Baltea-Lugojan et al. (2019), introduced low-dimensional approach for lighter linear relaxations, to overcome the problem of generating only one dense cut per negative eigenvalue of full-dimensional matrix, building on prior work of Qualizza et al. (2012). With \wp denoting the power set of the vertex set $V : \{1, \dots, N\}$ and $\rho \in \wp(\rho \subseteq V)$ any arbitrary index subset, let $x_\rho \in \mathfrak{R}^{|\rho|}$ and $X_\rho \in \mathfrak{R}^{|\rho| \times |\rho|}$. For any subset of \wp the following semidefinite relaxation is introduced,

$$(\forall F \subseteq \wp) \wp(F) := \{(x, X) \mid \forall \rho \in F : \begin{bmatrix} 1 & x_\rho^T \\ x_\rho & X_\rho \end{bmatrix} \geq 0, X_{ij} \leq x_i \forall i \in \rho\} \quad (3)$$

For n , ($n = |\rho|$) being the dimension of the subsets, the cardinality of \wp_n is determined in a naive way by the combination $\binom{N}{n}$. In practice, chordal extensions are used, to exploit the density pattern of the problem, for smaller $|\wp_n|$. Still, the number of subproblems is such, that a separation issue arises, for the selection of the most informative underestimators. In feasibility strategy, cutting planes are selected based on most negative eigenvalues of the augmented matrix.

3. Metrics and analytics in selecting cutting planes

The motivation behind integration of data analytics, in the separation problem, through the affinity clustering was the notion that qualitative and geometrical aspects matter. Data technology is subsequently applied to measure fathom and screen planes, also to represent data spaces of the dual problem. Research was expanded, by testing this theory on full and low dimensional spaces with the use of normal vector clustering and temporal sets method.

3.1. Affinity metric

The initial approach to the separation problem employed data analytics, in order to select the most informative cutting planes for the reconstruction of the convex space, with encouraging results. The key element of this approach was the formation of a custom metric; the affinity metric. The rationale behind the affinity metric was to prevent the proliferation of sub-spaces with very similar or identical pattern of variables. Sub-spaces featuring common dimensions (affine sets), are considered to hold similar information and could consequently be curtailed. The initial linear constrains, used in Eq. (2), include just the RLT constrains. When the solution is reached, decomposition follows, providing low-dimensional SDP cuts to choose from. Population of cuts is then ordered by means of feasibility and cuts that satisfy the feasibility condition $\lambda_p \leq 0$ constitute the power set \wp used for the analysis. The metrics that best described the correlations among the population were found to be the *Euclidean* distance and the custom *affinity* norm $d_a(x, y)$, that is defined below. The affinity norm serves the purpose of exploring the projection space by mapping the created cuts and revealing overlaps of the sub-spaces. That is achieved with the use of common clustering technics, such as *Kmeans* and *agglomerative* clustering, for varying number of clusters. Hybrid methods were tested to explore sequential implementations of Euclidean and affinity metrics. The affinity metric is defined by,

$$d_a(x, y) := \sum_{i=1}^N 1 - g(x_i, y_i), \text{ where } g(x_i, y_i) = \begin{cases} 1 & \text{if } x_i = y_i \\ 0 & \text{if } x_i \neq y_i \end{cases} \quad (4)$$

The proposed approach achieves significant gap closures that are especially evident in problems of higher complexity.

3.2. Full-dimensional sparse cutting planes: Normal vector clustering

On a new perspective on the reconstruction of the convex space, the low dimensional projections are transferred to the full-dimensional space in sparse form. Working in the original space instead of projections of it, favors the use of dynamic sets for the recovery of unselected planes, in the following rounds. Cuts not added as SDP constrains, could potentially result in loss of valuable information for the duality gap closure. Dynamic sets enable the retrieval of such cuts, by adding part of unselected cuts to the population, prior clustering. Memory limitations prevent the application of dynamic sets in normal vector clustering. The motivation behind this method is to include diversity in orientation of the hyperplanes, in cut selection. The feature of orientation is portrayed through the formation for the normal vector α . Parallel cutting planes are considered to hold similar information and thus are clustered together, based on the cosine similarity of their normal vectors. The ranking criteria are enhanced by considering the search space each hyperplane excludes.

The SDP relaxation of the referenced work in Eq.(3) is reformulated in full dimension. Sparse solutions $x_{\rho,s} \in \mathfrak{R}^N$, $X_{\rho,s} \in \mathfrak{R}^{N \times N}$ are formed, for every subset of \wp , from vector slices $x_{\rho} \in \mathfrak{R}^{|\wp|}$ and sub-matrix slices $X_{\rho} \in \mathfrak{R}^{|\wp| \times |\wp|}$.

Sparse eigen-decomposition is applied to each sparse augmented matrix $\begin{bmatrix} 1 & x_{\rho,s}^T \\ x_{\rho,s} & X_{\rho,s} \end{bmatrix}$, generating $N + 1$ cutting planes. For feasibility violations, the normal vector of every hyperplane is formed

from the eigenvectors, according to Eq.(8). All violated cuts ($\lambda_{\rho,s} \leq 0$) are added to the population, in contradiction to prior work, where one out of $|\rho|$ cuts was chosen per subset, according to feasibility measure ($|\lambda_{\rho}|_{max}$). The normal vectors are clustered with of-the-shelf clustering algorithm measuring cosine similarity. The PSD relaxation is as follows.

$$v^T \cdot \begin{bmatrix} 1 & x_{\rho,s}^T \\ x_{\rho,s} & X_{\rho,s} \end{bmatrix} \cdot v \geq 0, \forall \rho \in F \mid (F \subseteq \wp) \quad (5)$$

where, $v \in \Re^{N+1}$. The normal vector of each hyperplane is generated from the linear form of Eq.(6).

$$\sum_{i=1}^N 2v_1 v_{i+1} \cdot x_i + \left(\sum_{i=1}^N \sum_{\substack{j=i \\ j \neq i}}^N v_{i+1}^2 + \sum_{i=1}^N \sum_{\substack{j=i \\ j \neq i}}^N 2v_{i+1} v_{j+1} \right) \cdot X_{ij} + v_1^2 \geq 0 \quad (6)$$

$$a = [2v_1 v_2 \quad 2v_1 v_3 \quad \dots \quad v_2^2 \quad v_2 v_3 \quad \dots \quad v_{N+1}^2] \quad (7)$$

Cosine similarity measures the cosine of the angle between two normal vectors in the multi-dimensional space.

$$CS(\alpha_1, \alpha_2) = \cos \theta = \frac{\alpha_1 \cdot \alpha_2}{\|\alpha_1\| \cdot \|\alpha_2\|} \quad (8)$$

The corresponding cutting planes, of the clustered normal vectors are ordered by means of excluded search space. The magnitude of the part of the convex set, that is removed by a hyperplane ($\lambda_{\rho,s} \leq 0$), is connected to the minimization of the constant term v_1^2 in Eq.(7). The first eigenvector for every ordered cluster is selected and added as a PSD constraint to the Master problem.

3.3. Temporal sets in the low-dimensional space

The rationale behind this method is to compliment cutting plane algorithms, by conveying valuable information from previous rounds to the cut selection. In affinity clustering, the selection criteria include feasibility measure, as well as geometrical features of the population. With temporal sets, "memory" of used cuts is introduced, preventing the reselection of triplets, with respect to feasibility measure. This line of work aims to limit the deceleration of the algorithm, when reaching a plateau, hence achieving further closure of the duality gap, in large, dense problems. The proposed algorithm follows these basic steps.

1. **Solution** of Master problem with just *RLT* constrains
2. **Formation, clustering and evaluation** of 3-D cuts, according to feasibility measure
3. **Scanning and removal** of repetitive triplets
4. **Selection** of top-rank element and **renewal** of list of used cuts

Integration of temporal sets in cutting plane selection algorithms was most efficient for conventional *Kmeans* clustering, for euclidean distance, with **weak** elimination criteria, **strong** tolerance and for application **after clustering**. Diverse versions of temporal set algorithms were tested, through various rounds of experiments, without noting similar results.

- *Elimination criteria*
Strong: Eliminate triplets that share 3 dimensions with previously selected 3-D cuts
Weak: Eliminate triplets that share at least 2 dimensions with previously selected 3-D cuts
- *Tolerance*
Tight: Allow the minimal number of repetitions in triplets, so as to comply with the 100 cuts per round requirement
Loose: Allow sufficient number of repetitions, for the activation of the temporal set constrains

- *Elimination step*
 - Prior clustering:** Discard used triplets from a raw population
 - After clustering:** Discard used triplets at each cluster

The intuition behind the experiment design is to test performance of key combinations on basic algorithm alterations, regarding elimination criteria, tolerance and the elimination step. Tolerance was manually adjusted to problem size and to cut round.

4. Results

The test set of box quadratic problems (BoxQP) used in the experiments was provided by Baltean-Lugojan et al. (2019). For all computational experiments the dimensionality of the cutting planes is set to $|\rho| = 3$ and the cut selection measure is feasibility. The number of iterations and cuts are dictated by literature, so as to compare the proposed approach with the referenced algorithm (Rf1). The number of rounds is set to 20, the added cuts for each round are set to 100. In coordination with Baltean-Lugojan et al. (2019), the convergence limit is achieved when rounds are 40 and selection of cuts is 5% of the available sub-problems. The computational experiments are carried in python 3.5 using cplex 12.8 python API solver and scikit-learn v0.2 (Pedregosa et al., 2011) package for k-means and agglomerative clustering. Results are evaluated based on the convergence of the algorithm and the final solution

4.1. Normal vector clustering

Normal vector clustering was tested against conventional *Kmeans* clustering and the original referenced algorithm, for feasibility measure. A hybrid version was formed, to test complementarity with conventional clustering algorithm, where 50% of the cuts were produced by each method, independently. Two examples of small non-convex QPs were studied, due to memory limitations. Evidently, a problem of $N=70$, 50% dense, consists of 6608 sub-problems, while each element of the population has a dimensionality of 70. Eigendecomposition of 71×71 augmented matrix takes place, producing 71 eigenvectors of 71 dimensionality, each corresponding to a 2555-D normal vector.

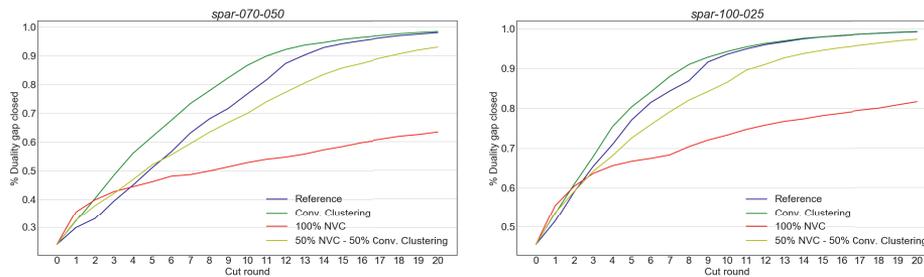

Figure 1: Progression of performance in duality gap closure, across 20 cut rounds, calculated for convergence limit of referenced algorithm. Cuts are selected for $\min(v_1^2)$ and must violate feasibility ($\lambda_{p,s} \leq 0$)

Initially, *NVC* is consistently preeminent for the test sets examined. Acceleration succeeded in the first cut round is dominated in the following rounds, resulting in a gap closure below the standards, set by previous algorithms. *Hybrid* version, is deprived of the for-mentioned edge in the first round and does not appear to complement conventional clustering. The large resource requirements, complicate further research, on *NVC* with temporal sets.

4.2. Temporal sets

Temporal sets noted the best performance, for tight elimination criteria, that loosen as the algorithm progresses, indicating the contribution of geometrical complementarity in the separation problem. Improvement was marginal on the small problems, but significant on the bigger ones, where population of violating cuts is vast and there was a significant duality gap left open from the referenced algorithm. This method appears to complement most, conventional clustering with euclidean metric, among similar algorithms tested.

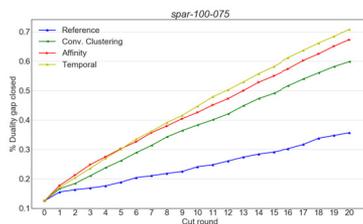

Figure 3: Comparison of % gap closure across 20 cut rounds, for largest test set (N=100, 75% dense)

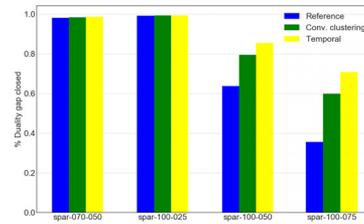

Figure 2: Comparison of % gap closure across different test problems

Performance is enhanced in large sets of sub-problems, where tight elimination criteria can be applied, without exhaustion of available cuts. Temporal sets were also applied to Affinity clustering, without noting comparable results, possibly due to similar approach to the separation problem. The progress made by the utilization of data analytics is most evident for the largest test problem in *Figure 3*. Affinity clustering starts off comparably better, but is dominated by the temporal sets method after cut round 5.

5. Conclusion

Temporal approach on low-dimensional spaces appears to benefit acceleration of bigger and denser problems. In the largest test problem, the temporal approach outperformed Affinity clustering. Algorithms with tighter elimination conditions performed the best, indicating the importance of geometrical diversity over feasibility measure on cut selection. Computational time improves in comparison to conventional clustering algorithm, but still exceeds that of the referenced algorithm. Normal Vector Clustering did not improve the overall performance of the algorithm. From a theoretical point of view, a consistently significant acceleration in the first cut round could potentially benefit a hybrid algorithm. Memory limitations prevent application in bigger and denser problems, as well as further efforts to incorporate dynamic methods. Computational time and resource requirements are restricting.

6. Acknowledgments

Prof. Kokossis is indebted to Prof Kevrekidis at Johns Hopkins University for his continuing encouragement to explore data analytics and machine learning in decomposition algorithms. He is also grateful to Prof Ruth Misener at Imperial College London who shared benchmark problems and her relaxed (sparse and dense) cutting plane approximations used in the experiments.

Abstract

This study describes a methodological framework designed for the systematic processing of experimental syngas fermentation data for its use by metabolic models at pseudo-steady state and at transient state. The developed approach allows the use of not only own experimental data but also from experiments reported in literature which employ a wide range of gas feed compositions (from pure CO to a mixture between H₂ and CO₂), different pH values, two different bacterial strains and bioreactor configurations (stirred tanks and bubble columns).

The developed data processing framework includes *i*) the smoothing of time-dependent concentrations data (using moving averages and statistical methods that reduce the relevance of outliers), *ii*) the reconciliation of net conversion rates such that mass balances are satisfied from a black-box perspective (using minimizations), and *iii*) the estimation of dissolved concentrations of the syngas components (CO, H₂ and CO₂) in the fermentation broth (using mass transfer models). Special care has been given such that the framework allows the estimation of missing or unreported net conversion data and metabolite concentrations at the intra or extracellular spaces (considering that there is availability of at least two replicate experiments) through the use of approximative kinetic equations.

Keywords: Syngas fermentation, experimental data processing, fermentation data reconstruction, data reconciliation.

1. Introduction

The development of a new fermentation technology starts at the laboratory where the chemostat is one of the main tools for studying microbial behavior. The chemostat is a fermentation setup where the concentrations of substances and cells are maintained nearly constant, and therefore a pseudo-steady state is reached at the intra and extracellular spaces (Noorman et al., 1996; Villadsen et al., 2011). The chemostat serves for gaining insights on the steady-state regulations of, on one hand, the whole metabolism such as the growth rate dependencies on substrates and products concentrations or the substrate requirements for maintenance, and on the other hand, the intracellular reaction rates that

allow cells to exhibit their behavior expressed as net conversion rates, or q-rates, as well as through the rates of growth and decay.

The measurements of substance concentrations is the main source of information about the state of a fermentation process. The net conversion rates are estimated from these measurements. The substances that are generally measured are the carbon and the electron sources, the excreted products, cells, oxygen (in aerobic fermentations), CO_2 , H^+ ions and the nitrogen source, (Stephanopoulos and Tsiveriotis, 1989). Yet, measurements are commonly prone to errors, both random and systematic (van der Heijden et al., 1994b). The reconciliation process is an adjustment of the measured rates aimed at improving their accuracy, such that they fulfill constraints formulated by, for instance a black-box description, which contains the energetic as well as the elemental balances of carbon, hydrogen, oxygen, nitrogen and charge (Noorman et al., 1996, 1991; van der Heijden et al., 1994a). In underdetermined systems, the reconciliation may allow the estimation of unmeasured quantities, whereas in overdetermined systems, the reconciliation allows to assess the consistency of the collected data and the identification of gross measurement errors (Stephanopoulos and Tsiveriotis, 1989; van der Heijden et al., 1994b, 1994a).

The development and up-scaling of the anaerobic syngas fermentor requires the design of mathematical models that are able to reproduce the *i*) characteristics of mass transfer from the gas to the liquid and the *ii*) microbial metabolic responses to the stimulus provided by the extracellular environment. The models on the side of the microorganism are much nurtured by the adequate collection and processing of experimental information. In this document we describe a systematic methodological framework we developed to process the experimental metabolite concentrations and conversion rates from syngas fermentation experiments. We have previously used the proposed framework for assessing the performance of the reported and own fermentation experiments in terms of the distribution of carbon and electrons among the fermentation products, as well as for the parameterization of metabolic models at pseudo-steady state and transient state.

The following pages describe the methodological framework formed by: *i*) data curation and smoothing, *ii*) reconciliation of net conversion rates and *iii*) reconstruction of missing concentrations of the dissolved gases.

2. Data curation and smoothing

In general, the curation and smoothing of the experimental data is useful for the design of kinetic expressions and the early assessment of trends. The use of curated and smoothed data is however not recommended for the parameterization of models because such procedure may introduce errors or may lead to the negligence of exceptional phenomena producing outliers in the data trends.

Curation is here referred to the process of filling missing concentration data in time points where samples have been withdrawn and for any particular reason the concentration of one or more substances have not been able to be measured or the measurements fell below the equipment detection limits. In either of the two cases the empty data points may be filled using the overall trends of the data as reference. For instance, if the missing data correspond to points where low concentrations are expected, as the low points in the oscillatory data collected by (Mahamkali et al., 2020), then the missing data can be replaced by values somewhere around the detection limit of the measuring equipment. If the missing data is instead expected higher than the detection limits of the measuring equipment, their estimation may be supported on the overall trend, where spline interpolation may be far more useful than linear interpolation. The maintenance of the trends in the time derivatives may also be used as a strategy for selecting the interpolation

method. Time derivatives of experimental concentrations (C_j) may be estimated using forward, central and backward differentiation for the first, middle and last points in a time series, respectively. Table 1 shows the equations applicable to the three mentioned differentiation methods.

Table 1 Equations used for the estimation of the concentration gradients with the experimental data

Type of differentiation	Equation	nr.
Central	$\frac{dC_j}{dt} \approx \frac{\Delta C_j}{\Delta t} = \frac{C_{t+1} - C_{t-1}}{2 \cdot \Delta t}$	(1)
Forward	$\frac{dC_j}{dt} \approx \frac{\Delta C_j}{\Delta t} = \frac{C_{t+1} - C_t}{\Delta t}$	(2)
Backward	$\frac{dC_j}{dt} \approx \frac{\Delta C_j}{\Delta t} = \frac{C_t - C_{t-1}}{\Delta t}$	(3)

Smoothing is here referred to the reduction of the noise in the trends of dynamic experiments. The earliest smoothing method to be tried may be moving averages. However, the higher and lower points in oscillatory data, as in (Mahamkali et al., 2020), may be neglected by moving averages. As more refined alternatives, the smoothing may be done using local regression methods that use weighted linear least squares or 1st degree polynomial models that assign lower weight to outliers in the regression. The last two methods may be found coded into MatLab's 'smooth' function as the algorithms 'lowess' and 'rlowess', respectively. In any case, the selection of smoothing algorithm may be, as described for the curation of data, supported on the trends of the time derivatives and on trends from a second experiment, provided it is available.

3. Reconciliation of net conversion rates

In general terms, the reconciliation process consists on the minimization of the mismatch between the reconciled data and the raw experimental data while closing the carbon, hydrogen, oxygen, nitrogen elemental balances as well as the charge balances. Prior to describing how the minimization problem is created, it is necessary to provide an introduction on how the mass balances are structured for the fermentation of syngas.

The fermentation of syngas employs the ability of diverse types of bacteria and archaea, often called as acetogens, to harvest the electrons from CO and H₂ and the carbon from CO and CO₂. CO, H₂ and CO₂ can be the sole sources of energy and carbon for these microorganisms. Acetic acid, ethanol and 2,3-butanediol are the most common native products of acetogenic microorganisms. The first step on the processing of experimental data is the establishment of stoichiometric relations between electron and energy sources, the products and cells. Equations 4 – 9 in Table 2, show the stoichiometries of the reactions leading from CO and H₂ towards acetic acid, ethanol and 2,3-butanediol. In equations 4 – 9, the amount of electron donor required to generate each product is calculated by balancing the degree of reduction (or the amount of electron available for redox exchange (Heijnen, 2002)) between the donor and the catabolic product; CO₂ is added to balance the carbon, H₂O balances the oxygen atoms, and H⁺ ions balance the hydrogen atoms. If the balancing is made correctly, in the mentioned order of steps, the charge should also be balanced with no additional modifications to the stoichiometry.

For simplicity, here we show only apparent species. CO₂, acetic acid and potentially the nitrogen source have different forms depending on the pH. More thorough descriptions can include these species and their equilibrium relations to improve accuracy.

The complexity of the sequence of reactions leading to the production of cells, or anabolism, may also be summarized using two equations, one for each electron donor (see equations 10 and 11 in Table 1). The derivation of the stoichiometry of the anabolic reaction follows the same steps as described previously.

In theory, the catabolic reactions of any syngas fermentation process where CO and H₂ are consumed and where acetate, ethanol and 2,3-butanediol are the main products should be described by a combination between equations 4 – 9. The same is applied to the anabolic reaction, which is derived from a combination between equations 10 and 11. The resulting catabolic and anabolic reactions may be joined to form one metabolic reaction using the biomass yield, which can be estimated using thermodynamics (Heijnen and van Dijken, 1992).

Table 2. Common reactions in syngas fermentations

Part of metabolism	Reaction	nr.
Catabolism from CO as the electron donor	$-4\text{CO} - 2\text{H}_2\text{O} + \text{C}_2\text{H}_3\text{O}_2^- + 2\text{CO}_2 + \text{H}^+$	(4)
	$-6\text{CO} - 3\text{H}_2\text{O} + \text{C}_2\text{H}_6\text{O} + 4\text{CO}_2$	(5)
	$-11\text{CO} - 5\text{H}_2\text{O} + \text{C}_4\text{H}_{10}\text{O}_2 + 7\text{CO}_2$	(6)
Catabolism from H ₂ as the electron donor	$-4\text{H}_2 - 2\text{CO}_2 + \text{C}_2\text{H}_3\text{O}_2^- + 2\text{H}_2\text{O} + \text{H}^+$	(7)
	$-6\text{H}_2 - 2\text{CO}_2 + \text{C}_2\text{H}_6\text{O} + 3\text{H}_2\text{O}$	(8)
	$-11\text{H}_2 - 4\text{CO}_2 + \text{C}_4\text{H}_{10}\text{O}_2 + 6\text{H}_2\text{O}$	(9)
Anabolism	$-2\text{CO} - 0.25\text{NH}_4^+ - 0.5\text{H}_2\text{O} + \text{CH}_{1.75}\text{O}_{0.5}\text{N}_{0.25} + \text{CO}_2 + 0.25\text{H}^+$	(10)
	$-2\text{H}_2 - 0.25\text{NH}_4^+ - \text{CO}_2 + \text{CH}_{1.75}\text{O}_{0.5}\text{N}_{0.25} + 1.5\text{H}_2\text{O} + 0.25\text{H}^+$	(11)

Going back to the structuring of the minimization problem for reconciling the net conversion rates, the mismatch between the reconciled and the experimental rates is the objective function; the mismatch may be quantified by the sum of the squared differences divided by the standard deviation (Villadsen et al., 2011). The reconciled net conversion rates for CO, H₂, CO₂, acetate, ethanol, 2,3-butanediol, biomass growth, water, nitrogen source and H⁺ ions may be used as decision variables. The elemental balances may be used as constraints. Additional constraints may also be applied for improving the precision; for instance, the mass balances of the different species in the two phases of the bioreactor, the liquid and the gas phases. The experimental preference for CO and H₂ uptake and for product generation may also be used as additional constraints.

It is standard procedure to fix the allowed variations of the experimental q-rates according to the error in the experimental data (known using data from multiple experiments at the same conditions); however, if that error is not reported in the source of experimental data, one may assume a percent variation of maximum 10 – 20 % for each reconciled rate. In this case, the use of additional constraints become very helpful to guide the reconciliation to values that are consistent not only with elemental balances but also with time dependent or independent balances of species.

4. Calculation of the dissolved gas concentrations

Techniques for in-line measurement of the dissolved concentrations of CO, H₂ and CO₂ have been developed (Mann et al., 2021; Mislov et al., 2015). However, it is rare to find reports that describe the use of such techniques in syngas fermentations. The calculation of the dissolved concentrations of CO, H₂ and CO₂ is therefore often necessary. This

calculation can be done using two approaches that are different if the experimental data can be assumed at steady state or at transient state.

If the experimental data is likely at steady-state, the time gradients are assumed equal to zero and the mass balances of CO and H₂ in the gas and the liquid phases, one overall CO₂ mass balance and one summation for the composition of the off-gas (see equations 12 - 17) may be enough to estimate the unknown concentrations of CO, H₂, CO₂ in the liquid phase, as well as the molar fractions of CO and H₂ in the off-gas and their flow rates. If CO₂ is a product of the fermentation, it can be assumed that it is saturated in the liquid, thus Henry's law may be applied to find its fraction in the gas phase.

$$\begin{array}{l} \text{CO in the liquid} \\ \text{phase} \end{array} \quad 0 = q_{CO} \cdot C_x + k_L a_{CO} \cdot (C_{CO}^* - C_{CO}) - C_{CO} \cdot D \quad (12)$$

$$\begin{array}{l} \text{H}_2 \text{ in the liquid} \\ \text{phase} \end{array} \quad 0 = q_{H_2} \cdot C_x + k_L a_{H_2} \cdot (C_{H_2}^* - C_{H_2}) - C_{H_2} \cdot D \quad (13)$$

$$\begin{array}{l} \text{CO in the gas} \\ \text{phase} \end{array} \quad 0 = F_{G,in} \cdot y_{CO,in} - F_{G,off} \cdot y_{CO,off} - k_L a_{CO} \cdot (C_{CO}^* - C_{CO}) - C_{CO} \cdot D \quad (14)$$

$$\begin{array}{l} \text{H}_2 \text{ in the gas phase} \end{array} \quad 0 = F_{G,in} \cdot y_{H_2,in} - F_{G,off} \cdot y_{H_2,off} - k_L a_{H_2} \cdot (C_{H_2}^* - C_{H_2}) - C_{H_2} \cdot D \quad (15)$$

$$\text{CO}_2 \text{ overall} \quad 0 = F_{G,in} \cdot y_{CO_2,in} - F_{G,off} \cdot y_{CO_2,off} + q_{CO} \cdot C_x \cdot V_L - C_{CO_2} \cdot D \cdot V_L \quad (16)$$

$$\begin{array}{l} \text{Summation of gas} \\ \text{phase composition} \end{array} \quad 1 = y_{CO,off} + y_{H_2,off} + y_{CO_2,off} \quad (17)$$

The saturation concentrations of the gases (C_{CO}^* , $C_{H_2}^*$ and $C_{CO_2}^*$) may be estimated using Henry's equation (a list of coefficients is given by (Sander, 2015)). Moreover, the estimation of the mass transfer coefficients ($k_L a$) requires making several assumptions about the fermentation broth, the dimensions of the bioreactor vessel and the dimensions of the stirrer; unfortunately, these details are commonly not reported. The calculation of $k_L a$ may be based on the power input by the stirrer (P_S in equation 6) and by the gas sparging (P_{SG} in equation 7). Note that equation 18 and 19 were developed for the transfer of oxygen to pure water at 20 °C; therefore $k_L a$ may be further corrected for the process temperature and the specific gas through their the film diffusivity (\mathfrak{D}) of CO and H₂ in pure water compared to that of O₂ (see equation 20). Equation 20 also contains a correction factor for the mass transfer coefficient ($f_{k_L a}$), which may account for other differences in the experimental set-up and liquid phase composition compared to the ideal case for which equation 18 - 20 were initially constructed and parametrized.

$$P_S = N_p \cdot \rho \cdot N^3 \cdot D_S^5 \quad (18)$$

$$P_{SG} = P_S \cdot \left[0.1 \cdot \left(\frac{N \cdot V_L}{\dot{V}_G} \right)^{\frac{1}{4}} \cdot \left(\frac{g \cdot H_S \cdot V_L^{\frac{2}{3}}}{N^2 \cdot D_S^4} \right)^{\frac{1}{5}} \right] \quad (19)$$

$$k_L a_j = f_{k_L a} \cdot [1.022^{(T-293.15)}] \cdot \left[0.002 \cdot \left(\frac{P_{SG}}{V_L} \right)^{0.7} \cdot v_{Gs}^{0.2} \right] \cdot \frac{\mathfrak{D}_{O_2}}{\mathfrak{D}_j} \quad (20)$$

If the experimental data is instead expected to be at transient state, the concentration gradients represent one more unknown variable per each gas in the balances. The additional equations needed may be formulated using kinetic equations linking the net conversion rates of CO, H₂ and CO₂ to their dissolved concentrations. Mechanistic or

approximative formats may be used (Heijnen, 2005; Rizzi et al., 1997). The combination between both formats has been useful in our work.

To improve the accuracy of the reconciliation of the ten conversion rates, the calculation of dissolved gas concentrations may be done simultaneously by including the unknown C_{CO} , C_{H_2} and C_{CO_2} , $y_{CO,off}$, $y_{H_2,off}$ and $F_{G,off}$ among the decision variables list.

Abstract

The present study is inspired by our current research work concerning the development of innovative solutions for the optimal use of resources in the industry in the context of circular economy. The outcome of the research is expected to be the development of a framework including prototypes and models for the process and manufacturing industry in order to make the optimal use of resources in the entire life cycle of materials and products. These prototypes and models, including materials reuse, water recovery and reuse, products remanufacturing, waste minimisation, all relevant to minimizing resource consumption and environmental impacts, will be implemented integrating industry 4.0 technologies, optimisation models, feasibility studies and life cycle analysis to support Circular Economy practices.

In the above context, the present paper introduces our wider research issues and parameters and describes the significant role of Process Systems Engineering in the Circular Economy context of the above industrial problems. In parallel, the importance of a new field of PSE tools implementation and expansion emerges as an outcome of the work providing very interesting and challenging perspectives in addition to their existing fields of application.

Keywords: PSE prospects, modelling and optimisation in circular economy.

1. Introduction and Rationale of the work

Many organisations, academics, companies and policymakers have acknowledged the circular economy as an opportunity for more sustainable industrial models and strategies. According to this viewpoint, companies can achieve substantial cost savings and additional revenues by adopting circular business models.

As sustainability gains more attention and is being used by industries, governments and academic cycles, there has been a considerable effort in moving towards sustainable development not only for environmental and societal needs but also as an important economic activity. A comprehensive framework to accomplish this is shifting to the principles of the so-called circular economy (CE), that is attracting more and more attention as a way to face materials scarcity and the growing demand for resources in general (e.g. water, energy, land).

The European Union defines Circular Economic as a model where the value of products, materials and resources is maintained in the production and use cycle for as long as possible, and waste generation is minimised. The Ellen MacArthur Foundation (2013) expanded this definition by stating that the Circular Economy is a systemic approach to economic development designed to benefit businesses, society, and the environment. In contrast to the ‘take-make-waste’ linear model, CE aims to develop design and operation of production systems that gradually decouple growth from the consumption of finite resources.

The concept recognises the importance of the economy needing to work effectively at all scales for big and small businesses, for organisations and individuals, globally and locally, based on three principles (1) minimisation of waste and pollution, (2) extension

of products and materials life and (3) regeneration of natural systems (Ellen MacArthur Foundation, 2013) thus setting the CE concept with the potential to generate economic, environmental and social benefit. In line with the previous principles, the European Union (EU) adopted an action plan in 2015 where the value of products and materials is maintained for as long as possible, bringing thereby significant economic, social and environmental benefits by making its members' states pioneers in making policies and framework to promote the CE in industries, businesses, and services.

In quantitative terms, according to the European Commission more efficient use of raw materials and resources throughout the supply chain materials could reduce the need for new raw material of 17% -24% by 2030, with savings for European industry estimated at 630 billion Euro per year. Several studies on the potential of circular economy indicate that European industry, thanks to substantial savings on the cost of raw materials, could push the growth of European GDP by about 3.9% and create a very large number of new jobs. (<https://www.cesme-book.eu/>)

2. Process Systems Engineering and the Circular Economy

On the other hand, Process Systems Engineering practice started from the need to define and solve increasing complexity problems in technical systems, understand and control these systems' characteristics as a whole. The PSE is focused on the integrated design and operation of complex technical systems. PSE relies on systems thinking, feature very essential to the Circular Economic approach.

Decision-making for supply chains and understanding Circular Economy and the transition from linear to circular models makes PSE a fundamental part of the CE as a solution (Falk et al., 2016, Walmsley et al., 2019, Dantas et al., 2021).

According to Reichel et al. (2016) and Avraamidou et al. (2020), the critical characteristics of CE, which also fall under the Ellen MacArthur Foundation (2021) goals, are (1) minimise the use of natural resources: less import dependence on natural resources by efficient use of natural resources, (2) increase of renewable resources and energy: substituted conventional resources to renewable and minimizing the virgin materials, (3) minimisation of emissions levels: reduction of pollutants through clean material cycles, (4) less material losses/residuals: waste minimisation through the recovery and recycling of materials and products, (5) manage resources to preserve value: promote the development of business models to increase the value of products in redesigning and high-quality recycling. Figure 1 shows indicative research fields with potential use in achieving CE goals (Avraamidou et al 2020).

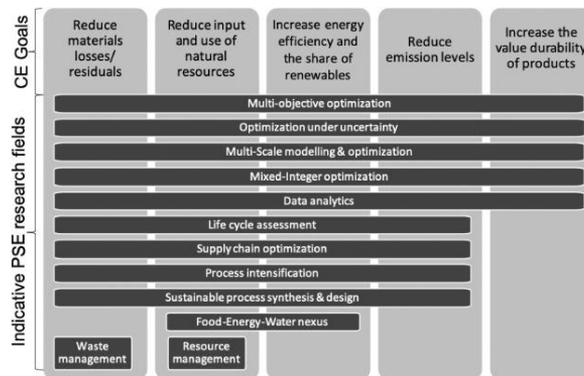

Figure 1: Indicative research fields with potential use in achieving CE goals (Avraamidou et al 2020).

As process systems engineering has become one of the first to acknowledge sustainability, it has become the leading model in process design. Even though the rationale to transform into a sustainable process may have been essentially economic, through the years, this notion changed as more industries wanted their process systems to not only see the economic value but also how the entire system interacts with the

environment (Silk et al., 2019). Their research discovered that in any attempt in modeling or optimizing circular economy, the most common approach to attain sustainability in a process design is through Life Cycle Assessment, which is a way of comparing different process design alternatives. Thus, Life Cycle Assessment (LCA) is being employed within the PSE community for years. The process systems engineering tools may enable a practical way for analyzing performance and improvement in a sustainable way within industries. The reason for this is that LCA quantifies all relevant issues related to the products or services and could evaluate sustainable development, making it a handy tool for CE.

In the present research LCA is one of the main tools to create and evaluate alternatives. Additionally, process optimisation, which relies on mathematical optimisation, gains more attention in the circular economy notion to industries as it can be used as a methodology for minimizing or maximizing suitably defined objectives and goals in the whole life cycle in a sustainable way (Kristoffersen et al., 2020). From the process systems engineering view, the progress of efficient design and state-of-the-art mathematical tools to support quantitative methods in the process optimisation applications with sustainability in mind has been growing in the academic cycles and industries. Besides, when circular economy and sustainability in supply chains are combined, it must include optimisation of supply chain industries to have efficient and circular systems that assist the progress of reducing, reuse and recycling and emphasise environmental, social, and economic demands. This implementation requires adjustment in design management by optimizing all factors to minimise resource consumption and maximise circular economy on materials, products and systems. As a result, circular supply chains management, information and knowledge issues are organised and planned to optimise resource allocation, increase benefits and achieve the circular economy notion. Optimisation model's development is a core issue in our in-progress research.

3. Research gaps and expected added value

In the industrial community a lot of attention has been given to the sustainability issues. According to Bjornbet et al. (2021), there is a promising future in transitioning towards CE in the manufacturing community through circular business models. Thus, acquiring experience in modeling such industries that are yet fully discovered by PSE is essential in modeling and optimizing the CE through supply chains. Making the resources use circular could increase their productivity in recovering an immense amount of those from being employed in manufacturing. Thus, circular economy could contribute to changing even the synthesis of the production system at the first place. In this manner, designing industries for availability, sustainability, and of course including design in reusing and remanufacturing will gain more attention and become vital. However, success in moving towards a circular economy depends on whether industries understand the importance of changing into it for efficient planning and management over time.

Industry is a very wide and complex system and certainly there is no unique or generic approach towards circular economy in this sector. It is important at this point to emphasise that circularity is a wider term and is not identical to sustainability, although most methods and approaches converge to that.

Therefore, more specific models expressing different industrial characteristics, objectives and constraints depending on the type of industry as well as its crucial issues in terms of circular economy principles need to be developed. As Pistikopoulos et al, (2021) mention the Circular Economy will be the framework and the context of Process Systems Engineering in the next years. Therefore, modeling will definitely play a crucial role in achieving CE goals, along with other tools such as Life Cycle Analysis and feasibility studies, that will lead to the economic evaluation of proposed measures and interventions.

4. Research questions, methods and tools

The suggestions – referring to each industrial type under consideration - extend from materials reuse, water recovery, products remanufacturing, waste minimisation, all relevant to minimizing resource consumption and negative environmental impacts.

The main research questions / objectives of the proposed work are (also shown schematically in Figure 2):

- To investigate the potential and the methods for the industry to use less resources and produce less waste when producing materials and products
- To identify the methods and tools and to develop the relevant models that will enable circularity in the manufacturing and process and manufacturing industry
- To focus on the recovering and reprocessing of materials and products that will lead to the optimisation of resources exploitation
- To develop advanced techno-economic modelling, life-cycle assessment and optimisation models, in order to predict/determine which technologies, both established and new, will perform best at scale and enable circularity.
- To investigate the suitability of the above methods and tools depending on the type of industry, i.e. determine the matching between methods/tools and sectors for modelling the industry innovation for circular economy
- To create certain specific models and paradigms and the relevant specific results to the selected sectors,
- To extend the scope of the models and paradigms to other industrial (and non-industrial sectors, such as the energy).

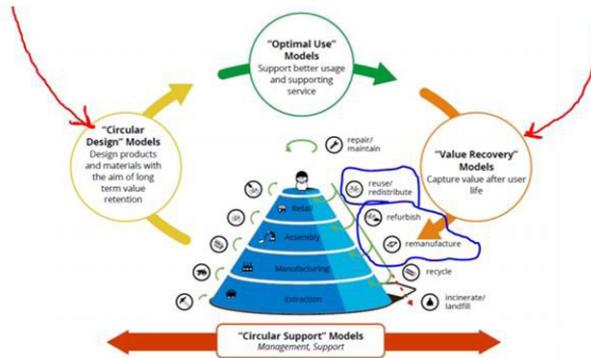

Figure 2: Main scope of the proposed research (figure inspired by The EIB Circular Economy Guide, https://www.eib.org/attachments/thematic/circular_economy_guide_en.pdf)

The expected outcome of the study is the specific recommendation of circular (technoeconomic, optimisation) prototypes and models for the process and manufacturing industry in order to make the optimal use of resources in the entire life cycle of materials and products. This will be implemented exploiting PSE existing tools, optimisation models, feasibility studies and life cycle analysis to support CE practices.

The main methods, tools and models for the assessment of different aspects of the circular economy for the industry, include advanced techno-economic modelling, life-cycle assessment, systems engineering models and tools and optimisation methods and tools (mathematical optimisation, multicriteria analysis). Forecasting work has already taken place concerning the evolution of circular economy on the industry (Angelopoulou, Kondili, July 2021). Furthermore, continuous collaboration with industrial partners for detailed description of cases and paradigms has been established.

The classification of the industries (sectoral classification) according to their suitability in one of the following basic axes of circular economy (as shown in Figure 2 above).

- The waste reprocessing and reuse
- The minimisation of resources utilisation
- The design of materials and products according to the main eco-design principles.

Currently, having completed the existing background work, a classification of the industrial sectors under consideration is taking place according to the resources where

each sector is intensive (metals, energy, water, land, other materials, etc.) as well as its classification according to the potential of materials and products remanufacturing and reuse.

5. Industry 4.0 and PSE

Today the model development based on these new business models is also linked to the Industry 4.0 (I4.0) paradigm, the fourth industrial revolution in production systems using a higher level of digitalisation. The core idea of Industry 4.0 is to use emerging technologies so that business and engineering processes are integrated by making production operate in a flexible, efficient, and sustainable way. (Singh et al., 2019, Rajput & Singh, 2020, Jamwal et al., 2021). Industries cannot prevent themselves from applying I4.0 systems, and the fundamental contribution of I4.0 is digitalizing CE practices through different forefront technologies. Industry 4.0 creates abundant opportunities for industries to improve circular performance and evolve ethical principles of social responsibility by optimizing the usage of resources with the improvement of the lifecycle of products (Rajput & Singh, 2020).

The problem considered here is of implementing Industry 4.0 along with Process Systems Engineering considering circular economy. There is an excess of research studies associated with industry 4.0, smart manufacturing, and the Internet of Things in industries. However, the combination of process systems engineering that focuses on circular economy is limited, with most researchers addressing real-time data availability, computing, and big data. It was proposed that industries adopt more model-driven and object-orientated information-driven models for increased optimisation, better efficiency, and circular economy support in an Industry 4.0 approach.

Thus, in order to be successfully implemented, as far as the supply chain management is concerned, Rajput & Singh (2020) proposed the CE principles that reduce, reuse, recycle, recover, remanufacture and redesign materials and products and life cycle analysis as possible solutions to this integration. Nevertheless, there is a need to quantify the relationships between Industry 4.0 in the industry's management, performance, and sustainability to identify specific stages of product life extension through optimisation. Thus, by adopting and implementing strategies with quantitative and real-time data about Industry 4.0, there is a need for new sustainable manufacturing practices and combining all, Industry 4.0 knowledge and process system engineering could create effective results in not only overall firm performance but also industry performance (Walmsley et al., 2019, Rosa et al., 2020, Bag et al., 2021). This is another important research objective of the present work.

6. Conclusions

Many comprehensive works have been developed concerning the theoretical background and the principles of Circular Economy. Concerning the process and manufacturing industry, there is a wide scope for the development of practical and implementable solutions that will have a real and measurable benefit to the industrial units. There is a need to step forward to establish new frameworks that, together with adequate data and actions in the notion of the CE in industries, could fulfil the CE goals. Enabling circular economy requires changing the business models from selling products to delivering services and from a linear system lifecycle to a circular one. Thus, there is a need for collaboration between the academic community, industries, and society. There has to be a better understanding of the implications of CE and how this can work together with I4.0 by examining case studies and using the appropriate PSE methods and tools as those could help in the whole notion of the CE.

In the present work the basis has been set for the identification of how CE models may be developed and solutions suggested by using PSE methods and tools.

1. The development of relevant integrated models to use less resources or use resources more efficiently when producing materials and products will enable circularity in the manufacturing and process industry focusing on the recovering and reprocessing of materials and products that will lead to the optimisation of resources exploitation. The work will highlight the real potential of the PSE tools for circular economy and at the same

time establish PSE in the context of circular economy, thus revealing an interesting field for expansion, application of PSE tools and developing excellent prospects in the field.

Abstract

In this work, the conventional scenario of the black liquor (BL) concentration and combustion is compared with the BL upgrading gasification process for ammonia production. The chemical processes synthesis, modeling and simulation are performed by using Aspen Plus® software. The determination of the heat recovery and the solution of the energy integration problem is handled by a mixed integer linear programming model. An incremental financial analysis incorporates the uncertainty related to the acquisition and selling costs of the feedstock and fuels produced and carbon taxation by using the Monte Carlo method. As a result, the incremental financial analysis found that only the integrated pulp and ammonia production route with partial electricity import may economically outperform the conventional kraft pulp mill for moderate carbon taxations (40-90 EUR/t_{CO2}), depending on the interest rate adopted. In this regard, middle-to-high carbon taxations may render ammonia co-production attractive in the Brazilian context of a highly renewable electricity mix.

Keywords: Black liquor, Kraft process, Uncertainty, Ammonia, Decarbonization.

1. Introduction

Ammonia is one of the most demanded bulk chemicals in the world, mainly for the production of fertilizers for the agricultural sector. In 2016, the ammonia production reached 175 million tons, and the trend from 2006 to 2016 shows a growth rate of 1.9% per year (YARA, 2018). The ammonia synthesis is also the largest carbon dioxide emitting chemical industry process, responsible for about 1.8% of global carbon dioxide emissions (Royal Society, 2020). Thus, several efforts are being made towards the decarbonization of the ammonia production supply chain and the mitigation of the environmental impacts of this sector. The thermochemical conversion routes for hydrogen production are among the proposed alternatives, which can also capitalize on the underexploited biomass potential in tropical countries with a well-established biomass conversion expertise, such as Brazil. This work proposes to produce ammonia by using the syngas coming from the gasification of black liquor (BL), a byproduct of the kraft

pulping process. The incremental financial analysis under uncertainty are considered as criteria for assessing the potential to implementing this technology under volatile market conditions.

2. Methods

2.1. Process modeling and optimization problem definition

Figure 1 illustrates the integrated system for ammonia production via black liquor gasification. First, the weak black liquor is dried in a mechanical vapor recompression system. Subsequently, the strong black liquor is gasified in a pressurized system using oxygen. The syngas obtained need to be treated, purified and its composition should be adjusted before enters the ammonia loop. To this end, autothermal reformer, water gas shift, CO₂ capture and methanation systems are required. Finally, ammonia is purified before follow to its end-use. This process is modelled in the Aspen Plus® software and the detailed description of the processes conditions is reported in (Domingos et al., 2021). The integration of the ammonia plant to the existing kraft pulp mill creates new utility demands. So, the determination of the minimum energy requirements (MER) and the solution of the energy integration problem is handled by the OSMOSE Lua platform. Three scenarios are considered: i) conventional: recovery boiler application, with only pulp production; ii) mixed: based on both chips fuel and electricity import, with ammonia and pulp production; and iii) autonomous: only chips import and cogeneration system enabled, with ammonia and pulp production. The market costs and selling prices for feedstock and products that are considered for the optimization problem solution are: wood 0.013 €/kWh; chips 0.016 €/kWh; oil 0.018 €/kWh; electricity 0.06 €/kWh; pulp 0.144 €/kWh; ammonia 0.098 €/kWh; and CO₂ 0.0084 €/kg, as reported in (Domingos et al., 2021).

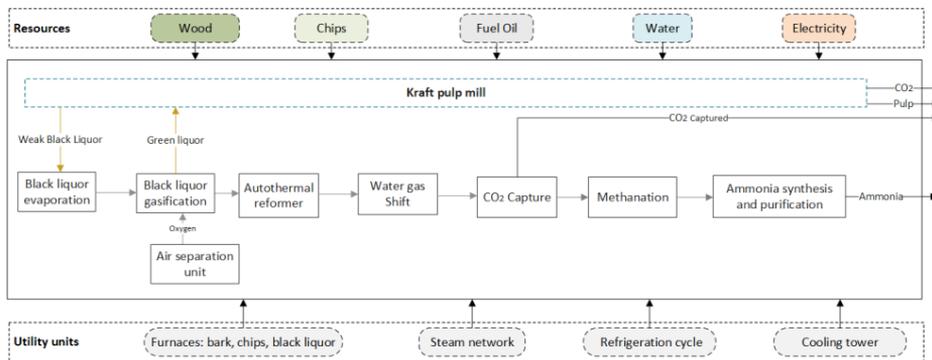

Figure 1. Integrated flowsheet of pulp and ammonia production.

2.2. Economic evaluation

The capital expenditure (CAPEX) is calculated using the methodology described in (Turton et al., 2018), in which actual costs are correlated to the cost of a reference equipment capacity using scaling factors. Equation 1 is used to estimate CAPEX of the black liquor gasifier, air separation unit, autothermal reformer, water gas shift reactors, CO₂ capture unit, and methanation, according to the data reported in (Larson et al., 2000, Williams et al., 1995, Hamelinck and Faaij, 2002, Holmgren, 2015), and corrected for inflation using CEPCI index (Jenkins, 2020).

$$C_1 = C_0 \left(\frac{S_1}{S_0} \right)^r \quad (1)$$

where S_0 represents the reference capacity with known capital cost C_0 ; S_1 represents the actual capacity for which the capital cost C_1 is unknown; and r is the power scaling factor which varies between 0.5 and 0.9 depending on the type of process considered. Also, the kraft pulp mill investment costs are scaled (0.6 factor) as per (Börjesson, 2015). A lifespan of 20 years is assumed for cash flow calculations. Besides, the total capital expenditure is divided between the first (60%) and second (40%) years. A decommissioning cost of 6% of the overall CAPEX is assumed. The operating costs (OPEX) are assessed using the methodology proposed by Turton et al. (2018), except for the kraft pulp mill, in which OPEX is assumed as 4% of the CAPEX as per (Kangas et al., 2014). A contingency cost increment of 20% is considered by reason of the technological risk level (Turton et al., 2018).

2.2.1. Incremental financial analysis

An incremental approach is proposed to compare the economic attractiveness of the integrated ammonia plant (Fig. 1) and the conventional process. This comparison is based on the incremental net present value (INPV), defined by Eq. (2) (Blank, 2011):

$$INPV = \sum_{n=1}^N \frac{[(Rev-Exp)_{n,option B}] - [(Rev-Exp)_{n,option A}]}{(1+i)^n} \quad (2)$$

where $(Rev-Exp)$ is the net cash flow (i.e. revenues minus expenses), calculated at each (n) of the N yearly periods, during which both the new (B) and the reference (A) configurations should operate. Besides, i is the average interest rate.

A sensitivity analysis of the variation of the INPV as a function of the carbon taxation (0-100 €/t_{CO2}) and the interest rate (0-21%) is performed. This analysis aims to consider the scenario of rigorous environmental regulations and the increased perception of the risks associated with these technologies.

Also, an incremental financial analysis that incorporates the uncertainty related to the acquisition and selling costs of the feedstock and fuels produced is performed through Monte Carlo method, by simulating the stochastic variation of the commodities price profiles. A normal distribution with mean prices as those reported in section 2.1 and a standard deviation of 30% is considered for the commodities prices.

As a result, the INPV of the integrated chemical plants can be calculated along the lifespan of those facilities and the so-called ‘likelihood of loss’, which measures the probability of achieving a negative incremental net present value, can be determined. Accordingly, three hypothetical scenarios are considered:

- i) Scenario DCTIR_SC: deterministic carbon taxes (0-100 EUR/t_{CO2}) and interest rates (0-21%), along with stochastic prices of the commodities;
- ii) Scenario LCT_DIR_SC: linearly-increasing carbon taxes over the lifespan (0-100 EUR/t_{CO2}), along with deterministic interest rates (0-21%) and stochastic prices of commodities;
- iii) Scenario SCTC_DIR: stochastic carbon taxes and variable prices of the commodities, along with deterministic interest rates (0-21%).

3. Results and discussion

The breakdown of the capital expenditure for both scenarios of the integrated ammonia plant (Fig. 2) suggests that the operation under the autonomous mode requires larger chips furnaces and Rankine cycle based power plants for supplying the utilities demands.

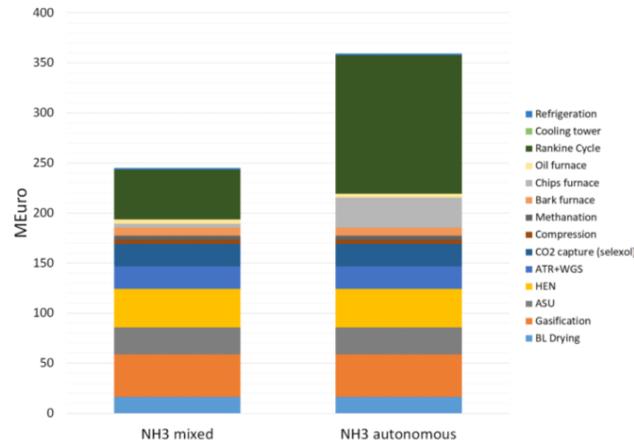

Figure 2. Capital expenditure breakdown.

According to Figure 3, the ammonia production route with partial electricity import (mixed case in Figure 3a) may economically outperform the autonomous setup, depending on the interest rate adopted, for moderate carbon taxations (40-90 EUR/t_{CO2}), such as those reported for Norway or France (World Bank, 2021).

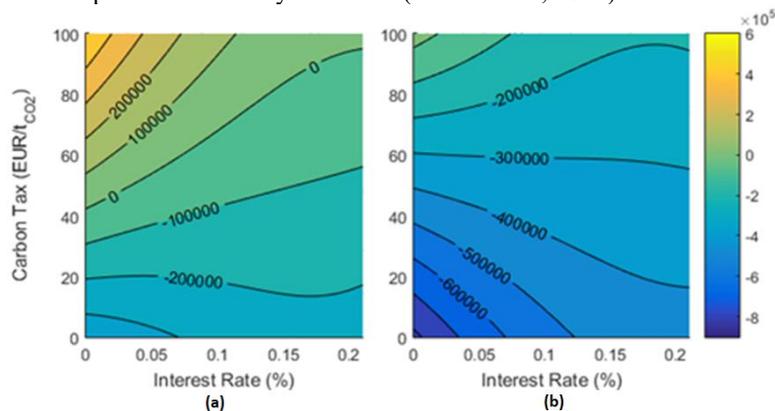

Figure 3. Contour plots of INPV (Euro) variation for integrated ammonia production via BL gasification under: a) mixed and b) autonomous operation modes.

The heat maps given in Tables 2 and 3 summarize the results obtained for the scenario DCTIR_SC. Table 2 suggests that, for the integrated plant co-producing pulp and ammonia while operating under the mixed mode, and for a region of middle to stringent carbon taxations (60-100 EUR/t_{CO2}), there exists a large probability of the INPV being positive, depending on the interest rate adopted. On the other hand, for the autonomous mode (Table 3), presents relatively unfavorable INPVs, regardless of how low interest rates become.

Meanwhile, the heat map shown in Table 4 summarizes the results obtained for scenarios LCT_DIR_SC and SCTC_DIR. For both scenarios, similarly to the previous analysis, only the integrated chemical plant producing NH₃ while operating under mixed mode presented more favorable results in terms of likelihood of loss, which may render NH₃ co-production attractive in the Brazilian context of a highly renewable electricity mix.

Table 2. Probability that INPV is negative (likelihood of loss in %) for scenario DCTIR_SC - ammonia production under the mixed operation mode.

21%	100.00	100.00	100.00	100.00

4. Conclusion

The incremental financial analysis under uncertainty of feedstock costs and carbon taxes allowed to understand the behavior of the integrated systems proposed by considering different market fluctuations. As a result, positive INPVs are achieved when moderate carbon taxes (40-90 EUR/tCO₂) are considered, provided that greener electricity import from the grid is enabled. Even when the system is subject to linear-increasing or stochastic carbon taxes, the scenario operating under the mixed mode points towards a great potential of decarbonization. The carbon taxation is reported as an effective measure to reduce CO₂ emissions, however other measures should be adopted, such as more stringent regulatory commitments, attractive fiscal incentives, and investments towards the equipment maturation and deployment.

Abstract

During the design of a process, the most economically impactful choices are often taken with limited data and details available on the specifics of unit operations. Despite this fact, the effect some of these choices have on the final economic performance of the plant can be dramatic and far more influential than later decisions. The availability of fast and reliable preliminary cost estimations based on few key design parameters for the most common units can go a long way in improving flowsheet design. Due to the early design stage, these estimates don't need to be very accurate since errors in the range of 50% are admissible as long as the estimation requires few input data. Automating the costs computation process and making the interface with the most common simulation packages standardized and easily accessible for users not accustomed to programming languages is very important in speeding up the cost evaluation of the plant and reducing the human resources tied to this task. These concepts stand at the core design of the CAPEX OPEX Robust Optimizer (CORO) developed in this work. Aspen HYSYS serves as the commercial simulation package to estimate the input variable of the economic libraries. Excel is used both as a GUI and as a data extraction tool from Aspen HYSYS due to its widespread diffusion in industry and versatility provided by Visual Basic for Applications. The CORO code is detached both from Excel and HYSYS and interacts only with a standardized xml data sheet to allow for in-house expansions to other simulation packages. The long-term development goal is a generalized CAPE-OPEN interface working with every commercial software that supports the interface. In the current CORO release, the interface can interact only with Aspen HYSYS. This paper will showcase the economic libraries implemented in CORO, the mathematical C++ optimization libraries, the overall structure of the tool, planned future expansions, and customization options.

Keywords: Economics, Aspen HYSYS, Simulation, Optimization

1. Introduction

As pointed out by Martin et al. (2007) during the conceptual design stage decisions have the most impact on the final capital expenditure of the project. At the same time, changing these decisions is rather cheap as there has been no concrete financial commitment yet. For this reason there is a strong incentive to estimate the costs as early as possible in the design phase of a new project to weed out the less competitive solutions. The issue lies with the limited data available on the units and the reliability of their estimation. While this might have been a bottleneck in the past,

modern commercial simulation packages allow for the development of process designs with low human and financial resource commitment and ever growing prediction precision. The automated development of process layout is still in the early phases of development, but the automation of cost estimation has already some commercial solutions implemented in simulation software such as Aspen One. The inherent design flaw with this solutions is that their extreme flexibility leads the correlations to some hard failure condition whenever the characteristic dimension of the unit is outside the boundaries of the correlation used for the cost estimation, or industry specific designs for unit operations are used (LNG, cryogenic equipment). Since the economic estimation package comes in a commercial solution the parameters and correlations are protected and not customizable by the user if not only in a limited way. Moreover, certain units will lead the cost estimation routine to fail and return either an error or a zero cost estimation. In this conditions the deep integration between the cost estimation libraries and simulation software does not allow for new unit operations to be integrated in the cost estimation routines. Here a new structure to deal with the cost estimation is presented as a detached structure from the specific commercial simulator interfacing with it only with a standardized .xml structure. This approach however has its own drawbacks;

- A specific add-on to write and read the .xml file must be developed for each simulation software
- The information required by the .xml file might not be available in the simulation software
- More human resources have to be invested in the development phase of the project

[noitemsep, nolistsep] the detached structure however also offers some opportunities:

- Once the interface between the commercial software and optimization package has been developed no further development is necessary beyond cross-release updates, on the long term, this will lead to less resources used in the cost estimation process
- The standard correlations used in literature can be heavily customized both in terms of fitting parameters and model variables
- Internal company database can be used and automatically digested by the software to refit the correlations for specific applications (Ammonia production, small scale plants, cryogenic operations)
- Unconventional units can be modeled using conventional simulation blocks (such as using a Gibbs reactor to model a Furnace, and later evaluate the furnace cost using the MW leaving the Gibbs reactor)

Critical to the success of such a solution is ease of use and low back-end responsibilities from the end user. In a long term vision this project should be included in a rigorous interface using the CAPE-OPEN protocol logic. This approach would allow the data extraction and writing to be inherently cross platform and use an already standardized protocol. However, the feasibility of this solution is still being investigated and, as a temporary solution for a proof of concept application, this application was specifically developed for the Aspen HYSYS package. The choice of the software comes from the availability of a functional library in VBA that makes interfacing data with HYSYS easy and fast. Moreover, it provides Excel as a versatile interface. From a theoretical point of view the structure of the solution is not impacted as well as its effectiveness. It is however marginally impacted in the performance, since data extraction and writing in Excel is not optimized for effective data transfer between software. At the current state of development the main aim is investigating the feasibility and convenience of such a solution, while optimization is left for later stages.

2. Methods

The automation process is based on three modules; the simulation package, the evaluation package, the optimization library. Each covers a standalone role and operates completely detached from the others except for a single file collecting the data in input and output of the module.

The simulation package has the role of modeling the physical and chemical problem as well as the characteristic dimensions of the unit and process flowsheet with a consolidated structure. Alongside this feature, already included in all commercial packages, the simulation package must also have an add-on to condense the relevant data in a standardized format and read data from the same format. This add-on could be developed using the CAPE-OPEN protocol and work for most of the currently popular commercial simulation packages, but conceptually, even a non-standard, standalone physical model of the system developed outside of the CAPE-OPEN framework could be optimized using the same library.

The evaluation package role is to provide a performance indicator for the optimization routine to use. The evaluation package used as a case study here is a financial key performance indicator: the Payback time of the process. In order to evaluate the payback time of the process an estimation of both CAPEX and OPEX is necessary. Operative expenditure estimation is rather straightforward since it can be estimated looking at input and output energy and material streams of the process and associating a price to each stream. Capital expenditures on the other side involve a much more complex and widespread set of information that will be discussed in a dedicated section.

The optimization library role is the robust search of the minimum or maximum of the performance indicator in the system domain. The function it covers is strictly numerical and does not involve a physical model which is instead kept separated in the simulation package.

2.1. The simulation package: Aspen HYSYS

The simulation package chosen for the conceptual design is Aspen HYSYS V10 release. The ease of use and already included macro-enabled library for Microsoft Excel VBA allowed to develop the data extraction and writing add-on in a limited amount of time exploiting Excel spreadsheets for user data input and plotting of the results. All the data necessary for the evaluation library are organized in and eXtensible Markup Language file (.xml). The xml file is structured data file organized in nodes to facilitate accessibility. For this specific case study the nodes are organized as follows:

- **Options:** this attribute includes the economic library used for the estimation, its parameters, and the units of measure
- **Streams:** this attribute includes child nodes corresponding to the single material stream and the thermodynamic properties of each
- **UnitsList:** this attributed groups all the supported unit operations of the simulation
- **Utilities:** this attribute groups all non material streams to be associated with operative expenditures
- **Specifications:** this attribute groups all the degrees of freedom used for each unit operation in the simulation

The combination of Aspen HYSYS and the Excel workbook managing the data processing is responsible for the description of the physical system.

2.2. The evaluation library: Capex/Opex estimation

The data extracted from the simulation into the xml file are read by the Capex/Opex estimation libraries implemented in C++. The economic libraries included in the software reach a study estimate precision on the final cost estimation with an estimated error ranging from +30% to -25%. For the sake of direct comparison two different libraries are included: the Peter and Timmerhaus (2001) library based on percentage of delivered equipment cost and the Guthrie (1974) and Turton

(2012) approach based on the bare module cost. The detailed discussion on this costing approaches is not the topic of this paper and can be explored in detail in . Both costing methods include in the Capital expenditure estimation:

- **ISBL:** Inside Battery Limits cost include purchasing and shipping costs of equipment, piping, catalysts, and any other material needed for final plant operation, or construction of the plant. ISBL costs also include any associated fees with construction such as permits, insurance, or equipment rental; even if these items are not needed once the plant is operational
- **OSBL:** Off site battery limits are defined as utilities, common facilities, and other equipment and components not included in the ISBL definition
- **Engineering and Construction:** indirect expenses associated with the actual building of the plant such as supervision, engineering and legal expenses.
- **Working Capital:** is defined as the money required to start and run the already constructed plant until income can be obtained from the products
- **Contingency:** allows for variation from the predicted cost estimate

The logic behind the Timmerhaus library is based on the assumption that each term of capital investment can be estimated as a proper percentage of the delivered equipment cost. By applying proper multipliers to the cost of the delivered equipment the overall cost of the plant can be estimated with accuracy in the +/- 25% range, but for similar plant configurations it can go as low as +/- 10%.

The Guthrie method operates by computing the cost of a single equipment in standard conditions and then, using appropriate cost factors, it scales the price of the equipment for actual operating conditions accounting for temperature, pressure, material, piping, contingency etc.

When the conventional approach to cost estimation fails due to out of boundary values then each library falls back to less precise, but more versatile methods such as the sixth tenth's rule. While these estimations have errors that be as high as +100% it is still preferable to completely neglect unit costs. Moreover, different exponents are implemented according to the specific unit as recommended by Turton et al. (2018)

Operative expenditures are managed separately and divided as follows:

- **Direct manufacturing costs:** this are the cost that vary with production rate
- **Fixed manufacturing costs:** this costs are independent from production rate
- **General expenses:** this costs are typically not related to production and include expenses such as marketing, management, financial investments and so on

Operative expenditures are known once cost of labor, cost of raw materials, cost of waste management, cost of utilities and fixed capital investment costs are known.

2.3. Robust Optimization: BzzMath library

The optimization problem is carried out by the BzzMath library developed by Buzzi Ferraris Buzzi-Ferraris and Manenti (2014) in C++. The library, developed in house at Politecnico di Milano offers a wide variety of numerical tools for the solution of linear and non-linear complex problems common in the chemical industry. The optimization variable chosen for the economic optimum design is the Payback time defined as:

$$\text{Payback Time} = \frac{\text{Total Initial Capital}}{\text{Average Annual Cash Flow}} \quad (1)$$

the optimization routine task is to look for the design and operating conditions minimizing this value. The convergence iterative procedure is reported in Fig 1. Excel covers 2 main functions: interacting with Aspen HYSYS, and acting as a GUI in which the user can input and visualize data necessary for the computations.

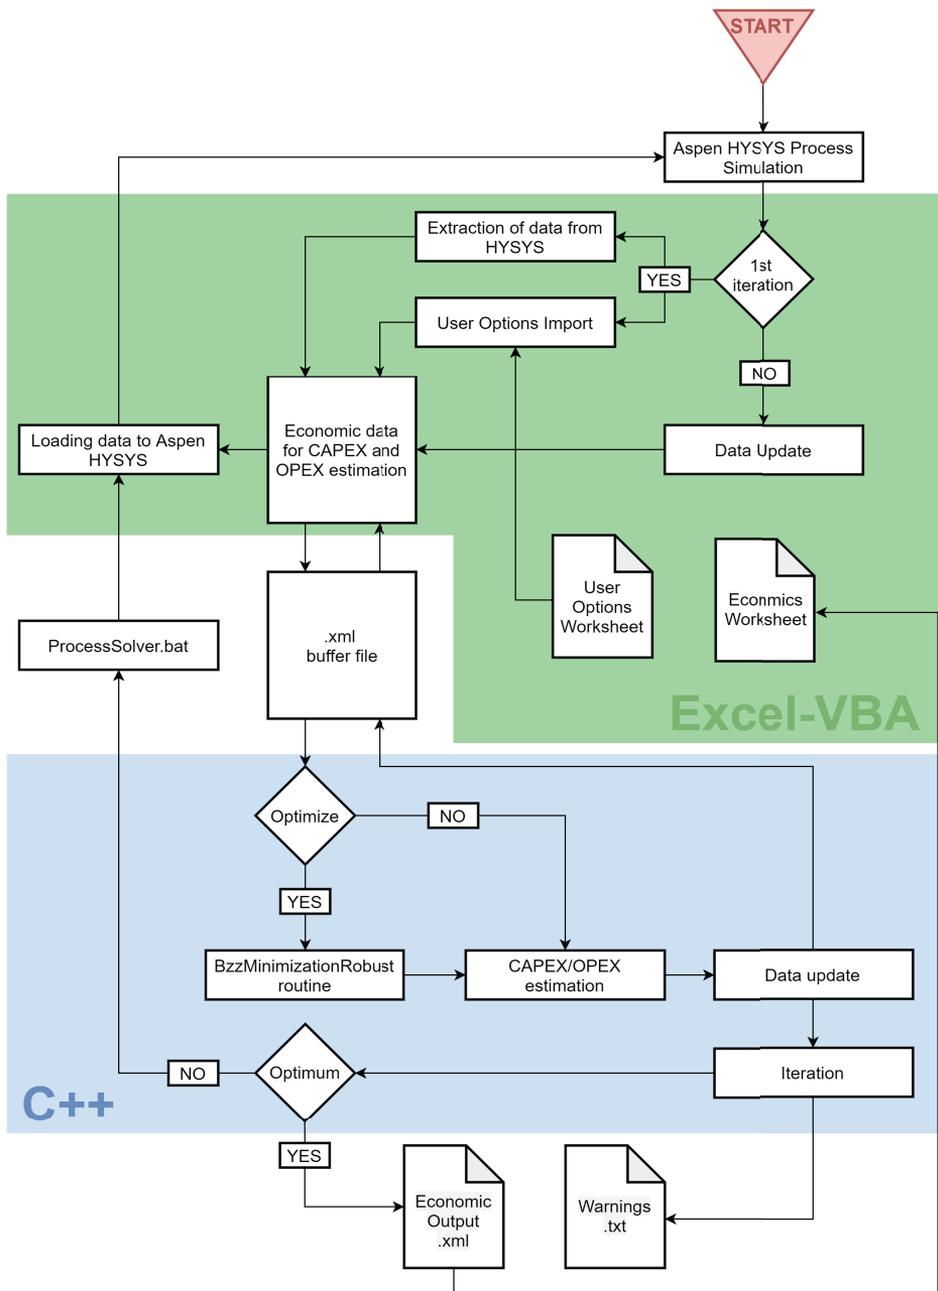

Figure 1: Iterative convergence structure

The xml files act as a buffer between the physical problem and the economic/mathematical one which are both implemented using C++. During the first iteration the data from a converged simulation is extracted into the Excel workbook and divided in Spreadsheets each containing the

information contained in a xml node.

The first spreadsheet contains the directory path to the simulation, the units of measure desired, the economic library of choice. The data extraction routine collects information into separate spreadsheets. The Material streams are organized together and their mass, molar flow as well as temperature and pressure are extracted. In a separate spreadsheet all the material streams are reported again and categorized by the user as raw material stream, process stream, waste stream, product stream or utility stream and associated with a price or value. Moreover, they can be reported as 'degree of freedom' allowing the optimization routine to act on them. If this option is chosen then boundary conditions must be provided by the user.

Following the material spreadsheets are the ones for the unit operations currently supported; compressor, heater, cooler, air cooler, LNG plate exchanger, Pump, Valve, Distillation column, Separator, Absorber, CSTR, PFR, Conversion Reactor, Equilibrium reactor. In each spreadsheet the unit operations of that category in the simulation are grouped and their characteristic dimension is reported and the user can choose the design of unit (i.e. Centrifugal, volumetric, axial for a compressor), the material (Carbon Steel, Stainless Steels of different grades, etc...), whether the unit operation must be optimized, and the optimization variable (output pressure for a compressor) with the possibility to provide upper and lower boundaries. Finally the last spreadsheets contain a set of parameters to customize the economic libraries changing the multiplication factors of both the Turton and the Timmerhaus methods.

3. Conclusions

The overall structure of a robust optimization toolbox was presented in its overarching logical organization discussing the advantages and disadvantages of a compartmentalized optimization routine and presenting each of its modules functions and purpose. This package has been developed using VBA and C++ to interface it with a commercial simulation software as a proof of concept and tested. The program is now entering the testing phase in its alpha version and being tested on custom made simulations. Further development is intended to generate another module to interface with the optimization routine capable of digesting data from the industry to automatically perform a regression on a Guthrie style equation to predict the cost of units for which extended historical data are available.

A soybean supply chain model to analyze the greenhouse gas emissions of the transport sector

Milagros Verrengia^a, Aldo Vecchietti^a.

^a*INGAR–CONICET, Avellaneda 3657, Santa Fe (3000), Argentina*
mverrengia@santafe-conicet.gov.ar

Abstract

This article presents a mathematical model of the soybean's supply chain for Argentina where the different stakeholders and the material flows among them are represented. The transport used in this sector are trucks, trains, and river ships. The objective is to analyze the emissions of greenhouse gases (GHG) generated by the transportation in this sector using electric trucks as an alternative to biodiesel ones.

The model generated is a mixed multi-period / multi-objective linear integer model, destined at minimizing operating and GHG emissions cost. The accuracy of the model is compared against two statistical studies made by the Transport Agency of Argentina in 2014 and 2017 regarding the soybean transportation. The results show a good fit with those reports. Two scenarios are compared, in the first one only biodiesel trucks are used for transportation, while in the second one trains, barges and electric trucks are included. Results show the tradeoff between investment costs and reduction of emissions where it is possible to achieve a 60% GHG decrease, which is far to compensate for the investment cost.

Keywords: soybean, supply chain, emissions, transportation

1. Introduction

Argentina has an important role as a privileged supplier of food to the whole world, it is the world's leading exporter of soybean meal, for other grains, such as corn and sunflower, it is among the top five exporters. Therefore, the agri-food sector has an important weight in the Argentine economy, both in production and in employment. It is the most important sector that generates foreign exchange and makes an enormous contribution to geographical equality given its wide territorial presence in the country [1]. Due to its importance, it is of great interest to study agri-food supply chains (SC), it is necessary to generate strategic information on market trends, their operating dynamics, the characterization of their main actors and production strategies [2].

There are works in the literature related to the proposal of this article. For reasons of space, we are only going to mention some of them. Courtonne et al. [3] carry out an analysis of the flow of materials in the cereal supply chain in France. The authors apply a material flow analysis (AFM) which is a systematic evaluation of flows and link them to the stock of materials in space and time. Mogale et al. [4] study the problem of storage and transportation of wheat in bulk in India, in a two-stage supply chain network that depends on the Public Distribution System (PDS) of that country. To do this, they develop an integer mixed non-linear programming model (MINLP), whose objective is to minimize the transportation, storage, and operating cost of food grain from producing states to consuming states. They employ a heuristic algorithm based on Taboo Search to solve the problem. He and Li [5] address the problem of harvesting and

transporting wheat in China, they propose a joint optimization framework and a general algorithm to optimize the wheat harvesting and transportation problem considering fragmented farmland.

Our approach proposes to analyze the soybean supply chain, its logistic from the harvesting to the industrial transformation in conjunction with the generation of greenhouse gases involved in the transport. A real-world representation of the soybean's supply chain is made. The objective is to evaluate economic and environmental issues, for this purpose, different transportation media are included in the model: diesel and electric trucks, trains and barges. The purpose is to provide an analysis tool for the optimization of the chain's operation. A MILP model (a linear mixed-integer program) was generated. Unlike the proposals of other authors mentioned, our model is a deterministic one, and there are no known cases involving an economic and GHG emission analysis of a real-world agro-industrial supply chain.

2. Methodology

2.1. Description of the problem

To reproduce the operation of the soybean supply chain, an important amount of data is collected from different public and private sources regarding the sowing, harvesting, production, transportation and export of soybeans and by-products. For our model, a three-level supply chain is proposed: the first corresponds to the production areas (i), where the soybean grain is harvested, the second level is formed by the stockage of grains in silos (j) from where grains are sent to the third level which corresponds to the destination zones (k) where the soybean grain is demanded for grinding or exportation. In Fig. 1 you can see the operation of the chain and its flows from production to its destination. The largest percentage goes to the industrial sector to produce flours and oils for exportation purposes.

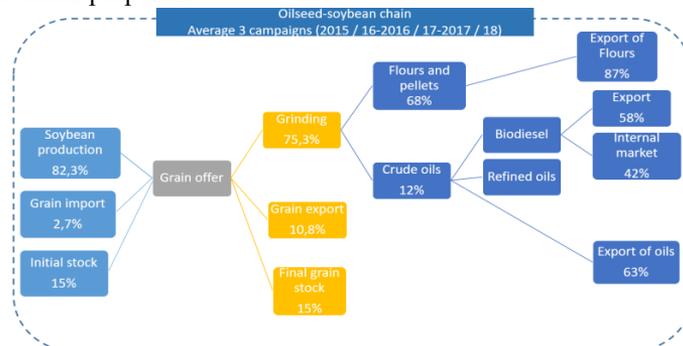

Fig. 1: Soy supply chain and flows between the different levels.

In Fig. 2, the map on the left shows the location of soybean production and the industrial establishments that process it in Argentina, on the right a graph of Argentine soybean production in millions of tons per year between years 2006 and 2018 and the percentage rate of change with respect to the previous year.

The most important assumption made in the model is that both the production, stockage and the final destinations areas are divided into different regions, each one composed of a centroid. To measure the circulation between the different levels of the soybean supply chain, the distances traveled between these centroids and the numbers of trips made between them are measured. The model is multiperiod one with 15 time periods, covering five years (from 2016 to 2020) corresponding each one to a four-month period.

To deal with economic and environmental objectives, the weighted sum method is used, to combine both objectives into one objective function. For this purpose, an economic value of the GHG emissions is set based on the value proposed by the Interagency Working Group on Social Cost of Greenhouse Gases [7].

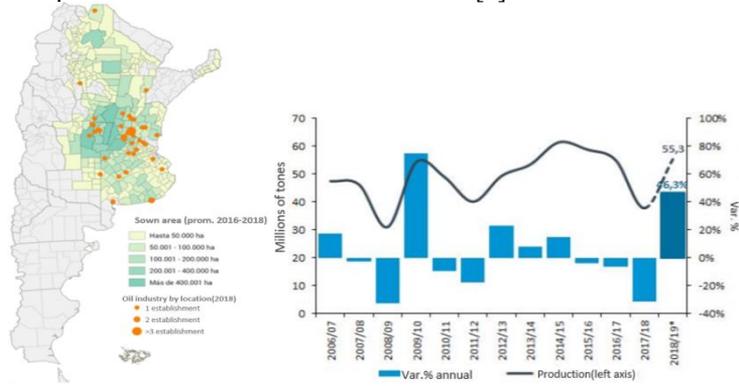

Fig. 2: (a) Map of soybean production, storage, and industries areas. (b) Soy production in annual tons from 2006-2018.

The decision variables of the model are soybean flows, in tons per time t , sent by using trucks from i to j and from j to k the flows delivered by different transports (trucks, trains and river ships), the number of trips made between the different levels and the transports used for each time t , the stock of soybeans (in ton) for each time t at location j and the amount of GHG emissions measured in equivalent tons of CO₂.

2.2. Formulation of the Model

For space reasons, in this section only the most important constraints of the problem are included so that the work done can be visualized, some logical and bounding constraints are omitted.

Eq. (1) and (2) establish that if there is a flow ($EIJcijt$) of soybeans with the type of truck c from production area i to stockpile j at time t , for which the binary variable ($ycijt$) must be equal to 1, the flow must be less than or equal to (Eq. 1) the number of trucks ($NCIJcijt$) times their maximum capacity ($KCMAX$) or greater than or equal to (Eq. 2) to the number of trucks times their maximum capacity ($KCMIN$). Two types of trucks c (1: using biodiesel 80-20 and 2: electric) are considered.

$$EIJcijt \leq NCIJcijt * KCMAX + M * (1 - ycijt) \quad \forall c, \forall i, \forall j, \forall t \quad (1)$$

$$EIJcijt \geq NCIJcijt * KCMIN + M * (1 - ycijt) \quad \forall c, \forall i, \forall j, \forall t \quad (2)$$

Similar restrictions are used for truck, train, and barge shipments from silos storage to consumption areas. These last two transports have limited origin and destination zones compared to those carried out by truck.

Eq. (3) corresponds to the material balance of the silos stockage by time (Ijt), where the inventory at time t is equal to the inventory at time $t-1$ ($Ijt-1$), plus the shipments received of the production area ($\sum \sum EIJcijt - lic$) minus the flows sent by different transports to the consumption areas, both at time $t-1$.

$$Ijt = \sum \sum EIJcijt - lic - \sum \sum EJKcikt - 1kc - \sum EVJKjkt - 1k - \sum EBJKjkt - 1k + Ijt-1 \quad \forall j, \forall t, t > 1 \quad (3)$$

In Eq. (4) the inventory is limited according to the storage capacity of silos.

$$Ijt \leq KACK \quad \forall j, \forall k, \forall t \quad (4)$$

Eq. (5) indicates that the sum of all shipments from all stockpiles to each destination area in time t must equal to or exceed its demand ($DSkt$).

$$\Sigma\Sigma EJKc_jkt_j + \Sigma EVJK_jkt_j + \Sigma EBK_jkt_j \geq cDSkt \quad \forall k, \forall t \quad (5)$$

Eq. (6) indicates that 10% of the truck fleet is changed annually (according to statistics of the trucks market), translated into 3.33% percent for time t . The model allows the purchase of new biodiesel or electric trucks from the first period. At the beginning of the time horizon electric trucks are 0, only biodiesel's are available. The differences are that electric cars are more expensive than biodiesel ones, but CO2 emissions are zero. We also consider that a truck can make up to 20 trips per time.

$$NEWT_{ct} = 0.033 * INITIALT \quad \forall c, \forall t \quad (6)$$

$$NT1_t = NT1_{t-1} + NEWT_{1,t-1} - \Sigma NEWT_{ct-1} \quad \forall t, t > 1 \quad (7)$$

$$NT2_t = NT2_{t-1} + NEWT_{2,t-1} \quad \forall t, t > 1 \quad (8)$$

$$NT_{ct} * 20 \geq \Sigma \Sigma NCJKc_jkt_k \quad \forall c, \forall t \quad (9)$$

2.2.1. Objective function

The objective function (10) is the minimization of the total costs which is function of transportation ($CIJ + CJK$), storage (CS), investment (new trucks) (CI) and emission (CE) costs.

$$CT = CS + CIJ + CJK + CI + CE \quad (10)$$

Eq. (11) represents inventory costs where CI is the financial cost of having the stock.

Eq. (12) is the transportation cost from harvesting areas i to the storage location j , which corresponds to the summation of the transportation cost per km (CAR) times the flow $EIJc_{ijt}$ and the distance between i and j ($DAij$). Similarly, Eq. (13) calculates the costs associated with shipping from the silos j to destination areas k . The first term of Eq. 15 represents a fixed cost of the delivery, the second term is a variable cost depending on the flow and the distance traveled. Then the costs of rail transport are added, corresponding to the train a cost per ton (CR) times the flow of the shipment ($EWJK_jkt$), and the last term is the river transportation, composed by the ton cost per barge (CB) multiplied by the quantity shipped (EBK_jkt).

$$CS = \Sigma \Sigma I_{jtt} * CI \quad (11)$$

$$CIJ = \Sigma \Sigma \Sigma \Sigma CAR * EIJc_{ijt} * DAij_{tj} \quad (12)$$

$$CJK = \Sigma \Sigma \Sigma (CFK * NCJKc_jkt + CVK * EJKc_jkt * DAjk)_{tkj} + \Sigma \Sigma (CR * EWJK_jkt + CB * EBK_jkt)_{tkj} \quad (13)$$

Eq. (14) corresponds to investment cost where CIT is the cost per truck multiplied by the amount purchased per time t . Lastly, Eq (15) calculate the costs of CO2 emission where CTE is the cost per ton of CO2, NTE is the amount of CO2 emitted per truck/(km.ton), similarly for trains (NWE) and barge (NBE).

$$CI = \Sigma \Sigma NT_{ct} * CIT_{cttc} \quad (14)$$

$$CE = CTE * (\Sigma \Sigma NTE * t_{ji} DAij * EIJc_{ijt} + \Sigma \Sigma DAjk * (NTE * EJKc_jkt + t_{kj} NWE * EWJK_jkt + NBE * EBK_jkt)) \quad (15)$$

CAR and CVK costs are \$ 0.072 per ton kilometer of soybeans shipped, data extracted from the Rosario Stock Exchange report [6]. For the cost of CO2 emissions (CTE), a value of 56 dollars per ton is taken from a report of the Social Cost of Carbon, Methane, and Nitrous Oxide, United States Government [7]. The purchase cost of a biodiesel truck for Argentina is about \$ 80,000, while for electric ones the cost reported internationally is about \$ 160,000.

2.3. Results

As a first step, the accuracy of the model was tested by solving two examples. Their results are compared with two statistical works [8-9] carried out in 2014 and 2017 by the Secretary of Cargo Transportation Planning and Logistics of Argentina. In Fig. 3 you can see the comparison between the results of the model and the government's work

for the year 2017, measured in number of trips among centroids. The model presents a very good approximation considering that the government work uses real data from “consignment notes” in the whole year, while in our case the results are provided by the execution of the model

The model is a multiperiod multiobjective mixed integer linear programming problem (MILP) that was posed in GAMS [10] system and solved with CPLEX 12.6.3 on a PC with an Intel i7 processor with 12 GB of RAM. The model consists of 127,249 equations, 204,581 variables, and 105,504 discrete variables solved in 80 seconds of CPU time

To achieve this result, the trucks were loaded with 28 tons. of soybeans on average, the lower bound is 25 tn, while the upper one is 30 tn.

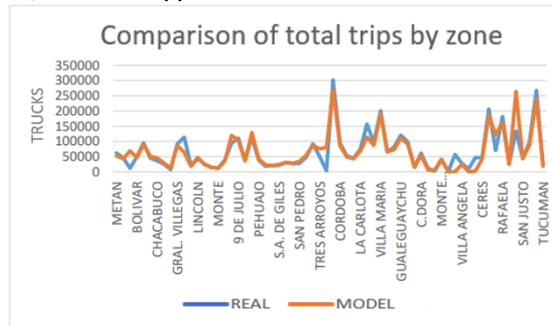

Fig. 3: Comparison of total trips by area between real data and model results for the year 2017.

We have executed two scenarios, in the first one only biodiesel truck are used for transportation and purchasing new ones. Then, scenario 2 includes the use of the railroad and barges for transportation from the silos to the destination areas, and the model considers the possibility of purchasing electric trucks for transportation.

Table 1 shows the results obtained from both scenarios, based on the costs and emissions. In Fig. 4, it can be seen the scenario comparisons.

As can be seen scenario 2 is more expensive in costs than the first one due mainly to the increase in investment costs of electric trucks, although the emissions are lower by about 60%. The cost of the emissions per ton of CO2 equivalent, taken from the USA government report, is too low to compensate for the investment cost in electric trucks. It means that the purchase of electric trucks must have incentives to diminish its price or to force its use.

Table 1: Cost and emissions comparison

COST COMPARISON	SCENARIO 1 [\$]	SCENARIO 2 [\$]
TOTAL COST	24.070.000.000	29.917.813.360
TOTAL TRANSPORTATION COST	4.578.500.000	3.342.866.680
TRUCK TRANSPORTATION COST SECTION 1	996.600.000	745.480.000
TRUCK TRANSPORTATION COST SECTION 2	3.581.900.000	2.473.500.000
RAILWAY TRANSPORTATION COST	-	103.400.000
BARGE TRANSPORTATION COST	-	20.486.680
INVESTMENT COST	15.840.000.000	23.232.080.000
EMISSIONS COMPARISON	SCENARIO 1 [TN]	SCENARIO 2 [TN]
TOTAL EMISSIONS	52.220.000	20.435.000
TRUCK EMISSIONS SECTION 1	11.333.500	5.700.100
TRUCK EMISSIONS SECTION 2	40.891.000	14.659.000
RAILWAY EMISSIONS	-	16.165
BARGE EMISSIONS	-	57.140

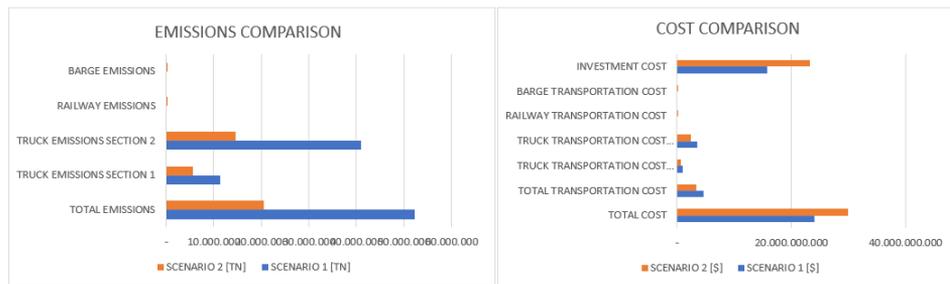

Fig. 4: Cost and emissions comparison

2.4. Conclusion

In this work, the objectives were met in two stages, initially with a model of the supply chain of soybean cultivation for Argentina. The model corresponds to a multiperiod multiobjective linear integer mixed mathematical program (MILP) to represent the supply chain in three levels: production area, silos, and destination areas. Although in our country the soybean industry has been studied from different perspectives, according to the knowledge of these authors, there is no proposal that models the CS and the flows of materials, their transport and GHG emissions with a mathematical program.

The scenarios executed by the models have shown that the investment costs in electric trucks does not compensate for the lower emissions obtained with their use. Therefore, in case of seeking the viability of the electric truck, the government should propose an incentive system that can level the difference in costs and thus promote better care for the environment.

In addition, this work only considers the use of trucks for transporting soybeans only, but the truck fleet is used for many other products that are transported in large volumes throughout the country, its analysis is part of a future work.

Abstract

The cyber-physical integration in the sense of industry 4.0, applied to industrial process control, needs to develop new methodologies. Both top-down hierarchies of commands for Enterprise Resource Planning, Optimization, Advanced Control, Local Control, and bottom-up flux of information from the plant floor to control system, optimization level, and planning strategy are dissolved, aiming to enhance the vertical and horizontal integration and flexible operability. Even though this is a requirement for Cyber-Physical Systems, it would be merely a coexistence of advanced optimization IoT technologies states of art. Therefore, there is a need for a new architecture of a functional system. Since it works essentially as an event-based system, ontology plays a key concept in the practical working of the new process control. First, an overview of the general ontologies framework applied in Industry 4.0, and on the other hand, some ontologies published for chemical process design are discussed extensively here. Then the practical ontology and taxonomy needed for industrial process control are discussed. Here is presented how to recover the functional layers to each specific application of former traditional hierarchy top-down and bottom-up, now named as semantic layers. A description's language development for process control using this ontology is another challenging task, also proposed. A case based on the transition of the traditional batch reactor process to modern industry 4.0 application illustrates the change of the operation mode. Finally, the potential gains and technology limitations are analyzed as a critique as the enabling technologies (or pillars) of Industry 4.0 to show what concepts apply to this enhanced process control. It also compares and analyzes this modern approach in the manufacturing process and the difference with the industrial process control. The construction of a complete system based on ontology and description language ready for application is an impressive task to be developed further. The main objective of the work, for now, is to clarify the concepts and show the methodology with its practical application, discussing limitations.

Keywords: Cyber-Physical Integration, Industry 4.0, Ontology, Process Control.

1. Introduction

The storm of technological advances driven by the German initiative Industrie 4.0 (I4.0), induces process system engineering to absorb a new format, where evolutions will be leveraged by intelligent production systems, vertically and horizontally integrated (Schwab, 2017). With event-driven architecture, microservices, and componentization of software elements there is a need for new methodologies aimed to apply industrial process control for digital transformation, where ontologies are a fundamental part of information

reuse and system interoperability. There are several frameworks and reference architectures proposed for the I4.0 scenario. The architectural proposal IMC AESOP (Karnouskos et al., 2014) is an example that offers an extension to the traditional model found in the ISA95 IEC 62264 standard for well-defined implementation of a network-structured modularized architecture. Kumar et al. (2019) discusses important aspects for I4.0 and survey the ontologies, considering the effort and importance of standardization in the scenario.

To consider the historical evolution of information technology and ontology design for chemical processes is a great path to understand PSE for I4.0 and industrial process control. Batres (2017) provides an ontology review for process systems engineering, discussing the use of different ontologies for various purposes in PSE: Multipurpose Ontologies, such as OntoCAPE (Ontology for Computed Aided Process Engineering), and ISO 15926, and discusses some methodologies for proposals to develop the well-designed ontology. See also Morbach et al. (2007), Schneider et al., (2019), Johnsson and Brandl (2021), Burns et al. (2019), Guarino (1997), and Lin and Harding (2007).

2. What you should know about Ontology Design in PSE

2.1. Before you start

There are no rules when choosing a method to engineer an ontology, and there is no explicit method that is better than others. On the other hand, there are some good practices that one should follow to build an ontology.

Ontology design must go from its idealization, through the definition of the scope, to the definition of classes, subclasses, their hierarchy, the definition of properties and their restrictions and definition of instances, and not just representing something through a drawing. Furthermore, the designer should try it on the domain of application and, using reasoners and validating test the consistency ontology. This session suggests a train of thought aiming to help those who would like to design an ontology for process system engineering.

2.2. What is an Ontology?

An ontology is a formal representation of something that exists in the real world (Gruber, 1995). As it happens when different people try to describe something, particular aspects likely appear in the same domain depending on the expertise of the ontology designer. To design a great ontology, one must be familiar with this concept.

In terms of knowledge domain representation, an ontology defines the concepts for entities present in a given domain and their relationships. As such, a great way to manage knowledge and enable flexibility and interoperability between systems through formal semantics (Yang et al., 2019). Arp et al. (2015) explain interesting concepts for ontology design.

2.3. Know your Domain

In the case of chemical processes, there is a tendency to think of a chemical process as a set of domains grouped by their characteristics (unit operations), which overturns a definition of classes, subclasses, and information, in a certain intuitive way. To build a great ontology, one should remember to define its scope well, raise questions that need to be answered by such ontology, and answer them. Also, one should keep in mind that this is an iterative process and that you can and should use methodologies to find inconsistencies (Abburu, 2012) (Chen, 2020) (Geng, 2018).

2.4. Reuse if it is possible

In addition to knowing your domain, designers should choose to reuse ontologies to avoid redundancies. The idea is to consult known ontologies with potential applications for the desired domain, try to use it, and propose an expansion, if applicable. An ontology aims to promote interoperability between systems with heterogeneous data. Therefore, reuse is something that, by its nature, must be considered (Wang et al., 2020).

2.5. Define Classes and Subclasses and Specify the Taxonomic Hierarchy

As mentioned in item 2.1, there is not a single methodology to structure classes and subclasses. On the other hand, the most common approaches are: top-down, when the reasoning goes from the most general concepts to their specializations, bottom-up, reverse process to the previous one, where you start from the more specific concepts and combination, highlighting the most salient ones and then generalizing and specified according to their nature.

2.6. Formalize Slots and Facets

One must define properties (slots) and slot restrictions (facets) for your ontology. Through the process control perspective, we can denominate properties accordingly to the variables involved in a given domain and its facets according to the boundary conditions (constraints) that each variable must-have for that process to run under its proper operating conditions.

2.7. Create Instances

After formalizing slots and facets, the next step is to set individual instances of classes in the hierarchy. One must choose a class and then create an individual instance in order to fill the slot values and the possible restrictions. Noy and McGuinness (2001) propose a guide for beginnings in the subject matter.

3. Case of Study: Batch Reactor Plant for I4.0

The semantic abstraction layers metamodel foundations of OntoCAPE were applied, see more in section 3.2. As presented by Engel et al. (2018), this article considers three abstraction layers: Upper Layer, Domain Layer, and Application Layer. On the other hand, we aim to focus on the approach of the control processes so that the batch reaction takes place. In the following sessions, the authors describe the design methodology in the mentioned domain.

3.1. Domain Description

The authors chose a classic batch reactor control scheme proposed by Zoss (1979). The intent is to represent this classic scheme in new ways, illustrating the change in the operating model and the transition from the traditional batch process to Industry 4.0. (Figure 1).

3.2. Designing the Ontology

The *Rbatch* domain, which represents the entire batch system (considered in this article as a part of OntoCAPE's Chemical Process System Partial Model), has four subclasses, classified in this article as Chemical Process System functions or CPS_function. Three of them according to the type of control we found in the example: *I/O* (interlocks and security alarms), *Scheduling* (Routine of reactor operation batch), and *Split_Range_Control* (temperature control through the reactor jacket). The reaction process is represented by *Reaction* ($A+B \rightarrow C$). Considering each of these subclasses, we

break the application layer into processes (Chemical Process System Realization) that happen during the operation.

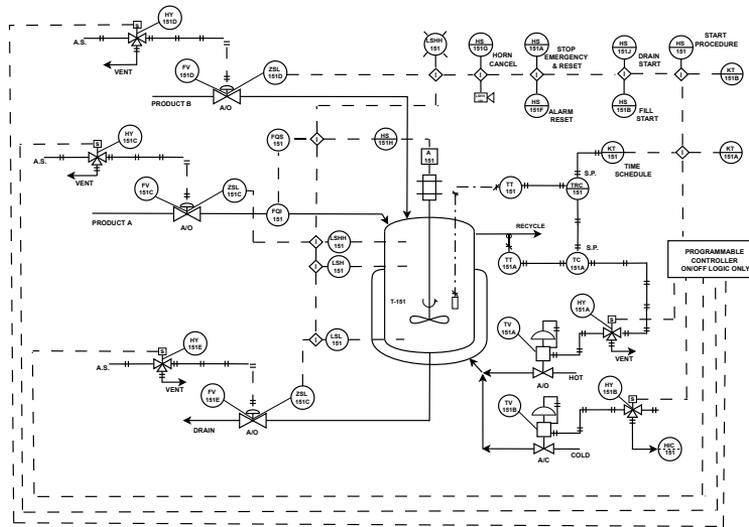

Figure 1: RBatch Domain.

3.3. Ontology Application

In order to apply the ontology in the RBatch domain, the authors chose Protégé, a software for ontology design, as in Figure 2. Furthermore, the ontology format is in OWL (Ontology Web Language) following Antoniou and Van Harmelen (2004).

The recommended practices follow McGuinness and Van Harmelen (2004). OWLViz and OntoGraph were used for ontology visualization as in Figure 3. The ontology modeling contemplates the representation of different control layers associated with the domain. The validation of restrictions of property values and the respective bindings were tested using the HemiT reasoner. The authors are working on an orchestration algorithm so that the ontology could be used in a proper way to facilitate interoperability for level, temperature, and reactor operating scheduling controls, considering alarms for level and temperature.

