \gamma \), and of the control input \( u \). As it can be noted, the period of a single cycle is about 5 s, hence a total of about 130 cycles has been used for the design of the four controllers. Fig. 4 shows the course of the wind speed during the time when the identification data were collected. The average wind speed was 5.44 m/s.

We have chosen polynomial basis functions of the following form:

\[
\varphi_i(y) = y_{j_1}^{\alpha_1} y_{j_2}^{\beta_2}, j_1, j_2 = 1, \ldots, n_y, \quad \alpha, \beta = 0, \ldots, 3.
\]  

(10)

For each combination of \( j_1, j_2, \alpha, \beta \) in (10), we assigned a progressive index \( i = 1, \ldots, M \) to the corresponding

polynomial, where $M = (g n_y + 1)(g n_y + 2)/2$. We estimated the values of the design parameters $\xi$, $\bar{\gamma}_g$, $\bar{\gamma}_f$, involved in Algorithm (1), by means of the algorithms presented in Subsection 3.2. The corresponding number of optimization variables in problems (8)-(9) is indicated in Table 1, too, together with the times required for the learning algorithm to derive the different controllers and the related numbers of resulting non-zero components. It can be noted that, starting from a quite large number of decision variables, the approach yields control laws with few non-zero terms, which we implemented on a real-time machine using the xPC Target® toolbox of Matlab®. The computational times for the learning phase (referred to a laptop with 2.8 Ghz core i7 processor, 8 GB RAM and the CVX tool, Grant and Boyd (2010)) are quite low. Indeed, a considerable number of data have been used for design: $N = 10501$. The data with indexes $l = 1, 30, 60, \ldots, N - 1$ have been used to form the constraints (b) in (8) and in (9) (we did not use all the data due to memory saturation). The total number of constraints in (8)-(b) and (9)-(b) resulted to be 61075. As regards the times required for the on-line control computation, these were of the order of $10^{-5}$ s (including the time required to condition the measured signals and to log the test results on a hard-drive), far below the employed sampling time of 0.02 s.

4.2 Experimental results and discussion

We tested the controllers in 15-minutes-long experiment batches (including take-off and landing phases), each one corresponding to roughly 140 full cycles of autonomous flight. We denote with $\bar{\theta}_k$, $\bar{\varphi}_k$ the average position, in spherical coordinates, of the $k$–th full cycle, and with $K$ the total number of cycles carried out in a test. In order to evaluate the results obtained with the different controllers, we computed the following quantities:

$$
\bar{\varphi} = \frac{1}{K} \sum_{k=1}^{K} \bar{\varphi}_k, \quad \bar{\theta} = \frac{1}{K} \sum_{k=1}^{K} \bar{\theta}_k, \\
\Delta \varphi = \sqrt{\frac{1}{K-1} \sum_{k=1}^{K} (\bar{\varphi}_k - \bar{\varphi})^2}, \\
\Delta \theta = \sqrt{\frac{1}{K-1} \sum_{k=1}^{K} (\bar{\theta}_k - \bar{\theta})^2}, \\
\Delta \bar{\varphi} = \max_{k=1, \ldots, K} |\bar{\varphi}_k - \bar{\varphi}|, \quad \Delta \bar{\theta} = \max_{k=1, \ldots, K} |\bar{\theta}_k - \bar{\theta}|. 
$$

(11)

The variables (11) provide the average position of the trajectories flown during each test, as well as an indication on the average and maximal deviation of each single flown trajectory from the overall average. The choice of these quantities as performance indicators is motivated by the fact that theoretical, numerical and experimental results show that, within quite slack limits, the most important aspect for the sake of power generation is the average position of a flown path, rather than its shape, Zgraggen et al. (2013). Hence, the flight control system shall achieve flying paths with consistent average position, and a flight controller can be considered to be “better” than another if it is able to obtain trajectories whose average position is less variable, i.e. with smaller values of $\Delta \varphi$, $\Delta \theta$, $\Delta \bar{\varphi}$, $\Delta \bar{\theta}$. The task of regulating the power...
output, i.e. of setting the average flown position according to the desired corresponding average power, can then be carried out by a supervisory control approach, like the adaptive strategy proposed in Zgraggen et al. (2013).

