Abstract: Task-level industrial robot programming is a mundane, error-prone activity requiring expertise and skill. Since humans easily communicate with natural language (NL), it may be attractive to use speech or text as instruction means for robots. However, there has to be a substantial amount of knowledge in the system to translate the high-level language instructions to executable robot programs.

In this paper, the method of Stenmark and Nugues (2013) for natural language programming of robotized assembly tasks is extended. The core idea of the method is to use a generic semantic parser to produce a set of predicate-argument structures from the input sentences. The algorithm presented here facilitates extraction of more complicated, advanced task instructions involving cardinalities, conditionals, parallelism and constraint-bounded programs, besides plain sequences of commands.

The bottleneck of this approach is the availability of easily parametrizable robotic skills and functionalities in the system, rather than the natural language understanding by itself.

Keywords: Robot programming, natural language, assembly, knowledge-based engineering

1. INTRODUCTION

Programming of a traditional robot cell requires considerable expertise and effort. The new generation of robots, that work in an unstructured environment, that might have more degrees of freedom and two arms, introduces an increased level of complexity in user interaction and instruction. Therefore, methods of robot instruction that are accessible to non-experts would lead to greater usability of industrial robotics. Yet another aspect of the problem lies in vendor-specific solutions, available for each brand of robots. Different tools of varying complexity, different robot programming languages and different abstraction levels of task descriptions make them inaccessible for a plain user.

Since humans communicate with natural language (NL), it may be attractive to use speech or text as instruction means for robots. This is non-trivial for two main reasons: First, NL is often ambiguous and its expressivity is richer than that of a typical programming language. Secondly, tasks can be expressed as goals as well as imperative statements, hence, even if the instructions are correctly interpreted, the description itself is often not enough to create a successful execution. There has to be a substantial amount of knowledge in the system to translate the high-level language instructions to executable robot programs.

In this paper, the simple method from Stenmark and Nugues (2013) for natural language programming of assembly tasks is extended. The core idea of the method is to use a generic semantic parser to produce a set of predicate-argument structures from the input sentences. The original algorithm allows extraction of only plain sequences of commands. Here we show that using the predicate-argument structures together with the dependency graphs facilitates extraction of more complicated, advanced task instructions, which involve cardinalities (e.g., pick two bolts and two nuts), conditionals (e.g., if...then...else) and constraint-characterized programs (e.g., do...until...)

2. RELATED WORK

By abstracting away the underlying details of the system, e.g., by demonstration, high-level programming can make robot instruction accessible to non-expert users and reduce the workload for an experienced programmer. A survey of programming-by-demonstration models in robotics is presented by Billard et al. (2008).

In industrial robotics, programming and demonstration techniques are normally used to record trajectories and positions. As it is desirable to minimize downtime for the robot, much programming and simulation is done offline whereas only the fine tuning is done online (Hägge et al., 2008). There is a plethora of tools, often visual, for robot programming. In robotics, standardized graphical programming languages include Ladder Diagrams, Function Block Diagrams and Sequential Function Charts (IEC, 2003). Using a touch screen as an input device, icon-based programming languages such as in Bischoff et al. (2002) can also lower the threshold to robot programming.

Natural language programming for robots has been investigated since the early 1970s. SHRLDU (Winograd, 1971) is an example of the first attempts to give robots conversational competences. To interpret and convert a users sentences into instructions, robotic system often make
use of an intermediate representation. Examples include MacMahon et al. (2006) and Tellex et al. (2011), where the authors have developed their own domain-specific semantic representations for robot navigation.

Tenorth et al. (2010) parse pancake recipes in English from the World Wide Web and generate programs for their household robots. They use the WordNet lexical database (WordNet, 2010) with a constituent parser and they map entries in the WordNet dictionary to concepts in the Cyc ontology (Matuszek et al., 2006). Finally, they add mappings to common household objects.

In order to bridge the sentence to robot actions, all the examples above use ad-hoc formalisms. FrameNet (Ruppenhofer et al., 2010), based on frame semantics, is a comprehensive dictionary that provides a list of lexical models of the conceptual structures. Propbank (Palmer et al., 2005) has developed a extensive database of predicate-argument structures for verbs and nouns, and annotated large volumes of text. The Propbank nomenclature is used by most current statistical parsers, including ours.

Only few robotics systems use existing predicate-argument nomenclatures. An exception is RoboFrameNet (Thomas and Jenkins, 2012). However, the authors wrote their own frames inspired by FrameNet. They built a semantic parser that consists of a dependency parser and rules to map the grammatical functions to the arguments. Such techniques are known to have a limited coverage.