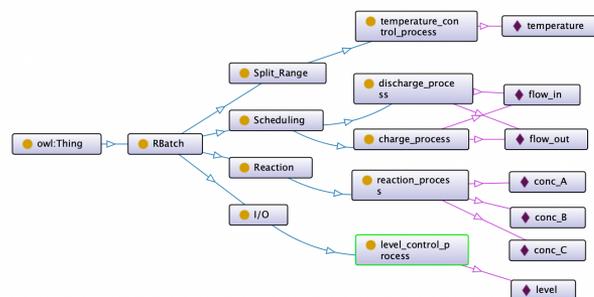

Figure 2: OntoGraph Visualization for class hierarchy view.

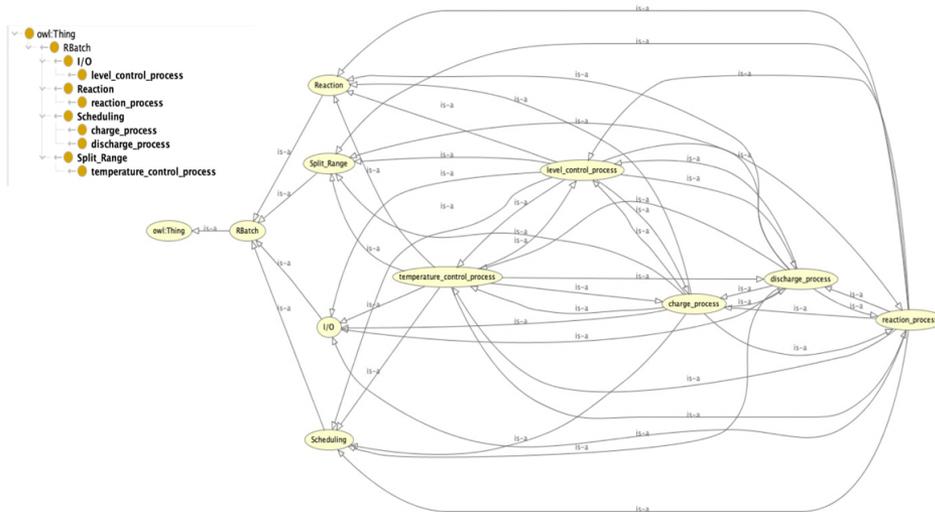

Figure 3: Inferred Hierarchy on OWLViz.

4. Conclusions

The conversion of the classic batch reactor control into an interoperable and flexible environment can be found elsewhere. Industry 4.0 as a concept of the IIoT evolves to Digital Transformation and Cyber-Physical Integration. Beyond the “enabling technologies” (Big Data & Artificial Intelligence, Cloud & Fog Computing, Vertical & Horizontal Integration, Virtual & Augmented Reality, Industrial IoT, Additive Manufacturing & 3D Printing, Autonomous Robots, Digital Twins, Cybersecurity, and so on), nowadays the “pillars” of more organizational concepts such as Technology and Business Transformation, Analytics and Information Management, Intelligent Automation, and Business Planning and Execution emerge with great interest. So, ontology as formal representation plays a key role in Product Design and Development, Process and Plant Design, Safer Processes and Plants, Supervision and Control, Work Processes, Process Systems Modeling.

The construction of a complete system based on ontology and description language ready for application is an impressive task to be developed further. Hence, the main objective of the work is to clarify the concepts and show the methodology with its practical application. There are no fully automatized constructions of Ontology for Process Control. Although OWL provides powerful help for the construction of formal ontologies, the propagation or chaining of properties in the multiple hierarchies interoperating in process control requires more direct experience in the practical applications than theoretical methodologies. Considering the use of the nomenclature Domain, Reusability, Classes and Subclasses, Taxonomic Hierarchy, Properties, Restrictions, and Instances, more familiarity with real control applications will organize the practical differences of ontology application in the PSE domain from Semantic Web Ontology.

Complementing Natural Gas Driven Syngas with Optimum Blends of Gasified Biomass Waste

Ahmed AlNouss, Gordon Mckay, Tareq Al-Ansari*

*College of Science and Engineering, Hamad Bin Khalifa University, Qatar Foundation,
Doha, Qatar*

*talansari@hbku.edu.qa

Abstract

Countries around the world strive to diversify their energy portfolio with a suitable and sustainable alternative to fossil fuels, whilst achieving the reduction in environmental impacts from released wastes. The co-conversion of biomass wastes and natural gas (NG) has received much attention due to the potential improvement in downstream power and production of fuels, while minimizing greenhouse gas (GHG) emissions. This study explores the optimal blending of synthesis gas generated from biomass wastes and NG feeds. Aspen Plus is utilized to develop the models of biomass and NG steam gasification considering Qatar's biomass and NG characteristics. Three types of biomass wastes; date pits, sludge and manure are gasified to generate the H₂-rich syngas which is blended later with the NG-driven syngas. The simulated flowsheets have then been used to optimize the blending of downstream generated syngas by means of manipulating the biomass wastes and NG feeds. The optimization problem is constrained by the downstream quality of produced syngas to be utilized for the generation of power and fuels. Typically, the generation of syngas involves high-cost subsequent purification prior to the production of downstream value-added products. However, the optimization attained in this study lowers the requirement of further syngas purification and waste removal, through the blending of NG and biomass-driven syngas and minimization of gasifying agents. This requirement can be further reduced by manipulating reaction agents and process conditions. The result of the optimization problem demonstrates an increase in biomass wastes utilization with the increase in syngas quality constraint. Dates pits biomass dominated the biomass utilization with a lower contribution from sludge and manure wastes.

Keywords: Natural Gas, Biomass, Co-Conversion, Optimization, Syngas, Blending.

1. Introduction

There is continuous growing demand for energy and conversion of natural gas (NG) into downstream value-added products given the large reserves of fossil-fuels worldwide. This is coupled with the growing need of utilizing renewable energy sources in the global energy mix to support environmental protection, and reduce the harmful emissions associated with fossil fuel burning. Therefore, the concept of complementing natural gas utilization networks with renewable energy sources has gained global attention within sustainable development and natural resources preservation targets (M. Wright et al., 2015). Biomass gasification as a renewable process has the potential to contribute in the downstream production of power and fuels and minimization of harmful emissions (Shahbaz et al., 2021). This study investigates the optimal co-conversion blends of biomass wastes and NG to meet the downstream quality of syngas. Aspen Plus is utilized

to develop the models of biomass and NG steam considering Qatar's biomass and NG characteristics. Three types of biomass wastes; date pits, sludge and manure are gasified to generate the H₂-rich syngas, which is blended later with NG-driven syngas. The simulated flowsheets are then used to optimize the blending of downstream generated syngas by means of manipulating the biomass wastes and NG feeds. Moreover, the quantities of gasifying agents required to convert the biomass and NG feedstock into syngas are minimized. The ultimate aim is to maximize the syngas production, while reducing the consumption of NG and gasifying agents and the process environmental emissions. The attention on this topic has been increasing recently with focus on the enhancement of process efficiency and reduction of environmental impacts. Wright et al. (2015) studied enhancing biofuels production from biomass with NG feedstock and using the Fischer–Tropsch (FT) technology. The study demonstrated the contribution of NG in enhancing FT biofuel production through achieving required H₂:CO ratio while reducing the requirement for water gas shift. However, the NG contribution had to be limited to 19% to eliminate the increase in process emissions. Caligiuri et al. (2021) explored experimentally the impact of completing bio-syngas in spark ignition engines with NG on the process efficiency and emissions. The experimental results demonstrated the impact of different feedstock blends on the power derating, where increasing syngas quantity in the mixture decreases power output by 2-6% in addition to NO_x and THC emissions. Hence, only minor power derating is anticipated considering the significant reduction in volumetric energy density. Zhang et al. (2018) investigated the techno, economic and environmental benefits from the co-processing of NG and biomass feedstock to produce liquid fuels. The results demonstrated that coupling biomass with NG increases the economic profitability of producing liquid fuels production, albeit with higher environmental impacts. A maximum NG limit of 28% was determined to meet sustainability targets with a minimum selling price of \$2.75 per gallon gasoline equivalent.

This study applies a unique optimization nature problem to identify the optimum blends of various biomass feedstock and NG to meet multiple end-use downstream options of H₂-rich syngas. The biomass gasification model has been detailed in an earlier study that utilizes oxygen and steam as gasifying agents (AlNouss et al., 2020), utilized to address energy-water-food nexus applications (AlNouss et al., 2019b), generate value-added products while involving captured CO₂ (AlNouss et al., 2021), and solve the superstructure optimization of downstream syngas utilization (AlNouss et al., 2019a). The optimization attained in this study is deployed to reduce the requirement of further syngas purification and waste removal, through the blending of NG and biomass-driven syngas and minimization of gasifying agents.

2. Methodology

Aspen Plus software has been utilized to develop the flowsheets of biomass and NG steam gasification as illustrated in Figure 2. The flowsheets are simulated under steady state and isothermal operation, neglected tar formation, char as a pure carbon (C), atmospheric pressure and negligible pressure drop. The fuel-bounds of chlorine, sulphur and nitrogen are converted to hydrogen chloride, hydrogen sulphide, and ammonia, respectively. The simulation model employs Peng-Robinson equation of state with Boston-Mathias modifications to account for the nonpolar and real components. The various biomass feedstock are blended in a mixer and fed to a drying and decomposition step to yield the conventional components from the non-conventional attributes of the three biomass wastes presented in Table 1. The effluent stream is purified from ash and a small portion

of char utilized to supplement the gasifier with heat through combustion. The purified stream enters the gasifier along with steam to yield syngas which is then mixed with the syngas generated from the steam reforming of NG fed according to the compositions in Table 2.

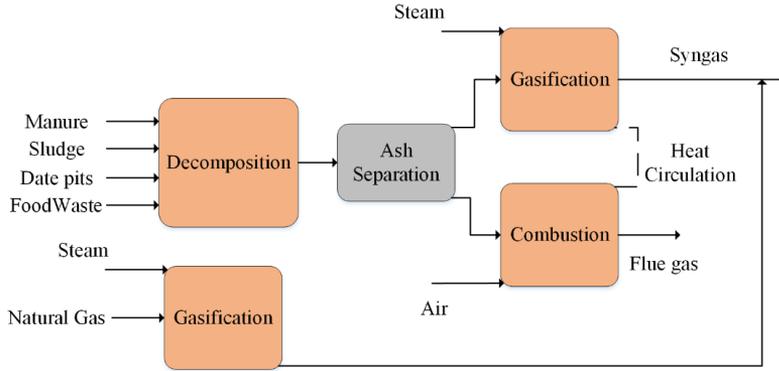

Figure 1: Overall block diagram of NG and biomass co-processing.

Table 1: Attributes of biomass wastes (AlNouss et al., 2018).

Biomass	Date Pit Waste	Dried Sewage Sludge	Manure
Moisture (wt %)	5.0	8.3	27.4
Proximate analyses (dry basis, wt %)			
Ash	1.0	71.8	21.6
Volatile matter	81.8	8.8	65.0
Fixed carbon	17.2	19.4	13.5
Ultimate analyses (dry basis, wt %)			
Ash	1.0	71.8	21.4
S	0	0.1	0.5
Cl	0	0	1.0
N	4.5	1.1	3.7
H	6.8	2.3	5.1
O	37.9	5.7	31.4
C	49.8	19.1	37.1

Table 2: NG feedstock compositions

Component	N ₂	CO ₂	CH ₄
Composition (mol.%)	9	1	90

The simulated flowsheets are used to optimize the blending of downstream generated syngas by means of manipulating the biomass wastes and NG feeds. The optimization is constrained by the potential H₂:CO ratios for further utilization of the generated syngas in different downstream applications. In this study, the downstream applications considered are ammonia/urea production (H₂:CO = 3), Fischer-Tropsch liquid fuels production (H₂:CO = 2), aldehydes production (H₂:CO = 1) and methanol production ($\frac{y_{H_2} - y_{CO_2}}{y_{CO} + y_{CO_2}} = 2$). This is reflected in the formulation of the optimisation problem presented in Eqs. 1-7. Moreover, the quantities of gasifying agents required to convert the biomass and NG feedstock into syngas have been minimized. The ultimate aim is to maximize the syngas production while reducing the consumption of NG and gasifying agents and the process environmental emissions.

$$\begin{aligned}
 & \text{Maximize} && \sum_{i=1}^n x_i \cdot \text{Syngas} - \text{Steam}_{NG} - \text{Steam}_{Biomass} \\
 & && \forall i \in \text{Biomass and NG Sources}
 \end{aligned} \tag{Eq.1}$$

$$\begin{aligned} \text{Subject to } \sum_{i=1}^n x_i &= 1 && \text{Eq.(2)} \\ \frac{y_{H_2} \cdot \text{Syn gas}}{y_{CO} \cdot \text{Syn gas}} &= \text{Application unique} && \text{Eq.(3)} \\ m_i &\leq 2,000 \frac{\text{kg}}{\text{h}} && \text{Eq.(4)} \\ m_{\text{Steam}_{NG}} &\leq 5,000 \frac{\text{kg}}{\text{h}} && \text{Eq.(5)} \\ m_{\text{Steam}_{Biomass}} &\leq 4,000 \frac{\text{kg}}{\text{h}} && \text{Eq.(6)} \\ \frac{y_{H_2} - y_{CO_2}}{y_{CO} + y_{CO_2}} &= 2 \quad (\text{methanol production case}) && \text{Eq.(7)} \end{aligned}$$

Where, steam is the mass flowrate of gasifying agent, Syngas is the mass flowrate of the produced H₂-rich gas, y_{CO}, y_{CO₂} & y_{H₂} are molar fractions of carbon monoxide, carbon dioxide and hydrogen, m is the mass flowrate of NG and biomass wastes, and x is the blending fraction of NG and biomass wastes.

3. Results and discussion

The results considered for the optimization problem and compared with the base case are:

1. Optimization of feedstock blending;
2. Optimization of gasifying agent;
3. Optimization of feedstock blending and gasifying agent.

The results of the base case are summarized in Table 3 with the equal contribution of biomass and NG feedstock presented in Figure 2.

Table 3: Base case data.

S/B Ratio	S/NG Ratio	Syngas yield	H ₂ /CO	CO ₂ % in syngas
0.74	3	2.08	4.59	9%

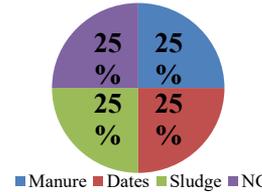

Figure 2: Base case feedstock blending.

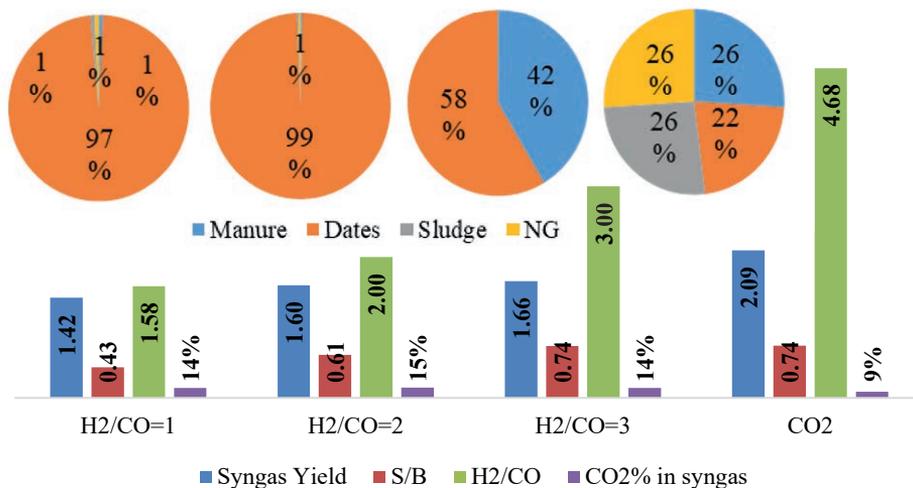

Figure 3: Case 1 results.

The results of case 1 presented in Figure 3 demonstrate the domination of dates biomass feedstock for the generation of H₂:CO ratios of 1 and 2. Whereas, the H₂:CO ratio of 3 presented the contribution of manure and dates mainly in the blended feedstock, while NG is only contributing in the CO₂ ratio case. The syngas yield is reduced slightly from the base case while the CO₂ emissions increased. The requirement of steam for biomass gasification is reduced compared to base case. For case 2, the results presented in Figure 4 demonstrate the contribution from NG and different biomass wastes in the feedstock blends. The syngas yield is increased slightly compared to case 1 while the CO₂ emissions are reduced. The requirement of steam for biomass and NG gasification is increased compared to case 1.

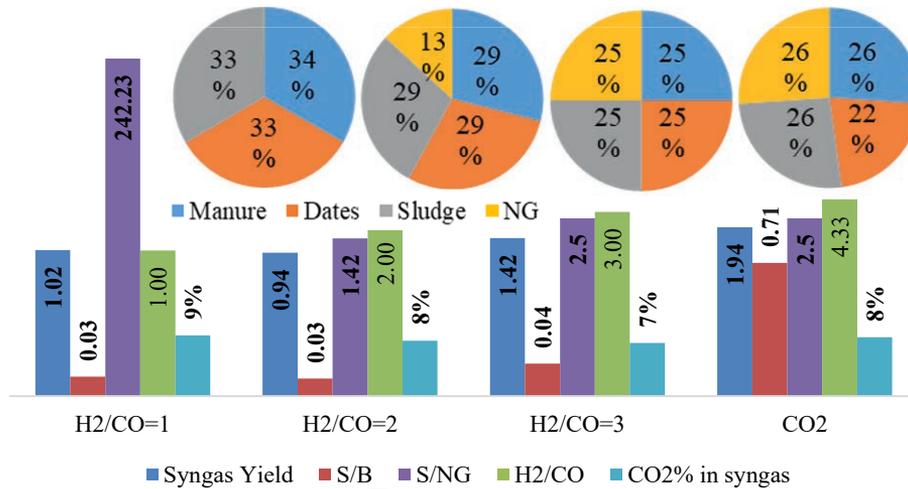

Figure 4: Case 2 results.

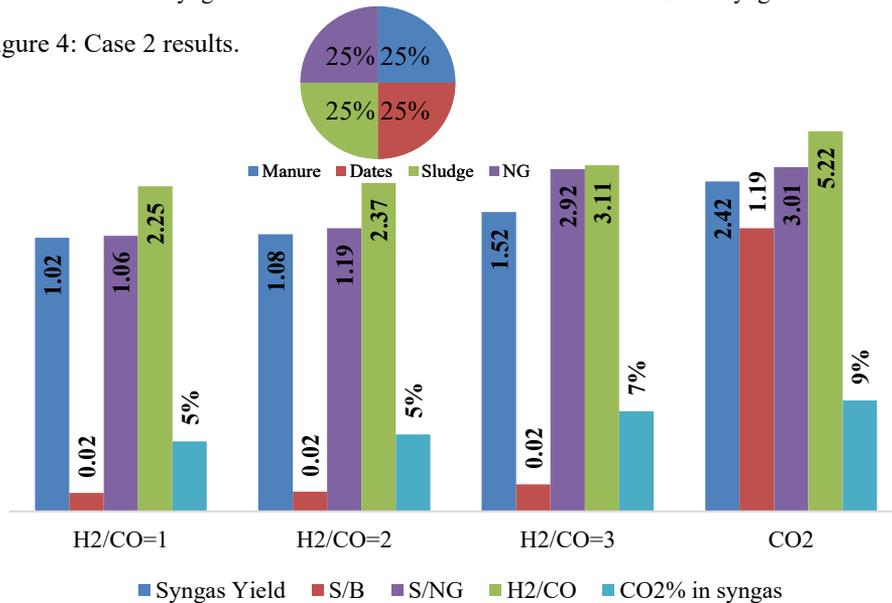

Figure 5: Case 3 results.

The results of case 3 presented in Figure 5 demonstrate equal contribution from NG and different biomass wastes in the feedstock blends. The syngas yield is similar to case 1, while the CO₂ emissions are reduced. The requirement of steam for biomass and NG gasification is decreased as compared to case 2.

4. Conclusion

The concept of complementing the natural gas utilization networks with renewable energy sources contributes to various sustainable development goals in parallel. This study applies a unique optimization problem to identify the optimum blends of various biomass feedstock and NG to meet multiple end-use downstream options of H₂-rich syngas. The outcomes of the optimization problem demonstrates an increase in biomass wastes utilization with the increase in syngas quality constraint. Dates pits dominated the biomass utilization with a lower contribution from sludge and manure wastes.

Abstract

The chemicals industry is facing a highly dynamic environment. Demand is continually fluctuating, and the pressure for new sustainable processes and products is rising. New environmental regulations are always expanding and becoming less harmonized globally, and customers are demanding sustainable products that are friendly to the environment. To follow all the market changes and remain competitive, companies need to invest to develop new processes and products. However, since it's a capital-intensive industry, new investments need to be carefully managed.

Today, companies need to find ways to be more efficient in the execution of engineering projects. One way is to compress engineering cycles and adapt processes and products to comply with sustainable Key Performance Indicators and new demands. The Unified Engineering methodology is one option enabled by the latest technologies and tools available. The data-centric approach is the first step to apply the Unified Engineering methodology, which will evolve later to the plant Digital Twin. The Unified Engineering methodology uses a single source of information that is available for all the teams involved in the project. Engineers become more efficient and work with reliable information as documents and models are updated in a controlled way as soon as any change is made.

Unified Engineering reduces capital project costs, risks, and delays enabling shorter engineering cycles required to deliver new sustainable projects. By minimizing engineering errors and accelerating project execution, companies can get 5% reduction in Total Installed Cost.

Keywords: sustainability, compressed engineering cycles, unified engineering, process engineering

1. Introduction

As an industrial software provider, we support chemical companies achieve superior performance in their quest to make sustainable products, align with the circular economy and demonstrate product stewardship throughout the product life cycle. By digitally connecting assets, process, and people, our solutions empower companies to run safe and responsible operations, mitigating EHS risks (Environmental, Health, Safety), and moving toward more circular systems, while remaining profitable.

With more than 50 years of industrial software innovation, AVEVA enables 13 of top 15 chemical companies and most of the world's petrochemical crackers, with the most comprehensive portfolio that ties profitability to sustainability goals.

Research typically identifies the following Critical Sustainability Drivers:

- Demand higher transparency on a company's Environmental, Social & Governance (ESG) performance by stakeholders
- Manage a complex environment and provide safety to employees, processes, products and local communities.
- Minimize energy and utilities consumption, so as emissions.
- Manage liquid effluents, waste and suppliers, seeking the circular economy.
- Commitments to global and local regulations
- Portfolio management towards innovation and sustainable products

Today's technology allows suppliers to develop better solutions to those markets that are in constant change. The Digital Twin technologies, initially adopted mainly by the automotive and aerospace industries, are now promoting big changes in how chemical plants are operated and managed. This type of technology can change the decision-making process since more reliable information is available in real time.

Significant step was taken recently in terms of process simulation driven by two major sustainability industry trends. For the circular economy industry trend, chemical companies are developing new chemical processes that yield materials that can be recycled rather than used one time. For the hydrogen economy industry trend, companies will substitute hydrogen fuels to reduce CO₂ emission into the atmosphere. Both the chemical and hydrogen economy trends lead to corresponding advancement in process simulation including modeling and thermodynamics.

Now it is possible for the engineering and operating companies to build the Digital Twin of the process plant. The Digital Twin is built on a simulation platform that will support the entire plant lifecycle, from design to operation, while also addressing new hydrogen and circular economy requirements.

2. The Digital Twin

The new generation of process simulation uses a platform approach that evolves the simulation model from the conceptual engineering to the operation optimization. It allows a new approach to be implemented so companies can transition from the conventional scenario to the use of the process simulation Digital Twin, expanding benefits to the entire plant lifecycle. The same platform is used for process simulation and process utilities (cooling water, flare, steam and others), allowing engineers to further evaluate how each system impacts the other. Heat and material balances can be re-evaluated after equipment and pipeline sizing, since that information is in the simulation from the beginning, as a result, little or no extra engineering effort is required. Once sizing is validated, the simulation is switched to dynamic mode, in which control loops are included to the simulation model to validate the process control strategy. As it is easier to shift the simulation to dynamic mode, rather than build a completely new model using the conventional approach or converting a model that cannot be taken back to the steady state mode, dynamic studies are performed earlier in the project lifecycle. This promotes savings in equipment acquisition and in operating costs, since control logic responses are evaluated in earlier stages. Plus, when something doesn't respond as expected, simulation is taken back to steady state mode, for re-evaluation of heat and material balance and re-sizing. The ability to go back and forth between steady state and dynamic modes is critical

to increase efficiency in the project lifecycle, leading to huge savings in engineering effort.

According to DECHEMA, one major obstacle for digital transformation is the division of process simulators into single-purpose point solutions. Today, separate models are created – often in different tools – for process design, control strategy design, operator training simulation, performance monitoring and online optimization. This drives up the total cost of modelling to a degree that can become prohibitively expensive. One single model should be able to cover the entire plant lifecycle from idea to operations.

3. Unified Engineering

Companies are beginning to make progress on their digitalization journey, finding the right applications for digital transformation and seeing increasingly better returns on their investment. While the age-old market environment challenges (such as supply and demand, cost and price) haven't gone away, competitive pressures are making the digital transformation opportunity more pressing than ever. Many have already started to leverage the latest data-centric technology and work processes for their workforce to collaborate and take control of their data, reducing the risk for errors, delays and increased project cost throughout the asset lifecycle. By doing so they are in a stronger position to become more competitive, increase their margins and win new business.

As outlined by an AVEVA whitepaper (2019), Unified Engineering is a new proposition to break down the silos between FEED and Detailed Design to minimize risk and maximize return on Capital Investment, Unified Engineering enables global multi-discipline teams to work concurrently in a common data-centric environment, controlling and managing change across the entire project. This breaks down the silos between FEED (Front End Engineering and Design) and detailed design. The simulation data created in FEED is readily available for use in detailed design and is checked and validated in real-time, increasing efficiency, minimizing risk, and maximizing return on investment on your Capital Projects.

Never have the stakes been higher for companies when it comes to making improvements to their engineering work processes to maximize Return on Investment (ROI) on Capital Projects. Productivity has not developed in decades – the average Capital Project schedule lags by 20 months and goes over budget by 80%. These are results that have been shared by Jayanth (2017) during the Rice Global E&C Forum Roundtable.

In many of today's Capital Projects, there is a disconnect between FEED and Detailed Design. In response, AVEVA are the first industrial software provider to pioneer a new solution to break down the silos between these project phases and engineering disciplines.

Unified Engineering consists of two main components, the Unified Lifecycle Simulation Platform (one model), and Integrated Engineering and Design (one database). The bi-directional integration of a steady state and dynamic process model with an engineering database makes the process seamless and eliminates the need for Microsoft Excel or other intermediate steps to transfer information between tools, enabling one single version of the truth to be kept ever up to date.

4. Process Simulation Lifecycle

Process simulators are irreplaceable tools for every process engineer. Since the nineteen seventies, process simulators have found widespread adoption within operating companies in oil & gas, refining and chemical industries, as well as the engineering companies and equipment manufacturers that service these industries. The tools available in the market today have incrementally improved over the years to provide more features and functionality. However, they trace their origins to legacy architectures, operating systems and aftermarket user interfaces, which create inherent limitations, see DECHEMA Tutzingen Thesen for more details. Today's simulators typically only support a single phase of the lifecycle and are often based on thermodynamics of different simulation vendors and different calculation methods. This not only leads to lack of trust in the results but causes substantial rework by having to build a new simulation model in each new tool. And the results are hard to compare. Willetts and Depew (2020) describe in detail the current challenges and how a Process Digital Twin will significantly help improve efficiency and drive increased sustainability.

Global competition, pricing pressure and energy alternatives are now driving the need for a new approach. The oil & gas industry has seen high volatility and the lower price level of today is seen as the “new normal”. The chemicals industry has a continuous need to innovate for greater agility and lower costs.

The next generation of workers also expects a modern, scalable and easy to use solution with technology they now take for granted – high speed internet access, mobile devices, touch screens and virtual reality. New concepts like the Industrial Internet of Things (IIoT), Industry 4.0, and Artificial Intelligence have created greater opportunities with a new next generation platform that provides a “Digital Twin” of the plant through the process lifecycle that cannot be provided with today's tools.

A next generation process simulation platform means that one process model is extended throughout the entire lifecycle of the plant, from concept through to operations. This requires a process design mode, a fluid flow/rating mode and a dynamic mode, in combination with the ability to toggle back and forth between modes. Optimization may be provided to any mode.

A single, easy-to-use simulation platform will allow engineers to move seamlessly between questions of design, analysis, and optimization. Engineers will be able to assess the impact of design and specification changes quickly and with a holistic view of multiple disciplines.

Intensive collaboration becomes commonplace. In this environment, organizations will be able to adopt agile engineering workflows based on smaller pieces of work with continuous integrated testing to reduce development cost while eliminating surprises at the end of the project. Further details can be found in C. Depew's Digital Transformation of Process Engineering presented during the 16th GCPS AIChE Spring Meeting in 2020.

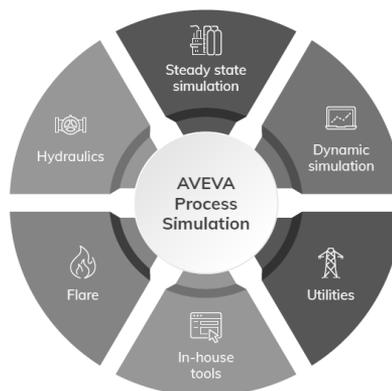

Figure 1: Next Gen Simulation Platform

5. Process Simulations for Sustainable Technology

Physics-based, first-principles models are a critical component of the asset digital twin. As industry develop new process technologies to serve sustainable industry trends such as the circular economy and the hydrogen economy, process simulation programs must adapt to become useful tools for process engineers to design sustainable processes. While academia research how to simulate model reactions or chemical thermodynamics, this modeling and thermodynamics must be integrated within industrial simulation products so that the unified engineering workflow may be applied to develop the digital twin of plants as they are engineered. The AVEVA whitepaper (2021), *Take the first step to the circular economy with AVEVA™ Process Simulation*, Top 5 reasons to adopt a transformational approach, further explains how modern technology allows to truly transform an organization and its outputs by speeding up the FEED stage by 50%, generating more options in less time, allowing for a more optimized process and more informed decision making as well as increasing engineering efficiency by 30%.

There are many Hydrogen-based projects under consideration around the world. Blue, Green, and Gray Hydrogen projects need common process simulation advancement that need to be modeled in processes that support the hydrogen economy.

Green hydrogen is produced by the electrolysis of water. Process simulators will include new electrolyzer equipment models. The Digital Twin for the operation of these plants may use an integrated model to optimize the use of wind and solar power generation for electrolysis.

Blue and gray hydrogen is produced by splitting the methane in natural gas into Hydrogen and CO₂ by steam methane reforming or auto thermal reforming. Development of integrated process plant simulation is required for removal of the CO₂ for capture and storage to produce blue hydrogen. New membrane adsorption models will separate hydrogen for greater purity for blending with natural gas. The carbon dioxide created must be removed using new generation of amines thermodynamics for CO₂ capture by companies that manufacture the amines and companies that use the amines for the separation of CO₂ for carbon capture.

Due to the low volumetric energy density of gaseous hydrogen when used as a fuel, plants must liquify the hydrogen to use it as a transportation fuel. Process simulators will include thermodynamic models appropriate for cryogenic hydrogen. In addition, ammonia is used as a transition fuel with models and thermodynamics required for ammonia pipelines and hydrogen conversion.

Circular economy trends are driving chemical companies to produce materials that may be recycled more readily. This drives the development of new thermodynamic methods and component data to study new process simulation. Chemical and energy companies are replacing fossil based raw materials with renewable feedstocks driving research and development of new reaction technology.

Finally, to make all processes more sustainability by reducing their energy consumption footprint, new simulation products will include the ability to calculate the cost of utilities such as steam, cooling water, and electricity, to minimize operating costs.

6. Conclusion

Lifecycle process simulation has been a vision for process simulation providers and their customers for a long time. Today's simulators cannot leverage the rapid developments occurring in the software industry due to legacy architecture.

Looking at the industry's increasing demand for higher transparency, this can only be achieved using a data-centric Digital Twin approach. This data-centricity enables an ideal platform for new product and process development to create new models and include the management of complex environments bringing together both steady-state and dynamic simulation with constant iteration and constant solving capabilities.

The integration of the process analysis and simulation with other disciplines also allows to breakdown the silos that were typically existing previously. Connecting and remotely controlling previously unconnected processes will increase sustainable operations and improve business efficiency in a sustainable environment. Over the long term the impact will drive resilience and sustainable performance through technologies.

The use of game theory in the analysis of marine lubricant markets in ports

Dimitra Tsakona and Antonis Kokossis*

*National Technical University of Athens, School of Chemical Engineering, Iroon
Polytechniou 9, Zografou 157 80, Athens, GR*

**corresponding author: akokossis@mail.ntua.gr*

Abstract

The supply of marine lubricants to vessels can be arranged by multinational companies (majors) or local suppliers (locals) who have interactions and contract agreements between them. The challenge of the paper has been to use game theory to analyze the market share that is attributed to each supplier and who it is connected to the level of interactions, the market constraints and how they can affect the overall profitability for each player. The paper presents the framework of players interactions that it formulates as a bilevel optimization problem with major (leader) and local players (followers) assigned to the outer and inner problems. The model is used to assess threats and promises. The bilevel approach can be used to calculate parameter sensitivity and key aspects to retain market balance and profit share. The approach has been validated with real data in which the analysis achieved to predict the actual market and profit share using the model-based approach. Model extensions subsequently test parameters responsible for system stability and player options that address threatening moves from other players.

Keywords: marine lubricants, multinational companies, local suppliers, game theory, bilevel approach

1. Marine lubricants and game theory

Lubricants are necessary for the proper operation not only of the main engine (cylinder oil, trunk piston oil and system oil) but also of other vessel's systems (hydraulic fluids, gear oil, turbine oils, greases and other). They may be classified into automotive, industrial, process, and marine oils. Even though marine oil lubricants make up a small percentage of lubricants consumed worldwide, the study of this market has a great deal of interest, as the global seaborne trade is projected to rise. According to recent studies, the global marine lubricants market size was valued at USD 8.01 billion in 2018, and it is estimated to reach USD 9.47 billion by 2026, with a CAGR (Compound Annual Growth Rate) of 2.13% over the forecast period.[1] Furthermore, around of 90% of world's trade is carried through maritime transport.

In the 1950-70s the supply of marine lubricants was controlled by the so-called "Seven Sisters" (BP, Shell, Gulf, Chevron, Exxon, Mobil Texaco). [2] Following acquisitions of the above companies and the fact that new local suppliers entered the market gaining market share, the market divided to major suppliers such as BP, Shell, Exxon-Mobil, Total and local suppliers such as Sinopec (China), Nippon (Japan), Petrobras (Brazil), Gazprom (Russia) and others. The level of equilibrium in the market is differentiated depending on the port and is worth studying as it can easily be modified by changing the

players' strategy. These changes can create threats and opportunities to the profitability for both suppliers.

The blending conditions of marine lubricants varies depending on the port. In key ports, such as Singapore, the ports of America or Belgium, both players have their own refineries to blend their lubricant, in which case the locals have a very small share of the market. Lubricants' quality for majors and locals is considered equal as the products of both players hold all the compulsory approvals for the utilization of oils. However, the extensive experience of the multinational companies as well as their strong R&D department helps them to design lubricants with special features such as their slowest consumption, which gives them another lead over the local companies.

The marine lubricants market constitutes a duopoly market, in which the multinational companies are "the leader". Due to their worldwide brand awareness and their long-term agreements with several shipping companies around the world, they can reassure the majority of market share without the followers to be able to compete them. On the other hand, the local firms, "the followers", have a better knowledge of their domestic market, thus they can be more flexible and provide more expeditious services. Furthermore, it is considered that selling price of the lubricant is the same for both suppliers.

The use of game theory holds an apparent and promising potential to better understand the context behind such developments. Still, it has never been tried, mainly due to the overall scepticism on whether such an approach could deliver realistic results and recommendations. The purpose of the paper has accordingly been to test the potential of game theory in real ports with a further view to postulate critical parameters and review stakeholder interactions. The paper first explains the application context, defines the problem, and next applies a mathematical approach for analysis using bilevel optimization.

2. Market and problem description

This study examines cases of peripheral ports such as Greek or Egyptian ports, where multinational companies do not have a physical presence and blend lubricants by utilizing locals' third-party blending plant. Under this conditions, major suppliers are charged from local suppliers with an additional fee know as premium, so to be able to blend their lubricants under their name and their specification standards. Both majors and local firms gain benefit from this cooperation since they manage to reduce productions costs. Major firms are willing to pay a premium fee to locals to avoid installation costs, while local firms reduce their own production costs by achieving economies of scale. Local firms pursued to keep premium mark up at low levels in order maintain the cooperation. As a result, both players can be considered as interconnected. Such players can also be characterized as connected, as they face several common threats and opportunities based on their price levels. By setting a high price level, the players maximize their profit. However, as the price for the same lubricant differs between ports, players risk losing business for vessels that may be supplied at a next port with more competitive price levels. On the other hand, low price levels may be beneficial for both players as the port will increase its demand but may also cause a loss of maximum profits. Although the selling price range is a common challenge for both players, they still compete each other. Strategic decisions leading to a change in each optimal production quantity and the market share gained create opportunities for one player that pose a threat to the other. For instance, a decision of locals to offer more competitive prices than multinational companies or the decision to increase premium price can be an opportunity for them, as they can gain a larger share of the market. This opportunity constitutes a threat to majors,

who should respond to avoid losing market share. The use of game theory is certainly justified even though never applied as the markets are not ideal and the terms of elasticity are discontinuous functions.

The cylinder oil accounts to approximately 50,31% of the requested lubricants. Market data collected for the study concern volumes of cylinder oil consumed in Greece and in Singapore in 2018 and relative price from both major brands (BP, SHELL, MOBIL) and local brands (AVIN, ELIN, ENOC, SINOPEC).

Fig 1 and 2 present market data for Piraeus and Singapore, the two cases studied in this paper. Major firms blend a quantity q_1 and local firms blend a quantity q_2 , while the selling price P is the same for both suppliers. Both suppliers produce lubricants under the same refinery of the local supplier, with the leader being charged a premium by the local. According to the Greek market data, the total domestic marine lubricants market was 31,30 million liters in 2018 [3]. They suggest that leaders and followers play on different terms in the markets: major players benefit from special relationships winning customers at lower volumes; locals compete at larger volumes with lower costs. Modelling market data constitute a challenge as they are scattered, and linear models may certainly not perform reliably.

In the Singapore market figure, the points collected and plotted were 26 for major suppliers and 11 for local suppliers, while in the Greek market, 12 data points were gathered and plotted for major suppliers and 6 data points for local suppliers.

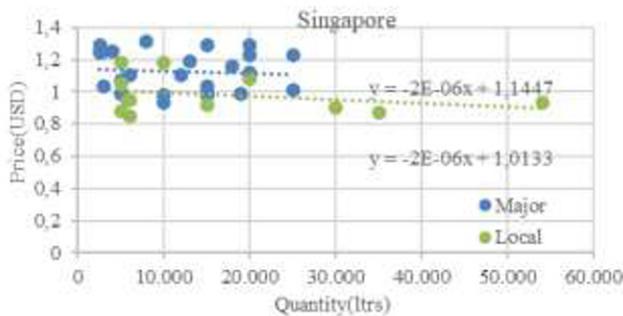

Figure 1: Indicative prices (USD) and Quantities (liters) for cylinder oil in Singapore ports in 2018

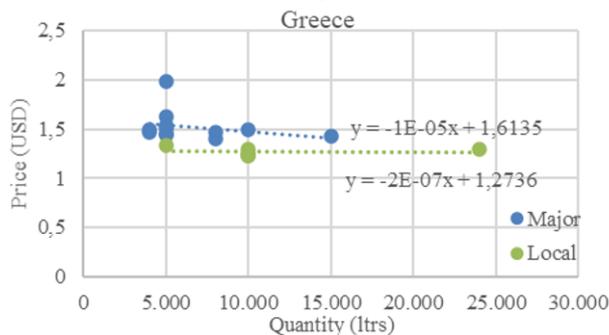

Figure 2: Indicative prices (USD) and Quantities (liters) for cylinder oil in Greek ports in 2018

Let majors and locals be respectively leaders and followers in a context of Stackelberg duopolies [4]. Stakeholders interactions are sketched in Fig 3:

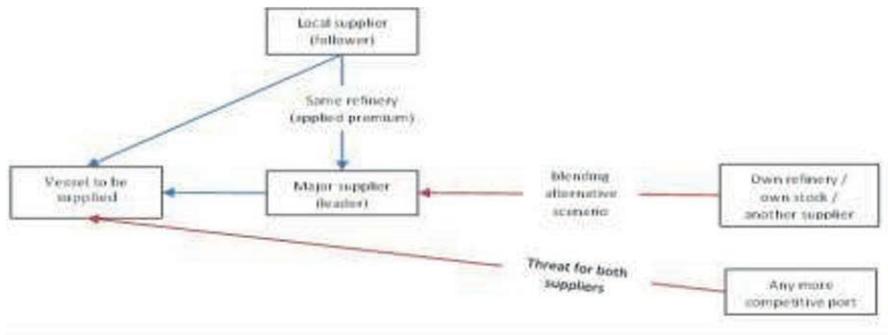

Figure 3: Marine Lubricants supply in peripheral ports

The purpose of the paper would then be to: (a) develop a game model based on Fig 3 accounting for the presumed interactions of stakeholders, (b) use market data of Fig 2 and 3 to assess equilibrium states comparing them with real-life market shares, and (c) evaluate market parameters and interactions holding significance to retain equilibrium.

3. Methodology and mathematical model

A leader-follower relationship is modelled as a bilevel optimization problem where the follower's lower-level program is embedded in the leader's upper-level program. Such problems are formulated as

$$\begin{aligned} & \text{Max}_x F(x, y) \quad \text{s.t. } G(x, y) \geq 0 \\ & \text{where } y \text{ solves } \text{Max}_y f(x, y) \quad \text{s.t. } g(x, y) \geq 0 \end{aligned}$$

x denotes upper-level variables; y : lower-level variables; F : the upper-level objective function; f : the lower-level objective function; G : the upper-level contains, g : the lower-level contains [5].

Given a market of two players, $Q = q_1 + q_2$ (1). Each firm aims to maximize profit. The profit of each player is: $\Pi_i = P(Q) \cdot q_i - c_i \cdot q_i$, where c_i is the cost of each player. The total cost of the leader is the cost of production plus the premium, while that for the follower is only the cost of production.

$$\Pi_1 = P(Q) \cdot q_1 - (C + m) \cdot q_1 \quad (2)$$

An additional amount $q_1 \cdot P$ is added to the follower's profit function (Π_2).

$$\Pi_2 = P(Q) \cdot q_2 - C \cdot q_2 + m \cdot q_1 \quad (3)$$

Concerning $P(Q)$ (4), one could argue that this is not a function but rather a bounded domain that contains market data. In the study we have attempted (a) linear and nonlinear approximations [6], and (b) convex relaxations. Using,

(i) linear approximations, $P(Q) = a \cdot Q + b$; For Greek port $a = -2 \cdot 10^{-15}$, $b = 1.5687$

(ii) Nonlinear elasticity functions, $P = a \cdot Q^{-b}$: Greek ports $a = -4.501$, $b = -0.128$; Singapore port $a = 1.57$, $b = -0.039$

(iii) Convex relaxations for the best fit of the market function $w = P \cdot Q$:

$$\tilde{w} \geq Q^L \cdot P + Q \cdot P^L - Q^L \cdot P^L; \quad \tilde{w} \geq Q^U \cdot P + Q \cdot P^U - Q^U \cdot P^U;$$

$$\tilde{w} \leq Q^U \cdot P + Q \cdot P^L - Q^U \cdot P^L; \quad \tilde{w} \geq P^U \cdot Q + P \cdot Q^L - Q^L \cdot P^U \quad [7]$$

with $\tilde{w} = 8268$; $P^U = 1,23$; $P^L = 1,99$; $Q^U = 24000$; $Q^L = 4000$

Premium (m) is also a parameter affecting results. The production cost (C) is common assuming the use of the same refinery. Sale prices are also identical for both players. Production costs account to 90% of the average sales price of supplies in local firms. Fair bounds on profitability are set at 30%; the maximum premium is set by market practices at 1%. The quantity produced is identical to the quantity sold. The bilevel problem is formulated using EMP of GAMS and solver Conopt. The variables of the upper level problem include the leader's quantity (q_1) and profit (Π_1), the leader's cost of production (C); premium (m) is a sensitivity parameter. The variables of the lower level problem include the follower's quantity (q_2) and profit (Π_2), and the follower's cost of production (C).

4. Results

4.1 Sensitivity analysis

Production cost and the premium are parameters whose values are derived from the market study. Sensitivity analysis for the two parameters led to the conclusion that the most premium is the most sensitive parameter; even a change by 1% may affect equilibrium. Changes in the premium do not affect both players equally. An increase in the premium increases the share of the follower in the market. Although sensitive, the cost of production has an equal impact on the players. An increase in the production cost leads to the reduction of supplied quantities. A decrease in the cost raises the profitability of both players

4.2 Market shares and profitability

Results for different types of approximation have apparently revealed different market shares for the players. Linear approximations concluded to market shares 65% (major), and 35% (local suppliers); profitability shares are respectively estimated at 59% and 41%. Nonlinear approximations concluded to market shares 53% (major), and 47% (local suppliers); profitability shares are respectively estimated at 48% and 52%. Convex relations finally estimated market shares 44% (major), and 56% (local suppliers); profitability shares are respectively estimated at 39% and 61%.

4.3 Equilibrium as key or peripheral port

In key ports both local and major suppliers have their own refineries; peripheral ports use only local suppliers. Game theory has set 30% as a profitability threshold for peripheral ports. In the case of Singapore, the market share corresponding to major suppliers is computed at 83% and 16% for local suppliers. The major's profitability rate is 78% while the local's is 22%. These numbers are not close to the threshold hinting that Singapore will not retain equilibrium unless the premium is 200% higher (leading to splits 67% and 32% for major and local players), a rather uncommon case for existing markets. Instead, the case for Piraeus suggests a peripheral port.

5. Discussion

5.1 Sensitivity analysis

Sensitivity analysis around the premium revealed that its increase would be beneficial to the local. However, this is also a threat to the major, that, to avoid losses, could consider alternative scenarios and options to discontinue the cooperation with the local refinery and opt to (a) import their own stock from a major's refinery located in other regions, (b) alliances with local suppliers of nearby ports utilizing those refineries as third-party

blending plant, or (c) install a new refinery on the site. These options create a threat to the locals and the premium can be set on the feasibility that such other options can prevail. The sensitivity analysis related to production costs leads to common threats and opportunities for both parties. Consequently, they both should aim at reducing the cost price to the minimum possible level.

5.2 Market share and profitability

The equilibrium numbers calculated by the game theory model can be compared with the real-life data for Piraeus. The latter suggest that a split of 54% and 46% for major and local, also a profitability split between 52% and 48%. The numbers are extremely close to the nonlinear approximation (53% and 47%); linear models and convex approximations appear to overestimate the share of the local players: they respectively predict 11% and 7% off the actual data.

5.3 Key ports

The model further confirms that Piraeus suits a profile of a peripheral port as profit/market shares and premium values fall within bounds. It also validates that ports such as Singapore assume profiles of key ports as the share for equilibrium falls outside bounds unless the premium is very high for common practices. However, such high premia are not usually acceptable by multinational companies, which, having the largest market share opt to expand and own refineries.

6. Conclusion

Game theory has proved instrumental to analyse marine lubricants markets. Bilevel optimization, even in considering the basic set of constraints outlined in the paper, constitute a useful resource for suppliers to review their status in the market, understand actions to secure and increase profits, also to prepare for competitors' actions. The model presented in the paper has been validated by the state of a large Greek port (Piraeus), both with respect to its status (peripheral port) as well as its equilibrium share. By a similar token, another large port (Singapore) has been validated as a key port where equilibrium is achieved once major players undertake third party blending plants.

Abstract

Property prediction models based on the principle of a quantitative structure-property relation (QSPR) such as the group contribution models are an important tool that provides a quick, simple, and costless evaluation of various thermophysical properties of chemicals for various applications such as P-V-T calculations and product design. These models rely heavily on the interplay between the chosen descriptor (molecular information), the chosen mathematical formulation (to relate the descriptor to the target property), and the data used to produce such models. Therefore, such models suffer heavily if the quality of experimental data is low (inaccurate) or if there are discrepancies in the descriptors used or the mathematical representation chosen. In this work, we apply a systematic methodology to detect and treat outliers on 18 thermophysical properties and showcase the model improvements across various statistical metrics. This results in significant improvements across all property models illustrated through an increase in the coefficient of determination (R^2), the standard deviation (σ), and the mean absolute error (MAE).

Keywords: Outlier Treatment, Group-Contribution models, Thermophysical properties, Property Prediction, Quantitative Structure-Property Relations (QSPR)

1. Introduction

Knowing the properties of a chemical plays an important role in various chemical engineering disciplines and applications such as risk assessment, process design, and product design. In fact, some of these disciplines would be impossible without this knowledge. These properties can either be related to the thermal properties (normal melting point, critical temperature), physical properties (molar volume, critical volume), flammability properties (lower flammability point and auto-ignition temperature), or the enthalpic properties (enthalpy of formation, enthalpy of fusion) of a compound. These properties are usually determined either directly from experiments or derived from other closely related experimental measurements. Some of these experiments can be cumbersome in terms of the resources needed to conduct them especially with regards to time and the experimental setup needed to provide accurate results. Large collections of experimental data for such properties are scarce and few in numbers. This creates a need for alternative approaches to explore the chemical design space to direct future experimental efforts towards the most promising chemicals for a given application. One way to do this is to correlate the molecular structure to the target property of interest through what is known as Quantitative structure-property relations (QSPR)(Austin *et al.*, 2016). These models take a numerical translation of the molecular structure as input (also

known as descriptors) to a mathematical model that relates these inputs to the target output. An example of such models is the group-contribution (GC) type of model where the model is described in terms of small fragments of functional and structural groups. The success of these models heavily depends on the interplay between the chosen descriptor, the mathematical model, and the equality of data used for the regression (Gasteiger, 2016). In this study, we apply a systematic methodology for outlier treatment to increase the models' predictive power. This methodology is applied to a group-contribution type of model and 18 different property datasets and is benchmarked against previously published results to highlight the effect of the outlier treatment.

2. Methods

2.1. Group-Contribution models

The molecular descriptor employed in this study is the group fragments defined by (Marrero and Gani, 2001), where the molecule is described through three levels of complexity with increasing resolution on the molecular structure. In total, the method defines 220 first-order groups, 130 second-order groups, and 74 third-order groups through which, a molecule can be described by an occurrence vector that indicates the number of time each fragment occur in the molecule. The generic form of a GC model is shown in Eq (1), where $f(X)$ is functional transformation in order to make the right hand side of Eq (1) linear, $c_y^{(x)}$ and $n_y^{(x)}$ are the contributions and occurrence of group y of order x respectively. Alternatively, the equation can also be represented in matrix format where G is the group occurrence matrix and θ are the corresponding group contributions. The left hand side of Eq (1) is determined by visual inspection of the trend of the property at increasing carbon number for various homologous series. On overview of the structure of these transformations can be seen in (Hukkerikar et al., 2012).

$$f(X) = \sum_{i=1}^{220} c_i^{(1)} n_i^{(1)} + \sum_{j=1}^{130} c_j^{(2)} n_j^{(2)} + \sum_{k=1}^{74} c_k^{(3)} n_k^{(3)} = G \theta \quad (1)$$

2.2. Parameter Fitting and Outlier Treatment

A systematic method has been developed by (Frutiger et al., 2016) to perform parameter fitting, outlier treatment, and uncertainty estimation. The same methodology with few modifications is applied in this work and is illustrated in Figure 1. The method is explained in the following:

Step 1 (S1): The exact form of the function is determined by inspecting the trend of the property with increasing carbon numbers across the homologous series.

Step 2 (S2): By taking advantage of the matrix representation of the GC model, an initial guess for the parameters can be produced by applying linear Algebra as seen in Eq. (2).

$$\theta^0 = (G^T G)^{-1} \cdot G^T \cdot f(X) \quad (2)$$

Step 3 (S3): The parameters are estimated sequentially based on their order: first-order groups are estimated first. Whatever the model fails to describe using only first-order groups is then rectified by adding the second-order groups and estimating the parameters for these while keeping the parameters for the first-order fixed. The same reasoning goes for third-order groups. For each group order, the parameters are first estimated using the simplex method to provide a good initial estimate for the gradient-based optimization

using the Levenberg-Marquardt (LM) algorithm. The optimization problem is shown in Eq (3), where y_i^{exp} and y_i^{pred} are the experimental and predicted property values.

$$\theta^* = \arg \min \sum_i (y_i^{exp} - y_i^{pred})^2 \quad (3)$$

Step 4 (S4): All parameters are allowed to vary during the simultaneous parameter fitting. In this step, only the simplex method is used. This ensures that the parameter fitting is more stable and less prone to diverge due to the large number of parameters.

Step 5 (S5): Outlier detection is done by constructing the empirical cumulative distribution function (ECDF) of the prediction errors. The ECDF aims to estimate the true underlying distribution of the residuals making it a suitable method for detecting the outliers without the need for any assumption related to the distribution of these residuals (Frutiger *et al.*, 2016). Data for which the residuals are below the 2.5% and above the 97.5% probabilities are considered outliers and are thus removed from the dataset.

Step 6 (S6) & Step 7 (S7): Sequential and simultaneous parameter estimation is performed on the remaining data using the previously optimized parameters as an initial guess.

Step 8 (S8): Although not discussed in this work, uncertainty analysis is also performed using the maximum likelihood estimation (MLE) by assuming that the measurement errors follow a Gaussian distribution white noise and are independently distributed (Frutiger *et al.*, 2016). This is done by linear propagation of error through asymptotic approximation of the parameter covariance matrix shown in Eq (4). SSE is the sum of squared errors, DoF is the degrees of freedom while J is the Jacobian. The $(1-\alpha_t)$ confidence interval for the prediction is calculated using Eq (5) assuming a student t-distribution.

$$COV(\theta^*) = \frac{SSE}{DoF} (J(\theta^*)^T J(\theta^*))^{-1} \quad (4)$$

$$y_{1-\alpha_t}^{pred} = y^{pred} \pm \sqrt{diag(J(\theta^*)COV(\theta^*)J(\theta^*))} \cdot t(DoF, \alpha_t/2) \quad (5)$$

Step 9 (S9): The final model performance is evaluated by calculating various statistics such as the coefficient of determination (R^2), the standard deviation (σ), and the mean absolute error (MAE) shown in Eq (6), Eq (7) and Eq (8) respectively.

$$R^2 = \frac{\sum_i (y_i^{exp} - y_i^{pred})^2}{\sum_i (y_i^{exp} - \bar{y})^2} \quad (6)$$

$$\sigma = \frac{1}{N} \sqrt{\sum_i (y_i^{exp} - y_i^{pred})^2} \quad (7)$$

$$MAE = \frac{1}{N} \sum_i |y_i^{exp} - y_i^{pred}| \quad (8)$$

The main modification compared to the methodology proposed in (Frutiger *et al.*, 2016) is that the simplex algorithm and the Levenberg-Marquardt algorithms are used alternatively during the sequential parameter estimation and that the final simultaneous parameter estimation is only conducted using the simplex methods. This was shown to provide more stability to the parameter estimation procedure as well as faster convergence and robustness towards the initial guess (starting point of the regression).

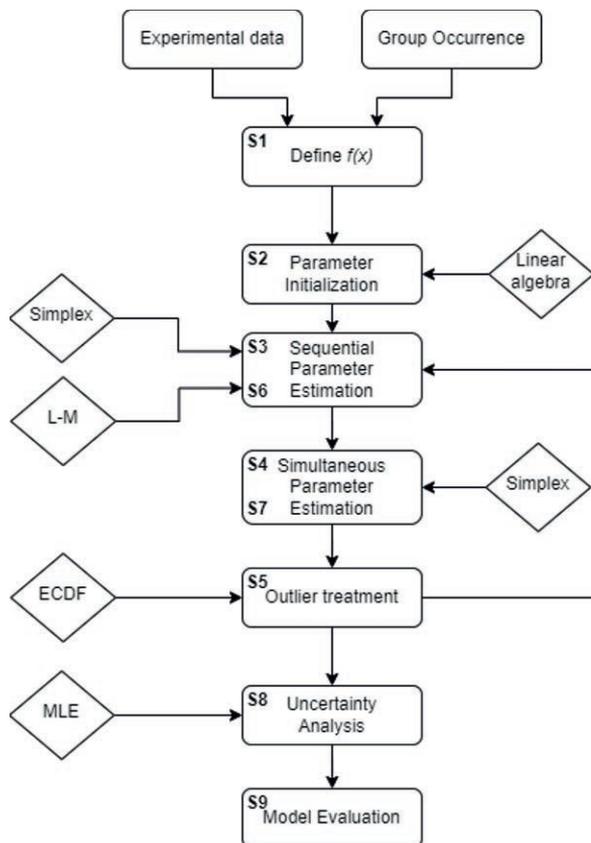

Figure 1: Systematic approach for parameter fitting and outlier treatment (rhombus shape signifies technique or method applied)

2.3. Property Data

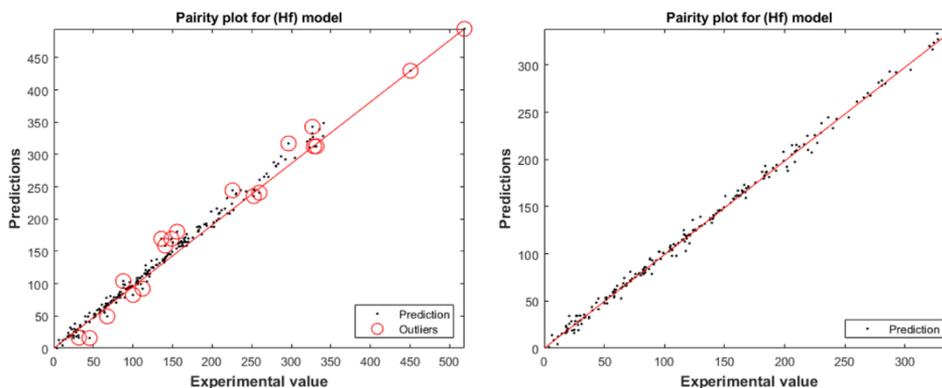

The methodology is applied to 18 property data covering: the normal boiling point (T_b), the critical temperature, pressure and volume (T_c , P_c , and V_c respectively), the normal melting point (T_m), the Gibbs energy of formation (G_f), the enthalpy of formation (H_f), the enthalpy of fusion (H_{fus}), the Octanol-water partition coefficient ($\log Kow$), the Hansen solubility parameters (δ_D , δ_P and δ_H), the enthalpy of vaporization at 298K (H_v), the enthalpy of vaporization at the normal boiling point (H_{vb}), the entropy of vaporization (S_{vb}), the Hildebrand solubility parameter (δ), the acentric factor (ω) and the molar volume (V_m). All data are retrieved from the CAPEC database (Nielsen *et al.*, 2001).

3. Results

An example of model prediction and outlier detection can be seen in Figure 2. An overview of the results and model statistics can be seen in Table 1. The improvement of each metric compared to the result in (Hukkerikar *et al.*, 2012) is also provided in Table 1. Note that for R^2 , the improvement is illustrated by an increase (+), while for σ and MAE is illustrated by a reduction of the metric (-).

4. Discussion

Outlier treatment greatly improved the performance of the GC model across all datasets without exception compared to the results obtained in (Hukkerikar *et al.*, 2012). Most significant improvements are seen for H_{fus}, δ_D , δ_P , S_{vb} and δ , where the R² increased between 0.1 and 0.2. The same effect is also observed on the standard deviations and the mean absolute error. Although the method does indeed improve the model performance, it is also important to note that the method does provide a drawback. The outlier deletion results in the removal of some groups for which a contribution will not be available. This reduces the chemical design space it can explore especially in the absence of any proven

method to predict the contribution of groups not present in the dataset. In fact, a vast majority of groups are not present in every dataset. Despite limiting the domain of exploration of the model, the method reinforces the accuracy for the compounds that remain after outlier deletion and thus increases the reliability of the model within the domain of applicability set by the present groups after outlier deletion. Furthermore, the outliers are defined based on the model performance, thus potentially more informative descriptors or a better mathematical model will result in identifying different outliers and thus the reason for identifying a given compound as an outlier cannot only be attributed to the quality of data but also the model and the descriptor in this case. Important to note is that GC type of models are additive models and thus might struggle for highly non-linear properties as seen e.g. H_{fus} , and various solubility parameters, additionally they do not capture any proximity effects e.g. arrangement of the groups does not affect the prediction. Advanced models capable of capturing highly non-linear trends such as deep neural networks could provide an alternative to the mathematical presentation and thus potentially provide more accurate predictions (Aouichaoui *et al.*, 2021).

5. Conclusion

In this study, we demonstrated that a systematic approach to treating outliers greatly improves the models' predictive performance by narrowing the domain of applicability and increasing the reliability of the model within this domain. One major drawback is, however, that some descriptors are lost in the process of data deletion which reduces the portion of chemical space that the model can explore. Further work will explore the analysis of outliers using different modeling approaches including machine learning and deep learning approaches such as deep neural networks and graph neural networks. This is needed to better understand what causes a data point to be an outlier: a) measurement error or b) a modeling error. In the latter case, the outlier is an observation that provides an opportunity to develop new models.

Data-driven, Image-based Flow Regime Classification for Stirred Aerated Tanks

Corinna Kröger,^a Valentin Khaydarov,^a Leon Urbas^a

^a*Technische Universität Dresden, Dresden 01062, Germany*
valentin.khaydarov@tu-dresden.de

Abstract

Monitoring and optimization of flow regimes in aerated stirred tanks is crucially important for process efficiency and product quality. To date, experimentally generated flow maps and correlations are mostly used to classify flow regimes. However, such an approach is highly limited in terms of scalability and transferability. We propose a model for a soft sensor to classify flow regimes of aerated stirred tanks based only on image data. To select an architecture for the model, we compared various modern architectures including LeNet, VGG16, MobileNetV2, Dense121. Of these, LeNet-5 and custom CNN show the best performance. Furthermore, we tested how disturbances of process and light conditions, and the fill level in the reactor affect the classification performance.

Keywords: stirred aerated tank, flow regime classification, computer vision, CNN.

1. Introduction

Monitoring and optimization of flow regimes in aerated stirred tanks is crucially important for the process efficiency and product quality. The flow regime has a direct impact on the spatial distribution and size of gas bubbles inside the reactor, which affects overall mass transfer rate. Operating the aeration process in an efficient and safe manner demands a comprehensive understanding of the occurring flow regimes (distribution of liquid and gas phases in the mixing process) and their classification. According to (Wang et al., 2017) the recognition and classification of flow regimes in general has a research gap. Stirred tanks in particular require special attention (Khopkar et al., 2005; Liu and Bai, 2019). Currently, manually generated flow maps and correlations are mostly used for this purpose. Boundaries between flow regimes are specified by substance properties, reactor geometry as well as process conditions such as temperature, fill level, flow rate of gas, stirring velocity and geometry of reactor and stirrer. However, such an open-loop approach has decisive drawbacks (Liu and Bai, 2019; Torisaki and Miwa, 2020). Pre-defined flow maps are inflexible regarding uncertainties and variance in substance properties and process conditions. Thus, creation of flow maps itself might be an extremely time intensive task for which effort is proportional to the number of possible parameter combinations. The use of a soft-sensor that could provide the information about the flow regime for a closed-loop control strategy independently of process conditions and the substances used is beneficial in terms of robustness, flexibility, and scalability. Among measurement-based in-line and on-line techniques, image analysis is the only low-cost, non-invasive approach which works with transparent media regardless of their physical properties and process conditions (Bowler et al., 2020). In recent years, artificial intelligence and particularly the use of Convolutional Neural Networks has indicated an enormous potential for solving image classification tasks (LeCun et al., 1998; Liu et al., 2020; Redmon and Farhadi, 2018; Shin et al., 2016; Zhang et al., 2019). The goal of this

paper is to examine the potential of CNNs for solving the flow regime classification problem in aerated stirred tanks with transparent liquids. The input basis for the classification is image data only.

2. Problem description and test set up

Aeration processes in stirred tanks is usually a two-phase problem with a goal to intensify the mass transfer from the gas phase into the liquid phase. Depending on the volume ratio of the two phases, different interface patterns (or flow regimes) can be observed (Pal et al., 2019). According to (Majumder, 2016), a flow regime depends on the following factors: dynamic process parameters, geometry of the reactor and agitators, thermodynamic variables, and physical properties of both phases.

This work focuses on bubbly flows, i.e. a continuous liquid phase with bubble inclusions. We consider only flow regimes in a vertically positioned cylindrical stirred tank equipped with a Rushton turbine, the standard type of the reaction equipment for biochemical and pharmaceutical processes. According to (Paglianti et al., 2000) there are three main flow regimes in such reactors: flooded, loaded and completely dispersed (see Figure 1).

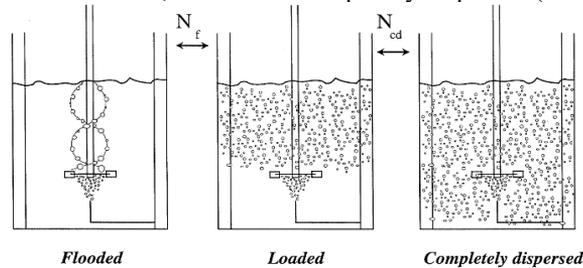

Figure 1: Flow regimes in the stirred tank (Paglianti et al., 2000):

Specifically, the optically visible pattern of gas bubbles in the reactor is proposed as distinguishing criterion for the classification of the flow regime. Stainless steel industrial bioreactors of up to 200 L usually have a single viewing port through which the aeration process can be inspected. Because of this limitation, unlike the cases with glass bioreactors, only image data with a limited view on the process can be used for modelling. We used a 30 L Stedim Biostat® D-DCU bioreactor (D=290 mm, H=640 mm) manufactured by Sartorius. The reactor is equipped with three flat blade turbine impellers (D=95 mm, H=20 mm) and a ring sparging system for aeration using normal air. The vessel is filled with water at the level of 30 L. A single light source is installed in the lid of the bioreactor. For image acquisition we used a Fujifilm X-T20 (aperture F4.5, resolution 1080p, ISO 12800, and shutter speed 1/1250 s).

To cover the operating range of the bioreactor, rotation speed of the stirrer and gas flow rate were varied from 50 to 600 rpm and 5 to 50 nlpm accordingly. Overall, about 10,000 images were collected with 70 combinations of parameters. Figure 2 shows sample images of different flow regimes.

Additional images were collected to test derived models against previously unexposed data where combinations of process parameters, lighting conditions and fill levels were slightly different from those in the training data set. In this way, we wanted to investigate the effect of disturbances that commonly occur in production plants.

3. Data preparation

To ensure that the data set includes only viable images, we manually removed blurred images, or images taken when the stirrer was not running.

The flow regime was determined for each agitator and gas flow setting by visual observation, and images were manually labelled accordingly. To validate the labels, a flow map was created. The position on the flow map, which results from the gas flow number and the Froude number, was used to determine whether the images were marked with the correct flow regime. Clearly incorrect flow regime labels, especially when single images of one class are surrounded by images of another class, were corrected.

Next, image preprocessing techniques were applied. They can improve image detection, for example, by using filters to increase contrast or applying thresholds. Independent A/B tests were carried out for each image preprocessing method and the effect on the model performance was evaluated. The following preprocessing algorithms were tested: Gaussian Blur, Sharpening Filter, Histogram Equalizer, Adaptive Thresholding, Scharr Operator, and Sobel Operator. Additionally, the effect of cropping and converting the color image to grayscale was tested. It was found that the following steps provided the best results: conversion to grey-scale color map, sharpening kernel filter (3x3), and padding with pixels of zero intensity. Data augmentation was carried out using the Keras data generator. During our experiments, we found that random translation, rotation, and horizontal mirroring of the input experimental image provided better results.

4. Modelling

Since there is no previous work about identification of flow regimes with a comparable setup, different CNN models were tested to determine which architecture is the most appropriate. The CNN models were implemented in Python programming language, using the TensorFlow and Keras libraries.

First, we chose the LeNet-5 model (LeCun et al., 1998) due to its simple architecture that has been used for image recognition for years and can be trained very quickly. LeNet5 consists of 5 layers: two convolutional layers, followed by one max pooling layer each. Finally, a fully connected layer and a SoftMax classifier are attached. For the activation we chose the state of the art ReLu function instead of the originally used tanh function. The LeNet model is designed for input data of a dimension of 28x28 pixels. We implemented LeNet additionally for images with 56x56 and 112x112 pixels. All three models were trained for 20 epochs with a learning rate of 0.001 and the Adam Optimizer. Next, we trained more sophisticated networks to compare. VGG16 (Simonyan and Zisserman, 2014), MobileNet (Howard et al., 2017) and DenseNet (Huang et al., 2016) were selected because they have very compact architectures and therefore relatively few parameters to train. For this reason, they have a higher potential for success with the relatively small dataset. For the implementation we used the models from the Keras API with average pooling, Softmax classifier, Adam optimizer and a learning rate of 0.0001. The input shape of the images varied from 56x56 to 224x224 pixels.

Last, we designed custom CNNs. Since smaller models consisting of only a few layers gave better results than larger ones, the LeNet architecture was used as basis: two groups of convolutional layers, ReLu activation, batch normalization and max pooling layer, followed by a fully linked dense layer, a dropout layer and the SoftMax classifier.

In order to find the best set of model parameters, we performed hyperparameter optimization with the hyperband approach using the Keras Tuner tool. The kernel size of the convolutional layers and the max pooling were kept at 3x3 and 2x2. The size of the convolutional layer filters, the size of the dense layer and the learning rate were varied.

We trained the model for 20 epochs with a batch size of 32. This approach resulted in a model with convolutional filters of size 48 and 32, a 768 size Dense Layer and a learning rate of 0.001 (CNN_48_32_768).

In addition, we designed a model consisting of four convolutional layers. The developed model has convolutional filters with the sizes 48, 16, 64 and 128, a 512 large dense layer and a learning rate of 0.001 (CNN_48_16_64_128_512).

The performance of the models and the overall F1-scores are shown in Table 1.

Table 1: Model overview (Prec – Precision, Rec – Recall)

Architecture	Input Shape	Flooded		Loaded		Fully dispersed		Overall F1-score
		Prec	Rec	Prec	Rec	Prec	Rec	
LeNet	(28,28,1)	96%	89%	82%	95%	98%	89%	91%
LeNet	(56,56,1)	99%	100%	96%	92%	94%	97%	96%
LeNet	(112,112,1)	100%	100%	100%	100%	100%	100%	100%
VGG16	(56,56,1)	100%	30%	21%	23%	53%	100%	48%
MobileNetV2	(160,160,3)	0%	0%	36%	100%	0%	0%	37.5%
MobileNetV2	(56,56,1)	0%	0%	30%	100%	0%	0%	29.3%
DenseNet121	(224,224,3)	100%	13%	15%	1%	32%	100%	35.7%
CNN_48_32_768	(56,56,1)	100%	100%	96%	92%	92%	96%	96%
CNN_48_16_64_128_512	(56,56,1)	100%	100%	95%	93%	93%	95%	96%

The LeNet models achieve relatively high F1-scores of over 90% while the other standard CNN models do not exceed values of 90% and therefore do not classify the images with sufficient accuracy. The possible reason is more complex architecture and therefore a higher demand on the training dataset size.

The performance of the implemented LeNet models were compared with an additional test data set. This data set consists of the images taken at different lighting and operating conditions to which the models had not previously been exposed. The results show that the 56x56 resolution images allow for the highest F1-score. Both custom designed CNNs achieved F1-score values of 96%, the same as the LeNet model did.

5. Evaluation and discussion

The best performing models (LeNet with 56x56 resolution and both custom CNNs) were evaluated visually, using saliency maps after (Simonyan et al., 2013). Figure 2 shows a visualization of the training images along with saliency maps for three classes of the 56x56 LeNet model. The relevant pixels are displayed with increasing importance from blue (irrelevant) to red (most relevant). It is apparent that the model focuses on the area where the agitator blades are. This proves that the model detects pixels that are relevant for classification from a chemical engineering point of view. According to (Nienow et al., 1985) exactly the area near agitators provides the most information about current flow regime because cavities build there.

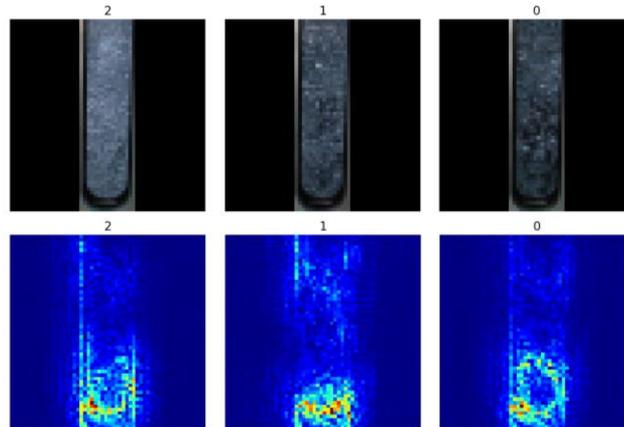

Figure 2: Image samples from collected dataset and corresponding saliency map of trained LeNet 56x56 (2 – completely dispersed, 1 – loaded, 0 – flooded)

The performance of all three models with the test dataset (10% of original dataset) is about 96%. The examination of precision and recall from LeNet for the different flow regimes shows that the flooded regime is identified very reliably (precision 99%, recall 100%). The other two regimes, which resemble each other visually, were more frequently misclassified, where images of loaded regime were classified as completely dispersed. This results in a lower recall for loaded regime (92%) and lower precision (94%) in completely dispersed regime. A similar phenomenon can be observed with the custom CNNs.

Two additional datasets, consisting of images taken under different lighting and operating conditions (different rotational speeds and gas flow rates) show the difference between the models: an F1-score of 73% for LeNet, achieves an 71% for CNN_48_32_768, and 77% for CNN_48_16_64_128_512. In order to compare the performance of the classification without using context data (parameters such as stirrer rotation speed and gas flow rate), 200 images were classified manually in the same test data set. Here, an F1-score of 85% was achieved, only slightly outperforming automatic classification.

Another realistic use case is different filling levels of the reactor, which is why we made an additional data set with levels of 28L and 26L (compared with 30 L for the standard training set). Using the models trained with the standard filling level, the models achieve 96% - 100% on the test dataset. This shows that the filling level has no relevant influence on the accuracy with a relatively small change of 2 to 4L.

6. Conclusion

When comparing various model architectures (LeNet, VGG16, MobileNetV2, Dense121 and custom LeNet alike architecture) for the flow regime classification problem in stirred aerated reactors, our results indicate that shallow networks in general perform better. LeNet and custom CNNs achieved F1-Scores of almost 100% on test dataset and up to 77% on a dedicated test dataset that includes combinations of process parameters to which the models were not exposed during training. Against fluctuation of fill level (up to 4L less) the models showed little or no decrease in performance (96% to 100%).

Abstract

Recent research with artificial neural network (ANN)-based predictive model has emerged as a solution to reduce the number of trial and error effectively. However, it is still challenging to develop a high-performance model using a sparse dataset. Especially, the high-dimension and the small number of polypropylene composite's (PPC's) material data make it difficult to develop a predictive model. In this study, we proposed the ANN-based predictive model using principal component analysis (PCA) to predict the physical property of PPC with the high performance. The optimal dimension reduction of the raw dataset was suggested by the proposed framework to overcome incomplete dataset of PPC materials including the zero values. The dimension reduced dataset was used to develop the ANN-based model for physical property prediction of PPC. As a result, the model accuracy based on the reduced dataset is 0.9061, and 4.6% higher than the model using the raw dataset. This result demonstrates that ANN-based model with dimension reduction improves the prediction performance by reducing the sparsity of PPC material data. Moreover, the proposed model is expected to reduce the number of trial and error in the PPC development process.

Keywords: polypropylene composite, principle component analysis, artificial neural network

1. Introduction

Accompanying the advancement of data science, many data-mining methods have been developed for the purposes of prediction. One such representative data mining method is an artificial neural network (ANN), which has been widely used to develop data-driven models owing to its high performance and effectiveness. An ANN analyzes the relationships between a dependent variable and independent variables, updates the relationships by minimizing the error, and calculates a dependent variable using such relationships when unknown independent variables are given. A data-driven model using an ANN, called an ANN-based model, has been applied to many fields to reduce the trial

and error required, which is one of the major issues in numerous industries, by replacing experimental values with predicted values. However, if an ANN-based model is developed with a sparse dataset where a higher percentage of the variable cells do not have actual data, the predicted values cannot be used owing to the reduction in the model accuracy.

This problem often occurs during the development of polypropylene composites (PPCs). Because many industries require the specific physical properties of PPCs for engineering applications, numerous experiments on their physical properties have been conducted to satisfy such requirements. Although the number of experiments should be reduced to increase the efficiency, it is difficult to reduce it using data-driven modeling because of the sparse dataset of recipes, which indicates the combination and ratio of raw materials used in PPCs. In addition, although the recipe dataset is composed of 90 types of raw materials, not every type of raw material is used in a recipe at the same time. Normally, only 12 types of raw materials at maximum are blended for a PPC. For this reason, the dataset includes many zeros values, becomes sparse, and decreases the performance of the data-driven model. Hence, a dimension reduction has to be applied when an ANN-based model is developed with a recipe dataset for a prediction of the physical properties.

This study proposes a data-driven model for the prediction of the physical properties of PPCs using an ANN and a principal component analysis (PCA). Figure 1 shows an overview of the study. First, data sparsity was found, and the sparsity problem was solved through a dimension reduction process. Among the dimension reduction methods, a PCA, a representative method, was applied. The explained variance ratio was calculated to select the optimal number of dimensions. Second, to validate the dimension reduction method, two ANN-based models were developed using the original and reduced datasets. The performance of the models was then evaluated and compared with R^2 .

The novelty and contributions of this paper are as follows:

- This is the first study to apply an ANN and a PCA to a polypropylene composite (PPC) dataset used in the commercial chemical industry.
- This study improves the model performance of an ANN-based model for a physical property prediction through a dimension reduction.
- This study demonstrates that the ANN-based model with a PCA is a powerful data-driven model for reducing the amount of trial and error required during the PPC development process.

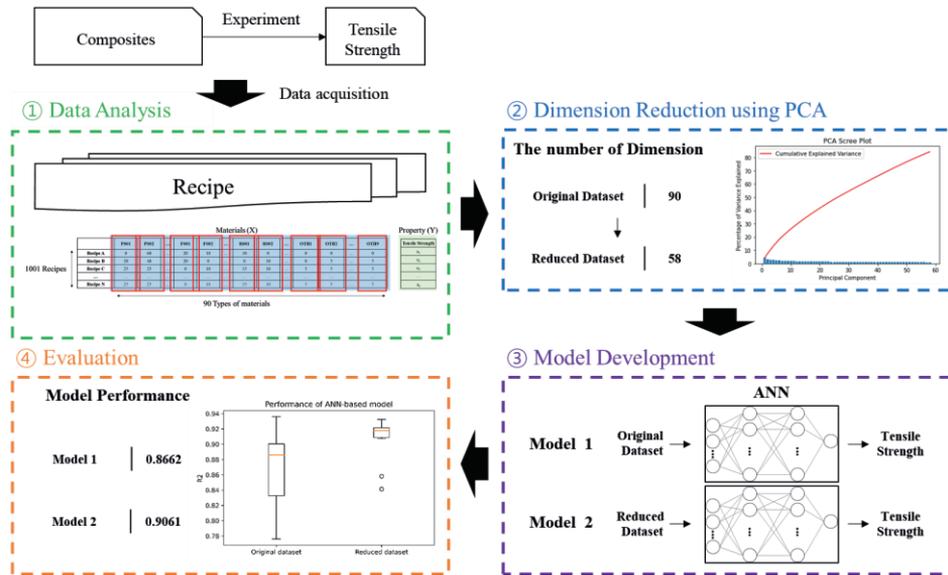

Figure 1 Overview of the present study

2. Method

2.1. Data Analysis

Figure 2 shows the PPC dataset used in this study. The dataset contains information on 1001 recipes, which consist of 90 materials including polypropylene (P), filler (F), rubber (R), and other additives (OTH), as well as the tensile strength. Most importantly, each recipe has many zero weight percentage because only 12 types of materials are used in the recipe at maximum, which means that each recipe has 78 zero values at minimum. The number of zero values determines the data sparsity and has an impact on data-driven modeling. Therefore, the analysis of data sparsity is crucial before modeling.

To analyze the number of zero values, the percentages of zero values in different materials are calculated using. In the PPC dataset, the percentages are distributed from 31.3% to 99.9%. This result shows that both popular and unpopular materials exist in the PPC development. For example, the minimum percentage of zero values (31.3%) is for OTH4, which means that 314 of 1001 recipes do not contain OHT4. By contrast, the maximum percentage of zero values (99.9%) is for P013, which means that 1000 of 1001 recipes do not contain P013. For these reasons, the PPC dataset is sparse owing to the existence of many zero values, and thus the number of zero values must be reduced for data-driven modeling.

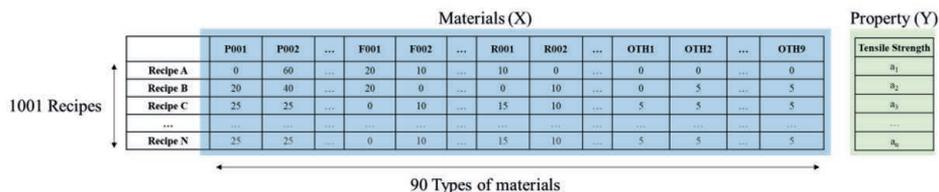

Figure 2 PPC dataset used in this study

2.2. Principal Component Analysis

The sparsity of the dataset can be solved using dimension reduction methods. One popular method is a principal component analysis (PCA), which has been a powerful method since its initial development. PCA transforms a large set of variables into a smaller set that still contains most of the information in a large set. The information is usually defined as a variance of variables, which cannot be maintained when the number of dimensions is too small. Therefore, selecting the optimal number of dimensions is important when reducing the number of dimensions to maintain the variance properly.

2.3. Artificial Neural Network

Among various data mining methods, artificial neural networks (ANNs) have been widely used for data-driven modeling due to their high performance. ANN consists of three layers: an input layer, a hidden layer, and an output layer. Each layer contains nodes and edges that contain mathematical relations with weights and biases. An ANN minimizes the error by updating the weights during model training, and the developed model estimates an unknown dependent variable from the known input and output pairs, including the mathematical relations.

3. Results and discussions

3.1. Selecting the number of dimensions

The variance ratio explained is calculated to select the optimal number of dimensions in the PCA. Figure 3 shows a PCA scree plot of the PPC dataset, with the blue bars representing the explained variance ratio. The ratio represents the variance explained by each of the principal components, starting with the first component, which is the principal component that explains most of the variance. When the ratios are summed, the total value is equal to 1, indicating that the 90 components together explain 100% of the variance of the dataset. More usefully, the variance ratio explained is used as a cumulative sum, such as indicated by the red curve in Figure 3. In this study, we found that 58 components are required to explain at least 85% of the information in the dataset from the cumulative explained variance. Hence, 90 types of materials were replaced with 58 principal components.

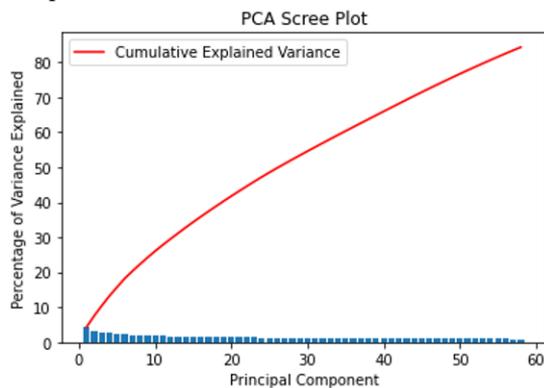

Figure 3 PCA scree plot of PPC dataset

3.2. Development of ANN-based models

After a dimension reduction, we developed ANN-based tensile strength prediction models using two datasets: the original dataset with 90 types of materials and the reduced dataset with 58 components. An ANN-based model uses weight percentage of 90 types of materials as inputs, whereas the other model uses the values of 58 components as inputs. The two datasets were randomly split into 60% training, 20% validation, and 20% test datasets. Although the training and validation datasets were used for data-driven modeling, the test dataset was used to evaluate the models. The performance of the models is evaluated using R^2 , which is a representative evaluation criterion for regression and is calculated through Eq. (1).

$$R^2 = 1 - \frac{\sum_{i=1}^N (S_{ia} - S_{ip})^2}{\sum_{i=1}^N (S_{ia} - \bar{S}_{ip})^2} \quad (1)$$

In the above equation, N denotes the number of data, S_{ia} denotes the i^{th} actual value, and S_{ip} denotes the i^{th} predicted value of the model.

The ANN used in this study has one input layer, one output layer, and two hidden layers consisting of 30 nodes, an Adam optimizer, and ReLU as an activation function for each layer. Namely, the hyperparameters of the two ANN-based models are identical, except for the number of nodes in the input layer.

Although the ANN hyperparameters are fixed, because R^2 depends on the datasets (training dataset, validation dataset, and test dataset), ten case studies were conducted. Each case consists of a comparison of the two ANN-based models after the random data split. Table 1 shows the results of the case studies. The average R^2 of the ANN-based model using the original dataset was calculated as 0.8662, whereas the average R^2 using the reduced dataset was calculated as 0.9061. This difference demonstrates that a dimension reduction contributes to the improvement of the model performance. The R^2 of the model increased by 4.6% after the dimension reduction in this study.

Table 1 Results of ten case studies

	R^2 of ANN-based model using the original dataset	R^2 of ANN-based model using the reduced dataset
Case 1	0.82931	0.93247
Case 2	0.84299	0.85808
Case 3	0.89898	0.91378
Case 4	0.79735	0.91785
Case 5	0.89373	0.90737
Case 6	0.93614	0.93069
Case 7	0.90797	0.91807
Case 8	0.77613	0.91948
Case 9	0.87827	0.92202
Case 10	0.90079	0.84131
Average	0.8662	0.9061

In addition, we analyzed the interquartile range, called IQR, of the results, as shown in Figure 4. The ANN-based model using the original dataset was unstable because the model had a wide range of R^2 values of 0.77613 to 0.93614. However, the ANN-based model using the reduced dataset was more stable than that using the original dataset because the range of R^2 was from 0.84131 to 0.93247. While the model using the original dataset is able to be tested with different inputs because maximum 12 materials are used

in 90 types, the model using the reduced dataset is tested with same inputs because the dataset is not sparse. Therefore, the sparsity in the dataset should be reduced before data-driven modeling when using sparse data. Consequently, a dimension reduction is required not only to improve the performance but also the robustness of the data-driven model.

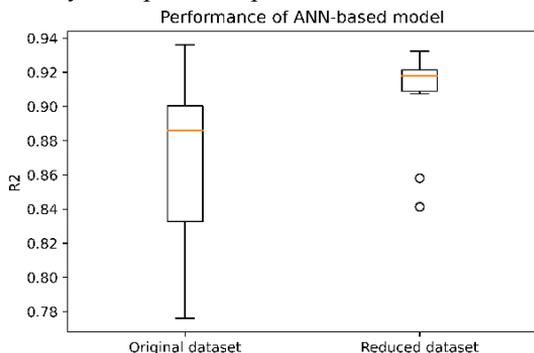

Figure 4 IQR graph of the R^2 of the two ANN-based models using the original and reduced datasets

4. Conclusion

In the PPC development process, an ANN-based prediction model is suggested to reduce the amount of trial and error required. However, the sparsity of the PPC dataset hinders the development of the prediction model. In this study, we proposed an ANN-based model for the property prediction of PPC using a PCA. A total of 58 components were selected as the optimal number of dimensions. To compare the performances of the proposed model using 58 components and the original model using 90 types of materials, two ANN-based models were developed with the same hyperparameters and evaluated based on the R^2 . The results illustrate that the proposed model outperforms the original model and is more robust than the original model. Thus, this study proved that a dimension reduction is essential for data-driven modeling when using sparse datasets.

The proposed model is expected to be applied to the other fields handling sparse datasets as a powerful solution to reduce the amount of trial and error, such as blending processes. In future studies, we will compare the use of a PCA with other dimension reduction methods and extend this study to other properties of PPC.

Babeş-Bolyai University of Cluj-Napoca, Faculty of Chemistry and Chemical Engineering, 11 Arany Janos Street, 400028, Cluj-Napoca, Romania

Abstract

The present work aimed the modelling and optimization of the Wastewater Treatment Plant (WWTP) operation based on predicting its energy and quality performance indices using Artificial Neural Networks (ANNs). The best model architecture and structure were searched among three different ANN types, with different topologies. A standard dataset originating from the plant calibrated first-principle model (FPM) data was used to develop the ANN models. Their performance was evaluated by the coefficient of determination and mean squared error (MSE) values, first at testing and subsequently at the prediction performed for a new input dataset. Using the most promising identified ANN types and topologies, two ANN structures were investigated, one with three single output neural networks and another one with a single network with three outputs for predicting WWTP performance indices: aeration energy, effluent quality and pumping energy. The analytical model and the two ANN structures were used in the study of the aeration optimization of the WWTP, for finding the optimal air distribution in the aerated reactors. The obtained results were tested and compared taking into account the performance index values as well as the required computation time. The developed ANN models showed similar results to the FPM in terms of performance indices, while the required computation time was reduced by several orders of magnitude.

Keywords: artificial neural network, wastewater treatment plant model, aeration optimization

1. Introduction

Artificial Intelligence (AI) techniques are gaining popularity in Waste Water Treatment Plant (WWTP) modelling, optimization and control due to their simplicity compared to the analytical models. The well-known Activated Sludge Models (ASMs) describe tens of subprocesses, leading to numerous model components and coefficients [1-4]. Relying on the complex ASM models used in operation optimization of the WWTP proves to be a demanding task for the model development [5], but also for the computing resources and time [6]. AI techniques present an alternative approach, as they have proved their applicability in the field of chemical and environmental engineering [7]. ANNs are widely used to develop data-driven models, and these networks are capable of modeling nonlinear processes, such as those specific to the WWTP, and also show adequacy for forecasting or classification tasks [8].

Several studies focused on developing ANN models for applications in WWTP modelling. Such networks determined the required alum dosage [9], or estimated plant costs [10]. ANN modelling was used in various areas of WWTP modelling, the focus being on effluent modelling and prediction. These studies successfully emerged in models capable of accurate predictions of the effluent variables, such as: Total Suspended Solids

(TSS) [11]; Biological Oxygen Demand (BOD), Chemical Oxygen Demand (COD) [12]; and pH, total nitrogen and COD [13]. Control of the effluent COD level was also implemented using ANN based predictions [14]. The aforementioned steady-state studies revealed that most often a simple ANN structure is sufficient in providing accurate results. The studies regarding the implementation of dynamic neural networks for prediction the dynamics of the WWTP effluent variables are scarcer, a representation being the network developed for the diagnosis of a biological wastewater treatment process that removes organic carbon residuals [15]. Another research showed that recurrent neural network models (RNN) are suitable for working with time series data and temporal changing behavior [16].

This work proposes to design, train and use the most suitable dynamic ANN model for the purpose of WWTP aeration optimization.

2. Methodology

The basic data and methods used for the development of the ANN models is shown next.

2.1. Data collection and ANN structure

Multiple ANN types were studied with the aim of finding the most efficient networks to be used for making predictions. Based on the proposed training methodology and best ANN results, new ANN models can be directly developed using exclusive industrial plant data. The data used for training was obtained from simulations with a calibrated FPM of a municipal WWTP, based on ASM1 (first from its family). Dynamic simulations on 458 days provided the database for the development of ANNs and data were collected with a sampling time of 0.5 hours. Simulation scenarios were selected using a full factorial Design of Experiment method, having 4 levels for each of the three gain factors of the air flowrate distribution in the aerated reactors, and resulting in a total 64 different simulation scenarios. This approach provided a statistically comprehensive training dataset.

The following WWTP influent variables (as mean values during each sampling period) were taken from plant measurements: chemical oxygen demand (COD), NH_4^+ & NH_3 nitrogen (NH) concentration, volumetric flow (Q) and temperature (T). The outputs of the networks were chosen as the three WWTP performance indices: aeration energy (AE), effluent quality (EQ) and pumping energy (PE), computed according to equations (1)-(3).

$$AE_i = \frac{SO_{sat}}{1.8 \cdot 1000 \cdot ts} \cdot \int_{t_{i-1}}^{t_i} \sum V \cdot K_L a(t) dt \quad (1)$$

$$EQ_i = \frac{1}{1000 \cdot ts} \cdot \int_{t_{i-1}}^{t_i} [PU_{TSS}(t) + PU_{COD}(t) + PU_{BOD}(t) + PU_{TKN}(t) + PU_{NO}(t)] \cdot Q_e(t) dt \quad (2)$$

$$PE_i = \frac{1}{ts} \cdot \int_{t_{i-1}}^{t_i} [0.004 \cdot Q_{NR}(t) + 0.008 \cdot Q_{RAS}(t) + 0.05 \cdot Q_w(t)] dt \quad (3)$$

The AE index is calculated based on the oxygen transfer coefficient ($K_L a$), the volumes of the aeration tanks (V) and the saturated oxygen concentration (SO_{sat}). The EQ index considers for computation the effluent concentration of total suspended solids (TSS), COD, biological oxygen demand (BOD), total Kjeldahl nitrogen (TKN), nitrate and nitrite nitrogen (NO) concentration and effluent flow rate (Q_e). The PE is computed based on the nitrates recirculation (Q_{NR}), return activated sludge (Q_{RAS}) and waste (Q_w) flow rates. The performance indices were computed at each point in time t_i by integration over period t_{i-1} to t_i and considering the sampling time ts . Two main structures were designed for each type of investigated ANN, one multiple input multiple output (MIMO) structure with a single network trained to predict all outputs and a multiple input single output (MISO) structure with 3 parallel networks, each trained for predicting one of the ANN outputs. Three ANN types were considered: Time Delay Neural Network, Recurrent Neural Network and Generalized Regression Neural Network.

2.2. ANN type and architecture

All of the investigated networks were trained using past and present data to obtain suitable models for time-series prediction. In each case, the inputs for point t_i in time consisted of the influent variables and output(s) past values, from points t_{i-12} to t_{i-1} in time, and the influent parameters at point t_i in time. They served to compute the output(s) at point t_i .

2.2.1. Time delay neural network

Time Delay Neural Networks (TDNNs) are feed-forward neural networks that have a so-called tapped delay line block between the inputs and the first hidden layer, allowing the networks to work with data from several past time moments. In our study the number of sampling time delays for the input data was chosen as 12. The dataset was divided into three separate subsets: training, validation and testing subsets. The training subset amounted to 70% of the total data, while the other two subsets amounted to 15% each. In order to find the best ANN architecture, the number of hidden layers and the number of neurons in each of the hidden layers were varied.

2.2.2. Recurrent neural network

Recurrent Neural Networks (RNNs) have a similar construction to the above mentioned TDNNs. These networks also contain the tapped delay line. However, the subset of inputs consisting in the past values of the outputs is directly fed by feedback from the network's own outputs. In this case only the number of neurons in the hidden layer was varied. The dataset was also divided in 70% used for training, while 15% and 15% was used for validation and testing.

2.2.3. Generalized regression neural network

The Generalized Regression Neural Networks (GRNNs) have two layers. The first one is a radial basis layer, while the second is called a special linear layer. The weights of the input layer consist in the transposed matrix of the input training dataset, while the weights matrix of the second layer is the matrix composed of the target training vectors dataset. As a result, this type of ANN is easily developed and has very good function approximation performance. The available data was divided in two subsets, 70% for training and 30% for testing. The GRNN spread parameter was varied from 0.1 to 2.

2.3. Selection criteria for the best ANN models

Two criteria were taken into consideration when selecting the best ANNs: the coefficient of determination (R^2) and the mean squared error (MSE). At the testing step they were used to select the best model from the different explored topologies. Then, these networks were used for predicting the performance indices for the next 7 days, using a new and not yet known set of ANN input data. In this process, the developed networks worked similarly to RNNs, i.e. their own computed outputs were used as inputs for the next time step prediction.

For this comprehensive testing procedure, all of the models were evaluated again for the prediction performance by calculating the R^2 and MSE given in equation (4), in order to assess the fit between the ANN predicted outputs and targets:

$$MSE = \sum_{i=1}^N \frac{(x_i - y_i)^2}{N} \quad (4)$$

where N is the number of data points, y_i is the desired output and x_i is the model output.

2.4. Optimization procedure

The optimization aims to find the optimal gain factors values for the airflows entering the three aerated reactors, taking into account the general objective function consisting in the sum of the averages of the three WWTP performance indices (AE, EQ, PE).

ANN design, training and optimization were carried out using Matlab and Simulink software environment.

3. Results and Discussion

3.1. ANN type and architecture

The results of the ANN model performance and selection criteria based on R^2 and MSE are presented in Table 2, both for the testing and prediction steps.

Table 2. Testing and prediction performance of the ANN models

ANN topology	No. of hidden layers	Output	Testing step		Prediction step	
			R^2	MSE* 10^{-3}	R^2	MSE* 10^{-3}
TDNN	1	AE	1.00	10.7	0.91	169
TDNN	1	EQ	1.00	0.16	0.93	1144
TDNN	1	PE	1.00	4.57E-04	0.96	2.83
TDNN	1	All	1.00	3.78	0.99	906
RNN	1	AE	0.99	32.0	0.97	75.3
RNN	1	EQ	1.00	1.77	0.89	2199
RNN	1	PE	1.00	0.21	0.82	21.8
RNN	1	All	1	18.55	0.99	587
TDNN	2	AE	1.00	12.5	0.94	113
TDNN	2	EQ	1.00	0.11	0.93	1199
TDNN	2	PE	1.00	3.21E-04	0.97	2.43
TDNN	2	All	1.00	3.87	0.97	1893
GRNN	2	AE	0.97	128	0.94	159
GRNN	2	EQ	0.97	381	0.92	1319
GRNN	2	PE	0.99	0.54	0.93	13.8
GRNN	2	All	1.00	166	0.99	477

3.1.1. Time delay neural network

In case of the TDNN models with a single hidden layer, the number of hidden neurons was varied from 2 to 20. The 7-16-1 network proved to be the best from all of the MISO models for predicting EQ.

