

## Extra exercises in STK4080 2021

### Exercise E4.1

- a) Simulate 100 observations of the triple  $(t, \text{delta}, x)$  by using the commands:

```
x=rgamma(100,2)
T=sqrt(rexp(100)*2*exp(-x))
C=rexp(100,.5)
t=pmin(C,T)
delta=1*(T<C)
```

Write down the density of the variables  $x$  and  $C$ . [*Answer:  $xe^{-x}$ ,  $0.5e^{-0.5c}$* ]

The triple gives a data set of 100 observations of  $(\tilde{T}_i, D_i, x_i)$ , according to standard notation,

Use the code to find an expression for the hazard rate function of the lifetime  $T$ . [*Answer:  $\alpha(t|x) = te^x$* ]

- b) Fit a Cox-model  $\alpha(t|x) = \alpha_0(t)e^{\beta x}$  to the data using, e.g., the command

```
cfit=coxph(Surv(t,delta)~x)          (*)
```

Then plot the martingale residuals with a corresponding lowess smooth (you may follow the setup of Slides 12). Give a comment to the plot.

- c) Now let  $x$  and  $C$  have the same distributions as before, but let  $T$  now be simulated by

```
T=sqrt(rexp(100)*2*exp(-log(x)))
```

Write down the hazard rate of the new  $T$  and put it on the form of Cox-regression with a transformed covariate. What is the transformation of  $x$ ? [*Answer:  $\alpha(t|x) = te^{\beta \log(x)}$* ]

- d) Then fit a Cox-model using (\*) with the new data, thus still assuming the hazard ratio to be  $e^{\beta x}$ .

Plot the new martingale residuals and the lowess smooth. Comment on the fit.

- e) Finally, try to find the correct form of a transformation of  $x$  in the Cox model, i.e., try to find an  $f(x)$  such that the hazard ratio is  $e^{f(x)}$ .

Since there is only one covariate, you should start by fitting an empty model and then look at its martingale residuals.

```
cfit.nox=coxph(Surv(t,delta)~1)
martres.nox = cfit.nox$residuals
```

Then make a lowess smooth and comment!

## Exercise E4.2

In this exercise we will study data simulated from a regression model where the “ $\beta$ ” depends on time. Let there be a single covariate  $x > 0$ , drawn from the same distribution as in the previous exercise, and let  $C$  now be exponential with hazard rate 0.3. Assume that the true hazard rate is

$$\alpha(t|x) = e^{\beta \log(t)x} = t^{\beta x}$$

- a) Is the given model a proportional hazards model?

Show that for given value of  $x > 0$ ,  $T$  has survival function

$$S(t|x) = \exp \left\{ -\frac{t^{\beta x + 1}}{\beta x + 1} \right\}$$

and hence is Weibull-distributed with shape parameter  $\beta x + 1$  and scale parameter  $(\beta x + 1)^{1/(\beta x + 1)}$  (with the parameterization used by R)

- b) The following code will simulate  $n = 200$  triples  $(t, \text{delta}, x)$  with the given distribution for  $t$  given  $x$ :

```
n=200
x=rgamma(n,2)
beta=.2
y=beta*x+1
T=rweibull(n,y,y^(1/y))
C=rexp(n,.3)
t=pmin(C,T)
delta=1*(T<C)
```

- c) Fit an ordinary Cox-model with hazard ratio  $e^{\beta x}$  to the data and comment on the results. You may also look at martingale residuals.

Then do the test of proportional hazards by using the `cox.zph` function, and draw a scaled Schoenfeld residual plot. Use for example

```
cox.zph(cfit,transform='log')
plot(cox.zph(cfit,transform='log'))
```

(see Slides 12). Comment on the result. (Note that the resulting  $p$ -value will vary if you simulate new sets of 200 observations. )

- d) Try other choices for “transform” in the `cox.zph` function. Here is from the R-documentation: **Transform** is a character string specifying how the survival times should be transformed before the test is performed. Possible values are “km”, “rank”, “identity” or a function of one argument.