The results obtained with the four designed controllers are reported in Table 2. The table also shows the performance achieved by the human operator, indicated as $\kappa$, in the test whose data have been used to learn the controllers. The learned controllers $\hat{\kappa}^1$, $\hat{\kappa}^2$ were able to keep the wing’s path inside the wind window and to stabilize the system, achieving a good consistency of average position of the flown paths. The differences in average position achieved by these controllers with respect to $\kappa$ are due to the difference in wind speed during the tests, whose average value $\overline{V}$ measured at 4 m above the ground is shown in Table 2. The wind speed can be considered as an exogenous, unmeasured disturbance, which can be embedded in the variable $e_v(t)$ of (4). Different wind speeds induce a change in the position of the closed loop trajectories in the $\phi$, $\theta$ plane. In particular, the lower was the wind speed, the closer were the flight paths to the ground. This result is consistent both with the theoretical results of Subsection 3.2 and with physical considerations on the system. The controller $\hat{\kappa}^4$ was able to achieve figure-eight trajectories, however with quite poor repeatability as evidenced by the high average and maximal deviations. Finally, the controller $\hat{\kappa}^3$ was not able to keep the wing airborne and the closed loop trajectories gradually neared the ground until the wing crashed. Considering that the same data set and the same form of the basis functions were used to design all the controllers, the main reason for such differences in performance lie in the choice of the feedback variables. The ones used by $\hat{\kappa}^3$, namely the current position and velocity of the wing, were not sufficient to extrapolate with high enough accuracy the behavior of the human operator. The use of the same values at the current time and 1 second in the past, adopted by $\hat{\kappa}^4$, yielded a controller able to stabilize the plant, but whose performance in terms of variability of the flown paths were the worst.

The use of the current position plus the velocity angle in controller $\hat{\kappa}^2$ provided much better results (a movie of the experimental tests with the controllers $\hat{\kappa}^2$ and $\hat{\kappa}^4$ is available online, Fagiano (2012)). It has to be noted that the velocity angle is determined by the wing’s position and velocity, so in principle the feedback variables used by controller $\hat{\kappa}^2$ provide the same information as those used by $\hat{\kappa}^4$. However such a relationship, given by (2), is not described exactly by the polynomials (10), hence the learning algorithm was not able to extract this information. The controller $\hat{\kappa}^1$, which uses the same feedback variables as $\hat{\kappa}^2$ both at the current time and with 1 second delay, gives performance similar to $\hat{\kappa}^2$, hence indicating that these additional variables do not provide significant new information. We remark that the controllers $\hat{\kappa}^1$ and $\hat{\kappa}^2$ have similar complexity in terms of number of non-zero terms, despite the fact that $\hat{\kappa}^1$ uses twice as many variables as $\hat{\kappa}^2$: this effect is due to the use of the $l_1$-norm cost function in (8), which encourages sparsity and hence the automatic selection of the terms (hence also of the feedback variables) whose importance is higher.

In summary, the obtained results highlight that 1) with the proposed approach, the control design effort lies mainly in the choice of the feedback variables and of the basis functions, 2) physical insight still plays an important role in selecting the most appropriate variables (like the velocity angle in this specific case), 3) the use of $l_1$-norm minimization allows the control designer to start with a relatively large number of candidate feedback variables, leaving to the algorithm the task to identify the most relevant ones. Finally, we comment on the comparison between the performance obtained by $\hat{\kappa}^1$ and $\hat{\kappa}^2$, which gave the best results among the learned controllers, and those of the human operator $\kappa$. From Table 2, it can be noted that the learned controllers were able to obtain less erratic flight trajectories than those pertaining to the identification data collected during manual flight, which are affected by larger deviations in the average trajectory position. The relatively poor performance of the human operator can be due to inexperience but also fatigue and loss of concentration. These aspects can be regarded as disturbances acting on the input variable, and their effect is accounted for by the design parameter $\hat{\epsilon}$. The experimental results indicate that the proposed approach is able to cope effectively with outliers and dispersed data sets caused by such disturbances.

### Table 2. Experimental results of 15-minutes test batches: average position and related deviations (rad), and average wind speed at 4 m above the ground (m/s).

5. CONCLUSIONS

We presented an approach to design a feedback controller that stabilizes crosswind flight patterns of a tethered wing. The proposed technique is able to derive a controller directly from the data measured on an existing feedback control system, where both the controller and the plant are not known. The learning algorithm involves the solution of convex optimization problems only, and converges to a stabilizing controller as the number of employed data points tends to infinity. We presented the experimental application of the approach on a small-scale prototype, showing promising results.