For the TDNN with 2 hidden layers the number of hidden neurons were varied from 1 to 15 for each layer. This 7-15-15-1 MISO architecture showed the best prediction results for PE, among all the designed and trained networks.

3.1.2. Recurrent neural network

The number of neurons of the hidden layer was varied from 2 to 20. In this case the best ANN model had 10 neurons and it presented the best results at the prediction step for AE.

3.1.3. Generalized regression neural network model

At training, the spread design parameter was varied from 0.1 to 2 by increments of 0.1. The best prediction results were achieved for the MIMO model with 0.7 value of the spread.

3.2. Selection criteria for the best ANN

Selection of the best networks was based on the R^2 and MSE results at the prediction step. Accordingly, the best MISO architecture was the one of the RNN type for AE prediction, the TDNN type with one hidden layer for EQ prediction, and the TDNN type with two hidden layers for the PE prediction. When all AE, EQ and PE aggregated indices were considered, the GRNN with multiple outputs showed the best results and this architecture was chosen as the MIMO model to be further used. The ANNs prediction and target series are shown in Figure 1 for the three best MISO (3MISO) and MIMO models respectively. It can be observed that MISO ANNs perform better at predicting the AE and PE values, while both MISO and MIMO ANN structures perform similarly for EQ prediction.

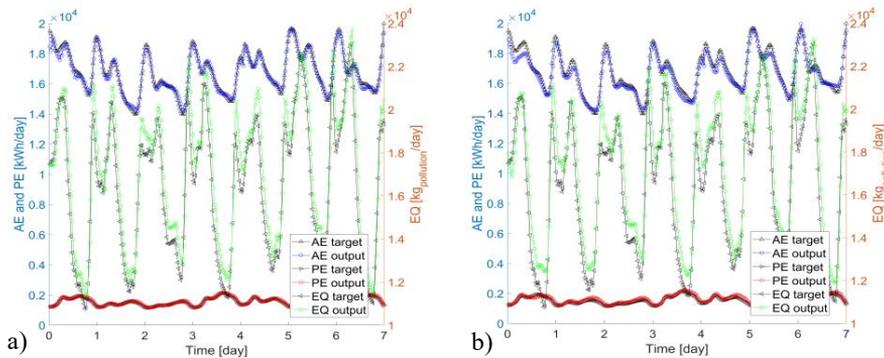

Figure 1. ANN predictions and targets for a) 3MISO and b) MIMO models

3.3. Optimization procedure

Optimization of the WWTP aeration was carried out for three different cases. The objective function was the sum of the averages of the WWTP performance indices for the investigated time period of 7 days, as shown in eq. (5).

$$f_{min} = \frac{\sum_{i=1}^N AE_i}{N} + \frac{\sum_{i=1}^N EQ_i}{N} + \frac{\sum_{i=1}^N PE_i}{N} \quad (5)$$

The optimization was performed for each of the three different cases using NOMAD algorithm [17]; firstly, with the FPM, secondly with the best ANN 3MISO models, and lastly with the best GRNN MIMO model. The WWTP performance simulation results with the optimized air distribution gain factors, for each of the cases, were compared and the computation times (Compt. time) for optimization is also shown in Table 2.

Table 2. Optimization results

Model Case	Gain 1	Gain 2	Gain 3	Compt. time [s]	AE [kWh/day]	EQ [kg/day]	PE [kWh/day]
FPM	0.80	0.41	0.38	56,460	16,616	16,572	1,602
3MISO	0.80	0.40	0.34	3.554	16,791	16,474	1,560
MIMO	0.95	0.40	0.40	1,719	16,794	16,473	1,584

All three types of models led to similar results. The structures based on ANNs succeeded to reduce the EQ and PE indices, while the FPM found the best solution for reducing the AE index. But notably, we may observe that the differences in computation time are much more significant than those of the WWTP performance indices. While the optimization took nearly 16 hours using the FPM, it concluded in a few seconds employing the 3MISO model, and took about half an hour for the MIMO structure. The difference in the computation time between the ANN structures can be attributed to the differences in their construction. TDNNs and RNNs were implicitly designed to work in a recurrent design, while this was added for the GRNNs as a extra task at each iteration. It is also worthy to mention the downside of the TDNNs and RNNs consisting in the typically large time duration needed for their training, when compared to the much faster training of GRNNs.

4. Conclusions

In this paper, the design and training ANN dynamic models for predicting the WWTP AE, EQ and PE performance indices are presented, with the aim to be further used for optimization of the WWTP aeration. Two ANN structures were taken into consideration, a mix of three different types of networks which showed the best results for the single

output predictions and the network that had the lowest error values when predicting all three WWTP performance indices. The R^2 of the designed ANNs was in the range of 0.93-0.99 and demonstrated very good prediction accuracy. Optimization performed using these ANN models revealed similar results to those obtained using the first principle analytical model. But the duration of the optimization time is dramatically reduced when ANN models were used. The MIMO structure was more than 30 times faster, while the optimization based on the 3MISO structure finished more than four orders of magnitude faster. The results prove the potential and applicability of these ANN models for the real time WWTP optimization aiming its operation improvement.

Abstract

Among the high-dimensional methods for process monitoring, the most widespread and researched are those belonging to the class of latent variable approaches. As more variables are continuously gathered, the existing latent variable methods start to experience difficulties in maintaining their good monitoring properties. Of particular importance is the decreased sensitivity in detecting localized faults through the Q statistic as the accumulation of residuals over a very large number of variables masks the deviations due to faults affecting one or a small number of sensors. To overcome this limitation, we propose the use of the truncated Q statistic. This statistic has the ability to identify the relevant residuals before summing them, by comparing their magnitude against a statistically motivated allowance threshold. Only the residuals beyond the threshold are kept and used to compute the truncated Q statistic (this step is then repeated for each new observation). The performance of the proposed statistic was analyzed through Monte Carlo simulations of several latent variable processes with 5 000 to 20 000 variables. Process monitoring was performed by replacing the Q statistic in the standard combination of T^2 & Q of MSPC-PCA, but other latent variables monitoring methods can benefit from this proposal as well. The results obtained clearly show that MSPC-PCA with the truncated Q statistic becomes much more sensitive than the original formulation; for instance, it can detect faults with a magnitude of 2 standard deviations more than 90 % of the times, whereas MSPC-PCA with the standard Q statistic only detected faults with a magnitude of 4 standards deviations less than 40 % of the times. This methodology was also applied in a real world process to monitor more than 17 000 variables associated to printed circuit boards (PCB) produced by Bosch Car Multimedia Portugal. For this case study, the proposed truncated Q statistic was able to identify 17 abnormal PCBs while the standard Q statistic only detected 5 PCBs.

Keywords: Statistical Process Monitoring; Latent variables; High-dimensional processes.

1. Introduction

As the number of monitored variables increases, the classic Statistical Process Control (SPC) methodologies start to lose sensitivity in detecting localized faults. This is more critical for the residual statistics since they accumulate the model's residuals over a very large number of variables, which effectively raise their basal level during normal operation conditions. Thus, faults are only detectable if they surpass not only the normal operation variation of the faulty variables, but also the sum of all irrelevant residuals,

which may be considerably high in very high-dimensional systems. To address this limitation, we propose the use of a truncated Q statistic that, for each new observation, screens for the relevant residuals before summing them.

This problem is here illustrated for the Q statistic of principal component analysis (MSPC-PCA) (Jackson et al., 1979, Jackson, 1959) since it is the most well-know and widespread methodology. Nevertheless, the proposed methodology can also be applied to other methods such as those based on artificial intelligence (Yin et al., 2019, Yan et al., 2019) or machine learning (Lee et al., 2020, Ge et al., 2017, Rato et al., 2017). Furthermore, the Q statistic of MSPC-PCA is equivalent to other residual statistics, such as the T_r statistic of canonical variate analysis-based monitoring (Jiang et al., 2015), the CVD index of Canonical variate dissimilarity analysis (Pilario et al., 2018), the SPE statistic for (non-linear) manifold-based SPC (Li et al., 2015), and the SPE statistic for nonlinear process monitoring based on kernel global-local preserving projections (Luo et al., 2016). As the proposed methodology effectively screens for the relevant residuals before applying the standard monitoring statistic, any monitoring methodology based on the analysis of residuals may potentially benefit from this proposal.

The rest of this paper is organized as follows. In Section 2, the proposed truncated Q statistic is described. In Section 3, the results for two case studies are presented and discussed. Finally, a summary of the conclusions is provided in Section 4.

2. Methodology

The standard Q statistic of MSPC-PCA directly sums the squared residuals over all variables. Thus, for very high-dimensional systems, deviations in a single sensor or a small set of sensors can be masked by the noisy residuals generated by normal variables. Instead of summing all residual, it is here proposed to screen, in each observation, for the relevant residuals, namely using a proper threshold, τ . Afterwards, only the residuals that were found to be relevant are used to build the so-called truncated Q statistic.

To define the subset of relevant residuals, they are first standardized as:

$$\check{e}_j = \frac{e_j - \bar{e}_j^{NOC}}{s_j^{NOC}}, \quad (1)$$

where, \check{e}_j is the standardized residual for the j -th variable, \bar{e}_j^{NOC} and s_j^{NOC} are the sample mean and standard deviation of the j -th residual under normal operation conditions.

Afterwards, the absolute value of the standardized residuals is compared against a threshold and those found to be below it are set to zero. Therefore, they will not impact the value of the truncated Q statistic. The threshold can be defined by the user. We propose to set $\tau = 3$, representing the typical “3-sigma” limits (Cinar et al., 2007). As the significant residuals (in absolute value) are always larger than τ , they are further corrected by subtracting this constant. This operation is analogous to that performed by the cumulative sum (CUSUM) control chart (Montgomery, 2008), and corresponds to save only the deviations beyond an allowance threshold. The aforementioned operations can be performed through a soft thresholding function $\Phi_\tau(x)$ with parameter τ :

$$\Phi_\tau(x) = \begin{cases} x - \tau & \text{if } x > \tau \\ x + \tau & \text{if } x < -\tau, \\ 0 & \text{if } |x| \leq \tau \end{cases} \quad (2)$$

Following these definitions, the truncated Q statistics is computed as:

$$Q_{\Delta} = \sum_{j=1}^m \left\{ \Phi_{\tau}(\tilde{e}_j) \right\}^2, \quad (3)$$

where m is the number of variables. The control limits for Q_{Δ} can be determined by adjustment of the empirical distribution obtained from normal operation conditions or by a kernel density estimator.

3. Results

3.1. Simulated Case Study

To evaluate the performance of the proposed truncated Q statistic, a series of very high-dimensional processes were simulated. For each process, a matrix of measured data (\mathbf{X}) is generated through a latent variable structure defined by,

$$\mathbf{X} = \mathbf{T}\mathbf{A}^T + s\mathbf{E}, \quad (4)$$

where \mathbf{T} is a $(n \times p)$ matrix of latent variables, \mathbf{A} is a loadings matrix with orthogonal columns randomly generated, \mathbf{E} is a $(n \times m)$ matrix of residuals and s is a scaling factor. Furthermore, n is the number of simulated observations, m is the number of variables and p is the number of latent variables. In this study, \mathbf{T} and \mathbf{E} are generated through random realizations of the standard normal distribution. The scaling factor (s) is tuned so that the error component represents about 5 % of the total variation of \mathbf{X} .

The data generation procedure was run with $p = 10$ latent variables and for four very high-dimension process with 5 000, 10 000, 15 000 and 20 000 variables (m). For each of the four very high-dimension scenarios, the data generation procedure was repeated 100 times. In each replicate, a calibration dataset with 1 000 observations is generated to train the PCA model. Similarly, a validation dataset with another 1 000 observations is generated to establish the control limits of the monitoring statistics.

Faulty datasets with 1 000 observations each were generated by introducing a step deviation in the first variable of the measurement matrix (*i.e.*, on the first column of \mathbf{X}). The magnitude of this fault is defined as k times the in-control standard deviation of the affected variable. Note that since the loading matrix is randomly generated, the index of the affected variables has no consequence. Faults are generated for k between 1 and 10. For each fault, the true positive rate (TPR) was computed as the number of faulty observations correctly declared as an alarm by either of the monitoring statistics, divided by the total number of faulty observations.

Two monitoring schemes are considered in this study. The first monitoring approach corresponds to the standard implementation of MSPC-PCA and is composed by the standard T^2 & Q statistics. In turn, the second monitoring scheme uses the T^2 to monitor the score subspace and the proposed truncated Q statistic to monitor the residuals subspace. Both monitoring schemes were set to an overall false detection rate of 1 %.

The average TPR along with their interquartile range are represented in Figure 1. These results clearly show that the truncated Q statistic leads to significantly higher TPR, regardless of the number of variables involved. In all cases, the proposed monitoring scheme can detect faults with a magnitude higher than 2 standard deviations. In contrast, the standard monitoring scheme only detects faults with 4 standards deviations less than 40 % of the times. In other words, faults with a magnitude twice as large are detected less than half of the times. It is also observed that the sensitivity of the standard monitoring scheme decreases with the increase of the number of monitored variables.

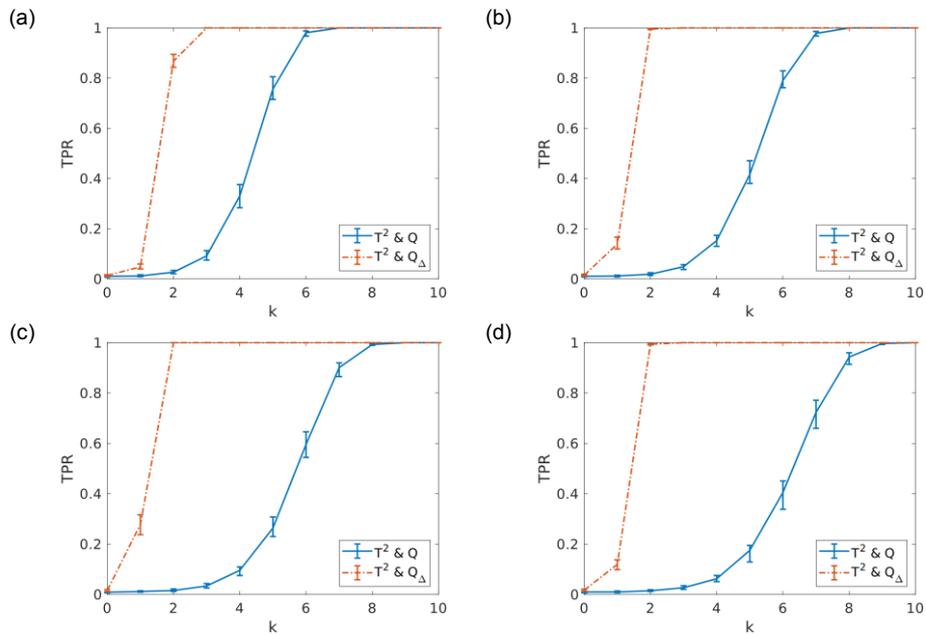

Figure 1 True positive rate (TPR) for processes with: (a) 5 000 variables; (b) 10 000 variables; (c) 15 000 variables; (d) 20 000 variables.

To exemplify the masking effect caused by summing several (irrelevant) residuals, the residuals obtained for a process with 20 000 variables with a fault of $k = 1$ standard deviation in one variable is represented in Figure 2. From visual inspection of Figure 2 (a) it is verified that the residual of the faulty variable is completely undistinguishable since several unaffected variables have either similar or even higher residuals. By summing the squared residuals, it is further verified that the contribution of this variable to the Q statistic is less than 0.1 %.

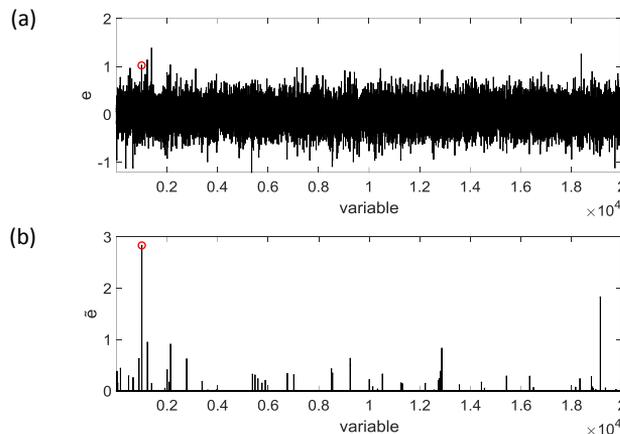

Figure 2 Residuals for a deviation of $k = 1$ standard deviation in the 1 000th variable (marked with a circle) for a process with 20 000 variables: (a) original residuals used by the Q statistic; (b) truncated residuals used by the truncated Q statistic.

On the other hand, with the proposed truncated Q statistic, the truncated residuals presented in Figure 2 (b) are obtained. In this case, the PCA residuals are firstly auto-scaled by their in-control sample mean and sample standard deviation. Afterwards, the allowance threshold is subtracted from the scaled residuals. The truncated residuals lower than zero (*i.e.*, bellow the allowance threshold) are set to zero. Following these operations, the irrelevant residuals are removed from analysis, while the fault's effect is highlighted. In this case, the contribution of the faulty variable to the truncated Q statistic is 45.6 %. Therefore, the fault has a significantly higher contribution to the monitoring statistic, which in turn improves the detection capability.

3.2. Real Case Study: Monitoring of Printed Circuit Boards

To further validate the proposed methodology, it was applied to an industrial Surface Mount Technology (STM) process of Bosch Car Multimedia Portugal. The process concerns the printing of solder paste deposits in copper pads of printed circuit boards (PCB). In this process, each PCBs has 3 507 copper pads and measurements for the (i) area, (ii) height, (iii) volume, (iv) offset in the x-coordinate and (iv) and offset in the y-coordinate are taken for each solder paste deposit. Therefore, each PCB comprises 17 535 variables.

The dataset used in this case study is composed by 3 747 PCBs. Most of these PCBs are within specifications, but a few of them have significant deviations. A training dataset was built by randomly selected 2 000 normal PCBs from the raw dataset. This dataset was split into a calibration dataset and a validation dataset with 1 000 PCBs each. The calibration dataset was used to train the PCA model, while the validation dataset was used to set the control limits of the monitoring statistics. The control limits were determined by taking the $(1 - \alpha/2) \times 100$ % upper percentile of each monitoring statistic computed on the validation dataset. The significance level α was set to 0.01. The remaining 1 747 PCBs were used as a test dataset.

The test dataset was monitored by the standard of T^2 & Q of MSPC-PCA, and the proposed T^2 & Q_{Δ} . The obtained Q and truncated Q statistics are presented in Figure 3. From these results it is verified that the standard Q statistic only detects 5 PCBs as faulty. On the other hand, the proposed truncated Q statistic signals 17 PCBs as abnormal. These detections include 3 PCBs there were already detected by the Q statistic and 14 additional PCBs that were not detected before. In turn, 2 of the PCBs detected by the Q statistic are considered normal by the truncated Q statistic. These PCBs have relatively low deviations in a few pads, and even the standard Q statistic is only slightly above the control limits (see PCBs #518 and #1046 in Figure 3 (a)). Therefore, it is concluded the truncated Q statistic led to a significant improvement in the detection of faulty PCBs.

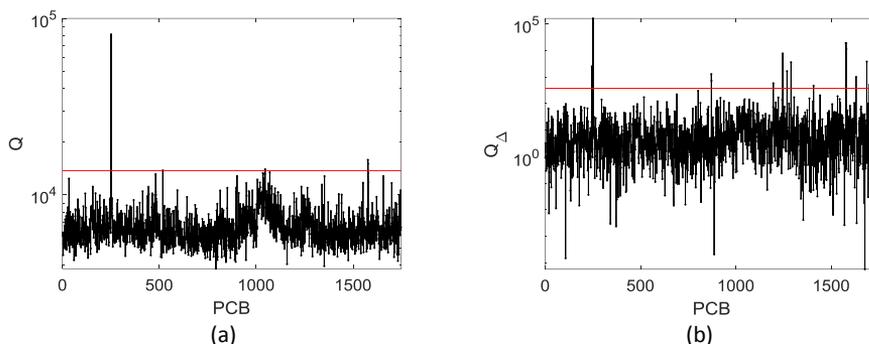

Figure 3 Monitoring statistics for the real case study: (a) Q statistic; (b) truncated Q statistic.

4. Conclusions

The standard Q statistic of MSPC-PCA is prone to sensitivity deterioration as the number of monitored variables increases. This is a consequence of summing the contributions of irrelevant residuals, raising the basal level of the Q statistic and masking the deviations due to faulty variables. To address this limitation, it is proposed to screen for the relevant residuals in each observation and then build a truncated Q statistic using only the relevant residuals. This methodology was tested on a Monte Carlo simulation study and a real case study from an industrial Surface Mount Technology (STM) process. The results show that MSPC-PCA with the truncated Q statistic is much more sensitive than the original formulation, leading to the detection of 14 additional PCBs that were not signaled by the standard Q statistic in the real case study.

The proposed methodology is expected to also improve the detection performance of other monitoring methodologies that monitor the residuals of high-dimensional processes.

Abstract

In this paper we present a study for the development of a predictive emission monitoring system (PEMS) through hybrid modeling. The system was built by coupling a thermodynamic equilibrium model based on the minimization of the Gibbs energy and machine learning (ML) models, such as artificial neural networks (ANN) with different architectures, supporting vector machines (SVM), decision-tree ensembles using histogram-based gradient-boosting (HGB) algorithms, among others. The ML models were trained with real operation data of a gas turbine from one of the three largest thermoelectric power plants in Brazil. The main goal of this study was to generate accurate NO_x prediction models in order to replace the current continuous emission monitoring system (CEMS) in operation. In the hybrid framework, the data-driven models were used to estimate the error of the theoretical model, then, the prediction of pollutant levels was made by the sum of both results. An analysis was made with 6,513 samples split between training and validation sets. Three key performance indicators: (i) maximum absolute error (MAE), (ii) average relative error (ARE) and (iii) the correlation coefficient were evaluated and the results have shown that the hybrid approach can be overall more accurate than the single models alone, at least for the gas turbine in study.

Keywords: PEMS, Machine learning, Hybrid models, Gas turbine

1. Introduction

The climate change debate has promoted a growing collective awareness about the impacts of emissions on the quality of life in general population. Because of that, many governments have created legislation mechanisms in order to monitor, reduce or even prevent the accumulation of environmental hazardous gases in the atmosphere. In this context, stationary emission sources such as thermoelectric power plants are targeted and rigorous monitoring methodologies based on expensive gas analyzers, known as continuous emissions monitoring system (CEMS), have been implanted on site. In order to mitigate those economic impacts, nowadays many countries have regulations for the implementation of virtual monitoring approaches such as the predictive emissions monitoring system (PEMS), a model-based software that can estimate emission levels using common measured process variables, as a less expensive alternative to the CEMS technology (Hadjiski et al., 2005).

Thermoelectric power plants, which, in most cases use natural gas as fuel in gas turbines, still represent around 8.3% of the overall Brazilian power generation. The main concern of local environmental agencies is the release of greenhouse gases to the atmosphere, such as the CO_2 , and other pollutants as the NO_x . Because of that, the national air quality control program (PRONAR) establishes the emission tolerance levels and requires their constant monitoring.

Many successful case studies of PEMS application, mostly using data-driven models, have already been presented in literature, a full-detailed review can be found in Si et al. (2019). However, the major challenge that still persists is the (high) dependence on industrial data for the model development. In many plants, for example, it is impossible to collect an ideal and rich data-set due to safety and operational constraints or even a flawed controlling system.

Despite being a low-complexity equipment, gas turbines have several design specifications that vary according to each manufacturer. Because of that, most of the commercially available PEMS use data-driven models in their conception (Allaire et al., 2007). It is undeniable that data-driven models such as neural networks are, by far, easier to obtain and to use in real-time industrial processes than first-principles ones. However, the quality of the prediction system becomes strongly dependent on the quality of the data used in the modeling. This could be a problem, especially in poorly instrumented factories where data reliability is a real issue.

We present, in this work, a hybrid approach for the NO_x emission modeling in a gas turbine fed with natural gas from a large thermoelectric industrial unit. This approach is based on the coupling of: (i) a thermodynamic equilibrium model obtained through the minimization of Gibbs free energy of the combustion reaction system; and (ii) machine learning models such as neural networks of several architectures, supporting vector machines, and decision-tree ensembles used to predict the phenomenological modeling error. Those ML models were built with a limited set of real operation data, as described in the following section. A more detailed review on hybrid modeling can be found in Sansana et al. (2021).

2. Methodology

2.1. The case study

The present case study focuses on a single gas turbine from the *Termorio* power plant, which has a total production capacity of 1,058 MW. The gas turbine in analysis operates around 100 MW through a combined cycle (see Figure 1), that is, the residual heat from the natural gas combustion is recovered in a boiler to produce steam. Then, the steam is sent to a steam turbine generating additional power. In this particular case, there is no supplementary combustion in the boiler.

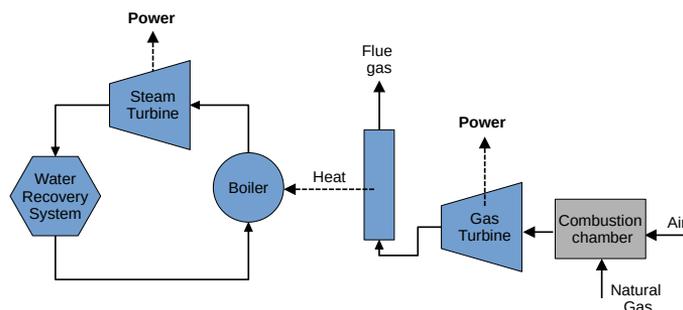

Figure 1: Combined cycle for power generation.

2.2. Thermodynamic model

The Gibbs free energy minimization is a classic approach for equilibrium calculations in chemical reactions. The problem can be formulated as

$$\min_{\mathbf{n} \in \mathcal{N}} G(T, P, \mathbf{n}) \quad (1)$$

subject to the following equality constraints, corresponding to the atomic balances:

$$\sum_j a_{i,j}(n_j - n_{f,j}) = 0 \quad (2)$$

where G is the Gibbs free energy, T and P are the temperature and pressure in the combustion chamber, \mathbf{n} is the equilibrium composition (in moles), $n_{f,j}$ is the feeding composition, and $a_{i,j}$ are the coefficients of the atomic balances matrix; i represents an atom in a species j . The optimization problem in Equations (1) and (2) can be solved with the Lagrange multipliers method, resulting in the non-linear algebraic problem (Smith et al., 2001):

$$\begin{bmatrix} \Delta G_{f,j}^o + RT \ln(\phi_j) + \sum_i \lambda_i a_{i,j} \\ \sum_j a_{i,j}(n_j - n_{f,j}) \end{bmatrix} = 0 \quad (3)$$

where $\Delta G_{f,j}^o$ is the Gibbs free energy of formation of the species j calculated from the database available in McBride et al. (2002), ϕ_j is the fugacity coefficient calculated by the SRK equation of state, and λ_i are the Lagrange multipliers. The system in Equation (3) was implemented in the process simulator EMSO (Soares and Secchi, 2003).

2.3. Machine learning models

Several machine learning models were used within the hybrid modeling framework. They were built considering the same ten input variables (features): (i-ii) temperature and pressure; (iii-vii) the fuel composition (methane, ethane, propane, nitrogen and CO_2); (viii) fuel flow rate; (ix) overall flue gas flow rate; and (x) output turbine power. The predicted output variable (label) is the NO_x concentration in the flue gas. It is worth pointing out that each architecture was trained 10 times, and only the best results of each kind were used for results comparison.

A total of 6,513 sampling points split between training and validation sets were used. The data were obtained directly from the industrial unit data historian within the period from Jan/2015 to Dec/2015. A minor data cleaning was performed to remove inconsistent samples. The training set was created with the first 70% of the samples (January to mid-September), and the validation set with remaining 30% (mid-September to December).

Among the different ML models, we highlight the structured neural network (SNN) in Figure 2. The SNN has two hidden layers, each one with 10 and 9 nodes, respectively. Because the turbine output power is strongly correlated with the NO_x concentration, we chose to bypass the hidden layers and connect it straight to the output layer, thus, giving more weight and relevance to the neural network parameters associated with this input. The SNN was built in Python with the PyTorch library.

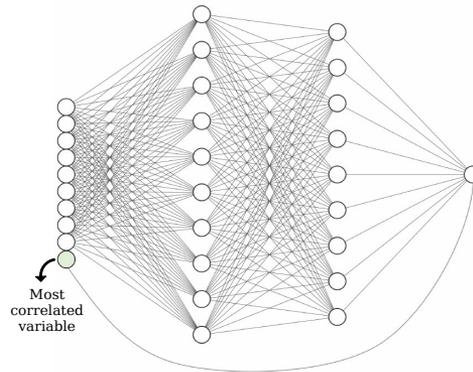

Figure 2: Structured neural network used within the hybrid modeling framework.

2.4. Hybrid model

The hybrid model architecture is presented in Figure 3. In this framework, the ML models are used to make predictions on the phenomenological modeling error, instead of the NO_x concentration itself. Then, the output of both models are combined in order to make the actual prediction:

$$y_{\text{predicted}} = y_{\text{model}} + \sigma_{ML} \quad (4)$$

The model was built in two steps: (i) the thermodynamic simulations to obtain the baseline prediction (using only the information on the input variables); and (ii) the ML training with the same input variables, and the modeling error as the output variable.

2.5. Accuracy evaluation

Three main performance indicators that are required by the US legislation were used to evaluate overall accuracy of the models, which are: the maximum absolute error (MAE)

$$MAE = \max_{i \in \{1, N\}} (|y_{p,i} - y_{m,i}|) \quad (5)$$

The average relative error (ARE)

$$ARE = \frac{1}{N} \sum_{i=1}^N \frac{|y_{p,i} - y_{m,i}|}{y_{m,i}} \quad (6)$$

and the correlation coefficient (CC)

$$CC = \frac{\sum_{i=1}^N (y_{p,i} - \bar{y}_p)(y_{m,i} - \bar{y}_m)}{\sqrt{\sum_{i=1}^N (y_{p,i} - \bar{y}_p)^2} \sqrt{\sum_{i=1}^N (y_{m,i} - \bar{y}_m)^2}} \quad (7)$$

where y_p and y_m are the predicted and the measured values, respectively, and N is the number of samples.

3. Results and Discussion

The time window with the training and test data sets used for the ML models is presented in Figure 4. The data was split congruently because our main concern was the extrapolation potential of such models, and not the interpolation one. The prediction results for all of the models using the test set are presented in Figures 5 and 6 for: (a) the Gibbs model; (b) a neural network like the SNN, but without the bypass; (c) the SNN; and (d) the hybrid model coupling Gibbs and SNN models. The performance indicators are presented in Table 1. It can be seen, in the time series of Figure 5, that the hybrid model (5d) can capture better the data tendency in comparison with the other models (5a-5c). The accuracy can be more easily perceived in the histogram of Figure 6, as one can observe that the distribution of the absolute errors for the hybrid model is more concentrated in the range of 0 to 1 ppm than the other models.

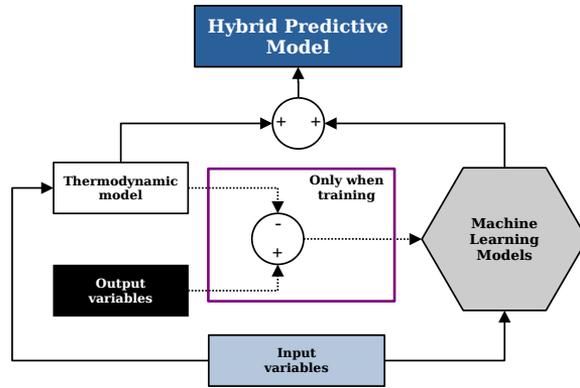

Figure 3: Architecture of the hybrid model predictor.

Figure 4: Training and test data sets.

Table 1: Performance indicators for some of the built models¹.

Model	MAE	ARE (%)	CC (%)
Gibbs	5.26	6.30	21
SVM	5.77	5.94	19
HGB	4.20	6.19	64
NN	4.08	4.20	27
SNN	3.87	4.01	54
Hybrid	3.62	3.91	69

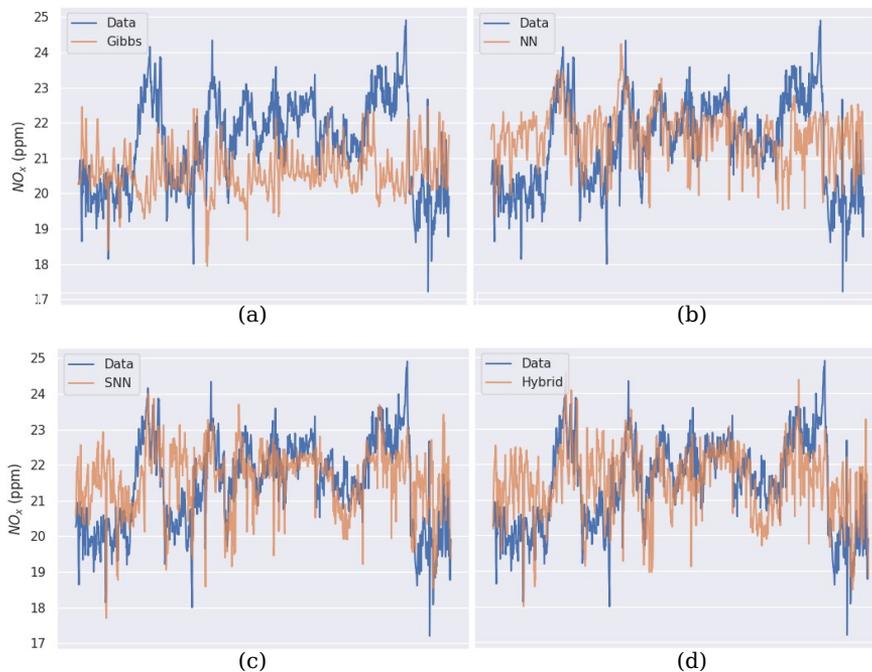

Figure 5: NO_x predictions: Time series for (a) Gibbs model, (b) Neural network model, (c) Structured neural network model, and (d) Hybrid model (Gibbs + SNN).

Those results show that the Gibbs model, despite being oversimplified, can describe reasonably well the levels of NO_x concentration, even though it has no estimated parameters, with an average error of 6.3%. However, it cannot capture the modulation of the output variable (it has a correlation of only 21%). This is probably due to the existence of three-dimensional temperature gradients inside the combustion chamber, forming different equilibrium regions, while only one temperature is specified on the model (the turbine output temperature).

Analyzing the two neural networks, we can see that the bypass used in the SNN improved its prediction capacity (its error is 5 to 6% smaller). The main reason for SNN's increased performance is that the parameters associated with the most correlated variable has more meaning, as the physical relation between the input and output is more preserved, improving the network awareness, as

¹Due to the lack of space, additional results for the SVM and HGB models will not be discussed in this paper.

shown by the correlation coefficient that is twice the NN's value.

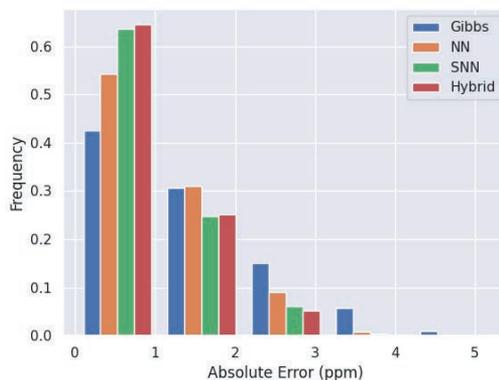

Figure 6: Histogram of the absolute errors for the analyzed models.

Then, we have the hybrid model using the SNN, which was chosen for being the best tested ML model. It can be seen that it is more accurate than the models alone, reducing the SNN's MAE by 6% and Gibbs's by 32%. However, the greatest improvement is in the correlation coefficient, that is three times higher than Gibbs's and 27% better than the SNN's. Although those correlation values can still be considered low, taking into account the high quantity of noise in data and the low variability in the turbine's range of operation, the results obtained so far are very promising, as the errors are also low, and visually the model can represent data tendency.

4. Conclusion

A hybrid approach for the modeling of NO_x emissions on gas turbines was presented. The hybrid predictor built with neural networks and thermodynamic equilibrium equations proved to improve the overall accuracy of each model considered alone, having errors up to 37% smaller and correlation coefficient up to three times higher. The quality of the industrial data is a key factor to improve the prediction potential, as the low variability and high quantity of noise reduce the quality of the data-driven modeling.

Abstract

Artificial intelligence-based models (AI) and in particular Graph Neural Networks (GNN) are considered a more promising approach for modeling molecular properties compared to the use of traditional descriptor-based models due to their enhanced ability to express the structural information and their ability to better generalize to unseen data. However, their 'black box' nature and the lack of transparency and interpretability could hinder their wider acceptance and usage. In this work, we combine knowledge-based molecular descriptors and two AI-based concepts, the junction tree model and the attention mechanism to produce an interpretable model. The model is trained on the enthalpy of formation of organic compounds and the insights gained are highlighted and compared to the insights gained from models with a higher level of interpretability such as the group-contribution models. The results obtained show consistency with the insight gained in the form of the relative importance of the molecular sub-structures to the overall property.

Keywords: Molecular Property Prediction, Quantitative Structure-Property Relations (QSPR), Machine-Learning (ML), Graph Neural Networks (GNN), Interpretability

1. Introduction

Integrating AI-based approaches into molecular property prediction models such as deep neural networks (DNN) has recently gained popularity. These models relate the structural information to desired property numerically are called quantitative structure-property relations (QSPR). An example of such a model is the graph neural network (GNN), which represents atoms and bonds by a set of nodes connected through edges respectively in the graph. However, despite these models achieving state-of-the-art for many properties, a major drawback is their black-box nature and the absence of interpretability. In this context, interpretability can be defined as insight into the relative importance of the molecular substructures towards the target property.

The aspect of interpretability should be considered significant to the scientific understanding of the parts of the molecule (substructure or functional group) that influence a specific property and evaluate whether the insights provided from the model coincide with those obtained from knowledge. (Coley *et al.*, 2017) compared molecular representation obtained from DNN with another known descriptor extended circular fingerprints (ECFP4), claiming there is a mapping relation between atoms and indices in representation. Accordingly, the most critical fingerprint indices can be found by estimating these mapping coefficients. But in classic GNN, the architecture would aggregate all nodes, eliminating the contributions from individual atoms.

The attention mechanism has since become a significant concept in neural networks, where importance weights are learnable through the backpropagation, enabling the model to focus on a specific part of the knowledge gained. (Veličković *et al.*, 2018) successfully introduced a self-attention mechanism into a classical GNN, updating the target node by summing up neighborhood nodes with attention weights. The attention mechanism has also been incorporated on a graph level (molecular level) to produce a learnable readout function by considering the molecule as a virtual node into which all node information is aggregated, e.g. AttentiveFP developed by (Xiong *et al.*, 2020).

In this work, we combine the original AttentiveFP with group-fragments from the well-known MG group-contribution models (by (Hukkerikar *et al.*, 2012)) to build a new architecture with an increased prediction accuracy and with the ability to show the importance of each fragment simultaneously. The insights gained are then compared to those gained by group-contribution models where the magnitude of the group contribution reflects the relative importance of the groups towards the overall property.

2. Method

2.1. AttentiveFP

The *Attentive Fingerprint* (AFP) by (Xiong *et al.*, 2020) is employed to illustrate the importance of single atoms to the target property in molecule-scale. The application of the attention mechanism makes this model capable of calculating the weights of information and assigning importance to each node (atom) w.r.t. the prediction. The aggregation or pooling employed differs from those usually used in other GNNs (based on summation or min-max pooling), the predicted context C^l at layer l in AttentiveFP is derived from a weighted summation readout operation as seen in E.q.1.

$$C^l = \sum \alpha_i^l \cdot h_i \quad (1)$$

In E.q.1 α_i^l refers to the coefficient weight of atom feature h_i at layer, l contributing to the property prediction. The implementation of the *softmax* function as an activation function to compute attention weights, normalizes the values into a range from 0 to 1, representing the degree of importance of every single atom.

2.2. Group contribution models and molecular Fragments

Group-contribution models use an occurrence vector/matrix to represent the molecule where each element indicates the number of times a specific fragment/substructure is present in the molecule. The fragments or groups considered in this work consists of the first-order groups developed by (Hukkerikar *et al.*, 2012). These fragments present no to little overlap and are mostly defined based on chemistry and thermodynamic knowledge rather than heuristics. Property models based on the group contribution model have a generic form as shown in Eq.2, where $c_y^{(x)}$ and $n_y^{(x)}$ are the contributions and occurrence of group y of order x respectively.

$$\hat{y} = \sum_i^{220} n_i^{(1)} c_i^{(1)} + \sum_j^{130} n_j^{(2)} c_j^{(2)} + \sum_k^{74} n_k^{(3)} c_k^{(3)} \quad (2)$$

As mentioned earlier, the first-order groups defined are the most knowledge-rooted groups out of all three scales (orders). If one specific motif (or group) has higher contributions to the target property, it is fair to assume that this group is overall more important compared to other present groups. The values of contributions are accessible in

previous work presented by (Hukkerikar *et al.*, 2012). Since sequential regression of the group orders is used to obtain the group contribution, the property is described well enough using the first-order groups only and the higher orders can be considered as a correction to the approximations gained by the first-order term.

2.3. Junction Tree

(Vats and Nowak, 2014) proposed the junction tree algorithm (also called 'Clique Tree') consisting of a method for extracting modified graphs (or sub-graphs) from an original graph by branching the supernodes into different smaller nodes, similar to a tree. (Jin *et al.*, 2021) used this concept to build a tree-structured architecture to aggregate features of some particular nodes into bigger super-nodes. In this work, the fragment-based networks use this tree structure to build a new graph for further training, as shown in Figure 1, the tetranitromethane molecule can be split into four supernodes (S_1, S_2, S_3, S_4) consisting of their corresponding structures in the original graph.

2.4. Architecture

The architecture of the new model is depicted in Figure 1. The original molecular graph is broken down into fragments and then fed in as features into the prediction model. Here some prior knowledge for division is introduced to guide the fragmentation process. Therefore, a junction tree (tree-structured scaffold over fragments) can be generated automatically, where the features in supernodes and original nodes are regarded as the root and branches respectively during back-propagation. The prepared super nodes features from the first block are used as the initial states for the node features in the last block. Note that the features of the edge connecting each of the fragments in the original graph are kept as attributes of the new edge between supernodes in situ. In the last step, the new graphs are forwarded to an *AFP* block to compute the importance of each fragment to the predicted property. Due to the employment of prior knowledge on group contribution, the model is named *Attentive Group Contribution (AGC) Model*. Similar to the attentions in *AFP*, the atom feature h_i in Eq.1 can be replaced by the fragment feature S_i obtained from the junction tree, thus the new attention weights α_i^1 can then represent the degree of importance of fragments instead.

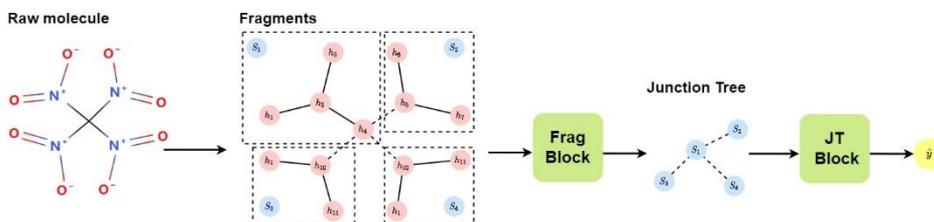

Figure 1: Illustration of Attentive Group Contribution (AGC) workflow for tetranitromethane

2.5. Data

The models were trained on the enthalpy of formation of 741 organic compounds obtained from the AICHE DIPPR database (Wilding *et al.*, 2017). The property was chosen as it exhibits a linear trend for the homologous series and thus the relative importance of the group fragments obtained here can be readily compared with the relative contribution of these fragments in the group-contribution model developed in (Hukkerikar *et al.*, 2012).

2.6. Visualization

In addition to visualizing the relative comparison between different atoms/fragments, the relative attention $\hat{\alpha}$ is introduced instead of weights obtained directly to overcome the

potential issue of bad distinction when all attention weights are lower than 0.5 and to account for the relative size of the molecule.

$$\hat{\alpha}_i = \frac{\alpha_i - \alpha_{\min}}{\alpha_{\max} - \alpha_{\min}} \quad (3)$$

α_{\min} and α_{\max} are the maximum and minimum of attention weights computed in a single molecule. A blue-red sequential color map is used to visualize the relative importance of atoms/ fragments to molecules, the motifs marked with red refers to high significance ($1 > \hat{\alpha}_i > 0.5$) while blue tells the specific motifs are not critical ($0 < \hat{\alpha}_i < 0.5$). Darker colors represent the importance closer to 0 (least important) or 1 /most important).

3. Results and Discussion

The models obtained all provide good predictions on the data. The R2 and mean absolute error (MAE) of *AGC* are 0.99-0.99-0.99 and 18.4-27.4-22(KJ · mol⁻¹) respectively across training, validation, and testing (8:1:1 ratio). Meanwhile, the *AFP* achieves 0.99-0.99-0.99 and 21.2-23.2-28.7(KJ · mol⁻¹) respectively for the three data folds.

To provide insights into the interpretability of the models, five case studies were selected to inspect and compare the computed importance of fragments obtained from the AttentiveFP model and the *AGC* model. These case studies include a diverse set of molecular families such as carboxylic acids, halohydrocarbons, benzylamines, acetylenes, and nitrate-esters. The visualization of atoms' importance (relative attention weights $\hat{\alpha}$ calculated by AttentiveFP is demonstrated in Figure 2.I, while the relative attentions of fragments with *AGC* are shown in Figure 2.II.

The importance weights considered are those from the final layer (in terms of the AFP model terminology, the last time-step), the corresponding visualization can be seen in Figure 2.I. The area surrounded by a dashed ellipse is the most significant group based on the scheme defined by (Hukkerikar *et al.*, 2012) and will be considered in this work as the benchmark with respect to the importance of the fragment towards the property value. As seen in Figure 2.I, the *AFP* model fails to reproduce the fragment importance of the GC models for all cases. Furthermore, the atom importance of the same functional groups is inconsistent and changes with increasing carbon chain length for carboxylic acids. For instance, C=O in the carboxyl group shown in butyric acid is more important than the same substructures in acetic acid and propanoic acid, despite only adding CH₂ to the molecules, unlike the true insights of the property. Similar issues also appear when it comes to the rest of the straight-chain aliphatic hydrocarbons, where their corresponding importance/coefficients are consistent neither in the same molecule nor in different compounds among the same family. In both cases of acetylene and nitrate-ester, this model succeed to detect the different substructures like triple bonds and ONO₂ respectively, but the prediction of importance does not adhere to insight obtained from **GC** models. When predicting hexafluoroethane and chloropentafluoroethane, the relative importance of carbon to fluorine are in contradiction.

The *AGC* model developed seems to provide insights that are overall in line with those obtained from the GC models. Considering the first set of molecules are carboxylic acids, as shown in Figure 2.II, the red fragments refer to the acid group *COOH*. In all carboxylic groups tested, the importance of this fragment always shows the highest significance. The raw attention weights reported in Table 1 also confirm this. Note that the parenthesis

marked by † denotes there are multiple of the same groups in the molecule. It is a remarkable fact that the attention weights are not the proportion of groups in a molecule, they instead represent how important these fragments are to the overall structure. Therefore, it is not straightforward to compare them parallel to others in different molecules, especially molecules of different sizes. However, the results obtained here are enough to extract the important part considering every single molecule individually. In the GC method, the absolute contribution of $COOH$ is higher than the other two groups CH_2 and CH_3 , which is consistent with the result we obtained here.

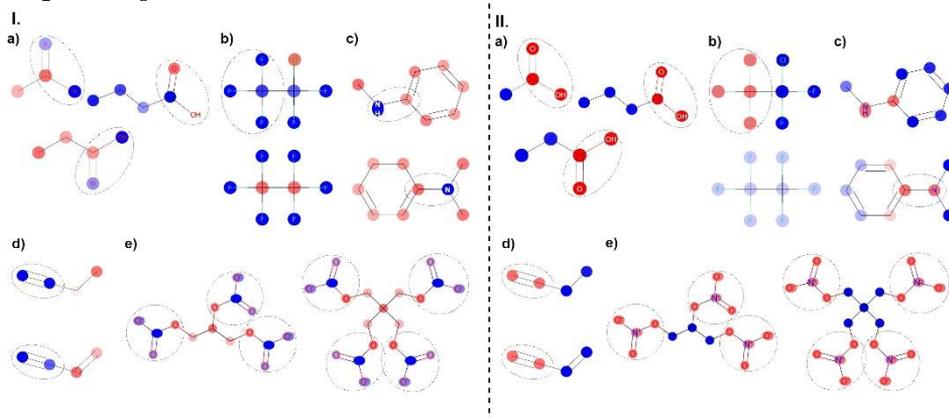

Figure 2: Visualization of atom significance by AFP (I) and AGC (II) for Carboxyl acids (a), Halohydrocarbons (b), Benzylamine (c), Acetylene (d), and Nitrate-esters (e)

Table 1: Raw attention weights of each fragment to final prediction on carboxylic acids

First-Order Groups	Acetic acid	Propionic acid	n-Butyric acid
COOH	0.6275	0.5365	0.4830
CH ₂	-	0.2397	(0.1702, 01782) [†]
CH ₃	0.3725	0.2238	0.1685

The second set of molecules shows the different fragments of CF_3 and $CClF_2$, where the only difference is the halo-atoms connected to carbon. Unlike the prediction done by the *AFP* model and seen in Figure 2.II, the architecture successfully detects the equal importance of fragments and highlight the more significant contribution from the group CF_3 than $CClF_2$. The raw attention weights of these two are reported in Table 2.

Table 2: Raw attention weights of each fragment to final prediction on halohydrocarbon

First-Order Groups	Chloropentafluoroethane	Hexafluoroethane
CClF ₂	0.3412	-
CF ₃	0.6588	(0.5, 05) [†]

The third and fourth sets are the representations of aromatic amines and carbon-carbon triple bonds respectively. In both cases, the new model manages to most distinguish fragments circling by dashed cycle. Meanwhile, it fixes the predictions of the same atoms at the same location in different molecules. In other words, the common part of various derivatives is expected to be extracted by similar contributions. The last set depicts the ONO_2 groups in nitrate-esters not only have equal contributions in the same molecular but also highlight this fragment as the most significant group.

The hybrid combination with group contribution theory adds a layer of interpretability compared to a purely data-driven approach, establishing the visualization of prediction on basis of chemists' knowledge on property prediction. However, due to the limitation of techniques, such interpretation can only be presented in the form of case studies and not in a general fashion. It is expected to obtain the influence of every single part on the overall prediction, and then it has a chance to reveal the structures of neural networks by adding or masking particular segments.

4. Conclusions

The combination of attention mechanism and prior knowledge adds a level of interpretability to AI-based models compared to a purely data-driven approach, establishing the visualization of prediction on basis of chemists' knowledge on property prediction. In this work, several cases are considered to test the performance and interpretability. By doing this, it is expected to get the effect of each part to the final prediction. Unlike the weights computed by the original *AFP*, *AGC* is able to present results better in accordance with a chemists' intuition. Moreover, the insights provided through the relative importance of the various molecular fragments are consistent with insights gained through the widely-accepted group-contribution models. This work can be beneficial to improve the transparency of models and overcome the possible objection from communities towards these data-driven methods. However, the extent of interpretability must be further tested on other linear and non-linear properties to assess the true extent of interpretability provided by the model developed herein. There will be one day a universal framework instead of isolated case studies can be developed to interpret the inner side of neural networks in the field of chemistry.

Abstract

With the advent of Industry 4.0, predictive maintenance is becoming increasingly popular. It has the potential to improve manufacturing capabilities by identifying equipment faults and preventing the shutdown of the production process. The sheer popularity of predictive maintenance has caused an abundance of research into developing new classification algorithms to successfully predict faults. However, more work is still required in the physical application of predictive maintenance to full industrial plants than in the development of new algorithms using single machines. This work focuses on the application of machine learning for predictive maintenance by prioritising a robust comparison of methods to investigate the accuracy of readily available classification methods. To achieve this, we used a large Fischertechnik (FT) model factory as a realistic and challenging case study to provide data rich with sensors and actuators such as that found in a cyber-physical production plant. We present a rigorous approach to compare and evaluate classifiers by analysing various error metrics. It was found that the Quadratic Discriminant Analysis (QDA) classifier performed the best with respect to the FT model factory dataset. The significance of the results provide validation that readily available machine learning methods are accurate enough to provide predictive maintenance and offer vital analytics. It further proves its suitability for robust maintenance scheduling in many industrial plants. It is expected that, the integration of machine learning and maintenance can significantly improve process safety and save money.

Keywords: predictive maintenance, machine learning, process safety, classification models

1. Introduction

Machine maintenance is of paramount importance to the process industry with regards to both safety and effectiveness. A poor maintenance system can be catastrophic to an organisation in terms of both performance and safety as it has a direct impact on costs, productivity, quality and accidents. It is thus common practise for companies to actively engage in maintenance activities for equipment items within the plant. This is mainly managed through three types of maintenance (Carvalho et al., 2019):

1. Corrective maintenance - maintenance tasks are conducted when a machine fails.
2. Preventative maintenance - maintenance tasks are conducted on a periodic schedule, also known as scheduled maintenance.
3. Predictive maintenance - uses techniques to estimate when maintenance is required.

Predictive maintenance is becoming increasingly popular with the transformation towards Industry 4.0 where process automation and digitisation are becoming the norm (Gilchrist, 2016). One of

the key advantages that Industry 4.0 presents is the abundance of data, which can be used in the control and operation of a plant, improving production efficiency and managing process safety. Predictive maintenance enables the estimation of when maintenance is required on a machine by continuously monitoring sensor information over time (Yan et al., 2017). The implementation of predictive maintenance has the potential to improve manufacturing capabilities by identifying equipment faults and preventing the shutdown of the production process. Currently, Industry 4.0 (Lee et al., 2014) is advancing due to Internet of Things (IoT) technologies providing many sensors that records data enriched by the control commands of actuators. This is transforming manufacturing environments into complex cyber-physical production systems (Gunes et al., 2014). The data measured by these sensors provides an invaluable resource that can be used to train a machine learning method to detect and predict failures. Predictive maintenance improves the decision-making process in manufacturing environments as faults can be predicted before they occur.

Machine learning methods have been increasingly applied to predictive maintenance applications (Carvalho et al., 2019). The most common method uses classification to predict a fault or failure occurring (Susto et al., 2015). Additionally, regression techniques have been used to predict Remaining Useful Life of machines (Van Horenbeek and Pintelon, 2013) and forecast industrial aging processes (Bogojeski et al., 2021). A systematic literature review by Carvalho et al. (2019) showed that the most common machine learning algorithms used are Random Forest, Neural Networks, Support Vector Machine and k-means clustering. Additionally, they found each machine learning method proposed was applied to a specific piece of equipment, for example turbines (Kumar et al., 2018), motors (Dos Santos et al., 2017) and compressors (Prytz et al., 2015). For this reason, it becomes difficult to compare various machine learning algorithms as each study uses vastly different data for validation. Additionally, Industry 4.0 is evolving at such speeds, applying predictive maintenance to just one piece of equipment is not useful when the data collected enables analysis on the whole production plant. As such, further research that compares proposed predictive maintenance strategies instead of developing novel machine learning algorithms is necessary (Carvalho et al., 2019). There is also an abundance of research solely concentrating on developing new machine learning techniques that use historical data to predict when maintenance is required, the integration of predictive maintenance remains briefly addressed in literature.

As noted, more work is required to apply predictive maintenance to full industrial plants and then to integrate it as a method to improve site maintenance. Therefore, this paper focuses on addressing the first issue applying predictive maintenance techniques to a large cyber-physical production system. We present an investigation into readily available classification algorithms for predictive maintenance by using them on a large collection of machine sensor data. We then consider the prospect of implementing the results as an initial tool in a promising application to develop robust maintenance scheduling in an industrial plant. Further, this study provides a rigorous approach to compare and evaluate the classification models, analysing various error metrics and ultimately choosing a machine learning method which can be used for further analysis.

2. Case Study Data

The comparison of predictive maintenance techniques requires the availability of historical maintenance and complex sensor reading data related to an industrial plant. However, the availability of real-data from industry is extremely limited due to confidentiality issues. For this reason, this study uses data provided by a cyber-physical production system developed by Klein and Bergmann (2019). The large Fischertechnik (FT) model factory records sensor readings enriched with control commands providing a realistic and challenging case study for detecting faults. The production plant consists of five workstations as described in an ontological knowledge base (Klein et al., 2019). Altogether, the FT plant consists of 14 machines which use 61 sensor readings indirectly

Table 1: A summary of the data used to train and test predictive maintenance techniques

Machine No.	Train	Test
No Fault	22,763	3,233
1	9	2
2	14	24
3	207	234
4	21	6
5	23	27
6	7	2
7	28	45
8	105	97
9	36	31
10	16	11
11	13	20
12	42	34
13	6	0
14	13	4
Total	23,303	3,770

related to each machine. Classification machine learning models are applied to the data providing an insight into the promising tools readily available to prevent failures in industry.

The large FT plant provides a realistic and challenging case study for detecting faults on 14 machines using the 61 sensor readings as input variables for predictive maintenance. Table 1 shows the raw data which is generated by multiple run-to-failure simulations where the sensor readings and the corresponding classes are recorded. Altogether, the data includes 27073 data points recording 28 different types of faults such as driveshaft slippage in the conveyor. In this work, the type of fault itself is not important as the objective of the predictive maintenance is to predict which machine a fault occurs on.

An investigation of this type requires a consistent methodology to compare each classification models used on the FT simulation data. Therefore, the full data is divided into training and test data based on complete simulations from start to finish. Each individual simulation that leads to a fault is included in either the test data or the training data (Klein and Bergmann, 2019). This means a fault that continues for multiple time steps will not be found in both training and test data. A summary of the classification data is shown in Table 1, where the clear split between training data and test data can be seen for each of the 15 classes.

3. Predictive Maintenance Methodology

This work compares five supervised classification techniques using the Python library, Scikit Learn (Pedregosa et al., 2011). The data described in Section 2 is used as a case study to test the following classification algorithms:

1. Decision Tree (DT) (Breiman et al., 2017)
2. Random Forest (RF) (Breiman, 2001)
3. Neural Network (NN) (He et al., 2015)
4. AdaBoost (AB) (Hastie et al., 2009)

5. Quadratic Discriminant Analysis (QDA) (Friedman, 1989)

The classification models are tested using the case study data and by calculating error metrics. These enable a robust comparison of prediction techniques by comparing the predicted labels to the true observed labels.

The Precision (P) score is defined as a ratio from the number of true positives (T_p) over the number of true positives plus the number of false positives (F_p):

$$P = \frac{T_p}{T_p + F_p} \quad (1)$$

The Recall (R) score is also a ratio. However, for this metric it is the number of true positives over the number of true positives plus the number of false negatives (F_n):

$$R = \frac{T_p}{T_p + F_n} \quad (2)$$

To combine both the Precision and the Recall, the F1-Score weights both Recall and Precision together as a harmonic mean:

$$F1 = 2 \frac{PR}{P+R} \quad (3)$$

Finally, the Accuracy (A) is the total number of true predictions (both true negatives (T_n) and T_p) as a percentage to the total number of predictions:

$$A = 100\% \times \frac{T_p + T_n}{T_p + T_n + F_p + F_n} \quad (4)$$

4. Results

4.1. Comparison of Classifiers

Figure 1 shows the QDA achieving the highest accuracy of 88.3% and all the other classification methods achieved scores above 85%. However, predictive maintenance data commonly shows a significant imbalance between classes and the same is true for the FT model factory. Out of a total of 3,770 data points, 3,233 are in the class "No Fault", therefore, constant predictions of "No Fault" would achieve an accuracy score of 85.8%. Table 2 show the weighted averages obtained for the Precision, Recall and F1-Score. Once again, we found that the QDA performed the best achieving the highest scores all round. Statistically, the significance of the results provide validation that the QDA is the best choice of method for this given dataset.

The results for all five machine learning models are satisfactory, but to get the best from predictive maintenance, trust in the predicted faults is of highest priority. This work has shown a methodology for analysing machine learning models to robustly choose the best method. For the given case study, the QDA was the chosen classification model for predictive maintenance.

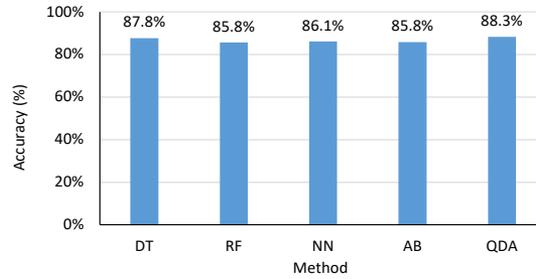

Figure 1: The accuracy score measured for the different classifiers.

Table 2: Resulting diagnostic values from the predictive maintenance

	Precision	Recall	F1 Score
Decision Tree	0.839	0.878	0.838
Random Forest	0.735	0.858	0.792
Neural Network	0.788	0.861	0.799
AdaBoost	0.736	0.858	0.793
Quadratic Discriminant Analysis	0.880	0.883	0.877

Table 3: A confusion matrix showing the condensed results from the QDA.

		True Label		Total
		No Fault	Fault	
QDA Predicted Label	No Fault	3086	95	3181
	Fault	147	442	589
Total		3233	537	3770

4.2. QDA Results

For predictive maintenance, a closer inspection of the label "No Fault" is important because incorrectly predicting a healthy state for all the machines would lead to undetected faults. Conversely, incorrectly predicting a fault (irrelevant to which machine it is on) would result in unnecessary maintenance. Table 3 shows the QDA results in a confusion matrix focusing on the class label "No Fault" by grouping the 14 machine fault classes into just one class, called "Fault". The confusion matrix shows the amount of predicted labels that were in the correct and incorrect label.

Previously, the accuracy of the QDA was given in Figure 1 with the QDA making 441 false predictions out of 3770 data points. Table 3 shows the QDA predicted 95 "No Fault" which were actually "Faults". Additionally the QDA falsely predicted 147 "Faults". This means 45.1% of the original false predictions (199 out of the 441 false predictions) did correctly predict a fault but on the wrong machine. Altogether, the QDA performed well, correctly predicting a fault 442 times out of 537 total faults and correctly predicting no fault 3086 times out of 3181. Therefore, when considering the class "No Fault" only, the QDA achieved an accuracy score of 93.6%. Showing the good performance from the QDA in terms whether a fault has occurred or not.

5. Conclusion

In this paper, we analyse classification models to be used for predictive maintenance in a cyber-physical production system. Confidentiality issues cause a lack of real-data. Hence, we conducted the robust comparison of machine learning classifiers using a case study from a Fischertechnik (FT) simulation model (Klein and Bergmann, 2019). Results showed that the machine learning

methods adopted were accurate in predicting faults, and suitable for predictive maintenance. The QDA classifier was also shown to be the best for this given dataset, achieving an accuracy of 88.3%. Although, when considering the class label "No Fault", the QDA achieved an accuracy of 93.6%, showing good performance from the algorithm for predictive maintenance.

In conclusion, this study investigated the performance of predictive maintenance on a complex cyber-physical production process. Accurate results from all five classifiers have shown that the machine learning algorithms are capable of predictive maintenance in Industry 4.0 when larger amounts of sensors are being used to analyse plant performance.

Future work could use the chosen predictive maintenance classifier to provide a route for robust maintenance scheduling by using it within maintenance workflow. Integrating machine learning techniques such as predictive maintenance, time estimation and schedule optimisation will enable smart maintenance policies to be implemented. This could provide a successful route for many industrial plants to significantly improve process safety and save money.

Abstract

An evolutionary framework has been developed for techno-economic assessment at a decision-making level. A Master-Worker strategy based on Genetic Algorithms is proposed. It was enhanced with an ad-hoc chromosome redefinition, exclusively designed for techno-economic optimization. Specialized crossover and mutation operators were implemented so that the decision-maker places value on the economy of scale and the efficiency in logistics. The methodology enables to tackle systematically changes in the supply of raw materials and market demand altogether. By way of illustration, the eventual natural gas (NG) winter scarcity in Argentina, where industrial plants are forced to work under low-supply conditions, is discussed. For this case, efficient tactical planning was achieved by means of the optimization of the plants' on/off status, together with the assessment of the weekly NG amounts to be individually provided.

Keywords: Techno-economic assessment, Optimization, Genetic algorithm, Planning

1. Introduction

Increasing productivity is a key issue in Industry 4.0. From this perspective, methodologies to achieve operational excellence with further cost reductions have been gaining importance. Decision-making can be facilitated by merging both the production and market scenarios. In an Industry 4.0 environment, techno-economic assessment is crucial in order to achieve a competitive advantage. Its benefits go beyond saving money since it also comprises sustainable actions towards environmental protection.

In this century, interest is focused on the simultaneous improvement of both energy consumption and production. For the operational planning of petroleum supply chains, Neuro and Pinto (2004) applied a large-scale mixed-integer nonlinear programming (MINLP) model. He optimized techno-economically a real-world corporation through the adoption of different strategies. Nowadays, an integrative strategy called enterprise-wide optimization (EWO) is being explored. It deals with the optimal operation of manufacturing facilities, which includes planning, scheduling, real-time optimization and inventory control. In particular, electrical supply-chain management under economic crisis was addressed by Manenti (2013), who proposed a MINLP optimization

methodology that merges enterprise-wide and operational aspects to plan the production of complex networks under a low energy offer for high demand. For EWO, Scholz Dias (2019) recently proposed a combination of data-driven methods and classical optimization techniques, partially incorporating artificial intelligence to the analysis. Techno-economic optimization problems can be challenging to solve, due to their complexity, nonlinearity and potentially high dimensionality. Then, it is worthwhile to devise alternative techniques that deal with complex optimization problems with complicated constraints. Nature-inspired metaheuristic algorithms have demonstrated some promising results in diverse applications where the optimization problems are tough. In particular, genetic algorithms (GAs) tend to be flexible, efficient, highly adaptable and easy to implement. Moreover, GAs can efficaciously be applied in broad practical issues by tailoring both the individuals and the genetic operators to the specific combinatorial problem under study.

2. Problem statement

Throughout history, there have been circumstantial cuts in the supply of non-renewable energy sources, mainly caused by restrictions on the supply side. In this sense, the global recovery in the post-pandemic demand for goods and services was not matched by an equivalent increase in energy supply. In particular, production companies have had their NG supply reduced. Moreover, given the excessive demand in winter seasons (Shuquan et al., 2018) and the lack of investment in infrastructure and production (De Meio Reggiani et al., 2019), both residential and industrial consumption will have to confront higher bills and/ or reductions in NG supply. Therefore, it becomes necessary to optimize the distribution of available NG with a business-planning approach.

It is challenging to expand the scope of evolutionary strategies to be able to exploit them in this complex context. In this paper a metaheuristic methodology is proposed in order to address the particular case of industrial plants that have to face the conditions of scarce NG supply. The adopted test case represents a Gas Supply Problem (GSP) that has recently occurred in Argentina since 2005 (De Meio Reggiani, 2018). In this design, a Central Planner optimizes techno-economic aspects, simultaneously considering both the NG demand by industrial plants and the costs associated with transmission.

3. Fundamental modelling

A metaheuristic approach based on Genetic Algorithms (GA) was designed. It is a parallel implementation of a Master-Worker architecture that performs collaborative optimizations. A module (GA-M) is executed by the Master, while the others (GA-W) are executed by the Workers. Both are standard GA procedures that not only differ in the fitness assessment, but in the genetic operators as well. Given a prospective scenario, GA-W is in charge of evaluating its NPV based on NG availability for each plant's production ($Fitness_W$). In turn, GA-M employs a comprehensive objective function that takes into account both plant-processing NPV and transmission costs ($Fitness_M$).

The Master generates at random the prospective scenario for each Worker, which is defined by some binary values. Then, the Worker executes a GA-W in order to find the best individual. As soon as he has found a candidate solution, he reports it to the Master, who uses GA-M to optimize all the scenarios. In this way, every Worker is simultaneously looking for a good solution, while searching for the most promising places in the space of prospective scenarios. Parallel programming was implemented so that the Workers can simultaneously explore different instances. Thus, many cases are solved as quickly as possible to give effective support to the decision-making task.

As to the representation of the solutions, a dual structure of the phenotype was adopted, where boolean and real genes are combined in a single chromosome. In this way, a wide variety of decision-making variables is included for a rolling horizon comprising H weeks. The chromosome structure is exemplified in Fig. 1. A single chromosome is divided in groups corresponding to the weeks in the rolling horizon H . Each of these groups (W_i) contains the information that corresponds to the i -th week. They consist of a set of tuples $W_i = \{S_i, P_i\}$ with $i = 1 \dots H$, where S_i defines a global scenario through p boolean genes from g_1^i to g_p^i , and P_i contains $(n - p)$ real-valued plant features included in the genes ranging from g_{p+1}^i to g_n^i . A weekly NG provision has to be distributed among p plants. Each plant is characterized by f features. Hence, $n = p + fp$.

The example given in Fig. 1 corresponds to the GSP. A total NG provision of 32 Mm³/day

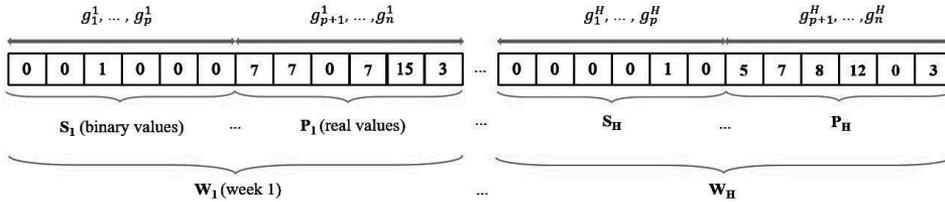

Figure 1. Conceptual representation of a single individual.

for the first week, where this amount has to be distributed among 6 plants with the corresponding NG feed as a single feature ($f = 1$). According to the binary string S_1 , it is proposed that the third plant will be stopped, i.e. $g_3^1 = 1$ and $g_9^1 = 0$.

Both the chromosome choice and the fitness function design are determined largely by the nature of the specific problem that is being tackled. In particular, our goal is to prevent economic losses when the weekly supply of operating industrial gases is forcefully restricted to a lower quantity Q_h^S . Therefore, Eq. 1 must be fulfilled for a time horizon H .

$$Q_h^S \geq \sum_{i=1}^p Q_{i,h} \quad \forall h = 1, H \quad (1)$$

For this problem, the optimization variables comprise the amount to be provided $Q_{i,h}$ for $i = 1, \dots, p$. Let us consider that there are p plants, where $Q_{i,h}^{baud}$ is the business-as-usual demand for the i -th plant and the h -th week. Besides, all plants require a minimum amount $Q_{i,h}^{min}$. Then, the constraints in Eq. 2 have to be incorporated into the formulation, which aims at finding the optima $Q_{i,h}$.

$$\{Q_{i,h}^{min} \leq Q_{i,h} \leq Q_{i,h}^{baud}\} \cup \{Q_{i,h} = 0\} \quad \forall i = 1, p; \forall h = 1, H \quad (2)$$

The Net Present Value (NPV) approach was adopted to assess the objective functions. It is the summation of the difference between the present value of the expected income and costs, which is discounted at a rate r that represents the opportunity cost of capital.

Each Worker calculates his own fitness function $Fitness_W$ related to plant processing (Eq. 3), where $I_{i,h}$, $VC_{i,h}$, and $FC_{i,h}$ are the average processing income, variable and fixed costs, respectively. The summation is discounted at the weekly interest rate r .

$$Fitness_W = \sum_{i=1}^p \sum_{h=1}^H (I_{i,h} \times Q_{i,h} - VC_{i,h} \times Q_{i,h} - FC_{i,h})(1 + r)^{-h} \quad (3)$$

In turn, the Master evaluates the corresponding global NPV by using an aggregation method (Eq. 4) with user-defined weights w_1 and w_2 . In the first term, the scenario is pondered using information about the NG transmission costs $TC_{i,h}$. The boolean

$\delta_{i,h}$ specifies the on/off status of the i -th plant during the h -th week, where $\delta_{i,h} = 0$ means the plant has stopped and $\delta_{i,h} = 1$ indicates that the plant is working. Moreover, it is mandatory to incorporate a Shutdown Constraint. To avoid too short shutdown periods, which would be techno-economically infeasible, a single plant is not allowed to stop more than once during the rolling horizon.

$$Fitness_M = -w_1 \sum_{i=1}^p \sum_{h=1}^H TC_{i,h} (Q_{i,h}^{baud} - Q_{i,h}) \delta_{i,h} + w_2 Fitness_W \quad (4)$$

Fig. 2 summarizes the algorithmic approach. In the first place, the Master’s goal is to intelligently select new starting locations. Then, he assigns them to a single Worker, who starts working from the suggested chromosome to breed the optimal child for the suggested scenario. As soon as possible, all Workers both reject infeasible scenarios and inform the Master about their candidate solution. Notice that there are separate assessment fitness functions: a Central-Planner one (Eq. 4 in GA-M) and a Plant-wide one (Eq. 3 in GA-W). The Master is in charge of judging the global appeal of the results. He ponders the candidate solutions by applying the aggregation method in order to assess the individual’s global fitness. The Master rejects poor solutions and ranks the good ones. The process iterates until the outcome is judged to be good enough. Finally, the Master reports the definitive solution.

Since production usually involves temporal dependency among processes, crossover and mutation operators were properly adjusted for GA-W, where the operations are on real-coded strings. A specialized crossover operator was designed on the basis of a real-coded Simulated Binary Crossover operator (Deb and Agrawal, 1995). It uses specific information about the problem’s constraints to make sure that all ensuing individuals were feasible. Moreover, the use of standard mutation operators was prone to create non-feasible individuals quite frequently. It should be noted that a single chromosome comprises time-ordered information corresponding to a rolling horizon, thus including

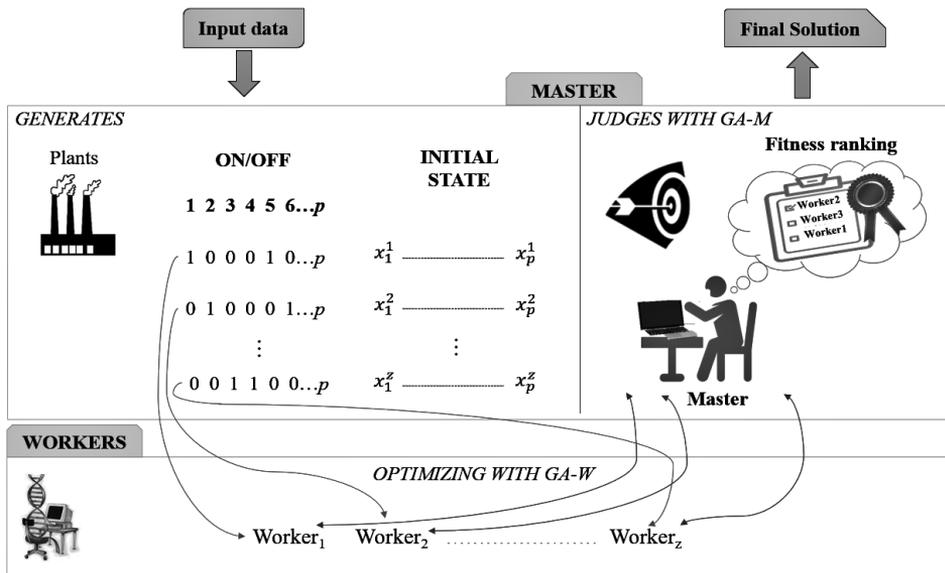

Figure 2. General framework for the techno-economic Master-Worker optimizer.

the state variables for various points in time. Since annual information should not be freely swapped, a mutation operator that always performs permutations within the same year was incorporated, based on a polynomial mutation approach (Deb and Deb, 2014). In contrast, a customized two-point crossover was implemented for the GA-M, where a binary approach with a Shutdown Constraint is necessary. This variation consists in randomly choosing a period of time and exchanging the genes between parents only within that time range. When a portion of each parent is swapped, there is a frequent violation of the constraint that requires that each plant should only stop once in the entire period H . After eliminating repetitions in the non-swapped sections of the children, the Shutdown Constraint is finally fulfilled. This strategy is complemented with a two-stage mutation operator. Firstly, the genes valued 1 are randomly converted to zero. Then, the bits valued 0 are randomly switched to 1, which are carefully assigned to only one plant.

4. Main results

Both technical and economic data for 10 plants of different capacities were considered for this GSP. These plants are located in various regions and the gas shortage lasted for 3 weeks. During this period, the total gas supply had to be reduced with respect to the usual demand in 65%, 55%, and 65% each week, respectively. The hyperparameters for both GAs are reported on Table 1. Since the GA-M model required greater diversity to succeed in finding the optimal pattern, higher population and mutation rates proved to be more effective in the Master's algorithm rather than in the Worker's.

Fig. 3 shows the performance of the optimization method. The parallel GA approach proved to be efficient because function evaluations could be distributed to different processors in order to be completed concurrently. Fig. 3.a depicts the speed-up evolution, showing a satisfactory growth of this ratio with the use of a higher number of cores. A sequential model needed approximately 30 min to find the best solution to this NP-Hard problem, while a 6-core implementation delivered the same result in 8 min. The curve slope implies that there is still room for speed improvement by adding new cores. Moreover, a well-known limitation of the traditional genetic algorithms is that they may fall into local optima quite easily. An alternative to overcome this limiting issue is to opt for methods based on game theory. In this context, parallelism allows the implementation of game operations. Thus, a more accurate and robust optimizer could be achieved.

GA	Population	Crossover Rate	Mutation Rate	Rank Choice	η
Master (GA-M)	100	1	0,2	0,8	-
Worker (GA-W)	50	1	0,05	0,8	15

Table 1. GA parameters.

Fig. 3.b shows the best $Fitness_W$ at each iteration and the corresponding $Fitness_M$, where $w_1 = w_2 = 1$. GA-M stopped when no significant improvements in the best fitness were detected in the last 20 iterations. When the Master stopped, he had found that 3 different plants should shutdown each week, yielding a maximum NPV of US\$ 99.972MM.

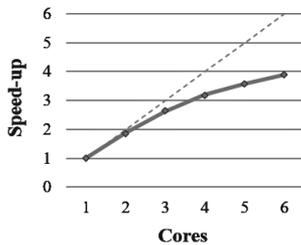

Figure 3.a. Parallel processing speed-up.

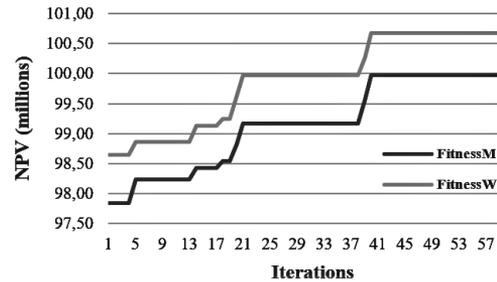

Figure 3.b. NPV variability.

5. Conclusions

Techno-economic assessment can provide energetic and economic incentives and reduce environmental impact when production is carefully optimized. In particular, a metaheuristic methodology based on GA is proposed in order to tackle low-demand conditions. This decision-making approach can anticipate future strategies aiming at NPV maximization. Suitable variants for both mutation and crossover operators were designed to guarantee feasible individuals. Testing on several realistic scenarios has shown that it is useful to make satisfactory comprehensive financial decisions, yielding economically viable scenarios when resource constraints have to be faced. At present, this software product can be considered as a lab-scale prototype, whose basic components have been integrated and computationally tested. The next step is to validate the actual system by testing its operation over a full range of Argentinian environmental conditions.

As to new ways of solving the GSP, it may be profitable to try a game-theory strategy, where population diversity is promoted by letting subgroups compete against each other. Future work should also focus on the incorporation of the metaheuristic approach in a comprehensive EWO framework, not only as a tactical planning methodology, but also at all levels of the decision-making hierarchy. It would also be interesting to determine the extent of model inaccuracies by incorporating uncertainties in the GA strategy.

Abstract

Anthropogenic CO₂ emissions reinforce global warming. The most mature technology to capture post-combustion CO₂ is the absorption with aqueous monoethanolamine (MEA) in spray or packed columns. However, this process is not considered economically viable. One reason for this hindrance is the low overall mass transfer coefficients ($K_G a$) resulting in large process volumes that are high in capital and operating costs. Spray columns offer some advantages over the packed columns such as the lack of expensive column internals, low pressure drop and higher $K_G a$. Although several spray columns have been investigated experimentally, there are only a few efforts to model this process. Because of the high intercorrelation between the process variables, modelling is a complex task. Machine learning techniques have shown great accuracy in modeling this kind of systems using large amounts of data. Artificial neural network (ANN) is one of the most promising and highly modular techniques in this field. The aim of this work is to find the ANN structure with higher accuracy and generalization capabilities to model the $K_G a$ for CO₂ absorption in spray columns using aqueous MEA. The ANN is trained using the back-propagation algorithm. The structure with higher accuracy and generalization properties is searched by a Bayesian optimizer. The trained model has a coefficient of determination (R^2) of 0.98, and a mean squared error (MSE) of 7.89e-4 on the validation set. It returns prediction errors below 20%. The optimizer found that the autoencoder structure had the higher prediction accuracy and generalization capabilities. This shape has great feature importance extrapolation capabilities, allowing the ANN to have a high prediction accuracy. The proposed procedure can be applied also for other processes where transfer coefficients need to be estimated and optimized.

Keywords: CO₂ capture, artificial intelligence, artificial neural network, absorption, spray columns

1. Introduction

Global warming is one of the main challenges that humanity needs to tackle soon. The anthropogenic CO₂ emissions reinforce it. Several strategies are available to reduce the

CO₂ footprint such as electrochemical separation, oxyfuel technologies, pre-combustion capture and post-combustion capture. Among these technologies, post-combustion capture requires little modification to the currently available processes (Luis, 2016). The most mature technology for the post-combustion CO₂ capture is the chemical absorption using aqueous monoethanolamine (MEA) solutions as absorbents (Luis, 2016; Wang et al., 2017). This process is often run in spray and packed columns. Although this is the most mature technology, it is not economically viable due to the high operating and capital investments required (Li et al., 2016). A strategy towards boosting the applicability of CO₂ capture processes is to increase the overall mass-transfer coefficient ($K_G a$) to enable compact processes which are easier and cheaper to retrofit on existing point carbon sources. $K_G a$ in a gas-liquid column is a combination of liquid-phase and gas-phase mass transfer resistances. Based on the two-flux theory (Afkhampour and Mofarahi, 2017), $K_G a$ can be calculated from the inlet and outlet CO₂ concentration and the inert gas flow rate as shown in (1).

$$K_G a = \frac{G_{inert} \cdot (Y_{CO_2,in} - Y_{CO_2,out})}{Z \cdot P \cdot (y_{CO_2} - y_{CO_2}^*)_{lm}} \quad (1)$$

where G_{inert} is the inert gas velocity (kmol*m⁻²*h⁻¹), P is the total pressure (kPa), Z is the height of the reactor (m), Y_{CO_2} the mole ratio of CO₂ to N₂ in the gas ($Y_{CO_2} = n_{CO_2}/n_{N_2}$), y_{CO_2} is the mole fraction of CO₂ in the gas phase and $y_{CO_2}^*$ is the mole fraction of CO₂ in equilibrium with the liquid phase which is assumed to be zero due to the fast reaction between MEA and CO₂.

An accurate prediction of $K_G a$ is crucial in the design of the absorption columns. Packed columns have been widely used in post-combustion CO₂ capture. For this case, several empirical and semi-empirical correlations for the prediction of $K_G a$ have been proposed (Wang et al., 2005). To the best of our knowledge, there are no empirical equations proposed to predict the $K_G a$ in spray columns for CO₂ capture. It is also not clear if an empirical correlation proposed for a specific column with a specific nozzle applies also to a different column and spray configuration. Therefore, more advanced prediction tools are needed to accurately estimate the $K_G a$.

Machine learning (ML) techniques have shown great capabilities in modelling complex systems with high intercorrelation and interdependency between the process variables (Schweidtmann et al., 2021). They build statistical models starting from a dataset by capturing the correlations between the input and the output variables available in it. Among the various ML techniques, artificial neural networks (ANNs) are very promising and modular (Lee et al., 2018). Their structure is a composition of an elementary unit called neuron. The neurons within the network are organized in layers; each layer takes as input information coming from the layer before, and its outputs are sent to the layers after it. At a given structure, the training of an ANN consists in finding the set of weights for each neuron that return the lower prediction error. Beside training of the neuron weights, number of layers and number of neurons per layer are critical hyper-parameters for the model that require an optimization to increase the performance of the network. The search of best structure is often carried out using the Bayesian optimizer (BO) (Snoek et al., 2012). The optimizer utilizes the previous experiences on the system to map the cost function to optimize it. Thus, the search of the best network is influenced by the past optimization attempt made by the optimizer.

In this work, we applied ML modelling with the aim to predict the $K_G a$ in a spray column for CO₂ capture with MEA solution from process parameters (liquid flowrate, gas

flowrate, CO₂ concentration in the gas, CO₂ concentration in the liquid, MEA concentration in the liquid and nozzle diameter). ANNs were trained on a dataset obtained from literature. ANN structure was optimized and tested. The search was performed using the BO.

2. Dataset description and data preprocessing

The data to train the model were obtained from the paper from (Kuntz and Aroonwilas, 2008) and (Wu et al., 2018). In both the papers, the authors employ single fluid nozzles to atomize the liquid. They reported the value of the $K_G a$ as function of the process variables, namely (1) the flowrate of the absorbent liquid, (2) the flowrate of the flue gas, (3) the concentration of the CO₂ within the gas, (4) the concentration of the sprayed MEA solution, (5) the concentration of CO₂ within the absorbent solution and (6) the diameter of the nozzle. These parameters were used as inputs of the model while the output was the $K_G a$ of the system. The dataset utilized was composed by 180 experimental points. To robustly evaluate the model performances, a cross-validation strategy was applied. From the original dataset, three sets were extracted: the training, the test and the validation sets. The training set contained 100 points and was used to train the neural network. The test set had 48 points. The MSE on this set was as loss function of the BO. The BO aims to minimize the MSE. The validation set contained by 32 points and used to benchmark the performance of the most performant network on the test set proposed by the BO. Prior the model training, the data were scaled in the range [0,1] to improve the performances of the optimizer.

3. ANN optimization description

The weights of the neurons composing the ANN were trained using the back-propagation algorithm. The Adam optimizer was employed (Kingma and Ba, 2014) and the mean squared error (MSE) between the prediction and the experimental value was used as loss function. In addition, Lasso (11) and Ridge (12) regularizations were applied on the training to avoid overfitting. The parameter for the l1 regularization was set to $\lambda_1=1e-5$ and the parameter for the l2 regularization was set to $\lambda_2=1e-4$. Each network structure was trained twice to reduce the impact of the initial guesses on the training performances as more repetition did not change substantially the result. The training returning the lower loss value on the training set was selected.

The BO algorithm implemented in Keras-tuner 1.0.1 was utilized in this study. It was employed to search the network structure with the lower MSE on the test set. To perform the search, we utilized 20 iterations of the algorithm. This value was experimentally observed to be a good balance between computational time and model efficiency. The BO could perform the search in the range [0,12] for the hidden layers number and [5,30] with a step of 5 for numbers of neurons per layer. These ranges were obtained experimentally. We gradually increased the size of the search space until the network found by the optimizer returned prediction with $MSE < 1e-3$ on the test set. The neurons contained in the internal layers of the network utilized LeakyReLU activation function. The output layer employed Sigmoid activation function. The capabilities of the obtained network are a-posteriori evaluated on the validation set. The lower the MSE on the validation set the higher are the generalization capabilities.

4. Results

4.1. Prediction accuracy of the best model

Figure 1 shows the prediction capabilities of the model structure with higher accuracy on the validation set identified by the BO. This figure reports the prediction performances both on the training set and on the validation set. In this figure all the points are clustered around the ideal prediction line with a narrow dispersion. In fact, both the prediction on the training and the validation points report error lower than 20% with only few exceptions. The coefficient of determination (R^2) on the validation set is 0.98 and the MSE is $7.89e-4$. This proves the high prediction accuracy and generalization capabilities of the most performant network identified by the BO. In addition, from Figure 1, one can detect how the dataset used in this study had an unbalanced output. Most of the experimental data points were clustered at middle values of the output with only few data points at the extreme values of $K_G a$. In open literature, it was shown that this data configuration decreased the accuracy of the predictions in the area where the data were rarer (Ribeiro and Moniz, 2020). The accurate prediction of the values located at high output rates was a crucial task when the aim of the model was process intensification. The prediction at high $K_G a$ had errors below 20% without any sensible bias, contributing to the high R^2 of this model. This is an important feature that allows the utilization of the model for design, control and optimization tasks. On the contrary, the model shows poor prediction capabilities at the extreme lower values of $K_G a$.

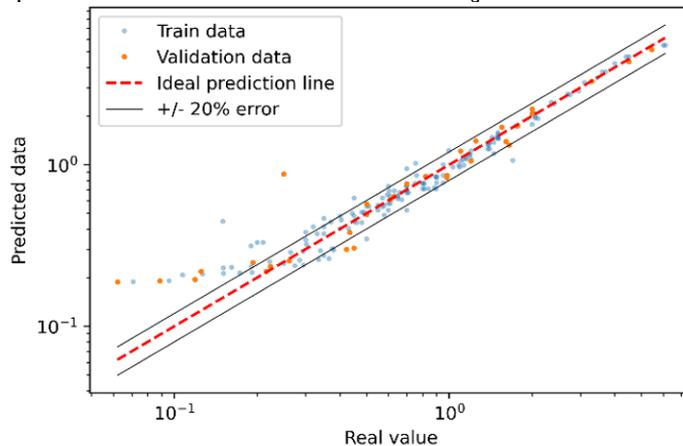

Figure 1: Prediction plot of the model with the higher accuracy on the validation set proposed by the optimizer. Most of the validation points are within the 20% error bend with only few exceptions. The only points with lower accuracy are located at lower output values where the points are rarer.

4.2. Analysis of the best structure

The optimizer identified the autoencoder structure to be the one with the higher accuracy on the test set (Figure 2). The first part of the optimal network is composed by one layer employed for the feature extraction in order to augment the input information (Layer 2 in Figure 2). The features extraction layer is followed by the autoencoder structure (from Layer 3 to Layer 7 in Figure 2). This structure is well known and applied in other fields (Bank et al., 2020). This network identifies the most important combinations of variables for the process and code them into internal variables of the network. This procedure is

done in the encoder of the network. For the case in analysis, the encoder terminates with 10 nodes encoding 10 internal variables (Layer 5 in Figure 2). This is the minimum amount of information that the network needs to perform the computation. Then, the information coded in the encoder are interpret in the decoder. The decoder is composed by two layers (Layer 6 and Layer 7 in Figure2) where the information is expanded and converted to the final output. Using this structure, the network returns low loss function values and very accurate predictions. From Figure 2 one can detect how some of the connections have the weight set to zero or its value is negligible compared to the other connections. This happens especially for the last two layers of the encoder (Layer 3 and Layer 4 in Figure 2). In addition, the optimizer chose 7 hidden layers even if the maximum allowed was 12. This avoided the overfitting on the training data and increased the generalization capabilities of the model. Moreover, the network reported in this study is quite deep and the amount of dataset used for its training could be not enough. However, the accuracy and the generalization capabilities of the model are ensured from the regularization and the cross-validation strategies employed for the training.

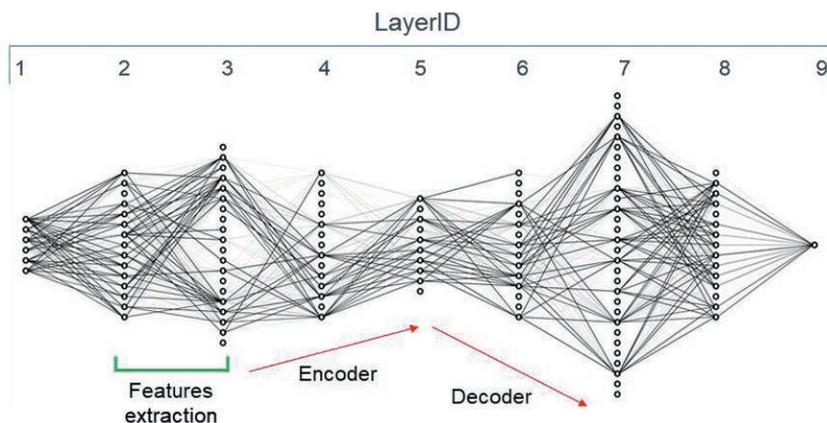

Figure 2: The network structure with the higher accuracy on the validation set proposed by the optimizer. It has the autoencoder structure. In this figure the darker is the color of the connection and the higher is the absolute value of the weight associated to it. The training has a major impact on the encoder. This allows a high selection of the variables used to encode the problem. One can detect how some of the connections have the weight set to zero or its value is negligible compared to the other connections.

5. Conclusions

In this work we proposed a network to predict the overall mass-transfer coefficient in a spray column for CO₂ capture into monoethanolamine. The best model structure returns highly accurate predictions with an R²=0.98 and remarkable generalization capabilities. The network was trained using a Bayesian optimizer to search the best network structure. The Bayesian optimizer identified the most proficient structure in the autoencoder. The network showed noticeable internal features selection to accomplish the prediction task. This methodology is a useful tool to predict internal parameters (such as the $K_G a$ as in this case) of first-principle models. It is a straightforward way to identify the best network structure and it is applicable to predict other process parameters using historical data.

Hierarchical Statistical Process Monitoring based on a Functional Decomposition of the Causal Network

Rodrigo Paredes,^a Tiago J. Rato,^a Lino O. Santos,^a Marco S. Reis,^{a,*}

^a *University of Coimbra, CIEPQPF, Department of Chemical Engineering, Rua Sílvio Lima, Pólo II – Pinhal de Marrocos, 3030-790 Coimbra, Portugal*

Abstract

With the continuous growth of data collection systems, even the state-of-the-art multivariate Statistical Process Monitoring (SPM) methods face difficulties in detecting localized faults, whose signatures easily pass unnoticed due to the large normal background noise associated to the many sensors under analysis. These methods are mostly non-causal and do not take into account the inner relationships between the variables or process units. In this work, we propose a new hierarchical monitoring approach based on a functional decomposition of the system's causal network. The methodology consists in finding the natural functional modules of the causal network, by exploring its graph topology and identifying the strongly linked “communities”. Two hierarchical monitoring schemes (aggregating information from the modules and their interactions) are then applied to monitor the overall state of the process. In this way, as the dimensionality of the modules is smaller, the sensitivity of the distributed system to small or localized faults is preserved. Furthermore, the causal nature of the method facilitates fault diagnosis, especially for sensor faults. However, the overall false alarm rate of the methodology must be controlled, which may take away some of the sensitivity of the proposed method. We report results that demonstrate a robust increase in the fault detection sensitivity of the proposed methodologies when compared to methods that monitor the complete causal network. The proposed approach also led to a more effective and unambiguous complementary fault diagnosis activity.

Keywords: Statistical Process Monitoring; Causal Network; Hierarchical Monitoring; Community Detection; Distributed Monitoring

1. Introduction

Causal networks hold a large amount of information on how process variables relate to each other. Nevertheless, most of the current Statistical Process Monitoring (SPM) methodologies, such as those based on Principal Component Analysis (PCA), Partial Least Squares (PLS) and Independent Component Analysis (ICA) (Ge *et al.*, 2013; Qin, 2012), are non-causal and do not account for this inner system structure. This not only reduces their ability to detect faults, but also impacts fault diagnosis due to a smearing-out effect that propagates the fault through non-causal related variables.

As an alternative, causal SPM methodologies have been proposed. One example, also adopted in this work, is the Sensitivity Enhancing Transformation (SET) method (Rato and Reis, 2014). SET uses the causal network to build a whitening filter that decorrelates the variables based on their inner relationships. If the relationships of the inferred causal network are still valid, the filtered variables should remain confined within a Normal

Operating Region (NOC). SET also facilitates fault diagnosis since a deviation on a filtered variable signals a change in the inferred relationships between the original variable and its causal parents.

However, the aforementioned methodologies (including those based on causality, such as SET) lose detection sensitivity with the increase of monitoring dimensionality (*i.e.*, the number of process variables to monitor). To overcome this limitation, decentralized monitoring methodologies have been proposed to segment the process variables into several modules and then perform local monitoring of each module (Ge *et al.*, 2010; Ge and Song, 2013; Tian *et al.*, 2019).

To combine the advantages of causal-based and decentralized monitoring, we propose two hierarchical monitoring schemes (CNET-C: **C**ausal **N**etwork-**C**entralized, and CNET-D: **C**ausal **N**etwork-**D**istributed) based on the functional decomposition of the causal network. In the proposed methodologies, the process variables are divided into modules (defined as *communities*) of closely related variables and then each module is monitored by the SET monitoring methodology. The subdivision into communities can be made based on the process and instrumentation diagram or analysis of the causal network through a community detection algorithm that evaluates the network topology and the density of associations between variables or process units (Masooleh *et al.*, 2021; Javed *et al.*, 2018; Harenberg *et al.*, 2014). As process monitoring is done at the community level, which aggregate subsets of the original variables, the proposed monitoring methodologies become more sensitive to localized fault affecting one or a few variables. Likewise, fault diagnosis also capitalizes from the decorrelation properties of the SET.