In the project described below we have used a multilingual high-performance statistical semantic parser (Björkelund et al., 2009, 2010) using the Propbank and Nombank lexicons. In contrast to RoboFrameNet, the parser we adopted can accept any kind of sentence. The NL processing module is a knowledge-based service in a larger programming environment (Stenmark and Malec, 2013). In particular, it allows one to create constraint-based task descriptions based on the iTaSC formalism, a property exploited here.

3. BACKGROUND

The system has been described in detail in our previous work (Stenmark and Nugues, 2013; Stenmark and Malec, 2013): a simplified view of its components is shown in Fig. 1. It is a cloud-based system for knowledge sharing and distributed AI reasoning. The knowledge and reasoning services are stored on a server called Knowledge Integration Framework (KIF), which contains data repositories and ontologies modeling objects and actions. KIF also provides servlets for planning, scheduling and code generation, as well as the NL-programming servlet described in this paper. These services are used for offline programming by the Engineering System (ES), which is a user-interface implemented as a plug-in to ABB RobotStudio (ABB Robotics, 2013) visual IDE.

Objects in the World The core ontology, rosetta.owl (Stenmark and Malec, 2013), contains devices such as sensors and robots. The ES also uses a separate ontology to describe parts, such as trays and workpieces. The ontologies describe object types and properties, while the data repositories contain instances of the types. E.g., a ForceSensor is a subtype of Sensor and of PhysicalObject, has property measures with value Force, and it also inherits properties such as weight from PhysicalObject. The object types and their property types are later used by the natural language programming system to link arguments to real world objects. Objects are displayed by ES using their CAD models. Each object has a number of relative coordinate frames called feature frames, attached to its main object frame. The feature frames are used to express relations between objects. A typical case is a gripping pose described as a relation between a gripper frame and an object feature frame.

Task Vocabulary The task vocabulary is limited to existing robot capabilities. In the KIF repositories, robot actions are stored as program templates, called skills. There are primitive actions, such as search, locate and move which can be combined into more complex skills such as pick and place. Each skill has parameters, e.g., velocities, other objects, their feature frames, or relations. Each skill has also a set of device requirements, pre- and post-conditions as well as optional properties such as natural language labels. The skills are downloaded from the KIF libraries into the ES and added to a task sequence, see Fig. 2. This sequence can be edited by drag-and-dropping objects and by editing parameters of each action or skill. As an additional modality, we have extended the system with natural language support for sequence generation. Using language to express a task is faster than downloading or selecting each skill separately; besides, speech allows hands-free instruction of the robot.

Natural Language Programming The task is expressed in unstructured English, either by typing it in a text box directly in the user interface, or by connecting an Android app to the ES and using its speech-to-text conversion. The text is sent to a servlet on KIF, which in turn
calls a general purpose statistical parser \(^1\) (Björkelund et al., 2010) that outputs predicate-argument structures in standard format (cf. Fig. 3).

![Diagram of NL parsing sequence](image)

**Fig. 3.** The NL parsing sequence.

**Predicate-Argument (PA) Structures** As an example we use an assembly where a printed circuit board, a PCB, is covered with a metal plate, a shield. First the PCB should be fixated, which can be expressed in English as **Take the PCB from the input tray and place it on the fixture.** The PA structures are \textit{take}(PCB, input tray) and \textit{place}(it, fixture). The parser labels verbs with different \textit{senses} depending on the context in which they are used. For example, take off (like a plane) is \textit{take.01} and take down is \textit{take.22}.

The parsing pipeline uses logistic regression to produce the PA structures, see Fig. 4. First, the dependency graph is extracted. The dependency graph connects the words in the sentence using their grammatical functions. It is technically a tree, where the root is the \textit{dominant} word in the sentence, most often a verb describing an action, and the arrows (see for example bottom part of Fig. 6) point from the \textit{parent} or \textit{head} to its \textit{children}. Then the predicates are identified, labelled with a sense and finally the arguments are identified and labelled. **Take** in our example has sense 1. The predicate \textit{take.01} has three arguments named \textit{A0-A2}, the actor (\textit{A0}), the thing being taken (\textit{A1}) and the source (\textit{A2}). In this case, the robot is not explicitly mentioned, hence there is no \textit{A0}. Pronouns, such as \textit{it} or \textit{them} are linked to their antecedents in the sentence.