This article is organized as follows. In Section 2, the proposed monitoring methodologies are briefly described. Then, in Section 3, we report the results for a simulated case study that compared the proposed methodologies against two monitoring benchmarks. The results are discussed in Section 4. Finally, we present our conclusions in Section 5.

2. Methodologies

2.1. Fault Detection

The proposed centralized (CNET-C) and decentralized (CNET-D) hierarchical monitoring schemes are based on the functional decomposition of the causal network.

The first modelling stage of both methodologies is the same. In this stage, the network is inferred by use of partial correlations (Rato and Reis, 2017) and the dominant causal directions are determined through analysis of the cross-correlation or Granger causality (Yuan and Qin, 2012). Afterwards, the variables are divided into communities using an algorithm that analyses the topology and density of the network. This division into communities effectively reduces the dimensionality of system, and improves the sensitivity to localized faults. To account for inter-community associations, each community is expanded to also include the Markov-blanket of each causal parent in the community. In the next stage, a SET model is built for each community. The SET model consists of a whitening filter that accounts for the causal structure of the data. The SET model is obtained by regressing each variable onto its causal parents (Markovian approach) (Rato and Reis, 2017). The filtering operation of the SET also produces uncorrelated variables, which improves the diagnosis task discussed in Section 2.2. Afterwards, for each community, the SET filtered variables are monitored through a Hotelling's T^2 statistic ($T^2_{SET,i}$, for $i = 1, 2, \dots, c$, where c is the number of communities). The difference between the two proposed methodologies lies in the way the information coming from the communities (*i.e.*, the $T^2_{SET,i}$ statistics) is aggregated.

In the decentralized CNET-D, the $T^2_{SET,i}$ are monitored separately and aggregated through a “OR gate”. In this approach the control limits are established at the $T^2_{SET,i}$ level, with the significance level corrected to control the false alarm rate due to the use of multiple monitoring statistics. The global alarm of the CNET-D is then triggered if at least one community has a monitoring statistic above its control limit.

In turn, for the centralized CNET-C, the $T^2_{SET,i}$ of all communities are concatenated to build a single monitoring statistic (Equation 1):

$$T^2_{SET_{CNET-C}} = (\mathbf{t}_j - \bar{\mathbf{t}}_{NOC})^T \mathbf{S}_{NOC}^{-1} (\mathbf{t}_j - \bar{\mathbf{t}}_{NOC}), \quad (1)$$

where $\mathbf{t}_j = [T^2_{SET,1}, T^2_{SET,2}, \dots, T^2_{SET,c}]$ is vector that concatenates all $T^2_{SET,i}$ at observation j , $\bar{\mathbf{t}}_{NOC}$ is a vector with the sample means of $T^2_{SET,i}$ in normal operation conditions (NOC), and \mathbf{S}_{NOC} is the sample covariance matrix of the $T^2_{SET,i}$ in NOC. For CNET-C, a global alarm is triggered if $T^2_{SET_{CNET-C}}$ is above its control limit.

2.2. Fault Diagnosis

The fault diagnosis is performed in two levels. In the first diagnosis level the communities with abnormal variables are identified. Afterwards, in the second diagnosis level, the abnormal communities are inspected to identify the abnormal variables within them.

In the CNET-D methodology, the first diagnosis level is direct. Since fault detection is carried out at the community level, it suffices to observe which communities triggered an alarm in the logical “OR gate”. In turn, in the CNET-C methodology, the first diagnosis level is performed by assessing the contributions of each community to the $T^2_{SET_{CNET-C}}$ statistic. After identifying the abnormal communities, the second diagnosis level is run to evaluate the contributions of each variable to the $T^2_{SET,i}$ statistics of the abnormal communities. At this point, the contribution of each variable is compared against a control limit, and those above it are deemed to be related with the fault’s root cause.

3. Results

To study the performance of the proposed methodologies, a static linear causal network simulator with 16 variables (Rato and Reis, 2014) was used to generate NOC and faulty data. In this study we considered process, sensor, and correlation faults in several variables, but for the sake of space, only one case is reported here. Each failure magnitude was replicated 100 times to account for variability. The replicated simulations have 5000 observations each. As this work is not focused on network inference, for the proposed monitoring methodologies it was assumed that the causal network was inferred accurately. Furthermore, the causal network was divided into 3 communities by an algorithm based on network density and topology applications. All monitoring methodologies were set to a false alarm rate of $\alpha = 0.01$ (with Bonferroni correction), by taking the $(1 - \alpha/N) \times 100\%$ upper percentile of the monitoring statistics in NOC data (where N is the number of monitoring statistics in the monitoring scheme).

3.1. Fault Detection

Figure 1 shows the fault detection sensitivity study (True Positive Rate (TPR) versus Fault Magnitude) of the proposed methodologies against two benchmark methodologies (SET-Hotelling- T^2 and PCA) for a process fault in variable 1. This figure clearly shows that CNET-C and CNET-D have significantly higher TPR than the benchmarks. This improvement is a result of the functional decomposition into communities as it increases the sensitivity to localized faults.

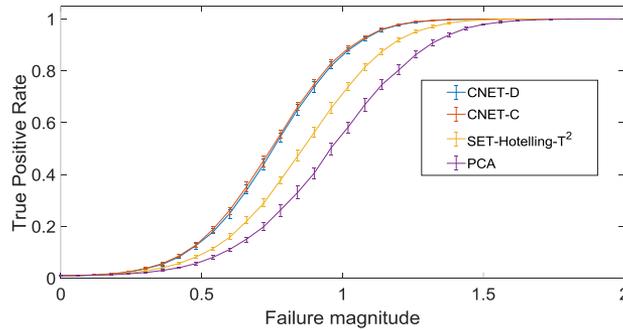

Figure 1: Median true positive rate and interquartile range for a process fault in variable 1. The fault magnitude is defined as k times the standard deviation in NOC.

3.2. Fault Diagnosis

To demonstrate the fault diagnosis capabilities of the proposed methodologies a process fault in variable 1 with a failure magnitude of 1 standard deviation was chosen. Fault diagnosis was performed by use of contribution plots for PCA (Qin *et al.*, 2001) and the contributions to the SET-Hotelling- T^2 (Rato and Reis, 2017). In Figures 2 and 3, the root cause diagnosis for the two benchmark methodologies is graphically represented. Figure 4 shows the two diagnostic levels of the proposed CNET-C methodology. For this case, only SET-Hotelling- T^2 and CNET-C (as well as CNET-D) provide an unambiguous diagnosis, correctly identifying variable 1 in all replicates.

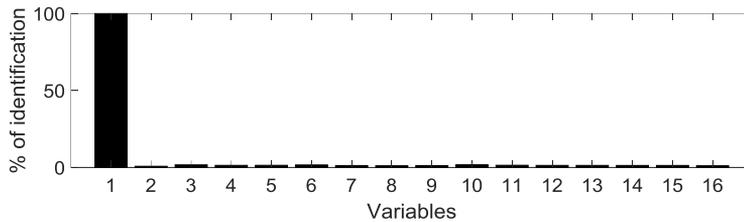

Figure 2: Percentage of times that each variable is significant to the SET-Hotelling- T^2 methodology monitoring statistics. Process fault located in variable 1 with a magnitude of 1 standard deviation.

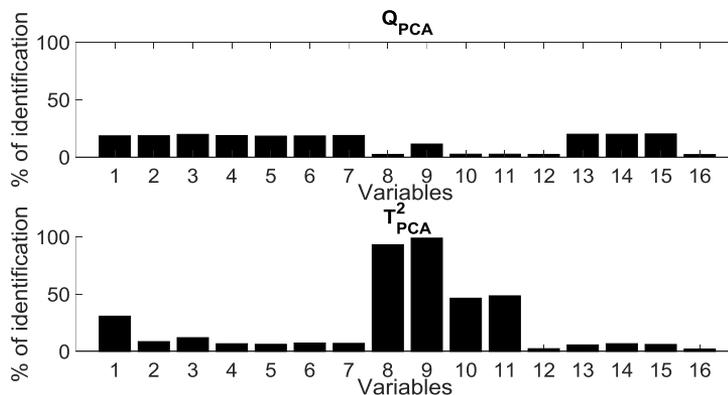

Figure 3: Percentage of times that each variable is significant to the PCA-based methodology monitoring statistics. Process fault in variable 1 with a magnitude of 1 standard deviations.

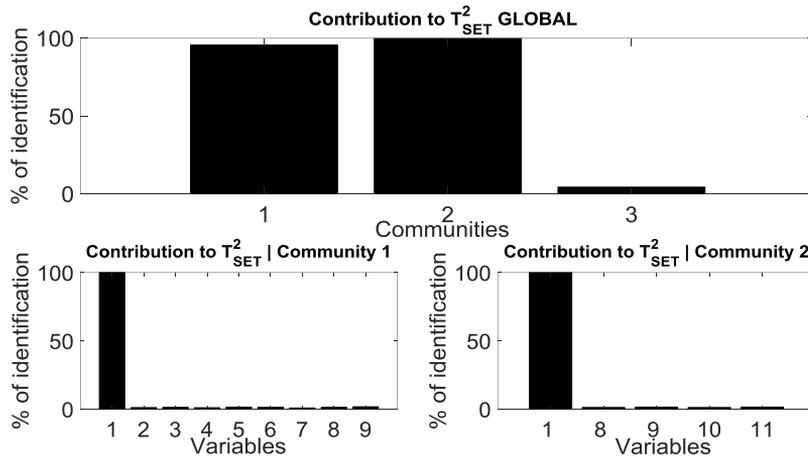

Figure 4: Percentage of times a community is significant for the CNET-C methodology monitoring statistic (first diagnostic level; on top), and the percentage of times a variable is significant for each community's $T^2_{SET,i}$ monitoring statistic (second diagnostic level; on bottom). Process fault in variable 1 with a magnitude of 1 standard deviations.

4. Discussion

Regarding fault detection, the results show that methodologies based on the causal network have greater sensitivity in most scenarios. The causal network functional decomposition into communities reduces the system monitoring dimensionality, which makes the proposed methodologies, CNET-C and CNET-D, to always have greater sensitivity when compared to the benchmark methodology that uses the complete causal network (SET-Hotelling- T^2).

The proposed methodologies have similar performances in terms of fault detection capabilities. Nevertheless, CNET-C tends to perform better in process and correlation failures, while CNET-D is generally better on sensor failures.

CNET-D can lead to sensitivity loss when applied to high dimensional systems due to the correction of the control limits. In this scenario, the high number of communities effectively increases the number of monitoring statistics, and their corrected significance level will tend towards zero. To overcome this limitation, we propose to correct the control limits using methods that control for the false discovery rate (Glickman *et al.*, 2014), instead of the Family Wise Error Rate (such as the Bonferroni correction).

For fault diagnosis, the introduction of the causal network into the monitoring schemes increases the diagnostic capacities compared to the conventional non-causal PCA (Figures 2 to 4). Figure 3 shows that the PCA diagnosis is ambiguous and inconclusive, *i.e.*, it does not diagnose only the variable at fault. In contrast, the SET-Hotelling- T^2 , CNET-C, and CNET-D have a conclusive diagnosis and identified the correct variable in all replicates, while the other variables are identified less than 2% of the times.

The developed methodologies include two hierarchical diagnosis levels. The first diagnosis level identifies the communities with abnormal variables. Afterwards, the second diagnosis level identifies the abnormal variables within the communities diagnosed in the first level. This greatly reduces the monitoring burden requested to process operators.

As the communities were extended to also include the Markov-blanket of the causal parents in each community, some variables may belong to more than one community. If

a fault occurs in these variables, then more than one community may be identified at the first diagnosis level. In these situations, the second diagnosis level is able to identify the correct root cause within the affected communities. Figure 4 represents a scenario where this situation happens: the faulty variable is correctly diagnosed in two communities, proving the good detection performance of the developed methodologies.

5. Conclusions

Causal networks contain information about systems that is typically not used in standard SPM methodologies. The introduction of causal structure into the monitoring methodologies leads to sensitivity gains in fault detection and diagnosis compared to conventional methodologies. Furthermore, the proposed causal network functional decomposition into several communities reduces the system dimensionality, and further increasing the sensitivity to localized faults. The application of the Markov-blanket to the causal parents in each community also allowed for inter-community associations to be included in the models. Fault diagnosis is also made on a reduced set of variables, which improves fault isolating, and leads to a conclusively and unambiguously diagnosis. The CNET-C and CNET-D methodologies demonstrated better performance in fault detection and diagnosis than their PCA and SET counterparts.

Abstract

Crystallization is a separation and purification process applied in many industrial sectors. The unit operation aims to achieve desired crystal size and shape distribution, making process control a key tool for its success. Despite the importance of controlling batch crystallization processes, there is still a lack of studies applying neural network-based control strategies. Therefore, this work aims to model a crystallization process to predict the moments of the particle-size distribution with neural networks used as the internal model in the predictive controller. Four different neural networks paradigms were considered: a classic single Multilayer Perceptron (MLP) network, a set of four MLP networks in series, and two recurrent networks, the Echo State Network (ESN) and the Long Short-Term Memory (LSTM). The dataset used for training and testing applied a co-teaching learning algorithm, which utilizes simulated and experimental data. The 479 experimental values of concentration, and particle number, length, area, and volume were obtained for several temperatures and ten different batch experiments of potassium sulfate (K_2SO_4) crystallization. The 9000 simulated data were generated using a population balance model for the system. First, the four network structures were trained to predict the moments of the particle size distribution values one step ahead, using the current temperature and moments values as feed. As a result, all strategies were successful, achieving values of R-squared of about 99% for the test samples. Then, the network's predictive performance was studied for larger prediction horizons. The ESN had the best performance, achieving values of R-squared above 90%, for eight out of 10 experiments and up to five steps ahead prediction. In comparison, the other strategies reached values below 90% for more than two experiments. Finally, a Nonlinear Model Predictive Controller (NMPC) based on the selected ESN was successfully applied to the batch crystallization process to maintain crystal size distribution on their desired trajectories by manipulating the operating temperature. The controller behavior was studied for four reference trajectories: constant, 1st order, 2nd order, and adaptive 1st order. As a result, the ESN-based NMPC presented better results, both in terms of performance and computational demand, than an NMPC based on the classic MLP, evidencing the potential of the proposed strategy.

Keywords: Crystallization, Neural Networks, Echo State Network, LSTM, NMPC.

1. Introduction

Crystallization is a purification and separation process applied in many industrial fields, such as the food and pharmaceutical sectors. This unit aims to generate a solid crystalline

product with high purity and desired crystal size and shape distribution, making process control a vital tool for its success [1]. In this way, model predictive control appears as a possible strategy for controlling of a crystallization unit.

Crystallization processes are usually modeled by population balances to predict the size and shape of the particles. One of the reasons for its use is the existence of an established kinetic model [1]. However, neural networks have been applied to model many chemical processes, and there is a lack of application for the modeling and control of crystallization processes.

This work aims to model a crystallization process to predict the moments of the particle-size distribution with neural networks. Four different structures of neural networks were considered: a classic single Multilayer Perceptron (MLP) network, a set of four MLP networks in series, and two recurrent networks, the Echo State Network (ESN) and the Long Short-Term Memory (LSTM). Also, the dataset used for training and testing applied a co-teaching learning algorithm, which utilizes experimental and simulated data [2]. The four networks were compared based on their five steps ahead prediction performance, and finally, the best option was used as an internal model in a Nonlinear Model Predictive Controller (NMPC).

2. Neural Networks

Neural Networks are a paradigm belonging to the class of machine learning techniques; they learn new patterns when presented to new data. The MLP is a feedforward network composed of fully connected neurons. Therefore, each neuron performs a weighted sum of inputs, and this result minus a bias value is sent to an activation function, such as a hyperbolic tangent. The result obtained by the activation function is used as the input for the subsequent neurons. Then, adjusting the weights and biases, the network seeks to learn the general function that relates the inputs and outputs of the given data. MLP is a feedforward network commonly used in the literature.

Recurrent Neural Networks (RNN) are a different kind of neural network created to represent sequential data. The difference between RNN and the feedforward networks is that they contain a feedback loop where data can be fed back to previous layers before it is fed forward again for further processing. This kind of structure gives the network the capability to simulate time-series and understand the dynamic behavior. LSTM and ESN are two different kinds of RNN. The first one presents a cell structure composed of three gates: forgot, input, and output. These gates have the function of controlling the flow of information inside the network [2]. On the other hand, ESN comprises an input layer, a dynamical reservoir, and an output layer. The reservoir layer is the recurrent part, where the outputs of the reservoir and output layers are feedback. Moreover, the weights of the reservoir layer are not trained but randomly fixed, avoiding local minimum problems.

Four different neural networks paradigms were studied to be used as the model for the controller. These networks structures were a single MLP, four MLP in series, ESN, and LSTM. The moments μ and temperature values in a time k were used as the inputs of the networks to predict the moments' values one step (i.e., one sampling time) ahead. Then, the network's capacity to predict the moments' values more steps ahead was studied, and all models were compared. Also, the dataset used for training and testing applied a co-teaching learning algorithm. The 479 experimental values of concentration and particles

number, length, area, and volume were obtained for several temperatures and ten different batch experiments of potassium sulfate (K_2SO_4) crystallization. The 9000 simulated samples were generated from the Population Balance (PB) Model developed by Moraes et al. [1], of which 3000 were used as test samples. The training dataset used data from one experiment and 6000 simulated data. For test samples, the dataset was composed of the other experimental data and three simulations. Each simulation was composed of 1000 data and used different initial conditions.

First, a single MLP network was designed using the temperature and the moments as inputs to predict the future values of the moments. This network structure was composed of a single hidden layer with 400 neurons. Also, a batch size of 350, Relu as the activation function, and the solver Adam were applied.

The second structure is composed of four MLP networks in series. The first network receives temperature and μ_0 values to predict μ_0 one step ahead. The prediction of the first network is used as input of the next one with the temperature and μ_1 at the same time to predict μ_1 one step ahead. The other two networks apply the same methodology, but the third one uses temperature, μ_1 and μ_2 to predict μ_2 one step ahead, and the last one uses temperature, μ_2 and μ_3 to predict μ_3 one step ahead. All four networks used the same specifications, which was one hidden layer with 195 neurons. Moreover, a batch size of 50, Relu as the activation function, and the solver Adam were applied.

The recurrent networks used the same inputs and outputs as the single MLP. For the ESN, a single reservoir and Identity activation function for the output layer and the output recurrence were used. For the LSTM, one LSTM layer with 120 cells and hyperbolic tangent as activation function were employed. Furthermore, sigmoid as a recurrent activation function, a batch size of 250, and the solver Adam were adopted.

3. Model Predictive Controller Design

The optimization problem considered as controlled variables μ_0 , μ_1/μ_0 , μ_2/μ_0 , and μ_3/μ_0 . The manipulated variable u is the process temperature. The MPC goal is to minimize the process performance index J , the objective function of the problem shown in Equation 1. The parameters $\delta(i)$ and γ are the weights of the outputs and the increment input, respectively; $y_i(k + j)$ is the i th predicted output at time $k + j$ and $y_i^r(k + j)$ its reference value. For the ESN, $\delta(i)$ was defined as 32 for μ_0 , and 5 for the other variables. For the MLP, $\delta(i)$ was defined as 45 for μ_0 , 30 for μ_2/μ_0 , and 15 for the other variables. The input increment is defined by $\Delta u(k)$ as a control horizon of 1 was assumed. P is the prediction horizon, which was chosen as 5 sampling intervals.

$$J = \sum_{i=1}^4 \sum_{j=1}^P \delta(i)[y_i(k + j) - y_i^r(k + j)]^2 + \gamma[\Delta u(k)]^2 \quad (1)$$

The optimization constraints are given by Equations 2-4, where C is the concentration of the solute, and C_{eq} is the concentration of the solute in equilibrium.

$$-1 \leq u(k) - u(k - 1) \leq 1 \quad (2)$$

$$C(k)/C_{eq}(k) \geq 1 \quad (3)$$

$$C_{eq}(k) = -686.2686 + 3.579165u(k) - 0.00292874u(k)^2 \quad (4)$$

4. Results and Discussion

First, all four structures were tested to make predictions one step ahead, achieving an R-squared value of 99% for test and training samples. Then, each network's performance was studied for predictions two and five steps ahead, and the results for predictions five steps ahead are illustrated in Figure 1. As a result, the ESN presented the best performance, reaching an R-squared higher than 75% for all experiments.

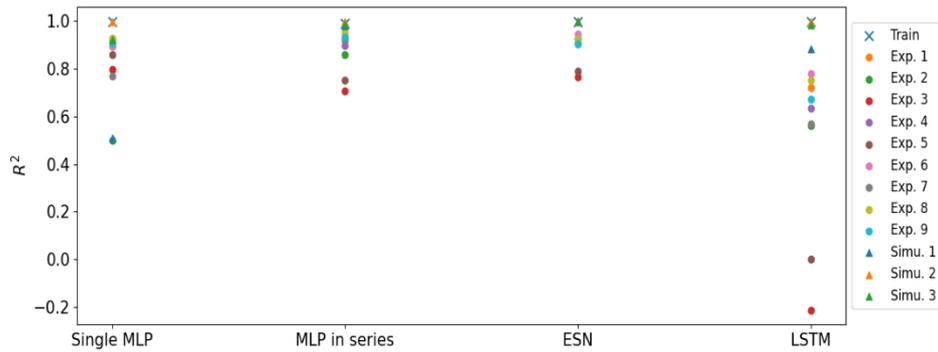

Figure 1: Performance of all neural networks for predictions five steps ahead.

After studying all neural networks behavior, the ESN was chosen to be the model for the predictive controller because it presented the best performance. However, the network's design had to be modified to achieve better control results. Therefore, one ESN was used to predict each moment with the same specifications as the design for four outputs. All four networks presented a performance very close to the other ESN design.

Using the ESN as the model, the controller's performance was compared to a more traditional control approach, using an MLP network. For this second case, four MLP networks were used to predict each moment value with the specifications presented in Table 1, in which T is the temperature. Also, a single hidden layer, Relu as activation function, and the solver Adam were adopted for all four cases. Both strategies predicted the moments five steps ahead and used the same inputs and outputs.

Table 1: Specifications for each MLP used in the MPC.

Inputs	T, μ_0	T, μ_0, μ_1	T, μ_1, μ_2	T, μ_2, μ_3
Outputs	μ_0	μ_1	μ_2	μ_3
Number of neurons in the hidden layer	50	295	300	300
Batch size	20	50	50	50

The proposed scheme for the control loop is illustrated in Figure 2. The process was modeled by the PB Model, and the optimizer used the Successive Quadratic Programming to find the optimum temperature value for each sampling. Also, a sampling time of one minute and the initial conditions of one experiment were chosen.

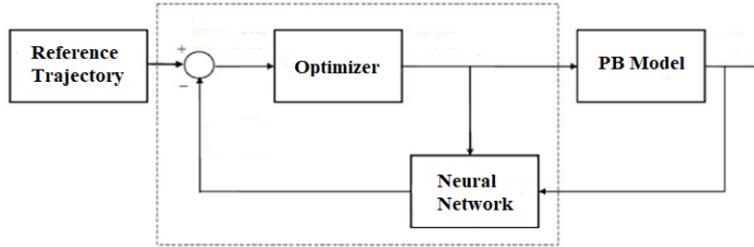

Figure 2: Control loop scheme.

The first reference trajectory tested was a constant trajectory, using the μ_i value at the end of the chosen experiment to define it. Then, a first-order dynamic reference trajectory was studied. This trajectory is described by Equations 5 and 6, which $\mu_i(t_{end})$ is the moment value at the end of the experiment, and γ is a constant equal to 0.9.

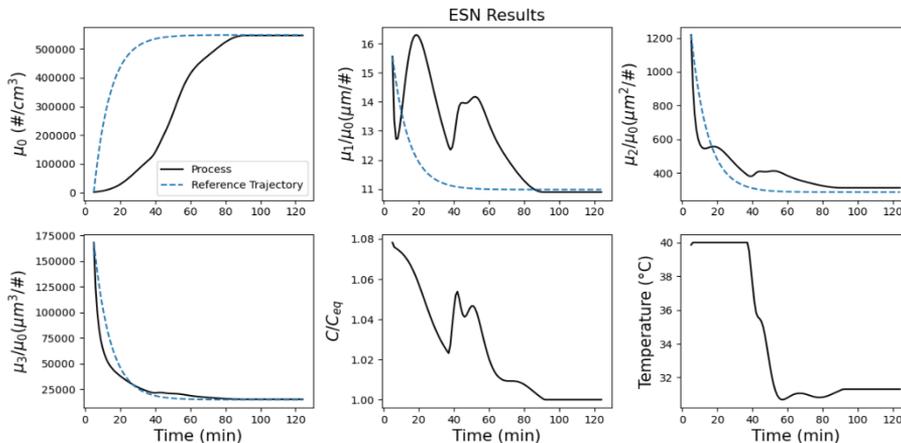

$$\mu_i^{RT}(t_0) = \mu_{i0} \tag{5}$$

$$\mu_i^{RT}(t) = \gamma\mu_i(t - 1) + (1 - \gamma)\mu_i(t_{end}) \tag{6}$$

A 2nd order reference trajectory was modeled as shown in Equation 7 for each μ_i . The parameter τ_i was calculated for each case, reaching the values 21.1, 20.4, 17.5, and 16.4 for μ_0 , μ_1 , μ_2 and μ_3 , respectively.

$$\mu_i = \mu_{i0} + (\mu_i(t_{end}) - \mu_{i0}) \left(1 - \left(1 + \frac{t - t_0}{\tau_i} \right) e^{-(t - t_0)/\tau_i} \right) \tag{7}$$

Finally, another trajectory was defined, which is similar to the 1st order trajectory but is named adaptive, as it departs from the actual system state at each time step.

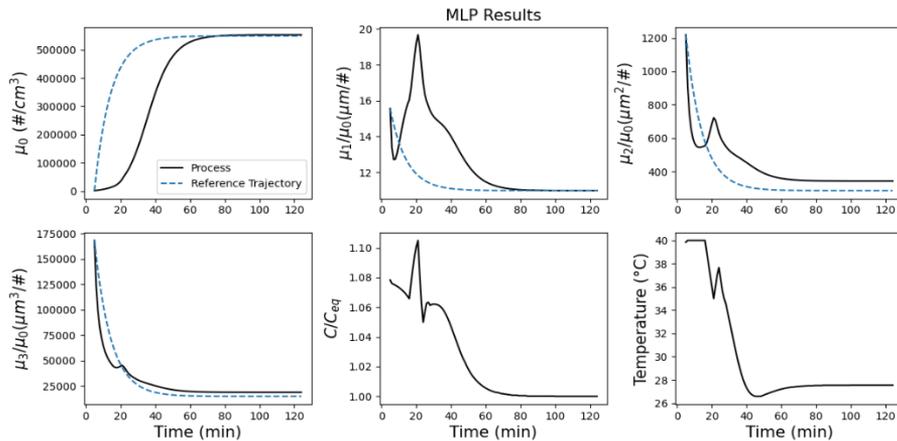

Figure 3: Simulation of the control loop for a 1st order trajectory.

After analyzing the controllers, both structures were efficient for a constant, a 1st order, and an adaptive 1st order reference trajectory, but had some issues for the 2nd order reference trajectory. The ESN had a better performance than the MLP because the calculated overall (considering all the trajectories and all the normalized variables) mean squared error (MSE) was 1.806 for ESN, while this value was 2.018 for the MLP. The results for both networks for a first-order reference trajectory are shown in Figure 3.

5. Conclusion and Prospects

In this work, an MPC controller was developed using a neural network approach to model the process. Four different neural networks designs were studied to predict the moments: a single MLP, a set of four MLP networks in series, LSTM and ESN. The dataset used for training and testing applied a co-teaching learning algorithm, using experimental and simulated data. As a result, the ESN presented the best performance to predict the moments, achieving values of R-squared higher than 75% for predictions five steps ahead.

The ESN was chosen to be the model of the controller, and its behavior was compared to a traditional approach, using MLP as the model. The controller based on the ESN produced better results than the one using the MLP, presenting a lower value of MSE. Four different reference trajectories were analyzed: a constant, a 1st order, a 2nd order, and an adaptive 1st order. Therefore, both structures were efficient for a constant, a 1st order, and an adaptive 1st order reference trajectory but had some issues for the 2nd order reference trajectory.

Finally, it is suggested to try different approaches of neural networks to model this process, such as Gated Recurrent Unit. Also, this same application could be tested on a continuous crystallization process.

Abstract

Materials design for functional applications carried out using conventional trial and error methodologies is expensive and time consuming. Machine learning techniques can be used to design materials suitable for functional applications and discover materials for specific applications from existing literature. This study demonstrates a machine learning approach where a combinatorial analysis was used to design perovskite structures and a novel methodology was devised to calculate descriptor values which were used for property prediction of the designed perovskites. Further, natural language processing (NLP) technique was used to obtain word embeddings of perovskite materials. The obtained embeddings were used to identify perovskites that could be used as electrocatalysts. The candidate materials predicted by the NLP algorithm have been investigated for their electrochemical properties and they could be tried as electrocatalysts for the reactions discussed in this study.

1. Introduction:

Lithium-ion batteries (LIBs) have played a huge role in enabling the digital revolution. The technology has established itself as a reliable energy storage mechanism over the past 20 years. Over the past decade they have become popular for vehicular applications. With increasing energy demand there is a need to look beyond the lithium-ion technology alone to meet the future requirements for energy storage.

Some of the other popular battery chemistries include, lithium-sulphur batteries, lithium-air batteries, zinc-air batteries, etc. Of specific interest is the lithium-air battery. This battery has much higher gravimetric energy storage density compared to all other chemistries (Girishkumar et al. 2010). Because of this it is being researched for use in vehicular applications where weight of the battery system is important. The usable energy density of gasoline for automotive applications is approximately 1700 Wh/kg (Richter et al. 2008). For the present lithium-ion battery technology to achieve this there needs to be a 7-fold increase in the energy density. This warrants a change of approach, which is to look at other battery chemistries. The oxidation of lithium provides 11,680 Wh/kg of energy which is quite close to that of gasoline. This potential of the lithium metal could be made use of by using the lithium-air battery. The working mechanism of the lithium-air battery involves an oxygen reduction reaction (ORR) in the cathode while discharging

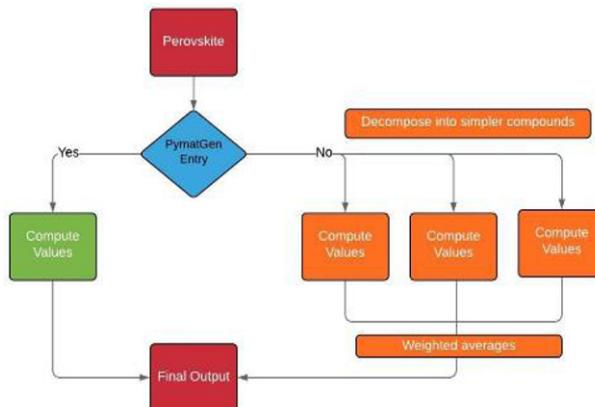

Fig. 2. Descriptor preparation methodology.

The descriptors calculated were then used as features for the machine learning model to predict catalyst activity values which are used to evaluate the suitability of the perovskite to be used as an electrocatalyst. Fig. 1 and Fig. 2 show the methodology for dataset preparation and descriptor calculation. The activity values are reported in different metrics. The details of the metrics are given in the following section.

2.1. Metric transformation and conversion:

Given the widespread scientific reporting of activity results in current as well as voltage units, and the absence of a universal metric to report OER/ORR performance, simple transformations were used to facilitate comparison of activities reported using different metrics. The conversions used for the different metrics are given below.

- Overpotential measurements: The potential values were considered in their native measurements in the case of ORR. For OER, the potential values were converted to negative scale after conversion to overpotentials.
- Current density measurements: For both OER and ORR, the current density values were converted to log scale.
- Experimental data reference compounds: All the activity values were taken as relative percentage changes with respect to LaCoO_3 and LaMnO_3 for OER and ORR respectively. The choice of selecting LaCoO_3 and LaMnO_3 is justified by the fact that they were the most widely reported perovskites for OER and ORR reactions.
- Activity data transformations: To account for the difference in spread resulting from difference in units, each group was normalized by its respective standard deviation.

2.2. Machine learning models and validation techniques:

Different machine learning models such as Ordinary least squares (OLS), Ridge regression (Ridge), Lasso regression (Lasso), Elastic net regression (11 ratio set as 0.25 [EN025], 0.5 [EN05] and 0.75 [EN075]), Random-forest regression (Random_Forest), Gradient boosting regression (gbr), Huber regression, Least angle regression (LARCV), Support vector regression (SVR) and Principal component regression (PCA_CV) were employed for modeling the data and obtaining predictions. Four different validation techniques were used and mean squared error (MSE) was the primary metric used to assess model performance. The best model found using validation was used to give predictions on different unknown A, B combinations of perovskite oxides. The validation techniques are described below.

- K-fold cross validation: 5-fold validation was used to evaluate the model performance on multiple hyperparameters.

- b. Blind A-blend: Model is trained on perovskite data discarding a certain A-element (e.g., La). Whereas, model performance is evaluated using that discarded unseen A-element. Averaging the model performance for different A-elements can be good metric for model validation.
- c. Blind B-blend: Model is trained on perovskite data discarding a certain B-element (e.g., Ni) and model is evaluated using that discarded unseen B-element.
- d. Blind Combination (AB): Combination (combo), here refers to a specific combination of A-site blend and B-site blend. The model was trained on perovskite data discarding a certain AB combination (e.g., SrCaMn) and model is evaluated using that discarded AB combination.

2.3. Materials selection using SciBERT embeddings:

SciBERT (Beltagy, Lo, and Cohan 2020), which is a language model developed based on BERT framework is pretrained on scientific literature across multiple domains. This model was developed to improve performance of BERT framework on downstream scientific NLP tasks. However, the SciBERT model is not trained in the domain of perovskites or electrocatalysts. To get over this hurdle, the model was retrained in these domains using abstracts from Springer and Elsevier journals. 102,260 abstracts were obtained by querying the keywords ‘electrocatalyst’ and ‘perovskite’ directly. The corpus prepared from the abstracts was pre-processed to remove Chinese texts and subsequently the model was trained. Embeddings of perovskites of type ABO_3 were obtained from the trained model. The obtained word embeddings were used to identify candidate electrocatalysts by obtaining the cosine similarities of the perovskites with the keyword ‘*electrocatalyst*’.

3. Results:

3.1. Machine learning model predictions:

Fig. 3. Training and validation results for OER dataset.

Fig. 3 shows the results obtained from training and validating OER dataset using various machine learning models. The train test split was chosen as 80:20. Test_MSE is test data mean squared error, CV_MSE is 5-fold cross validation mean squared error. A_MSE, B_MSE, AB_MSE are blind A, blind B and blind AB validation mean squared errors respectively. From the results it can be seen that the Gradient boosting regression has outperformed all the other models. gbr is an ensemble learning method. In gbr, while the decision trees are built, each new tree corrects the errors made by the previously trained

trees. This feature enhances the accuracy of the model. The validation of activities predicted using gbr is shown in Fig. 4.

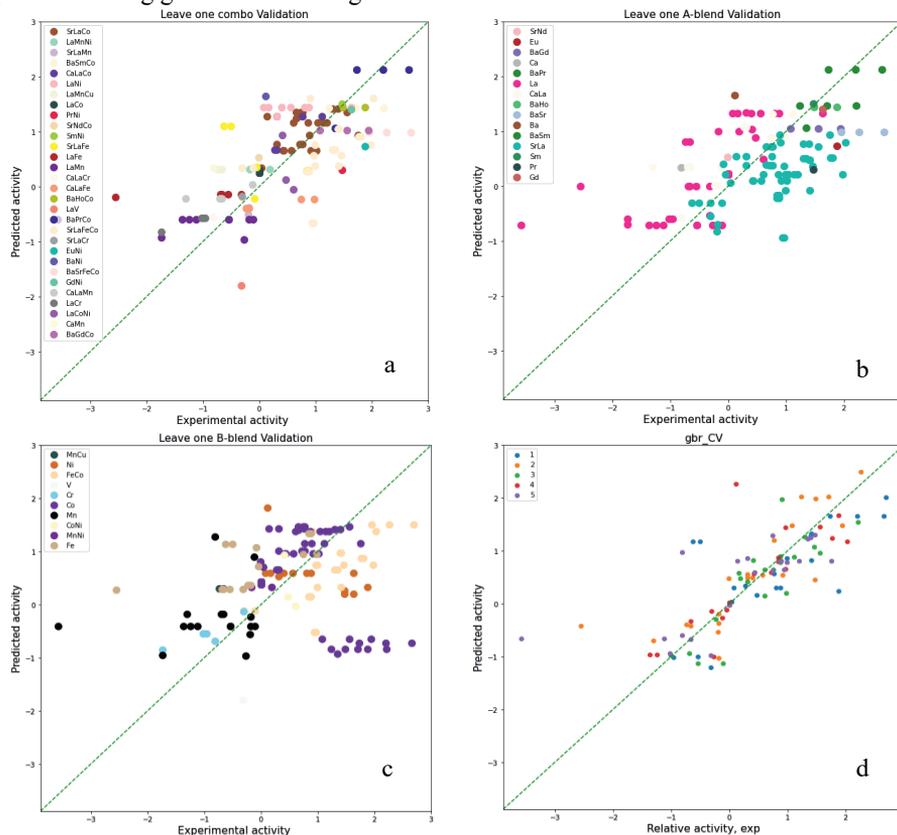

Fig. 4. Validation for OER activities predicted using gbr model, a. Validation using blind combination, b. Validation using blind A-blend, c. Validation using blind B-blend, d. Validation using 5-fold cross validation.

Scatter plot of blind A-blend validation has lesser MSE compared to blind B-blend validation. This suggests that blinding A element did not affect the model performance whereas blinding B element did. According to the results obtained from the study it can be said that B elements are more important in finding the OER activity of a perovskite. If we blind a random B element and train the model the model fails to predict the activity accurately (for most of the perovskites considered in the plot) for the B element which is blinded. This demonstrates the importance of B element. Table 1 shows the top 4 perovskites ranked based on scaled activities. These perovskites can be seen as candidates for non-precious metal based electrocatalysts. Similar analysis was carried out with ORR dataset and the candidate materials obtained are shown in Table 1.

3.2. SciBERT embedding predictions:

The SciBERT language model, unlike other language models (Skip-gram, CBOW, etc.) is a context-dependent model and is trained on scientific text. The word embeddings are computed taking into consideration all the words in a sentence along with their position in the sentence hence are better than the embeddings obtained from other models.

The top 8 perovskites predicted by computing cosine similarity with the keyword ‘electrocatalyst’ are shown in Table 2. Cosine similarity measures the cosine of the angle between two vectors projected in a multi-dimensional space. Vectors oriented in similar direction will have a high cosine similarity. A literature review of the predicted materials revealed that some of these materials have already been studied for their electrochemical properties (e.g., LaCoO_3 , SrCoO_3 , $\text{SrCo}_{0.7}\text{Ni}_{0.3}\text{O}_3$, etc.). One of the most popular electrocatalyst for OER and ORR is platinum. It was observed that the cosine similarities of ‘Pt’ with ‘*electrocatalyst*’ and ‘*LaCoO₃*’ with ‘*electrocatalyst*’ were alike (0.095 for ‘Pt’ and 0.102 for ‘*LaCoO₃*’). These prove that the predictions are consistent with existing scientific knowledge and are capable of possibly identifying newer materials.

Table 1. Top 4 perovskite-based electrocatalysts for OER and ORR predicted from ML analysis.

OER		ORR	
Perovskite	Scaled activity	Perovskite	Scaled activity
$\text{Sr}_{0.5}\text{Ba}_{0.5}\text{Fe}_{0.5}\text{Co}_{0.5}\text{O}_3$	2.113	$\text{Sr}_{0.5}\text{Sm}_{0.5}\text{Cu}_{0.5}\text{Ni}_{0.5}\text{O}_3$	0.200

4. Conclusion:

This study demonstrated a ML based approach for materials design and an NLP based approach for materials discovery. Through the ML based methodology, perovskites of a certain structure were generated and their electrochemical activities were predicted. The designed perovskites could be seen as novel materials that could be synthesized. The NLP results clearly demonstrate the usefulness of the methodology for materials discovery. This technique shows how existing knowledge can be analyzed in a better way. Since the volume of scientific literature is growing by the day, this approach can be seen as a paradigm shift in the way literature has been analyzed and assimilated.

5. Future work:

Following the extraction of the embeddings for the perovskites, they will be subsequently used as features for training the ML model along with the already present descriptors. Research is in progress to develop newer descriptors and metrics.

Abstract

Modular plants provide the opportunity to increase flexibility and reduce time-to-market in the process industry. Process validation is time-consuming and limits the realization of this potential. Therefore, it should be supported efficiently. Smart process equipment assemblies (sPEAs) built from the real module, a digital twin (DT), and suitable methods and algorithms provide high potential to do so. In this paper, we investigate how a suitable DT should look like to support the process design phase in process validation. Therefore, the semantics and information demand of different relevant simulation and optimization problems are analyzed. We reason that the DT should combine structural information like engineering data, e.g. through DEXPI, and behavioral models in form of simulation models. Furthermore, it should provide the descriptive capability to capture the semantics of different application cases like e.g. design of experiments. We suggest a linked-data-based architecture to meet these requirements. The simulation models are semantically lifted into linked data through an information model describing its purpose, quality and variables. The approach provides the potential to reduce manual effort of the user since information is interconnected, accessible and processible automatically.

Keywords: Modular plants, smart PEA, digital twin, linked data, process validation

1. Introduction

Modular plants (MPs) built from process equipment assemblies (PEAs) strive to reduce time-to-market and increase production flexibility in the process industry. Therefore, this technology is attractive for industry sectors with small product charges and short product life cycles like the pharma industry. This industry is highly regulated and requires a rigid process validation (Katz and Campbell, 2012). The MP concept accelerates construction and automation of process plants. To develop MPs into highly flexible and smart production systems, process validation should be efficiently supported as well.

Process design is the first stage in process validation (Katz and Campbell, 2012). In recent years, the quality by design (QbD) approach is adopted in the pharma industry to set a sound scientific foundation in this stage. The approach emphasizes knowledge management, risk-based approaches, and design of experiments. We are convinced, that smart PEAs built from the real PEA, its digital twin (DT) and tailor-made methods and algorithms can reduce manual efforts of the owner/operators (O/Os) and therefore accelerate process validation. Thus, this paper aims to answer the question how a DT of a sPEA should be structured to support the process design phase in process validation and the solution of related simulation and optimization problems as efficiently as possible. Simulation and optimization methods (e.g. black-box optimization methods) for systems

with distributed knowledge are not considered in this publication. The remainder of the paper is structured as follows: section 2 introduces an illustrative example; section 3 reviews the DT and key simulation and optimization problems to derive requirements to the DT for process validation; section 4 presents a concept for a linked-data-based DT of sPEAs to integrate structural and behavioral information for process validation; section 5 provides a conclusion and further research potential.

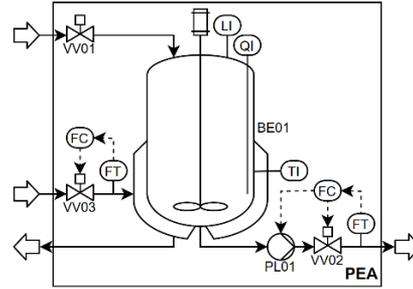

Figure 1: P&ID of a simple STR-PEA

2. Illustrative example

Let us assume that an O/O aims to carry out an irreversible, exothermic reaction $A \rightarrow B$. The quality target product profile (QTPP) requires the concentration of component A c_A to sink below 1 mol/L in the product stream F , while the process must not reach a temperature T above 80 °C in the vessel. The educt stream is expected to vary in volume flow F_{in} , concentration $c_{A,in}$ and temperature T_{in} in the production. The O/O chooses the stirred tank reactor (STR)-PEA in figure 1 to carry out the process. The PEA can control the product volume flow (VV02, PL01) and the cooling water flow (VV03). Furthermore, it provides a service to open the valve VV01 to receive any process stream provided to it. The PEA has sensors to measure the temperature T , the level in the tank L , the concentration c_A , and the flows F_{in} and F . Assuming constant physical property parameters, the following model equation system can be derived:

$$\begin{aligned} \frac{dV}{dt} &= F_{in} - F; \quad L = \frac{4V}{\pi D^2}; & \frac{dT}{dt} &= \frac{F_{in}}{V}(T_{in} - T) - \frac{\lambda}{\rho c_p} k c_A - \frac{UA_J}{\rho V c_p}(T - T_J) \quad (1) \\ \frac{dc_A}{dt} &= \frac{F_{in}}{V}(c_{A,in} - c_A) - k_0 \exp\left(-\frac{E_A}{RT}\right) c_A; & \frac{dT_J}{dt} &= \frac{F_J}{V_J}(T_{J,in} - T_J) + \frac{UA_J}{\rho_J V_J c_{p,J}}(T - T_J) \end{aligned}$$

We assume that the O/O already knows about the density ρ and specific heat capacity c_p and did choose a suitable kinetic model. Yet, the O/O has only rough estimations of the kinetic parameter values k_0 and E_A as well as the reaction enthalpy λ . The sPEA now shall provide a DT, and methods and algorithms to support the O/O to identify the model more precise and derive the design space (DS) of the process.

3. Requirements analysis

3.1. A digital twin for smart PEAs

Smart PEAs are envisioned to support their user in application beyond the capabilities of current PEAs. Therefore, it is necessary to extend their descriptive capabilities. The DT concept provides a far superior form of description to sPEAs. Currently, descriptions to PEAs focus on single aspects. For example, the module type package (MTP) describes the automation interface of a PEA (VDI/VDE/NAMUR, 2019), or DEXPI which describes piping and instrumentation (Wiedau et al., 2019). Boschert et al. (2018) define the DT as a *'linked collection of [...] engineering data, operation data and behavior descriptions via several simulation models'*. These simulation models are use case specific and therefore of varying, suitable fidelity (Boschert et al., 2018). Networking structural models from the planning phase, such as the MTP and DEXPI, was considered in preliminary work (Rahm et al., 2021). For the DT of our illustrative example, the MTP would e.g. describe the services controlling the control loops and the input valve. To

support process validation, the DT of a sPEA must additionally integrate behavioral models to capture process behavior. Furthermore, it must integrate with simulation and optimization methods, which accelerate process validation through an increased degree of automation and reduced manual efforts. In addition, an integration of structural models describing process validation data like e.g. the QTPP would provide an added value.

3.2. *Quality by Design methods for smart PEAs*

Design space identification is an important task in process validation. Von Stosch et al. (2020) argue that a dynamic DS can provide increased process flexibility. Thus, a dynamic model should be used to capture the process behavior. Since, smart PEAs will be reused in different application scenarios, they can be expected to become pre-characterized. Therefore, model-based design of experiments (MBDoE) and system identification approaches should be foreseen to identify the dynamic model. Finally, Ochoa et al. (2021) did consider flexibility analysis (FA) for DS identification from static simulation models. This approach can be extended applying the dynamic flexibility analysis developed by Dimitriadis and Pistikopoulos (1995).

3.2.1. *Dynamic modeling for behavioral models*

As derived above, the DT of a sPEA should provide dynamic behavioral models of the PEA and the process happening within the PEA. Differential algebraic equation systems (DAEs) of the following form provide a well-known form of dynamic model:

$$\begin{aligned} \mathbf{0} &= \mathbf{f}(t, \dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}); \quad \mathbf{x}(t_0) = \mathbf{x}_0 \\ \mathbf{y} &= \mathbf{g}(\mathbf{x}(t), \boldsymbol{\theta}) \end{aligned} \quad (2)$$

Herein, t represents the time, \mathbf{x} are the differential and algebraic states, \mathbf{x}_0 are the initial states of the DAE-system, $\dot{\mathbf{x}}$ denote the derivatives of the differential states, \mathbf{u} are external inputs, \mathbf{y} are the outputs, and $\boldsymbol{\theta}$ are equipment or physical property data related parameters. These variables are defined in the mathematical domain. In our illustrative example e.g. the external inputs \mathbf{u} have to be mapped to the input mass flow F_{in} , T_{in} , $c_{A,in}$ and the input information flows F and F_j . Thus, PSE software defines a semantic layer upon the mathematic model, which allows to differentiate between these input types. Meanwhile, the semantic meaning of a variable can often be related to information in other structural models. E.g., equipment properties like the volume of the jacket V_j are described in DEXPI. In a DT, potentially conflicting descriptions of the same quantity should be prevented. Therefore, the behavioral model should be integrated into the structural model. But since the semantic is usually proprietary to a software, a digital connection between the behavioral model and the structural model is often not established yet. Our new DT concept must overcome this obstacle. Furthermore, the DT must provide meta information on the purpose and quality of a simulation model and describe the relationship between different simulation models which are part of the DT.

3.2.2. *Simulation and optimization problems applying the digital twin*

In the following, the optimization problems **MBDoE** and **FA** are analyzed as examples. **MBDoE** is an optimal control problem. It is applied to design highly informative experiments. An example are D-optimal experiments. The related optimization problem can be formulated as follows:

$$\begin{aligned} \min_{\mathbf{u}(t), \mathbf{x}_0} & \left[\det \left(\left[\sum_{iExp=1}^{NExp} \left[\sum_{iy=1}^{Ny} \sum_{jy=1}^{Ny} \sigma_{iy,jy} \mathbf{S}_{iy}^T \mathbf{S}_{jy} \right]_{iExp} + \mathbf{FIM}^0 \right]^{-1} \right) \right] \\ s.t. & \quad \mathbf{0} = \mathbf{f}(t, \dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}_{CP}, \boldsymbol{\theta}_{TP}); \quad \mathbf{x}(t_0) = \mathbf{x}_0; \\ & \quad \mathbf{y}(t) = \mathbf{g}(\mathbf{x}(t), \boldsymbol{\theta}_{CP}, \boldsymbol{\theta}_{TP}); \quad \mathbf{u}_L(t) \leq \mathbf{u}(t) \leq \mathbf{u}_U(t); \quad \mathbf{x}_L(t) \leq \mathbf{x}(t) \leq \mathbf{x}_U(t) \end{aligned} \quad (3)$$

Herein, **FIM** denotes the Fisher information matrix, θ_{CP} the capability property parameters (cf. Bamberg et al., 2021), θ_{TP} the transformation property parameters, σ are the variances of the different measurement signals and **S** denotes the parameter sensitivities of the measurements. Firstly, it is important to recognize the ‘factors’ of the experiments are formed by the information flow and mass flow related inputs **u** and the initial state \mathbf{x}_0 . In our illustrative example, these are the information flows F, F_j along with the mass flow related variables $F_{in}, c_{A,in}, T_{in}$ and the initial states $V_R, c_{A,0}, T_0$ which might be adjustable under experimentation conditions. The parameter vector θ must be split into capability property parameter θ_{CP} , which characterize the sPEA capabilities and are known beforehand, and the transformation property parameters θ_{TP} , which are related to varying substance systems processed by the PEA. In the illustrative example, θ_{CP} the variables V_j, UA_j, ρ_j and $c_{p,j}$ are capability parameters, while ρ, c_p, k_0, E_A and λ are transformation parameters. The parameter sensitivities **S** are not provided by the model according to equation (2). For this purpose, numerical differentiation might be applied or a related model including the sensitivity equations might be included in the DT. The simulation model must be considered for nonlinear equality constraints. Furthermore, inequality constraints might be provided through information from a structural model like e.g. a maximal operation temperature of an equipment.

FA can be used to calculate the design space (Dimitriadis and Pistokopoulos, 1995):

$$\chi = \max_{\mathbf{cma}(t)} \left[\min_{\mathbf{cpp}(t)} \left[\max_{ih \in \{1, N_h\}} \left[h_{ih}(\mathbf{x}(t), \mathbf{cqa}(t), \mathbf{cma}(t), \mathbf{cpp}(t), \theta) \right] \right] \right] \quad (4)$$

s.t. $\mathbf{0} = \mathbf{f}(t, \dot{\mathbf{x}}(t), \mathbf{x}(t), \mathbf{cma}(t), \mathbf{cpp}(t), \theta); \quad \mathbf{x}(t_0) = \mathbf{x}_0;$

$$\mathbf{cqa}(t) = \mathbf{g}(\mathbf{x}(t), \theta); \quad \mathbf{cma}_L(t) \leq \mathbf{cma}(t) \leq \mathbf{cma}_U(t); \quad \mathbf{cpp}_L(t) \leq \mathbf{cpp}(t) \leq \mathbf{cpp}_U(t)$$

In process validation, critical material attributes (CMAs), critical process parameters (CPPs) and critical quality attributes are differentiated (CQAs). FA can be used to check if the CQAs can be met under varying CMAs adjusting the CPPs. CMAs and CPPs are both related to the input variables **u**. Thus, the optimization problem requires an adjusted semantic. In our illustrative example, CMAs could be related to the variables describing the feed mass flow F_{in}, c_A, T_{in} , which are dictated by a prior process step in the MP, while potential CPPs are F_j and F . In addition, a connection to structural models describing process validation quantities like requirements to the CQAs could provide added value.

In summary, (1) the DT of a sPEA should be built from integrated structural and behavioral models to provide networked information spaces and hence make information accessible more easily or even automatically. Furthermore, (2) the DT should provide the capability to describe and connect the different semantic contexts to make it understandable. In addition, (3) the DT should be extendable easily, allow the integration of new information models, and be adjustable to different PEA configurations easily.

4. A linked-data-based digital twin concept for smart PEAs

Over the life cycle of a PEA, different domain-specific models emerge that have specific views of a PEA (Wiedau et al., 2019). The systematic networking of models is an essential prerequisite for a smart PEA. Existing information relationships can thus be used directly. In addition, the networking is a basic prerequisite for the synchronization of the models, so that all models are always free of contradictions regarding defined rules (Rahm et al., 2021). Graube et al. (2012) developed a concept using linked data that meet the requirements for a shared and distributed information space in industry. The basis are graph-based structures that are described using the Resources Description Framework (RDF) (Graube et al., 2012). The SPARQL query language can be used to retrieve the

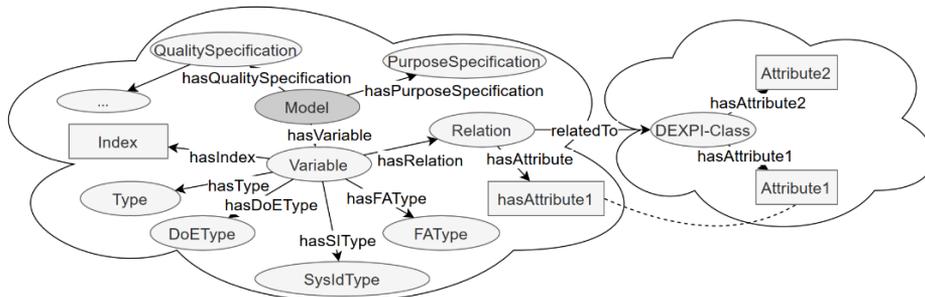

Figure 2: Information model for simulation models in linked data information. Behavioral models like simulation models must be semantically lifted into the graph-based structure to unlock the descriptive power of linked data for the DT. We suggest defining an additional structural model in linked data which describes meta information of simulation models (see figure 2). This structural model relates simulation models to variables, a purpose specification, and a quality specification (cf. Mädler et al., 2021). This paper does focus on the variables. The most important attributes of a variable are the type and the index. These are used to relate the variable to the characterizing vectors of a simulation model according to equation (2). The type might therefore be ‘input’, ‘output’, ‘state’, ‘initial state’, or ‘parameter’. The index attribute provides the index of a variable in the vector. The further attributes provide information on the semantic meaning of the variable e.g. in the DoE context. Therefore, the DoEType might be ‘dynamic factor’, ‘constant factor’, ‘measurement’ or ‘none’. These types do not force the user to use a variable as factor, but rather indicate its semantic meaning. In addition, the variable can have relationships into other information models like DEXPI. In this case, an additional attribute to a variable must indicate the relation, point to the node in the foreign information model and name the related attribute. In this way, the semantic lifting of simulation models into linked data permits the connection of the considered quantities in a simulation model with several other information spaces (see figure 3). Firstly, e.g. variables representing quantities related to a sensor might point to the particular sensor in DEXPI. Secondly, the same variables could become directly or indirectly connected to digital representations of equipment data sheets. Thirdly, information models describing the knowledge space of process validation including process design, process qualification and continued process verification might be integrated. Finally, meta information models for experiments in linked data can be envisioned. This would allow to relate time series data to digital data sheets of the sensors and to the outputs of the simulation model. The combination of a linked data information space for structural models, a repository for behavioral models and a time series database for experimental data does provide a well-suited containment for each type of data and its semantic interconnection. SPARQL queries can be used to set up simulation and

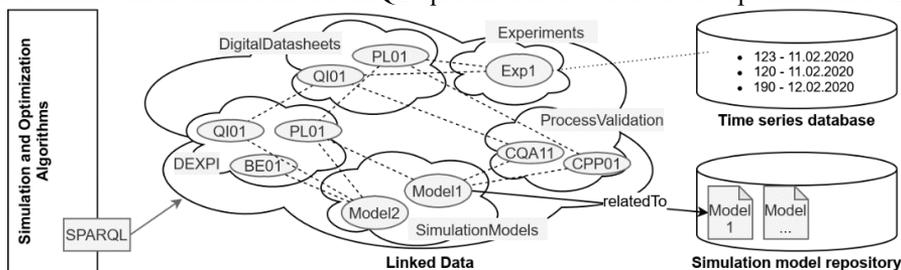

Figure 3: Information architecture for the digital twin of smart PEAs

optimization problems by asking the DT for simulation models of suitable purpose specification and quality specification. Furthermore, the information model provides knowledge on the semantic structure of the simulation model.

5. Conclusion

This paper aimed to answer the question how a DT for the support of process design in process validation in sPEAs should be constructed. It was reasoned that the DT should include and interconnect structural and behavioral models to provide information for different simulation and optimization tasks. We suggested a linked-data-based architecture to build a digital twin integrating structural models like engineering data, behavioral models like simulation models and time series data. The simulation models are semantically lifted into linked data using a descriptive information model. This reduces manual efforts for the O/O since information becomes digitally interconnected, accessible, and automatically processible. In future work, this approach must be extended to include the purpose specification and quality specification of simulation models. Furthermore, the relationship between different simulation models for the same PEA should be added to the information model. Finally, the information models related to digital datasheet, experimental data and process validation must be integrated.

Abstract

Pressure swing adsorption (PSA) can remove CO₂ from flue gases. The full potential of the technology can only be exploited if the optimal combination of adsorbent material and process is identified. This identification requires screening the large database of adsorbent materials by performing computationally intensive process optimizations. To ensure a suitable compromise between accuracy and computational lightness, the PSA process can be described by reduced-order models. However, those models might involve several discrete states making the objective function discontinuous and not continuously differentiable, challenging gradient-based methods. The selection of suitable optimization methods is therefore an open issue. This study compares three optimization algorithms, Bayesian optimization, NOMAD and KNITRO, for two cases and adsorbent materials.

For the tested cases and adsorbent materials, none of the three algorithms is clearly superior to the other. Bayesian optimization (BO) needs fewest function evaluations and computational time to converge and outperforms the other two for one case. However, BO is less reliable than NOMAD and KNITRO for the other case tested.

Keywords: pressure swing adsorption, CO₂ capture, techno-economic optimization, Bayesian optimization

1. Introduction

Rigorous pressure swing adsorption (PSA) models consist of a set of partial differential and algebraic equations and are thus computationally intensive to solve. In addition, the performance of a PSA cycle must be assessed at cyclic steady state, which requires to simulate several cycles. Rigorous PSA models are discontinuous and are not continuously differentiable. An overview of the related challenges, with a focus on efficient simulation and optimization strategies for the design of PSA systems, is provided by Biegler et al. (2004).

A key for the design of an efficient PSA process is the choice of the adsorbent (Farmahini et al., 2021). To maximize the economic efficiency of a PSA process, adsorbents have to be assessed using a thermo-economic process metric. However, the impact of the adsorbent properties on the economic performance is challenging to predict (Leperi et al., 2019). To address this challenge, a techno-economic framework is developed to screen thousands of adsorbent structures for PSA processes and rank them for a given set of process metrics (Riboldi et al., 2020). For efficient screening, fast and robust process optimization is essential. In this study, a reduced-order

PSA model is used (Riboldi et al., 2020) and linked to a Bayesian Optimization algorithm (BO). BO uses Gaussian Process (GP) regression to identify a surrogate model of the original objective function and optimizes the surrogate to find the next evaluation point in each iteration. GP is a probabilistic, non-parametric modelling technique well known in the machine learning community (Rasmussen and Williams, 2006). The advantage of using GP regression is that it is not bounded by specific model structures as e.g. parametric models. Consequently, it can identify the surrogate model in a flexible manner (de Avila Ferreira et al., 2018). We compare the BO algorithm to two optimization algorithms from the literature, namely an algorithm implemented in the software library KNITRO (Byrd et al., 2006) and the blackbox optimisation software NOMAD (Abramson et al., 2021), and discuss their performance in terms of objective function value, computational time and how reliable they converge to the same optimum.

2. Optimization algorithms

2.1. Bayesian Optimization

BO minimizes a function $f(\mathbf{x})$. For this purpose, a probabilistic model for the function $f(\mathbf{x})$ is constructed using Gaussian process regression, which is used to decide where to evaluate the function next. Thus, BO is a sequential approach in which first a regression model is trained as surrogate model, which is then minimized instead of the original function $f(\mathbf{x})$. The optimum of the surrogate model is evaluated using the original function $f(\mathbf{x})$, the surrogate model updated, and the optimization repeated. BO is especially powerful when function evaluations are computationally expensive (Snoek et al., 2012) as it is the case for the investigated PSA model.

Gaussian Processes (GP) are non-parametric, probabilistic kernel methods (Rasmussen and Williams, 2006) and aim to identify a function f , which describes a data set. The noisy observations of $f(\mathbf{x})$ are given by

$$y = f(\mathbf{x}) + v, \quad (1)$$

where the noise v is Gaussian with zero mean and variance σ_m and x is the input vector. Smoothness properties of the underlying function $f(\mathbf{x})$ are enforced by choice of mean and covariance function without relying on parametric assumptions (Snelson and Ghahramani, 2006). In this article, a zero-mean function and the automatic relevance squared-exponential covariance are chosen. The performance of the GP depends on the hyperparameters Φ , which are commonly unknown and need to be inferred from data. The hyperparameters are the noise variance, signal variance and the values in the scaling matrix of the covariance function. Here, the marginal likelihood is used to estimate the hyperparameters.

An important choice for BO is the formulation of the acquisition function. The acquisition function is used to determine the next point to evaluate. In this work, we test two acquisition functions: First, the GP lower confidence bound (GP-LCB) is chosen

$$\mathbf{x}_{i+1} = \arg \min_{\mathbf{x}} (\mu(x; \{\mathbf{x}_i, y_i\}, \Phi) - \kappa \sigma(x; \{\mathbf{x}_i, y_i\}, \Phi)), \quad (2)$$

where μ and σ mean and variance of the GP regression model. The observations are in the form $\{\mathbf{x}_i, y_i\}_{n=1}^N$ and κ is a parameter balancing exploitation against exploration (Snoek et al., 2012). The second acquisition function tested is maximizing the expected improvement (GP-EI) over the current best.

$$\mathbf{x}_{i+1} = \arg \max_{\mathbf{x}} (\sigma(x; \{\mathbf{x}_i, y_i\}, \Phi)(\gamma(\mathbf{x})\Psi(\gamma(\mathbf{x})) + \mathcal{N}(\gamma(\mathbf{x}); 0, 1))), \quad (3)$$

where Ψ is the cumulative distribution function of the standard normal and $\gamma(\mathbf{x})$ is defined as:

$$\gamma(\mathbf{x}) = \frac{f(\mathbf{x}_{best}) - \mu(x; \{\mathbf{x}_i, y_i\}, \Phi)}{\sigma(x; \{\mathbf{x}_i, y_i\}, \Phi)}. \quad (4)$$

2.2. NOMAD

NOMAD is a blackbox optimization tool suited for difficult problems with a small number of variables. NOMAD uses Mesh-Adaptive-Direct-Search to perform the optimization, which is a gradient-free optimization method (Le Digabel, 2011). In this work, NOMAD version 4 is used, which is available from the website (Abramson et al., 2021).

2.3. KNITRO

KNITRO is a commercial optimization software library for solving nonlinear mathematical optimization problems (Byrd et al., 2006). The library contains several local optimization solvers and algorithms for continuous and discrete problems with and without constraints. KNITRO allows for gradient-based or derivative-free and black-box optimization. In this work, we use KNITRO version 12.3. For a description of the used settings, please see Section 4.1.

3. PSA model

The PSA model builds on an approach presented in the literature (Maring and Webley, 2013), which assumes local equilibrium, i.e., CO₂ gets instantaneously adsorbed on the adsorbent materials. The PSA model is customized to simulate a 4-step cycle process (adsorption, blowdown, evacuation, light product pressurization) (Riboldi et al., 2020). The model includes a realistic representation of the operation of vacuum pumps, based on the work from Maruyama et al. (2020). The model has four optimization variables: the minimum, intermediate and maximum pressure and the adsorption temperature and two constraints, purity and recovery. A techno-economic analysis (TEA) framework is integrated into the PSA model enabling the consideration of the CO₂ avoidance cost (CAC) as objective function of the optimization. The TEA model is based on rigorous simulation of PSA (Subraveti et al., 2021) and adapted for utilization in the reduced-order model. The model embeds external models and functions, so the optimization algorithm must be able to handle blackboxes. Two adsorbent materials are investigated in this study: a zeolite 13X (Haghpanah et al., 2013) and a metal-organic framework (MOF) UTSA-16 (Agueda et al., 2015). The competitive adsorption isotherms are described by the dual-site Langmuir model. The CO₂ emission intensity of energy demands and reference processes is taken fromecoinvent version 3.7.1, using the impact assessment method "Environmental Footprint 2.0" and allocation at the point of substitution (Wernet et al., 2016).

4. Case study

4.1. Setup of the optimizations

Each algorithm is tested 20 times considering randomly generated initial values. For NOMAD and KNITRO, the same 20 initially generated initial values are considered. In contrast, the BO needs an initial set of several function evaluations to create the first GP regression model. The size of the initial set is set to ten. Each initial set contains the initial value of NOMAD and KNITRO of the corresponding test run and additionally nine randomly generated evaluations. The BO does not evaluate gradients of the original function, but only of the surrogate. Therefore, BO is terminated if the maximum amount of function evaluations is reached, which is set to 56. In addition, BO is terminated if the constraints are satisfied, and the last iterations is within 1% of the best previously obtained objective function value and the scaled inputs (between 0 and 1) of these two points have a distance of less than 0.015. A large exploration factor prevents quick convergence towards the same region and premature termination of the optimization. A multi-start gradient-based optimization is used to maximize the marginal likelihood to estimate the hyperparameters and optimize the acquisition function.

The NOMAD algorithm terminates when the maximum amount of function evaluations are reached. We test a maximum amount of 100 and 150 function evaluations. The constraints are handled with a progressive barrier approach. Therefore, constraints must just be satisfied at the solution. For KNITRO, we performed a parameter study to identify the solver setting resulting in a good compromise between accurate gradients and reliable convergence due to discontinuities of the model. From this study, we chose the Active Set algorithm to solve the problem. The gradients of the objective and constraints are approximated using forward finite differences and the Hessian of the Lagrangian by (dense) quasi-Newton BFGS Hessian. To account for the discontinuities in the objective function, constraints and gradients, we select a comparatively high relative step size of 0.05 for finite-difference gradients.

4.2. Cases

The performance of the two adsorbent materials is tested on the adsorption of CO₂ from flue gas for two relevant industries, namely a cement kiln and a natural gas (NG) offshore combined cycle power plant. The two cases are representative of rather different CO₂ concentrations (25% and 4% of CO₂ in N₂, respectively). The power required by the PSA process is drawn from the grid for the cement case while internally generated in the case of the NG offshore combined cycle.

5. Result

The optimization algorithms are compared in Table 1. For the cement case, BO achieves the smallest average CAC with the smallest computational time. In addition, it reaches the same optimum with high reliability. KNITRO achieves a similar objective function value in case of the zeolite 13X adsorbent but requires more function evaluations and thus, computational time. For UTSA-16, the mean objective function value differs by 10% for both of KNITRO and NOMAD 100/150 from the mean CAC obtained with BO. Moreover, the maximal difference in the objective function value is 39% and 24% for NOMAD 150 and KNITRO, respectively, while it is only 14% and 15% for BO EI and BO LCB, respectively. For the cement case, BO is also about twice as fast compared to the other algorithms. The optimal values of two of the four process degrees of freedom are at the bounds. This result is identified consistently by the BO, while KNITRO and

		NOMAD 150	617.9	4.8	609.2	93.7	1.5	150	0	3.8
		KNITRO	626.5	9.7	612.3	61.9	9.1	109.3	15.8	6.7
		BO LCB	642.5	21.7	612.2	40.6	5.4	54.3	6.1	13.1
		BO EI	629.9	28.8	610.0	40.9	8.1	50.8	9.7	17.8

NOMAD converge to sub-optimal solutions in some test runs, where these variables are not at the bounds. Nevertheless, all algorithms converge to the same optimum in at least one run. Therefore, the best achieved objective function values are almost identical.

For the NG offshore case, KNITRO achieves the best mean objective function value for the zeolite 13X adsorbent and NOMAD 150 for the UTSA-16 adsorbent. BO still needs less computational time than the other algorithms but is less reliable for this case. In one to two of the 20 test runs, the maximal difference in the objective function is 18% for BO. For these cases, at least one optimization variable gets stuck close to or at a bound. The BO LCB is more prone to this behavior than the BO EI. The BO EI has a stronger focus on exploring the optimization region, which improves converging to the global optimum when many local solutions exist. Nevertheless, the best function value achieved by every algorithm over the 20 tests is very similar.

The optimization time mainly results from evaluating the PSA model. BO needs fewest function evaluations but needs more overall optimization time per function evaluation than the other algorithms. The time difference per function evaluation between BO and KNITRO is about 0.2s. BO optimizes hyperparameters of three surrogate models (objective function plus two constraints) and minimizes the surrogate model in each iteration, which causes the larger time consumption per function evaluation.

6. Discussion

For the considered cases and adsorbents, none of the optimization algorithms can be recommended unconditionally. The discontinuities in the PSA model result in many local optimal solutions making it difficult for the optimization algorithm to converge consistently to the global optimum. The BO is the fastest algorithm. For the BO algorithm, the user has to choose the covariance function, the maximum allowed function evaluations and the termination criteria. More function evaluations improve the reliability but lead to unnecessary function evaluations around the optimum. The maximum number of function evaluations chosen in this work balances reliability of finding a solution close to the global optimum and computational time. The chosen criterion to terminate the BO before reaching the maximum allowed function evaluations decreases the number of iterations by about 15 in the cement case, while it almost never triggered in the NG offshore case. Defining a suitable termination criterion for BO can be challenging. However, without additional termination criterion, the computational time of the BO for the cement case would just increase by about 10 s. For the BO, a squared exponential covariance function is chosen, which expects a certain smoothness of the system. The convergence might be improved by a less smooth covariance function, for which a suitable optimization method has to be chosen to optimize the Gaussian Process regression model, e.g., a gradient-free optimization method. For GP-LCB, we choose $\kappa = 16$ to focus on exploration since the BO-LCB tends to converge to local optima if κ is too small. The main reason for choosing the LCB acquisition function is to avoid exploring likely uninteresting regions, which is counteracted by a large κ . The EI acquisition function is easier to apply for this case, which does not contain a tuning parameter.

For NOMAD, a maximum of 100 and 150 function evaluations are tested. For these investigated cases and adsorbents, fewer than 100 function evaluations are not recommended without the risk of significantly degrading performance. 150 function evaluations increase the reliability but also the computational time. The advantage of the NOMAD is the easy applicability and the convergence to the global optimum giving enough function evaluation. Similar to BO, KNITRO achieves a good balance between reliability and computational time. However, a detailed study of the user options has to be performed in advance (e.g., algorithm, methods for gradients and Hessian or step size of finite differences) to tackle the challenges of the discontinuities of the model. A combination of BO and KNITRO, where BO provides the initial values for KNITRO, could reduce the computational time of KNITRO.

7. Conclusions

A Bayesian optimization algorithm is tested for optimizing the carbon-avoidance cost of a PSA process for two adsorbent materials and two industry cases and compared to two optimization algorithms from the literature. For the investigated cases, BO shows a good balance between computational time and reliability and is thus a promising option for adsorbent screenings. However, no algorithm outperforms the others in all investigated cases. Each optimization algorithm is at least for one case/adsorbent combination less reliable than the other algorithms. Consequently, in future work, a detailed comparison of the algorithms has to be performed for more cases and adsorbent materials.

Abstract

As electric vehicles (EVs) become popular, the use of lithium-ion batteries is increasing. However, it is difficult to ensure the reliable use of the battery because the state of charge (SoC) of a lithium-ion battery cannot be measured directly. SoC estimation is necessary to ensure the safety of battery systems by preventing over-charge and discharge of the battery and to extend battery life through efficient use. The optimal battery balancing strategy, estimation of the remaining driving range of EV, and Vehicle to Grid strategy can be developed through accurate SoC estimation. Therefore, it is necessary to study how to estimate the SoC of the battery in real-time. As methods for estimating SoC, equivalent circuit model, electrochemical model, and recently artificial neural network-based model are being studied. The electrochemical model is not suitable for real-time use due to its high computational complexity. Artificial neural network-based models require a large amount of data for learning, but most of the data is collected in the lab, which can lead to a lack of data and is difficult to ensure accuracy in such cases.

In this study, a surrogate model based on electrochemical models for SoC estimation is developed to solve computational complexity problems of electrochemical models and the accuracy problems of data-driven models due to data dependence. Based on the 1C discharge experimental data, parameter identification of the electrochemical model was performed using a Genetic Algorithm. Output variables such as Li-ion amount in the negative electrode and voltage for various drive cycle loads are derived from this model to create a sufficient amount of data for model training. The surrogate model is trained using these output variables and compared with data-driven models in terms of accuracy and computational complexity. Based on the Long Short Term Memory (LSTM) architecture, the artificial neural network-based model was trained gradually with driving cycle data and then compared with the surrogate model at each step. As a result, the surrogate model based on an electrochemical model using fewer data showed feasible computational complexity and high accuracy. Through the proposed method, it is expected to accurately estimate battery SoC in real-time and make the battery use efficiently.

Keywords: Lithium-ion battery, Battery modelling, State-of-Charge

1. Introduction

As electric vehicles (EVs) become popular, the importance of lithium-ion battery management is increasing. However, it is impossible to accurately monitor the electrochemical behavior in a lithium-ion battery, so it is very difficult to estimate the State of Charge (SoC) required for optimizing the use of the battery. Representative methods used to estimate SoC include the Coulomb Counting Method, the Open Circuit Voltage Method, the electrochemical model based method, and the data-driven model based method. The Coulomb Counting Method measures the current of the battery and integrates the current over time. The limitation of this method is that when the battery is used for a long time without being fully charged or discharged, errors accumulate, making it difficult to accurately estimate SoC. The open circuit voltage method uses the SOC versus OCV curve. However, to measure the relaxed OCV, the battery has to reach equilibrium, so it is difficult to use it in real-time because it takes several hours. The electrochemical model based method uses the electrochemical model to simulate the electrochemical behavior inside a battery. This method shows very accurate performance, but the model is so complex that it is difficult to use in real-time. The data-driven model based method is training and using artificial neural networks with sufficient data. If the data is sufficient, it shows high performance, but if the data is insufficient, the reliability of the model decreases.

Chemali et al. introduced a deep neural network to map battery signals directly to SoC. Chemali et al. used the Long Short Term Memory (LSTM) based artificial neural network model to estimate SoC. Jiao et al. introduced a GRU-based artificial neural network to estimate. Dawson-Elli et al. developed the surrogate model of P2D by using machine learning techniques such as a random forest, decision tree, and gradient boosted machine. Tian et al. employed an adaptive cubature Kalman filter to reduce the fluctuation of LSTM network estimation. In this study, the LSTM-based data-driven model, the P2D model, and the P2D model-based surrogate model are compared and analyzed in terms of accuracy and calculation time.

2. Datasets

This research uses a dataset obtained from a Panasonic 18650PF cell. The battery is described in Table 1. The dataset involves 1C discharge data, HPPC (Hybrid Pulse Power Characterization) data, drive cycle data at ambient temperatures 25 °C

Table. 1. Panasonic 18650 Cell Parameters

Nominal Open Circuit Voltage	3.6V
Capacity	Min. 2.75 Ah / Typ. 2.9 Ah
Min / Max Voltage	2.5V / 4.2V
Mass / Energy Storage	48g / 9.9Wh
Minimum Charging Temperature	10
Cycles to 80% Capacity	500 (100% DOD, 25)

3. Method

As methods for estimating SoC, the performance of the data-driven model, electrochemical model, and surrogate model is compared in terms of accuracy and computation time in this study. A flowchart representing the methodology is shown in Figure 1.

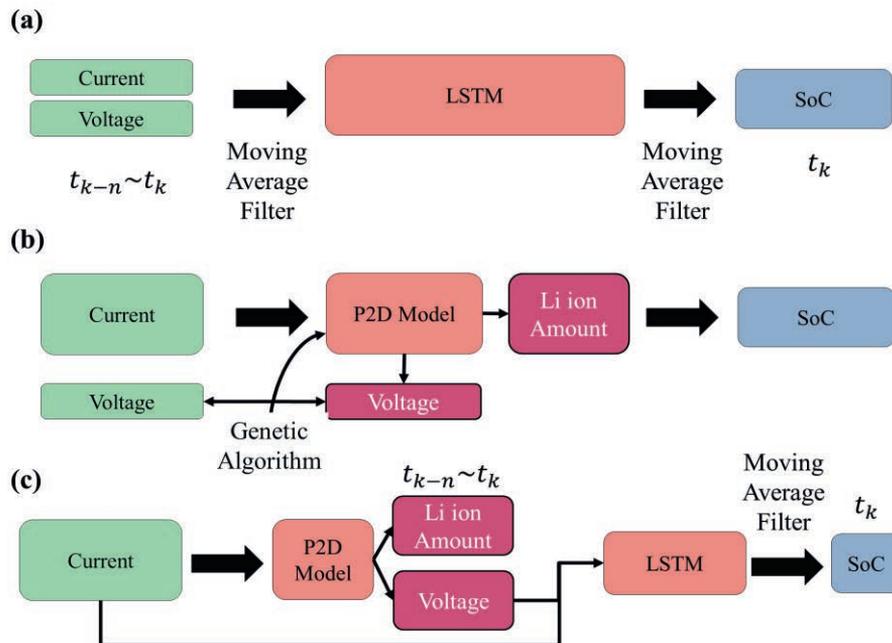

Fig. 1. Process Flowchart for Developing Models (a) Data-driven model (b) P2D model (c) Surrogate model based on electrochemical model

3.1. Data-driven model

LSTM is introduced to solve the performance degradation of RNNs in long-term sequences. Fig. 2 presents the structure of LSTM, in which x , h are the input of the network at time step k ; σ is sigmoid function and \tanh is hyperbolic tangent function. There are three gates in LSTM to capture long-term dependencies. The input gate, output gate, and forget gate allow the LSTM to forget or memorize newly acquired information to the memory cell. The LSTM model is trained on 9 drive cycle data. Of the ten drive cycle datasets, 80% of 9 datasets are used for training and 20% for validation. The model was tested with the remaining dataset. The exponential weighted moving average filter is used for smoothing input data.

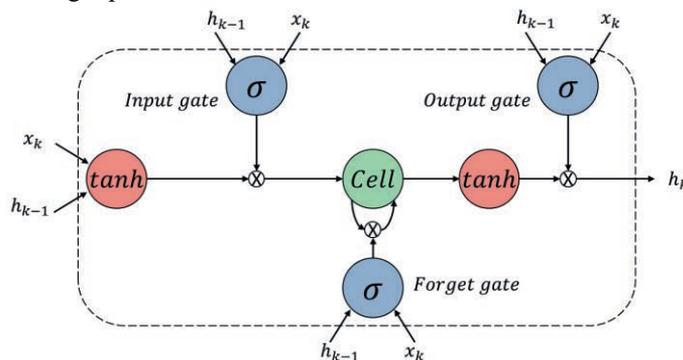

Fig. 2 Structure of the LSTM

3.2. Electrochemical model

The pseudo-two-dimensional(P2D) model, also called the Doyle-Fuller-Newman(DFN) model, is based on the porous electrode theory and the concentrated solution theory. Table. 2 shows nonlinear partial differential equations that represent mass balances, charge balances, electrochemical reaction kinetics. The 1C Discharge data is used to identify the parameters for the P2D model by Genetic algorithm.

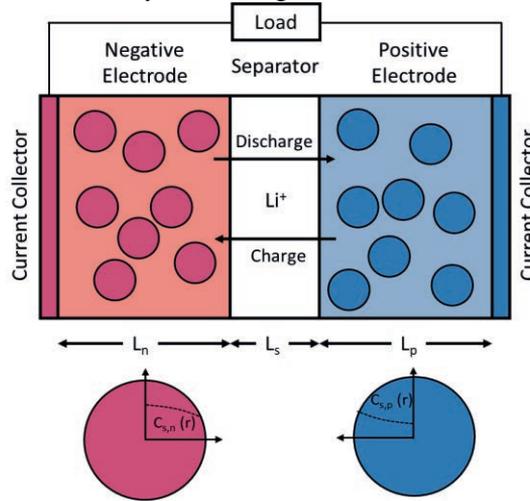

Fig. 3 Schematic of P2D Model

Table. 2 Governing Equations of P2D Model

Region	Governing equations
Charge Conservation in the solid particles	$\sigma_{eff,s,i} \frac{\partial^2 \phi_{s,i}}{\partial t} = a_{sep,i} F j$
Mass Conservation in the solid particles	$\frac{\partial c_{s,i}}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left(D_{s,i} r^2 \frac{\partial c_{s,i}}{\partial r} \right)$
Charge Conservation in the electrolyte	$-\sigma_{eff,s,i} \frac{\partial \phi_s}{\partial x} - \kappa_{eff,i} \frac{\partial \phi_l}{\partial x} + \frac{2\kappa_{eff,i} RT}{F} (1 + t_+) \frac{\partial \ln c}{\partial x} = \frac{I_{app}}{A}$
Mass Conservation in the electrolyte	$-\varepsilon_{l,i} \frac{\partial c_l}{\partial t} = D_2 \frac{\partial^2 c_2}{\partial x^2} + a_{s,i} (1 - t_+) j$
Intercalation at the particle surface	$j = 2k_i (c_{s,i,max} - c_{s,i r=r_i})^{0.5} (c_{s,i r=r_i})^{0.5} (c_l)^{0.5} \sinh \left(\frac{0.5F}{RT} (\phi_s - \phi_l - U_i - FR_{SEI}) \right)$

3.3. Surrogate Model

The Surrogate model was trained in the same way as the Data-drive model using simulated data. The current datasets of nine drive cycles are used for the P2D model. It is different from the data-driven method in that it is trained using simulation data, not actual measurements. Based on the P2D model in which parameters are identified using 1C discharge data, the voltage dataset for training can be generated using any current dataset, which can be used if the measurement dataset is insufficient.

4. Result

The SoC estimation results of each method are shown in the Table. 3. The algorithms are executed on Core i7 4.0 GHz processor with 16 GB RAM. The surrogate model showed competitive performance without experimental data. Figure. 4 presents the graphs of the

estimated and actual values. In Fig. 5 below, the Mean Absolute Error(MAE) of the data-driven model becomes lower than the MAE of the surrogate model.

Table. 3. SoC estimation results

Model	MAE(%)	Computation time(s)
Data-drive model	1.21	1.02
P2D model	0.72	103.74
Surrogate model	2.01	0.77

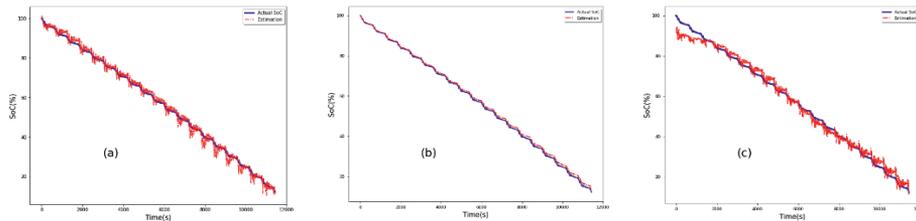

Fig. 4. SoC estimation results of models (a) data-driven model; (b) electrochemical model; (c) Surrogate model based on electrochemical model

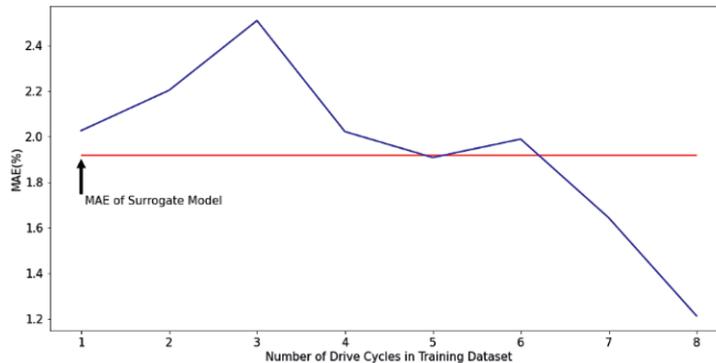

Fig. 5. MAE of the data-driven model

5. Conclusion

The P2D model estimated the SoC most accurately, but the computation time took the longest. The surrogate model and the data-driven model show similar computation times. The MAE of the data-driven model is lower than the surrogate model after training 5 drive cycles datasets. If data is insufficient, the Surrogate model could be an alternative to the data-driven model. The surrogate model also can be trained using more simulated data from the P2D model. If the battery condition changes by aging, it is difficult to gather sufficient data to train the data-driven model. However, simulated data can be gathered after the parameter identification of the P2D model. It is considered to be an advantage of the surrogate model for real-time SoC estimation rather than the data-driven model, which requires a lot of data when the battery condition changes.

Nomenclature

$i = (p, sep, n)$	T = ambient temperature [K]
p = positive electrode	A = cross section [m ²]
sep = separator	c = lithium concentration [mol/m ³]
n = negative electrode	D = diffusivity of lithium ion [m ² /s]
s = solid phase	j = the rate of lithium ion flowing out of a particle across a
l = liquid phase	boundary between the solid and the electrolyte [mol/m ² ·s]
κ_{eff} = effective conductivity of the electrolyte [S/m]	k = intercalation/deintercalation reaction-rate constant
ϕ = electrical potential [V]	[m ^{2.5} /mol ^{0.5} ·s]
σ = electronic conductivity [S/m]	r = radius of particle [m]
σ_{eff} = effective electronic conductivity [S/m]	R_{SEI} = resistance of SEI layer [Ω /m ²]
ϵ = volume fraction [-]	t_+ = transference number in the electrolyte [-]
F = Faraday constant [C/mol]	U = Open circuit potential [V]
R = ideal gas constant [J/mol·K]	
I_{app} = current applied to the lithium-ion battery [A]

Abstract

Ionic liquids (ILs) is an organic salt in the liquid state, which have an excellent property as a favorable solvation for a range of polar and non-polar compounds. Recently, a number of ILs have been widely used for a chemical separation, e.g., extraction of aromatic and aliphatic compounds from hydrocarbon mixtures, due to its high-energy efficiency compared to conventional separation processes that requires a considerable thermal energy or electricity. One of critical properties forward a wide application of ILs is the infinite dilution activity coefficient (IDACs) of solutes and the equation of state (EoS) parameters. However, the discovery of a perplexing principle of ILs behaviors requires highly sophisticated experiments on a number of solutes.

Moreover, the validity of conventional property models such as UNIFAC, Abraham and COSMO-RS for predicting IDACs show some limits in that only few solutes are applicable within a certain range of operating temperature. Therefore, in this work, we aimed to propose the machine learning (ML) based IDAC prediction model to rapidly provide precise properties and parameters of ILs separation process. First, ILs experimental data and their physicochemical features are collected from the literature. We then developed an IDACs prediction model using artificial neural networks (ANNs) and validated the model with accuracy metrics such as coefficient of determination (R^2) and root mean square error (RMSE). Finally, the capability (accuracy and quantity) of the ML-based prediction model is discussed by comparing conventional models. As a result, it was revealed that the ML-based approach shows higher accuracy (approximately 10~50%) compared to conventional property models. A database of predicted properties based on data-driven strategy could lead to wide applications of ionic liquids in separation technique. From proposing a strategy for ILs utilization, the ML-based approach was able to provide the essential information on the ILs design and promote the future environmental-friendly separation processes.

Keywords: Ionic Liquids; Infinite-dilution activity coefficients; Machine-Learning.

1. Introduction

Ionic liquids (ILs) are the green solvents, which receive the great attention as replacement for conventional separation media. Since ILs could bring the significant economic and environmental benefits, the potential of ILs in industrial deployment has been proven (Urszula et al., 2010, Pablo et al., 2019, Siliang et al., 2020).

While ILs are indeed a promising separation technology, there are obstacles delaying the real-world deployment. The precise modelling of ILs process is the one of the most difficult problems. Conventionally, the ILs behavior is largely understood by the thermodynamics such as the equation of state (EoS). Even though such empirical approaches have described the principle of solute-solvent interactions in ILs, identifying critical parameter for EoS such as infinite dilution activity coefficient (IDACs) are extremely difficult. Because the experiments take time and trial-and-errors, which eventually became a bottleneck of ILs application.

Machine learning (ML) has been a practical tool for discovering and understanding the perplexing patterns in chemical domain. Especially, artificial neural networks (ANNs) have successfully assisted wide range of chemical engineering R&Ds including novel catalyst discovery, battery lifecycle prediction, and metal-organic-framework candidate material screening.

Fabian et al. utilized the matrix completion method (MCM) to develop ML-based activity coefficients prediction model (Fabian et al, 2020). Although such an approach successfully analyzes the mixture behavior of the 240 solutes and 250 solvents, the accuracy of the proposed model is a limitation for generating reliable prediction data. Therefore, we propose the ML-based IDAC prediction model for the precise and rapid modelling of ILs process. To implement such data-driven method, the ILs experiment datasets and solute-solvent property descriptors are collected. Then, ANNs were exploited to develop the ML-prediction model. Finally, from comparing to the conventional IDAC prediction model, the reliability of ML-based IDAC prediction model is evaluated.

2. Data and method

2.1. Overview

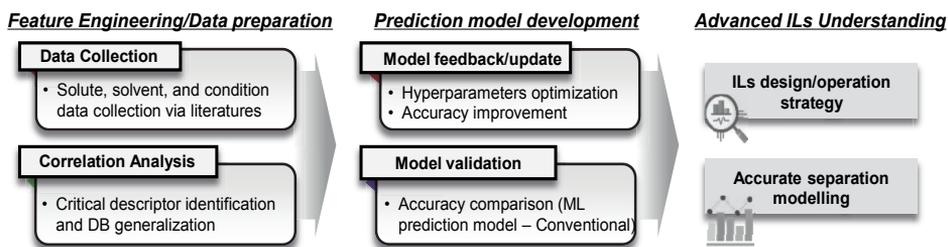

Figure 1: ML-based IDAC prediction model development overview

The main step of ML-based model development is described in Figure 1. It is composed of three steps: *Feature engineering and data preparation*, *Prediction model development*, and *Advanced ILs understanding*. Firstly, at *Feature engineering and data preparation* step, ILs synthesis and operation data are collected via literature survey (Urszula et al., 2009, Li et al., 2011). Since defining the chemical dimension of ILs process is important to develop highly-reliable prediction model, the most meaningful descriptor is extracted by using correlation analysis. As generalized ILs database is constructed, the datasets are randomly divided into two different datasets, which are for the model train and model validation. In this case, 70% of total datasets are used for model train and 30% are used for model test. Then, by using model train data, artificial neural networks (ANNs) develop the IDAC prediction model. To develop the accurate prediction model, the model

hyperparameters are optimized through a manual search technique. Also, the accuracy of the prediction model is evaluated by Pearson coefficient of determination value (R^2). Finally, by comparing the accuracy of ML-based prediction model and conventional prediction model (UNIFAC), the merits of ML-based prediction model are argued.

2.2. ILs separation data acquisition

As shown in Table 1, there are 9 types of solute and 7 types of solvent are used. Also, in Table 2, the properties and conditions of solvent and solute are described. Property descriptors include the thermodynamical-, physical-, electrochemical-, and interaction property. Firstly, thermodynamic properties at critical point (critical temperature, pressure, volume) and acentric factor are collected since it is important for navigating the phase change. Physical properties include the molecular weight, density, and viscosity. Electrochemical properties (dipole moment, Kamlet-Taft parameters) are also collected since the separation principle using ILs rely on different electric interaction property of substances in the mixture (Lee et al., 2008). Interaction property indicates the Hildebrand's solubility parameter, which determines the solubility and structural affinity of a solute-solvent couple (Marciniak, A., 2010). As a result, 1679 datasets with 14 descriptors are comprised.

Table 1: Solvent type and solute type of ILs separation data

Solute type		
n-Pentane	n-Hexane	n-Heptane
n-Octane	n-Nonane	n-Decane
Benzene	Toluene	Ethylbenzene
Solvent type		
[BMPYR][CF ₃ SO ₃]	[EMIM][TCB]	[4BMPy][NTf ₂]
[EMIM][TFA]	[BMIM][CF ₃ SO ₃]	[BMIM][SCN]
[3BMPy][SF ₃ SO ₃]		

Table 2: ILs separation process descriptor

Data description		
Descriptor type	Descriptor Name	Unit
Solute property	Critical temperature	K
	Critical pressure	bar
	Critical volume	cm ³ /mol
	Dipole moment	D
	Molecular weight	g/mol

2.3. Prediction model development

Figure 2 (a) and (b) show the topology of ANNs and activation function used in this model. The optimal topology (50-100-150-200-250-150-100-50) is found by the manual search technique. Datasets were normalized for preventing the over-fitness of model. The activation function of ANNs is ‘swish’ function (in figure 2 (b)), which is well-known to outperform other activation functions in training deep neural networks.

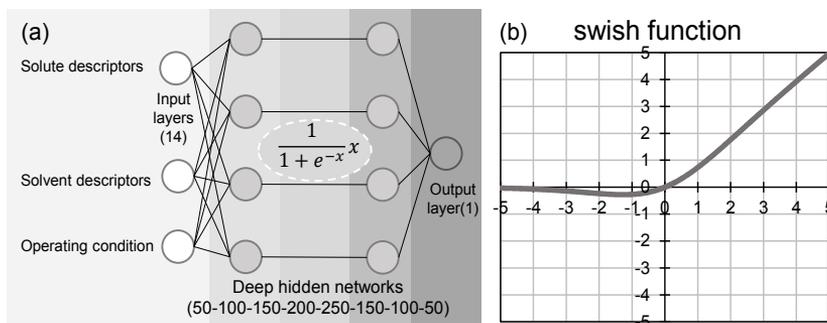

Figure 2: ANNs prediction model development details

Validation of the model was performed in the leave-one-group-out cross-validation (LOGOCV) method. LOGOCV is a cross-validation scheme which holds out the samples according to third-party provided array of integer groups. In order to numerically represent the reliability of models, the Pearson correlation coefficient (R^2) is employed.

2.4. Results

From developing more than 100 models while diversifying topologies, the final model is finally gathered. The train/test set validation of IDAC prediction model is described in Figure 3. For the accuracy evaluation, experimental IDACs and predicted IDACs are measured by R^2 value and compared to each other. Note that R^2 value above 0.95 means high accuracy. In Figure 3 (a) and (b), the prediction accuracies of training data sets and test data sets are almost perfect ($R^2 = 0.984$ and 0.974 , respectively). Also, small difference between two accuracy means that the model overfitting is quite unlikely. Since the ML-based prediction model shows the high accuracy and secure from the overfitting, the capability of this model is further investigated.

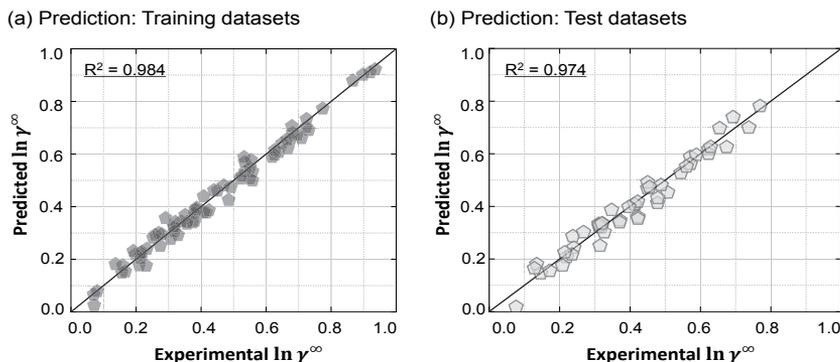

Figure 3: Predicted result and accuracy of training datasets and test datasets

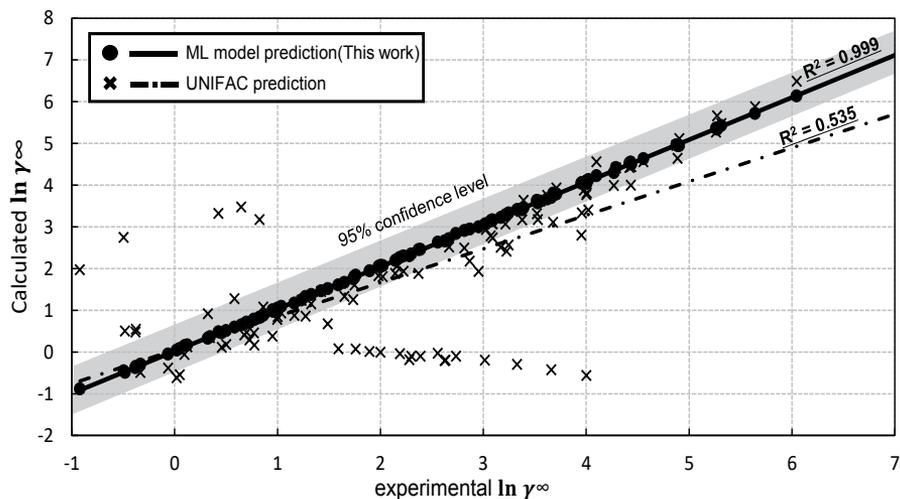

Figure 4. Accuracy comparison of the ML-based prediction model and UNIFAC

The accuracy of the ML-based prediction model and the conventional prediction model (UNIFAC, Thomas et al., 2019) is compared in Figure 4. Each model predicted the IDAC of test data sets where random solute and solvent combinations are given. Note that two types of point are the predicted results of each model (ML model – O, UNIFAC – X). In result, the ML-based model shows better prediction accuracy with higher R^2 value (0.999). It is interesting that the ML-based prediction model produces a relative confident result over 95% level in all prediction cases. In such event, it could be concluded that the ML-based model successfully found the IDAC patterns of ILs process. On the other hand, UNIFAC produced a result of relative high variance. Even though many predictions show a high accuracy, there are unignorable numbers which show incorrect prediction.

3. Conclusion

In this study, we developed and introduced the ML-based IDAC prediction model for ILs process applications. By collecting and defining the critical descriptors, the preliminary chemical dimension of ILs process is constructed. As descriptors, the thermodynamical,

physical, electrochemical, and interaction properties of solute and solvent are utilized. In result, the ML-based IDAC prediction model successfully achieved the high accuracy ($R^2 > 0.95$) and secured from overfitting problem. Also, from comparing the ML-based IDAC prediction model to the conventional IDAC prediction model, it is concluded that the ML-based model is more precise and understood the solute-solvent interaction trend in ILs process. Based on this work, it is able to i) suggest the proper ILs design and operation strategy, ii) provide the efficient and clean separation method from promoting and facilitating the real-world deployment of ILs.

Abstract

In order to reduce CO₂ emissions, electricity networks must increasingly integrate renewable energies. Microgrids are distributed electrical networks with their own generation and load, often supported by an electrical storage system. It can be connected to the external electrical network or isolated. Since electricity consumption, price and renewable production are stochastic phenomena, the control of microgrids must adapt to uncertainties. Data-driven models and in particular reinforcement learning (RL) have become efficient algorithms in high-level microgrid control. RL are agent-based algorithms, which interact with their environment and learn with a numerical reward signal. A certain behavior can implicitly be expected when the reward system is formulated. For example, a reward system that encourages the agent to interact as little as possible with the external network will explicitly increase the autonomy of the microgrid. Implicitly, it can be expected to schedule the battery to maximize the ratio of renewable energy used to the amount producible. Q-learning algorithm has been used due to its performance in discrete action space, which simplified the benchmark complexity. An agent is trained with different reward functions commonly found in the literature related to data-driven microgrid control algorithms. The agent parameters do not vary from one case study to another. Indicators are set up to evaluate the agent behavior. They are based on implicit behavioral criteria in the definition of the reward system such as the ratio of renewable energy used, the amount of energy stored during peak hours, etc. This study enables to find a way to rationalize the choice of a reward system to control in a near-optimal way microgrid while meeting implicit secondary objectives. It could lead to a choice on weighting coefficient in a combination of reward functions.

Keywords: Microgrid, Reinforcement Learning, Control, Reward

1. Introduction

1.1. Electricity storage scheduling with reinforcement learning

To remain reliable despite uncertainties in renewable electricity production and consumption, microgrid control must be efficient. Bidram and Davoudi (2012) has distinguished 3 categories of control. The first 2 categories are frequency and voltage regulation with very low time scale. The third category is what is called high-level control in this study. It concerns power flow long-term planning with higher time granularity (minimum 15 minutes). This high level planning can be done with several methods (Abdelhedi et al. (2018)): rule-based, optimization-based or learning-based methods are efficient. However, with uncertainties of electricity consumption, price and renewable generation, complete physical model based approaches are inappropriate. Thus, optimization-based methods will have difficulties to achieve optimal planning without predicting the future values of the stochastic variables. Data-driven methods are proven to be efficient in this context.

Especially, reinforcement learning (RL) algorithms (Sutton and Barto (1995)) learn policies given an environment and objectives. A RL agent makes decisions in its environment using Markov decision processes, the environment responds and the agent receives a reward signal, indicating if the reached environment state is suitable or not in respect to the objective. With this signal, it learns to value states or actions taken in specific states and thus can build a control policy according to the defined reward system.

High-level control can focus on every microgrid unit, including consumption (demand side management), controllable production (unit commitment) and electricity storage scheduling. This study aims to provide a view of the impact of the choice of reward signal in storage scheduling with respect to implicit indicators.

1.2. Case Study

The system studied is a simulation of a microgrid composed by photovoltaic (PV) panels for electricity production, a point of consumption, an electrochemical battery for short-term storage system and hydrogen storage for long-term electricity storage. This simulation has data-driven units (electricity consumption and PV production) and analytical models (storage). Both data and short-term storage characteristics are taken from François-Lavet et al. (2016). The microgrid has two operation modes: connected to the main grid and isolated.

Some simplifications were made: The maximum power of the battery is not taken into account, the power to be supplied is multiplied by its efficiency and it automatically balances the network provided that its energy capacity is high enough. The RL agent controls the hydrogen storage system. Its maximum power is 1.1kW, its electrolyser efficiency is 0.65 and its fuel cell efficiency is 0.5. No maximum storage capacity is considered. The data are two years of PV production data in Belgium and consumption data respectively. When the net demand for electricity cannot be supplied, the short-term storage is discharged and charged when there is a surplus of energy. The main goal here is to test different reward functions to observe their effects on in behaviors that are implicitly expected from the agent. These behaviors are tracked with indicators.

The RL algorithm used is Deep Q-learning (Mnih et al. (2013)). The agent receives continuous state values that are the electricity consumption, the PV electricity production and the short-term battery state of charge (SOC). All these values are normalized between 0 and 1. The actions that are available for the agent at each timestep are the operating mode of the hydrogen storage system. These actions are discrete, the first action available uses electricity to charge the long-term storage with electrolysis at maximum power if possible. The second action discharges the hydrogen storage with fuel cell at its maximum nominal power (if enough energy is stored). The agent can also choose to do neither. Thus, its action space is composed of three actions.

2. An introduction to Q-learning and deep Q-learning

2.1. Q-learning

The objective of a RL algorithm is to find policies (i.e. probability to take one action from a given state) that maximize the rewards received in an episode (i.e. a series of interaction within the environment). To decide between several actions, the agent values state and action pairs through the rewards following the choice. These pairs are called Q-values and denoted $Q(s, a)$, a stands for action and s for state. The idea behind building an efficient policy is to select the action that maximizes this value from the state in which the agent is located. However, in order to value these pairs, the agent has to explore states and values to sample rewards. A Q-learning agent uses a behavioral policy to sample actions and a learned policy to update the different pairs value. With this algorithm, only the immediate reward perceived by the agent after his action and the following

action (from the next state) that brings to the maximum Q-value are taking into account to update the learned policy.

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha \left[R_{t+1} + \gamma \max_a Q(S_{t+1}, a) - Q(S_t, A_t) \right] \tag{1}$$

This update rule for Q-value mapping is shown in Equation 1, with $\gamma \in [0; 1]$ the discount factor to level out the extent to which future actions are considered in the estimation of a Q-value. Once the agent is trained, an estimate of every Q-values is stored in a table. The agent can then choose every action that maximizes immediate and future reward directly according to this table.

2.2. Deep Q-learning

With Q-learning, the main drawback is from the use of a table, which implicitly requires countable and therefore discrete spaces. Also, wide spaces lead to long computations before the agent is trained.

With Deep Q-learning, the table is replaced by a neural network (NN). In deep learning, the target of a NN has to be stationary. Here, as showed in Figure 1, the target value the NN must predict Q-values, the second part of equation 2 (which the same equation as 1 but factorized in an different way).

$$Q(S_t, A_t) = (1 - \alpha)Q(S_t, A_t) + \alpha \times (R_t + \gamma \times \max_a Q(S_{t+1}, a)) \tag{2}$$

With these Q-values, the problem is that a part of the target, $\max_a Q(S_{t+1}, a)$ (with S_{t+1} the state at time $t + 1$ and a the action that can be taken from state S_{t+1}) depends on the NN that is updated. To solve this problem, an other NN with the same parameters is used to estimate $Q(S_{t+1}, A_{t+1})$. These parameters are frozen and actualized slowly. Another reinforcement learning problem is the influence of the output on the next input. This problem is solved with a *ReplayMemory* that injects randomly a sample of state, action, reward, next state and next action into the NN. In this way, the impact of previous prediction is negligible for incoming output and the idea of transition in the system is kept.

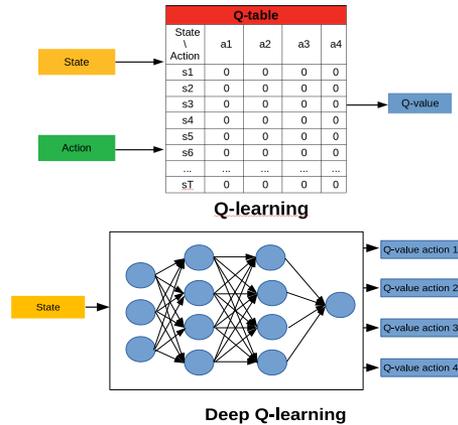

Figure 1: Visual comparison between Q-learning and deep Q-learning

3. Analysis on the impact of reward shaping on implicit indicator

Each and every microgrid system is built with a particular objective. Isolated microgrids follow the objective to be autonomous for example. Some have diesel generator as support electricity production (Kofinas et al. (2018)), and the objective can be to supply users autonomously without this support. Grid-connected microgrids can minimize operation cost or emissions for example. Even though objectives and therefore reward systems can be different, whoever made them implicitly expects awaited behaviors. In the case study microgrid presented in 1.2, whether the reward system depends on autonomy or operating cost, the system is expected to buy less energy from the main grid. Of course, in an isolated grid that aims to be autonomous, the equivalent of buying electricity from the main grid to compensate the grid imbalance is poor quality electricity or even blackout periods. Thus, this need of extra energy can be penalized the same way for these very

different systems. Also, systems aims to be energy efficient. Electricity production can not much exceed consumption, or else equilibrium is lost. However, it is important to get as much electricity as possible from the PV panels, whatever the objective. When the system does not need electricity (consumption is supplied, battery is fully loaded and long-term storage is supplied at maximum power), the remain production is extra-energy and lost. Another implicit objective in every case is to minimize excess of electricity.

3.1. Methodology

Every hour, the agent makes a choice in its microgrid. It can charge or discharge the long-term storage, or do nothing. Its action is perceived as an extra electricity demand or production, if the long term storage is charged or discharged respectively. In order to underline the impact of reward shaping, deep Q-learning agents are trained with different reward systems and indicators are identified. First, in an objective of operating cost minimization, different microgrid configurations are tested. The microgrid buys electricity from the main grid at a price of 2€/kWh. As the time granularity of the simulation is one hour, the agent perceives a -2 reward in this case. It occurs when the microgrid net demand (electricity demand action minus electricity production) including additionnal production or consumption from agent action (hydrogen storage charge or discharge perceived as consumption or production) is positive and superior to the electrochemical battery capacity. On the opposite, when this net demand is negative and the extra energy exceeds electrochemical battery capacity, the remaining produced energy is wasted.

Whatever which mode (isolated or grid-connected) is selected, this system is adopted, and the negative reward for buying electricity is applied to penalize isolated microgrid instability (in this case, no electricity is bought, but the simulation is similar). In the grid-connected mode, three configurations are tested, with the objective of reducing operating cost:

- Case 1 The system can not sell energy to the main grid. With the operating cost reward system, the only perceived rewards are negative and correspond to the electricity purchased from the main grid.
- Case 2 The system can sell energy to the main grid, without power constraint at the common coupling point (the electricity exchange point between the micorgrid and the main grid). In this configuration, agent can receive rewards from selling extra-energy to the main grid. In this specific case, it is impossible to waste energy and PV panels produce 100% of what they should. The electricity sold is four times cheaper than the bought electricity.
- Case 3 The system can sell energy to the main grid, with a power constraint at the common coupling point. The agent sells its extra energy and receives positive rewards in this case. However, this amount of sold energy is limited by a power constraint and so is the reward.

In isolated microgrid, as the main objective is to be autonomous, a negative reward for system instability is applied. It is exactly the same system configuration as the first case listed above.

What if the reward system is explicitly giving the agent penalties for wasting excess energy ? To analyse this situation, the first and last configuration are adopted with an extra negative reward equal to the wasted electricity. Again, it has no sense to use this reward system on the second case because no energy waste is allowed. At last, the energy excess negative reward will be applied without the energy bought negative reward to know how the system behave with only this objective.

A comparison of the quantity of excess energy and bought energy from the main grid will be done in the next section.

3.2. Results and analysis

Agents were trained in every case, with three reward systems for each except the second case in which extra energy does not exist. It means seven agent were trained. The convergence of obtained rewards converged at approximately 30 episodes for every agent. Once the training is over, data of their control behavior in the last training episode (1 year) are collected to analyse results.

3.2.1. Excess energy and purchased energy

Surprisingly, there is very little variation in excess energy between the reward systems for each case.

The same pattern is observed with some small variations. Obviously, this amount is smaller when only excess energy governs the agent’s reward system. It is larger when reward system only considers operating cost. This has many common features with the purchased energy curves. As shown in Figure 2, more energy is brought from the main grid in winter. The agent tends to buy more energy when its reward system penalize it.

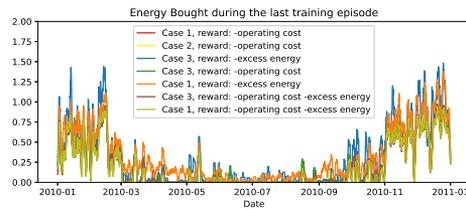

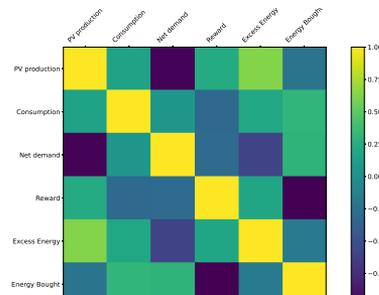

Figure 2: Smooth curve of hourly bought energy in the 3 reward systems

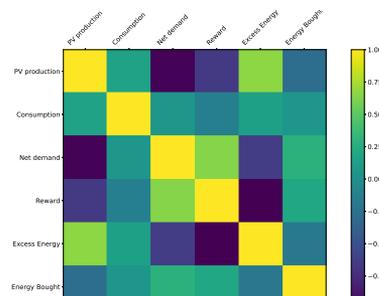

3.2.2. Correlation between variables

Correlation matrices between exogenous variable have been made. It gives important information on how the agent behaves.

Figure 3a shows that rewards are negatively correlated with net demand when operating cost defines reward system. Of course, purchased energy is negatively correlated with rewards. Net demand is the only parameter affected by the agent decision. To increase net demand, the agent has to discharge the long-term storage. In order to do that, the hydrogen storage can not be empty. The agent’s game would therefore be to charge and discharge the hydrogen storage at the right time, so that it can discharge when the purchase of electricity is necessary, to alleviate the negative reward. On the contrary, Figure 3b shows that rewards are positively correlated with net demand when excess energy penalizes the agent. The agent’s action must therefore charge the hydrogen storage when the PV production exceeds the consumption. He can buy energy without being penalized and emptying the storage (infinite in capacity) does not increase his reward. The graph of stored energy (Figure 4) is interesting, it underlines the fact that long-term

(a) Correlation matrix of exogenous variables in Case 1 with only operating cost considered in reward system

(b) Correlation matrix of exogenous variables in Case 1 with only excess energy considered in reward system

storage is used as short-term storage to increase the rewards when buying and selling energy define the reward system. What was observed in the correlation matrix is confirmed in the agent behavior, giving penalties only for excess energy tends to make the agent store bigger hydrogen quantity when it is possible. When both excess energy and operating cost are considered, the agent also tends to store hydrogen the way expected in Case 3. Net demand is highly correlated with PV production and very little correlated with consumption. This is because PV energy production has a range of values that can go very high when non-zero, compared to the consumption which is more constant and low.

When PV panels produce a lot of electricity (between July and September), it may be more attractive to store energy to avoid big excess energy penalties rather negative reward for energy bought. In Case 3, the stored energy can be sold to the main grid in winter. This explains why the agent prefers to store energy in summer in Case 3 rather than in Case 1 (where energy can not be sold) with multi-objective reward system.

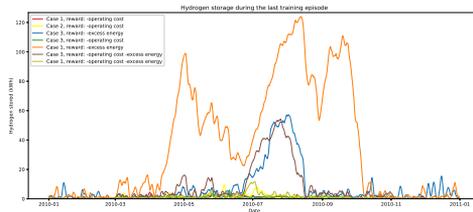

Figure 4: Energy stored in long term storage during the last training episode in every cases

4. Conclusion

The reward functions defines the behavior of a RL based control algorithm in microgrid. Making explicit certain implicitly expected behaviors changed totally the decisions. The multi-objective reward system seems more interesting for the microgrid control in this case study. However, the way to modelize electrochemical battery and hydrogen storage was too simplistic. The sizing of the storage systems and PV panels was arbitrary, as was the price of energy both when purchased and when sold to the main grid. In these simulation conditions, the sensibility study of the defined reward system can not be unbiased. However, it highlighted a behavioral difference of the agent on how to store hydrogen. With a robust sizing of the system and a good storage systems modeling, optimal weights for reward systems can be found through sensibilization analysis on different criteria.

Abstract

This work proposes a systematic method consisting of state-of-the-art text processing approaches and human-machine interaction for the extraction of useful sentences and data in tabular, graphical, and numerical form, containing information particularly relevant for hybrid modelling. It is applied to the domain of acute aquatic toxicity of chemicals, which is particularly relevant for the safety, health, and environmental hazard assessment of chemicals. Nearly 400 papers from 2000-2021 were identified and processed with the proposed method. The results indicate that the vast amount of knowledge can be efficiently processed in orders of magnitude faster than conventional methods without loss of detail and interpretation depth. The information is in a form that can be useful in hybrid modelling with respect to model and predictor selection, prioritization, and constraints, addressing data gaps, and validating and interpreting model performance.

Keywords: machine learning, text mining, sustainability

1. Introduction

Properties of molecules lie in the heart of any sustainability assessment method. Predictive models, developed via typical statistical regression or advanced machine learning (ML) approaches, reduce the amount of experimental testing but strongly depend on availability of pre-existing data. Limitations on data often hinder the development of robust models, leading often to overfitting of model parameters and decreasing their applicability domain (Galushka et al., 2021). This can be, for instance, of great importance during computer-aided design of novel materials. An approach combining ML methods with knowledge existing in the field, typically called hybrid modelling, might be one of the solutions to this problem (Willard et al., 2020). However, the amount of work required to process the enormous volumes of information might hinder the utilization of the existing knowledge. In different disciplines the expertise has been accumulated for years in form of scientific publications. The enormous volumes of information exist in almost every domain and researchers have been striving to reduce the amount of manual work required to process this information (Shahid et al., 2020). Nevertheless, systematic and to the extent possible fast methods of knowledge extraction from the vast amount of scientific literature are still lacking.

This step resulted in the identification of around 400 publications. Analysis of bibliometric information of the collected articles is presented in Figure 1 using a term map for words with minimum co-occurrence equal to ten. The map is based on text data of titles and abstracts of the articles. The larger the circle the more frequent the term is. More correlated terms have a shorter distance between the circles. The lines between the terms represent co-occurrence links. The earlier studies seem to be dealing with modes and mechanisms of toxic action, analysis of the relationships between structure, molecular descriptors, and toxicity. The later publications are addressing prediction models and their performance. Overall, model-related topics also seem to dominate the research area of the collection of articles.

2.2. Text mining

A python-based package was developed containing several modules that automate the text mining step consisting of three main parts: extraction of article texts and single sentences, key phrase extraction, and extraction of the relevant sentences. Single sentences were identified and checked for completeness using the library for natural language processing spaCy (<https://explosion.ai/blog/introducing-spacy>). From the complete sentences relevant sentences were extracted on the basis of reader-provided input. First, main terms were used to reduce the number of sentences to those that include any main terms. Then, key phrases were extracted from this reduced set of sentences using the open source python-based “pke” package (Boudin, 2016) with the implemented graph-based key-phrase extraction model SingleRank (Wan and Xiao, 2008). The sentences whose key phrases contain the main words and the connection words were extracted as relevant sentences. The main terms included words such as “toxicity”, “acute”, “LC50”, “EC50”, while the connection words such as “increase”, “decreas”, “relat”, “correlate”, “structure”, “fragment”, “class”, “significant”, “high”, “affect” etc.

2.3. Analysis of results and secondary text screening

The extracted set of the relevant sentences was then inspected based on human expertise to identify useful sentences. The potential use of the extracted knowledge defines the usefulness of the sentence. In this study, a sentence was considered useful if it contained information that could be used in hybrid predictive modeling. The useful sentences were collected either as directly extracted knowledge or used to identify articles and parts of the text for additional manual screening. The article screening was also performed to extract tables, figures, and equations since it was not yet possible to retrieve all of them automatically in a readable format. The analysis of the extracted sentences and/or article screening can be iterated based on altered input parameters (e.g., main terms, connection words, addition of articles). The information retrieved in this step in the form of useful sentences, models, figures, and tables was used for structuring knowledge in the next step.

2.4. Knowledge collection

The information extracted from the articles published in 2000-2014 (225 articles) was used to develop the initial knowledge structuring. The information extracted from the rest of the articles (165 articles) was used to demonstrate an update procedure (Figure 2). The newly extracted information is considered to compete with the previously collected if it provides the same type of information (e.g., a QSAR for the same species and class of chemicals using the same molecular descriptors as predictor variables). When this kind of information improves the results of the previous studies (e.g., a QSAR model with better performance based on a larger dataset), then the newly acquired knowledge replaces the previously collected one, otherwise it can be discarded or stored depending on the purpose of the classification. The new information could also contradict the

previously extracted one, for instance when the descriptors of the QSAR model are reported to have a positive correlation with the toxicity endpoint instead of a negative one reported by the information analyzed earlier. In that case, the decision can be to either replace the previously collected knowledge (e.g., if the new information is supported by more extensive experimental work), not to replace it but store the new information (e.g., a new and sufficiently diverse argument is provided that still lacks extensive experimental evidence) or completely discard it. If the new information complements the previously extracted information by providing additional depth (e.g., QSAR for the same class of chemicals but based on a different set of molecular descriptors or species), the new information is added to the previously collected information. If the new information does not satisfy the criteria to be considered competing or complementary knowledge, then the information is collected under a new classification category.

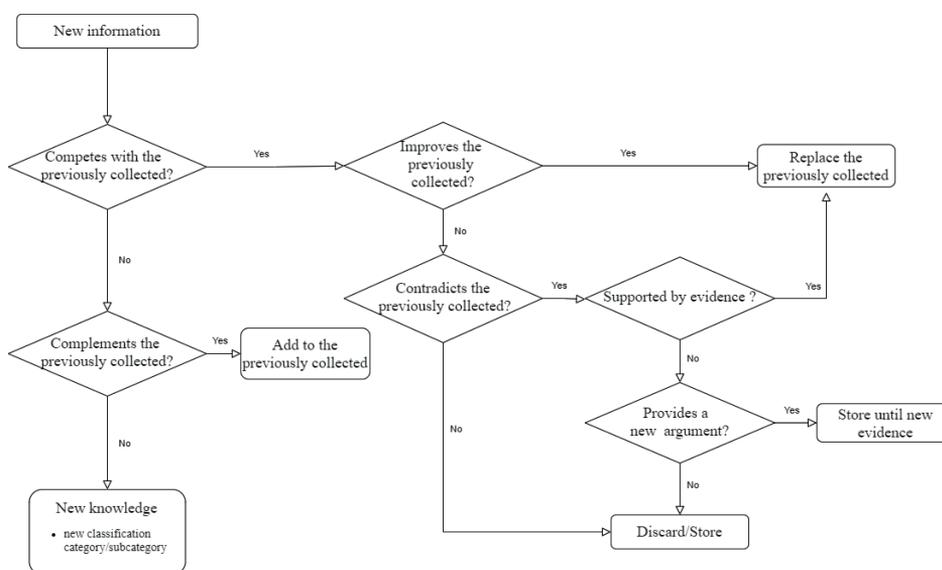

Figure 2: Update mechanism for knowledge collection and classification.

3. Results and Discussion

The method resulted in a significant reduction of text for initial reading (>85%). Most of the sentences extracted by the proposed method are directly useful for hybrid modeling or indicate to certain parts of the initial article for the manual screening. The collected knowledge was first classified to quantitative and qualitative information. The quantitative knowledge was further classified to QSAR models and experimental data and the qualitative knowledge in general statements (20) and key aspects, trends and patterns (650), single feature and structural alerts and multi-feature and combinatorial alerts (240). The QSAR models were further classified depending on the functional form (430 linear, 180 non-linear), the descriptors (600), the interspecies relationships (50), and the endpoint metric for specific species (50). Then, with respect to the applicability domain, quantitative and qualitative classes of the collected knowledge were further associated with the mode of action (i.e., narcosis, reacting, specifically acting, unidentified) and the chemical classes (40, i.e., aliphatic, aromatic, cyclic aliphatic, and application based such as pharmaceuticals, pesticides, surfactants). Most of the QSARs applied linear modeling due to its simplicity and interpretability. The nonlinear models often showed an increased

accuracy. The nonlinear models included most frequently support vector machine (SVM), k-nearest neighbors, neural networks, tree-based methods or gradient boosting. Examples of the extracted quantitative knowledge are presented in Table 1.

Table 1: Examples of quantitative knowledge extracted with respect to mode of action.

	Model type	Endpoint	Descriptors	Performance
Nonpolar narcosis	Interspecies relationship	log(1/LC50) <i>Pimephales promelas</i>	log(1/LC50) <i>Oncorhynchus mykiss</i>	n=19, R ² =0.96
Reactive chemicals	Linear modeling	log(1/EC50) <i>Pseudokirchneriella subcapitata</i>	nN>0: GATS1e, \bar{V}^+_s , SpMin1_Bh(p)	n=10, R ² =0.89
			nN=0, n(C=O)=0: logK _{ow}	n=9, R ² =0.80
Specifically acting chemicals	Linear modeling	log(1/LC50) <i>Poecilia reticulata</i>	E _a (max), $\sum C_a$, Nv1	n=31, R ² =0.77

It is generally accepted that acute toxicity is defined by the mode of toxicological action and chemical characteristics. Higher molecular toxicity values were often associated with increased lipophilicity. Most toxic compounds are related to hydrophobicity and their behavior as hydrogen-bonding or electron-acceptors. Specific functional groups like cyano, isothiocyanate, halogens were reported to enhance the toxicity of molecules, depending also on the molecular structure and position of the group in the molecule. Halogens are reported to increase toxicity. However, the contribution is more significant if the halogen is activated. Examples of qualitative knowledge are presented in Table 2.

Table 2: Examples of qualitative knowledge extracted with respect to molecular features reported to increase or decrease toxicity.

	Toxicity increase	Toxicity decrease
Property	Lipophilicity, hydrophobicity, increase	electrophilicity
		LogPo/w < 2 and ΔE (LUMO-HOMO) > 9 eV
Structure	Cyano, isothiocyanate, halogens (enhanced by activation (e. g., adjacent to an ester or other unsaturation)), amino group, nitro group, nitrile, disulfide, phosphoric acid derivatives, pyrazolyl group, formamide groups, ring aromaticity, sulfur, aromatic esters vinyl moiety, double and triple bonds, acrylate, carbamate groups	Higher polarity substitution of a hydrophobic group Presence of nitrogen in sp ² state Simultaneous presence of Sulfur together with double bond

The extracted knowledge can guide predictor variables selection, prioritization, or even identify which new predictor variables may add valuable information. Experimental data collected from various studies can serve for training or external validation of the developed models. Interspecies correlations can be used for closing the data gaps in a toxicity dataset of certain species. Data on the species' sensitivity, outliers could be used to explain the results of the prediction or deviations in the predictions. QSAR equations

or alerts could be directly integrated into the training phase of the data science models. The previously observed aquatic toxicity trends and patterns could be helpful for the evaluation of the results obtained by the developed models. Table 3 conceptually summarizes examples of the potential use of the extracted knowledge.

Table 3: Examples of potential use of the extracted knowledge.

	Model parameter selection	Predictor selection	Model constraints	Addressing data gaps	Model validation	Interpretation of results
QSAR models	√		√		√	√
QSAR descriptors		√				√
QSAR statements	√	√			√	√
Interspecies relationships				√	√	√
Experimental data	√			√	√	
Alerts		√	√			√
Applicability domain						√

4. Conclusions

The work performed the extraction and collection of knowledge existing in the field of acute aquatic toxicity. The procedure reduces the amount of manual work required to process a high number of scientific articles while extracting both generic and case-specific models, statements and alerts. The overall collected knowledge and its classification could be useful in hybrid modelling studies with respect to model and predictor selection, prioritization, and constraints, addressing data gaps, and validating and interpreting model performance. Thus, this work demonstrates one more aspect of digitalisation in PSE, in particular regarding knowledge about sustainability related properties, which is indispensable for multicriteria evaluation of process design.

Abstract

In this work, the use of ML methods for the prediction of the enthalpy and entropy of formation of molecules is investigated on the basis of different molecular and structural properties of these molecules, also known as "descriptors". Accordingly, different families, containing between 19 and 247 molecules, are extracted from the DIPPR (Design Institute for Physical Properties) database and used to train Support Vector Regression (SVR) models. 5666 molecular descriptors are calculated using dedicated software and a preliminary data preprocessing work is also carried out. The first results are very promising for the prediction of the enthalpy of formation of almost all the considered families of molecules, while the trained models for the prediction of the entropy of formation display lower accuracy and higher variations among the different families. This work, which is still under development, is carried out within the framework of a larger project aiming at the design and discovery of new molecules that meet specific requirements for use in thermodynamic cycles.

Keywords: machine learning, enthalpy of formation, entropy of formation, molecular descriptors, feature selection

1. Introduction

In recent years, machine learning (ML) methods have shown very good performance in tackling particularly complex problems, extending beyond the domains of computer science and automatic recognition. In this sense, they represent an interesting alternative to commonly employed quantum chemistry (QC) or group contribution (GC) methods, for the prediction of the thermochemical properties of molecules. Indeed, although QC and GC methods have been largely employed to calculate these properties due to their accuracy and low computational cost respectively, their applicability is often limited to small or simple molecules. QC methods see their computational cost increase drastically with the size and/or complexity of the molecules. With GC methods, on the other hand, the main difficulty lies in the decomposition of large or complex molecules into known (i.e., already identified) groups as well as in the necessity to account for important interactions (Li et al. (2021)). Inversely, data-driven ML methods have already demonstrated their ability to tackle complex problems in other fields, when classical approaches fail or are inefficient (Trinh et al. (2021)). Additionally, the use of diverse approaches (QC, GC, ML...) can also be proven extremely valuable in confirming the validity and reliability of the predicted values in the absence of relevant experimental data. Several works have already been published on the use of ML methods for the prediction of thermochemical properties of molecules (Yalamanchi et al. (2019, 2020); Dobbelaere et al. (2021); Plehiers et al. (2021)). However, these works are often

focused to specific families and/or properties of interest. The present work, investigates the use of ML methods for the prediction of both the enthalpy and entropy of formation of molecules from a large number of different families. In this respect, an exhaustive analysis of different eventual dimensionality reduction approaches, for the optimal selection of the most relevant molecular characteristics for each property, is carried out and several regression techniques are tested. The work is part of a larger project aiming at designing reactive working fluids for thermodynamic cycles. Since the work is still ongoing, this paper describes the implemented methodology along with some preliminary results, as well as the envisioned future steps for model improvement.

2. Methods

2.1. Data set

Public data from the Design Institute for Physical Properties database (DIPPR), containing 2230 molecules in SMILES notation and classified in different families and subfamilies, were used to train different ML prediction models. In particular, this work was focused on alcohols, alkanes, alkenes, alkynes, aromatics, esters, ethers, halogen compounds and sulfur compounds, as these families present a specific interest with respect to the objective of discovering molecules for implementation in thermodynamic cycles. The number of molecules per family varied significantly (i.e., between 19 and 247 molecules), as shown in Table 1, which can significantly affect the choice and performance of the ML technique. As for the enthalpy and entropy of formation, they have an average uncertainty of respectively 3 kJ/mol and 7 J/mol/K, for the considered molecules.

Table 1: Classification of DIPPR molecules per family

Family	Alcohols	Alkanes	Alkenes	Alkynes	Aromatics	Esters	Ethers	Halogen compounds	Sulfur compounds
Molecules	168	171	144	19	153	213	67	247	99

2.2. Descriptors calculation

The molecular descriptors are different properties, characteristic of the molecular and topological characteristics of the different molecules, that are commonly employed in similar regression studies. They can be calculated by means of different software tools, such as PaDEL (Yap (2010)), RDKit (Landrum (2021)), CDK (Steinbeck et al. (2003)) or AlvaDesc (Mauri (2020)), on the basis of a standardised description of the molecules, such as their SMILES (Simplified Molecular Input Line Entry System) notation. In this work, two free-source (PaDEL and RDKit) and one closed-source (AlvaDesc) tools were tested. Among them, AlvaDesc was finally retained on the basis of different factors, such as the number of calculated molecular descriptors (i.e., 5666 descriptors were provided by AlvaDesc), the robustness in the provided results, the execution speed and the proposed documentation and support. Note that, some geometrical descriptors required information that cannot be provided via the SMILES notation (i.e., related to the 3D conformation of the molecules). It was therefore necessary to convert the molecules' SMILES notation to a "MDL MOL" standard, prior to importing them into AlvaDesc, which was realized using the RDKit ETKDG method for conformer generation (Riniker and Landrum (2015)). The ETKDG method, which is a stochastic method using knowledge-based and distance geometry algorithms, is considered to be an accurate fast conformer generation method, especially for small molecules (Hawkins (2017)).

2.3. Data preprocessing and feature selection

The use of well-curated data sets is of profound importance to the implementation of any data-driven technique. In this sense, an important step of this study consisted in preparing the data

(e.g., removal of molecules or descriptors with missing values) and selecting relevant molecular descriptors (i.e., features influencing the targeted thermochemical properties) for the different molecules. This step is crucial as using data with missing, constant, redundant or irrelevant values can affect significantly the performance of the ML algorithm. For example, constant descriptors do not display any effect on the target property and, thus, should not be considered by the algorithm. In addition, the selection of only a subset of the most relevant descriptors will help to decrease the computational effort and prevent overfitting phenomena (Bommert et al. (2020)).

Accordingly, the first step of the performed data preparation procedure was to remove molecules with missing property values as well as descriptors with missing, constant, or quasi-constant values (i.e., when at least 95% of their values were identical). Finally, Pearson correlation coefficients were calculated for all descriptors and the ones that were correlated to more than 98% to another descriptor were removed. For the family of alkanes, the final number of descriptors obtained after the implementation of the aforementioned steps was reduced from 5666 to 586.

Following these initial data treatment steps, the implementation of feature selection methods is necessary to further reduce the number of descriptors and assess their effect on the targeted properties. Feature selection refers to a class of dimensionality reduction techniques, consisting in identifying a subset of the initial features that best represent the property of interest. These methods can be classified into different groups (i.e. filter methods, wrapper methods and embedded methods) (Danishuddin and Khan (2016); Saeys et al. (2007)), according to the adopted statistical tests and to whether the correlation between the features and the performance of the algorithm is taken into account. For example, filter methods rely only on the intrinsic properties of the data and use feature relevance score to identify the most significant features while wrapper methods select the relevant features by calculating the feature impact on the performance of a learning algorithm (Danishuddin and Khan (2016)). In the context of this work, the implementation of several feature selection techniques is investigated. This work is currently underway.

2.4. Training, hyper-parameters optimization and performance evaluation

An initial test of the implementation of a regression technique was performed on the data after the pretreatment steps described in the previous paragraph. Support Vector Regression (SVR) was selected as it can perform with high precision and generalization with a small number of training samples, high dimensional and noisy data (Trinh et al. (2021)). Prior to the implementation of SVR, the data within each family of molecules was randomly shuffled (i.e., due to the fact that the original data from DIPPR were grouped into sub-families, within each family). The data was then partitioned into distinct groups, following a k -fold cross-validation principle (with $k=5$), where for each fold k , the k^{th} data subset served for testing the performance of the algorithm, this latter trained on the basis of the remaining $k-1$ groups. This procedure ensures a representative use of the data and allows assessing the average overall regression performance of the trained model. The value for k was selected so that 20% of the available data, for each family, is implemented for testing within each fold. Generally, $k=5$ or $k=10$ ensures a good trade-off between low computational cost, low bias and low variance for the evaluation of the model performance (Kohavi (1995)).

In parallel to the training of the SVR model, a set of hyperparameters (i.e. kernel function, box constraint, kernel scale, epsilon, kernel polynomial order, etc.) of the algorithm were optimized within each fold (i.e., using the *OptimizeHyperparameters* option of the *fitrsvm* function of the Matlab toolbox). A more detailed description of the hyperparameters can be found in Vapnik (1995). In this sense, within the $k-1$ data sets, used for model training, a secondary j -fold partition took place (with $j=5$) for further identifying and separating a validation data set, serving for the identification procedure of the algorithm hyperparameters. The performance of the algorithm was evaluated in terms of the typically employed performance indexes (i.e., RMSE, MAE and R^2). Matlab was used for all the above developments.

3. Results and discussion

The obtained performance results and the corresponding optimized hyperparameters at each fold for the SVR algorithm, as implemented for the prediction of the enthalpy of alkanes, is given in Table 2. As can be seen, the mean value of the coefficient of determination R^2 for training-validation and test data sets are both quite satisfactory as they are respectively equal to 0.999 and 0.984.

Table 2: Performances for enthalpy prediction for alkanes for each fold k and with the associated optimized hyperparameters.

Fold	RMSE (kJ/mol)		MAE (kJ/mol)		R ²		Kernel function	Box constraint	Kernel scale	Epsilon

The overall performance of the models trained for enthalpy and entropy of formation prediction, for the different families of molecules as well as for the combination of all of them, is shown in

Tables 3 and 4. For the prediction of the enthalpy of formation, the performance of the models on all the molecule families, except that of esters, displayed a value for the determination coefficient superior to 0.96. On the other hand, the predictive capabilities of the trained SVR models for the entropy of formation was satisfactory only for the families of alkanes, alkenes, alkynes and halogen compounds, while some families (i.e., esters) displayed a significantly low model predictive capacity. However, it was more generally observed that considering the molecules per family resulted in better prediction performances. Note that, these are only preliminary results obtained using a single regression ML technique and after only a preliminary data pretreatment step. In addition, some families (e.g., esters) contain some very large molecules (e.g., glycerides such as tripalmitin or tristearin) for which the conformer generation is quite complex, introducing additional uncertainty in the descriptors calculation step, which needs to be further analyzed (Wang et al. (2020); Cleves and Jain (2017)).

Finally, some preliminary tests on the implementation of some feature selection methods were implemented to identify the most influencing descriptors for the family of alkanes. The tested methods are: univariate feature ranking for regression using F-tests, importance ranking of predictors using RReliefF algorithm, Pearson correlation coefficient (between a descriptor and the target) and low-variance. The two first methods were available as Matlab functions and were chosen according to the supported problem and data type while the two other methods are commonly encountered feature selection techniques (Pedregosa et al. (2011); Mangal and Holm (2018)). The top 5 ranking descriptors with highest scores, resulting from these different filter techniques, are presented in Table 5. It can be observed that very different descriptors have been identified by the different techniques. Although filter techniques are simple and fast to implement, their drawback is that they rank features independently from the ML algorithm. Conversely, the comparison with wrapper methods (such as forward selection or backward elimination) could be very interesting.

Table 5: Top 5 descriptors with highest scores using different filter techniques (*the bold italic indications correspond to the descriptors category as defined by AlvaDesc*).

	Univariate feature ranking for regression using F-tests	Importance ranking of predictors using RReliefF algorithm
1	<i>Information indices</i> Structural Information Content index (neighborhood symmetry of 0-order)	<i>Drug-like indices</i> Modified drug-like score from Zheng et al. (2 rules)
2	<i>Charge descriptors</i> Relative positive charge	<i>Ring descriptors</i> Normalized number of ring systems
3	<i>P_VSA-like descriptors</i> P_VSA-like on Molar Refractivity, bin 5	<i>Walk and path counts</i> Self-returning walk count of order 5
4	<i>Information indices</i> Complementary Information Content index (neighborhood symmetry of 1-order)	<i>Charge descriptors</i> Submolecular polarity parameter
5	<i>Information indices</i> Complementary Information Content index (neighborhood symmetry of 0-order)	<i>Charge descriptors</i> Maximum positive charge
	Pearson correlation coefficient	Low-variance
1	<i>Information indices</i> Complementary Information Content index (neighborhood symmetry of 1-order)	<i>Chirality descriptors</i> Number of neighbouring atoms of the chiral centre (level 1)

5	<i>RDF descriptors</i> Radial Distribution Function – 020 / unweighted	<i>2D Atom Pairs</i> Presence/absence of C – C at topological distance 9

4. Conclusions

In this work, SVR data-driven models were developed to predict the enthalpy and entropy of formation for different families of molecules, each one containing between 19 and 247 molecules extracted from the DIPPR database. 5666 molecular descriptors were calculated using dedicated software and some preliminary work was done on the data preprocessing and feature selection. The obtained results are especially promising for the prediction of the enthalpy of formation for

the majority of families, whilst the prediction of the entropy of formation displays higher variations between the different molecular families. Further work is currently underway for the improvement of the model performance, especially in terms of a more thorough analysis of feature selection, model selection and hyperparameter optimization. More generally, this work is carried out within the framework of a long-term project, whose ultimate objective is to employ the developed ML models for the design and discovery of new molecules that meet specific requirements for use in thermodynamic cycles.

Abstract

In this contribution, we propose a new CAMD approach for solvent design by combining machine learning with deterministic optimization. Variational autoencoder (VAE), a powerful generative machine learning method, is used to transfer a molecular structure into a continuous latent vector with an encoder and to convert the latent vector back to the molecule with a decoder. Solvent properties of interest are estimated by a feedforward neural network (FNN) using the latent vector as input. Through the joint training of the VAE and FNN-based property model with collected data, a continuous latent design space can be constructed for the optimization-based solvent molecular design. Specifically, nonlinear optimization is first performed to identify optimal latent variables featuring desirable solvent properties based on the established property prediction model. Knowing the optimal latent vector, the corresponding target molecule is then generated by the pre-trained VAE decoder. The separation of 1-butene and butadiene is used as an example to investigate the reliability of the proposed design method. A set of solvent candidates showing superior separation performance are generated. To further filter suitable solvents for industrial applications, additional analyses on molecular synthesizability are conducted.

Keywords: molecular design, solvent discovery, machine learning, variational autoencoder, nonlinear optimization

1. Introduction

The selection of suitable solvents is of central importance in separation processes, such as gas purification and extractive distillation, for achieving a high product purity and reducing energy consumption. High-throughput computational screening can help discover solvent candidates showing desirable properties. Unfortunately, the huge number of possible organic molecules (Bohacek et al., 1996) makes the brute force solvent screening extremely costly and time-consuming. By contrast, computer-aided molecular design (CAMD) of solvents based on available property estimation models (Song et al., 2020; Wang et al., 2020) is much more efficient for direct targeting of optimal solvents possessing certain desirable properties.

In the past decade, the CAMD method has been developed and widely used for solvent design from a given set of molecular building blocks under the constraints of molecular structural feasibility and property specifications (Song et al., 2018; Scheffczyk et al., 2017; Papadopoulos et al., 2020; Zhou et al., 2021; Zhang et al., 2021). In most of the

previous CAMD studies, group contribution (GC) based property models are typically used for solvent property prediction (Adjiman et al., 2021). However, one should note that standard GC models cannot accurately predict certain properties, and more importantly, they cannot well distinguish between structural isomers. These limitations can be potentially tackled by combining advanced machine learning (ML) methods with special molecular representations such as chemical text (e.g., SMILES string) and molecular graph.

Variational autoencoder (VAE), a powerful generative ML method, can generate simple but informative latent variables from complex inputs (such as image, text, and graph) and reconstruct these inputs from the latent variables (Sanchez-Lengeling and Aspuru-Guzik, 2018; Gómez-Bombarelli et al., 2018). In this contribution, we propose a new CAMD approach for solvent design by combining VAE with deterministic optimization. Using SMILES strings as input, we first build a VAE to transform molecules into latent variables. Using these variables as input, a feedforward neural network (FNN) model is trained to predict molecular properties of interest. Nonlinear optimization is finally performed to identify optimal latent variables and the corresponding molecules featuring desirable properties. The proposed CAMD approach is applied to 1-butene and butadiene separation. A set of solvent candidates with high separation performance and molecular synthesizability are identified.

2. Method

The CAMD approach consists of two stages, namely generative modeling and molecular design, as shown in Figure 1. In the first stage, the VAE model is built to freely transform between molecules and continuous latent variables. Using the latent variables as input, an FNN model is trained to predict molecular properties of interest. In the next molecular design stage, based on the property prediction model, a nonlinear optimization problem is formulated and solved to identify the optimal latent variables featuring desirable properties. By decoding the optimal latent variables with the VAE decoder, the corresponding best molecular structure can be finally generated.

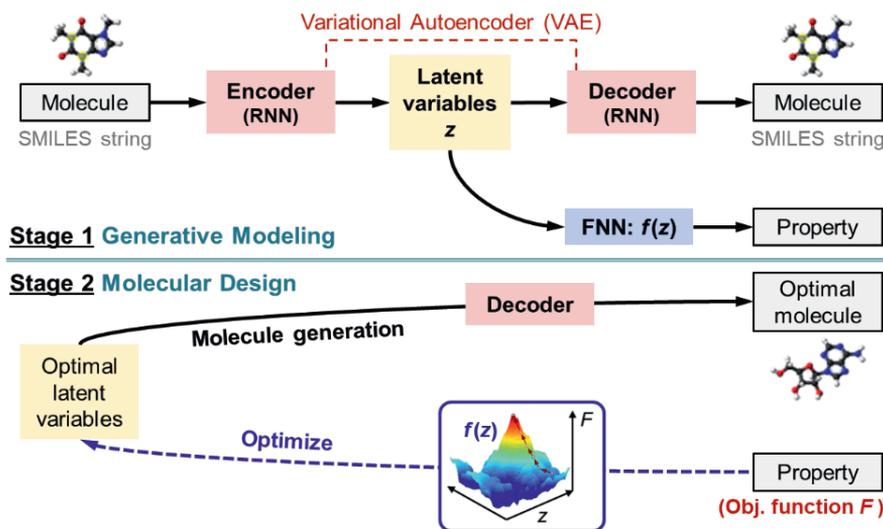

Figure 1. The proposed ML-based optimization approach for molecular design

2.1. Generative modeling

The VAE model is composed of two components, an encoder and a decoder. Starting from the molecular structure (represented by the SMILES string), the encoder converts it into a continuous latent vector while the decoder enables the reproduction of the original molecule from the latent vector. In this work, both encoding and decoding are achieved by recurrent neural networks (RNNs). Using the latent vector as input, molecular properties of interest are predicted by another FNN model. Notably, the VAE and FNN models are trained simultaneously so that the molecules close to each other in the latent space exhibit similar properties.

2.2. Molecular design

Relying on the FNN model, the mathematical relation between latent variables and molecular properties is obtained. With an objective function defined on molecular properties of interest, a nonlinear optimization problem is formulated and solved to identify the optimal latent variables. The corresponding SMILES string is generated by decoding the latent variables and the molecular structure is reconstructed using RDKit (2021).

3. Results and Discussion

C4 hydrocarbons (mostly consisting of 1-butene, 2-butene, isobutene, and butadiene) are mainly co-produced by the thermal cracking of various feedstock such as naphtha and gasoil (Streich et al., 2016). These unsaturated components are important intermediates in the chemical industry. For example, butadiene is a monomer in the manufacture of synthetic rubbers, and therefore it needs to be purified from the C4 mixture. However, similar physicochemical properties of these components make them difficult to separate by conventional methods. Adding a suitable solvent into such a mixture to change the relative volatility, extractive distillation can be conducted to achieve efficient separation.

In order to illustrate our proposed method for solvent design, the separation of simplified C4 mixtures (butadiene and 1-butene) is carried out as a case study. Because butadiene generally shows strong interaction with organic solvents in contrast to 1-butene, a suitable solvent can be designed to efficiently extract butadiene from the mixture. Two important solvent thermodynamic properties (i.e., selectivity and capacity at the infinite dilution condition), indicating the separation performance of the solvent, are considered (Zhou et al., 2019). The infinite dilution selectivity is defined by

$$S_{C_4H_6/C_4H_8}^\infty = \gamma_{C_4H_8}^\infty / \gamma_{C_4H_6}^\infty$$

The infinite dilution capacity of the solvent toward butadiene is determined by

$$C_{C_4H_6}^\infty = 1 / \gamma_{C_4H_6}^\infty$$

As represented above, both the selectivity and capacity are calculated with activity coefficients at infinite dilution. Notably, an increase in the selectivity usually leads to a decrease in capacity (Krummen et al., 2000). Thus, the product of selectivity and capacity is used as the objective function for solvent design.

3.1. Model Training

A dataset consisting of 2,496 solvents is adopted, with infinite dilution activity coefficients of 1-butene and butadiene calculated using COSMO-RS (Klamt and Eckert, 2000). The training and test sets are randomly selected and they account for 90% and 10% of the dataset respectively. ML models (i.e., VAE and FNN) are constructed using the

open-source ML framework TensorFlow (2021), and they are optimized on the training set and evaluated using the test set. Table 1 summarizes the accuracy of the VAE model for molecular reconstruction and the performance (i.e., mean absolute error (MAE) and coefficient of determination (R^2)) of the FNN model for property prediction. As indicated, both ML models present high performance on both training and test sets. Thus, for an unknown solvent represented by a latent vector, the decoder of the VAE model can reliably reconstruct its molecular structure and the FNN model can accurately predict its infinite dilution activity coefficients toward 1-butene and butadiene. This guarantees the reliability of the solvent design results.

Table 1. Model performance in the molecular reconstruction and property prediction

Dataset	Molecular reconstruction accuracy	$\ln(\gamma_{C_4H_8}^\infty)$		$\ln(\gamma_{C_4H_6}^\infty)$	
		MAE	R^2	MAE	R^2
Training	90.91%	0.0833	0.9504	0.0769	0.9221
Test	89.24%	0.0896	0.9625	0.0886	0.9323

3.2. Solvent design

To achieve energy-efficient extractive distillation of butadiene and 1-butene, the solvent should be optimally designed by maximizing its separation performance (i.e., the product of selectivity and capacity). Based on the FNN model, we first identify the optimal latent vector by solving a nonlinear optimization problem where the solvent performance is maximized. Later, the VAE decoder is used to convert the optimal latent vector into solvent molecular structure. In this way, a new solvent (the red star) showing superior separation performance is designed with the objective function of 7.930, as shown in Figure 2. It is significantly better than the best solvent in the employed dataset (blue star, objective function 5.413). The grey dots indicate the locations of all the 2,496 solvents in the latent space visualized in two dimensions using principal component analysis.

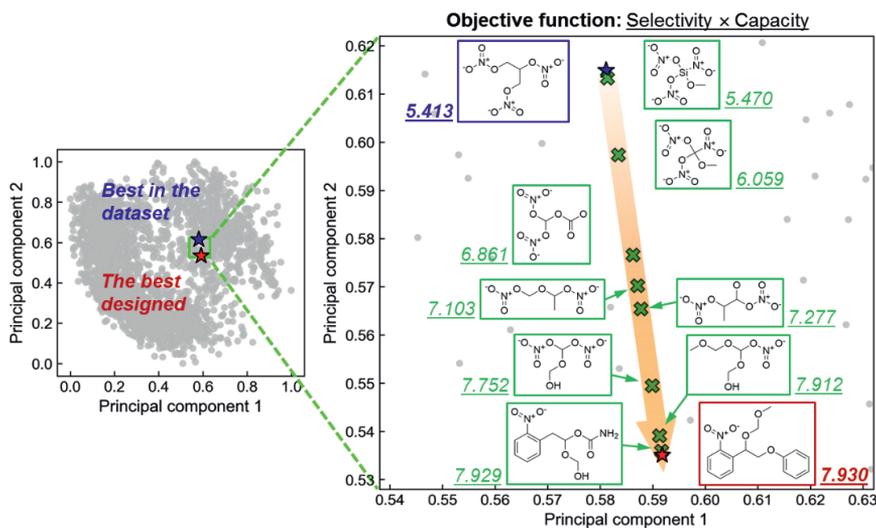

Figure 2. Interpolation-based solvent design for the separation of butadiene and 1-butene

When training the VAE model, the latent space tends to cluster molecules with similar structures. Meanwhile, because the VAE model is jointly trained with the FNN model,

the distribution of molecules in the latent space is indicated by the molecular property. In this case, molecules locating closely in the latent space should also share similar properties. Taking these into account, interpolation is performed between the best solvent in the original database (blue star) and the optimally designed solvent (red star) to generate more solvent candidates (green crosses), as indicated in Figure 2. Following the route, an increase in the solvent separation performance is identified, and structural similarity is also observed between neighboring solvents. This demonstrates that the latent space allows smooth navigation of solvent performance because of its local similarity on both solvent structure and property.

To further filter suitable solvents from the above-designed candidates, additional analyses on molecular synthesizability are carried out. The synthetic accessibility score (SAscore) (Ertl and Schuffenhauer, 2009) can estimate the ease of synthesis of compounds based on available synthetic knowledge and molecular structural complexity, and it varies between 1 (easy to synthesize) and 10 (very difficult to synthesize). Table 2 lists the SAscore for the top five solvent candidates presented in Figure 2. In addition to SAscore, another two synthesizability indicators, Retro score (RScore) and Retro step (RStep), are estimated from the Spaya platform (2021) based on literature reaction templates. RScore indicates the probability of the synthetic route matching with existing reaction templates, and RStep is the number of reaction steps of the considered route. Obviously, a large RScore and a small RStep are preferred. As shown in Table 2, the optimal solvent with the best separation performance also displays the highest synthesizability, as revealed by the three indicators.

Table 2. Evaluation on the synthesizability of designed solvent candidates

Rank	Molecular SMILES string	Performance	SAscore	RScore	RStep
1	<chem>COCOC(COclcccc1)clcccc1[N+](=O)[O-]</chem>	7.930	2.67	0.8	2
2	<chem>NC(=O)OC(Cc1cccc1[N+](=O)[O-])OCO</chem>	7.929	3.19	0.7	3
3	<chem>COCOC(OCO)O[N+](=O)[O-]</chem>	7.912	4.18	0.6	4
4	<chem>O=[N+](O)OC(OCO)O[N+](=O)[O-]</chem>	7.752	4.00	0.7	4
5	<chem>CC(O[N+](=O)[O-])C(O)O[N+](=O)[O-]</chem>	7.277	4.32	0.8	2

4. Conclusion

Combining ML and deterministic optimization, we propose a new CAMD approach for the molecular design of solvents. After developing accurate ML models, deterministic nonlinear optimization is first performed to identify the optimal latent variables, and the corresponding optimal solvent structure is then obtained by decoding the latent variables. Besides the best solvent, a few more candidates are identified by interpolating in the latent space and the practical applicability of all the solvent candidates is evaluated from the perspective of molecular synthesizability. The proposed CAMD approach has been successfully applied to solvent design for butadiene and 1-butene separation.

The generated molecules represented by SMILES strings sometimes are proven to be structurally infeasible by RDKit. Imposing grammar constraints in encoding and decoding steps or replacing SMILES strings with molecular graphs can potentially guarantee the feasibility of the designed molecules. Additionally, density functional theory calculations can provide further evaluations on molecular structural stability, and process design can be incorporated into the CAMD framework in order to generate solvents better serving industrial processes.

Abstract

For the application of advanced process control and optimization methods, a dynamic process model is necessary. Developing a purely mechanistic white-box process model is time consuming and challenging when the underlying physical, chemical or biochemical phenomena are not fully understood. Black-box models can be used in such cases when sufficient process data is available. These models on the other hand suffer from limited accuracy for inputs that are not well represented in the collected data. For extended extrapolation capabilities and improved interpretability, gray-box models can be used where white-box and black-box parts are combined. If the black-box models describe embedded variables of the white box model, the determination of a suitable black-box model structure is a challenging task. In this work we present a methodology to systematically decompose the parameter estimation and model structure selection tasks. The methodology is applied to a fermentation use case with promising results.

Keywords: machine-learning, gray-box modeling, dynamic modeling, fermentation

1. Introduction

The problem of finding a suitable process model for a chemical or biochemical process is challenging. Oftentimes the underlying phenomena are not fully understood and only basic equations of the system dynamics that result from heat and mass balances are available where not all terms are fully specified. If by simple correlations or kinetics, the experimental data at hand cannot be matched sufficiently accurately, one way to improve the model accuracy is to embed data-based or machine learning (ML) models into the fundamental equations. This combination of traditional modelling efforts with ML approaches is commonly known as gray-box modelling.

There exists a multitude of ways to realize combinations of different types of models, an overview can be found in [1]. Here, we consider the case that a set of ordinary differential equations derived from process knowledge is available, where some variables in these equations are described by ML models. These kinds of systems have been studied by different authors already. One important distinction between different situations is whether there exists data specifically for the input/output relation that the ML model is supposed to represent, as investigated in [2], or not.

In the case that such data is not available, there are two ways to approach the issue. First, an artificial data-set can be estimated from the available dynamic data. Several techniques have been applied in the literature, for example the use of a state observer that estimates the unknown parameter [3]. [4] and [5] replace the embedded variables by functions of

time which are fitted to data to generate a training set for the parameterization of the ML model. Second, one can learn the parameters of the machine learning model by performing a full dynamic parameter estimation for the overall model, including the parameters of the embedded ML models and other parameters of the balance equations, which involves simulating the full model and minimizing the errors with respect to the experimental data.

Also a combination of the two approaches is possible, as proposed in this work.

2. Simulation model use case: Fermentation of a sporulating bacterium

We are considering the use case of a fermentation of a microorganism that undergoes sporulation. Fermentation processes are a typical example of processes where deriving a fully mechanistic model is complicated as a complete mathematical description of the cell internal metabolism would be necessary. The simulation use case involves three state variables: the dry basis concentration of vegetative cells X_v , the dry basis concentration of sporulated cells X_s and the concentration of substrate S . These state variables undergo two main reactions resulting in the following dynamics. In these equations it is assumed for simplification that the cell weight does not change and is the same for both vegetative and sporulated cells.

$$\begin{aligned}\dot{X}_v &= r_g(T, S)X_v - r_s(T, S)X_v \\ \dot{X}_s &= r_s(T, S)X_v \\ \dot{S} &= -r_g(T, S)X_v Y_{X/S}^{-1}\end{aligned}\quad (1)$$

Here, r_g and r_s denote growth and sporulation reaction that both nonlinearly depend on temperature and substrate concentration with relations taken from [6–9]. $Y_{X/S}^{-1}$ is the yield coefficient. This system is modelled using the following gray-box model structure.

$$\begin{aligned}\hat{\dot{X}}_v &= \varphi_1(T, \hat{S}) \hat{S} \hat{X}_v - \varphi_2(T, \hat{S}) \hat{X}_v \\ \hat{\dot{X}}_s &= \varphi_2(T, \hat{S}) \hat{X}_v \\ \hat{\dot{S}} &= -\varphi_1(T, \hat{S}) \hat{S} \hat{X}_v \hat{Y}_{X/S}^{-1}\end{aligned}\quad (2)$$

The main issue of fitting this model is finding an appropriate machine learning (ML) model structure for the two embedded variables φ_1 and φ_2 . To this end a methodology is developed, which is described in the next section.

3. Novel methodology for gray-box modelling of nonlinear ODE systems

In this work we discuss a methodology to find a suitable structure and parameters for dynamic gray-box models of the general structure shown in Eq. 3:

$$\dot{x} = f_{\Theta} \left(x, u, \varphi_{\Theta_{ML}}(d) \right) \quad (3)$$

Here, x denotes the state vector and u denotes a vector of input variables. Additionally, there are embedded variables φ that are described by ML models. They depend on a set of ML-model parameters Θ_{ML} . The inputs to these ML-models are denoted by the vector of descriptors d . The elements of this vector are a subset of the elements of the other variables of the system x and u . The differential equations are described by the possibly nonlinear functions f_{Θ} . These itself depend on a set of parameters Θ which occur in the mechanistic relations.

To find a suitable ML model structure for φ and values for the sets of parameters Θ and Θ_{ML} , a full dynamic parameter estimation problem can be set up as shown below.

$$\begin{aligned}
 & \min_{\Theta, \Theta_{ML}} J(\mathbf{Y}^{exp}, \mathcal{P}) \\
 & \text{s. t.} \quad \dot{x} = f_{\Theta}(x, u, \varphi_{\Theta_{ML}}(d)) \\
 & \quad x_i(t_{j,0}) = x_{i,j}^{0,exp} \quad \forall i = 1, \dots, n_x, j = 1, \dots, n_{exp} \\
 & \quad \hat{y} = h(x)
 \end{aligned} \tag{4}$$

In this optimization problem, the cost function J depends on the set of measured output values \mathbf{Y}^{exp} and the set of simulated output values $\hat{\mathbf{Y}}$ as shown in Eq. 5.

$$J(\mathbf{Y}^{exp}, \mathcal{P}) = \frac{1}{n_y} \sum_{i=1}^{n_y} \frac{1}{n_{exp}} \sum_{j=1}^{n_{exp}} \frac{1}{n_{samp}} \sum_{k=1}^{n_{samp}} J_r(r_{i,j,k}) \tag{5}$$

Here, n_y denotes the number of outputs and n_{exp} the number of experiments. n_{samp} denotes the number of samples taken, which is assumed to be the same in each experiment for ease of notation. J_r describes the kind of cost function used. Commonly, the mean squared error is used with $J_r(x) = x^2$. $r_{i,j,k}$ refers to a residual, which is defined as

$$r_{i,j,k} = y_{i,j,k}^{exp} - \hat{y}_i(t_{j,k}^{exp}). \tag{6}$$

Solving the full parameter estimation problem in Eq. 4 is a difficult task as the evaluation of the fitness, described by the cost function J , requires the simulation of the dynamics of the system. The iteration over all parameters and hyperparameters is computationally costly especially because good initialization of Θ_{ML} are not known and therefore many simulations will diverge.

To overcome this issue, we propose to decompose the model selection and parameterization problem into several steps as shown in Fig. 1.

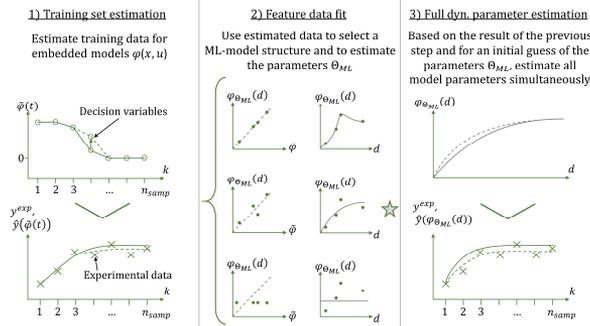

Fig. 1: Steps of applying the methodology for dynamic gray-box modelling

Step 1) involves the estimation of training data of the embedded functions by replacing the embedded variables φ by placeholders $\tilde{\varphi}(t)$, which are computed as continuous piecewise linear functions of time as shown in Eq. 7, similar to the approaches in [4] and [5].

$$\tilde{\varphi}_i(t) = \frac{\tilde{\varphi}_{i,j,k+1} - \tilde{\varphi}_{i,j,k}}{t_{j,k+1} - t_{j,k}}(t - t_{j,k}) + \tilde{\varphi}_{i,j,k} \quad t \in [t_{j,k}, t_{j,k+1}] \tag{7}$$

Here, $\tilde{\varphi}_{i,j,k}$ denote the values of the piece-wise linear function at the sampling time points $t_{j,k}$. With this replacement, determining the set of descriptors d and estimating the parameters Θ_{ML} is simplified. To estimate training data for the embedded functions, the

knot values of the piece-wise linear fit are adjusted as degrees of freedom in the parameter estimation problem shown in Eq. 8.

$$\begin{aligned} \min_{\Theta, \tilde{\Phi}} \quad & J(\mathbf{Y}^{exp}, \hat{\mathbf{Y}}) + \lambda \text{Reg}(\tilde{\Phi}) \\ \text{s. t.} \quad & \dot{x} = f_{\Theta}(x, u, \tilde{\varphi}(t)) \\ & x_i(t_{j,0}) = x_{i,j}^{0,exp} \quad \forall i = 1, \dots, n_x, j = 1, \dots, n_{exp} \\ & \hat{y} = h(x) \end{aligned} \quad (8)$$

In this optimization problem, the set of all values $\tilde{\varphi}_{i,j,k}$ is denoted as $\tilde{\Phi}$. As there is a large number of degrees of freedom, regularization is applied to prevent overfitting. This can be realized by adding the mean absolute slope $\text{Reg}(\tilde{\Phi})$ to the cost function, weighted by a regularization constant λ , see Eq. 9.

$$\text{Reg}(\tilde{\Phi}) = \frac{1}{n_{\varphi}} \sum_{i=1}^{n_{\varphi}} \frac{1}{n_{exp}} \sum_{j=1}^{n_{exp}} \frac{1}{n_{samp} - 1} \sum_{k=2}^{n_{samp}} \left| \frac{\tilde{\varphi}_{i,j,k} - \tilde{\varphi}_{i,j,k-1}}{t_{j,k} - t_{j,k-1}} \right| \quad (9)$$

The results of solving the optimization problem in Eq. 8 are the values of the predicted state \mathbf{X}^* and input variables \mathbf{U}^{exp} and the corresponding values $\tilde{\varphi}_{i,j,k}$.

In nonlinear dynamic systems, it can occur that the deviation from the experimental data is insensitive to changes of the values $\tilde{\varphi}_{i,j,k}$. One such example is when the embedded variable is multiplied with a state variable that vanishes during an experiment. To ensure that the estimated data is reliable, the collected optimal values $\tilde{\Phi}^*$ are filtered using the sensitivity of the residuals $r_{i,j,k}$, see [10] for further details.

Using the resulting data $\tilde{\Phi}^*$, the descriptors d , a suitable ML-model structure and a set of parameters Θ_{ML} can be found efficiently during step 2), the feature data fit.

This model structure and the estimated set of parameters are initial values for performing step 3), the full dynamic parameter estimation, described by Eq. 4.

4. Results

The methodology presented in section 3 is applied to the simulated case study from section 2. Experimental data was generated in silico by generating random initial conditions and simulating the ODEs presented in section 2. Afterwards, Gaussian noise was added to the measured outputs. X_t is the total cell concentration as $X_t = X_v + X_s$.

In step 1), the optimization problem in Eq. 8 is solved using the simulated data and a regularization constant with a value of $\lambda = 2$, the results are shown in Fig. 2.

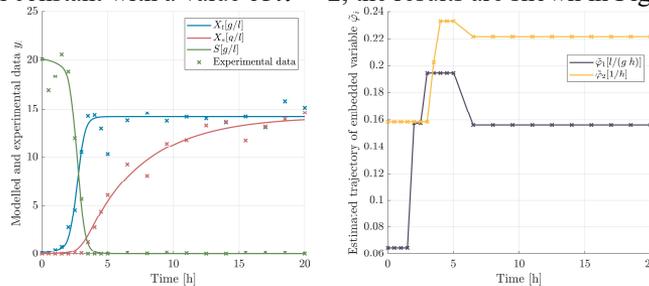

Fig. 2: Results of the training data estimation step. Left: predicted and measured output values; Right: Corresponding continuous piece-wise linear trajectories of the embedded variables

In Fig. 2 on the left hand side, the simulated and experimental values of the measured variables are shown. It can be seen that even though the experimental values are subject

to significant noise, the overall behavior is represented well. The substrate concentration S is initially high but decreases monotonously as the cells grow. This growth leads to an increase in the total cell concentration. After about 4-5 h the growth process is concluded and the sporulation begins. The sporulated cell concentration increases until about 20 h. On the right hand side, the corresponding estimated values of the embedded variables are shown. The fact that a penalization term on the slope is added to the cost function is reflected by the fact that intervals of constant $\tilde{\varphi}$ emerge.

Conducting step 2) of the methodology, different surrogate models were trained on the estimated data. Due to the training data estimation, any ML-toolbox can be used. In this case a constant value and a linear model were applied. Additionally two symbolic regression routines were applied, a Lasso regression [11] and an ALAMO [12] model were trained based on the same set of basis functions. Lastly, an artificial neural network model with 1 hidden layer and 5 nodes was fitted to the data. All models use the temperature T and substrate concentration \hat{S} as descriptors d . The regression plots are shown in Fig. 3.

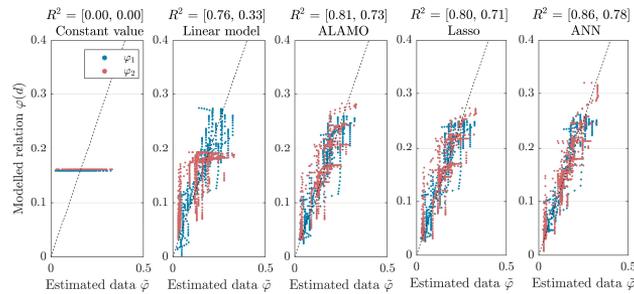

Fig. 3: Regression plot of all considered ML-model structures

From Fig. 3, it can be seen that both the constant value as well as the linear model fail to accurately describe especially the embedded variable φ_2 , thus nonlinear models have to be used. The highest coefficient of determination can be achieved using ANN models. Initialized with these parameters, the full dynamic parameter estimation problem in Eq. 4 (step 3)) was solved. The results of this optimization are displayed in Fig. 4.

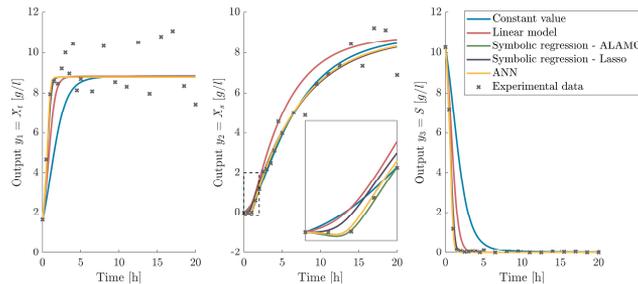

Fig. 4: Results of the full parameter estimation

From this figure, it can be seen that the sharp initial increase of the number of vegetative cells is not accurately represented using a constant value or a linear model for the embedded variable φ_2 . While there is a slight undershoot in the dynamic prediction of the ANN and of the ALAMO model, these model structures describe the dynamic behavior well. The Lasso model can be considered the best model as no negative concentrations of sporulated cells X_s are predicted.

5. Conclusions and outlook

The proposed methodology of systematically determining a dynamic gray-box model of nonlinear dynamic systems was successfully applied to a simulation use case of a fermentation process. It was shown that using a training data estimation step enables the training of data-based models using common ML-toolboxes. The model selection can be performed efficiently without the need of dynamic simulations. Finally, the validated model structures are fine-tuned by solving the full dynamic parameter estimation problem.

In further work, we will include constraints into the parameter estimation to ensure that the resulting models are meaningful.

Optimal aeration of wastewater treatment plants based on recurrent neural networks and real plant data

Christian Hoffmann,^a Joris Weigert,^a Gerardo Brand Rihm,^a Erik Esche,^a and Jens-Uwe Repke^a

^a*Technische Universität Berlin, Process Dynamics and Operations Group, Str. des 17. Juni 135, 10623 Berlin, Germany*

Abstract

A significant share of the energy consumption by wastewater treatment plants stems from the air compressors in the aerobic processing steps. To minimize their energy consumption, dynamic optimization is a viable option. Modeling the complex (bio)chemical processes within wastewater treatment plants is a complex task and the simulation based on those models requires significant computational effort and is hard to initialize. An alternative to this approach is data-driven modeling of these plants. Therefore, this work features recurrent neural networks. These networks are trained and tested with real data from a German wastewater treatment plant. The identified models are used to obtain optimal control trajectories. The obtained trajectories are compared to the control actions applied in reality to assess the economic benefit of this approach.

Keywords: Machine learning, Recurrent neural networks, Wastewater treatment, Optimal control, Dynamic real-time optimization.

1. Main Text

In wastewater treatment plants (WWTPs), sewage is recycled in several anaerobic and aerobic processing steps. The aeration for these aerobic steps is done via compressors, which account for 50-60 % of the consumed energy of these plants (Viholainen et al., 2015). Therefore, minimizing energy consumption of the compressors would have major economic and environmental benefits. Consequently, rigorous, dynamic models were proposed to describe the transient behavior of WWTPs. Many of these models were critically analyzed and compared (Hauduc et al., 2010; 2013). However, while these models are certainly helpful in assessing the process dynamics, they may not be suited for online optimization because many of the required inputs for these models, e.g., some of the balanced pseudo-components, cannot be measured online.

Contrarily, data-driven models offer many advantages as they do not require the complex (bio)chemical phenomena to be modeled rigorously and can thus be evaluated much faster. This approach works if the available data amount and quality suffices for identifying a data-driven model with acceptable prediction error. As a result, machine learning methods have been proposed for applications in WWTPs. For example, Cheng et al. (2020) and Arismendy et al. (2020) studied different types of neural networks to forecast various process variables. An extensive review of machine learning methods for wastewater plants is given by Newhart et al. (2019). As of now, however, machine learning methods have hardly been used for optimal control in WWTPs. Only recently, Icke et

al. (2020) used a self-learning algorithm for control and reduced energy consumption by 15 %, thus showing the large economic potential of such approaches. In this contribution, recurrent neural networks (RNNs) are used to model the process dynamics of WWTPs. In RNNs, the feedback of outputs allows previous regressors to have an impact on the current prediction. This is advantageous for dynamic systems and gives these models much flexibility. The RNNs are trained with real data from a plant in Germany within (1) TensorFlow 2 (Abadi et al., 2015) with simple RNN architecture and with a long short-term memory (LSTM) layer and (2) a self-implemented RNN based on a multi-layer perceptron from Scikit-learn (Pedregosa et al., 2011). Instead of choosing the hyperparameters of the RNNs by trial-and-error, a hyperparameter tuning is carried out for optimal performance (Akiba et al., 2019).

2. Wastewater treatment plant

A simplified flowsheet of the WWTP that provided the data for this contribution is shown in Figure 1. The influent enters the plant and may be split into a stream that fills the rain basins (RB1–RB4). These basins usually fill in the case of heavy rain. Eventually, the sewage enters the sewer route (B1–B6) in which the (bio)chemical decomposition processes take place. Basin B5 and B6 are aerated. This aeration is realized by the compressors COM1–COM4. Furthermore, oxygen can be measured online in B5 and B6. Additionally, pH value and the concentrations of NH_4^+ and PO_4^- ions, and total suspended solids (TSS) are measured online in B6. The influent flow, the liquid volumes in the rain basins, and the power consumption P of the four compressors will be treated as inputs to the model whereas the measured concentrations will be outputs. This means that none of the basins are modeled in detail. Instead, only the input-output relation between the named variables must be found via training of the RNN. In general, the compressor duties depend on the required volume flow of air to achieve the desired oxygen concentration in the aerated basins.

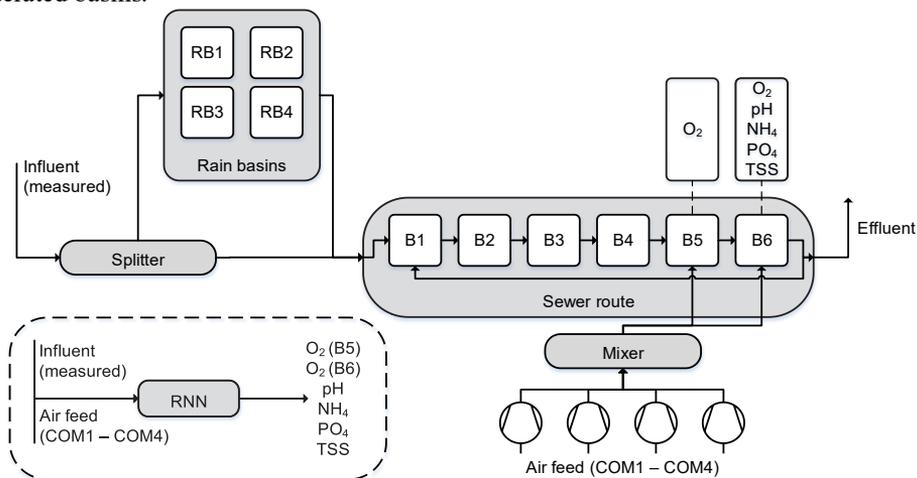

Figure 1: Simplified flowsheet of the WWTP in Weinheim (Germany). A representation of the RNN, including inputs and outputs, is given in the bottom left corner.

3. Training framework

The Python framework used in this contribution is illustrated in Figure 2 and based on the preliminary work by Weigert et al. (2020). In the data processing step, the plant data is read from Excel sheets and stored as a pickle file for efficient storage. Afterwards, the data is split into training and testing data. Throughout this work, the training-to-testing ratio is 9, i.e., the first 90 % of the data are used for testing while the remaining 10 % are used for cross validation and hyperparameter tuning. Once the training and testing data have been set and the input data have been windowed, the training data is also shuffled as part of the training algorithm.

In the model generation step, the data are separated into inputs and outputs as described in the previous section. Before the training begins, the training data are normalized so that all inputs have mean 0 and standard deviation of 1 whereas outputs lie between 0 and 1. In an external loop, the hyperparameter tuning via Optuna (Akiba et al., 2019) is initiated. Starting from an initial set of parameters, Optuna varies the hyperparameters of the respective model in the intervals defined in Table 1. Within the inner loop, the RNN is trained using the algorithms provided by TensorFlow 2 (Abadi et al., 2015) and Scikit-learn (Pedregosa et al., 2011), respectively. The objective function of the inner tuning is the mean squared error (MSE) of measurement data and prediction. The hyperparameter tuning minimizes the MSE for the testing data. Here, it is possible to use the MSE of the one-step prediction, the recurrent prediction – the prediction of the entire time horizon using the original data only in the first time point – or the MSE of an arbitrary prediction horizon. Within this contribution, the hyperparameter tuning was always minimized subject to a prediction horizon of 4 prediction steps. The inner tuning is repeated until the number of pre-defined outside iterations (here: 400) is reached. This number of iterations must be sufficiently large. In this study, the best solution was usually found after approximately 200 iterations, further increasing the number of iterations revealed no additional benefit. Finally, the hyperparameter set with the lowest MSE is chosen and the model is stored. In the optimal control step, the horizon is initialized by starting the optimization at time step $t_{\text{start}} = t_0 + n \Delta t_k$ where $n = \max(n_c; n_s)$ (see Table 1 for definitions). This ensures that enough past regressors are available to solve the RNN at the initial point. During the optimization, the plant influent remains an input to the RNN, but it can obviously not be used as degree of freedom. Contrarily, the liquid volumes in the rain basins and the energy consumption of the compressors are decision variables. The length of the prediction horizon can be

Table 1: Possible parameter range for hyperparameter tuning via Optuna.

Parameter	Range
Number of neurons in hidden layer (NN)	[10 ... 200]
Activation function (AF)	tanh or relu
L2 regularization weight (α)	[1e-5 ... 10]
Number of past states (n_s)	[3 ... 20]
Number of past controls (n_c)	[3 ... 20]

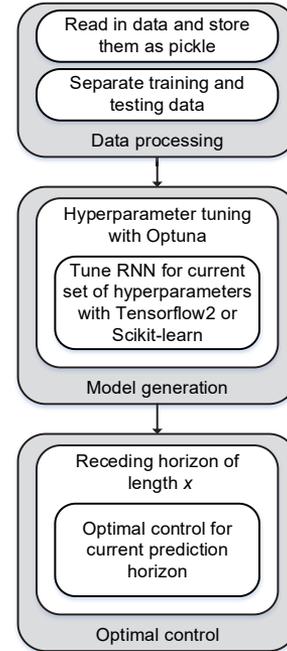

Figure 2: Framework for model generation and optimal control within Python.

repeated until the number of pre-defined outside iterations (here: 400) is reached. This number of iterations must be sufficiently large. In this study, the best solution was usually found after approximately 200 iterations, further increasing the number of iterations revealed no additional benefit. Finally, the hyperparameter set with the lowest MSE is chosen and the model is stored. In the optimal control step, the horizon is initialized by starting the optimization at time step $t_{\text{start}} = t_0 + n \Delta t_k$ where $n = \max(n_c; n_s)$ (see Table 1 for definitions). This ensures that enough past regressors are available to solve the RNN at the initial point. During the optimization, the plant influent remains an input to the RNN, but it can obviously not be used as degree of freedom. Contrarily, the liquid volumes in the rain basins and the energy consumption of the compressors are decision variables. The length of the prediction horizon can be

chosen arbitrarily: on the one hand, the horizon should be long enough to ensure a stable solution of the dynamic optimization; on the other hand, the prediction error usually increases with increasing time horizon. Therefore, a suitable horizon length must be determined. In this contribution, a prediction error of 1 led to profiles that occasionally violated inequality constraints. This did not occur for a prediction horizon of 2 for which the following results are shown.

4. Results and discussion

In the following, we compare the results obtained with different RNNs using the hyperparameter tuning described above. Results were obtained for three multiple-input-single-output (MISO) RNNs and one multiple-input-multiple-output (MIMO) RNN. For MISO RNNs, one RNN is trained per output variable. In the case of the MIMO RNN, one RNN is trained that predicts all outputs simultaneously. Figure 3 shows the results obtained with the MIMO RNN, which is based on a multi-layer perceptron in which the outputs are fed back as inputs (pseudo-RNN). Surprisingly, both the available training and testing data can be predicted very well given the small number of inputs. Table 2 shows a comparison of the obtained results for all trained RNNs. The first three columns contain ranges as every output is described by a separate model with different parameterizations.

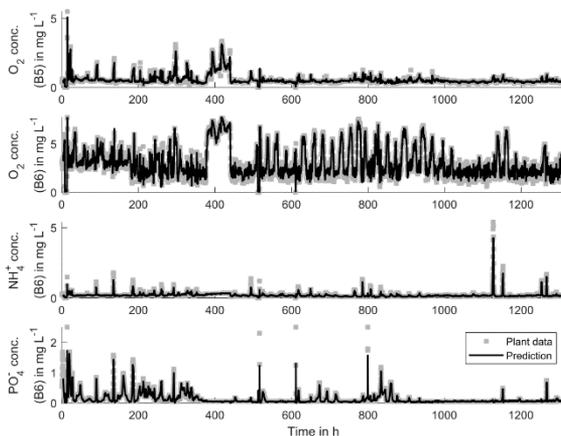

Figure 3: Comparison of plant data and prediction with MIMO RNN.

Table 2: Training results for all investigated RNNs in TensorFlow (TF) and Scikit-learn (SL) after hyperparameter tuning. Models in TensorFlow do not use external past states since the amount of recycled information is determined internally.

Parameter	Trained RNNs			
	MISO RNN	MISO RNN	MISO RNN	MIMO RNN
RNN Type	simple (TF)	LSTM (TF)	pseudo (SL)	pseudo (SL)
NN	35 to 143	61 to 196	46 to 165	164
AF	relu and tanh	relu and tanh	relu	relu
α	0.002 to 4.37	$6.5 \cdot 10^{-5}$ to 3.39	0.017 to 0.33	0.036
n_s	n. a.	n. a.	9 to 19	15
n_c	6 to 15	3 to 20	3 to 8	3
MSE $\cdot 10^3$	11.39	10.1	2.57	2.40

The differences in the obtained hyperparameters are significant and include a large variation in the number of neurons and the weighting parameter, and different activation functions. Moreover, the number of past states is much higher for the MISO RNNs compared to the MIMO RNN. Overall, the models trained in Scikit-learn perform better than those trained in TensorFlow 2. In addition, the MIMO RNN is slightly better than the MISO version. A possible explanation is that the MIMO model also considers the interdependency between the various outputs. Therefore, the MIMO architecture is used in the following. The influent profile for this case study is shown in Figure 4 (bottom). The objective function is the MSE between measured concentrations and pre-defined setpoints. As Figure 4 shows over a period of about one week, the effluent concentrations show notably less fluctuations for both ammonia and phosphorous components. As in the original data, compressors 3 and 4 are only used irregularly. However, this applies to compressor 2 as well in the optimization. In the case of lower plant load (between hour 30 and hour 75), the overall compressor power is also reduced. As a result, a reduction of the energy consumption of about 50 % is predicted for this week.

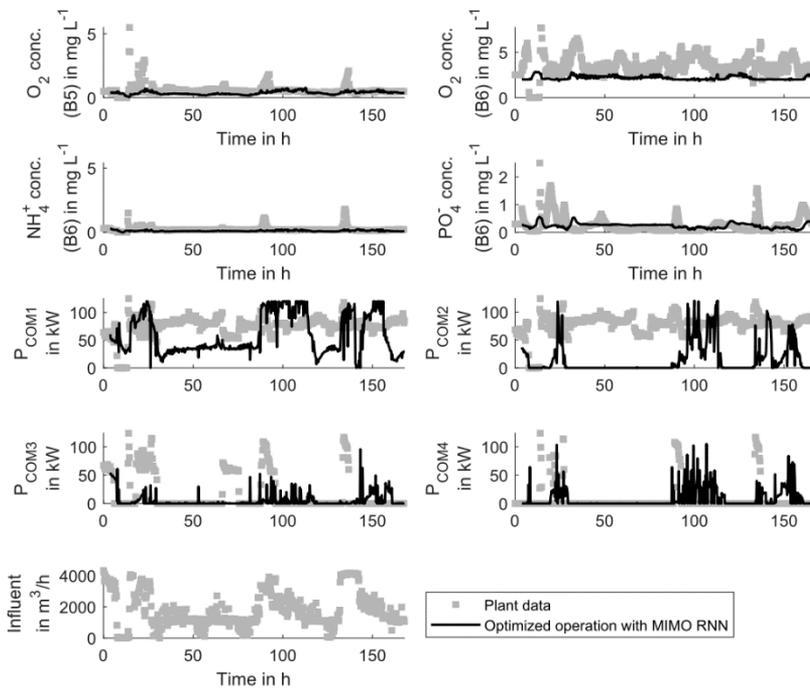

Figure 4: Optimized trajectory for 1 week. Levels of the rain basins are not shown here for brevity.

5. Conclusion and outlook

This contribution showed that a MIMO RNN can reliably predict the concentrations of components that are decisive for the effluent quality of a WWTP. The MIMO RNN also performed better than MISO RNNs where a single RNN per variable is trained at a time. The obtained MIMO RNN was used for optimal control in a receding horizon. Both the energy consumption and the liquid volumes in the rain basins were selected as decision

variables. This approach resulted in significantly lower energy consumption compared to the original plant data: a reduction of 50 % was predicted for the investigated week. In future work, the number of data points for the RNN must be extended and should include other seasons as well. In particular, the accurate description of outputs for small concentrations of dissolved oxygen should be checked to verify that the determined optimal solution is indeed physically feasible and not only a pseudo-solution of the trained RNN.

Abstract

Recirculating Aquaculture Systems are known to have its water quality conditions controlled, despite being common to have a simple control structure and a lot of human interaction to achieve that. To avoid long-term exposure to toxic levels of carbon dioxide and ammonia, its concentration needs to be monitored more often than manual measurements are available. In this work, we analyze the multilayer perceptron's ability to monitor water quality components that are important for the development of the fish. This alternative method for monitoring has the potential to complement the current sensor structure and laboratory procedures for manual measurement collection, but more studies need to be done on the type of machine learning model.

Keywords: Soft sensor, Recirculating aquaculture systems (RAS), Feedforward neural networks

1. Introduction

Recirculating Aquaculture Systems (RAS) have two dynamic sub-systems: fish metabolism and water treatment. The water treatment system is responsible by keeping the water quality at high standards, reducing water consumption, and reducing contact with external pathogens (European Market Observatory for Fisheries and Aquaculture Products, 2021).

Regarding the water quality, some components are important to be monitored and controlled due to toxicity, but are hard or not able to be measured continuously, such as ammonia. In addition, it requires either several sensors or a central sensor station with sampling system to get information about the levels of dissolved carbon dioxide and ammonia in all fish tanks and water treatment system. One way of using information of the process to estimate the concentration of these toxic components is by using soft sensors (Fortuna et al., 2007).

The soft sensor technique is a combination of data, for parameter estimation, and process knowledge, for feature selection. The development of the data-driven models can be done, for example, using machine learning models, such as feedforward neural networks (FNN). In this work, the main objective is to apply multilayer perceptron (MLP) (Werbos, 1974), which is a classic type of FNN and a universal approximator (Hornik et al., 1989), as a soft sensor for recirculating aquaculture of Atlantic salmon (*Salmo salar*).

In RAS, even if fish, feed and waste production increase in an exponential way, the goal is that the water quality should be kept stable and good. Measurements of ammonia are performed manually

daily, whereas CO_2 is measured continuously at least in one point in the system. However, their levels might vary during the day depending on feeding and other factors, and data about this may be missed. Optimizing the water quality and fish growth would be easier with higher resolution of information. In addition, manual collection and laboratory analyzes are time consuming and therefore costly. Therefore, it is useful to develop an alternative method to monitor these water quality variables.

As the system is assumed to reach a steady state after each day, the water treatment system is approximated to a steady-state model developed in previous work (Dos Santos et al., 2021). The training and validation data are acquired from this model, where some parameters are considered as uncertainties. To improve the soft sensor identification, the uncertainties are changed using latin hypercube sampling (LHS) (Jin et al., 2005), so it contains the operating region, which provides condition for fish optimal growth. After addition of white noise, the data is used to train different MLP configurations for predicting carbon dioxide, ammonia and ammonium concentrations.

2. Process Description

Figure 1 shows a diagram of the RAS this work is focused on. The process consists of a fish tank, a biofilter, a stripper and an oxygen cone. The model is a simplified version of the process, as it does not consider the effect of the water quality on the fish metabolism, if the conditions are kept within bounds. This assumption is reasonable for each phase of the fish life, which can last from weeks to years depending on a lot of factors. Therefore, this work is only valid for the phase the model represents, which is the smolt phase. This could be easily extended to other phases by changing some parameters in the model, such as the amount of product generated by the fish metabolism per kg of fish feed.

The measurements that are available from sensors or human addition include recirculating volumetric flow rate, q ; pH ; fish feed rate, F ; buffer additions, \dot{m}_{buffer} ; base additions, \dot{m}_{base} ; makeup water, q^m ; air inlet flow rate, \dot{m}_{air} ; makeup oxygen, \dot{m}_{O_2} ; average salinity, S ; average temperature, T . More details about the process can be found in Dos Santos et al. (2021).

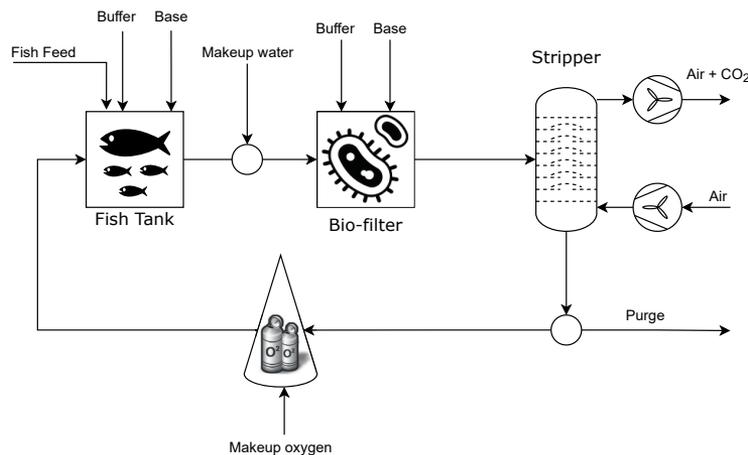

Figure 1: Process diagram of a recirculating aquaculture system

3. Methodology

In order to develop a soft sensor, a standard procedure was followed. Gather data, preprocess it and divide it into training and validation data. After that, fit the model and choose the best model of validation phase. And finally, test it with industrial data.

3.1. Training and Validation Data Acquisition

For the training and validation data acquisition, 6967 steady-state data points were generated within the region described by Table 1, using CasADi v3.5.5 (Andersson et al., 2019) in Python v3.8.8. 5967 of these data points were generated using latin hypercube sampling (LHS) built in pyDOE package in Python. LHS is a popular algorithm for planning computer experiments covering the entire range of uncertainties and disturbance in an optimally and distributed way for training. The rest was generated randomly within the same region for validating the soft sensor. After that, 1% white noise was added to both input and output data of both training and validation data.

Table 1: Region of operation

Parameter	Mean	Unit	Range	Description
G/L	2.7	-	$\pm 50\%$	Gas-liquid ratio in equilibrium over the stripper
ξ_B	0.8	-	$\pm 25\%$	Biofilter efficiency
T	14	$^{\circ}\text{C}$	$\pm 30\%$	Average temperature of the system
pH ^m	7.0	-	$\pm 10\%$	pH of the makeup water
$y_{\text{CO}_2}^{\text{in}}$	4.15e-04	-	$\pm 10\%$	CO ₂ composition in the air inlet
S	15.95	ppt	$\pm 30\%$	Average salinity of the system
pH _{des} ^B	7.2	-	$\pm 1\%$	Desired pH for the biofilter
q	20	m ³ /min	$\pm 50\%$	Recirculating volumetric flow rate
F	580.6	g/min	+ 50%	Fish feed rate

3.2. Data Preprocessing

Some concentrations are really low in RAS, when comparing with other concentrations. Therefore, it is essential that all data is submitted to preprocessing. As the soft sensor model applied in this work is a deep learning neural network, the normalization of the datasets uses a minmax calculation of the training dataset. After that, the datasets are ready to be used to train and validate the soft sensor.

3.3. Soft Sensor

The feedforward neural network (FNN) architectures were created and optimized using Auto-keras package (Jin et al., 2018), which is a package in Python that automatizes the neural architecture search (NAS) of models supported by another python package named Keras.

In this work, the FNNs are multilayer perceptron (MLP), trained using backpropagation method with a batch size of 500 samples. The objective function of the NAS was the validation loss, the loss function was the mean squared error, and the maximum number of trials is 50. The features were chosen based on knowledge of the process and the available measurements in a real RAS.

After choosing the model with the lowest validation loss, the MLP performance was tested predicting the targets concentration from real data. To avoid breaking the non-disclosure agreement, the collected industrial data was normalized. The performances were compared using the root mean squared error between scaled predicted and scaled data.

4. Results

The choice of inputs was based on the available measurements from sensors or manual insertion of inlet streams described on the previous section. Three types of models were tested: multiple-input, single-output MLP (MISO-MLP), multiple-input, multiple-output MLP (MIMO-MLP), and a hybrid model, which consists of a MIMO-MLP predicting ammonium and dissolved CO₂ concentrations with ammonia concentration being calculated using the equilibrium equation, see Eq. 1. The inputs of the models were the same for MISO-MLP_{NH₄⁺} and MISO-MLP_{NH₃} models: fish feed rate, F , recirculating volumetric flow rate, q , pH in the tank, pH^T . The MIMO-MLP, MISO-MLP_{H₂CO₃} and the hybrid models' features included the same as the previous with addition of a new feature: air inlet flow rate, \dot{m}_{air} .

$$c_{NH_3}^T = \frac{K_3(S, T) c_{NH_4^+}^T}{c_{H^+}^T} \quad (1)$$

where the equilibrium constant, K_3 , is dependent on salinity and temperature, and the concentrations unit is mmol/L.

Figure 2 shows the prediction of the validation data using the MISO-MLP models, Figure 3 shows the results using the hybrid model, and Figure 4 shows the results using the MIMO-MLP model. Comparing Figures 2 and 3, prediction of ammonium and dissolved carbon dioxide were similar, but ammonia predictions are worse using the hybrid model. Comparing Figures 2 and 4, prediction of ammonia is slightly worse on the extremes using MIMO-MLP, and the other predictions were similar.

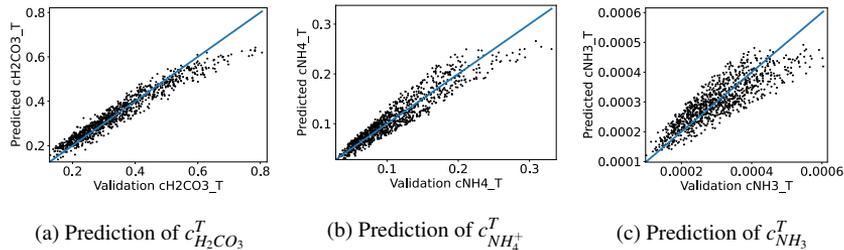

Figure 2: Prediction of validation data using the MISO-MLP models separately

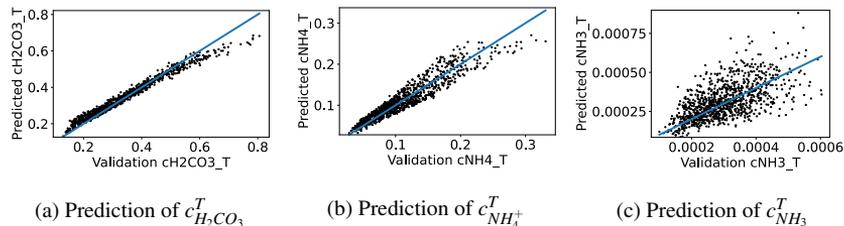

Figure 3: Prediction of validation data using the hybrid model

In Table 2, we summarize the performance of the models at the validation phase using the RMSE index. The best MLP architecture for this case study was the MISO-MLP models put together, which gave the lowest final RMSE at the validation phase, and MIMO-NLP model was the second best giving similar, but slightly higher, RMSE.