Previous work (Stenmark and Nugues, 2013) defined an algorithm describing how predicates can be mapped to robot skills, and arguments linked to specific world objects in order to create an executable sequence of the task, as displayed in Fig. 2. However, the supported programming features were limited, excluding e.g., such control structures as conditionals, temporal constraints, control parameters, parallel execution and references to program features. The contributions of this work are that predicate-argument pairs can be mapped to complex skills and the novel methods we are using to extract constraints and control structures from NL instructions.

**Code Generation and Execution** The executable code for primitive actions is generated in native controller language (RAPID). E.g., each gripper can have a predefined native code to open and close it. On the other hand, the sensor-controlled skills use a framework based on iTaSC (De Schutter et al., 2007), together with external force/torque sensors. These skills are specified by state machines using JGrafchart (2012) language, where states are simple motions and transition conditions are, e.g., timeouts or force and torque thresholds. A motion is specified by constraining outputs (e.g., positions or force values) from a \textit{kinematic chain}. The kinematic chain is a specification of the relation between task variables and the robot, which are represented by a list of transformations. The state machine is generated by ES for all skills and all constrained motions (Stenmark and Stolt, 2013).

4. **PATTERN-MATCHING ALGORITHM**

In this section, we present our method of extracting motion constraints and control structures from unstructured English in more detail. At the moment, the system supports cardinality, parallel execution, conditionals and program references. The algorithm that runs on KIF server is presented in Algorithm 1. It matches the output from the semantic parser to program statements, using the semantic labels, the part of speech (POS) tags and dependency relations between the words. The following examples illustrate how the matching of the different statements is carried out.

**Cardinality** refers to the number of elements. In the sentence **Take all needles and put them in the pallet,** the cardinality of the needles is \textit{all}. **Take three of the needles** has cardinality three. The cardinality is easily extracted from the arguments. In these examples, the arguments \textit{A1} to \textit{take.01} are \textit{all needles}, and \textit{three of the needles}, respectively. In the first case, the verb is labelled as plural (NNS) and the determiner \textit{all} is used. In the second case, where there is an explicit numbering (CD) in the argument, it is used as cardinality. Personal pronouns, such as \textit{them} or \textit{it}, are assumed to refer to all the objects in the previous argument (this is done in the ES). There is a subtle difference between **Take the needle** and **Take a needle,** which is expressed in the use of determiner. In the first case, a specific needle is referenced, while in the second, it is only the object type that is mentioned and any needle can be chosen. When linking entities to specific objects in the world, the system will look for a specific

            wildcard ← getWildcard(p)
            if wildcard found then
                Add wildcard to actions with sentenceNbr
                Remove nested predicates in stm from q
            end
            end
        end
    end
    Remove nested predicates in stm from q
    end
end

return actions and unknownStatements

---

Function createArgs(p)

a1 ← argument "A1" of p
if a1 does not exist then
    a1 ← search for an argument labelled "TMP", "IN", "AM-LOC"
    if a1 is not found then
        a1 ← search among children to p labelled "LOC"
    end
end

a2 ← argument "A2" in p
if a2 is not found then
    a2 ← search for an argument labelled "TMP", "IN", "AM-LOC"
end
if a1 is not found and a2 is found then
    a1 ← a2
    a2 ← void
end
return (a1, a2)

---

Function sortPredicates(semOutput)

if semOutput has a root element then
    Let q be an empty queue
    root ← get root predicate from semOutput
    if root is a predicate then
        Add root to q
        Parse the tree breath first adding all predicates to q
    end
    end
else
    predicates ← all predicates from semOutput in input order
    Add all predicates to q
end
return q

---

Function getWildcard(p)

manner ← get argument from p with tag "AM-MNR"
if manner found then
    word ← recursively search all descendants of manner for a word labelled "NN", "NNS" or "NNP"
    if word found then
        stm ← new statement("use", word)
        return stm
    end
end
return empty statement

---

Object where the name matches the argument value in the first case, but in the second case, the argument value is an object type and the system will return objects of the given type instead. When the cardinality of an argument is larger than one, the resulting program structure is a loop, the sentence number is used to determine its scope, where actions in the same sentence are in the same loop. "Take all needles. Put them in the pallet." will thus be two loops, and in a single robot system the planning service will complain about such instructions.