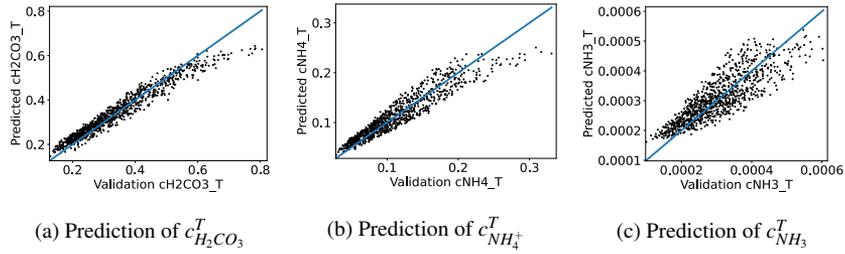

Figure 4: Prediction of validation data using the MIMO-MLP model

Table 2: Summary of the models performance at the validation phase - RMSE index

Output	MISO-MLPs	Hybrid	MIMO-MLP
$c_{H_2CO_3}^T$	0.0645	0.0787	0.0694
$c_{NH_4^+}^T$	0.1204	0.1201	0.1230
$c_{NH_3}^T$	0.1322	0.2611	0.1351
Final	0.1097	0.1720	0.1129

Their architecture of the MLPs are described in Table 3. MISO-MLP $_{H_2CO_3}$ model has two dense hidden layers with 32 nodes each using the rectified linear activation function (ReLU), while the others have one dense hidden layer, but with 64 and 128 nodes using the same activation function on MISO-MLP $_{NH_4^+}$ and MISO-MLP $_{NH_3}$ models, respectively. Note that ammonia concentration turned out to be harder to estimate when compared with ammonium, and possibly the NAS found a flat optimum, which means that probably a MLP with lesser nodes would not improve but would not make the prediction much worse also.

Table 3: Number of nodes in each layer of each MISO-MLP model

Layers	MISO-MLP $_{H_2CO_3}$	MISO-MLP $_{NH_4^+}$	MISO-MLP $_{NH_3}$
Input	4	3	3
Normalization	3	3	3
Dense ₁	32	64	128
Dense ₂	32	0	0
Dropout	0	64	128
Output	1	1	1

The prediction of the industrial data using the MISO-MLP models is shown in Figure 5. The predicted values of ammonia concentration seem to be closer to the real data compared with ammonium predictions, which is unexpected. The predicted $c_{H_2CO_3}$ were the same for the first few samples, which means that the model could not extract enough information from the features on those points.

5. Discussion

The prediction of ammonia was revealed to be much harder than of ammonium, resulting in a poor prediction of that variable. This might be due to the noise of the input variables that affects a lot the ammonia concentration, as its magnitude is much smaller. This effect does not disappear after

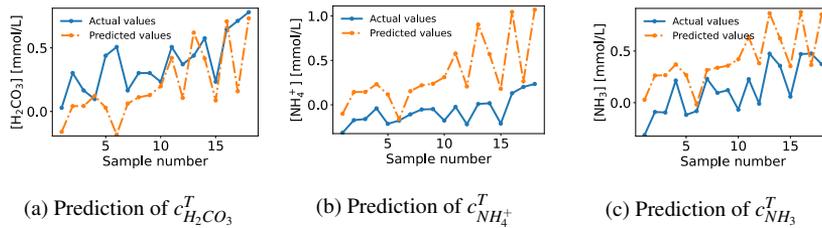

Figure 5: Prediction of industrial data using the MISO-MLP models

preprocessing the data; it expands instead, as the magnitude after normalization is approximately 1000 times higher.

The MISO-MLP models gave the best performance due to different input features to each model, as adding not so important features can make NAS more complex and add a lot of useless cases, as happened with the MIMO-MLP model. This could be solved by increasing the maximum number of trials at the NAS step, but it would take longer, and would still have the possibility of finding different local minimum, for better or worse.

6. Conclusion

The measurement of key waste products are not always easy to collect in real-time or at a required frequency, which reduces the possibility to stabilize and optimize the water quality for the fish. This can be improved by using machine learning models, such as multilayer perceptron.

The MLP models trained in this work are deep neural networks, and its architectures were optimized using an automated neural architecture search and tuning of hyperparameters. Three configurations were compared: MISO-MLPs; hybrid model; and MIMO-MLP. The best configuration was the MISO-MLP models together, although their performance was not so good. This might be due to the possibility of NAS reaching a local minimum or the models could not capture the information it needed, so a different type of model could perform better. A soft sensor using these models for monitoring would perform better than the hybrid model, and the MIMO-MLP model, but would also complement the manual measurements, when estimating dissolved CO_2 and NH_3 concentrations.

Abstract

Recently, machine learning methods such as neural networks have been applied in various applications thanks to their accuracy and flexibility. However, the main drawback of these methods is the lack of interpretability, which is the reason for being uncommon in chemical engineering applications. At the same time, the recent rise of interpretability research has led to some confusion in various communities. In order to deal with this issue for the CAPE community, we propose to discuss the notion of interpretability under the prism of neural network predictions using an example from chemical engineering. To do this, we first set out the framework for defining interpretability for machine learning methods. Then a post-hoc method for model evaluation, explicitly named "model-agnostic methods", will be presented. In this study, we try to enhance the interpretability of the neural network predictions and visualize the effect of features on the model's output by a model-agnostic method named Accumulated Local Effects. As a case study, we work on predicting electrical power output and prioritizing the parameters of a combined cycle power plant. We could conclude that the most influential input parameter among Ambient Temperature (AT), Atmospheric Pressure (AP), Vacuum (V), and Relative Humidity (RH) is AT, and the most interaction is between AT and V.

Keywords: Interpretability, Neural network, Model-agnostic method, Accumulated local effects

1. Introduction

Recently, Machine Learning (ML) techniques, especially deep neural networks models, have become a crucial tool for various engineering applications such as chemical engineering (Zhang et al., 2020). These techniques have achieved high predictive accuracy primarily due to their ability to model complex nonlinear interactions between predictors and model outcomes. However, most accurate predictions remain in the black box frameworks, meaning that interpretation of the model's parameters interaction and explanation is partially (or entirely) hidden to the experts. Understanding the reasons behind predictions is very important to one plan to act based on these predictions.

In this paper, we will restrict the definition of the concept of *interpretability* to the ease of understanding the relationships established by ML models, which are able to work with non-linearly related variables. More precisely, for prediction problems, interpretability can be defined as the process of extracting relevant knowledge from a model about the learned relationships between features and model outputs. The knowledge referred here concerns information with a given meaning, allowing a particular audience to understand a chosen problem better (Murdoch et al., 2019).

To this end, we have two options, namely model-specific tools (easily interpretable models) and model-agnostic methods. Model-specific methods have their own tools to interpret the results, such as weights (statistical significance) in linear or logistic regression and the hierarchical graphical tool for decision trees. Nevertheless, they cannot be generalized to other ML models, particularly regarding the nonlinear impacts between variables in the Neural Networks learning. Thus, model-specific interpretation tools have a significant disadvantage: the limitation to one type of model and the difficulty of switching to other ML regression methods. The second approach, which is the model-agnostic interpretation method, is designed to remedy these shortcomings. Model-agnostic tools can be used on any machine learning model and are applied after the model has been trained (post-hoc) (Molnar, 2019).

In this paper, in order to enhance the interpretability in machine learning predictions, Model-agnostic methods are used and applied to real complex data and prediction problems. The prominent advantages of model-agnostic methods are their flexibility in model, explanation, and representation (Molnar, 2019). These methods separate the explanations from the machine learning model and could be applied to any ML model (regression and classification) (Ribeiro et al., 2016). The visualization provided by these tools is an important model diagnostic technique.

Model-agnostic methods can be distinct into local and global methods. Global methods concentrate on how features affect the prediction on average. In comparison, local methods explain the individual effect on predictions. Global methods are mainly represented as expected values based on the data distribution. Global methods include Partial Dependence Plots (PDP), Accumulated Local Effect plots (ALE), global surrogate models. Local methods include Individual Conditional Expectation curves (ICE), Local Interpretable Model-agnostic Explanations (LIME), and counterfactual explanations (Molnar, 2019).

One of the interesting model-agnostic methods available is ALE Plots. Our previous work dived into PDP and ICE plots as model-agnostic methods and discussed the main effect of each predictor x_1, x_2, \dots, x_n on $f(x_1, x_2, \dots, x_n)$ (Danesh et al., 2021). This study will work on ALE Plot to detect the lower order interaction effects among different predictors and compare it with other visualization tools for interpretability purposes.

As a real-world application, data from Combined Cycle Power Plant (CCPP) proposed by Tüfekci (2014) are used. The dataset is collected over six years and comprises 9568 data points. The paper focused on testing and comparing some machine learning regression methods. It aimed to extend an accurate predictive model and evaluate the prediction accuracy by Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE).

This paper's main contribution falls within the framework of the interpretability methods of neural network predictions (the Multi Layer Perceptron (MLP)) from model-agnostic points of view. The primary purpose of this study is to present to the CAPE community a simple way to interpret, evaluate and validate a machine learning prediction model. For this purpose, we used ALE plots as model-agnostic methods to visualize the behavior and effect of inputs on the output.

2. Accumulated Local Effects

2.1. Theory

Accumulated local effects explain the average impact of features on the prediction of a machine learning model (Apley and Zhu, 2020). ALE methods could work while the features are dependent, although the assumption of features independence is the biggest problem with PDPs.

In what follows, upper case X is used to identify random variables, and lower case is used to identify specific values of the random variables. The total feature space x contains two different sets. The first one, x_i represents the features that their effect on the prediction is studied. The

second one named x_j represents the other features that exist in the machine learning model except for x_i .

The ALE main effect of predictor $x_i, i \in \{1, \dots, d\}$ is defined by the following equation:

$$\hat{g}_{i,ALE}(x_i) = \int_{z_{0,i}}^{x_i} E[\hat{g}^i(X_i, X_j) | X_i = z_i] dz_i - C$$

Where, $\hat{g}^i(X_i, X_j) = \frac{\partial \hat{g}(X_1, \dots, X_d)}{\partial X_i}$. Here, $g(x)$ is assumed a black box supervised learning model that is a neural network in our study. $\hat{g}(x)$ represents the fitted model. $z_{0,i}$ refers to an approximate lower bound of X_i , and it affects the vertical translation of the ALE plot. C is considered as a constant that aims to make the mean of $\hat{g}_{i,ALE}(x_i)$ equal to zero concerning the marginal distribution of X_i or to center the plot vertically.

The ALE second-order effect of predictors $\{x_i, x_l\}, \{i, l\} \subseteq \{1, \dots, d\}$ is defined by the following equation:

$$\hat{g}_{\{i,l\},ALE}(x_i, x_l) = \int_{z_{0,i}}^{x_i} \int_{z_{0,l}}^{x_l} E\left[\frac{\partial^2 \hat{g}(X_1, \dots, X_d)}{\partial X_i \partial X_l} | X_i = z_i, X_l = z_l\right] dz_i dz_l - f_i(x_i) - f_l(x_l) - C$$

Where, $z_{0,i}$ and $z_{0,l}$ refer to approximate lower bounds of X_i and X_l , respectively. The functions $f_i(x_i)$ and $f_l(x_l)$ are the function of single variables X_i and X_l , respectively. The functions and the constant aims to make the mean of $\hat{g}_{\{i,l\},ALE}(x_i, x_l)$ equal to zero concerning the marginal distribution of X_i and X_l .

2.2. Estimation

For estimation, the features are divided into many intervals, and then the differences in the predictions are computed. We could approximate the derivatives by this procedure. The advantage of this procedure is that it is able to work for models without derivatives. The equation of estimation, as proposed by Apley and Zhu (2020), is as follows:

$$\hat{g}_{i,ALE}(x) \approx \sum_{k=1}^{k_i(x)} \frac{1}{n_i(k)} \sum_{j: x_{j,i} \in N_i(k)} [\hat{g}(z_{k,i}, x_{j,\setminus i}) - \hat{g}(z_{k-1,i}, x_{j,\setminus i})] - C$$

Where the notations are as follows: the constant is chosen to $\frac{1}{n} \sum_{j=1}^n \hat{g}_{i,ALE}(x_{j,i}) = 0$. For each $k \in \{1, 2, \dots, K\}$, $n_i(k)$ refers to the number of training observation that falls into k th interval $N_i(k)$. Let $x_{j,\setminus i} = (x_{j,m} : m = 1, \dots, d; m \neq i)$ where the subscript $\setminus i$ refers all variables except the i th. For each $i \in \{1, 2, \dots, d\}$, $N_i(k) = (z_{k-1,i}, z_{k,i}] ; k = 1, 2, \dots, K$ indicates an enough good partition of the sample rang of $x_{j,i} : j = 1, 2, \dots, n$ into k intervals (K is an input argument in the ALEPlot function, and we typically use K around 100, with larger values often give better result.). $z_{k,i}$ is chosen as the $\frac{k}{K}$ quantile of the empirical distribution of $\{x_{j,i} : j = 1, 2, \dots, n\}$ that $z_{0,i}$ is chosen below the smallest observation, and $z_{K,i}$ is chosen as the largest observation.

3. Case study: Combined Cycle Power Plant

A combined cycle power plant was selected as the real-world application to carry out the study. The components of a CCPP are Gas Turbines (GT), Steam Turbines (ST), and Heat Recovery Steam Generators (HRSG). One of the advantages of CCPP is using waste heat to produce supplementary steam in order to generate additional electricity (Niu and Liu, 2008). One of the efficient machines to generate mechanical and electrical power from gas fuels is the gas turbine. Consequently, gas turbines are more common for power generation. They are utilized especially in combined cycle mode to recover the waste heat to produce extra electricity. In addition to the high

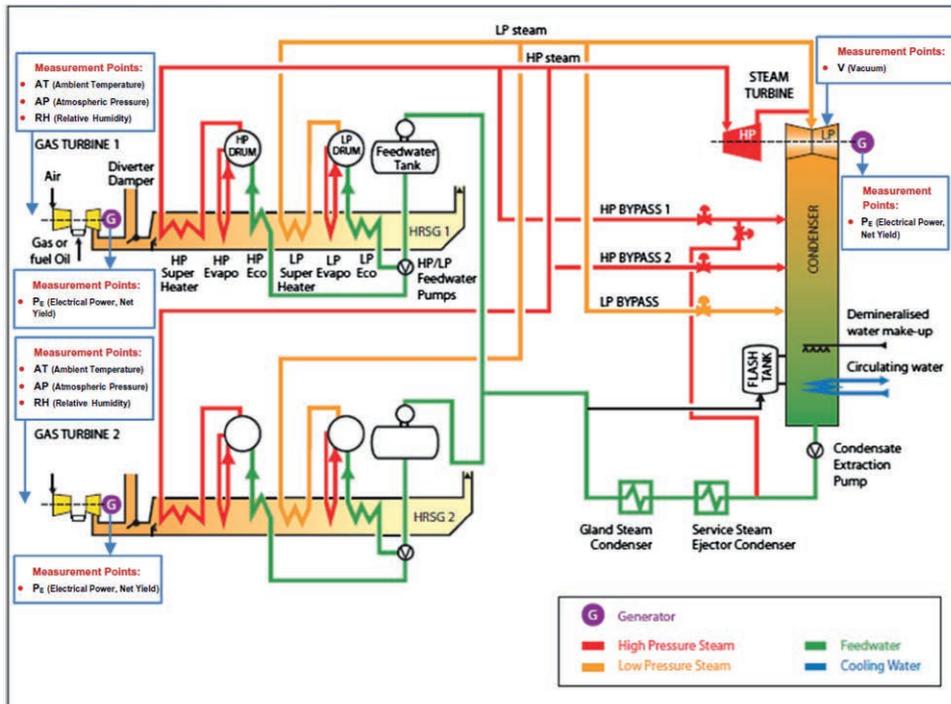

Figure 1: The combined cycle power plant layout (Tüfekci, 2014). It contains two gas turbines, a steam turbine, and heat recovery steam generators. The figure shows the measurement points of the input and output variables.

power outputs of CCPPs, they release partly low exhaust gases. CCPP generates 68% of electricity and the remaining 32% waste. In contrast, other kinds of power plants can generate only 33% electricity.

Given the advantages listed, it is clear that the use of CCPP increases, and predicting and interpreting the prediction model of a power plant became a trending topic for researchers and a critical problem. We need to have information on the influential factors and interactions between them to accurately predict a power plant's power output. Furthermore, it is favorable to have a power plant with high efficiency, reliable and sustainable and to maximize the income from the available megawatt-hours (MW/h). Figure 1 shows the CCPP layout and the sensors location (Tüfekci, 2014). The parameters that affect the CCPP are the ambient conditions such as ambient temperature (AT), atmospheric pressure (AP), and relative humidity (RH); and the exhaust steam pressure (or vacuum, V) effect on the steam turbine. These parameters are the input variables of the system, and the electrical power from both gas and steam turbines is the target variable.

The power plant was designed with a nominal generating capacity of 480 MW, consisting of two 160MW ABB 13E2 Gas Turbines, two dual pressure heat recovery steam generators, and one 160MW ABB Steam Turbine. The dataset contains data over six years. The dataset from the plant and data preprocessing is described in detail in the original paper (Tüfekci, 2014). The dataset consists of 9568 data points collected when the plant worked with a full load over 674 different days. This study is performed on the dataset of the mentioned paper with the same CCPP. The significant contribution of the paper is that we bring interpretability and explainability point of view in the framework of supervised machine learning approaches to realize and visualize the

effects and interaction of the predictor variables on the predicted response.

4. Results and discussion

Here we present the ALE plots used to visualize the effects of the predictors and interaction between them. All the results are attained from R software (R Core Team, 2020).

Figure 2 shows the ALE main-effect plot of input variables for an MLP prediction with one layer and 50 neurons. The AT main effect has sigmoidal behavior. Increasing the AT makes PE decrease. The RH main effect behaves quadratically. The V main effect has almost sigmoidal behavior, and the AP and RH main effects have quadratic behavior.

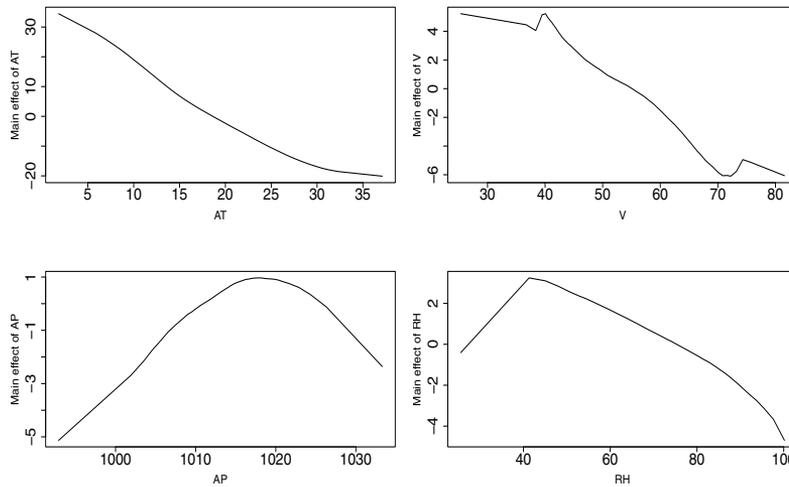

Figure 2: ALE main-effect plots for neural network with 50 neurons.

Figure 3 is the ALE second-order effect plot without the main effect of each input variable. They reveal the interaction between input variables for a neural network with 50 neurons. The numbers on the contours show the function values. The darker the chart color shows, the higher the function value. Figure 3 reveals notable interactions between AT and V since the contour values change over a range of 90 units (from -90 to 0), which is almost as large as the range for the main effect of AT in figure 2. Figure 3 shows almost moderate to negligible interaction in other subplots.

We can conclude that AT and V have the most interaction and AT-RH and AP-RH has the most negligible interaction based on figure 3.

5. Conclusion

This study aimed to improve the interpretability and explainability of a prediction model for the output of a CCPP as a case study by applying model-agnostic methods. A clarification on the concept of interpretability of machine learning predictions was provided. The importance of this study comes from the fact that most of the prediction models are like a black box. However, they are more accurate and faster than physical approaches with many nonlinear equations that might give undesirable and invalid results.

This study was performed on the same data set as Tüfekci's paper (Tüfekci, 2014). She studied different regression methods to present a model to predict an electrical power output. We worked

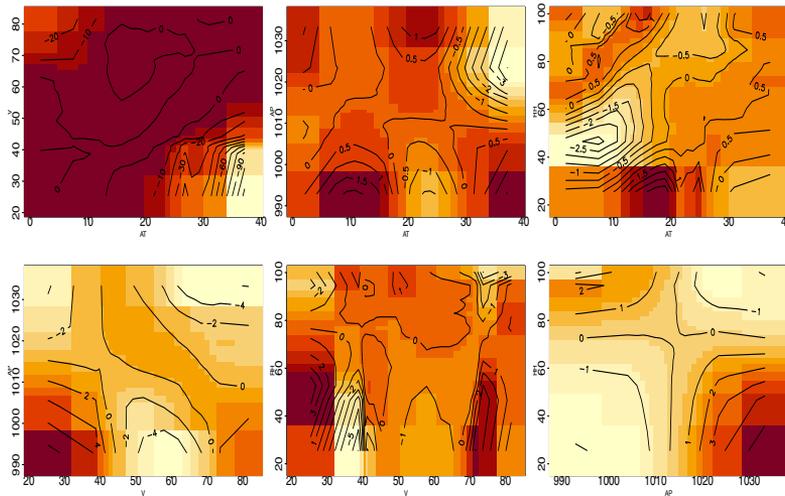

Figure 3: ALE second-order effect plots for for neural network with 50 neurons.

on the interpretability point of view of neural networks as machine learning methods. More precisely, our study focuses on analyzing the interactions between different variables and their individual effect on the output of the system. It is based on the accumulated local effects tool as a model-agnostic method for visualization to make more effortless interpreting. The model-agnostic flexibility is their remarkable advantage because it can be applied to any ML model. ALE would show the most important input variable, the relation between the input and output variables, and the second-order interaction between the input variables and the output variable.

To sum up, we can use ALE when the features of a machine learning model are correlated. While other model-agnostic methods, such as PDPs, are not trustable because they may average predictions of unrealistic artificial data instances in the mentioned case. A further research objective will include the comparison of ALE for different neural network architectures. Moreover, we could apply other model-agnostic methods such as partial dependence plots, global surrogate models, individual conditional expectation curves, and local interpretable model-agnostic explanations.

Abstract

Recent successes of machine learning in applications such as gaming, computer vision, and natural language processing, have generated considerable excitement for the application of purely *black-box* data driven techniques in other areas. However, unlike such applications, chemical engineering systems are governed by fundamental principles comprising of conservation laws and constitutive equations. Incorporating such natural constraints is valuable in many applications. However, as the complexity of systems increases, obtaining these first-principles models becomes exceedingly difficult. Hence the appeal of black-box models, which manage to perform well in some practical applications. This, however, comes at the cost of not being able to interpret and explain such a model's performance, which might limit its acceptance. As a result, hybrid AI models that combine first-principles with data driven techniques have been proposed in the literature. These attempt to eliminate the drawbacks of both approaches and provide insights into the system. Hybrid AI models can be developed for different end-user purposes – interpretability, interoperability, meeting desired performance targets and constraints, etc. This review article describes these disparate but related approaches, and provides a summary of recent progress in this field. Further, it provides a perspective for potential future research in this domain.

Keywords: mechanistic models, hybrid models, data driven model, reduced-order model

1. Introduction

In this emergent era of artificial intelligence (AI), particularly machine learning (ML), purely data driven *black-box* models are gaining great importance in many applications. Driven by their successes in game playing, natural language processing, and computer vision, they are seen as a panacea in all other domains as well.

However, unlike such applications, many science and engineering based systems, such as the ones in chemical engineering and materials science, are governed by fundamental principles comprising of, but not limited to, conservation laws and constitutive equations. Incorporating such natural constraints is valuable, even critical, in many applications. The complexity of many practical chemical engineering systems, however, poses challenges in formulating such *mechanism-based* transparent models. Often, in many practical settings, such models cannot be developed as not enough fundamental information is available to formulate them. Further, even if developed, they tend to be a large set of differential and algebraic equations, often nonlinear, with many variables and parameters that are hard to measure or compute and hence solve satisfactorily. Such drawbacks

have motivated people to develop data-driven "black-box" models with their own limitations, such as their inexplicability.

The recent trend on 'explainable AI', or XAI, focuses on making existing black-box systems explainable and interpretable to the end-user – a system that can explain its recommendation and reasoning, preferably in a natural-language-like fashion. While such an explanation might not be crucial for movies recommendations (*e.g.*, by Netflix), or for dinner choices (*e.g.*, by Yelp), they are critical for many engineering applications such as in control and safety (Venkatasubramanian, 2019). As the recent Boeing 737 Max-8 control system failures have demonstrated, the cost of a mistake is potentially high. Thus, the need to explain and justify the recommendations of an AI agent is imperative in such applications.

Combining first-principles knowledge with data driven techniques seems like a reasonable compromise to address this challenge. Hybrid models can be developed for different end-user purposes, such as to achieve interpretability, interoperability, meeting desired performance targets and constraints, etc. One of the earliest hybrid-AI model was developed by Sundaram et al. (Sundaram et al., 2001) for the inverse design of fuel additives. They combined a population balance-based, equations-driven, fundamental model that exploited physicochemical mechanisms of fuel additive function with a neural network-based model. The same group further developed a different hybrid AI model, but with a similar structure, for the inverse design of rubber compounds (Ghosh et al., 2003). Yet another example was the Reaction Modeling Suite system for catalyst design (Caruthers et al., 2003, Katare et al., 2001, 2004). All three approaches leveraged the underlying physics and chemistry effectively, even though they were all very different owing to the diverse nature of the applications. Such exploitation resulted in more explainable and reliable predictive models that did not require great amounts of data that were hard to acquire. These hybrid AI models combined *symbolic AI* (*i.e.*, a priori knowledge in the form of rules, schemas, and equations) with *numeric AI* (*i.e.*, data-driven techniques such as neural networks) and were implemented and used in industrial settings. Despite such early successes, the development of hybrid AI models remains a major challenge requiring a lot of time, effort, and considerable modeling skills. Hence, there is an urgent need to make such development more systematic, routine, relatively easy, and quick in a variety of applications.

Consequently, we feel there is a need to provide a coherent narrative to the various hybrid modeling approaches, specifically from the perspective of the end-user's purpose. We depict the wide range of models that one can obtain, and that hybrid AI models attempt to combine the best

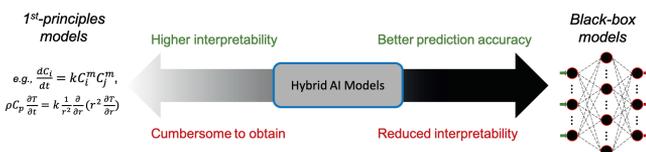

Figure 1: Combining 1st principles with black-box models yields hybrid AI models.

of the two extremes, in fig. 1. The various levels of granularity that go into developing a hybrid model often depend on the problem it aims to solve. In particular, this ranges from achieving interpretability, incorporating fundamental physicochemical mechanisms, targeted performance (execution speed and accuracy), adherence to constraints, interoperability (including extrapolation), etc. In this paper, we discuss the opportunities and challenges underlying such approaches.

2. Objectives of Hybrid Models

2.1. Interpretability

As noted, many safety-critical applications in chemical engineering and materials science require the models to be interpretable. This involves, among other things, being able to describe the underlying phenomena (*e.g.*, type and/or order of reaction kinetics) in fundamental mechanisms-based terms, explaining the quantitative dependence of state variables, demonstrating dimensionally consistent models, and producing causal models.

Recent work in attempting to model process systems considering the above guiding principles, has resulted in the combination of symbolic knowledge with domain dependent (intelligent) feature engineering into a machine-learning system. Symbolic knowledge (*i.e.*, symbolic AI) is accounted for through symbolic regression, where the task is to identify the model form that could have generated the data, and subsequently obtain the parameters. Genetic algorithms have been used as a feasible method for searching through the large function space, under user specified first-principles-based mechanistic constraints (Chakraborty et al., 2020). These models can be linear or nonlinear (Chakraborty et al., 2021). Constraints can be applied on the dimensionality of features generated, as has been successfully demonstrated in the domain of computational physics (Udrescu and Tegmark, 2020).

Such symbolic AI based models are inherently more simpler than black-box models. For a plant operator, one can easily perform a sensitivity analysis and obtain the dependence on such a model. Further, statistical techniques that provide uncertainty estimates of the parameters allow insight into the importance of features of the model. Parametric models such as these require significantly lower number of parameters than black-box models. One can even account for a priori knowledge (*e.g.*, in the form of priors, for Bayesian regression). Such parametric models can be beneficial in surrogate-based modeling.

Domain knowledge can also be injected into such models by penalizing intractable function transformations. This drawback is a recurring theme in purely black-box approaches, where overly complex function transformations are used to represent the model trajectory, resulting in poor generalizability. Additionally, such symbolic models tend to require much less data than their purely black-box counterparts. This is a major differentiator for hybrid models in many engineering applications that are in the 'precious data' domain, as noted, in contrast with standard machine learning techniques for 'big data' domains (such as computer vision, natural language processing, gaming, etc).

2.2. Adherence to Constraints

To deploy predictive models in many engineering applications, it is of great importance that the models respect constraints imposed by the first principles. Such constraints can be of varying nature, such as univariate limit constraints to more complex linear and nonlinear constraints that involve multiple input and output variables simultaneously. Examples of constraints derived from first principles that commonly occur in chemical engineering are mass, atom, and energy balance, or constraints on concentrations prescribed by the chemical reactions taking place in the equipment. Each of these constraints is typically linear in all or a subset of the variables considered, whereas some of these can be nonlinear as well. Atom balance constraints, for instance, are almost always nonlinear constraints.

In many applications, model predictions need to meet such constraints for the model to be deployable. In fact, one could consider machine learning models that respect a set of constraints, to be a first subset of hybrid models that combine black-box machine learning techniques with domain knowledge, with the latter being represented by the constraints. Several approaches can be taken to build machine learning models that respect such constraints. These approaches differ along

the guiding principle: either first-principles models generate the eventual estimate, adjuvated by inputs from machine learning, or the models are mainly data-driven machine learning models, but learning and predictions are adjusted such that they respect constraints. The former category is an active field of research, referred to as *Physics-Inspired Neural Networks* (PINNs) (Raissi et al., 2019) or *Neural Differential Equations* (NDE) (Chen et al., 2018). While such models are mathematically elegant, they can still lack predictive accuracy as they represent an approximation to the true first principles, since typically more phenomena take place than those represented by the differential equation layer in them. For these reasons, one can also consider the opposite approach, where the model is mainly data-driven but just slightly adjusted to the constraints. This can be done post-hoc, e.g., by reconciling predictions such that they meet constraints (Narasimhan and Jordache, 1999), but the best predictive performance can be obtained when the constraints are embedded into model estimation. For models that are defined according to an explicit optimization criterion, one can train models by numerically optimizing in the presence of first principle constraints. An example of such a model could be a sparse linear regression model that meets mass balance. In the case where all flows are defined, that becomes a mixed-integer linear optimization problem that can be solved numerically. On the other hand, more complex models such as (deep) neural networks are not defined according to single optimization problem. To build neural network models that inherently respect first principle constraints, one has to ascertain that the constraints are embedded into the training framework. In such case, common neural network optimization techniques such as ADAM can still be applied.

2.3. Scientific Machine Learning

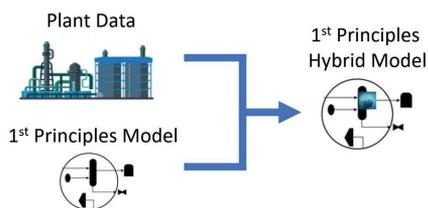

Figure 2: Combining 1st principles model knowledge and plant data yields 1st principles-driven hybrid model.

There has been a resurgence in the recent years in the field of incorporating domain knowledge into hybrid models through the use of known a priori model equations; however, the reader will find it interesting that this approach is not recent, as noted, with early contributions in 1990s and 2000s, e.g., (Psychogios and Ungar, 1992; Sundaram et al., 2001; Ghosh et al., 2003). Similar remarks apply to building more general hybrid models as they do to the approaches to account for constraints. Both first-principles-driven models (fig. 2), and predominantly data-driven models can be built (fig. 3), in pure form or as a nuanced mix of both approaches.

While first-principles-driven hybrid models such as neural differential equations do respect the constraints established through the differential equation, they obviously embed more first-principles information than just the constraints. However, as there are often multiple governing equations to the phenomena that describe a certain piece of equipment, data driven approaches' flexibility can be enticing.

Again there are several ways in which first-principles knowledge that extends beyond constraints can be embedded into models that are essentially data-driven. A first, and often successful, approach consists of domain-based feature engineering. Chemical engineering knowledge can both complement and simplify common statistical transformations, such as expanding the data with all cross products of variables and/or their squares. Governing physicochemical first-principles can inspire transformations specific to only a few variables that greatly enhance predictive power, taking advantage of the sparse nature of the dynamic system (Brunton et al., 2016). Examples of such variable transformations are common dimensionless numbers, such as the Reynolds or Damköhler numbers. In many cases, such transformations can already successfully describe the nonlinearity present within a certain operating window in (chemical) manufacturing processes. Therefore, to build predictive models in such a context, it can be sufficient to combine these transformations

with common regularized regression estimators, *e.g.*, the LASSO (Tibshirani, 1996) or Partial Least Squares (PLS) (Wold, 1975). Note that this approach can still be adopted when the data can be expected to contain outliers and uninformative variables, in which case one can substitute PLS for Sparse Partial Robust M-regression (SPRM) (Hoffmann et al., 2015), which is a sparse version of the older Partial Robust M-regression (PRM) (Serneels et al., 2005).

Of course, there are applications where the non-linearity provided by domain inspired feature engineering is insufficient to describe a real world process or piece of equipment, even when constrained to a narrow operating window. In such case, more involved nonlinear models should be estimated. Variable transformations such as the ones mentioned above can also be applied in combination with decision trees, where the interpretability of a certain split in the tree being based on a given threshold in a dimensionless number, can be valuable to a process engineer. Likewise, less involved transformations can be of great practical importance, such as being able to interpret the model's actions in terms of ratios of additives dosed to the bulk mass instead of the plain mass flows of those additives. Note that a lot of progress has recently been made to calculate decision trees optimally (Bertsimas and Dunn, 2019), which in many cases obliterates the necessity to combine decision trees into (random) forests. Such trees can be estimated from original and transformed variables and the required set of constraints can be passed on into the numerical mixed-integer optimization.

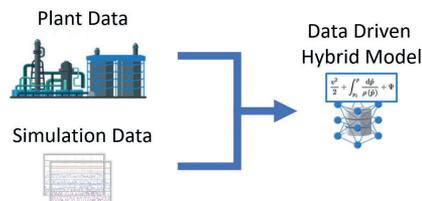

Figure 3: Combining simulation data and plant data yields a data-driven hybrid model.

It is well known that deep neural networks are efficient universal approximators for nonlinear functions (Kreinovich, 1991) and therefore, do not per se require nonlinear variable transformations to attain a satisfactory model fit. However, neural networks can also benefit from having input based on domain specific transformations, which can lead to simpler models (fewer variables, fewer hidden layers), which then on its turn will facilitate interpretability when model agnostic tools are applied to them for such purpose, such as LIME (Ribeiro et al., 2016). Moreover, the resulting simpler neural network models require lower amounts of training data and are less prone to over-fitting. Beyond variable transformations, it is possible to design custom layers that embed first principles knowledge. The effect of these first principles can then be analyzed by inspection of the corresponding layer estimates. Note that in a similar way, one can design the final layer and/or activation function in such a way that constraints are respected (Beucler et al., 2021).

3. Conclusion & Future Perspectives

This article has highlighted that different end-user requirements result in the need for different hybrid modeling approaches. Mechanistic insight can be obtained through symbolic models, where knowledge is captured through the relationships of state variables and their transformations. They facilitate interpretable models. On the other hand, enhanced predictive capabilities with the injection of domain knowledge, are the forte of constraints-based models. These account for mechanistic knowledge about the system by virtue of formulating the problem as a parameter estimation exercise, within the permissible regions in the parameter space. Consequently, we obtain models that are capable of predicting the system with considerable accuracy, but at the cost of providing mechanistic insight. Additionally, there has been a resurgence in the domain of scientific machine learning, where the strengths of function approximating neural networks are combined with first-principles knowledge, to yield mechanistically feasible neural networks. Such models are able to extrapolate outside the domain of training data.

As the future is aimed towards the goal of Industry 4.0 (Sansana et al., 2021), hybrid models will play a major role. The increasing availability of data opens a multitude of possibilities. It is imperative that we take advantage of the same – by augmenting the rapid progress of AI in data driven modeling with process/system knowledge. Further research is needed to develop systematic frameworks that quickly and easily help develop hybrid AI models that incorporate first-principles knowledge of physicochemical mechanisms, cause-and-effect relationships, constraints, performance targets, and more.

Abstract

This paper discusses the estimation of adsorption energies for reaction intermediates for a given metallic surface and molecule. Regression models are learned from DFT data available in the literature in a two step approach. First, metallic surfaces are characterized by a principal component analysis (PCA) followed by a suitable orthonormal rotation to find a set of species that can be used as descriptors for the metallic surface. Then, different machine learning techniques are considered for the regression using the previous descriptors for the metallic surface and molecular descriptors such as the number and type of bonds for the adsorbate. With the available data, CH_3 , CO_2 and CH_2 were found to explain 93% of the total variance, thus were used as surface descriptors. Three of the tested models were found to adjust similarly well to validation data.

Keywords: Adsorption energies, Machine Learning, Electrocatalysis

1. Introduction

Electrocatalytic reactions have recently gained a lot of attention as they can be powered by electric energy from renewable non-programmable sources to achieve zero or even negative carbon processes. In particular, reduction of CO_2 on metallic surfaces is a promising process to transform industrial CO_2 emissions into valuable fuels and products. However, electrocatalytic processes are characterized by their very low selectivity; for example in the case of CO_2 many C1 and C2 products including acids (e.g formic acid, acetic acid), alcohols (e.g methanol and ethanol), and light hydrocarbons (for example ethylene) have been experimentally reported.

It is clear that the properties of the metallic surface play a role on the selectivity. As examples, copper and copper alloys or copper oxides seem to favor the production of ethylene and methanol from CO_2 (Dinh et al. (2018), Wang et al. (2018)), and platinum the production of CH_4 (Umeda et al. (2020)). Yet, the reaction mechanisms are not completely understood, and the lack of understanding hinders reactor and process design. Reaction network generators can be used to build the possible reaction pathways; still, thermodynamical properties of the proposed adsorbates need to be known to infer which of the pathways are feasible. One option to compute the required thermodynamical properties is the use of density functional theory (DFT). However, this approach requires very specialized knowledge, is time consuming and resource intensive in terms of computational power. Thus, it may not be suitable if a large amount of DFT-derived data is needed for calculations in a particular application.

In this work, we have taken another approach to estimate the required thermodynamic properties (adsorption energies) which is based on machine learning using data from DFT that is already available in the literature. Figure 1 schematizes the procedure. The rationale is that adsorption

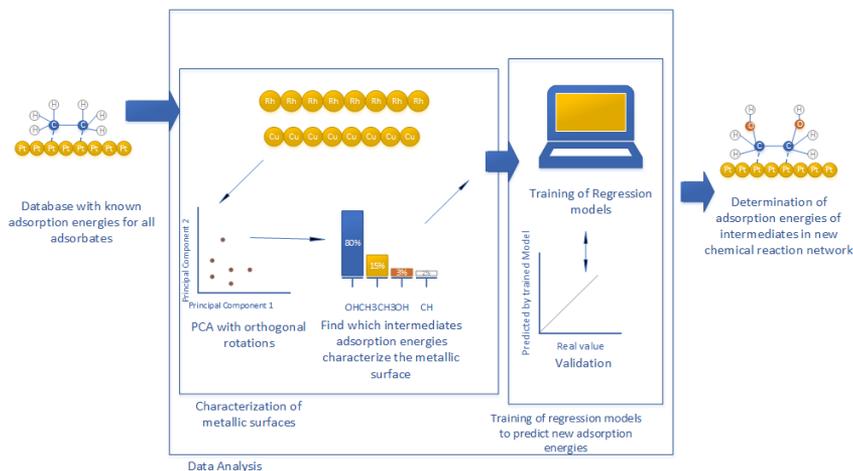

Figure 1: Schematic of the machine learning approach to find a model for estimating adsorption energies of adsorbates in metallic surfaces.

energies depend on properties of the adsorbates (molecules) and properties of the metallic surfaces. While it is fairly clear which properties should be considered as descriptors of the molecules (e.g. atoms, type and amount of bonds, etc.), it is not that clear which ones should be considered for the metallic surfaces. Therefore, the main hypothesis is that given a dataset containing the adsorption energies for several adsorbates in different metallic surfaces, it is possible to find a set of descriptors for the surfaces that are based on a subset of these energies. This idea is not new, Chowdhury et al. (2018) has proposed a similar approach using a dataset of 29 molecules and 8 metallic surfaces. In here, we have largely expanded the dataset including new surfaces and adsorbates, as a result, a different set of descriptors is obtained. On the basis of these new descriptors for the surfaces, and those of the molecules, a regression model was trained to predict adsorption energies of other molecules on the previous surfaces. The longer term objective is to use this regression model together with network generators to predict preferred reaction pathways for electrocatalytic reactions of different species on different surfaces.

2. Selection of descriptors of the metallic surface

As mentioned in the introduction, in order to find a correlation able to estimate the adsorption energies of any pair of adsorbate/metallic surface, a way of characterizing the surfaces needs to be found. A traditional DFT approach to describe a surface would need for example information on the atoms that compose the surface and their geometrical arrangement. These characteristics will affect the adsorption energies of all the adsorbates, although the effect on the possible adsorbates is different for each one, and depends mainly on the adsorbate itself. The idea then is to find those adsorbates whose energy of adsorption changes the most when the metallic surface changes. If this set of adsorbates is small, then using them as descriptors of the surface is a very practical and efficient way to characterize the surface, as instead of performing DFT calculations for all the components, we need DFT calculations for just a few.

2.1. PCA analysis of the energy of adsorption data

Principal component analysis (PCA) is a technique that given a data matrix $M_{N \times P}$, finds a new space of reduced dimensions which conserves a maximum amount of the variance of the original

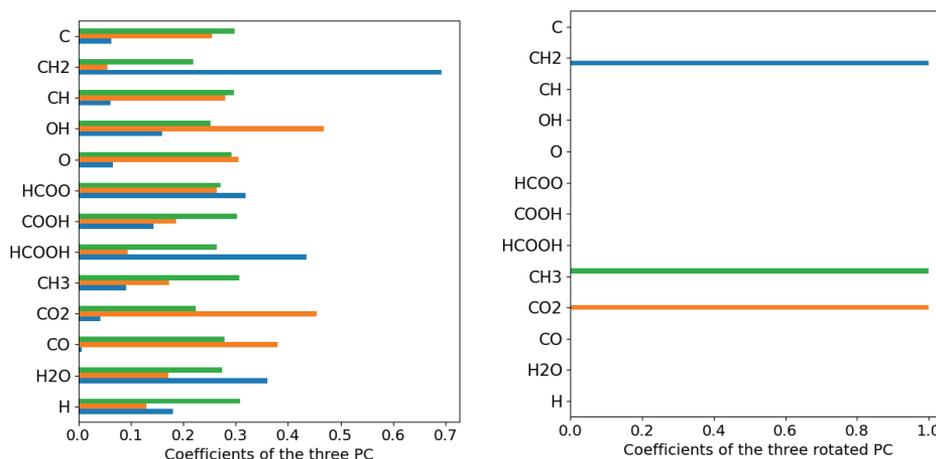

Figure 2: PCA analysis: left plain PCA; right PCA+varimax rotation. In both, green, blue and red are first, second and third component respectively.

data. This new space can be built by finding the eigenvectors of the covariance matrix (Σ_M) of the data in M . To establish which are the principal components of the data in M we look for the eigenvectors of Σ_M associated with the largest eigenvalues. In practice, those that added together make up for a certain threshold of the variance (usually 90-95%).

In our case, M is the matrix of adsorption energies (taken from DFT databases); each M_{np} entry is the adsorption energy for the p -th adsorbate on the n -th metallic surface. Figure 2 shows the results of applying PCA to a dataset built using adsorption energies reported in Plauack et al. (2016); Herron et al. (2012, 2013, 2014); Xu et al. (2018a); Bai et al. (2019); Ford et al. (2010); Mavrikakis et al. (2002); Ojeda et al. (2010); Scaranto and Mavrikakis (2016a); Singh et al. (2014); Scaranto and Mavrikakis (2016b); Ferrin et al. (2012); Greeley and Mavrikakis (2002); Ford et al. (2005); Chen et al. (2019); Xu et al. (2018b); Kregelberg et al. (2004); Hahn and Mavrikakis (2014); Grabow and Mavrikakis (2011); Gokhale et al. (2008); Li et al. (2016); Herron et al. (2014); Saliccioli et al. (2010, 2012); Lu et al. (2015, 2012); Schmidt and Thygesen (2018); Wellendorff et al. (2015). In here, it is important to mention that to apply PCA-techniques, M has to be complete, which means that only those adsorbates for which we found DFT data for *all* the surfaces of interest (Cu,Pt,Pd,Rh,Re,Ru,Ag,Au,Fe,Ir,Os,Co,Ni) were included.

Figure 2-left shows the three principal components as green (first component), orange (second component) and blue (third component) bars. Together these three are able to explain 93% of the variance of the original dataset (results obtained using the `scikit-learn` package in Python Pedregosa et al. (2011)). The adsorption energy for each adsorbate can then be expressed in terms of these three principal components; the absolute value of the weights that need to be applied are represented in the figure by the length of each bar.

2.2. PCA with varimax rotation

Unfortunately, the results in Fig.2-left are of little use as they are, as the principal components lack of physical interpretation. It would be desirable to have results where each component is clearly dominated by one or a few adsorbates. This is accomplished by finding a new set of orthogonal axis that represent a basis of the same space as the principal components, but in which the axis align better with some of the adsorbates. In this way, the coefficients of many of the adsorbates

Table 1: Summary of the performance of the regression

Method	KRR-poly	KRR-rbf	KSVR-poly	KSVR-rbf	CART	RF
RMSE	0.22	0.25	0.23	0.27	0.2	0.15
RMSE wo/H	0.12	0.13	0.12	0.13	0.18	0.11
sign mismatch	CO_2	-	CO_2	-	O	-

become zero, and those that are non-zero can be interpreted as the descriptors.

What was discussed was solved by Kaiser (1958) who proposed to find the new axes by solving the optimization problem in Eq. 1.

$$\max_R \sum_{j=1}^{j=K} \left(\frac{1}{N} \sum_{i=1}^{i=N} ((A'R_{ij}^2)^2) - \alpha \frac{1}{N^2} (A'\bar{R}_{ij}^2)^2 \right) \quad (1)$$

$$s.t : R^T R = I$$

In here, A is the original $P \times K$ eigenvector matrix ($K = 3$ as there are three principal components in our case study) and R the $K \times K$ rotation matrix. α is a parameter of the problem, if $\alpha = 1$ Eq. 1 is the Varimax rotation.

Fig.2-right shows the results when applying the varimax rotation. These results indicates that CH_3 , CO_2 and CH_2 , as first (79% of the variance), second (9% of the variance) and third component (5% of the variance) respectively, can be used as descriptors of the metallic surface (results also obtained with `scikit-learn`). Notice that this is different from the results in Chowdhury et al. (2018) who obtained OH and $CHCHCO$ as descriptors. The difference lies in the expansion of the dataset to include data from different sources, as the exactly same results as in the Chowdhury et al. (2018) are obtained when considering their database.

3. Learning a model to predict adsorption energies

After a suitable set of descriptors for the metallic surfaces is found, a regression problem that uses them and those of the adsorbates, can be formulated to learn a model for the energies of adsorption from data. As descriptors of the molecules we have considered the number and type of bonds in the adsorbate; we have also added facet and coverage as additional descriptors for the metallic surface when available. Notice now that completeness of the data is not required for this step, thus all available data can be used.

The following techniques were considered for learning the model: Kernel Ridge Regression (KRR, with polynomial and radial basis functions as kernels), Kernel Support Vector Regression (KSVR, with polynomial and radial basis functions as kernels), Classification and regression trees (CART) and Random Forest (RF). For the sake of space, we will not describe these methods, they are well explained in several references including `scikit-learn` documentation Pedregosa et al. (2011). In all cases, an 8-fold cross validation scheme was performed to define the set of possible values for the hyperparameters for each technique. Learning/ validation division of the dataset was 85/15% respectively. A summary of the results is in Table 1. As seen KRR-rbf KSVR-rbf and RF provided similar results in terms of RMSE over the validation set. Most importantly, they did not predict positive energies as negative nor the other way around. This was a problem that we observed when using polynomial kernels (wrong sign prediction for CO_2) and CART (wrong sign prediction for O). From a physical viewpoint, this is troublesome because it would imply that certain adsorbates cannot be adsorbed when in reality they can. In here, it has to be commented that we identified some outliers for the energy of adsorption of H (2 out of 90 datapoints for H) from the reported DFT data; the table includes the RMSE results with and without considering these outliers.

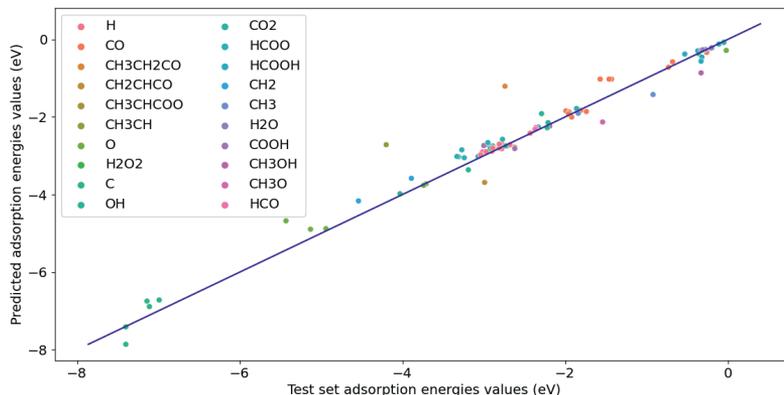

Figure 3: Results of the regression using Random Forest. Adjustment for $y = x$: $R^2 = 0.96$

Finally, Fig.3 presents the predicted vs DFT adsorption energies for data in the validation set. This type of plot showing a good regression is typical for all the techniques we have tested. This stresses the need of verifying that the chosen model correctly assigns the sign of the energy of adsorption for all data in the validation set, a point that may be overseen by just looking for the best RMSE and predicted vs real data fitting.

4. Conclusion

A large data set of DFT-based adsorption energies for different metallic surfaces and adsorbates was used to train a regression model. In a first step, PCA followed by Varimax rotation was found to be able to characterize the metallic surfaces using CH_3 , CO_2 and CH_2 as principal components, with a loss of information less than 10% in terms of variance of the data. Six regression models based on either Kernel Ridge, Support Vector, CART or Random Forest were considered. All models were found to provide good estimations in terms of RMSE, but some had trouble in assigning a correct sign to those adsorbates whose energy of adsorption was close to zero. Those that can correctly estimate the sign could be used together with reaction network generators to predict thermodynamically feasible pathways.

Abstract

In this paper, we proposed a new pathway enrichment analysis for reaction schemes based on Bayesian Network (BN). Several reaction schemes are proposed in the waster waters treatment literature, however, these data diverge greatly and, to date, are unexploited. As an innovative alternative, probabilistic graphical models could allow establishing parentage between the most relevant molecules and Transformation Products (TPs). Based on the analysis of an extensive bibliography gathering more than 45 articles for more than 140 molecules, this study proposed an innovative methodology based on knowledge graphs, pathway data enrichment, and Bayesian Networks (BN) analyses. The proposed methodology has been applied to elucidate the degradation of the sulfamethoxazole. Probabilistic approaches and graphical models bring a new light on the identification of the TP parentage.

Keywords: Bayesian Networks, Graphical Models, Pathway Enrichment Analysis, Knowledge Engineering,

1. Introduction

Water is a scarce resource, the ultimate receptacle of anthropogenic pollution. Its preservation and treatment are the subject of new paradigms in terms of analytical development, processes and even data management. In the last decades, the scientific community has pointed out the presence of new synthetic molecules (manufactured products) in all aquatic compartments (domestic, surface and groundwater). Several studies have proposed various breakdown pathways of a targeted micropollutant, which could be different depending on study objectives, analytical methodology, etc. Often these studies are oriented on the formation of Transformation Products (TPs) in controlled conditions and with a singular process. Most of TPs can retain or sometimes amplify toxic effects on aquatic life. The formation and the evolution of TPs remains a subject in full expansion in wastewater treatment. Their prediction is difficult as there is no consensus on their pathways even if a same couple "parent compound – process" is applied. The available data on the occurrence of TPs remain fragmentary, but sufficient to prevent any attempt at manual synthesis. Indeed, the reaction schemes proposed in the literature diverge greatly, as much in their structure as in the number and nature of the molecules (elements) represented. It is assumed that these differences are the result of a combination of causes including the type of process(es) used, their operating conditions, the analytical power (resolution) available and finally the expertise intrinsic to the research consortium.

However, even considering recent studies Chen et al. (2019); Yazdanbakhsh et al. (2020) con-

ducted on the same contaminant (sulfamethoxazole, an antibiotic) and the same type of process, here oxidation, it appears that only one of the produced molecules is common between the two examples considered. To date and to the authors' knowledge, the pool of data generated by these mechanistic (physicochemical) studies is unexploited from statistical methodology point of view. Also, no attempt has been made to consolidate these data. Therefore, data science appears to be an innovative alternative to establish the most probable filiation between molecules and to identify the preferential reaction pathways. To address these issues, the ANR TRANSPRO project (2019-2022), led by a consortium of public partners (EPOC, LGC and INRAE), aims to improve knowledge on the nature, origin and dynamics of TPs. In view of the set of molecules breakdown pathways proposed in the literature, graph data mining techniques would provide new insights into the most common degradation paths of a targeted micropollutant. It is in this perspective that probabilistic graphical models have been chosen to conduct this study. From the table of all the molecules observed on the analyzed literature. The analysis of data would allow disentangling the relevant relations between the molecules, the dependencies or independences between several groups of molecules. The use of Bayesian networks will allow the extraction of a compact representation of pathways of degradation without loss of information. In addition to the reaction schemes identification, a methodology of data enrichment of the pathways' degradation database and specific data analysis have been proposed. From a preferential degradation scheme, it is possible to prioritize the most recurring Products of Transformation (TP) and thus to privilege them for all environmental and toxicological studies. The methodology was applied to a largely described micropollutant, sulfamethoxazole (SMX).

2. Methodology

2.1. Literature analysis of degradation Pathways of micropollutants

This study is articulated around the three complementary parts (Figure 1): **(A)** deals with pathway enrichment analysis step and data mining pre-processing from dedicated search engines such as ScienceDirect. Part **(B)** consists of the identification of molecules breakdown pathways of a target pollutant (here, SMX) and matrix representation of degradation levels, and finally part **(C)** represents the use of information from different reaction schemes for Bayesian Networks (BN) analysis and probabilistic graph based analysis.

Part (A) : Data pathway enrichment analysis. In this step, 45 scientific papers have been selected and analyzed for the SMX degradation pathways identification. To date, no automatic method to extract pathway information is proposed in the literature. For this reason, part **(B)** is designed to feed a database, which is created for this purpose. **The part (B)** is dedicated to the extraction of degradation pathways, requiring a manual transcription of all the molecules as well as their breakdown level, or position, in the degradation scheme. To date, this part of the data enrichment is done manually. Two different types of processes have been distinguished in these papers, 30 scientific papers based on Advanced Oxidation Processes (AOP) and 15 present the degradation of SMX through the implementation of various BIOlogical processes (BIO). From these 45 papers, 141 molecules (SMX + 140 TPs) and 177 reaction pathways were considered. Then, an adjacency matrix weighted by the number of arcs observed between the different by-products is deduced.

Figure 2 shows an example of the transcription procedure of two degradation patterns into an easily exploitable matrix in data processing step. Assuming that there are two papers in which two SMX degradation patterns leading to the formation of the following products: A, B, C, D and E. In the matrix, we consider the molecules in the column as the incoming molecules from the degradation of the starting molecules that are in the row. The values in the matrix correspond to the number of times the degradation of the parent molecule into the child molecule is observed in all the articles for all the proposed reaction pathways. This example allows to better understand, from two articles, the challenge and the complexity of the data enrichment part, especially when

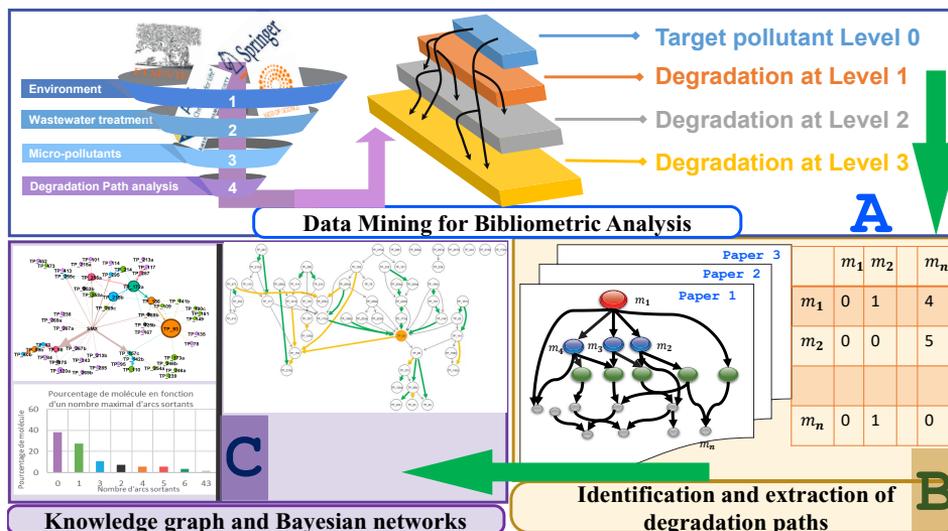

Figure 1: General scheme of the methodology followed for the analysis of the degradation pathways of molecules observed in the literature in water treatment. Two complementary blocks (A-B) for the enrichment of the database and a block (C) for the analysis by probabilistic graphical models and knowledge graph based analysis.

Table 1: Data matrix used for Bayesian networks analysis. For each paper, the process (AOP or BIO) of degradation of the SMX molecule is identified. The transformation products (TP) are identified at their respective level of degradation.

Paper	Path	SMX	TP(1)	TP(2)	...	TP($n-1$)	TP(n)
Paper 1	path1	AOP	level 5	level 2	...	level 5	level 7
	path2	AOP	level 2	level 1	...	level 2	level 3
	path3	BIO	level 1	level 4	...	level 1	level 8
Paper 2	path4	AOP	level 6	level 3	...	level 2	level 4
	path5	BIO			...		
...
Paper p	path m	AOP	level 6	level 3	...	level 7	level 8

the number of papers to analyze becomes high.

Part (C) consists in representing the graphs of interactions between the target molecule (SMX) and a set of its transformation products. Two approaches have been used. First, by integrating information on the number of direct links between molecules (arc weight) and the number of arcs coming out from the different molecules (node weight). In this case, the data is extracted from and the model is assumed to be faithful to the physical reality. Then, from the table 1, Bayesian networks modeling based approach is applied to find similarities with the reference model. In the latter case, very little information is provided: a table with 177 rows (pathways) and 141 variables (molecules). The molecules obtained from the degradation of SMX were noted by TP followed by their m/z ratio: the mass of the molecules relative to their charge number. For example, TP_{93} corresponds to the transformation product with an m/z ratio of 93. In some cases, two molecules with a different structure are detected with the same molar mass. It was therefore chosen to add a letter to their molar masses to differentiate them, as in the case of 283a and 283b. For each molecule, a binary coding has been applied: observed molecule (Yes) for a given pathway and unobserved molecule (Not Observed).

2.2. Bayesian Networks

The main topic of this work can be summarized in one question: *can we conceive of graph mining methods that can extract the most probable pathways from several reaction schemes?* Probabilistic graphical models, and more precisely Bayesian networks, seem to us appropriate to shed new light on this question. Moreover, a graphical model has the advantage of being easy to interpret, and according to the modeled properties (independence for example) can be more or less powerful to detect relationships of parentage between molecules. From the table obtained in part B (see table 1), it is possible to use a Bayesian Network on nominal variables. In the absence of an a priori structure, the use of this type of model requires learning of the graphical structure (nodes and arcs) as well as the estimation of the conditional probability distribution associated to each molecule (random variables). In our case, an a priori structure can be attributed to the graph obtained from the adjacency matrix. We will first test a model with an a priori structure, then a series of simulations is performed for graph learning. The probabilistic relationships in a Bayesian network are represented by a qualitative description- a graph (\mathcal{G}), and a quantitative description- an underlying joint probability distribution. Formally, a Bayesian network $B(\mathcal{G}, \theta)$ is defined by (i) a directed acyclic (without circuit) graph $\mathcal{G}(X, E)$ whose nodes are associated with a tuple of categorical random variables $X = \{X_1, X_2, \dots, X_n\}$ and E represents a set of arcs, and (ii) a set of probabilities $\theta = \{\mathbb{P}(X_i | Pa(X_i))\}$ of each node conditional on the state of its ancestors (parents) $Pa(X_i)$ in \mathcal{G} . In the case where all variables are observed, the simplest and most used method for estimating probabilities is the Maximum Likelihood (ML) method which gives $\widehat{\mathbb{P}}(X_i = x_k | Pa(X_i) = x_j) = \widehat{\theta}_{ijk}^{ML} = \frac{N_{ijk}}{\sum_k N_{ijk}}$, where N_{ijk} is the number of instances in the data table where X_i takes its k^{th} value x_{ik} and the variables in $Pa(X_i)$ takes their j^{th} configuration for all k . Regarding the learning of the graph, there are two types of techniques to build the structure of the Bayesian network: Score Based Algorithm (SBA) and Constraint Based Algorithm (CBA). For a review of the graph learning methods, we recommend the very complete books by Koller and Friedman (2009) and Murphy (2012). The use of CBA based algorithms on SMX physico-chemical reaction data often leads to a construction of graph that are not very faithful to the structures observed in the literature. For this reason, this study focuses on the score methods and more particularly on the Hill-climbing (HC) algorithms (Chickering, 2002). Score-based approaches range into the search space by examining only possible local changes in the neighborhood of the current solution and applies the modification (add arrows, delete,...) that maximizes the score function. Very briefly, these algorithms structure the network from an empty, randomly generated or predefined graph (a priori structure). Then, a score is computed on the

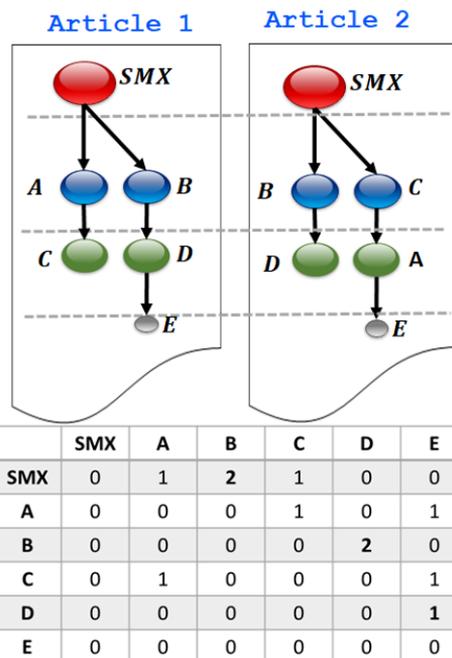

Figure 2: Simplified example of two degradation paths with the associated adjacency matrix. A value greater than or equal to 1 shows the number of times a direct link between two molecules was observed in all papers. The value 0 codes the absence of link detected between the molecules.

basis of this initialization and the modifications in the graph (addition, inversion or deletion of an arrow) are performed. If the modification does not increase the score, the algorithm returns to the previous state and another modification is performed; if on the contrary the score increases, the new state is kept and a new modification is performed. The algorithm stops when no modification increases the score. The score-based methods are easily trapped in the numerous local minima and the final graph obtained depends strongly on the initial conditions. Thus, an empty graph represents the most frequent choice in the absence of a priori knowledge. Regarding the choice of the score, the Bayesian Dirichlet Equivalent (BDe) score proposed in (Heckerman et al., 1995) provides a graphical structure most similar to the graph obtained via the literature database we implemented (*cf.* data from the table 1).

Let the values $\{x_{i1}, \dots, x_{ir_i}\}$, $r_i \geq 1$, $i = 1, \dots, n$ of all the set that each X_i can take, r_i is the number of states of the finite random variable, D is the database, and G the structure of the network on X (set of random variables). The number of possible configurations for the parents of X_i is determined by $q_i = \prod_{X \in Pa(X_i)} r_i$. From these elements, BDe score and is defined by:

$$\mathbb{P}(G, D) = \mathbb{P}(G) \mathbb{P}(D | G) \iff \mathbb{P}(D | G) = \prod_{i=1}^n \prod_{j=1}^{q_i} \frac{\Gamma(\alpha_{ij})}{\Gamma(\alpha_{ij} + N_{ij})} \prod_{k=1}^{r_i} \frac{\Gamma(\alpha_{ijk} + N_{ijk})}{\Gamma(\alpha_{ijk})} \quad (1)$$

where $\mathbb{P}(G)$ represents the a priori probability assigned to the structure G . The parameters α_{ijk} defined by $\alpha_{ijk} = \eta \times \widehat{\mathbb{P}}(X_i = x_k, Pa(X_i) = x_j | G_c)$ with G_c the complete connected graph and the equivalent sample size η expresses the strength of our belief in the prior distribution.

3. Results and discussion

Developing Bayesian networks was also one of the main objectives of our study. These networks allow the observation of dependency or independence relationships between the different variables (here, molecules). Figure 3-(A) shows the representation of the Bayesian network (HC algorithm with a BIC score) obtained, as well as the common parentage to the knowledge graph from the literature review. Three different colors are proposed, green if the observed parentage is identical and orange if one of the two molecules (parent or child) is reversed. The black arcs illustrate false detections or the absence of parentage between the molecules. First, we notice that there are 40% of links (green arcs) that coincide with the knowledge graph from the literature (green color code). Furthermore, note that nodes with no direct relatives are considered the first level of degradation of the SMX, so arcs (not shown in the graphs) from the SMX to these molecules are considered "valid". The molecule *TP_93* was also detected as a very frequent transformation product, i.e. several incoming arcs from different nodes. In view of the results obtained, we can confirm our hypothesis on the usefulness of Bayesian networks for the identification of preferential reaction patterns. For all the scores tested, the BDe gives a good compromise between graph structure and interpretation.

Figure 3-(B) presents a Bayesian network built with an a priori structure initialization: the graph is extracted from the literature review. The advantage of this approach compared to the knowledge network is to be able to (i) simulate the preferential paths, (ii) identify and control the monitoring molecules, and (iii) analyze the behavior of some degradation pathways. It is also possible to perform any kind of inference based on the conditional probabilities obtained from this graph and the collected data. For example, the joint probability of the most recurrent pattern ($\mathbb{P}(SMX, TP_{98}, TP_{83}, TP_{98b}, TP_{60b})$) can be obtained through a table of calculation of all the modalities taken by the TPs. The probability of simultaneously observing TPs of preferential path and SMX is about 7.5%. It is also easy to retrieve all the tables of conditional or marginal probabilities associated with the different transformation products. As a simple example, $\mathbb{P}(TP_{98} | SMX) = 19.15\%$, $\mathbb{P}(TP_{98}, TP_{83} | SMX) \approx 8\%$, or as presented in (Figure 3):

$$\mathbb{P}(TP_{93} = \text{Observed}, TP_{172a} = \text{Observed} | \{SMX, TP_{255a} = \text{Observed}\}) = 31.9\%.$$

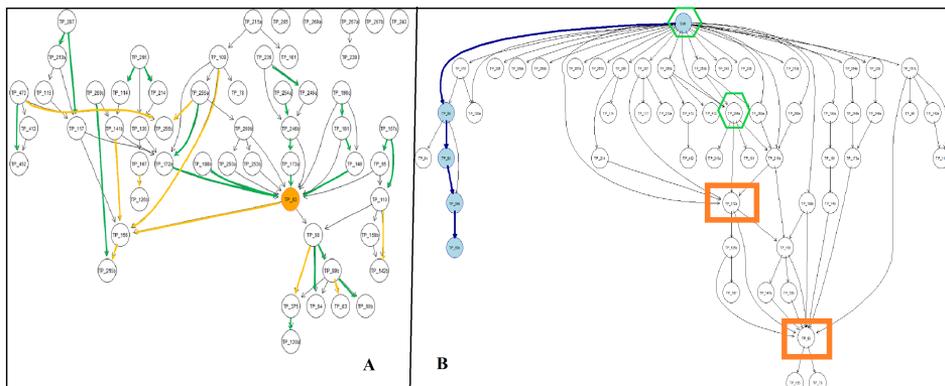

Figure 3: Bayesian networks obtained for Biological processes. Left (A), without “a priori” network, the structure was learned from data (BIO processes) and compared to the knowledge graph from the literature review. Right (B) Bayesian network with structure initialization and highlighted (blue path) the most recurrent degradation path. A query such as searching probability of orange molecules knowing green ones : $\mathbb{P}(\text{orange rectangles} \mid \text{green hexagon}) = 31.9\%$ is possible from the BN inference (Right B)

Specifying the arguments in the inference procedures requires some care, but the result is an extremely flexible framework to compute the probability of arbitrary combinations of events. As an example of a more complex query, we can compute:

$$\mathbb{P}(TP_{93} = \text{Observed}, TP_{172a} = \text{Observed} \mid \{SMX, TP_{255a} = \text{Observed}\} \cup \{TP_{89b} = \text{Observed}\}) = 22.3\%$$

4. Conclusions and future work

To day, no methodology for consolidating and processing data from molecule degradation pathways are considered in the literature. The proposed methodology explores a new way and attempts to respond to this lack, to create consensus on the basis of studies where data are widely dispersed, from heterogeneous or even contradictory sources. Regarding the Bayesian networks, the graphical models shed new light on the data enrichment pathways of molecule degradation between the transformation products when passing through wastewater treatment plants. To date, the part of the database enrichment is done manually. This database is often fed by updating the articles and identifying new molecules and reaction pathways. The most ambitious perspective is the automation of the database enrichment phase. In future work we intend to develop a framework for the data retrieve automation of degradation pathways. In these conditions, an identification of molecules and their properties would be possible by extending our field of investigation in graph mining.

Abstract

Viscosity represents a key indicator of product quality but has traditionally been difficult to measure in-process in real-time. This is particularly true if the process involves complex mixing phenomena operated at dynamic conditions. To address this challenge, a promising solution to monitoring product viscosity is to design soft-sensors which correlate viscosity with easily measured process variables. In this study, we developed an innovative machine learning based soft-sensor construction framework by integrating different types of advanced artificial neural networks. The framework first employs a deep learning autoencoder to generate information-rich statistic latent variables by compressing high-dimensional industrial data, and then adopts a heteroscedastic noise neural network to simultaneously predict product viscosity and process variance based on the extracted latent features. To evaluate its accuracy and robustness, the data-driven soft-sensor was used to predict product viscosity for a number of industrial batches operated over different seasons. It is found that the soft-sensor has both high accuracy (prediction error <12%) and high robustness in most of the cases, indicating its great potential for industrial batch process monitoring and quality control.

Keywords: Machine learning, data analytics, dimensionality reduction, quality control, uncertainty estimation.

1. Introduction

Quality control is paramount to many industrial processes to avoid the viscosity of the final product falling outside the predetermined acceptable boundaries, otherwise, the entire batch must be discarded, effectively wasting the entire process time. Not only does this lead to excessive losses due to material wastage, but it also incurs costs involved with safe disposal of the defective products. Ideally, advanced fault detection technique should be available to monitor the progress of the batch over the process time however, there is currently no efficient approach to quickly measure the viscosity of complex liquid formulations during their industrial scale production.

Real time prediction of viscosity has historically been a challenge within the consumer goods industry. The difficulties stem from the current lack of understanding of rheology within the context of highly viscous fluids, making it impractical to derive any accurate

physical models for viscosity prediction. It is common for industrial processes to sample measurements during a process to directly measure the viscosity. However, this is time consuming and if poor batch quality is observed, there is little opportunity to adjust the process to prevent deviations of viscosity outside acceptable boundaries. A solution to this can be applied with the usage of data-driven models which find the underlying relations that lie within the data recorded from a series of sensors on a plant and the measured viscosity. These data-driven models are then used as a soft-sensor for new process prediction. In addition, to mitigate false confidence, these data-driven soft-sensors should be able to make accurate estimations and represent the aleatoric uncertainty present within the data, analogous to the uncertainty specified within the instrument used to record the viscosity values. A further challenge associated with data-driven models is the capability to generalise to different processes. To resolve this, an excess of data is required by the model from different processes. However, this data is usually not readily available and is time consuming to produce and sort.

2. Problem statement

This study focuses on a batch process for consumer goods product production. The aim is to develop a robust soft-sensor for final viscosity prediction using real-time process sensors' recordings. Three datasets are available and are referred to as Alpha, Beta, and Gamma dataset, respectively, where the first two were obtained from the same process line and the latter being obtained from a similar, but different process. These datasets contain 30, 16 and 11 batches, respectively. Each batch contains 28 sensors recording temperature, pressure, and flowrate in different locations in the process. The actual batch process generates around 7000 times series data points and real-time data is recorded once per second or once per two seconds. In our previous work (Hicks et al., 2021), partial least squares has been used to identify commonly important sensors and critical time regions within the datasets, leaving us with only information relevant to predicting viscosity. This process reduced all 3 datasets to a 3-rank tensor of n batches, 300 timesteps and 8 sensors (n being dependent on the dataset). Before being used for training or validation purposes, the 3-rank tensors are timewise unfolded to generate a 2-rank matrix for soft-sensor construction.

Dimensionality reduction is necessary in this case to mitigate problems associated with high dimensional data analysis (Min, 2005) and to improve accuracy of the data-driven soft-sensor. Dimensionality reduction techniques remove multi-collinearity, improves the capability of the model to generalise to new datasets and will remove redundant features whilst retaining important characteristics of the data. Here we offer the usage of an autoencoder for dimensionality reduction as opposed to traditional linear regression techniques such as PCA and PLS. Although the usage of autoencoders is well demonstrated in a number of recent studies, the implementation in chemical process soft-sensing and monitoring is sparsely explored. Once key process information is extracted through dimensionality reduction, we adopted a heteroscedastic noise neural network (HNN) to make accurate viscosity predictions and meaningful uncertainty estimations. Successful predictions are those which replicate the industrial measurement errors (~10%). In addition, to effectively identify the best structure for the autoencoder and HNN, Bayesian optimisation is performed to optimise the hyperparameters of these models through construction of a Gaussian process surrogate model.

3. Methodology

First, we will introduce the structure of the autoencoder. For a given input (the process data) x , we obtain a projection z , and a reconstruction x' . The autoencoder is defined by two neural networks (Fournier & Aloise, 2019):

An encoder – This is defined by a function $f(x) = z$, where x and z are the respective inputs and outputs of the network.

A decoder – This is defined by a function $f(z) = x'$, where z and x' are the respective inputs and outputs of the network.

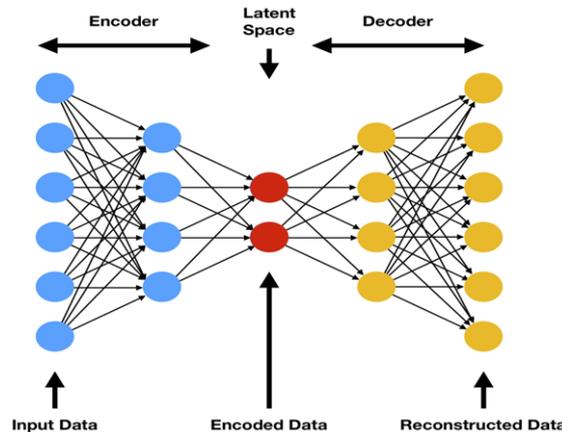

Figure 1: Diagram of a general autoencoder and its respective components.

The training objective is defined by a cost function in which the distance between the input and reconstruction error is to be minimised. Henceforth, the cost function assumed for the construction of the autoencoder will be the mean squared error; for an input of n datapoints, the error $E = \frac{1}{n} \sum (x - x')^2$ and the activation function applied to all hidden layers will be ELU (exponential linear unit) defined by $ELU(x) = \begin{cases} x & \text{if } x > 0 \\ \alpha(e^x - 1) & \text{if } x < 0 \end{cases}$ (Clevert et al., n.d.). A condition must be enforced on the model to copy the input data as its output (i.e. reconstruct the dataset), in the interest of extracting useful properties and characteristics from the process data. The autoencoder found after hyperparameter optimisation and used throughout this paper is defined in Table 1.

Table 1: Representation of the parameters used for the construction of the autoencoder.

Hidden layer	Number of nodes	Learning rate	Epochs	Activation function
1	1404	0.001477	782	ELU (Exponential linear unit), $\alpha = 0.15$
2	94			
3	50			
4	16			
5	50			
6	94			
7	1404			

Let us now describe the structure of the heteroscedastic neural network (HNN) generating the viscosity predictions. The objective of the HNN is to accurately predict batch quality and associate each prediction with an uncertainty metric representing the confidence of the model in its predictions. Intuitively, it is essential for the model's uncertainty estimates to provide very high coverage probabilities for its predictions. Hereafter, the following metrics will be defined to establish a consistent method of comparison between soft sensor models: the mean average percentage error, $MAPE = \frac{|y - \mu(x)|}{\mu(x)}$; the percentage uncertainty, $PPU = \frac{3\sigma(x)}{y}$ and the coverage probability, $CP = P(PPU > MAPE)$ where $\sigma(x)$ is the standard deviation of the HNN's prediction, $\mu(x)$ is the output viscosity from the HNN and y is the measured viscosity. Using these predefined metrics, we can determine the best HNN structure based on its performance using cross validation. An important note is that the PPU was not considered to be a priority in determining the best performing model, as long as its estimated standard deviation is around 10%. It was however essential that the model's prediction errors were covered by the uncertainty estimations, so the following condition was created to ensure a viable soft-sensor, $CP > 0.8$. It is required to provide a meaningful uncertainty estimate for each prediction so, a gaussian negative log likelihood term has been implemented for the loss function of the HNN, where the loss, $L = \frac{1}{2} \ln(\sigma^2(x)) + \frac{(y - \mu(x))^2}{2\sigma^2(x)}$ (Hirschfeld et al., 2020). $\sigma(x)$ represents the uncertainty estimation of the HNN (one standard deviation), y is the measured values of viscosity and $\mu(x)$ is the predicted viscosity values.

Both the autoencoder and the HNN were optimised using Bayesian optimisation techniques assuming a GP surrogate function (Song et al., 2019), this allowed for efficient searching and mapping of the hyperparameter space, especially useful for when large numbers of hyperparameters must be optimised; such is true for the autoencoder. Once viable optima were found, manual refining was employed to further explore the regions surrounding each optimum to ensure the quality and stability of the solution.

4. Results and Discussion

Two-fold cross-validation on the alpha dataset was used to optimise the hyperparameters of the HNN soft-sensor using the latent space extracted from the autoencoder, averaging the MAPE and PPU over the 435 possible combinations. The final HNN structure, activation function, epochs, MAPE, PPU and CP are shown in Table 2 below.

Table 2: Parameters of the optimised HNN soft-sensor.

Number of hidden layers	2
Number of nodes [layer1, layer2]	[31, 3]
Learning rate	0.0125
Activation function	Sigmoid
Number of epochs	160
MAPE [training, validation]	[7.8, 10.0]
PPU [training, validation]	[28.9, 28.3]
CP [training, validation]	[1, 1]

The finalised model, as shown in Table 2 was used to predict the batch quality of both the beta and the gamma datasets.

The viscosities have been normalized to a range of 0-1 and the results are as shown below in Figures 2a and 2b.

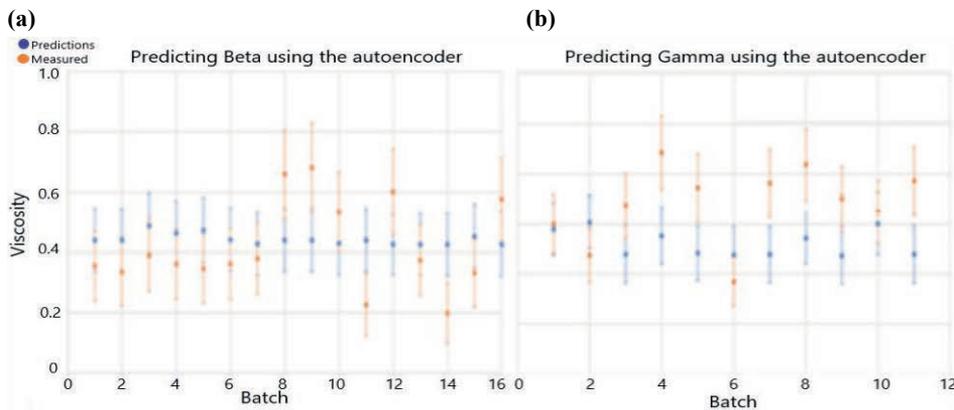

Figure 2: Plots of the soft sensor predictions against the measured values for batch data for datasets Beta (a) and Gamma (b). The error bars represent one standard deviation.

As shown in Figure 2 (a), the soft-sensor is capable of predicting Beta dataset’s batch quality to a reasonable degree of accuracy on data derived from the same process as the training set (Alpha), with an average MAPE of 11.3%. Similarly, the uncertainty estimations average to $\pm 26.0\%$ for three standard deviation (± 8.67 for one standard deviation). Notably, 87.5% of the datapoints for the measured and predicted viscosities have overlap between the error bars. This means that the soft-sensor’s predictions are lying within the acceptable range of values determined from experimental procedure; the expected standard deviation of measurements taken for the viscosity is $> \pm 10\%$ due to standard experimental errors (i.e. uncertainties of measurement equipment and human error in experiments). The significance of this is such that the soft-sensor seems to have successfully replicated the error within the process data in its predictions. The MAPE, PPU and CP for the HNN’s validation results of the beta dataset can be found in Table 3.

A similar conclusion can be drawn of the models capacity to predict the batch quality of the Gamma dataset as to that of the Beta dataset. The results indicate slightly worse performance with an average MAPE of 15.5% this, however is expected due to the data being derived from a different process. The model also seems to provide less overlap between the error bars with only 54.5% of them overlapping for one standard deviation. The MAPE, PPU and CP for the HNN’s validation results of the gamma dataset can be found in Table 3.

Table 3: Validation result of the HNN soft-sensor.

Dataset	MAPE	PPU	CP
Alpha	10.0	28.3	1
Beta	11.3	26.0	1
Gamma	15.5	26.8	1

Overall, it was anticipated that the HNN would provide better performance on the Alpha and Beta datasets than on the Gamma data due to them both being obtained from the same process line, meaning their characteristics should be similar. Eventhough the datasets were obtained at different times of the year, the performance on beta would indicate that this had little effect on the models capacity to accurately predict batch quality meaning that the inherent features of the process data was similar. On Figure 2(a), it can be seen that there is little variety in the estimation of viscosity made by the HNN. This could be attributed to the nature of the autoencoder as viscosity is not taken into account when extracting the feature space of dataset provided. This leaves the possibility that the important physical relations between the sensor data and the viscosity, that are necessary for making accurate predictions are partially lost when reducing the dimensionality. A second explanation could be that there is no identifiable difference between the features of each batch that would give rise to a reason for the model to predict largely different viscosities. This pattern also arises within the Gamma dataset, shown on Figure 2(b), however the extent of which is less severe.

5. Conclusion

In conclusion, autoencoders are a viable dimensionality reduction method and can be used in conjunction with machine learning regression models to help build a robust model to predict outcomes of industrial processes such as batch quality. The autoencoder is able to effectively produce small latent spaces which accurately represent large datasets thus removing the problems associated with high dimensionality. Through the use of data-driven models and non-linear dimensionality reduction techniques, it is possible to reduce the computational cost whilst identifying a high-quality solution to industrial problems. Through cross validation, it is observed that the HNN model has both high accuracy and high reliability when predicting final viscosity. The developed soft-sensor was also found to be able to predict different processes operated over a broad time span with a relatively large viscosity variation. This is the significant benefit over conventional linear regression based dimensionality reduction and modelling methods. Overall, this work demonstrates the innovative combination and potential impact of different machine learning techniques for high dimensional industrial data analysis and batch process monitoring.

Abstract

This paper presents an analysis of green hydrogen production from geothermal and solar energy sources through a Monte Carlo simulation approach, using a first version of a digital twin for the intelligent design of hydrogen facilities. The proposed methodology allows comparing hydrogen production based on three different configurations (case study 1, 2, and 3) by calculating the internal rate of return and the levelized cost of hydrogen. The trade-off between system availability and capital investment to reduce investment risks was also studied. The results show that hydrogen production from geothermal energy source presents business opportunities even in conservative scenarios. The valorization through batteries of surplus solar electricity implies significant investment risks. The cost of electricity and the investment costs of electrolysis were identified as the parameters with the highest impact on the LCOH. In addition, the best trade-off between system availability and return on capital has been studied, concluding that redundancy in the electrolyzers is sufficient for achieving it. Future research will need to improve the calculation of system availability and maintenance costs.

Keywords: Green hydrogen, Monte Carlo simulation, renewable energy, Digital Twins.

1. Introduction

Hydrogen is an emerging energy vector that has been identified as a key driver for achieving sustainable development goals. However, some challenges must be overcome. In this regard, the future of hydrogen economy depends on reducing costs (i.e., CAPEX and OPEX) and minimizing investment risks. Furthermore, hydrogen facilities are complex systems that involves the interaction between different energy sources and feedstock, technologies, hydrogen physical form, and storage modes (Carrera and Azzaro-Pantel, 2021), being required to address the uncertainty linked to the data available for its optimal design.

Digital Twin (DT) solutions could help to address these challenges. The DT concept is based on the development of multi-physical, multiscale and probabilistic models considering the integration of physical and virtual products through the exchange of data (Wang et al., 2020). Methodologies based on data-driven DT approaches have been used for optimal operation and simulation of green hydrogen technologies (Jaribion et al., 2020; Meraghni et al., 2021). However, this approach has not necessarily been applied to the design of entire facilities. To address these gaps, our study proposes a methodology based on stochastic simulations for the evaluation of green hydrogen facility designs. The main contribution of this work is thus to address data uncertainty and its propagation to KPIs, identify the parameters that have the highest impact on LCOH, and choose the

facility design that presents the best trade-off between system availability and CAPEX. The paper is divided into five sections following this introduction. The methods and tools are presented in Section 2 with a focus on the stochastic simulations. The case studies are described in Section 3. Finally, the main results are analyzed in Section 4, followed by the conclusions and perspectives presented in Section 5.

2. Methods and tools

A methodological framework for the analysis of hydrogen production facilities from a Monte Carlo approach is presented. It is summarized in the Fig. 1.a.

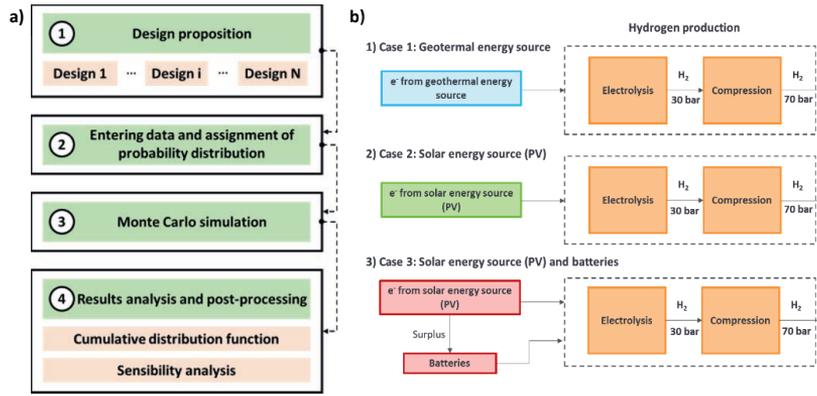

Fig. 1. a) Methodological framework; b) Case studies

2.1. Design proposition

Different hydrogen production configurations are proposed to analyze business opportunities, which may consider redundancy between equipment.

2.2. Entering data and assignment of probability distribution

The data considers the characteristic parameters of each component of the system. This involves capacities, CAPEX, OPEX, mean time to failure (MTTF), main time to repair (MTTR), among others. The MTTF and MTTR are used to calculate system availability, which is defined as the probability that the system will be operational at a given time "t" (Hou et al., 2015). The failure (λ_i) and repair rate (μ_i) are considered and calculated through Eq. (1.a) and (1.b). The availability of each equipment is then determined through Eq. (2) (Hastings, 2015). Finally, the system availability is calculated considering series (A_s) or parallel (A_p) configurations through Eq. (3.a) and (3.b), respectively (Hastings, 2015). Other input parameters considering the data that is independent of the equipment are also involved (i.e., indirect cost).

$$a) \quad \lambda_i = \frac{1}{MTTF_i} \quad ; \quad b) \quad \mu_i = \frac{1}{MTTR_i} \quad (1)$$

$$a_i(t) = \frac{\lambda_i}{\lambda_i + \mu_i} + \frac{\mu_i}{\lambda_i + \mu_i} \exp [(-\lambda_i + \mu_i)t] \quad (2)$$

$$a) \quad A_s(t) = \prod_{i=1}^n a_i(t) \quad ; \quad b) \quad A_p(t) = 1 - \prod_{i=1}^n (1 - a_i(t)) \quad (3)$$

2.3. Monte Carlo simulation

The Monte Carlo method (Johansen, 2010) can be summarized in the following steps. First, the cumulative distribution function (CDF, $F_X(x)$) (see Eq. (4)) of each input parameter is defined. It describes the probability that a random variable “X” with a given probability distribution will be found at a value less than or equal to x (Arora, 2017). Secondly, random values between 0 and 1 are chosen, allowing random values to be taken from the CDF. Then, the output variables of interest or KPIs are calculated. Finally, the process is repeated "n" times according to the precision required, to obtain the CDF for the outputs.

$$F_X(x) = P[X \leq x] = \int_{-\infty}^x f_X(u) du \tag{4}$$

2.4. Results analysis and post-processing

The CDF of the key performance indicator (KPI) of interest (i.e., internal rate of return, levelized cost of hydrogen, etc.) are analysed for each design, considering the “opportunity index”. This index indicates the probability of obtaining a value equal to or lower than the desired value for a given KPI.

3. Case studies

The methodology described above was applied to four case studies for green hydrogen production, which are shown in Fig. 1.b and described below:

- Case 1: Using geothermal energy (facility located in Iceland).
- Case 2: Using solar energy (facility located in southern Spain).
- Case 3: Using solar energy and storing the surplus electricity to be valorized in the electrolysis plant.
- Complementary studies from Case 2, keeping the same solar energy source but analyzing the business opportunities associated with equipment redundancy and availability of the system. Three configurations are studied, which are shown in Table 1.

The main assumptions of the case studies are:

- Energy facilities are entirely used to meet hydrogen demand.
- Triangular probability distributions using minimum, maximum, and average values are involved (See Fig. 2).
- Electrolysis plant capacity: 100 MW.
- Lifetime: 35 years.

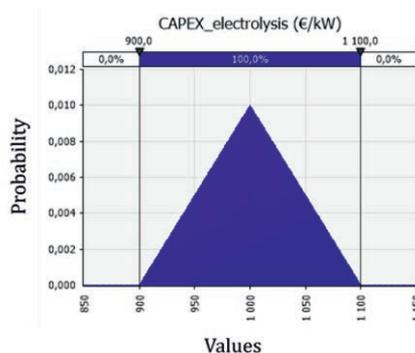

Fig. 2. Example of triangular probability distribution

Table 1. Green hydrogen facility design configurations for complementary studies of case 2

Design	Description
1 (Initial Case 2)	Project in the south of Spain
2 (Hypothetical Case 2.1)	Design 1 with 20% increase in electrolysis capacity.
3 (Hypothetical Case 2.2)	Design 2 with doubled compression capacity

4. Results and discussion

4.1. Case studies 1 to 3 - Evaluation of hydrogen production from geothermal and solar sources

The main results obtained in this study are discussed in this section. Fig. 3 shows the business opportunities associated with Case Studies 1, 2, and 3. The geothermal energy source presents reduced investment risk compared to the use of solar energy, since its IRR value remains positive even for a conservative scenario (opportunity index close to one). This is mainly due to the load factor of geothermal electricity production (about 92%) compared to the solar load factor (about 31%), which allows the IRR to rise by up to 48% in an optimistic scenario. The scenario with the highest investment risks would be case study 3, in which the probability of obtaining a positive IRR is 0.48. This implies that adding batteries to valorize the total available energy to produce hydrogen cannot be profitable according to our results. However, other case studies can be economically viable (i.e., isolated regions) (Marocco et al., 2021).

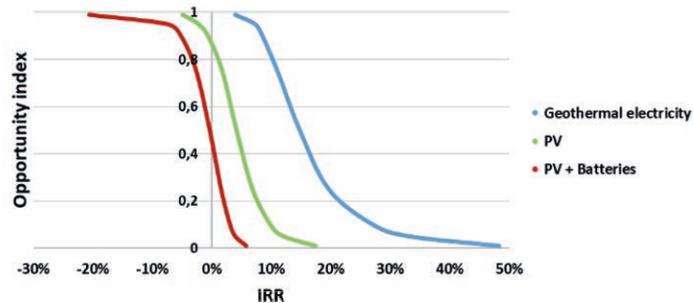

Fig. 3. Opportunity index vs IRR for case studies 1, 2 and 3

In addition, a sensitivity analysis on LCOH was performed for each major parameter, which is shown in Fig. 4. The LCOH varies between 2.11 and 3.29 €/kg H₂. The results indicates that electricity cost, electrolyzer capital cost, and system power composition are the major inputs influencing the LCOH. These should be prioritized from an optimal design and operational point of view. The investment cost of batteries has an important impact in Case 3, being the parameter that increases the LCOH compared to Case 2.

4.2. Complementary studies to case 2- Finding the best trade-off between CAPEX and availability

Several business opportunities associated with three production system designs and system availability (SA) are explored, which are indicated in Table 1. Fig. 5 shows the IRR for each design at the P50 point (opportunity index of 0.5) as a function of their CAPEX. “Case 2.1” offers an increase of a 0.26% in IRR despite having a higher CAPEX. This is achieved through increased system availability. In this regard, an improvement in the availability of the electrolyzers is sufficient to increase the probability of better economic performance. “Case 2.2” implies a decrease of 0.43% in IRR, degrading economic performance compared to Designs of Case 2 and 2.1.

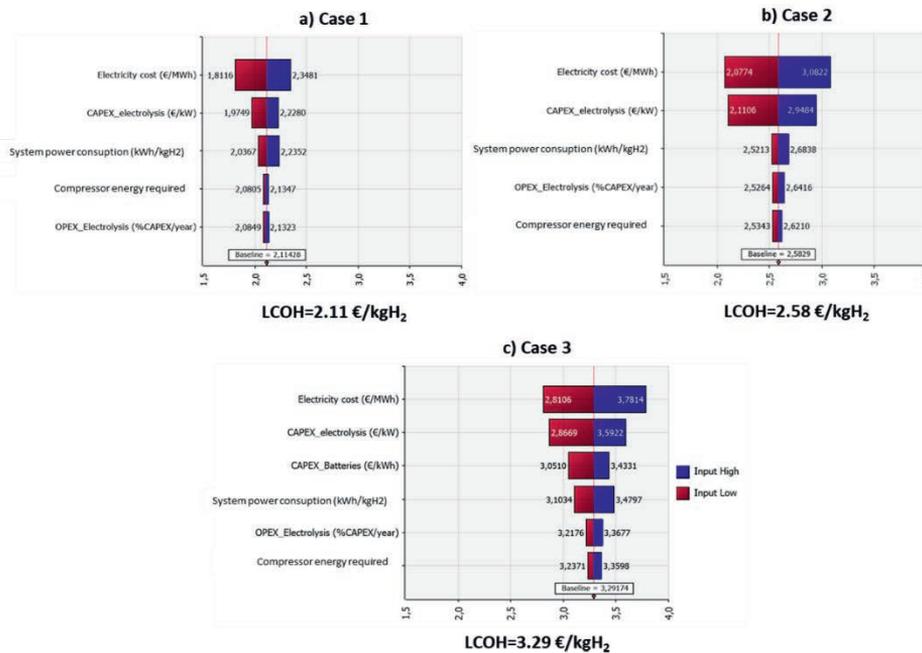

Fig. 4. Inputs ranked by effect on LCOH for a) Case 1, b) Case 2, and c) Case 3

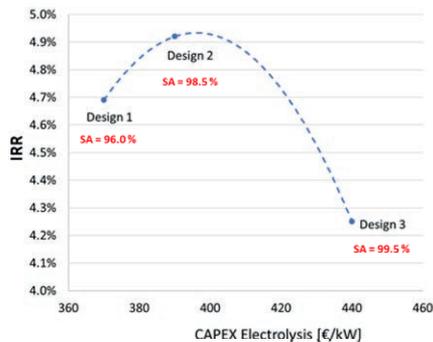

Fig. 5. IRR as a function of CAPEX at P50

5. Conclusion and perspectives

In this paper, a methodological framework for the economic risk analysis and design of green hydrogen facilities was proposed. It was demonstrated that an approach driven by Monte Carlo simulations generates substantial value-added insights to decision-makers. Firstly, the methodology addresses the uncertainty inherent in the parameters and its propagation to the KPIs. Secondly, the investment risk related to different facility designs is considered by an opportunity index and providing confidence intervals. Thirdly, sensitivity analyses can be carried out to identify the parameters with the highest impact on KPIs. Finally, several facility designs can be proposed and evaluated, identifying the best trade-off between the capital invested and the system availability.

The added value of the methodology was shown in several case studies. It was found that the geothermal energy source offers business opportunities even in conservative scenarios, compared to solar energy source. The valorization of the overproduction of electricity from batteries to produce hydrogen implies high investment risks. In addition, it was possible to choose between three design configurations including equipment redundancy to increase system availability. For this case study, we conclude that a redundancy in the electrolyzers is sufficient to increase the economic performance of the project, and then represents the best trade-off between CAPEX and system availability. Future research will require studying how to improve the calculation of system availability and O&M cost to precisely capture the stochastic behavior of the facility.

Abstract

Widespread adoption of high-temperature electrochemical systems such as polymer electrolyte membrane fuel cells (HT-PEMFCs) requires models and computational tools for accurate optimization and guiding new materials for enhancing fuel cell performance and durability. In this contribution, knowledge-based modelling and data-driven modelling are combined using Few-Shot Learning and implementing an Automated Machine Learning framework for the generation of Machine Learning-based surrogate models.

Keywords: Surrogate Models, Derivative Free Optimization, Transfer Learning, AutoML, data-driven modeling, high-temperature polymer electrolyte membrane fuel cells.

1. Introduction

The discovery of new materials like catalysts, polymeric membranes, and biomolecules, is driven by industrial needs such as improving reaction or separation selectivity, enhancing therapeutic effects on medical treatments, or reducing manufacturing costs. However, deployment of these advances in industrial applications is often hindered by the lack of models needed for design and optimization. Due to the novelty of the materials and devices, experimental data and first principles knowledge is scarce, making it hard to build models either via data-driven or knowledge based approaches. In this context, a way to efficiently combine domain knowledge with data could provide a pathway to streamline new materials discovery for industrial applications. Transfer Learning (TL) is an extension of Machine Learning (ML) in which knowledge learned for a particular task can be leveraged to ease the training for a new task. In terms of modeling for electrochemical systems, models developed for a given device or material can be leveraged to reduce the amount of data needed to accurately predict how new materials, operating parameters, and device configurations affect system performance. When the data for the initial training stage comes from a simulation, domain knowledge can be easily incorporated into the data-driven model, while at the same time reducing the number of experiments to be conducted – which can be timely and costly. This approach generates surrogate models that approximate the real behavior of the systems with adequate accuracy at a reasonable cost.

In this work, a TL framework for the development of Machine Learning-based surrogate models (MLBSM) to be used with a derivative free optimization algorithm is presented. Simulations from a compositional knowledge-based model validated using experimental data was used to generate training examples for a MLBSM. Then, TL learning was used to improve the performance of the MLBSM by using experimental data as training examples. Finally, an implementation of Particle Swarm Optimization (PSO) was used as demonstration of the applicability of this approach for derivative free optimization.

2. Transfer Learning

Transfer Learning (TL) (Pan & Yang, 2010) is a ML technique in which a data-driven model previously trained (general training) for a given task (source domain) is used as the base to build a model for a new task (target domain), with less data being required for the new training stage (task-specific training). Typically, the source and target domains are similar or closely related. Formally, given a source domain \mathcal{D}_s , and learning task \mathcal{T}_s , a target domain \mathcal{D}_T and a learning task \mathcal{T}_T , transfer learning aims to help the learning of the target predictive function $f_T(\cdot)$ for the target domain using the knowledge in \mathcal{D}_s and \mathcal{T}_s , where $\mathcal{D}_s \neq \mathcal{D}_T$ and $\mathcal{T}_s \neq \mathcal{T}_T$ (Yang, Zhang, Dai, & Pan, 2020). In this work, the source domain \mathcal{D}_s and learning task \mathcal{T}_s come from simulations generated using a low fidelity knowledge-based model. The target domain \mathcal{D}_T and learning task \mathcal{T}_T come from experimental data. A useful extension of TL is the so-called few-shot learning (FSL) in which the task-specific training stage uses a very small amount of data (i.e., on the order of 1×10^1) (Yang et al., 2020).

The overarching strategy of this implementation is described in **Figure 1**. A knowledge-based explicit equation model (EEM) for a HT-PEMFC was used as the source domain. An experimental dataset was used as target domain. A fully connected neural network optimized using a genetic algorithm-based Automated Machine Learning framework (AutoML) was implemented.

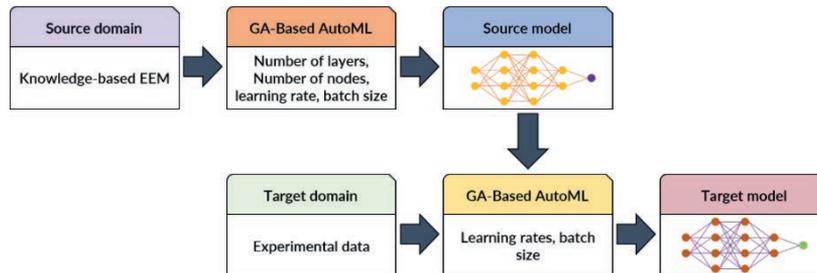

Figure 1. Transfer learning-based modeling strategy.

3. Data preparation

For the general training stage, simulated data was generated using the knowledge-based model reported elsewhere (Briceno-Mena, Venugopalan, Romagnoli, & Arges, 2021). To obtain a balanced dataset, the values for the input variables were structured following a full 3-level factorial experimental design using 11 variables (3^{11}). It is important to note that all HT-PEMFC models and data only consider pure oxygen as the oxidant. For each set of inputs, 5 points in the polarization curves were generated. The resulting datasets were arranged to generate a total of 887,735 input vectors of size 12 (the 11 input variables plus the current density) and the corresponding labels of size 1. For the target

domain, experimental data reported by Venugopalan et al. (Venugopalan et al., 2020) was used. Data were scaled using over min-max scaling in all cases.

4. Few Shot Learning and Automated Machine Learning Framework

Broadly, FSL strategies are based upon the notion of preserving information obtained through a first stage of training and reusing it in some fashion to develop a target model. FSL was implemented through regularization where the target model has the same architecture as the source model, and the learned parameters (weights) are adjusted during a new training stage, but some restriction is applied to prevent the model from overfitting the new data (Yang et al., 2020). In artificial neural networks (ANN), regularization takes the form of restricting how much the weights of the model can be updated. By applying setting different restrictions for each layer in the ANN, influence of the new data over the model can be controlled. The problem of obtaining the MLBSM can then be divided in two stages: (i) find a good source model and (ii) find the best way to perform the task-specific training. The first stage involves finding the proper architecture and training conditions (number of hidden layers (L), number of nodes (N), the learning rate (lr), and the batch size (n)) for the given source domain. The second stage requires finding a proper set of learning rates and batch size for a given target domain. Here, the selection of L , N , lr and n is defined as a Mixed Integer Nonlinear Programming problem and solved using a multi-objective evolutionary algorithm (Vishwakarma, Haghghatlari, & Hachmann, 2019), namely the Non-dominated Sorting Genetic Algorithm (NSGA-II) (Blank & Deb, 2020; Deb, Pratap, Agarwal, & Meyarivan, 2002). For tuning the hyperparameters of the neural network at source training, the multi-objective optimization problem (**Optimization problem 1**) is formulated as the minimization of $f_m(x)$ subject to $x \in R^4$ and $x_i \in \mathbb{Z}, i = 1, 2, 3$ where, x_1, x_2, x_3 are L, N and n respectively and x_4 is the learning rate. $f_1(x) = E_{training}^S$, $f_2(x) = E_{testing}^S$, and $f_3(x) = E_{validation}^S$ are the mean values for training, testing and validation in the 5-fold cross validation. The testing and validation errors are included in the multi-objective optimization problem to prevent overfitting. To obtain a model for a given source domain, a new neural network is built for each individual using the set of hyperparameters x (in addition to a fixed input layer $12:N$ and 2 fixed output layers $N: \lfloor \frac{N}{2} \rfloor : 1$) and then its performance is cross validated. For the FSL stage, a similar optimization problem (**Optimization problem 2**) can be formulated to obtain the appropriate learning rates ($lr_{input}, lr_{general}, lr_{task}$) and batch size (n) for a given target domain. In this case, x_1, x_2, x_3 are $lr_{input}, lr_{general}$ and lr_{task} respectively and x_4 is the batch size.

5. Derivative Free Optimization using MLBSMs

Once the surrogate model is obtained, the next step is use it to inform both the design of new materials for the fuel cell and its operating conditions. This task can be defined as an optimization problem (**Optimization problem 3**) in which the power density of the fuel cell estimated using surrogate model, $G(x)$, is the objective function and the physical realizability of the input variables ($x \in \mathbb{R}^{10}$) sets the upper and lower bounds for the problem variables. Since knowledge about the derivatives of the objective function is often unavailable, the problem is well suited for derivative free optimization (DFO) (Rios & Sahinidis, 2013). Furthermore, DFO benefits from the ability of ANN to perform well in high dimensional spaces (Bhosekar & Ierapetritou, 2018), opening the opportunity to exploit the flexibility of both MLBSMs to represent complex systems and DFO to

perform optimization using black-box models. In this work, Particle Swarm Optimization (PSO) (Kennedy & Eberhart, 1995) is implemented as a demonstration of the potential of coupling MLBSMs obtained via transfer learning with DFO.

6. Results and Discussion

6.1. Source model training

From **Optimization Problem 1**, it was found that a neural network with 3 hidden layers, each with 36 nodes (12:36:36:36:18:1), a batch size $n = 331$, and a learning rate $lr = 9.94 \times 10^{-5}$ was the best architecture. For the 5-fold cross validation source model training using the optimized neural network the mean relative root mean squared error (rRMSE) values for training, testing and validation were 2.80%, 2.87% and 29.16% respectively. The simulated data was obtained from an explicit equations model first developed for MEA0 and reported elsewhere (Briceno-Mena et al., 2021). **Figure 2** shows the accuracies and their variability for the source model (**Figure 2A**) and the target model (**Figure 2B**). The high validation error for the source model stems from the inaccuracy in the original explicit equations model used to generate the simulations for training, namely the estimation of the activation polarization.

6.2. Target model training

When the source domain is a simulation and the target domain is real experimental data for the same system, TL can be used to obtain a better model. As shown in **Figure 2A**, although the optimized neural network reached very low errors for the training and testing data, the error for the validation data is still high. This is consistent with the fact that at pretraining the ANN have not been exposed to real experimental data and the source domain is known to have inferior performance at very low current densities. For the task-specific training, the optimized learning rates and batch size from **Optimization Problem 2** ($lr_{input} = 1.99 \times 10^{-8}$, $lr_{general} = 8.80 \times 10^{-6}$, $lr_{task} = 0.00097$, $n = 7$) (the number of nodes and layers remained unchanged) were used. Validation data corresponds to the 200 °C polarization curve. As it can be observed, the validation error decreases by a factor of 3 for the target model. These results demonstrate the applicability of TL to improve existing models using small datasets, thus reducing the burden of generating experimental data.

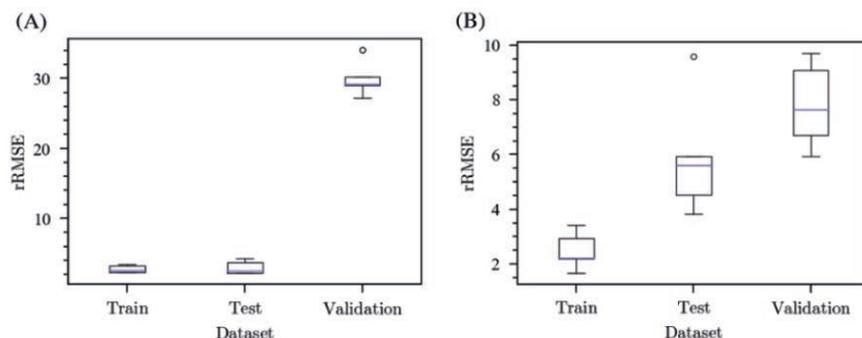

Figure 2. 5-fold cross validation results for model improvement. Boxes represent the standard deviation of the errors. (A) source model. (B) target model.

As the EEM models contains physical knowledge (e.g., Butler-Volmer kinetics for informing the activation overpotential and Ohm's Law for determining the ohmic overpotential from electrolyte conductivity) (Briceno-Mena et al., 2021), TL enables the introduction of this information into the MLBSM. An illustrative example of this is shown

in **Figure 3**. Here, the change in the polarization curve with changes in pressure is represented for both the source model (**Figure 3A**) and the target model (**Figure 3B**). Although the target domain does not contain information about the effect of pressure over the system (all examples correspond to the same pressure), the target model preserves some of this knowledge from the pretraining stage, which was introduced via the Nernst equation and physics-informed expressions for the exchange and limiting current density values. Therefore, new information on all the predictors in the source model is not required. This opens the opportunity for a faster development of models for new materials and device designs and optimal operating parameters, helping guide new materials by identifying the necessary properties for enhancing fuel cell performance (e.g., peak power density or power density at 0.7 V). Furthermore, the MLBSM can assist with future optimization activities such as pathways to reduce PGM loadings in the MEA while minimizing device performance losses such as power density.

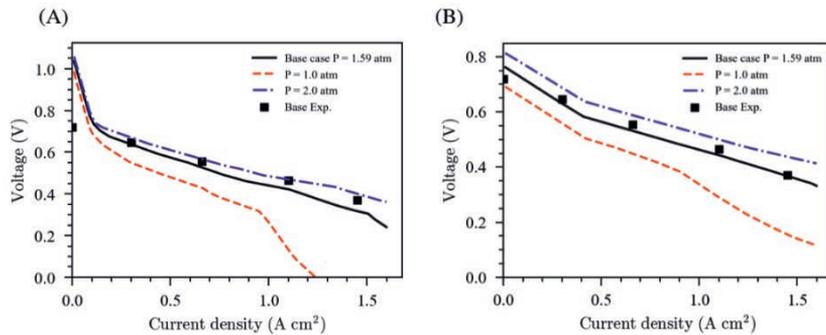

Figure 3. Effect of pressure as predicted by the source model (A) and the target model (B). The base case corresponds to 200 °C.

6.3. Derivative Free Optimization

Figure 4A shows the convergence of the optimization algorithm and **Figure 4B** shows the values for the problem variables corresponding to the optimal solution.

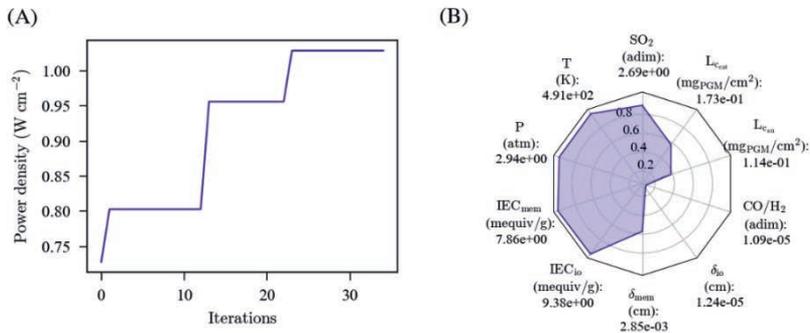

Figure 4. (A) Convergence of the optimization algorithm. (B) values of the problem variables for the optimal solution. The values are normalized by the upper bound in the optimization problem and grow in the direction of cost/difficulty of realization.

The optimization results suggest that the conductivity properties of both the membrane and ionomer binder (IEC_{mem} and IEC_{io}) are crucial for enhancing the performance of the fuel thus warranting further research on new materials to achieve higher conductivities. Furthermore, the ability to optimize operating conditions for a given set of materials could

allow researchers to test the potential of these materials *in silico* which can in turn reduce the cost of experiments and accelerate the timeline for bringing new materials to market.

7. Conclusions

A ML framework that exploits FSL in an AutoML framework for the generation for MLBSMs was demonstrated. Using FSL, the validation error was effectively reduced by a factor of 3, showcasing the capabilities of this approach to improve existing models using small datasets. The final surrogate model preserved physical knowledge included at pretraining, which is key advantage for the development of physics informed ML applications. Finally, the usefulness of the MLBSM was demonstrated by using it as the objective function in an optimization problem solved via a derivative free optimization algorithm. PSO converged after 25 iterations and rendered physically meaningful results that can inform future developments in materials for the components and operation conditions of the HT-PEM fuel cell.

Abstract

Process simulation and digital twins are of paramount importance to design new processes or optimize already existing plants and equipment. The main drawback with current process simulation software is the computational time required to obtain a solution convergence towards a new steady-state. Especially when the input or the output to a system are perturbed. This procedure may take up to minutes in large systems or with strong non-linear recycles. Surrogate modelling of digital twins offers the possibility to speed up the time to convergence required by process simulators by substituting the fundamental or rigorous models with machine learning methods and models. In this work, a surrogate modelling methodology is described for extracting a useful amount of data in a domain near the nominal steady-state of the plant for which a digital twin has been created. For each process variable, a plethora of machine learning models are trained and compared. The best-performing models are chosen to predict the behaviour of such process variables. The application of the surrogate modelling framework thus created has been successfully applied to a steady-state simulation, i.e. digital twin, of an acid gas dimethylamine washing process at the Itelyum exhausted oil refinery in Pieve Fissiraga (LO), Italy.

Keywords: surrogate model, machine learning, digital twin, amine washing

1. Introduction

Surrogate models are gaining more interest in the field of chemical process simulation (McBride and Sundmacher, 2019). Their strength lies in the ability to substitute rigorous fundamental models, thus accelerating computationally intensive tasks like superstructure optimization (Granacher et al., 2021) or dynamic non-linear process prediction (Shokry et al., 2020). One key step for accurate modelling using surrogates is the data sampling technique. Surrogate models have found applications in Bayesian optimization where data samples are generated mainly near the optimal conditions, thus making the surrogate able to predict optimal working conditions (Keßler et al., 2019). On the other hand, surrogate models have also been applied with wider data samples in order to explore working conditions outside of the canonical domain for a given process (Ganti et al., 2020). It is needless to say that each application requires a tailored solution and so does the data sampling procedure. Different data sampling techniques are described in Liu et al. (2017). This work focuses on the usage of surrogate models for the substitution of digital twins of real processes around nominal steady-state conditions. For this reason, the data sampling procedure adopted is both wide and narrow. Narrow, like in the case of the Bayesian optimization, for samples close to the nominal steady-state, and wide for the feasible domain around the steady-state. This is done, firstly, to enable the model to consistently predict the production near the steady-state, where

the plant is going to operate the majority of times. Secondly, data samples far from the nominal conditions should enable the model to be used for exploration purposes. An example is real-time steady-state optimization. In this case, it is advantageous to extend the computation to the cloud for faster results (Galeazzi et al., 2021). The methodology just described has been applied to a process of acid gas removal with amine washing using diethanolamine in the bio-oil regeneration refinery of Itelyum in Pieve Fissiraga (LO), Italy.

2. Data Generation

The data generation procedure is of key importance since a correct mapping of the operative domain of the process enables the surrogate model to make good predictions everywhere inside this domain. Especially when it is used for testing purposes rather than training. Several advanced methods exist for adaptively sampling the design space, an example can be found in Eason and Cremaschi (2014). For this work, the preferred method for data sampling is the Latin-Hypercube (McKay et al., 1979) design of experiment (DoE) since it spreads the samples uniformly within the constrained domain. The data thus generated is preprocessed to remove eventual outliers and, most importantly, non-converged simulations. These are all Aspen HYSYS simulations that did not arrive at a solution, with the desired operative conditions, in a reasonable amount of time at the imposed numerical tolerance. Generally, the data generation is slow due to the presence of non-linearities in the simulation and recycle loops. An optimization that has been implemented is to sort the samples, in ascending (or descending) order, generated through the DoE for the principal variables, e.g. the temperature of a stream entering a column. Thus, the starting point for the next sample of the DoE is much closer and the simulator should go to the solution more quickly.

3. Modelling framework

After the data is gathered and preprocessed the surrogate modelling framework starts the training of several machine learning (ML) algorithms. The type and amount of algorithms chosen are arbitrary and a specific case study may require a tailored solution. In this case, the proposed algorithms are, in inverse order of complexity, linear regression, polynomial regression, support vector regression (SVR), decision tree regression, random forest, AdaBoost, gradient boosting, and artificial neural networks. For this particular case study, every feature variable has been used to make a prediction about the target variables. Eventually, the framework should benefit from a previous feature selection to reduce the total number of variables given to each algorithm, thus speeding up the training time. Every ML algorithm is trained and compared against each other with a k -folds cross-validation method (with $k = 5$, in this case). The comparison of each model has been performed through the analysis of the mean absolute error (MAE), in Eq. 1, and the root mean squared error (RMSE), in Eq. 2.

$$MAE(y, \hat{y}) = \frac{1}{n} \sum_{i=0}^{n-1} |y_i - \hat{y}_i| \quad (1)$$

$$RMSE(y, \hat{y}) = \sqrt{\frac{1}{n} \sum_{i=0}^{n-1} (y_i - \hat{y}_i)^2} \quad (2)$$

where y is the target value, \hat{y} is the predicted value, n is the number of samples, and i is i -th data sample.

4. Case study

The surrogate modelling framework has been applied for the process of acid gas removal with amine washing in the exhausted oil refinery of Itelyum in Pieve Fissiraga (LO), Italy. The process flow

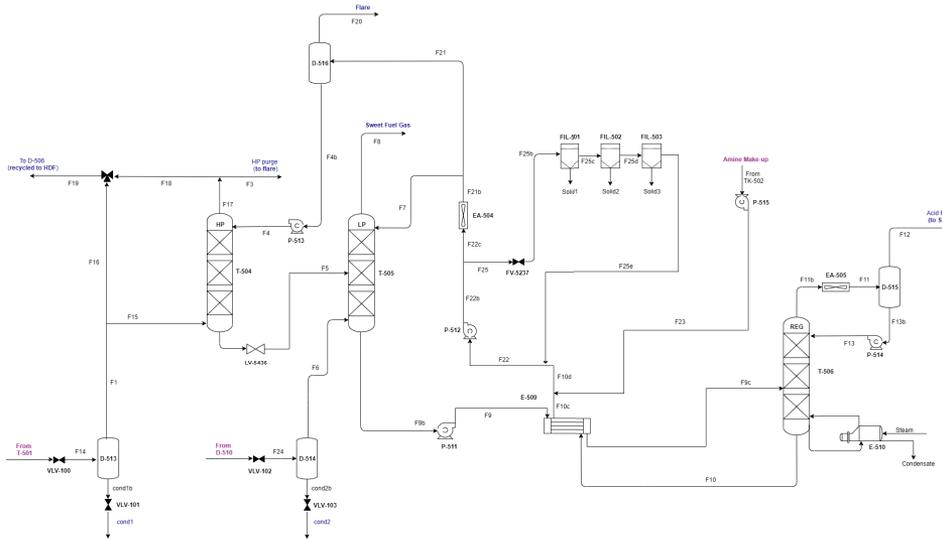

Figure 1: PFD of the amine washing section of Itelyum exhausted oil refinery in Pieve Fissiraga (LO), Italy

diagram (PFD) is shown in Figure 1. It is composed of two main sections, namely the absorbing section and the regeneration section. The absorbing section is composed of two absorbers, one being at high pressure (T-504, in Figure 1) and the other at low pressure (T-505, in Figure 1). The regeneration section is composed of a single column (T-506, in Figure 1) used to regenerate the spent diethanolamine (DEA) coming from the previous HP and LP absorbers. These unit operations are part of the Revivoil process, created by Itelyum and Axens, and the streams entering the amine washing subsection are coming from the hydrofinishing units. They are rich in light hydrocarbons, hydrogen, and hydrogen sulfide. Hydrogen is separated in the HP absorber and recycled back to the hydrofinishing while H_2S is sent to a sulfur recovery unit (SRU). The small amount of light hydrocarbons remaining after the separation are finally purged in the flare.

First, a steady-state simulation was created using Aspen HYSYS. Several simplifications have been implemented in order to reduce the time to convergence of the HYSYS simulator. Moreover, for computational reasons, the two main sections described above have been split into two different flowsheets as shown in Figures 2 and 3. The steady-state digital twin solution has been validated against plant data taken from the distributed control system (DCS) through Yokogawa’s Exaquantum platform. The simulation has shown a small deviation of 4.4 % on average from the process data. An example is shown in Table 1.

Table 1: Methane mass flow [kg/h] in amine washing process.

	F18	F9	F8	F5	F4	F7
Digital twin	297.47	0.00061	6.17	0.00029	0	0
Process data	297.44	0	7	0	0	0

The data are generated for each section independently. The data extracted from the simulation are the temperature, pressure, flow rate, and composition of each stream shown in Figures 2 and 3. A total of 4000 data points for each section have been generated with box constraints around the

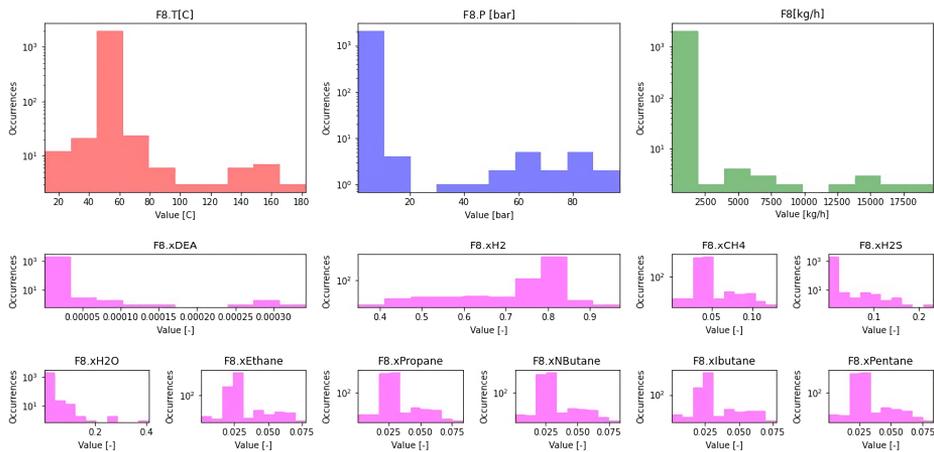

Figure 4: Histograms of the occurrences of data points in the range of process variables for stream F8.

nominal conditions and with a Latin-Hypercube DoE. Two different domains, i.e. box constraints, have been defined, the former being closer to the operational range with an arbitrary $\pm 10\%$ from the nominal conditions while the latter being wider with a range of $\pm 40\%$. Figure 4 shows an example of data extraction for stream F8. The split ratio for the data created in both domains is 50%. However, due to the relative width of the second domain ($\pm 40\%$), only a few data samples have found a convergence with the desired tolerance (64 out of 2000 for the case of the HP and LP absorbers). On the other hand, for the first box constraint of $\pm 10\%$ the case is inverted, and only a few operative conditions did not result in convergence (1947 converged out of 2000 for the case of the HP and LP absorbers). The convergence/non-convergence information is still insightful. In fact, by applying a binary classification algorithm, like logistic regression (for example), it is possible to understand the feasible domain for process convergence.

After this initial preprocessing, features and targets were defined. The features chosen for the modelling framework are all those inputs needed for fixing all the degrees of freedom of the simulation. Viceversa, the targets are all those process variables (temperature, pressure, composition, and flow rate) calculated by the same simulation. Once the variables are set, the training of each algorithm described in Section 3 starts, and the residual errors (MAE and RMSE) are taken for establishing the best-performing algorithm. The results of the best-performing algorithms chosen are shown in Table 2. It is worth noticing that not always the most complex model is the best performing one. For example, the linear regressor has always been chosen for predicting the pressure variables. This is explained by the fact that pressure drops are set as constants in the HYSYS simulation. Moreover, other more advanced models like artificial neural networks were always underperforming their lower complexity competitors, even though they took more computational time for training. Finally, the overall residual error for the first domain of exploration ($\pm 10\%$) is approximately 2% for the absorbers section and 5% for the regenerator. If we calculate the residual error also for the case of the wider domain ($\pm 40\%$) the percentage is higher by orders of magnitude. This is explained by the fact that the actual converged solutions in this domain are very few, and the models may neglect these measurements given the higher amount of data of the first domain. Solutions to this problem may range from the addition of weights that try to rebalance the domains disparity during the regression procedure, to the generation of more data inside the actual feasible domain, possibly with a binary classifier guiding the DoE inside the actual boundary of convergence.

Table 2: Number of occurrences for each best-performing algorithm for the regenerator and HP/LP absorbers sections

	Regenerator section		Absorbers section	
	Occurrences (#)	Occurrences (%)	Occurrences (#)	Occurrences (%)
Linear regression	2	7.7%	3	7.7%
Polynomial order 2	1	3.8%	-	-
SVR	12	46.2%	-	-
Decision tree	2	7.7%	-	-
Random forest	6	23.1%	28	71.8%
AdaBoost	3	11.5%	8	20.5%

5. Conclusions

In conclusion, the surrogate modelling approach has been successfully applied for a case study of a real industrial process. The surrogate modelling framework has been written in Python and, for communicating with the process simulator (Aspen HYSYS), an interface was developed in Excel via visual basic (VB) using the native libraries of HYSYS for VB. This approach is optimal for creating surrogate models of steady-state digital twins of industrial plants, given the data generation procedure that creates many data points near the nominal operating conditions of the process. With these surrogate models, it is now possible to apply optimization strategies or applications for real-time usage since the amount of time required to obtain a result from the surrogate model itself is lesser. This methodology should be further enhanced to make it able to treat dynamic digital twins. Furthermore, the final goal of this method is to substitute the need for a process simulator that generates the data and take this data directly from the DCS of the industrial plant, automating the process of surrogate models creation.

Abstract

With the growing urbanization process in several cities around the world, air pollution mitigation has become one of the main environmental challenges of the present time. Recently, low-cost air pollution sensors have become a current trend in the air quality control area since they are an affordable alternative for deploying air quality monitoring systems with high spatial resolution. However, the main drawback of these sensors is that they tend to provide measurements with lower accuracy and reliability compared to traditional air quality monitoring stations. Therefore, periodical calibration of these sensors is essential to maintain the quality of their measurements. This work presents a novel air quality sensor calibration method based on a Bayesian neural network model. The proposed method is assessed using a real public available dataset. The test experiment results show that the method has a good accuracy performance, with a lower mean absolute error compared to other machine learning-based calibration methods applied to the same dataset. In addition, the method presents the advantage of directly providing estimations of the uncertainty of the calibrated measurements, which is an important metric used to assess the quality and reliability of data provided by air pollution sensors and that most other calibration methods usually cannot provide.

Keywords: air quality evaluation, sensor calibration, machine learning, Bayesian neural network.

1. Introduction

Air pollution mitigation has become one of the main environmental challenges of the present time. It is estimated that 96% of the urban population is exposed to air pollution levels that exceed the recommended limits (Lewis and Edwards, 2016) and, just in 2016, more than 4.2 million deaths in the world were caused by factors related to air pollution exposition (WHO, 2016). Therefore, the implementation of air quality monitoring systems that collect detailed data about air pollution concentration in urban areas and assist city managers to remediate problems related to air pollution has become crucial for large cities. Most cities, however, use air quality monitoring systems based on expensive monitoring stations that are sparsely distributed in their urban areas. As such, they can only monitor air pollution with low spatial resolution and they cannot collect detailed information about air pollutants in their whole urban area. In this context, low-cost air pollution sensors have recently become a trend in the air quality monitoring area, as they are a potential alternative for increasing the spatial resolution of the air quality monitoring systems. Since these devices can be acquired at a much lower cost compared to the

traditional air quality monitoring stations, they can be widely deployed in urban areas and support the traditional monitoring stations carrying out air pollution concentration measurements in regions that the stations cannot cover. However, the main drawback of these sensors is that they tend to provide lower accuracy and reliability measurements compared to traditional air quality monitoring stations. They suffer from cross-sensitivities between different air pollutants, they are affected by external factors (such as temperature and humidity), and their measurement performance degrades over time due to aging and poisoning effects on their components (Maag et al., 2018) (Concas et al., 2021).

To improve the accuracy of these sensors, a widely used strategy is to periodically calibrate them. The calibration of these sensors is traditionally performed in laboratories, by exposing them to controlled atmospheres with known concentrations of pollutants. However, as these devices are widely deployed in urban areas, this calibration approach tends to become unfeasible, since a massive number of sensors would have to be removed from their deployment site and then transported to laboratories. In this context, calibration methods based on machine learning models have recently emerged as excellent alternatives for air pollution sensor calibration as they allow in-field calibration. The general idea of these methods is to use measurements of a monitoring station (or an already calibrated sensor) located in the proximity of the low-cost sensor as references to train a machine learning model that can correct the errors of its measurements and output more accurate measurements (Concas et al., 2021).

Artificial neural networks have become commonly used machine learning models for air quality sensor calibration. They showed to be flexible multivariate calibration models, as they are capable of handling the cross-sensitivity between air pollutants, the influence of external conditions, and the nonlinear relationships between a sensor measurement and a reference measurement, which are challenging problems in the sensor calibration task (De Vito et al., 2018). These models, however, are known to suffer from overfitting problems, which can affect their generalization capability (Concas et al., 2021). Thus, this study proposes a novel low-cost air pollution sensor calibration method based on a Bayesian neural network model, which is a probabilistic neural network model that has the advantages of presenting natural mechanisms of regularization against overfitting and directly providing estimates of the uncertainty of its predictions (Jospin et al., 2020).

2. Methodology

2.1. Bayesian Neural Network

A Bayesian neural network (BNN) is a stochastic artificial neural network trained using Bayesian inference (Jospin et al., 2020). Stochastic neural networks are a type of artificial neural networks (ANNs) built by introducing stochastic components into their architectures that allow the estimation of uncertainty of their predictions. In the case of BNNs specifically, the network parameters θ are usually considered stochastic and this allows the networks to simulate multiple model parameter configurations according to their associated probability distribution $p(\theta)$. In this way, while training a BNN, instead of training one single model, a set of models is trained and their predictions are aggregated into probabilistic distributions. This characteristic avoids problems of overfitting for the neural network and gives access to uncertainty estimates of its predictions.

To design and train a BNN denoted by $y = F_{\theta}(x)$, the following Bayesian inference process is carried out. Given a training dataset with $X = [x_1, \dots, x_N]$ as its input variables and $Y = [y_1, \dots, y_N]$ as their respective target outputs, the first step is to choose a proper neural network architecture (i.e. feed-forward, recurrent, convolutional) for the problem

in hand. Then, the next step is to choose a prior distribution $p(\theta)$ over the model parameters, that describe the prior beliefs about the parameters before analyzing the dataset, and a likelihood distribution $p(Y|X, \theta)$, that describes a prior confidence in the predictive power of the model F_θ . In the case of a regression problem, such as the calibration sensor problem, a Gaussian distribution is normally used for the likelihood distribution (Gal, 2016):

$$p(y|x, \theta) = N(y; F_\theta(x), \sigma) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(F_\theta(x) - y)^2}{2\sigma^2}\right) \quad (1)$$

Then, applying the Bayes' theorem, the Bayesian posterior distribution can then be computed as:

$$p(\theta|X, Y) = \frac{p(Y|X, \theta)p(\theta)}{\int p(Y|X, \theta')p(\theta')d\theta'} \quad (2)$$

This posterior distribution describes which are the most likely values for the parameters θ to have generated the data, according to the combination of prior knowledge about θ and the information about θ provided by the training data. Finally, given this Bayesian posterior, it becomes possible to compute a marginal probability distribution of the network's output, given a certain new input x^* , which quantifies exactly the uncertainty of model predictions:

$$p(y^*|x^*, X, Y) = \int p(y^*|x^*, \theta')p(\theta'|X, Y)d\theta' \quad (3)$$

In practice, however, this predictive distribution is summarized by a few statistics computed using a Monte Carlo sampling approach. In this approach T samples of θ are sampled from the posterior distribution $p(\theta|X, Y)$ and then used to compute statistics of the predictive distribution. For instance, to summarize the prediction of a BNN used in regression problem, the usual procedure is to perform model averaging:

$$\tilde{y}^* = \frac{1}{T} \sum_{i=1}^T F_{\theta_i}(x^*) \quad (4)$$

While the uncertainty of the prediction is computed as follows:

$$\tilde{\sigma}^2 = \frac{1}{T} \sum_{i=1}^T (F_{\theta_i}(x^*) - \tilde{y}^*)^2 \quad (5)$$

One problem while training a BNN is that the posterior distribution computation is usually an intractable problem, since computing the evidence $\int p(Y|X, \theta')p(\theta')d\theta'$ cannot be done analytically. To address this problem, Bayesian inference approximation methods are normally used to train BNNs in practice. A review of Bayesian inference approximation methods specific for BNNs is presented in Gal (2016). For this study, the variational inference method called Monte Carlo (MC) Dropout (Gal and Ghahramani, 2016) is adopted, since it allows to approximately perform Bayesian inference in BNNs with only simple adaptations of traditional neural networks training techniques.

2.2. Bayesian Neural Network Calibration Method

The BNN-based air quality sensor calibration method proposed for this study is schematized in Figure 1. As illustrated, the goal of this method is to train a BNN calibration model that takes as input a raw sensor measurement (x_{raw}) and external conditions data (x_{ext}) (such as temperature, humidity, and concentration of other pollutants sensors), and returns as output a calibrated concentration measurement of the target pollutant of the sensor (y_{cal}^*). To train the model, the Bayesian inference

approximation method MC-Dropout (Gal and Ghahramani, 2016) is used. Previously collected raw sensor measurements and external conditions data stored in a historical database are used as the input variables of the training dataset, and reference measurements provided by some reference meter close to the sensor (such as a traditional monitoring station or another previously calibrated sensor) are used as target outputs Y of the training dataset. Once trained, the BNN model is then deployed to calibrate new raw sensor measurements. Since the trained model is Bayesian, when receiving as input new inputs $x^* = (x_{raw}^*, x_{ext}^*)$, it returns a predictive probabilistic distribution of calibrated pollutant concentration values corresponding to the new raw sensor measurements $p(y_{cal}^* | x^*, \theta)$. To simplify the model output, only the mean of the predictive probabilistic distribution (\tilde{y}_{cal}^*) and its respective uncertainty value ($\tilde{\sigma}_{cal}$) are outputted by the model.

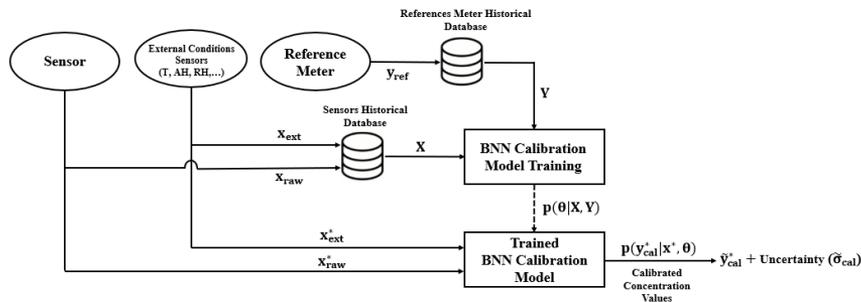

Figure 1 - BNN calibration method

3. Experiment

3.1. Data

To evaluate the proposed method's performance, an application experiment was carried out. For this experiment, the ENEA (National Agency for New Technologies, Energy and Sustainable Economic Development) dataset (De Vito et al., 2008) was utilized. This dataset was chosen for this experiment since it has already been used as a benchmark for evaluation of other machine learning-based sensor calibration methods (De Vito et al., 2018), thus enabling the performance comparison between the proposed method and methods already tested against this dataset. A complete description of this dataset can be found in De Vito et al. (2018).

3.2. Experimental Setting

The specific case of the CO sensor calibration was chosen for this experiment since the performance of other machine learning-based methods in the calibration of this specific sensor were described in De Vito et al. (2018) and it can be used for performance comparison. To allow a fair comparison between the proposed methods and the methods used in De Vito et al. (2018), a similar dataset split configuration was used: the first 504 instances were used to train the BNN model and the remaining instances were used to test the trained model. To assess the performance of the model, the mean absolute error (MAE) was used, since it was the performance metric used to evaluate the other machine learning models in De Vito et al. (2018).

3.3. Calibration Model

To calibrate the CO sensor, a Bayesian feed-forward neural network model was chosen. The model was structured to receive as input the responses from CO, NMHC, NOx, NO2, O3, temperature, relative humidity, and absolute humidity sensors and to return as output CO concentration values. To train the model, the CO ground truth concentrations values

provided by the reference monitoring station were used as target outputs. The model was implemented using the Python programming language and the Pytorch library (Paszke et al., 2019). The optimal model was determined using the Optuna framework (Akiba et al., 2019). The optimal Bayesian neural network model was structured with a single hidden layer containing 24 processing units that use the ReLU activation function and an output layer containing only one processing unit. This model was trained using a dropout rate equal to 0.163, a learning rate equal to 0.012, 400 training epochs, and an RMSprop optimizer (Tieleman et al., 2012).

4. Results and Discussion

To evaluate its performance, the optimal model was tested against the test dataset. The test experiment showed that the model has good accuracy in the calibration of the CO sensor with a good generalization capacity. As highlighted in Table 1, the model presented an MAE value of 0.47, which is lower compared to the MAE values obtained by the models evaluated in De Vito et al. (2018) for the calibration of the same sensor. Furthermore, as can be seen in Figure 2, uncertainty estimates for the calibrated measurement are directly provided by the calibration model. Uncertainty measures are an important metric in the context of validation of air quality sensors (Council of European Union, 2008), as they allow to evaluate the quality and reliability of the measurements provided by them. In the literature, only a few machine learning-based methods for the calibration of air pollution sensors address the obtainment of uncertainty estimates of calibrated measurements, and usually, in their approaches these estimates are not obtained directly by the calibration model, requiring the use of extra mechanisms to compute the uncertainty values (Esposito et al., 2016). Therefore, the proposed method proves to be novel in this sense.

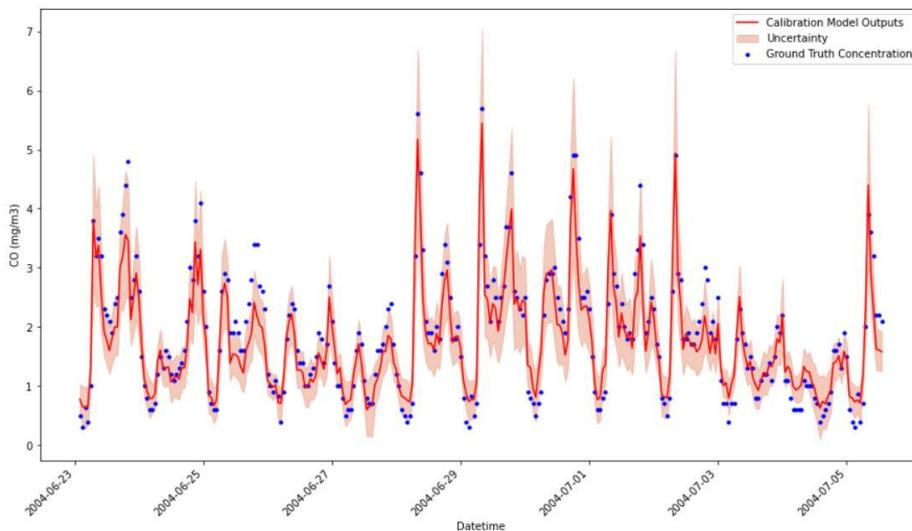

Figure 2 - Uncertainty estimates for the calibrated measurement

5. Conclusion

A Bayesian neural network calibration method for low-cost air quality sensors was proposed in this study. The experimental results show that the method has a good accuracy performance, with a lower mean absolute error compared to other machine

learning-based calibration methods applied to the same dataset. In addition, the method presents the advantage of directly providing estimations of the uncertainty of the calibrated measurements, which is an important metric used to assess the quality of data provided by air pollution sensors and that most other calibration methods usually cannot provide.

Table 1 - Performance comparison

Model	Mean Absolute Error (MAE)
Multiple Linear Regressors	1.09
Support Vector Machine	0.64
Gaussian Process Regression	0.55
Neural Network	0.61
Bayesian Neural Network	0.47

Abstract

The design and control of biological reactors depends upon the correct calibration and selection of kinetic parameters from the exponential phase in the microbial growth. Nowadays, kinetic microbial parameters reported in the literature of biochemical engineering are obtained based on specific growth conditions, thus limiting their possible application in a wide variety of dynamic models. In this paper, we propose an adaptive machine learning approach to predict microbial growth and provide information on the effect that variations of pH (5, 7, 9) and concentration of the culture media (10, 20, 40, 60, 80, 100%v/v) have on the growth rate. We study biological reactions and obtain a set of experimental exploratory data using the *Pseudomonas aeruginosa*. The versatile and robust metabolism of *P. aeruginosa* is responsible of its ability of growth in different environment conditions even at low nutrient and oxygen levels, in a sample range of temperatures (4°- 42° C) and polluted sites. As first contribution, we propose a technique to gather experimental data via measurements of optical density, microbial growth, from the Multiskan™ FC Microplate Photometer, Thermo Scientific. Our second contribution consist in integrating the Hyperconic Multilayer Perceptron (HCMLP) as computational and mathematical approach to predict microbial growth across all the set of conditions of the experimental design. HCMLP is a state-of-the-art method to define complex non-linear decision boundaries, in the parameters' space, using a mix of ideas from conformal geometry and neural networks, and focusing on quadratic hyper-surfaces through multiple hidden layers. As a consequence, we generate precise hyper-surface responses which predicts microbial growth even in values not evaluated during the experimental stage. Finally, our statistical testing and comparisons validate that the proposed experimental, mathematical and computational framework is robust and capable of predicting the dynamic growth of bacteria *P. aeruginosa* using two main operation conditions: pH and concentration culture media. In the future, we plan to apply our proposed methodology to other bacterial strains and advance HCMLP for forecasting dynamics of other multiple microbial measurements under a wide variety of conditions.

Keywords: Microbial Growth, Machine Learning, Fitting Experimental Data, Hyperconic Multilayer Perceptron

1. Introduction

The chemical, biochemical and pharmaceutical industries have always focused on the development of new products. However, the scaling of equipment is an important bottleneck in the transition from chemical, biochemical and pharmaceutical research to the development of processes for which a large amount of experimental data is necessary, which subsequently allows the generation of models to describe the behavior of the process. A crucial part of this procedure is the development of a kinetic model of the chemical or biological reaction system. The tools that engineers provide, in combination with the use of specialized software, allow us to reduce time and development costs through a reduction in laboratory experiments, rapid expansion and avoidance of the need for expensive tests pilot. In the particular case of microbial kinetics, existing models only govern processes for specific operating/growth conditions; that is, if the operating conditions change, the kinetic parameters must be obtained through new experiments, thus increasing both the material and monetary costs. Here, the development of more robust and precise kinetic models for predicting microbial growth emerge as a novel approach to build profitable and faster chemical process which, in turn, lower monetary costs for the end-user.

Modelling of microbial kinetic behavior through mathematical computing, particularly machine learning (ML), is a still vastly unexplored field. The biokinetic parameters for microbial growth of *P. aeruginosa*, assuming static growth conditions, are experimentally determined by Bakke et al. (1984); and Tuovinen (1984) and Beyenal et al. (2003) in biofilms, planktonic cultures and double substrate growth kinetics of *P. aeruginosa*, respectively. Tochampa et al. (2005) develops a model of xylitol production by the yeast *C. mogii* ATCC 18364 in the presence of glucose as the cosubstrate using a genetic algorithm, further improved by Sirisansaneeyakul et al. (2013) through mathematical optimization. Lee et al. (2015) provides growth kinetic models for microalgae cultivation using multiple factors but only under single operation conditions. Recently, Eze et al. (2018) designed a kinetic model to describe the growth of microalgae strain *Desmodesmus sp.* in wastewater cultures using numerical methods for differential equations. As shown in literature, although there are models of microbial kinetic behavior, most of them lack of adaptability using various dynamic factors and under multiple operation conditions.

Our contributions focus in both experimental design for data collection, and modelling through a novel machine learning technique, with particular emphasis on prediction of microbial growth. Section 2 describes the proposed framework, from biochemical experimentation to the machine learning application. Section 3 analyze and statistically validate the prediction under various conditions. Finally, Section 4 summarize our findings and states future work.

2. Methodology

The proposed framework include two distinctive phases: 1) biochemical experimentation, and 2) microbial growth data approximation. As first contribution, we study the microbial growth of the *P. aeruginosa* bacteria on selective media, and introduce a technique to analyze their cellular growth under various conditions of pH, culture media and agitation speed. We keep an oscillating temperature between 23° C and 32° C for kinetic inspection during all experiments. Thus, in our second contribution, the proposed kinetic model

predicts the microbial growth and its dynamics using pH, medium and agitation speed as inputs.

2.1. Biochemical experimentation

Experimental design takes into account two values in the culture medium, 80% and 100%, whilst pH is set to three different values, 5.0, 7.0 y 9.0. We perform four runs of each experiment in a Multiskan microplate spectrophotometer with a 5% measuring error, at most. To statistically verify that microbial growth is affected by pH values and the culture medium, we apply an analysis of variance ANOVA with 95% confidence interval. The *P. aeruginosa* strain (SA1-12) is isolated from Lerma river in Salamanca, Guanajuato, Mexico; and identified through 16S DNAr amplification and comparison analysis in public databases. To evaluate the growth of *P. aeruginosa* (SA1-12) at different pH and levels of nutrients and intensities of agitation during the first stages of development, we prepare overnight cultures of the bacteria in King's B Medium at 28° C and 100rpm. Bacterial pellets are recovered by centrifugation and resuspended in diluted culture media according the experimental condition (pH; 5.0, 7.0, 9.0; King's B medium; 10, 20, 40, 60, 80, 100% v/v). The fresh cultures media are inoculated with 0.01% of pre-inoculums and 200µL are deposited in 96-multiwell plate. The optical density is measured every 15min for 8h ($A = 620\text{nm}$, in a microplate reader Multiskan™ FC Microplate Photometer, Thermo Scientific) at two intensities of agitation, low and medium, at 28° C. We use a multiwell plate during our testing stage.

2.2. Microbial Growth Data Approximation

The second phase consist in learning data patterns using collected experimental data of microbial kinetics growth of *P. aeruginosa*. We develop a surface response model via modern approaches from machine learning based on geometric algebra. Well tested capabilities of modern artificial intelligence tools, e.g. novel versions of neural networks, provide us with an efficient way to predict microbial growth on unknown values of the exogenous variables.

The proposed Hyperconic Multilayer Perceptron (HC-MLP) includes neurons in the hidden layer named Hyperconic Neurons (HCN), which use transfer functions to define decision boundaries via hyperboloids, paraboloids, spheres, and ellipsoids. Figure 1a shows the architecture of the proposed HCMLP in this study. The architecture consists of three layers: 1) input layer, 2) hidden layer and 3) output layer. The input signals are propagated through the network from left to right, where the output scalar y comes from the final output layer. The calculation of the HCN includes the estimation of a conic. In this study, we use the HCMLP as function approximation and predictive model to estimate the absorbance y using as input the time x_1 and the percentage of the culture media concentration x_2 as is illustrated in Figure 1b. For practical purposes and for convenience of the reader, we present a brief description of the computed calculations for the HCN. By identifying points $x = (x_1, x_2) \in \mathbb{R}^2$ with points $\vec{x} = [x_1, x_2, 1]$, it is well known that given a symmetric 3x3 matrix A , the set of points $x = (x_1, x_2) \in \mathbb{R}^2$ such that $\vec{x}A\vec{x}^T = 0$ lie in a conic, i.e.

$$[x_1 \quad x_2 \quad x_3] \begin{bmatrix} a_{1,1} & a_{1,2} & a_{1,3} \\ a_{2,1} & a_{2,2} & a_{2,3} \\ a_{3,1} & a_{3,2} & a_{3,3} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ 1 \end{bmatrix} = 0 \quad (1)$$

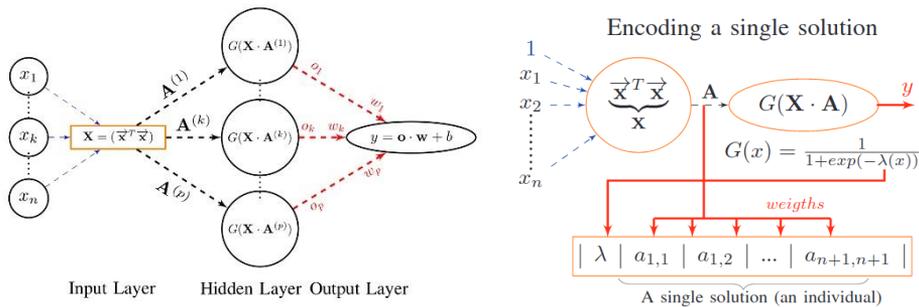

On the other hand, the relative position of a point (x_1, x_2) with respect to a conic can be obtained by means of the sign of the following number $(\vec{x}^T \vec{x})A$. Finding the best approximation of a solution to the equation $(\vec{x}^T \vec{x})A = 0$ for a set of points (x_1, x_2) is usually called the algebraic estimation of the conic passing through these points. Therefore, the output of the neuron in the hidden layer can be written as a function composition of a non-linear associator and the sigmoid function G (Serrano-Rubio et al., 2017). Thus, the output of a neuron o_i in the hidden layer is written as follows

$$o_i = \frac{1}{1 + \exp(-\lambda(\vec{x}^T \vec{x}) \cdot A^{(i)})} \tag{2}$$

Where $\lambda \in \mathbb{R}$ is the slope of the sigmoid function. Note that the machine learning problem, from an optimization perspective, consist in finding parameters $a_{i,j}$ and λ .

The Spherical Evolutionary Algorithm (SEA) is implemented for training the HCMLP (Serrano-Rubio et al., 2018). The population of SEA represents the potential solutions that determines an optimal approximation to the target outputs. These solutions are vectors which are encoded as individuals for the evolutionary algorithm. Therefore, the goal of the training is to find the vector of parameters that determines an optimal approximation to the target dataset. Figure 1b shows the encoding of a single solution.

The experimental setup is given as follows: The number of neurons in the hidden layer is varied to obtain the best topological-architecture for our Evolutionary Artificial Neural Network. The number of neurons is as follows: 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10. We use a dataset of 190 feature vectors. The population for the evolutionary algorithm was set to 30 individuals with uniform random initialization in the domain $[-1, +1]$. The stop criteria of the training occurs when the algorithm reaches an error of 0.0001 or 10000 fitness function evaluations. As fitness function we use the widely tested least square function during the training stage. Our model is validated using standard growth factors. We train the machine learning model using three pH values (5.0, 7.0 and 9.0) and multiple medium concentrations (100%, 80%, 60%, 40%, 20% and 10%). Our model predicts absorbance values for any configuration of pH in $[5.0, 9.0]$, concentration of medium in $[10\%, 100\%]$, and any timestamp, hours (h), between $0 h$ and $8 h$.

a) Hyperconic Multilayer Perceptron.

b) Technique to encode a single solution. Each solution consist of weights $a_{i,j}$ where $a_{i,j}$ represents the parameters to estimate for each conic neuron.

Figure 1. Hyperconic Machine Learning Framework.

3. Results

Common mathematical approaches, on microbial growth kinetics, assumes specific conditions for optimal bacterial growth. However, biological reactors cannot keep the same exact settings during prolonged periods of time due to inherent unpredictability on the reactor system. Thus, designing and deploying an approach capable of modelling the nonlinear behavior of microbial growth, lessen the amount of resources necessary for complex experiments in bioreactors. A key advantage is the reduction of spent time in laboratories because our proposed method can learn a characteristic surface, and predict outputs for conditions not present in the experimental dataset. In this study, we focus on the robust *P. aeruginosa* strain which flourish in pH values around 7.0. Our mathematical and computational model predicts the dynamic growth of bacteria *P. aeruginosa* when tuning two main operation conditions: pH and concentration media culture. Inputs/outputs of learning model F are as follows

$$\text{absorbance} = \beta = F(\text{pH}, [\text{media culture}], t),$$

Where β is the output-absorbance value, pH is the acidity or basicity of the solution, in our case of study pH=7.0, concentration media culture is the solution concentration and t represents a specific time. We perform statistical hypothesis testing to verify that microbial growth depends upon bioreactor's operation conditions. Here we use an ANOVA test with a significance level of $\alpha = 0.05$, thus confirming the impact on microbial growth when varying growth conditions. Figure 2 shows a visual comparison of experimental-data time series using different media culture during the 8h time interval, versus output surface response using our hyperconic multilayer perceptron.

Validation of the proposed model is performed in two different phases. In phase 1, we obtain the training error of 6.6939E-4, which refers to the difference between the value predicted by the HC-MLP and the experimental value, considering only the data set with which the network is trained. In phase 2, the testing error of 6.9530E-4 is obtained, i.e., the difference between the predicted value and the test-experimental value of some growth condition that is within the established interval for the input variables (pH, time and concentration media culture). Table 1 shows the comparison of the absorbance value predicted by the HC-MLP algorithm and the experimental value for the *P. aeruginosa* strain at pH=7.0. The calculated error presents an order of magnitude between 10E-3 and 10E-5. The order of magnitude of these errors can be compared with similar studies carried out in the area of food microbiology, regarding the prediction of microbial growth in foods exposed to environmental conditions. In this sense, the proposed mathematical models in literature receive pH and temperature as inputs (Pla et al., 2015). Such models are used to predict the growth of 3 strains: *Pseudomonas spp.* (Baranyi et al., 1999), *Listeria monocytogenes* (Oksüz and Buzrul, 2021) and *Bacillus cereus* INRA-AVTZ 415 (Pla et al., 2015) in different culture media obtaining in all cases errors in the adjustment of the order of 10E-3.

If the testing error of the HC-MLP algorithm is compared with the error obtained in the literature, it is evident the reduction of 1 order of magnitude in the fit of the data by the proposed algorithm. This means, that our tool improves on what is reported in the literature with respect to similar works for fitting experimental microbial growth data. Therefore, our most important contribution is the development of a methodology for the prediction of microbial kinetics based on robust and modern machine learning tools, and versatile enough to fit experimental data of any kind.

Table 1. Experimental value versus predicted value absorbance when training HC-MLP with $pH=7.0$

Exp	Microbial Growth condition		Absorbance (β)		Error (SSE)
	t (h)	[Culture Media] %	Experimental	Predicted	
1	0.25	80	0.0559	0.0650	8.281E-5
2	3.5	60	0.2728	0.2670	3.364E-5
3	5.25	40	0.3860	0.4210	1.220E-3
4	6.00	20	0.3879	0.3910	1.600E-5
5	7.25	10	0.2991	0.3380	1.140E-3

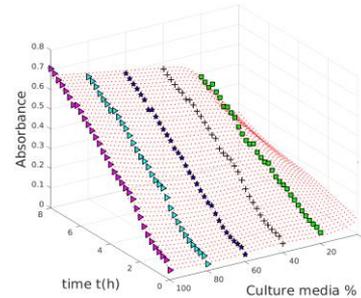

Figure 2. Surface response using our hyperconic multilayer perceptron

4. Conclusions

We have proposed the first model to predict the growth of the native bacterial strain *P. aeruginosa* based on Hyperconic Networks and conformal algebra. We have developed a mathematical and computational method to systematically select the structure of kinetic models and partially automatize the laboratory process. We have collected experimental data of our bacterial strain and statistically validated our approach to predict the microbial growth under operation conditions. Our studies indicates that an artificial intelligence-based predictor of microbial growth can be generated that takes into account changes in growth conditions. In the future we plan to apply our proposed approach to other bacterial strains and advance HCMLP to forecasting dynamics of multiple microbial measures. This methodology can be extended to adjust microbial growth data of any microorganism to obtain a characteristic growth surface as a response to changes in the conditions that most affect it.

Abstract

This work presents an integrated planning and scheduling framework for the optimal contract selection problem of Contract Manufacturing Organisations (CMO) under uncertainty. Considering a multistage, multiproduct, batch facility of a secondary pharmaceutical industry, an aggregated MILP planning model is firstly proposed including material balances and allocation constraints. Utilizing a rolling horizon approach, the production targets are then provided to a precedence-based MILP scheduling model to define batch-sizing and sequencing decisions in detail. To model demand uncertainty, a scenario-based approach is proposed, considering the Value-at-Risk (VaR) and Conditional Value-at-Risk (CVaR) measures. Since large number of scenarios imposes significant challenge to computations, a scenario reduction framework is integrated to reduce the total solution time, when considering large-scale problem instances. The proposed methodology increases the profitability of CMOs by selecting the optimal contract combinations depending on their risk tolerance while considering the availability and optimal utilization of underlying production resources.

Keywords: Contract Manufacturing Organizations, Conditional Value-at-Risk, MILP.

1. Introduction

Over the past few years, large R&D pharmaceutical companies have increasingly outsourced non-core activities, such as manufacturing, to Contract Manufacturing Organisations (CMOs), which are companies without their own product portfolio. This policy enables multinational pharmaceutical industries to reduce their costs and emphasise on drug discovery and marketing, which are considered as key parts for their value chain. Typically, drug development is a time-consuming process, as it takes at least 10 years on average for a new medicine to be in the marketplace. Additionally, demand of newly developed pharmaceutical products is usually highly uncertain. Lower drug efficacy can affect the demand and total sales, while in the worst case, it can lead to the suspension or even the withdrawal of the drug. Under this dynamic and uncertain environment, a CMO must decide the best contract combination to accept, so as to maximize its profits (Marques et al.' 2020)

2. Problem statement

The problem under consideration is mainly concerned with the optimal contract selection of a secondary, multistage, pharmaceutical contract manufacturer (CMO). Secondary pharmaceutical manufacturing is focused on the further processing of active ingredients (APIs), by adding excipient inert materials to produce the final products, usually in SKU

form. Secondary manufacturers consist typically of three main production stages operating in batch mode: granulation, compression, and coating (Marques et al., 2020). In each stage, the production takes place in multiple parallel lines, while product-dependent changeovers occur between consecutive product batches, due to the necessary cleaning operations. To ensure the required purity and quality of final products, batch splitting or mixing is not typically allowed in these industries. Although there is no intermediate storage capacity between stages, if necessary, product batches can remain in a production unit after completing their process. The pharmaceutical plant operates 24 hours per day, for five days a week, in order to satisfy a weekly order-driven demand. Contract manufacturers (CMOs) don't produce their own product portfolio but serve other companies in the pharmaceutical industry on a contract basis to provide comprehensive services related to drug manufacturing. The length of contracts usually ranges from six months up to one year or more. A contract can include currently-developed products, characterized by highly volatile demand and high selling prices, or drugs with less uncertain demand and lower profit margins (Johnson. 2005). Currently-developed products are subject to unsystematic risk, while products that have been already placed into the market are affected only by systematic risk. Systematic risk is inherent to the whole market, reflecting the impact of economic, geo-political and financial factors, while unsystematic risk is unique to a specific drug or a group of products. Drugs that are subject only to systematic risk are characterized by similar demand fluctuations. Hence, an unexpected event can lead to an increase or a decrease in the demand for all mature drugs. On the other hand, new pharmaceutical products are characterized by strong demand fluctuations which are mainly related to their level of efficacy and unexpected side effects. In the worst case, strong side effects can lead even to the withdrawal of the drug. Considering these facts, decision-makers must determine the best contract combinations to be signed in order to increase expected profits, while considering the capacity of equipment, plant operational and design constraints, and the risk tolerance of the company.

3. Solution strategy

To model the problem under consideration a hierarchical approach is proposed based on the idea of rolling horizon framework (Johnson. 2005). An aggregated MILP model is proposed for determining planning level decisions such as weekly production and inventory targets. A general precedence MILP model, inspired by the work of Cerdá et al., (2020), is then proposed, for making batch sizing, timing, allocation and sequencing decisions. A feedback loop is included as well, to converge the produced amount of both decision levels.

Given a set of available and already agreed contracts, a CMO must define the best contract mixture to maximize its profits while avoiding high risk exposure. For each contract, demand uncertainty is modeled using several independent scenarios which represent different possible instances while they are associated with a weight representing the probability of the scenario realization. All contract combinations and all the individual scenarios are independent, thus the integrated planning and scheduling problem of each scenario can be solved separately (Johnson. 2005). The planning MILP model and the proposed solution algorithm are presented in the following sections in detail.

3.1. Planning MILP model

$$q_j^{\min} WV_{p,j,w} \leq Q_{p,j,w} \leq q_j^{\max} WV_{p,j,w} \quad \forall p \in P, j \in PJ_p, w \in W \quad (1)$$

$$\sum_{j \in JS_s} Q_{p,j,w} \leq \sum_{j \in JS_{s-1}} Q_{p,j,w} + I_{p,s,w-1} \quad \forall p \in P, s \in S, w \in W: s > 1 \quad (2)$$

$$I_{p,s,w-1} + \sum_{j \in (JS_s \cap PJ_p)} Q_{p,j,w} = I_{p,s,w} + d_{p,s,w} - B_{p,s,w} + B_{p,s,w-1} \quad (3)$$

$$\forall p \in P, s \in S, w \in W$$

$$N_{p,j,w} \geq \frac{Q_{p,j,w}}{q_j^{max}} \quad \forall p \in P, j \in PJ_p, w \in W \quad (4)$$

$$T_{p,j,w} = fx_{p,j} N_{p,j,w} + \frac{Q_{p,j,w}}{vt_{p,j}} \quad \forall p \in P, j \in PJ_p, w \in W \quad (5)$$

$$I_{p,s,w} \leq cap_{p,s} \quad \forall p \in P, s \in S, w \in W \quad (6)$$

$$\sum_p \sum_s I_{p,s,w} \leq wc \quad \forall w \in W \quad (7)$$

$$\sum_p T_{p,j,w} + \sum_p cl_{p,j} W V_{p,j,w} \leq h \quad \forall j \in J, w \in W \quad (8)$$

$$\sum_{j \in (JS_s \cap PJ_p)} T_{p,j,w} \leq avl_s \quad \forall s \in S, w \in W \quad (9)$$

$$\begin{aligned} \max \quad & \overbrace{\sum_c in_c}^{\text{initial contract payment}} + \overbrace{\sum_w \sum_p \sum_{j \in (JS_s \cap PJ_p)} W_{p,j,w} d_{p,s,w} pr_p}^{\text{total sales}} - \\ & \overbrace{\sum_w \sum_p B_{p,s,w} bc}^{\text{backlog cost}} - \overbrace{\sum_w \sum_p \sum_s I_{p,s,w} ic_p}^{\text{inventory cost}} - \overbrace{\sum_w \sum_p \sum_{j \in PJ_p} Q_{p,j,w} qc_p}^{\text{production cost}} - \\ & \overbrace{\sum_p fr_p rc_p}^{\text{raw material fixed cost}} - \overbrace{\sum_p rc_p \sum_{j \in PJ_p} \sum_w (Q_{p,j,w} - fr_p)}^{\text{raw material variable cost}} \end{aligned} \quad (10)$$

Constraints (1) impose upper and lower limits on the production of each product $Q_{p,j,w}$, equals to the maximum (q_j^{max}) and the minimum capacity (q_j^{min}) of the production unit j , respectively. According to the constraints (2), the amount of a product p at each stage s at the end of week w , should not exceed the amount that has been produced at the previous stages plus the amount being stored from the previous week, $I_{p, s,w-1}$. Material mass balances are expressed via constraints (3). The total produced and the stored amount of a product p , must be equal to the weekly demand ($d_{p,s,w}$) and the new stored amount, minus the unsatisfied demand of the current week (backlog, $B_{p,s,w}$), plus backlog from previous weeks. The number of batches of each product is expressed by integer variable $N_{p,j,w}$, which is determined by constraints (4). It is assumed that each production unit will process a certain number of batches at a full capacity and a single batch at flexible size at every stage, which is a valid assumption for realistic case studies. Furthermore, the processing time of each product at each processing unit j , $T_{p,j,w}$, is provided by constraint (5). The terms $fx_{p,j}$ and $vt_{p,j}$ express the coefficient for the fixed and the variable processing time, respectively. Constraints (6) and (7) guarantee that the stored amount doesn't exceed the total warehouse capacity of the plant wc , and the individual capacities of each product at each stage $cap_{p,s}$. According to constraints (8), the total processing time and

the average cleaning time $cl_{p,j}$ of each production unit must be lower than the available time horizon. Additionally, constraints (9) impose an extra upper bound on the total production time of each production stage. The upper bound is given by parameter avl_s , and its initial value is equal to the time horizon h . Since the planning model doesn't include timing and sequencing constraints, in some cases the production targets provided to the scheduling level could be infeasible. To converge the production amounts of the two MILP models, the upper bound is adjusted to the maximum production time defined by the scheduling level. Hence, the planning MILP model becomes more accurate. Finally, the objective function focuses on the maximization of the total profit of the plant. The main income is related to the initial payment of each signed contract and the total revenue of sales. On the other hand, costs include backlog, inventory, production and raw material costs. It is also assumed that if a contract is signed an initial amount of raw materials must be purchased regardless of the actual demand and the produced amount of products.

3.2. Solution algorithm

The proposed solution framework involves three phases. The first phase is concerned with the examination of the feasibility of each contract combination. In particular, the predominant scenario of each combination is solved by using the aggregated planning MILP model. If the generated solution leads to full demand satisfaction, the underlying contract combination is proven feasible. If a contract combination is shown to be infeasible, then any combination which is a superset of the former must also be infeasible. For example, if the combination of contracts C1 and C2 is infeasible then a combination with the contracts C1, C2 and C3 is also infeasible.

In the second phase, the predominant scenario of each combination that has been proven feasible in the first phase is solved by using the integrating planning and scheduling MILP framework. If the solution of any iteration of the rolling horizon framework leads to unsatisfied demand (generation of backlog) then the contract combination is proven infeasible and thus, any combination which is a superset of the former, deemed infeasible as well.

Since all contract combinations and the individual scenarios of each combination are independent, the proposed integrated planning and scheduling MILP framework can be solved separately for each combination and each contract. Thus, regarding the third phase of the proposed algorithm, the planning and scheduling problem of each combination is solved for each scenario. To cope with problems that involve large number of scenarios, a scenario reduction framework based on the work of Li and Floudas (2014), is utilized. Considering scheduling level decisions, the total profit is accurately reported for all scenarios and thus, risk metrics such as Value-at-Risk and Conditional Value-at-Risk can be calculated. As a result, decision-makers can determine the optimal contract combination based on their risk tolerance.

4. Application study

The efficiency and applicability of the proposed solution strategy is illustrated using a representative case study concerning a secondary pharmaceutical CMO. The problem is focused on a multistage batch facility, which consists of three stages (granulation, compression, and coating). Each stage includes multiple production units with varying capacity and production rates. The CMO must decide the best contract combination among 6 contracts, as it is presented in Table 1, while contract C1 is already agreed. Each contract has four demand scenarios: high, target and low demand, and failure. Contracts C1-C3 includes products with less demand volatility and smaller profit margins while

contracts C4-C6 are related to new products with higher selling prices. The time horizon is 1 year (52 weeks) and a weekly demand has to be satisfied for each product. The 6 contracts lead to 28 combinations with different demand distributions. Since contracts C1-C3 are subject only to systematic risk, their combinations consist of the same scenarios including high, target and low demand with the same realization probabilities. On the other hand, if a combination includes contracts with new drugs, the probability of combined scenarios is calculated as the product of the probabilities of the new drugs and the probability of the developed products.

Table 1 Contract data

contracts	Contract availability / Product type	Products	Demand multiplier for each scenario and probability of realization			
			High	Target	Low	Fail
C1	Agreed/developed	1,2	1.2 (10%)	1 (80%)	0.8 (10%)	0 (0%)
C2	non agreed/developed	3,4	1.2 (10%)	1 (80%)	0.8 (10%)	0 (0%)
C3	non agreed/developed	5,6,7	1.2 (10%)	1 (80%)	0.8 (10%)	0 (0%)
C4	non agreed/new	8,9,10	1.2 (15%)	1 (60%)	0.5 (20%)	0 (5%)
C5	non agreed/ new	11,12	1.4 (20%)	1 (50%)	0.4 (20%)	0 (10%)
C6	non agreed/ new	13,14	1.7 (25%)	1 (40%)	0.2 (15%)	0 (20%)

Table 2 Summary of results

Feasible Contact combination	Exp. Profit	VaR _{90%}	VaR _{95%}	CVaR _{90%}	CVaR _{95%}	Max. Profit
C1-C3	0.96	0.76	0.76	0.76	0.76	1.15
C1-C4	1.83	1.12	0.43	0.76	0.42	2.46
C1-C5	0.74	0.27	0.27	0.27	0.27	1.09
C1-C6	1.83	0.42	0.42	0.42	0.41	3.42
C1-C3-C5	1.50	1.15	1.15	1.10	1.06	1.99
C1-C3-C6	2.36	1.29	1.29	1.22	1.16	4.30
C1-C5-C6	2.66	0.76	0.76	0.76	0.76	4.23

*The values represent millions of relative monetary units (r.m.u.)

According to the first phase of the proposed solution algorithm, all combinations are solved using the aggregated planning model for the predominant scenario, by considering the target demand. Then, the feasible combinations are solved by applying the integrated planning and scheduling framework. The feasible combinations according to the second phase are presented in Table 2. Contract combinations C1-C3-C4 and C1-C4-C5 were proven feasible in the first but not in the second stage of the algorithm. Regarding the third phase of the solution framework, the planning and scheduling problem of each scenario is solved for all feasible combinations. To reduce the computational time, a scenario reduction algorithm is utilized so as to consider up to 10 scenarios for each combination. The expected profit, the Value-at-Risk, the Conditional Value-at-Risk, and the maximum profit for each combination are summarized in Table 2. Also, Figure 1 illustrates a bubble chart comparing expected profit, VaR and CVaR for all contract combinations. The diameter of the bubble represents the CVaR value of contract combinations. A favorable contract combination should be represented by a large bubble in the top right-hand corner of the diagram, implying high expected profit, VaR and CVaR values. A risk-neutral approach indicates that combination C1-C5-C6 is the optimal one since it leads to the highest expected profit. However, considering VaR_{90%} and CVaR_{90%}, the combination C1-C3-C6 seems more attractive, when a risk-averse policy is applied. In that case, the profit will exceed 1.29 million of relative monetary units (r.m.u) with a

90% confidence interval, while the mean of the lowest 10% profits will be equal to 1.16 million r.m.u.

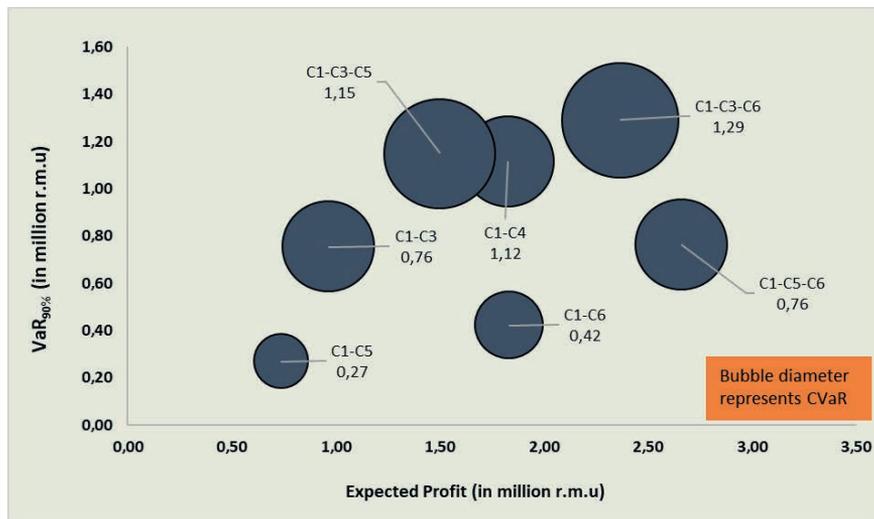

Figure 1 Expected profit, VaR_{90%} and CVaR_{90%} of each contract combination

5. Conclusions

In this work and optimization framework is proposed for the optimal contract selection problem of a CMO in the secondary pharmaceutical industry. Demand uncertainty is modeled by using discrete independent scenarios with known probabilities, while the consideration of scheduling level decisions into an hierarchical planning and scheduling approach leads to accurate profit estimations. In contrast with risk-neutral approaches, the proposed methodology allows decision makers to choose the optimal contract combinations depending on their risk tolerance.

Abstract

Carbon dioxide emission from the industrial sectors in Italy is second only to emissions from the energy sector. The implementation of carbon capture and storage chains, while considered an ideal solution to decarbonize the industry sector, is cause for additional concern due to the seismic profile of the Italian peninsula. A nationwide multi-objective carbon capture and storage chain is here optimized through a mixed integer linear programming framework, aiming at both cost minimization and reduction of the risk factor linked with the susceptibility of transport to local seismic activity. The resulting minimum specific CO₂ avoidance cost resulting from the economic optimization is 64.7 €/t for a 50% carbon reduction target, while the minimization of seismic risk determines an increase in infrastructural costs up to 79.4 €/t (+22.5%).

Keywords: Cement, steel, oil refining; Carbon capture and storage; Seismic risk; Multi-objective optimization; Mixed integer linear programming.

1. Introduction

Cement plants, steel mills and refineries are responsible for a significant share of carbon dioxide (CO₂) emissions (EEA, 2020), which are among the greenhouse gases responsible for the global threat of climate change. Implementing carbon capture and storage (CCS) technologies is key to reduce a significant portion of CO₂ emissions from these hard-to-abate sectors (Bui et al., 2018). A CCS system is an ensemble of technologies aimed at reducing anthropogenic CO₂ emissions. In particular, the capture of CO₂ consists in its separation from a process stream through different methods depending on the industry and the applied technology, then the transport step is necessary to move the captured CO₂ from emission sources towards areas suitable for sequestration, the latter carried out by injecting the CO₂ deep into underground geological basins. Given the inherent complex, multi-stage nature of CCS chains, the optimization of such systems proves fundamental to achieve a substantial level of decarbonization. Mixed integer linear programming (MILP) models are commonly regarded as powerful methodologies to optimize complex, multifaceted systems, such as energy systems, and they have been recently exploited for the case of CCS networks (Tapia et al., 2018). Several studies optimized CCS chains at different scales, such as region-to-country scale (Lee et al., 2017; Elahi et al., 2017)). Additionally, higher-level continent-wide analyses were proposed as well (Hasan et al.,

2015; d'Amore et al., 2021). One key issue in the deployment of CCS infrastructures is their social sustainability. Although being practiced for over 30 years, CCS is nowadays still rising public concern, especially when the possibility of leakage is taken into account in the vicinity of densely populated areas (d'Amore et al., 2018). In this context, seismic activity poses an additional requirement during the planning, installation, and operation of a CCS system, particularly with regards to pipelining (Psyrras and Sextos, 2018). In this work we will focus on optimizing a comprehensive CCS framework to abate the CO₂ emissions from the Italian industry sector. However, considering the widespread seismic activity in the Italian peninsula, our model will aim at simultaneously minimizing cost and risk (with respect to seismic phenomena) of a CCS system in Italy. Italian industrial stationary sources (i.e., cement, steel and refinery sectors) will be taken into account within a multi-objective MILP modeling framework.

2. Modelling framework

This section will describe the three echelons of the optimized Italian CCS system in terms of key model input parameters. The level of CO₂ emissions and location of industrial plants are taken from EEA (2020) and referred to the year 2017. The total number of emission points was reduced from that reported in the EEA database to decrease the computational burden while ensuring the representativeness of the sample (i.e., at least 80% of the emissions from each sector are included in the optimization). The reduced dataset includes a total of 27 CO₂ emitting nodes n , subdivided into 20 cement plants (described through subset c), 5 refineries (described through subset r) and 2 steel mills (described through subset s).

The CO₂ capture stage is modelled through a set $k = \{kc, ks_{1,2,3}, kr_{1,2,3}\}$ whose components refer to: (kc) oxy-fuel capture for cement plant; (ks_1) absorption from power plant stack at steel mill; (ks_2) absorption from (ks_1) and coke oven flue gas at steel mill; (ks_3) absorption from (ks_1+ks_2) and capture from sinter plant at steel mill; (kr_1) pre-combustion capture from steam methane reformer at refinery; (kr_2) capture at (kr_1) and post-combustion capture on power unit at refinery; and (kr_3) which comprises (kr_1+kr_2) and post-combustion capture from further emission points at refinery. A complete description of capture plants can be found in d'Amore et al. (2021), including the parameters for determining the CO₂ avoidance cost $CCA_{k,n}$ [€/t] of capture plant k installed in an industrial node n , comprising scale effects on capture plant size. In this study, the CO₂ can be transported through either onshore or offshore pipelines, which are discretized through set p into possible ranges of flowrate to account scale effects of total transport scale on unitary transport cost UTC_p [€/km/t] (Rubin et al., 2015). Offshore transport cost is increased by a $\gamma_{n,n'}$ [=1.71] (d'Amore et al., 2021). Differently, sequestration entails a fixed unitary cost USC [=7.2 €/t (Rubin et al., 2015)], which is increased by a θ_n [=2.5] factor to account for offshore basins (d'Amore et al., 2021). The positional and capacity data on storage are taken from Donda et al. (2011).

The seismicity-related parameters are obtained through a dataset containing the coordinates of polling points over the entire Italian peninsula, which are then averaged into seismic areas and implemented to calculate the risk specific to each pipeline in the transport stage of the CCS system (Gehl et al., 2014).

3. Mathematical formulation

The MILP model aims at minimizing both the total cost TC [€/year] of the CCS system and the total risk TR [ruptures/year] associated to the transport stage:

$$objective = \min\{TC; TR\} \quad (1)$$

The total cost of Eq.(1) is given by the contributions of capture (TCC [€/year]), transport (TTC [€/year]), and sequestration stages (TSC [€/year]):

$$TC = TCC + TTC + TSC \quad (2)$$

In particular, TCC of Eq.(2) is evaluated according to the captured CO_2 flowrate $IN_{k,n}$ [t/year] through capture plant k in node n :

$$TCC = \sum_{k,n} (IN_{k,n} \cdot CCA_{k,n}) \quad (3)$$

TTC of Eq.(2) depends on the transported flowrate $Q_{p,n,n'}$ from node n to n' (resulting from the mass balance among nodes), on the distance between nodes $LD_{n,n'}$ [km], and on unitary cost factors UTC_p [€/t/km]:

$$TTC = \sum_{p,n,n'} (Q_{p,n,n'} \cdot LD_{n,n'} \cdot UTC_p \cdot \gamma_{n,n'}) \quad (4)$$

Storage cost TSC of Eq.(2) is proportional to the yearly stored amount OUT_n [t/year] and to the unitary storage cost USC [€/t], the latter increased by θ_n if located offshore:

$$TSC = \sum_n (OUT_n \cdot USC \cdot \theta_n) \quad (5)$$

The overall stored amount is imposed to be larger than the set Italian carbon reduction target of 50% of yearly emissions from industry. TR of Eq.(1) is the sum of all the repair rates $RR_{n,n'}$ [ruptures/year] pertaining to the pipelines employed in the transport grid, the latter accounted through a binary variable $\lambda_{p,n,n'}$ associated to sizes p between n and n' :

$$TR = \sum_n (\lambda_{p,n,n'} \cdot RR_{n,n'}) \quad (6)$$

$$RR_{n,n'} = 0.002416 \cdot K_l \cdot LD_{n,n'} \cdot \max\{PGV_n; PGV_{n,n'}^{mid}; PGV_{n'}\} \quad \forall n, n' \quad (7)$$

where K_l is a parameter representing the effect of transport characteristics and construction material over repair rate, $LD_{n,n'}$ is the length of the arc, and PGV (calculated as its maximum among its values in n , at the center of the pipe, and in n') is the peak ground velocity, defined as the highest horizontal ground velocity during a seismic event expected in the next 50 years, with an exceedance probability of 10% (USGS, 2021). In particular, K_l [=0.6] was taken from ALA (2001) by assuming carbon steel pipelines transporting dry CO_2 , while PGV was evaluated from 16852 points (then discretized into 315 squares of 50 km of size) of spectral acceleration S_A [g] computed by the Istituto Nazionale di Geofisica e Vulcanologia – INGV (Stucchi et al., 2011), according to the formulation proposed by Allen and Wald (2007):

$$PGV = (386.4 \cdot S_A) / (2\pi \cdot 1.65) \quad (8)$$

4. Results

The MILP multi-objective problem was implemented in GAMS software and optimized through CPLEX solver (maximum optimality gap < 3.9 % and solution time < 2 hours). Results exhibit a clear trade-off between the two objectives (Table 1 and Figure 1), with the cheapest configuration (64.7 €/t) being characterized by the highest value of risk (13.9 ruptures/year) (Case A).

Table 1. Results in terms of specific total costs (TC [€/t]), specific costs breakdown (TCC , TTC , TSC [€/t]), total risk (TR [ruptures/year]), optimality gap ($Opt. gap$ [%]) and solution time ($Sol. time$ [s]).

	TC	TCC	TTC	TSC	TR	$Opt. gap$	$Sol. time$
Case	[€/t]	[€/t]	[€/t]	[€/t]	[rup./y.]	[%]	[s]
A	64.7	51.8	5.7	7.2	13.9	3.87	6631
B	75.6	64.2	4.2	7.2	1.7	0.01	300
C	79.4	67.8	4.4	7.2	1.3	0.01	54

The safest infrastructure (1.3 ruptures/year) is the most expensive (79.4 €/t) (Case C). Case B represents an interesting configuration, characterized by a reasonably balanced solution between costs (75.6 €/year) and risk (1.7 ruptures/year). The costs breakdown shows the significant contribution of the capture stage, independently from the optimized case study, with specific capture costs varying from a minimum of 80.1% (Case A) up to a maximum of 85.4% (Case C) of total costs, while transport and sequestration represent an expenditure in the range of 14.6% (Case C) – 19.9% (Case A) altogether.

More detailed analysis on the capture stage reveals for Case A (best economic network) the significant contribution of cement plants and steel mills in terms of captured CO₂, being these the cheapest options implemented in this model (Figure 1a). As for refineries, these are generally not employed as CO₂ sources, except for the site located in Sardinia, to which a capture plant kr_1 is installed to the steam methane reformer to exploit the beneficial effect on costs of this particularly large emitter. On the other hand, Case A makes extensive use of transportation arcs crossing areas with high values of spectral acceleration, with negative consequences on the performance of this network in terms of seismic risk results. Differently, the risk-oriented optimization takes advantage of the lack of seismicity in the Sardinian area by installing full-scale capture plants at its refinery, which determines the substantial increase in capture costs of Case C (Figure 1c). However, this increase in costs can be limited if considering Case B, which still takes advantage of the non-seismicity of the Sardinian area for safely transporting significant amounts of CO₂, but nonetheless suggests some minor modifications to the captured and transported flowrates to optimize the costs of these two stages (Figure 1b).

A sensitivity analysis on the minimum carbon reduction, which is set as lower bound for CO₂ capture (here varied between 20% and 80% of Italian emissions from industry, against the 50% target already discussed as base case) reveals a minimum specific cost (Case A) ranging between 59.0 €/t for a 20% capture target (-9.0% over base case) and 80.7 €/t for a 80% capture target (+24.5 % over base case). The cost increases alongside the capture target due to the necessity of exploiting progressively more expensive CO₂ sources and more complex transport infrastructures. Oppositely, the best networks in terms of risk minimization show a total risk varying between 0.1 ruptures/year for a 20 % capture target (-88.6% over base case) and a significant 9.9 ruptures/year for a 80% capture target (+675.8% over base case), the latter due to the vast network of pipelines that is needed to achieve such a challenging reduction target. Summarizing, the safest networks entail an increase in costs of +64.4% (20% capture target), +22.5% (50% capture target) and +0.7% (80% capture target) with respect to their respective best economic results.

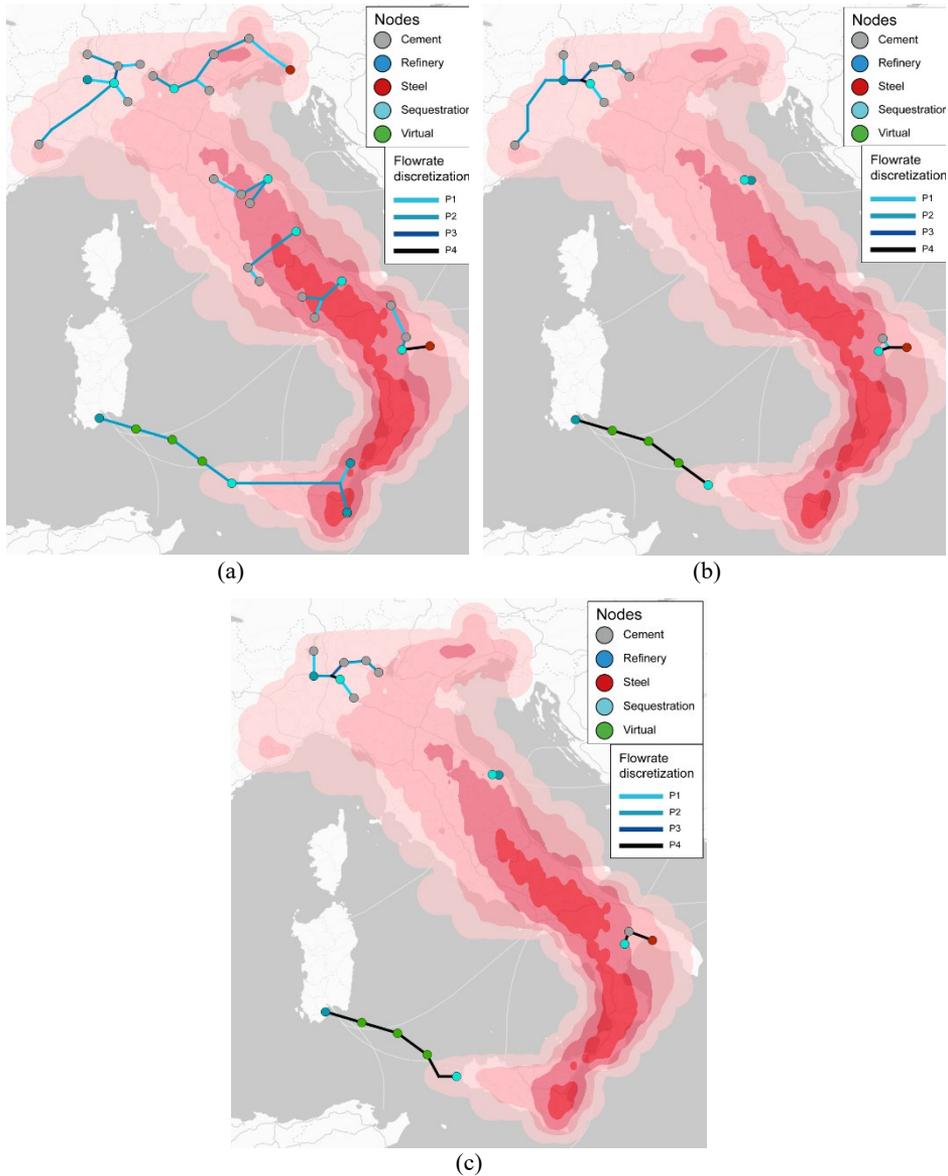

Figure 1. CCS chain configurations for (a) Case A (minimum cost), (b) Case B (trade-off result), and (c) (minimum risk).

5. Conclusions

A nationwide multi-objective carbon capture and storage chain was here optimized through a mixed integer linear programming framework for the context of decarbonizing the Italian industry. The model aimed at minimizing both the total cost (economic objective) and the total seismic risk (risk objective). Depending on the chosen carbon reduction target, the best networks in terms of economic result entailed a total cost of 59.0 €/t (20 % capture target), 64.7 €/t (50 % capture target), and 80.7 €/t (80% capture target). The minimization of risk determined an increase in costs in all analyzed cases due to the

necessity of diverting the transport infrastructure towards areas with low seismic activity and resulted equal to 97.0 €/t for 20% capture target (+64.4% with respect to best economic network), 79.4 €/t for 50% capture target (+22.5%) and 81.3 €/t for 80% capture target (+0.7%). Trade-off configurations were identified that could allow achieving an optimal balance between the two conflicting objectives hence simultaneously reducing costs and minimizing the exposure towards seismic risk.

Abstract

Food, energy and water resources are heavily interconnected in many process systems and therefore need to be taken into consideration holistically for sustainable decision-making, via a systematic food-energy-water nexus (FEWN) framework. A FEWN study represents a promising decision-making support for regions characterized by scarce water resources, abundant renewable energy resources and significant population growth, as it tackles these different challenges simultaneously while taking into account the effect of each solution strategy on the resource systems at different scales. In this work, we investigate the impact of a FEWN strategy on small-scale farming within agricultural activities. Varying water demands are evaluated on the basis of renewable, and non-renewable based energy sources, along with varying water sources. To this end, a greenhouse connected to a reverse osmosis desalination plant is modeled as a mixed-integer non-linear optimization problem and optimized for an array of objectives to enable a cost-comparison on the basis of water scarcity. The decision-making tool is then extended towards energy-water scheduling decisions for the optimization of agricultural scenario planning.

Keywords: food-energy-water nexus, irrigation planning, energy-water scheduling, mixed-integer optimization.

1. Introduction

Due to a rising global population, rapid urbanization, expanding international trade, cultural and technological changes, diversifying diets, and economic growth the demand for food, energy and water are ever-increasing. It is estimated that by 2070 the global energy consumption will be at least doubled, whereas the global food production already has to be doubled by 2050. The water demand on the other hand is prognosticated to increase between 20% and 30% by 2050. To tackle these challenges sustainably, one has to consider food, energy and water as interconnected resources and model these holistically, which is summarized in the so called food-energy-water nexus (FEWN) (Nie et al., 2019). The necessity of FEWN solution generation is underlined by the following: Agriculture is the world's largest fresh water consumer and around 30% of the energy used globally is expended on food production and supply. Additionally, 90% of the global

power generation is water intensive. Therefore, it is essential to tackle challenges regarding these resources not as isolated problems but rather as interconnected systems, where solution strategies of one resource system influence the other two.

Especially for arid and semi-arid regions like Qatar where water is scarce, renewable energies are plentiful available, the country's food supply relies heavily on imports and the majority of vegetables can only be produced during a limited period of time due to harsh climate conditions, sustainable solution generation has to take into account food, energy and water as interconnected resource systems. Consequently, fully climatized greenhouses using available renewable energies and saline groundwater sources for agricultural applications can overcome these challenges by enabling yearround farming and therefore food supply. Subsequently, this work tackles the analysis and optimization of the energy consumption of a greenhouse connected to a reverse osmosis (RO) system for water purification. The goal is to enable qualitative and quantitative comparisons of varying greenhouse energy-water-food set-ups.

Energy-water systems for agricultural applications have already been investigated in the literature. Li et al. (2021) used a generic optimization approach of agricultural benefit and non-point pollution considering crop and livestock farming policies for distinct regions. Further, Lee et al. (2020) performed a country wide investigation of irrigation management regarding the impact of climate change on productivity, irrigation requirement and energy input of a representative crop. In these cases the focus of the work was set on region or country wide solutions for an agricultural sector based on energy-water systems. Work has also already been performed for interconnected greenhouse farming and RO systems. Rahimi et al. (2021) for example conducted region- and crop-specific techno-economic studies of nexus systems. In addition, detailed RO system modeling is often disregarded, especially when various farming scenarios are to be evaluated (Sadeghi et al. (2020)).

In this work, we introduce a generic framework to link water and energy supply systems for greenhouse farming. For the supply systems, detailed mathematical models are defined in which an array of possible objectives are considered for food-energy-water nexus trade-off analysis (Avraamidou et al., 2018), including cost and water utilization. Section 2 provides an overview of the framework. Section 3 describes the mathematical model for each subsystem, while Section 4 applies the framework to a Qatar based greenhouse case study.

2. FEWN Framework Overview

The framework integrates decisions regarding the energy supply in terms of renewable energy resources, the RO desalination system to supply purified water and the greenhouse farming as the agricultural application. The idea is to use the framework to minimize the overall energy consumption of the system while fulfilling various irrigation scenarios. Further, the model can also be applied to energy-water planning and scheduling decisions for multi-period greenhouse farming.

Thus, the framework consists of a water supply system, energy supply system and farming system, which altogether build an energy-water analysis tool for agricultural planning. These key components, as well as their interactions are illustrated in Figure 1.

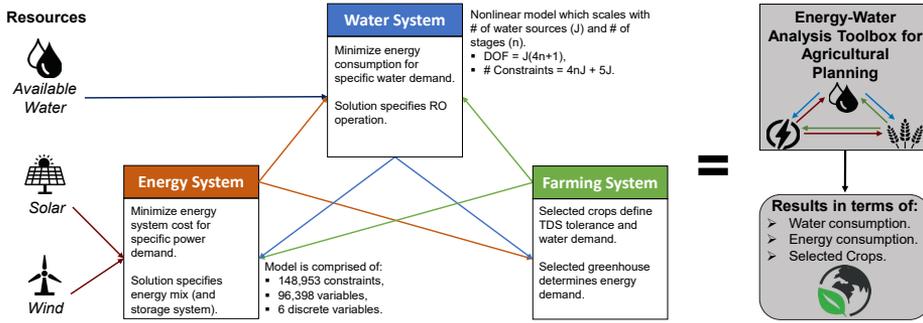

Figure 1: Visualization of the FEWN framework, the interconnected resource systems and their interactions.