Until is a keyword for extracting the exit condition. Until is used to express guarded motions such as Search.
in the z-direction until contact. The conditions can be nested PA structures as well, for example: Move in the z-direction until you measure 5 N. The results from the parsing of the two example sentences are displayed in Figs 5 and 6. In order to extract the program statements, the analysis starts with the root in case the root is a predicate. If the predicate belongs to the set of understood predicates, it is added as a program statement, together with its arguments. In the first example, the direction was identified as argument A1 to search.01, however, in the second sentence, the direction is considered a location argument to move.01. In the case of missing object arguments, the location arguments are used instead, since these are valid parameters to motions. The default frame of the direction is the tool frame.

Fig. 5. The parse result of “Search in the z-direction until contact”, together with the dependency graph.

Fig. 6. The parse result of “Move in the z-direction until you measure 5 N”.

If the predicate has any temporal constraints, expressed by for example until and while, these are labelled TMP in the dependency graphs. The temporal constraints can be either a noun describing an event, or nested PA structures such as measure (pred) 5 N (A1). The temporal constraints are added as a condition to the main program statement (Move - z-direction) and will later be used to create transition conditions and thresholds for the guarded motion. Conditions will be discussed in more detail later.

While. In most programming languages while statements are equivalent to until, however, in natural language they also express parallelism. For example “While holding 5 N in z-direction, search in x-direction until contact” is a guarded motion along one axis, while adding a constraint in another direction. The result is translated into program statements similarly to until-statements. This sentence results in a while-statement describing the parallel actions of searching and holding, while the search is a nested until-statement with the transition condition.

Conditions. Conditions can be events or PA structures. In our system, the events that can be used are contact, collision and timeout. The predicates that are allowed are limited to measure, reach, sense, thus limiting the expressions to sensor values. The system also supports nested conditions using AND and OR, such as contact or timeout, because and or are tagged as coordination conjunctions (CC) by the dependency parser.

If and when. In our system, these are considered equivalent, however, in the if-sentence the condition is considered an adverbial while in the when-sentence it is a temporal, see Fig. 7 and Fig. 8. This difference is ignored and the PA structure is used as a condition in both cases.

Fig. 7. Result for an if-sentence.

Fig. 8. Result for a when-sentence.

Keywords. All robot skills are not suited to be mapped to predicates, e.g., in a Snapfit skill two plastic pieces are snapped into position. Hence, the predicate use is dedicated as a keyword, where the argument is either another program or a device that is not part of the assembled parts, such as sensors or tools. That allows sentences such as “Assemble the shield can and the PCB using my skill”, see Fig. 9. Here myskill can be snapfit or peg-in-hole, or be replaced with tool such as gripper2. When a use-predicate is evaluated by the system, it first searches among the sensors and tools for devices that the skill can use, and then online for a skill which can be used to replace the generic assemble action.

Fig. 9. Example of the usage of the wildcard word use.

Another way to express similar commands is by using the word with. This will naturally not be parsed into a predicate, but rather be an argument to assemble.2 called manner which is labelled AM-MNR in the result shown in Fig. 10. Adverbs typically describe the manner of a predicate, such as Carefully assemble.... In case the
manner contains with and a noun it is simply interpreted as a use with the noun as its argument.

**Program references.** A small set of predicates and PA structures are used to describe the program itself. For example Repeat the task. The predicates are pause, stop, start, repeat, and restart, while the arguments can be skills or general references such as the task and the program.

**Negation.** Predicates with negation are ignored. Although it is possible to imagine commands such as Don’t go close to the human, we have chosen to require usage of an active command such as Avoid the human. For a negation to be meaningful, both an action and its negation have to be mapped to different skills, since the complement of an action is not a well defined concept.

When the program statements have been extracted from English sentences, the predicates are mapped into programs and functions, and the arguments are linked to objects in the world or to skills that are downloaded to the station. Thresholds for sensor values and parallel constraints are added to the guarded motions. Executable robot code for the task is generated from the guarded motions and skills. The resulting code has been verified by virtual robot execution in the Engineering System.

5. DISCUSSION

Using the standard predicate argument-structures together with the dependency graphs, it is possible to extract the semantic meaning of complicated assembly task descriptions from unstructured English. The bottleneck is rather the availability of robotic skills and functionalities in the system, not the natural language understanding by itself.

In a virtual world, control parameters and sensor thresholds can be set to default values. In order to carry out robust task execution on a physical platform though, the damping and stiffness factors of the impedance controller and force signatures should be learnt for the task. The parameters to the impedance control can be learnt by experimentation, as shown by Stolt et al. (2012).

The approach and algorithms presented in this paper are not limited to just assembly tasks, or just to industrial robot task descriptions. After having completed experiments involving skill parameter learning, we plan to extend this approach to other manufacturing domains.