3. Mathematical Modeling

The farming system determines the necessary water generation ($\frac{m^3}{day}$), the TDS constraint ($\frac{mg}{L}$), as well as the energy required to operate the greenhouse. For tomatoes for example the RO permeate concentration should not be higher than $1920 \frac{mg}{L}$ (or $3 \frac{mS}{cm}$). The daily irrigation requirement can be derived as specified in Eq. (1) or based on the average yearly water demand of the specified crop type in the respective farming environment. Regarding the required energy for the greenhouse operation the daily electricity consumption over a ten month period of a fully closed pilot greenhouse study in Qatar conducted by Hassad Food, Qatar Fertiliser Company and Yara International ASA is consulted (see section 4). Thus, the framework requires greenhouse specific information, i.e. the necessary energy for successful operation (kWh), and crop specific information, i.e. the TDS tolerance and the water demand.

$$Q_{sum}(\frac{L}{day}) \geq \frac{Yield(\frac{kg}{m^2}) \cdot Area(m^2) \cdot Water Used(\frac{L}{kg})}{Days of Operation} \quad (1)$$

The water supply system is based on the detailed mathematical RO desalination model as defined by Di Martino et al. (2021). The model optimizes for an array of objectives the necessary pressurization, the water recovery, the membrane surface area and the parallel flows for each stage and available water source, as well as the feed flow for each available water source. The employed model is nonlinear and scales with the number of water sources (J), as well as number of RO stages under investigation n , resulting in $J \cdot (4 \cdot n + 1)$ degrees of freedom, together with $4 \cdot n \cdot J + 5 \cdot J$ number of constraints. In this case the system design, i.e. number of stages and operational parameters, are based on the irrigation requirements of the crops under investigation. The key points of the selected water supply model are that a detailed mathematical model is employed which incorporates constraints based on the crops selection to minimize the system's energy consumption by adjusting the operational parameters of the RO process.

The overall energy demand is driven by the RO and greenhouse system. To fulfill the specified demands a combined mixed-integer linear model (MILP) is consulted to determine the optimal mix of solar panels and wind turbines based on supplied renewable energy data as described by Cook et al. (2022). The overall energy supply tool is summarized in Figure 2 and is comprised of 148,953 constraints, 96,398 variables, together with 6 discrete variables for a one year time horizon. The combined model determines a cost optimal energy and storage system to satisfy a

specified power demand over a predefined time horizon based on detailed mathematical modeling. To this end, solar direct normal irradiance (DNI) and wind speeds are preprocessed to obtain correlations of the total annualized cost vs. the desired power output for fixed angle and single axis tracking solar panels, as well as for wind turbines. On the basis of these surrogates together with the supplied climate data, the combined MILP model determines how the energy demand will be fulfilled. For the study conducted here, biomass as a possible energy resource has been disregarded.

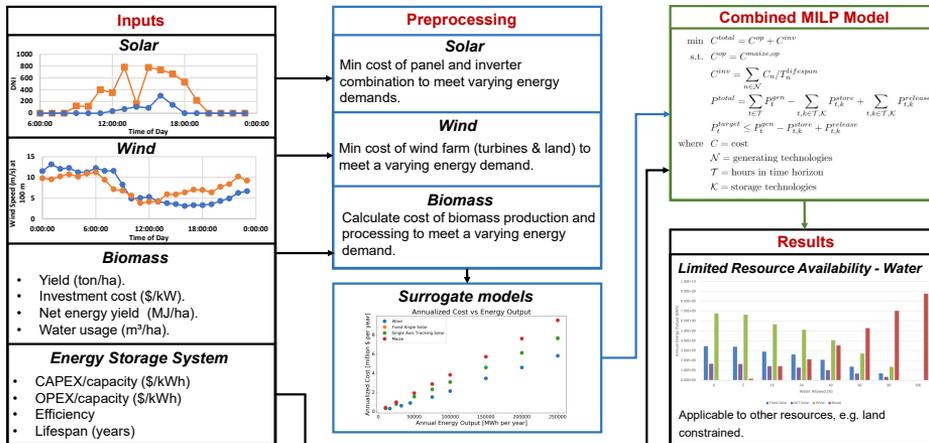

Figure 2: FEWN framework - The energy system.

Overall, this results in a mixed-integer programming model which can minimize the total system costs, the used energy and maximize the water usage for a specified energy-water-food mix and predefined time horizon, i.e. one year. Therefore, trade-offs and synergies between water and energy supply systems can be evaluated. Furthermore, by updating employed constraints, i.e. producing more water in the RO system, the overall optimization model can be modified according to the ϵ -constraint method enabling multi-objective optimization.

4. Case Study

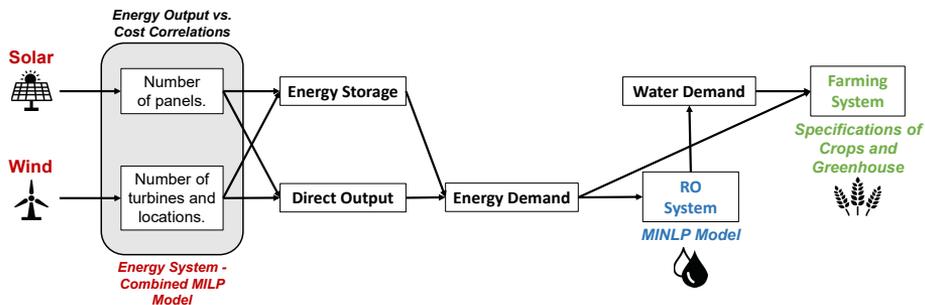

Figure 3: Simplified FEWN framework superstructure - Key features.

To illustrate the capabilities of the derived tool, we applied the simplified FEWN superstructure

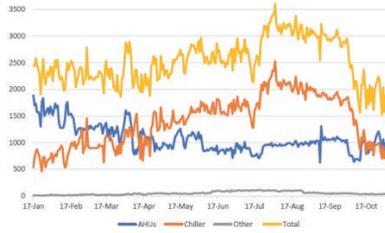

Figure 4: Daily consumption of electricity by components of the system, $\frac{kWh}{day}$, Qatar greenhouse trial 2020 (AHUs - Air handling units).

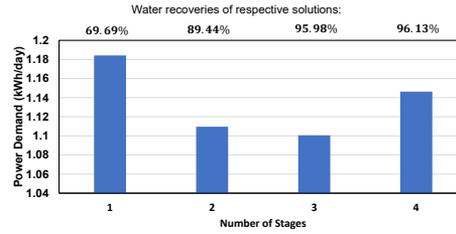

Figure 5: Comparison of results of RO operation optimization for minimizing energy consumption for different number of RO stages.

as shown in Figure 3 to a glass greenhouse using traditional farming practices to farm tomatoes ($C_p \leq 1900 \frac{mg}{L}$) on a $800 m^2$ farming area. Using the specified annualized yield of the previously mentioned pilot greenhouse in Qatar together with the specification of how much water per kg of produced tomatoes was used results in a constant daily water demand of $5 \frac{m^3}{day}$. The energy consumption of the greenhouse is assumed to be the same as the data provided in Figure 4.

Furthermore, it is assumed that only brackish water with a TDS concentration of $2560 \frac{mg}{L}$ is available. Additionally, the water recovery of the RO system is restricted to be at least 60%. The energy supply system has to provide energy for the RO process, as well as for the greenhouse farming system. The solar DNI and wind speed data have been obtained from the National Renewable Energy Laboratory (NREL). Moreover, the time horizon of this study has been fixed to one year. These specifications result in a three stage RO system in which the concentrate of a previous stage is used as the feed of a successive stage with an overall permeate output of $Q_{P,SUM} = 5 \frac{m^3}{day}$, an overall permeate concentration of $C_{P,SUM} = 1899 \frac{mg}{L}$ and a system water recovery of $WR = 95.98\%$ with a minimum overall energy requirement of the system of $1.1 \frac{kWh}{day}$ or $0.22 \frac{kWh}{m^3}$. The detailed results and operational parameters for each stage are summarized in Table 1. Further, in Figure 5 the results of minimizing the energy of the system for changing number of stages together with the respective water recoveries is shown. It can be deduced that indeed a three-stage system results in the lowest energy consumption closely followed by a two-stage process. One and four stages require the highest energy consumptions. In all cases the water recovery is comparably high, especially compared to the enforced lower bound water recovery restriction of 60%. After further analysis, i.e. minimizing the energy for step-wise increases of a newly introduced feed flow restriction while the energy requirement and water recovery of the system are monitored, it can be deduced that for this scenario the lowest possible feed flow is most advantageous for the energy consumption of the system, which results in high water recoveries. It is suggested that the energy for pressurization throughout the system is reduced by reducing the feed volume flow which offsets the possible energy recovery after the last stage.

Table 1: Results of RO operation optimization for minimizing energy consumption. m - parallel flows per stage.

Stage	$Q_f [m^3/d]$	$C_f [mg/L]$	$P [bar]$	$WR [%]$	$C_p [mg/L]$	$C_r [mg/L]$	m
Stage 1	5.21	2560	5	70.00	1392	5284	1
Stage 2	1.56	5284	5	62.99	2532	9968	1
Stage 3	0.58	9968	5	63.76	5221	18320	3

Based on the energy requirements of the RO system and the greenhouse, the energy supply system has to fulfill an overall power demand of $0.7 \cdot 10^6 \frac{kWh}{year}$ or alternatively an average demand of $80kW$. The results of minimizing the system's cost for these two cases are summarized in Table 2. In all cases only solar power as a generating technology is selected. Further, the first case does not require an energy storage system, whereas the second case requires a storage system with a capacity of $20300kWh$ and power rating of $530kW$. These evaluated cases underline the possible scenario analyses of the energy supply system, as well as the influence of renewable energy availability, together with the importance of the correct sizing of the energy generating technologies.

Table 2: Results of energy supply optimization for minimizing the total system cost to satisfy varying power demands. FA - Fixed angle solar panels, SAT - Single axis tracking solar panels.

Power demand	Power Output FA	Power Output SAT	Total Area	Cost
$0.7 \cdot 10^6 \frac{kWh}{year}$	$700000 \frac{kWh}{year}$	$0 \frac{kWh}{year}$	1.4 ha	$165500 \frac{\$}{year}$
$80kW$	$760250 \frac{kWh}{year}$	$99470 \frac{kWh}{year}$	1.72 ha	$284890 \frac{\$}{year}$

5. Conclusion

An energy-water decision tool for food production has been presented. The generic model has been applied to a greenhouse case study in Qatar. For this case the cost and energy optimal energy and water supply system has been determined for tomato farming. Future work will focus on extending the framework to (i) dynamic planning of irrigation schedules considering dynamic RO production schedules based on seasonality, and (ii) detailed greenhouse modeling to analyze and compare farming systems for varying agricultural scenarios.

Abstract

Increasing demands and climate change are critical challenges to ensure water, energy, and food security. The water-energy-food nexus requires integrating tools to guide the allocation of resources and promote sustainability. This work presents a mathematical formulation for the optimal design and management of resources to enhance the water-energy-food nexus security. Resource security is measured through indicators related to the availability, access, and sustainability of the water, energy, and food sectors. Furthermore, the problem was analyzed under different allocation schemes (social welfare, Rawlsian, Nash, and Rawlsian-Nash) to maximize resource security and obtain the optimal design of the system. To show the applicability of the model, a Mexican state evaluated by regions was selected as a case study. Results show that through this approach, it is possible to increase 14%, 44%, and 15% the security of the water, energy, and food sectors, respectively, and 25% security of the water-energy-food nexus in the addressed case study. The proposed framework can be applied to any region with the corresponding data.

Keywords: Resource security; Allocation schemes; Sustainability; Optimization; Water-energy-food nexus.

1. Introduction

The water-energy-food (WEF) nexus introduced in the Bonn Conference (Hoff, 2011) has become a relevant topic to promote the study of synergies in the water, energy, and food sectors to achieve sustainable development. In the last years, growing resource demands and limited access and availability of resources have caused increasing concern about water, energy, and food security. Due to the multidimensional nature of the WEF nexus, decision-making methods have been used to address the challenges that the nexus faces and new approaches have been proposed to enhance the synergies between resources and face climate change events and globalization using quantitative analysis methods (Zhang et al., 2018; Radini et al., 2021). In this context, optimization models have been proposed for the sustainable design for resource management, the planning of the WEF nexus involving multiple objectives in conflict, and the performance of the WEF nexus when policies are incorporated (Ogbolumani and Nwulu, 2021; Chamas et al., 2021; Sušnik et al., 2021). However, despite the progress made towards the WEF nexus, there is still a relative lack of methods that allow quantifying, optimizing, and evaluating the nexus security in the planning and design of a WEF system.

It has been highlighted that a driving factor to achieve long-term sustainability is the security of the WEF nexus, therefore, the planning, distribution, and resource management policy should be improved. The allocation of resources is one of the main concerns in social planning. Typically, when optimization models are solved, resources allocation is guided by the maximization of the sum of the player's utilities or objectives in interest. However, it has been proved that solving problems based on this approach may lead to non-unique solutions since different allocations of resources can give the same total utility of the system (Sampat and Zavala, 2019). Therefore, some allocation or distribution schemes have been reported and have been associated with fairness measures. Through these distribution schemes, it is possible to solve the problem through different perspectives and find solutions that capture the scales of stakeholders or objectives in interest and that are unique. Nonetheless, fairness measures related to allocation schemes in integrated WEF systems have not been addressed. Therefore, the novelty of this work is the development of a model formulation for the integration of the WEF nexus involving indicators to measure the WEF security nexus, where the optimal distribution of resources is evaluated through different allocation schemes.

2. Problem statement

Water-energy-food nexus security has been threatened by climate change impacts and increasing resource demands. Allocation and distribution of resources are important factors in the decision-making for planning WEF nexus systems. In this context, several efforts have been made to explore synergies between resources and improve the management of these sectors. However, there are required tools to quantify resource security involving the optimal resource allocation to improve WEF nexus security and achieve sustainable development. In this sense, this work presents a mathematical model of a macroscopic water-energy-food nexus integration for a set of regions that involves water, energy, and food availability, accessibility, and sustainability indicators to quantify the WEF nexus security. The developed model is based on the superstructure (see Figure 1) that indicates the possible alternatives to integrate water, energy, and food resources.

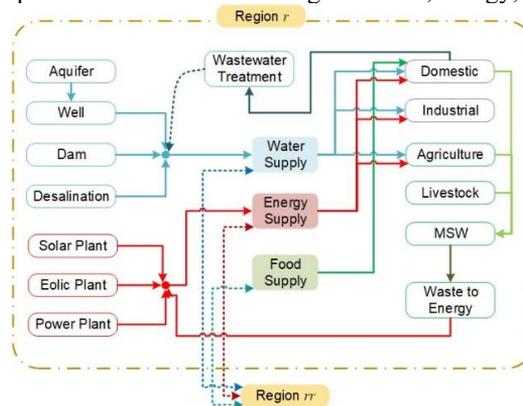

Figure 1. General Superstructure.

3. Water- energy-food nexus optimization framework

The mathematical model is composed of material balances and constraints to determine the existence of the technologies proposed in the superstructure in order to integrate the resources properly. Security indices related to water (I^{Water}), energy (I^{Energy}) and food (I^{Food}) are included, and they are based on availability ($I^{Availability}$), accessibility ($I^{Accessibility}$)

and sustainability ($I_{Sustainability}$) of resources. The average of these indicators equals the WEF nexus security index (I^{WEF}) which is maximized according to different allocation schemes.

3.1. Objective functions: Allocation schemes

A suitable way to generate solutions that can help decision-making and address a deemed fair resource distribution is through the implementation of allocation schemes (social welfare (SW), Rawlsian (R), Rawlsian Nash (RW-N), and Nash (N)).

The social welfare scheme is commonly used to allocate resources by maximizing the sum of the utilities of stakeholders (Equation 1). However, solutions including multiple allocations of resources could be found since this scheme may provide non-unique solutions, and thus, this method causes ambiguity. Furthermore, it cannot capture the scales of the stakeholders involved in the problem. For purposes of this work, a new function to solve the social welfare scheme is introduced, which consists in maximizing the sum of the water, energy, and food security indexes:

$$\phi^{sw} = I^{water} + I^{energy} + I^{food} \quad (1)$$

The Rawlsian scheme is an alternative to allocate resources; the principle of this scheme is to maximize the smallest utility of the stakeholders. One of the disadvantages of the Rawlsian scheme is that it does not capture scales properly; therefore, large stakeholders may be ignored. The formulation of the Rawlsian scheme for this problem consists in including a new variable (Θ) that is minimized:

$$\phi^{rw} = \Theta \quad (2)$$

$$-I^{water} \leq \Theta \quad (3)$$

$$-I^{energy} \leq \Theta \quad (4)$$

$$-I^{food} \leq \Theta \quad (5)$$

In the Nash scheme, it is possible to capture the scales of the stakeholders since a logarithm function is used. The Nash allocation generates a unique solution that is obtained by maximizing the sum of the logarithms of the water, energy, and food security indexes.

$$\phi^n = \ln(I^{water}) + \ln(I^{energy}) + \ln(I^{food}) \quad (6)$$

Finally, a combination of the Rawlsian and Nash schemes is included. The formulation of this scheme is similar to the Rawlsian scheme, but in this case, the constraints are modified to include the logarithm function, and another one is included to represent the Nash scheme:

$$\phi^{rw-n} = \Theta \quad (7)$$

$$-\ln(I^{water}) \leq \Theta \quad (8)$$

$$-\ln(I^{energy}) \leq \Theta \quad (9)$$

$$-\ln(I^{food}) \leq \Theta \quad (10)$$

$$-\left(\ln(I^{water}) + \ln(I^{energy}) + \ln(I^{food})\right) \leq \Theta \quad (11)$$

4. Case study

The Mexican state of Sonora was selected as a case study to demonstrate the applicability of the model. Sonora has been one of the most important economic entities in Mexico because it has a diversity of natural resources that facilitate the development of economic activities such as agriculture, livestock, fishing, mining, and services. Nevertheless, the

availability and distribution of resources in Sonora are unequal due to its geographical and hydrological conditions. The northern of the state is covered by the Sonoran Desert, which is the hottest desert in the country, while the south of the state has potential for agriculture activities. However, providing access to water for the different economic sectors represents a great challenge. Furthermore, considering that Sonora has potential for renewable energy, the design of an integrated WEF system is addressed to increase the security of the WEF.

In this work, the Sonora state was divided into four representative regions to evaluate the security of the WEF Nexus; the border region (R1), center region (R2), central-mountain range region (R3), and southern region (R4). **Table 1** presents the water, energy, and food indices associated with the availability, accessibility, and sustainability of resources to date. Currently, the central-mountain range region (R3) presents the lowest water availability, while the center region (R2) presents the highest water availability of the state; therefore, water from R2 is used to help satisfy water requirements in the near regions. On the other hand, it is shown that energy production is centered in R2, and R3 exhibits the lower energy production of the state.

Table 1. Current water-energy-food nexus security indices.

	Water			Energy			Food		
	$I^W_{Availability}$	$I^W_{Accessibility}$	$I^W_{Sustainability}$	$I^E_{Availability}$	$I^E_{Accessibility}$	$I^E_{Sustainability}$	$I^F_{Availability}$		
R1	0.465	0.981	0.465	0.400	0.988	0.400	0.751	I^{Water}	0.836
R2	2.494	0.991	1.000	2.171	0.978	2.171	0.751	I^{Energy}	0.814
R3	0.030	0.971	0.030	0.140	0.980	0.140	0.751	I^{Food}	0.751
R4	0.823	0.958	0.823	0.215	0.970	0.215	0.751	I^{WEF}	0.800

The Sonora's regions present unequal distribution of resources availability and production. It can be seen that R2 presents the highest water and energy production, which is associated with its industrialized nature. On the other hand, R3 corresponds to the least urbanized region of the state, therefore, technologies for energy production are not abundant. In addition, it is important to mention that this region does not have access to the sea, and the existence of desalination plants that increase the water production in the region is not an option. R2 has the highest availability, accessibility, and sustainability indicators of the regions of the state. Nevertheless, it is important to notice that the potential of Sonora for renewable energy can be exploited, and increasing the renewable energy capacity could improve security in the energy sector. In the same way, water reuse and irrigation techniques could enhance the security of the WEF substantially.

5. Results

The mathematical formulation for the analyzed fair allocation schemes was implemented in the software GAMS. The models of the schemes correspond to a Mixed Integer Linear Programming Model (MINLP) and were solved using the solver LINDOGlobal. **Table 2** shows the costs, freshwater consumption, and GHGE generated in the different allocation schemes. The social welfare scheme presents the lowest GHGE generation, but also it is the scheme with the highest costs and freshwater consumption. On the other hand, the Rawlsian scheme presents the lowest cost for the system and the lowest freshwater abstraction.

Table 2. Economic and environmental aspects of the allocation schemes.

	Social welfare	Rawlsian	Nash	Rawlsian-Nash
--	----------------	----------	------	---------------

WATER (hm³)	6,135.56	5,471.93	5,363.63	5,511.55
COST (MMUSD)	27,212.2	26,768.6	27,104.6	26,948.1
GHGE x 10³ (Ton CO₂)	20.864	24.103	20.95	24.523

The results of the security index for water, energy, and food for the social welfare, Rawlsian, Nash, and Rawlsian-Nash schemes are presented in **Table 3**.

Table 3. WEF Security Index for the schemes analyzed.

	Social welfare	Rawlsian	Nash	Rawlsian-Nash
I^{Water}	0.957	0.870	0.853	0.869
I^{Energy}	1.177	0.886	1.164	1.157
I^{Food}	0.869	0.870	0.825	0.869
I^{WEF}	1.001	0.875	0.947	0.965
Water				
$I^W_{Availability}$	1.086	0.839	0.774	0.831
$I^W_{Accessibility}$	1	1	1	1
$I^W_{Sustainability}$	0.784	0.772	0.784	0.775
Energy				
$I^E_{Availability}$	1.383	0.942	1.364	1.353
$I^E_{Accessibility}$	0.987	0.974	0.987	0.987
$I^E_{Sustainability}$	1.16	0.741	1.141	0.775
Food				
$I^F_{Availability}$	0.757	0.761	0.674	0.757
$I^F_{Accessibility}$	1	1	1	1
$I^F_{Sustainability}$	0.849	0.849	0.802	0.849

The results obtained in the social welfare scheme present the highest WEF Security Index (1.001) compared with the other schemes. The water, energy, and food security indexes were higher than those of the other schemes. In the case of the water sector, the availability index was approximately 29% higher than in the other schemes, this is mainly attributed to the water production in R2, which exceeds the demand and can be exported to other regions of the state to cover the water requirements. Similarly, in the case of the energy sector, the security index is also the highest in comparison with the other schemes, energy production in R2 is 3.33 times the energy demand in the region, and it is exported to other regions to cover their energy demands. In this scheme, even the availability of energy exceeds the demand of the region, the model determines that the energy is distributed to other regions without access to energy rather than to provide access to all the population in R2. On the other hand, in the food sector, a value of 1 was obtained for the food accessibility index, which indicates that all population has access to a balanced diet where food is supplied by the associated region and by the imported food.

The results of the system design for the Rawlsian scheme show a WEF security index of 0.875, which corresponds to the lowest security index resulting from the evaluated schemes. This is mainly attributed to security in the energy sector, which is around 30% lower than the energy security index of the other schemes. Specifically, energy production in region 2 (R2) is equivalent to 2 times the demanded energy in the region, while for the other schemes the energy production capacity was 3.33 times the energy consumed. The WEF security index in the Rawlsian-Nash scheme is equal to 0.965, and it is 3% lower than the WEF security index resulting from the social welfare scheme. However, it is important to mention that it is possible to obtain a unique solution by using the Rawlsian-Nash formulation, unlike the social welfare scheme. For the Nash scheme, the accessibility to water, energy, and food is completely covered for all the population as in the social welfare scheme. In the water sector, it is observed that R2 does not produce

more water than the demand in the region, therefore, there are no internal water imports between the regions.

6. Conclusions

This paper has presented a water-energy-food optimization framework to maximize the security of the nexus considering different allocation schemes, which supports the decision-making for better management of resources and performance of the sectors. As a case study, regions of the state of Sonora from Mexico were used to implement the proposed framework. By the application of the proposed approach, and comparing the results with the current water-energy-food nexus security indices, results show an increase in the security index of the water sector of 14%, 44% of the energy sector, and 15% of the food sector. This gives an increment of 25% in the WEF security index. Results for the design of the Rawlsian scheme present the lowest costs (\$26,768.6 MMUSD) and the lowest freshwater consumption (5471.93 hm³) among the different allocation schemes. Moreover, this scheme presents the lowest WEF security index of 0.875. On the other hand, the social welfare scheme presents a WEF security index of 1.001, in addition, its design presents the lower GHGE (20,864 ton CO₂) but the highest freshwater abstraction (6135.56 hm³) and costs (6,135.56 MMUSD). The main contribution of the proposed framework is the development of a model that provides the optimal allocation of water, energy, and food and quantifies and maximizes the security of the water, energy, and food sectors. The proposed water-energy-food nexus framework can be applied to any region at any scale with the corresponding data. However, its main limitation is the uncertainty related to the lack of time dimension.

Abstract

In this study, we are tackling systems design with assessments for emerging technologies. Because of the data limitation on the systems and processes adopting emerging technologies, computer-aided process engineering (CAPE) tools such as process design heuristics, process simulation, optimization, parametric analysis for characterizing sensitivity and alternative generation, and decision making with uncertainties have huge potential to compensate such data limitation and jump up to the deep technology assessments with quantified results. In this paper, we examine the applicability of CAPE tools for systems design and assessment adopting emerging technologies with a case study of recycling systems design of Lithium-ion battery (LiB).

Keywords: Spent lithium-ion batteries, Recycling, Positive electrode active materials.

1. Introduction

Recently, Lithium-ion batteries (LiBs) have been widely utilized not only for electronic devices such as mobile phones and laptops, but also for electric vehicles and stationary energy storage systems. Because this increase in LIB demand causes significant increases in demand for certain materials, i.e., lithium (Li), cobalt (Co), nickel (Ni), and manganese (Mn), it is necessary to secure these resources by recycling, as well as through mine developments. In recent years, there has been an increase in the number of case studies using prospective life cycle assessment (LCA), which take into account the future potential of the technology and aim to predict the environmental impacts on the technology under development (Arvidsson et al., 2018; Moni et al., 2020; Thonemann et al., 2020).

In this study, we are tackling systems design with assessments for emerging technologies. Because of the data limitation on the systems and processes adopting emerging technologies, computer-aided process engineering (CAPE) tools such as process design heuristics, process simulation, optimization, parametric analysis for characterizing sensitivity and alternative generation, and decision making with uncertainties have huge

potential to compensate such data limitation and jump up to the deep technology assessments with quantified results. In this paper, we examine the applicability of CAPE tools for systems design and assessment adopting emerging technologies with a case study of recycling systems design of Lithium-ion battery (LiB). The recycling of cathode particles and aluminum (Al) foil from positive electrode sheet (PE sheet) dismantled from spent LiBs was experimentally demonstrated by applying a high-voltage pulsed discharge (Tokoro et al., 2021). This separation of LIB components by pulsed discharge was examined by means of prospective LCA (Kikuchi et al., 2021). The indicators selected were life cycle greenhouse gas (LC-GHG) emissions and life cycle resource consumption potential (LC-RCP). We first completed supplementary experiments to collect redundant data under several scale-up circumstances, and then attempted to quantify the uncertainties from scaling up and progress made in battery technology. When the batch scale of pulsed discharge separation is sufficiently large, the recovery of cathode particles and Al foil from PE sheet by pulsed discharge can reduce both LC-GHG and LC-RCP, in contrast to conventional recycling with roasting processes.

2. Materials and methods

2.1. Application of CAPE tools into prospective LCA

Figure 1 shows the description of systems assessments applying CAPE tools for prospective LCA. In management activity and resource provider, data estimation and interpretations are assigned to CAPE tools considering the conditions in prospective LCA.

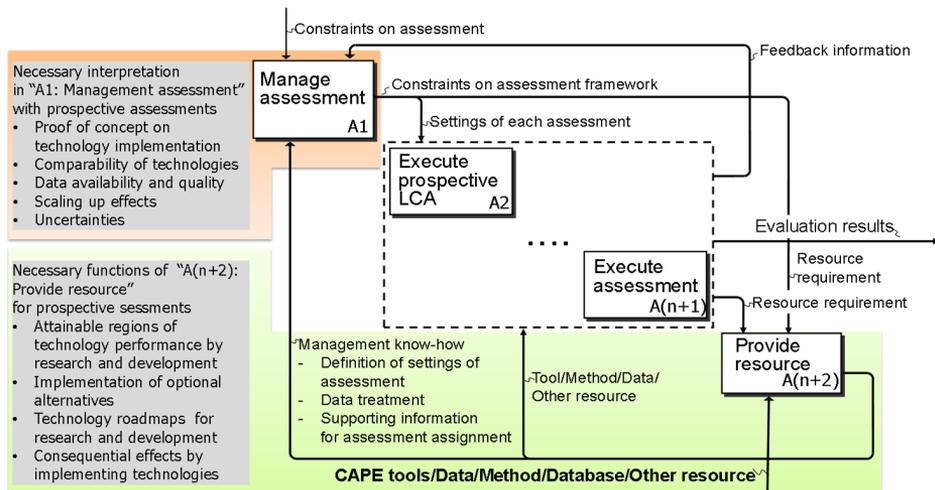

Figure 1 Description of multiple assessment activities with the necessary conditions for prospective assessments including LCA. The parameter n is the number of assessment methods. (Modified from previous studies (Kikuchi, 2014; Kikuchi et al., 2010; Kikuchi and Hirao, 2009))

Conventional LCA does not take into account changes in technology level, because it refers to information on the current technology level and specifically estimates the environmental impacts of each process related to the provision of products and services. On the other hand, efforts to tackle climate change have become more active in recent years, and new products and technologies are changing concepts and models more rapidly, making the transition to a low-emission society more urgent.

The significance of conducting a strategic LCA of emerging technologies for the 30-year time horizon up to the target year of 2050 arose regarding the issues on the climate change.

Emerging technologies, as defined by Rotolo et al. (2015), are; “innovative and rapidly growing technologies that have the potential to have a significant social and economic impact in the domains in which they are structured, with some degree of persistent coherence, actors, institutions, ways of interacting with them and related knowledge production processes. It is characterised by its potential to have significant social and economic impacts. However, its most prominent impact lies in the future and is therefore somewhat uncertain and ambiguous at the stage at which the technology emerges.” These technologies are characterized as “innovative”, “rapid growth”, “consistent”, “significant impact” and “uncertain”, which makes technology assessment difficult due to lack of existing data and knowledge.

Four main issues were identified as needing to be addressed in conducting prospective LCAs of emerging technologies (Thonemann et al., 2020; Moni et al., 2020). (1) comparability of technologies; (2) availability and quality of data; (3) scale-up challenges; and (4) uncertainty of assessment results. Process modeling and simulation are effective in estimating the missing process inventories in industrial scale production, because these technologies are under development in lab or pilot scale.

2.2. Case study: Recycling Systems Design of Lithium-Ion Battery

Figure 2 shows the life cycle model of conventional and the proposed alternative recycling systems. The dashed-line boxes are not included in the life cycle inventory analysis. (M-SO₄: metal sulfate, i.e., CoSO₄, NiSO₄, and MnSO₄; positive electrode active material (PEAM): Li(Ni_xCo_yMn_z)O₂, raw materials of positive electrode active material (rawPEAM): (Ni_xCo_yMn_z)(OH)₂, and R- (recycled-). The functional unit of this LCA was defined as the use of a positive electrode as a component of LIBs for vehicles. The LIB components assessed in this study are provided in the previous study (Kikuchi et al., 2021). The pulsed discharging process applies a novel technology to separate cathode particles, i.e., cathode black powder (Co and Ni) from Al foil (Tokoro et al., 2021). The technology readiness level (TRL) of this technology is the lab-scale demonstration, where the process inventory data required for LCA was not sufficiently obtained from the experimental demonstration considering the upscaling of throughputs of pulsed discharging. For such technology, modeling and simulation can be employed to fill the gap of foreground data (Tsoy et al., 2020). As for the prospective thinking for LIBs recycling applying the novel pulsed discharging separation process, three types of uncertainties should be addressed by the application of CAPE tools.

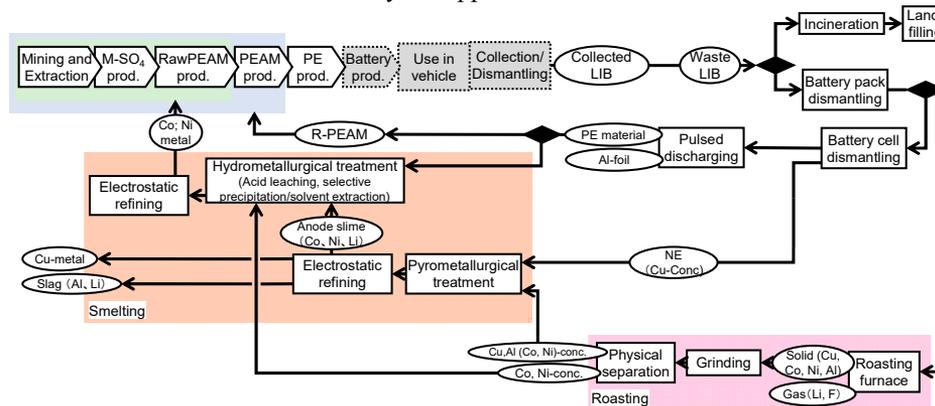

Figure 2 Life cycle model of conventional and alternative case settings to compare recycling processes for LIB and to consider the shift of elemental composition in positive electrode active materials. (Modified from the previous study (Kikuchi et al., 2021))

2.2.1. Settings on LCA

The operating ratios of precise cell dismantling and high-voltage pulsed discharge separation should be carefully examined. Because the pulsed discharge device contains high capacitance capacitors, the lifetime throughput is highly sensitive to the life cycle impacts (Kikuchi et al., 2021). The elemental composition in PEAM in LiB cathodes has changed with technological development. While PEAM of LiBs, which has been used for several years in the market, can be reused, the technology of the reused PEAM may become outdated during its period of use.

2.2.2. Application of CAPE tools

The process system combining precise cell dismantling and high-voltage pulsed discharge separation is semi-batch system. The residence times of contained unit operations were measured, and then the number of equipment items for cell dismantling and pulsed discharge was optimized. To improve the performance of the process system, the scale of pulsed discharge was re-designed and experimentally demonstrated to reduce the takt time of the treatment of unit LiB module. If the lifetime throughputs could be increased sufficiently, the environmental loads induced by the initial manufacturing of machines could become small due to the allocation of such initial environmental loads to the throughputs.

The increase of the lifetime throughputs determined by the processing scale of precise cell dismantling and pulsed discharge can reduce the environmental impact of equipment manufacturing per throughput. On the other hand, since the number of LiBs depends on the number of vehicles produced and disposed of in the market, it is not possible to determine whether the processing scale is necessarily sufficient. This could be considered by dynamic material flow analysis to forecast the future availability of spent LiBs from markets by assuming the shipments and wastes of products (Kikuchi et al., 2014; 2021).

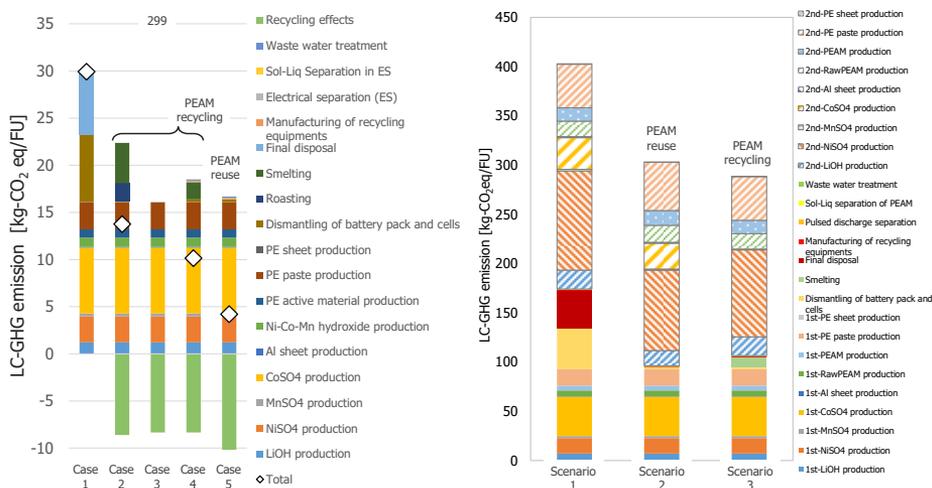

3. Results and discussions

Figure 3 shows the results of prospective LCA applying CAPE tools. The same tendencies were also observed for LC-RCP (Kikuchi et al., 2021), where (a) Results of LCA for treatment of unit amount of PE sheet, where Case 1 treats spent LiBs in incineration and land filling, Case 2 is roasting and smelting, Cases 3 and 5 are the recycling of PEAM applying pulsed discharging with low and high lifetime throughputs, respectively, and Case 4 is the reuse of PEAM applying pulsed discharging. (b) Results of LCA for scenarios with a shift in elemental composition in PEAM, where the NCM111, i.e., $\text{Li}(\text{Ni}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3})\text{O}_2$, cathode is first manufactured using 1 kg-Co in all scenarios and is then used in the LIB. In Scenario 1, all products are incinerated or landfilled (Case 1). In Scenario 2, 80% of the LIB is recovered and reused as PEAM for the NCM111 (Case 5). In Scenario 3, rawPEAM is recycled from the recovered LIB (Case 4) and PEAM of NCM811 is produced. Since the total amount of LIB capacity in each scenario is different, the capacity in Scenario 3, which has the largest storage capacity among these scenarios, is used as the reference flow of the functional unit, i.e., 4.83 kWh, and the shortage in Scenarios 1 and 2 is compensated for by newly manufactured NCM811. The storage capacities for NCM111 and NCM811 were assumed as 0.16 kWh/kg-Cathode and 0.25 kWh/kg-Cathode, respectively. As shown in Figure 3(a), lifetime throughput is an essential variable to understand the scale of the process and to design the process and to be dominant factor to the total LC-GHG. The lifetime throughput varied with the treated positive electrode sheet length at pulsed discharge, residence time of each item of equipment, and adjustment of the number of items of equipment for cell dismantling and pulsed discharge. The number of equipment items for cell dismantling and pulsed

discharge were optimized, considering the rate-determining step of their batch unit processes. This optimization is required for revealing the plausible effects of the newly implemented machines into society.

The development of the elemental composition in cathode particle resulted in the change of preferred recycling system. Fig. 3(a) shows that the reuse of PEAM had less environmental impacts than the recycling of rawPEAM. Comparing Figures 3(b), the LC-GHG of Scenario 3 were less than those of Scenario 2. This is because of the improvement of cathode capacity per Co use from NCM111 to NCM811. Even though the smaller circle recycling considered in Case 5 has less environmental impacts than the larger circle recycling in Case 4, as shown in Figure 3(a) for the same battery chemistry, the shift in elemental composition results in a different conclusion. As it is possible that the future trend of battery chemistry will be dominated by lithium nickel cobalt manganese oxide, or other battery chemistries, e.g., lithium iron phosphate, novel lithium-sulfur, or lithium-air (Xu et al., 2020), the need for lithium, nickel, cobalt, and manganese will remain for the next decades. Pulsed discharge separation can provide the option to recover such metal resources from spent LIBs. Based on the trends of battery chemistry, metal efficiency could be considered in the selection for reuse as PEAM or recycling of rawPEAM (Figure 3(b)) to meet future demand for batteries (Xu et al., 2020). Metal recycling with pulsed discharge separation can thus influence the direction of future technological developments of battery cathodes.

At present, there are more than 3,400 car dismantling plants in operation in Japan, and the scale of processing in Case 4 would be able to process about 1,000 spent LIBs per year; this would be sufficient to process about 3.4 million cars, assuming that the precise cell dismantling and pulsed discharge separation were installed in all dismantling plants. While the number of waste hybrid vehicle in Japan was estimated as from 0.11 million to less than 1 million, the uptake of low emission vehicles is promoted more and more recently as like European Union. Since the number of new vehicle registrations and sales in Japan in 2019 was about 5 million, the order of magnitude is about the same for processing.

(a) Treatment of unit amount of PE sheet

(b) Scenarios in composition in PEAM

Figure 3 Prospective assessments results on LC-GHG emission. (Modified from the previous study (Kikuchi et al., 2021))

4. Conclusion

CAPE tools can become methods applicable for acquiring data for prospective assessments. Prospective LCA should be applied into the technology assessment that employs modelling tools which focus on potential environmental impacts arising from various technologies even still at the R&D stage, i.e., low technology readiness level. With CAPE tools, the inventory data for prospective LCA can be connected with the design methods for optimizing the throughputs of unit operations, analyzing the upscaled process systems, and conducting the quantification of environmental loads with plausible process system design.

Through the case study on LiB recycling, it was demonstrated that the application of CAPE tools into prospective LCA enables the strategic technology assessments for systems design. Especially in the proof of concept on technology implementation can be verified and validated with the ranged values of uncertainties in emerging technology under development.

Abstract

To achieve sustainable development, certain objectives must be considered. A fair allocation of resources is key for long-term sustainability. Therefore, these objectives can include attaining environmental fairness and sustainability metrics. Besides considering the fair allocation of resources, equity in policies, implementation, and equality in outcomes need to be addressed. Recently, several fairness schemes have been applied as measures to allocate resources in multi-stakeholder systems. These schemes have been analyzed in different sectors, such as an agricultural system and an integrated residential complex. These studies have verified the deficiencies of certain approaches and highlighted the importance of comparing different allocation schemes. On the other hand, an economic approach to include sustainability in process integration projects has been reported recently. Here, a new sustainability metric is proposed. This metric is denominated as the Sustainability Weighted Return on Investment metric (SWROIM). The metric is based on the economic return on investment but also evaluates the contribution to sustainability. Extended forms of the metric have been proposed to include safety and resilience. In this work, we propose a fair-sustainable approach that involves applying fairness schemes along with the sustainability metric SWROIM for the optimal income allocation of an integrated system to produce fuels and simultaneously capture emissions. The analyzed schemes are the social welfare, Rawlsian welfare, and Nash approaches. The involved stakeholders in the integrated system include refineries, biorefineries, and eco-industries. To foster the reduction of emissions, we include economic compensations for the eco-industries. Furthermore, we analyze the avoided emissions (environmental function) and the generated jobs (social function) obtained through the different schemes and the sustainability metric. To demonstrate the applicability of the optimization approach, a case study for the future planning of the energy system in Mexico was presented. In the results, important differences are observed for the stakeholders' income allocation, as well as for the environmental and social functions under the schemes and the sustainability metric. These differences highlight the importance of exploring these different allocations since they can be key for decision-makers. The results also show that the Nash scheme can provide fair trade-offs among the stakeholders' income and the environmental and social functions.

Keywords: Optimization, Fairness schemes, Sustainability metric.

1. Introduction

Previous works have proposed approaches to include a fairness environment for stakeholders and an evaluation of sustainability metrics separately. Recently, fairness schemes for the allocation of resources in multi-stakeholder systems have been reported (Sampat and Zavala, 2019). These schemes have been applied to allocate resources in different systems (see for instance: Munguía-López et al., 2019). These studies have highlighted the importance of comparing different allocation schemes in diverse systems and verified some deficiencies of other approaches that may guide to solutions that are not fair. The desired aim would be to simultaneously foster equity, environmental protection, and economic growth (Rosa, 2009). However, these aspects represent a great challenge. In this regard, an economic approach to involve sustainability in process integration projects has been reported by El-Halwagi (2017). Here, sustainability is included by proposing a metric that is based on the economic return on investment but also evaluates the contribution to sustainability (SWROIM). Extended forms of the metric have been proposed to include safety and resilience (Guillen-Cuevas et al., 2018; Moreno-Sader et al., 2019). As a fair allocation of resources is key for long-term sustainability, we propose a fair-sustainable approach that includes applying the fairness schemes along with the sustainability metric SWROIM for resource allocation in complex engineering systems that include economic, environmental, and social objectives.

This work uses this fair-sustainable approach for the optimization of an integrated system to produce fuels and simultaneously capture emissions. The involved stakeholders in the integrated system include refineries, biorefineries, and eco-industries. In this approach, the eco-industries are taken as endeavors for forest plantations resulting in capturing emissions. To further foster the reduction of emissions, we include economic compensations for the eco-industries. The optimal allocation of income among these stakeholders is evaluated by using different fairness schemes (social welfare, Rawlsian welfare, and Nash approaches) and the sustainability metric SWROIM. Furthermore, the environmental and social functions (avoided emissions and generated jobs) obtained through the distinct schemes are analyzed.

2. System Description

In the proposed integrated system, there are three types of industries: refineries, biorefineries, and eco-industries. These industries are considered as the stakeholders that compete for income allocations (economic function). The integrated system includes the production of fuels and biofuels by refineries and biorefineries. Moreover, it includes the eco-industries or forest plantations that can capture part of the emissions generated by the fuels and biofuels production processes (an economic compensation for the eco-industries is involved). The avoided emissions by the eco-industries and the generated jobs by all the types of industries (environmental and social functions) are also evaluated through the analysis. Parameters such as potential locations for the industries, biomass types, availability restrictions, and climatic conditions are given. The objective of the work is to find the optimal allocations for the involved stakeholders through the fair-sustainable approach. Here, allocation schemes (social welfare, Rawlsian welfare, and Nash approaches) that have been previously used to allocate resources in a fair manner are evaluated. The sustainability metric SWROIM is also used for evaluating the allocations because it allows assessing the impacts on sustainability while considering the economic profitability. Each allocation scheme and the SWROIM metric result in different mathematical models since the objective function and some constraints vary. The schematic representation of the system is shown in Figure 1.

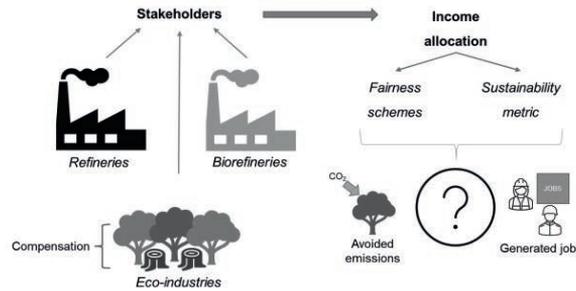

Figure 1. Schematic representation of the integrated system.

3. Model Formulation

The formulation of the proposed model includes the following steps. First, the mathematical model to describe the integrated fuel production system was developed. Here, the mass balances to represent the interactions among industries, the technical relationships to compute costs and incomes, and the disjunctions to find the optimal installation of industries were included. Also, the economic compensation for the eco-industries, the evaluation of the environmental and social impact of the system by estimating the avoided emissions and the generated jobs, and the introduction of the fairness schemes and the SWROIM metric as alternative objective functions were included. Then, the utopic solutions of the economic, environmental, and social variables were estimated. The environmental function refers to the emissions captured by the eco-industries from refineries and biorefineries ($Emcap_i^{Ref}$, $Emcap_b^{Bio}$).

$$AEM = \sum_e \left(\sum_i Emcap_{i,e}^{Ref} + \sum_b Emcap_{b,e}^{Bio} \right) \quad (1)$$

The social function in this work refers to the total generated jobs and it is defined as the sum of the number of jobs in refineries, biorefineries, and eco-industries:

$$TOTALJOBS = Jobs^{Refinery} + Jobs^{Bioref} + Jobs^{Ecoind} \quad (2)$$

The economic functions refer to the incomes of refineries, biorefineries, and eco-industries. The income of refineries and biorefineries includes the sold products and bioproducts. They are estimated considering the unitary sale cost of each product, the operating days, and the total flow rate of products and bioproducts.

$$Income^{Refinery} = \sum_i \sum_{p1} UC_{i,p1}^{p-ref} HY F_{i,p1}^{p-ref} \quad (3)$$

$$Income^{Biorefinery} = \sum_b \sum_{p2} UC_{b,p2}^{p-bio} HY F_{b,p2}^{p-bio} \quad (4)$$

The income of eco-industries depends on the captured emissions from refineries and biorefineries (see Equation (5)). Here, we can observe that the cost of the emissions generated by refineries ($CEmis_r^{Ref}$) and biorefineries ($CEmis_b^{Bio}$) is multiplied by the captured emissions by eco-industries for each type of refinery. Furthermore, the economic compensation is also included.

$$Income^{Ecoind} = \sum_e \left(\sum_i CEmis_i^{Ref} Emcap_{i,e}^{Ref} + \sum_b CEmis_b^{Bio} Emcap_{b,e}^{Bio} + Comp_e^{pl} \right) \quad (5)$$

Considering the economic functions of each stakeholder, the allocations through the fairness schemes are computed. First, the social welfare scheme is estimated by maximizing the sum of the utilities of the stakeholders as follows:

$$SW = \text{Income}^{\text{Refinery}} + \text{Income}^{\text{Bioref}} + \text{Income}^{\text{Ecoind}} \quad (6)$$

Similarly, the Nash allocation is given by maximizing the function N that corresponds to the sum of the logarithms of the utilities of the stakeholders.

$$N = \ln \text{Income}^{\text{Refinery}} + \ln \text{Income}^{\text{Bioref}} + \ln \text{Income}^{\text{Ecoind}} \quad (7)$$

Then, for the Rawlsian scheme, the objective function RW is minimized and the following constraints are included:

$$-\text{Income}^{\text{Refinery}} \leq RW \quad (8)$$

$$-\text{Income}^{\text{Bioref}} \leq RW \quad (9)$$

$$-\text{Income}^{\text{Ecoind}} \leq RW \quad (10)$$

This formulation corresponds to maximizing the smallest utility of the stakeholders. Regarding the sustainability metric SWROIM, the following objective function is maximized:

$$SWROIM = \frac{\left(\text{Income}^{\text{Refinery}} + \text{Income}^{\text{Bioref}} \right) + \text{Income}^{\text{Ecoind}} - TCI}{TCI} \left[\begin{array}{l} 1 + w^A \left(\frac{AEM}{AEM^{\text{target}}} \right) \\ + w^J \left(\frac{TOTALJOBS}{TOTALJOBS^{\text{target}}} \right) \end{array} \right] \quad (11)$$

Here, the economic, environmental, and social functions mentioned above are involved and TCI is the total capital investment.

4. Results and Discussion

To illustrate the applicability of the model, we addressed a case study of an integrated system that involves existing refineries in Mexico and potential locations for installing new refineries, biorefineries, and eco-industries (Sánchez-Bautista et al., 2017). Different biomass types for the biorefineries and availability restrictions for suppliers were included. Regarding the eco-industries, one forest plantation for each Mexican state was considered. First, Figure 2 presents the income of each stakeholder (refineries, biorefineries, and eco-industries) through the distinct schemes: SWROIM, social welfare (SW), Nash (N), Rawlsian welfare (RW), and their difference with the utopia point (UP). For the refineries, the differences between the schemes and the utopia point are minimal in percentage. However, since this income is high, a minimum difference can represent a great variation of income. The SWROIM scheme gives the closest income to the utopic solution (with 1.491E+07 USD MM/year of difference) while the Rawlsian approach attains the lowest income. This behavior occurs because the refineries' income corresponds to the greatest part of the total income. For the biorefineries, the differences in income are greater among the schemes and have the opposite behavior. The Rawlsian scheme provides a solution equal to the utopia point and the SWROIM analysis allocates no income to this stakeholder. Moreover, the social welfare scheme allocates almost half of the utopic solution, while the Nash approach allocates 14% more. The biorefineries' income is smaller than the income of the other stakeholders. Because of this, we observe that the Rawlsian approach favors this stakeholder. For the eco-industries, the SWROIM and Rawlsian schemes provide the worst solutions. However, the social welfare gives the same income as the utopia point. The Nash scheme provides a similar allocation since it attains only 12% less. The difference between these schemes is similar in percentage to their difference for the biorefineries' income, but opposite in direction. The results for the

integer decisions including the installation of new refineries, biorefineries, and eco-industries are represented in Figure 3. For the SWROIM scheme, the refineries are the only new industries that are installed (3 out of the 3 new possible refineries). For the rest of the schemes, the same number of new refineries is installed. However, in some approaches, this proportion is smaller than the proportion related to the installation of the other industries. For instance, for the social welfare and Nash schemes, the highest proportion of eco-industries is observed. Regarding the biorefineries, the possibility of installing 6 new industries of this type was considered. For the social welfare and the Rawlsian schemes, this maximum number of new biorefineries are installed.

Figure 4 shows the environmental and social functions under the distinct schemes and their difference with the utopia point. We observe that the behavior of the eco-industries' income (see Figure 2) is almost equal to the environmental and social functions. This occurs because the economic objectives of the eco-industries are not conflicting with these functions. On the contrary, they increase in the same direction since the eco-industries' income depends on the captured emissions that are the avoided emissions. The allocations for the number of generated jobs are also similar, only with a slight difference in the SWROIM and Rawlsian schemes. It should be noticed that through the SWROIM analysis no emissions are avoided. However, 30,715 jobs are generated due to the existing refineries as well as the installation of new refineries.

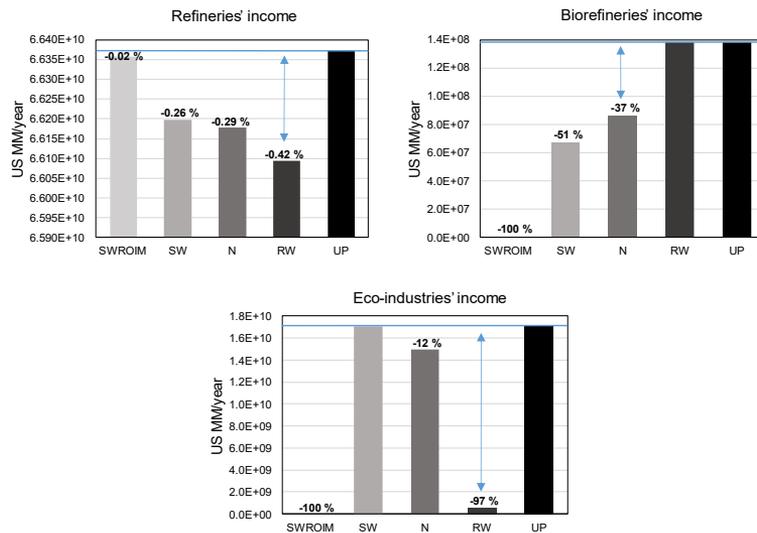

Figure 2. Refineries, biorefineries, and eco-industries income through the different schemes.

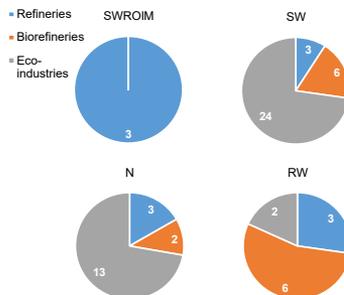

Figure 3. Proportion of the installation of new industries through the different schemes.

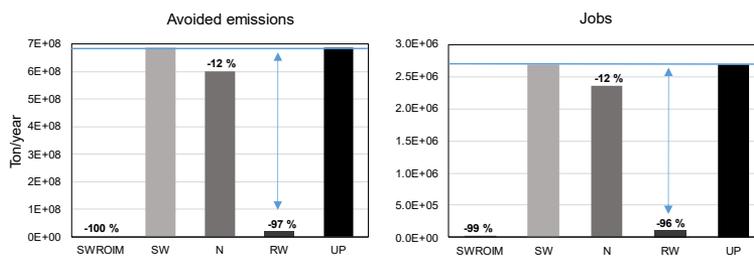

Figure 4. Avoided emissions and generated jobs through the different schemes.

5. Conclusions

This work presented an approach for the evaluation of fairness schemes (social welfare, Rawlsian welfare, and Nash approaches) and the sustainability metric SWROIM for the optimal allocation of income among different stakeholders (refineries, biorefineries, and eco-industries). The differences in incomes with each evaluated scheme highlight the importance of analyzing these possible allocations since they can be key for decision-makers. We found that certain schemes attain the utopic solution (or a value close to it) for one of the stakeholders; however, there is not a specific scheme that can provide the utopic solution for all stakeholders. Also, it was found that the SWROIM metric does not favor the environmental and social functions of the addressed system. On the contrary, this metric gives preference to the economic function and favors the stakeholder that contributes the most to the total profit. Furthermore, there is no installation of new biorefineries and eco-industries in the solution given by this scheme. Additionally, the Nash approach allows identifying trade-off solutions among the incomes of the stakeholders. Simultaneously, this allocation scheme provides trade-offs for the avoided emissions and the generated jobs. Moreover, through the Nash approach, an optimal design that allows the installation of biorefineries and eco-industries was found.

Abstract

Reducing the CO₂ emission from the power sector is one of the effective ways to mitigate global warming. Net-zero-emission power generation implies the control of not only pollutants such as NO_x, CO and organic air pollutants but also greenhouse gas CO₂. In traditional gas power plants, a huge amount of CO₂ is generated, which has to be captured to achieve the near-zero emission target. Carbon capture in the power industry is technically and economically challenging due to the energy penalty and high capital cost. CO₂ taxation among others is expected to accelerate the progress of zero-emission power plants. The concept of zero- and near-zero-emission power plants can be realized by combining advanced power cycles and carbon capture technologies. Scientists and engineers are striving hard to improve the efficiency of power cycles and decrease the cost of carbon capture. Novel systems combining carbon capture technologies and advanced power cycles are reviewed in this paper. Each country has its own roadmap and timeline to achieve the zero-emission target in power sector. Therefore, the role of the zero-emission natural gas power plants in the future energy supply depends heavily on the country. In this paper, the prospect of the zero-emission natural gas power plants in the USA, China and Denmark are analyzed.

Keywords: zero-emission, natural gas, power plants, future energy supply

1. Introduction

Global warming has become one of the most contentious scientific and technological challenges in the last two decades. Among the greenhouse gases, CO₂ is the largest contributor to global warming (NASA 2019). Reducing the CO₂ emission from power plants is one of the effective ways to limit global warming to less than 2°C. Previous attempts to capture CO₂ in power plants have decreased the efficiency of the power plant by about 10% (Fu and Gundersen 2012). Generally, carbon capture on a natural gas power plant is not economic due to the high operating cost and capital cost. However, with the increasing concern on climate change, carbon capture and storage

(CCS) is attracting more and more attention from both industry and academia. To achieve the target of the zero-emission power plant, advanced power cycles with CCS becomes the primary measure to take. There are many advanced power cycles and carbon capture technologies in power plants. In this paper, power cycles and carbon capture technologies are reviewed first. Based on this, the most promising natural gas power plants with zero- or near-zero-emission are reviewed and analyzed. The prospect of natural gas power plants in the future energy supply depends on the country. The role of natural gas power plants in the USA, China and Denmark in the near future is presented in the last section of this paper.

2. Power cycles

Commonly used power cycles in natural gas power plants are briefly reviewed. (I) Gas turbine cycle: The gas turbine cycle is the primary cycle for natural gas power plants. The high temperature and pressure flue gas expands in a gas turbine to generate electricity. The higher temperatures at the inlet of the turbine, the higher the thermal efficiency of the system (Unger and Herzog 1998). However, the materials cannot bear too high combustion temperatures in the gas turbine and thus the material is the main limitation of the gas turbine efficiency. (II) Steam Rankine cycle: Since the temperature of exhaust flue gas from the gas turbine is still very high, the steam can be generated in a heat recovery steam generator (HRSG). The generated steam can be utilized to drive a steam Rankine cycle. Therefore, the steam Rankine cycle is often integrated with the gas turbine cycle to form the well-known natural gas combined cycle (NGCC) plants. (III) Steam injection gas turbine cycle: The steam generated in the HRSG can be injected into the combustor to increase the power output of the simple gas turbine cycle (Nishida et al. 2005). The steam and air can mix at the outlet of the compressor or in the combustor and thus the thermal efficiency of a combined cycle can be improved. (IV) Allam cycle: This is a new, high-pressure, supercritical CO₂ cycle that generates electricity from fossil fuels with near-zero emissions. CO₂ is used as the working fluid rather than steam or air. All CO₂ generated by the system is produced as a high-pressure, pipeline-ready by-product. It is reported that Allam Cycle with carbon capture has a similar levelized cost of energy compared with NGCC power plants without carbon capture (Allam et al. 2014). (V) Organic Rankine cycle (ORC): ORC has been widely used for waste heat recovery (Yu et al. 2016). ORC can generate power at low-temperature or even cryogenic temperature levels. Therefore, ORC can improve the system efficiency with the recovery of low-temperature heat and LNG cold energy in a liquefied natural gas (LNG) fired power plant. (VI) Direct expansion cycle: LNG regasification process can be integrated with the power plant. In the natural gas direct expansion cycle, LNG is firstly pumped to very high pressure, then heated up to a gaseous or supercritical state, and finally expands in an expander to generate power (Franco and Casarosa 2015).

3. Carbon capture technologies

There are generally four categories of carbon capture technologies in power plants: (i) Pre-combustion carbon capture: Reforming of natural gas with oxygen produces a mixture of CO and H₂, and then the water-gas shift reaction converts CO into CO₂. Pre-combustion carbon capture refers to capturing CO₂ in a synthesis gas after the conversion of CO into CO₂. CO₂ can be separated by physical absorbent and hydrogen can be the fuel to generate electricity (Kanniche et al. 2010). (ii) Post-combustion

carbon capture: CO₂ is separated from the flue gas after the combustion. There are many different ways to separate CO₂ from flue gas, such as chemical absorption, adsorption, membrane separation and cryogenic CO₂ separation. Solvent-based absorption (MEA-CO₂ absorption) has become a benchmark for post-combustion carbon capture (Alie et al. 2005). (iii) Oxy-combustion carbon capture: Pure oxygen is employed in the combustion process. Therefore, the flue gas mainly consists of water and CO₂. Oxy-combustion provides an effective way to burn natural gas while allowing the capture of CO₂ through simple physical separation processes. The concentration of CO₂ in the flue gas can reach 80%, which is an advantage for the carbon capture process. However, an air separation unit (ASU) is required, thus both the operating cost and capital cost are higher compared with the conventional power plants. (iv) Chemical looping combustion (CLC): A metal oxide as the oxygen carrier is circulated between two interconnected fluidized bed reactors: an air reactor and a fuel reactor. CLC is similar to oxy-combustion where there is no direct contact between air and fuel. Oxygen is extracted from the air by oxygen carriers in the air reactor. The fuel is oxidized by the lattice oxygen of the metal oxide and produces CO₂ and vapor in the fuel reactor. The main advantage of chemical looping resides in the inherent separation of both CO₂ and H₂O from the flue gases. In addition, the NO_x formation is minimized since the combustion takes place in a nitrogen-free environment.

Among the above-mentioned carbon capture technologies, solvent-based chemical absorption post-combustion capture is the most popular choice because of its relatively low cost and the maturity of the technology. Pre-combustion, post-combustion and oxy-combustion carbon capture technologies are energy-intensive, resulting in a significant decrease in the overall efficiency and increase in the cost of produced electricity. CLC technology is energy efficient, but commercial scale-up of the CLC depends on the availability of the performance and stability of oxygen carriers.

4. Review of zero-emission natural gas power plant

To achieve zero- and near-zero-emission goal, both power cycles and carbon capture have to be considered simultaneously in a natural gas power plant. Bolland and Sather (1992) presented the analysis of natural gas-fired seawater cooled combined cycle power plants with CO₂ capture. 90% of CO₂ was captured by amine scrubbing. A fraction of the flue gas is recirculated back to the gas turbine compressor to reduce the volumetric flow and increase the concentration of CO₂ for the downstream CO₂ recovery plant. Shao et al. (1995) proposed a natural gas-fired power plant with virtually zero emission. The plant operates in a gas-steam turbine combined cycle with oxy-combustion mode. The liquid oxygen is used to liquefy CO₂ from the flue gas to save the compression work. Mathieu and Nihart (1999) proposed a novel MATIANT cycle, which is a gas cycle with CO₂ as the working fluid and O₂ as the oxidizer. In this system, CO₂ is compressed to very high pressure and then cooled down by cooling water and finally removed in the liquid state. The temperature of the combustion chamber is 1300 °C and the condensation temperature is 29°C at 70.5 bar. Deng et al. (2004) proposed a cogeneration power system with LNG regasification process. This system can not only generate electricity but also produce natural gas for other end users. The power system is an oxy-combustion power cycle and CO₂ in the flue gas is liquefied by LNG. Sanz et al. (2005) proposed an S-Graz Cycle to achieve the zero-emission goal of the power plant. They declared that S-Graz Cycle could be the most economical solution for CO₂ capture once the development of new turbomachinery

components is realized. Zhang and Lior (2006) proposed a quasi-combined cycle mode with a supercritical CO₂ Rankine-like cycle and a CO₂ Brayton cycle. The top Brayton cycle and the bottom supercritical CO₂ Rankine cycle are coupled. The LNG cold energy is reutilized to capture the CO₂ in the flue gas and cool down the inlet stream of compressors to save compression work. Zhang and Lior (2008) also proposed two novel systems for oxy-combustion natural gas-fired power plant integrated with steam reforming and CO₂ capture. Natural gas is converted into H₂ and CO to improve the fuel heating value and the turbine exhaust heat can be recovered by the reforming reaction. They declared that the net energy efficiency is in the range of 50–52%. Liu et al. (2009) proposed an oxy-combustion gas turbine cycle with LNG cold energy utilization, which is based on the flowsheet proposed by Deng et al. (2004). The primary difference is the integration of the LNG evaporation with the CO₂ condensation. Xiong et al. (2014) proposed a combined cycle with LNG cold energy recovery. The combined cycle consists of a gas turbine cycle and a steam Rankine cycle. LNG cold energy is utilized in ASU and CO₂ capture processes. The electrical exergy efficiency can reach 54.9% with 90.6% CO₂ recovery. Scaccabarozzi et al. (2016) performed thermodynamic analysis and optimization of Allam cycle. The maximum efficiency is 54.8% with 100% CO₂ capture. Chen et al. (2017) proposed a novel gas and steam mixture cycle. In this system, peak shaving, energy storage and CO₂ capture are considered along with power generation. Liquefied oxygen is produced during off-peak hours. The main advantage of the novel cycle is that the pressure of LNG and liquefied O₂ is increased to the combustion pressure by pumps instead of compressors, thus a huge amount of compression work is saved. Naqvi et al. (2004) proposed a chemical looping combustion natural gas power plant with CO₂ capture. The oxidation reactor outlet stream drives the gas turbine and the exhaust from the fuel reactor drives CO₂-turbine. The results show that an optimum efficiency of 49.7% can be achieved under given conditions with a CLC-combined cycle at zero emissions level.

5. The role of zero-emission natural gas power plants around the world

Each country is at a different point in the decarbonization journey. Therefore, natural gas plays different roles in decarbonization all over the world. The USA is the largest natural gas consumer in the world. Annual electricity generation from natural gas power plants in the USA increased by 31% in the Northeast region, by 20% in the Central region, and by 17% in the South region between 2015 and 2019. Natural gas power plants will continue to play an important role in the USA. Net power technology, which is a company focusing on zero-emission electricity, intends to build two natural-gas power plants in the U.S. that will have all its emissions captured and buried deep underground. Almost all new power plants built in 2021 will be carbon-free. However, for the existing natural gas power plants, revamping with carbon capture is expected to be done to achieve carbon neutrality in 2050.

China is the largest CO₂ emission country, accounting for about 30% of the world's total emission in 2013 (Friedlingstein et al. 2014). Currently, natural gas plays a relatively small role in China's power sector despite the growth in recent years. Coal remains the dominant fuel in China's power sector, but wind and solar generation have risen more rapidly than gas power. China has pledged to peak carbon dioxide emissions before 2030 and achieve carbon neutrality before 2060. China's energy consumption is dominated by coal. Natural gas will play an important and stable role in the Chinese

energy market with a share of 12% in 2030 and 11% in 2060. China has committed to increasing support for other developing countries in developing green and low-carbon energy, and not to build new coal-fired power projects abroad. Natural gas power plants are key to stable power systems in the energy transition. Natural gas is expected to be a key bridge fuel over the next two decades. China will fundamentally revamp its natural gas power plants to achieve the zero-emission target. Natural gas power plants are expected to be retrofitted with CCS by 2050 in China (Qin 2020).

As regards Denmark, the country has been playing a leading role in the carbon-neutral society. Copenhagen, the capital of Denmark, committed to becoming carbon-neutral in 2010-five years before the Paris Agreement and will become the world's first carbon-neutral capital by 2025 (Damsø et al. 2017). Denmark has set up two targets to achieve the carbon-neutral goal: year 2050 with 100% renewable energy from biomass, wind, solar and wave energy; year 2030 with 50% renewable energy, as the first important milestone on the way to carbon-neutral society (Lund and Mathiesen 2009). Currently, there are only two natural gas-fired power plants in Denmark. Towards the target of carbon neutrality, biogas will play an increasingly important role. Biogas is abundant in Denmark due to its advancement in biomass utilization (Korberg et al. 2020). Biogas can replace natural gas after upgrading. Thus with biogas as the fuel, the existing power plants do not need to be revamped with CCS. If CCS is implemented, a negative emission goal can be achieved. Natural gas power plants will be replaced by various sources of renewable energy in Denmark. In summary, natural gas power plants will be phased out in Denmark soon. The advancement of technologies in natural gas power plants seems to be of no interest to Denmark.

6. Conclusion

To combat climate change, decarbonization in the power sector is a necessity. Natural gas power plants play an important role in the power sector. The advancement of zero and near-zero-emission natural gas power plants is reviewed in this paper. Even though it is technologically viable to achieve the zero-emission target, there are more challenges in putting the concept into practice considering the cost of carbon capture. All the studies are focusing on reducing the cost for carbon capture while maintaining an acceptable thermal efficiency of the power plants. For the policymakers in different countries, zero-emission natural gas power plants play different roles on the journey to carbon neutrality depending on the country. The prospect of the zero-emission natural gas power plant in the USA, China, and Denmark are analyzed in this paper. Zero-emission natural gas power plants will still be of interest to the USA and China on the journey to carbon neutrality, while Denmark will phase out the natural gas-fired power plants in the near future.

Abstract

The criticality of climate change is such that any further delay in mitigation action would result in irreversible damage. This work develops a novel software framework for optimal decarbonisation in energy planning to determine the optimum deployment of renewable energy sources, alternative low carbon fuels, negative emission technologies (NETs) and CO₂ capture and storage (CCS). The mathematical programming-based tools in this work provide rigorous optimal solutions, subject to budget, demand, and emission constraints. The application of the software framework is demonstrated with a Malaysian energy decarbonisation case study. The results indicate a heavy reliance on NETs, alongside reductions in coal and natural gas use to achieve CO₂ neutrality by 2050.

Keywords: Multiperiod Energy Planning; Negative Emission Technologies; Process Integration; Policymaking; Decarbonisation Software

Introduction

Global leaders recently gathered at COP26 to agree on emission reduction targets. Limiting warming by 2100 to 1.5 °C is technically feasible but time is short to achieve this. An emissions cut of 45% must be achieved by year 2030 relative to 2010 (International Renewable Energy Agency, 2021) to meet the Paris Agreement targets. On a positive note, the recent plummeting costs of renewable energy sources offers hope for climate change mitigation. The challenge is to optimally deploy different decarbonisation measures to reduce emissions strategically and rapidly within economic and environmental constraints.

Sustainable energy planning via Carbon Emissions Pinch Analysis (CEPA) was pioneered by Tan and Foo (2007). Later, Tan et al. (2009) extended the CEPA approach by incorporating CCS as a decarbonisation option. The initial graphical approach was followed with the development of an automated targeting model by Lee et al. (2009), which was applied to CCS deployment by Ooi et al. (2013). The deployment of carbon dioxide removal (CDR) via negative emission technologies (NETs) was then addressed with graphical (Nair et al., 2020) and algebraic targeting tools (Nair et al., 2021). Equally, several energy planning tools e.g., MARKAL, TIMES etc. had been developed to analyse

energy and electricity systems (Ringkjøb et al., 2018). These models conduct short and long-term planning, considering the technical and economic constraints. This work develops a decision-making software framework based on mathematical programming for planning decarbonisation. A multiperiod model is used to allow progressive targets to be incorporated subject to technical and economic constraints. The novelty of this work is that it includes fuel substitution, NETs, and CCS as concurrent alternatives, along with process integration-inspired visualisation tools and detailed strategic scheduling and technology selection for a Malaysian case study.

1. Problem Statement

A superstructure mathematical programming formulation is developed to synthesise an optimal decarbonisation plan with the following specifications. For time-period $k \in K$, the CO₂ emission limit, L_k and energy demand, D_k are specified. Power plant $i \in I$ with lower, $F_{i,LB}$ and upper bound energy output, $F_{i,UB}$, and CO₂ intensity, CS_i constitute the energy planning system for period k . To meet CO₂ emissions and energy demands in period k , CCS $n \in N$ of different types can be employed at each power plant, as well as energy-producing NETs (EP-NETs) $p \in P$, energy-consuming NETs (EC-NETs) $q \in Q$ and compensatory renewable energy $c \in C$ that are considered for deployment. Additionally, alternative solid-based fuels $s \in S$ and gas-based fuels $g \in G$ are available to substitute the use of coal and natural gas respectively for power generation.

2. Mathematical Programming Formulation

Within period k , the energy outputs from all power plants $i \in I$ ($\sum_i FS_{i,k}$) must satisfy energy demands (D_k), as shown in Eq.(1).

$$\sum_i FS_{i,k} = D_k \quad \forall k \quad (1)$$

Carbon intensities of power plants with CCS technology n installed in period k ($CR_{i,n}$) are determined from Eq.(2) (Ooi et al., 2013).

$$CR_{i,n} = \frac{CS_i \times (1 - RR_n)}{1 - X_n} \quad \forall i \forall n \quad (2)$$

where RR_n and X_n are the CO₂ removal ratio and power loss associated with installing CCS.

Eq.(3) is used to calculate the net energy output from power plants with CCS retrofit (FNR). Note that there will be a reduced energy output from power plants with CCS retrofit due to the technologies' power consumption. Eq.(4) is a Big-M constraint associated with CCS selection.

$$R_{i,k,n} \times (1 - X_n) = FNR_{i,k,n} \quad \forall i \forall k \forall n \quad (3)$$

$$R_{i,k,n} \leq F_{i,UB} \times B_{i,k,n} \quad \forall i \forall k \forall n \quad (4)$$

where $B_{i,k,n}$ is a binary variable associated with selection to retrofit CCS technology n to power plant i in period k and $R_{i,k,n}$ is the extent of CCS retrofit.

The total extent of CCS retrofit of power plant i with all CCS technologies ($TR_{i,k}$) is obtained from Eq.(5). Additionally, the energy output from the power plant i cannot be less than the total extent of CCS retrofit with all CCS technologies, represented by Eq.(6).

$$\sum_n R_{i,k,n} = TR_{i,k} \quad \forall i \forall k \quad (5)$$

$$TR_{i,k} \leq FS_{i,k} \quad \forall i \forall k \quad (6)$$

In any period k , the total energy from a plant ($FS_{i,k}$) must be equal to the summation of the net energy output without CCS retrofit ($FNS_{i,k}$), the extent of CCS retrofit ($R_{i,k,n}$) and the alternative solid ($SD_{i,k,s}$) and gas-based fuels ($GS_{i,k,g}$); shown in Eq.(7).

$$FNS_{i,k} + \sum_n R_{i,k,n} + \sum_s SD_{i,k,s} + \sum_g GS_{i,k,g} = FS_{i,k} \quad \forall i \forall k \quad (7)$$

Eq.(8) ensures that in any period k , total energy output from all energy sources is equal to total energy demands, which includes the total power demands (D_k) combined with those required by EC-NETs ($EC_{k,q}$). Similarly, Eq.(9) enforces total CO₂ load from all energy sources is equal to total CO₂ emissions over period k (TE_k).

$$\begin{aligned} \sum_i \sum_n (FNS_{i,k} + FNR_{i,k,n}) + \sum_c FC_{c,k} + \sum_p EP_{k,p} + \sum_s SD_{i,k,s} \\ + \sum_g GS_{i,k,g} = \sum_q EC_{k,q} + D_k \quad \forall k \end{aligned} \quad (8)$$

$$\begin{aligned} \sum_i \sum_n (FNS_{i,k} CS_i + (FNR_{i,k,n} CR_{i,n})) + \sum_c FC_{c,k} CIC_{c,k} \\ + \sum_p EP_{k,p} CIEP_{k,p} + \sum_q EC_{k,q} CIEC_{k,q} \\ + \sum_s SD_{i,k,s} CISD_{i,k,s} + \sum_g GS_{i,k,g} CIGS_{i,k,g} = TE_k \quad \forall k \end{aligned} \quad (9)$$

where $CIC_{c,k}$, $CIEP_{k,p}$, $CIEC_{k,q}$, $CISD_{i,k,s}$ and $CIGS_{i,k,g}$ represent the carbon intensities of compensatory energy c , EP-NETs technology p , EC-NETs technology q , alternative solid-based fuel s and gas-based fuel g in period k respectively.

The total energy costs for period k (TC_k) are obtained using Eq.(10).

$$\begin{aligned} \sum_i \sum_n (FNS_{i,k} CT_{i,k} + (FNR_{i,k,n} CTR_{i,k,n}) + (CFX_{i,k,n} B_{i,k,n})) \\ + \sum_c FC_{c,k} CTC_{c,k} + \sum_p EP_{k,p} CTEP_{k,p} + \sum_q EC_{k,q} CTEC_{k,q} \\ + \sum_s SD_{i,k,s} CTSD_{i,k,s} + \sum_g GS_{i,k,g} CTGS_{i,k,g} = TC_k \quad \forall k \end{aligned} \quad (10)$$

where $CTR_{i,k,n}$ and $CT_{i,k}$ are costs of energy output by power plants with and without CCS technology, while $CTC_{c,k}$, $CTEP_{k,p}$, $CTEC_{k,q}$, $CTSD_{i,k,s}$ and $CTGS_{i,k,g}$ are the cost associated with compensatory energy c , EP-NETs technology p , EC-NETs technology q , alternative solid-based fuel s and gas-based fuel g . Meanwhile, $CFX_{i,k,n}$ represents the fixed cost of retrofitting power plant i with CCS n in period k .

Eq.(11) ensure that decisions taken to retrofit power plants with CCS in earlier periods is not reversed in later periods; the extent of CCS retrofit at later periods is at least equal to that in previous periods.

$$(R_i)_{k+1} \geq (R_i)_k \quad k = 1, 2, \dots, n - 1 \quad (11)$$

Total CO₂ emissions and total energy costs are subject to limits in Eq.(12) and Eq.(13), relating to emission limits L_k and budget allocation BD_k .

$$TE_k \leq L_k \quad \forall k \quad (12)$$

$$TC_k \leq BD_k \quad \forall k \quad (13)$$

Objective functions for the optimisation problem can either be Eq.(14) if the total costs are to be minimised subject to meeting certain emissions limits, or Eq.(15), where total CO₂ emissions are minimised subject to budgetary constraints.

$$\min TC_k \quad \forall k \quad (14)$$

$$\min TE_k \quad \forall k \quad (15)$$

This mixed-integer linear programming (MILP) model is implemented in Pyomo with a spreadsheet as an input interface and can be solved using the users' choice of solver. The code and supporting documents are available at <https://github.com/mchlshort/DECO2>.

3. Case Study

The application of the optimal decarbonisation software framework is demonstrated with a Malaysian energy planning case study. Malaysia is one of the fastest-growing economies within ASEAN (Association of South-East Asian Nations). This rapid economic growth makes Malaysia a carbon-intensive country, but a carbon-neutrality pledge by 2050 has been made with the 12th Malaysia Plan (Salim, 2021). This goal will require a revamp of the country's carbon-intensive grid. In year 2020, the power generation sector alone generated 109 Mt CO₂ (Energy Commission, 2020). Due to the Paris Agreement, renewable energy share is projected to hit 40% by year 2035 (The Straits Times, 2021). However, an increase in renewable energy share alone would not be sufficient. A recent study concluded that a carbon pricing policy must be implemented in Malaysia to achieve its target CO₂ emission reduction (Izlawanie, 2021). However, an ambiguous carbon tax framework and political instability would hinder its implementation. On the other hand, Malaysia, being one of the top palm oil producers in the world has significant potential for the use of crops as biomass (Loh, 2017). Given that coal plants are expected to be operational till at least year 2040, other alternatives i.e., fuel substitution and the use of NETs must be considered.

We consider energy planning for Malaysia across six 5-year periods starting in 2025, each with a specified demand, emission limit and budget allocation, based on forecasts. The CO₂ emission reduction is achievable with the potential deployment of three types of EP-NETs i.e., bioenergy with CCS and biochar and EC-NETs i.e., direct air capture and enhanced weathering, alongside two choices of CCS technologies and compensatory energy. Two types of biomass and biogas, each with a specified CO₂ intensity and cost are also available to replace coal and natural gas respectively. Table 1 presents the demand and CO₂ emission constraints for each period. The case study was solved for the minimum budget objective function (Eq.(14)) using CPLEX as the optimisation solver. Figure 1 presents the energy planning pinch diagram for period 6 (years 2045 – 2050).

Table 1: Energy Planning Data

Period k	Years	$D_k /$ TWh y^{-1}	$L_k /$ Mt y^{-1}
1	2022 - 2025	133	116
2	2025 - 2030	142	115
3	2030 - 2035	156	110
4	2035 - 2040	166	94
5	2040 - 2045	184	60
6	2045 - 2050	203	0

Figure 1 shows that the carbon-neutral target in 2050 can be achieved with the deployment of NETs, renewable energy and CCS.

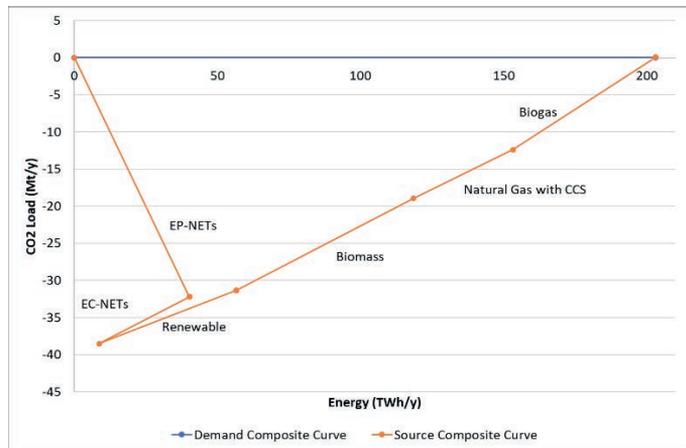

Figure 1: Energy planning pinch diagram for Period 6 (2045-2050)

The optimisation results demonstrate that all coal power plants would be decommissioned to be replaced by biomass by 2050. As of 2040, 13 of the available 19 natural gas plants were operational to generate 68.23 TWh electricity annually. In 2050, while one natural gas plant is decommissioned, four plants generating 43.5 TWh electricity are CCS retrofitted, with the remaining being transitioned to accommodate biogas as feedstock, generating 39.2 TWh electricity annually. The results of this software framework align with Malaysia’s aspiration for a gradual decommissions of coal power plants in light of its climate change target.

4. Conclusion

An optimal decarbonisation policy software framework was developed in this work based on mathematical programming models for energy planning. It can aid policymakers in crafting decarbonisation strategies. The MILP model provides solutions for optimal deployment of NETs, CCS, compensatory energy and fuel substitutions to meet emissions caps in each period. As demonstrated using a Malaysian decarbonisation case study, this software framework could contribute to the achievement of the net-zero emissions targets.

Results show that there is a need for energy planning models to consider fuel substitutions in existing plants, as well as techno-economic constraints down to the individual plant level. Future work on the open-source software will focus on incorporating uncertainty associated with parameters, as well as considering economy-wide CO₂ emissions from other industries/sectors e.g., petrochemical, cement etc. aside from incorporating the technical constraint i.e., availability, implementation time, cost etc. for each technology.

Acknowledgements

The team would like to offer their sincerest gratitude to the British Council for funding provided towards the COP26 Trilateral Research Initiative. Additionally, the team would like to offer thanks to Dr Yasunori Kikuchi and Dr Disni Gamaralalage from the University of Tokyo for their continuous support throughout this research.

Abstract

Today's Industry 4.0 (I4) is re-designing industrial activities and re-shaping communities into the so-called Society 5.0 (S5), enabling the creation of a new industry-society-environment nexus. The application of novel technologies such as pervasive sensing, widespread internet of the things (IoT), artificial intelligence (AI), and robotics aims to sense, calculate, and actuate by employing data-driven architectures and automated decisions for reaching more efficient processes that reduce environmental impacts and transform manpower workloads. This work introduces a cyber-physical system (CPS) towards more innovative operations within the mining industry's mine-to-mill process, whereby the operations' decision-making and executions are often done by human intelligence. However, the increasing use of autonomous machines or mechatronics (MEC) such as trucks, drills, drones, and conveyor belts, combined with advanced modelling and solving algorithms (MSA), can achieve the necessary autonomous operations for handling such hazards and harsh environments, where no or reduced manpower is required. For that, information and computing technologies (ICT) facilitate innovative solutions to re-shape and re-design production systems. The interplaying of advanced technologies of the I4 mandate and circular economy (CE) ideology towards the mines of the future creates a smart connected mining industry that embeds vast amounts of data into predictive and fully integrated intelligent systems. This paper discusses how I4's technological developments in mining sector applications generate opportunities to re-design and re-execute stockpiling to conveyor-belt processes into enhanced production states from a CE perspective (environmental, economic, and social). CE theories within I4-S5 offer innovative sustainable industrial concepts driven by safer, more environmentally friendly towards precision and autonomous mining.

Keywords: Industry 4.0, Society 5.0, mining, circular economy, sustainable development.

1. Introduction

Human beings have engaged in mining since the stone age. Since then, we have used natural resources from the earth for utilitarian purposes to support global development. Mining is generally considered to be the activity of recovering minerals and other materials from the earth and is often associated with further processing of minerals to concentrate the amount of metal and to remove impurities. The combination of industrial organisations involved in traditional mining and oil and gas recovery is often described

as the extractives sector. There are many interpretations of mining and its associated activities, and some terms are used interchangeably. Mining can be classified according to various criteria, including the location of activities and the scale at which it occurs. Figure 1 summarises common mining pathways, including underground, quarrying, sand, artisanal small-scale, undersea, in addition to the promising lunar or beyond Earth mining.

As our world's population and economic growth increases, the demand for total global metal production continues to increase in scale with its associated impacts. Some metals experience cycles of demand as older uses are phased out, such as cryolite, while other historically less-exploited metals have come to prominence as a result of technological innovations, such as the increasing production of lithium due to its use in batteries (Martin et al., 2017). Since the world of mining is changing with new technologies reshaping mining practices, traditional value chains (input, exploration mine development, blasting load and haul, processing, transportation, further processing, and products) are disrupted and society's expectations of mining companies have never been higher. The digital transformation and the introduction of CPSs towards smarter operations within the mining industry have put huge ambition towards global prosperity and sustainable development. The interplaying of advanced technologies and CE ideology towards the mines of the future creates a smart connected mining industry, whereby vast amounts of data are embedded into predictive analytics capabilities for achieving fully integrated intelligent systems (Kelly and Menezes, 2019). Such Industry 4.0 (I4) autonomous machinery and tools are fundamental to provide safer and more efficient environments. For example, mechatronics (MEC) with sophisticated modelling and solving algorithms (MSA) are needed for autonomous handling of hazards and the severe environment when no or little human intervention is required. ICT enables novel solutions to reshape and re-design mining production processes towards a complete digitalization of the processes.

At a process level in the mining system (from the crushing and to the milling), improved stockpiling to conveyor-belt operations can be achieved by employing better processes for separating and transporting ore, preventing evaporation, and producing drier tailings through a hybrid dynamic control application. Thus, additional safety, stability, and predictability can be achieved to maximise the ratio of metal to ore output while minimising the environmental impacts and the operating and capital costs. In addition, this creates sustainable communities to identify socio-economic development opportunities. This paper addresses how I4 technological advances drive opportunities to re-design and re-execute operations at the process level (of stockpiling to conveyor-belt) into an improved state under CE ideologies within the scope of the environmental, economic, and social pillars. In this context, CE theories within I4-S5 introduce novel sustainable industry principles for innovative processes that are driven by safer and more efficient, accurate, precise, and autonomous mining processes.

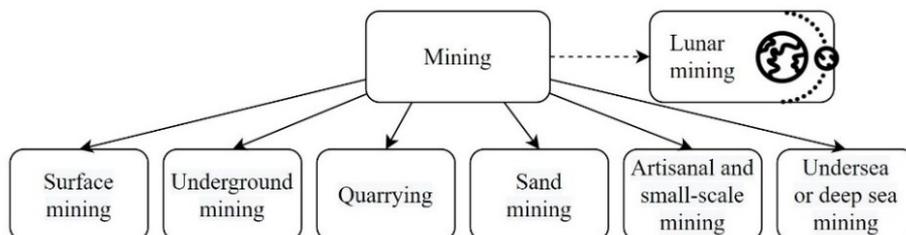

Figure 1: Mining pathways.

2. Mining challenges from a CE perspective

The life cycle assessment of mining and mineral processing as well as oil and gas industries use heavy equipment that consumes electrical, thermal and mechanical energy, which are key contributors to the overall industrial impacts on the environment (Farjana et al., 2019). The mining industry has been undergoing significant changes as companies adopt automation technologies to decrease costs, increase efficiency, and improve safety. The accident and ill-health record of the mining sector compares poorly to that of other economic sectors such as manufacturing, construction, and rail, leading to mining's reputation as the most hazardous industrial sector (Domingues et al., 2017). Mining poses significant health issues due to airborne contaminants such as silica and coal dust, as well as noise, heat, and vibration. Other severe health concerns include chemical hazards unrelated to the subterranean, such as air pollution, gases, skin diseases, ergonomic strains, and ionic, cosmic, and radioactivity radiations, among others. Although health problems can be mitigated by applying tight controls at the source in the workplace, developing such measures for mining operations provides significant hurdles given that dust and noise are created by mining operations themselves. The impacts of shifts in employment patterns and tedious working hours that increase site exposure are added to the complexity of assessing the likelihood of health risks. Many mineworkers have worked in mines for over two decades, with increasing risk of occupational diseases. Lately, the effectiveness of protective systems based on occupational exposure limits for eight-hour working days has been questioned (Komljenovic et al., 2017).

Besides social risks, the world faces the biggest environmental threat in generations, and low-carbon technologies are needed to resolve this issue. However, the development of such technologies increases the demand for the mining of raw materials. Electric vehicles, as an example, are made with around 70% of copper. The mining industry faces an interesting future with growing demand as well as severe challenges (Sánchez and Hartlieb, 2020). The current technological trend is to vastly increase the level of automation driven by enhanced I4 capabilities. Within this context, many challenges arise. First, local mining enterprises have become multinational giants and mine sites are usually very remote and with harsh climatic conditions. Recruiting and retaining skilled personnel to operate the mines in distant locations such as deserts or mountains is difficult. Second, decreased ore grades, which leads to exploring more ore bodies. As a result, the trade-off between drilling deeper with increased costs is to maintain profitable throughput. Third, despite continuous improvements, workforce safety incidents and accidents continue to occur, prompting policies to impose stricter laws, rules, and regulations. The safety of workers must be addressed, particularly in subterranean operations and on-ground areas where people working close to heavy machines are exposed to risks. Fourth, the mining sector has long been concerned about growing energy costs, efficiency, and measuring power consumption. Assuring tightly integrated plant processes and power units would be considered key for improving energy efficiency. Fifth, the lack of information unity, in which there are several independent pieces of equipment, machinery, systems, and subsystems in the mining site, and each has its own information and interfaces. Thus, decision-makers have separate pieces of information at hand with no holistic overview, known as "islands of automation". The lack of unity and integration imposes difficulties in performing proper decisions in a timely manner.

Complementary to the I4 adaptation in organisations, concerns in resource utilisation, conversation, and recycling, aligned with environmental issues worldwide, have transformed the old-fashion profitability objective to be maximised in the short-term

horizon to the sustainable economic growth targeting a long-term prospectus. With the support of the I4 technologies, the sustainable deployment, also referred to as CE in manufacturing systems and supply chains, implies efficient use of natural resources, reduced energy consumption, minimum generation of wastes, as well as high-performance production, logistics, and services. Therefore, identification and design opportunities for the resource-process-product within the I4-CE adoption are expected to increase (Song and Wang, 2018). Modern MEC-MSA-ICT fundaments of the I4 transform production and service operations models, reducing energy and optimising material flows and inventories. The consequence of such transformations is the reduction of waste and greenhouse gases (GHG) emissions. Such an evidence of GHG reduction by virtue of the capabilities of the augmented information age in transportation, logistics, smart cities, efficient buildings, and facilities, etc., demonstrate more sustainable environment while offering economic benefits (GelenbeErol and CaseauYves, 2015; Moyer and Hughes, 2012; Murugesan and Laplante, 2011).

3. Sense, calculate, and actuate cycle within CPSs for mine-to-mill process

From a laboratory-level to mature processes, advanced production in the industry is evolving to re-identify, re-design, re-execute, and re-evaluate new opportunities within research, development, and deployment (RD&D) stages into the I4 improved state. In the mining case, a real-time dynamic predictive control model based on I4 capabilities relies on the cycle of sensing, calculating (via optimisation), and actuating (SCA) within CPS in the stockpiling to conveyor-belt process. In this context, Menezes et al. (2019) address a conveyor-belt intermittently delivering crushed-ore to form multiple stockpiles considering targets of their inventories to avoid the so-called bridging, reducing the flow-out beneath the stockpiles, which feeds other conveyor-belts to the mills. In such a system, a dynamic online optimisation for shuttle-conveyor-belt tripper car is treated as a real-time hybrid model predictive control (HMPC) with shifting prediction time-horizon. The HMPC aims to enhance the performance of the stockpiles' level by autonomously adjusting the idle-time (actuation or manipulated variable) of the robotic apparatus of the tripper car that moves over each stockpile position (as seen in Figure 2). The motion from one stockpile to the next in a neighbour-to-neighbour fixed sequence forms multiple stockpiles instead of one per belt. The problem is solved as a mixed-integer linear programming (MILP) problem to minimise the deviation of the given targets to the actual or live inventory of the stockpiles (sensed by industrial radar technologies using ultrasound). In this coordinating of the conveyor-belt for multiple stockpiles, the robotic arm idle-time in the schematics of Figure 2 is the actuation or manipulated variable depositing the solids into each stockpile to automatically control its inventory. Then, the robotic apparatus goes back and forth as a smart sweeping movement since it counts on the smart manufacturing ground bases of the ICT, MSA, and MEC pillars to be implemented within a continuously controlled cycle of sensing, calculating (via optimisation), and actuating.

The bottlenecks of such a CPS in mining have been surpassed by the development of fast discrete optimisation in the calculating stage of the SCA cycle to continuously determine idle-time as a binary variable per time-window of the positions (Kelly and Menezes, 2019). By moving from one to multiple stockpiles per belt, CE implications of its three pillars exist. Economically, more efficient flow-to-stockpile increases the utilisation factor of the equipment, while reducing dust, raw material losses, and energy consumption. Nevertheless, the raise of such I4 technologies leads to social impacts by increasingly closing low-skilled positions and requiring high-qualified personnel.

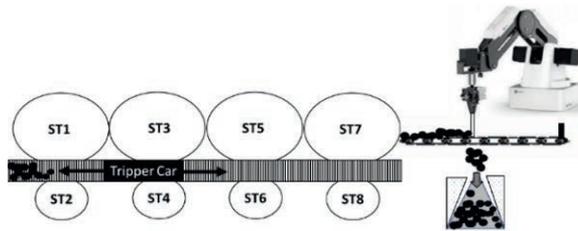

Figure 2: Robotic arm apparatus schematics feeding eight stockpiles in the multiple stockpiling per belt system.

Such control application considers advancements in manufacturing toward the I4 mandate involving ICT and MEC fundamentals evolving together with advances in MSA. In the latter, advances in network (flowsheet) optimisation, solving algorithms, and computer-aided resources allow faster and more efficient solutions (Franzoi et al., 2021). Moreover, the ICT expansion provides the demanded velocity of the communication of the online data measurement of complete process networks for the massive volume and variety of information from the plant, which permits the viability of the addressed control strategy. Such advances provide proper capabilities for the development and implementation of tools and sustainable strategies in mining operations with safer and more efficient process conditions towards the mines of the future.

By employing hybrid dynamic control applications in the mine-to-mill processes, stockpiling operations can be improved to better segregate and convey ore methods, reduce evaporation, and create drier tailings. As a result, increased human safety and predictability can be reached to maximise the metal to ore output ratio while reducing social and environmental consequences and operational and capital costs. Furthermore, this builds sustainable communities capable of identifying socioeconomic growth prospects.

4. Discussion and conclusion

After the hunter-gatherer, agrarian, and industrialisation stages of mankind, our current society in the wake of the S5 stage, referred to as an augmented society, moves towards the transformations of economic and environmental targets to the collection of individuals' and communities' well-being as a core of the new business models. Although the adoption of technologies is an economic added value, industries have faced difficulties in hiring skilled people since it requires specialised knowledge, abilities, and competencies in ICT, MEC, and MSA branches of the I4 age (Fitsilis et al., 2018). Mining is a labour-intensive industry with a harsh and dangerous working environment, and I4 facilitates replacing humans with autonomous machinery. The consequences affect employment profiles, but it ensures to maximise human safety in such remote and harsh places like deserts or mountains. Mine settings are particularly complex to handle since they deteriorate quickly and alter as the mining processes progress. Furthermore, mining emits hazardous pollutants into the atmosphere, and crushing rocks is intrinsically connected with dust and noises, whereby oxygen and lights must also be artificially provided in subterranean mines. Also, on- and under-ground miners operate heavy machinery and perform hard and tedious work in cramped contexts; thus, ergonomic risks are widespread in such industries. These hazards are connected to poor technical design and add higher safety risks (Komljenovic et al., 2017). The trade-offs debate between the pros and cons of increasing automation level depends on the society and its technological

evolution. If society's policies and procedures force industries to work towards the so-called CE ideology, an increased level of automation would create new job positions in remanufacturing and recycling activities with the high skills demanded in the I4 mandate.

The mining sector's accidents and ill-health records compare severely to those of other industry sectors, contributing to mining's reputation as being the most dangerous industrial sector. Intuitively, occupational injuries and illnesses records can negatively impact public safety, health, and the environment (SHE), where people's health and safety have monetary costs and environmental consequences. Furthermore, it connects initiatives to improve workplace health and safety to a wider societal agenda from a corporate social responsibility perspective, i.e., sustainable development. The experimental simulation of the current practice of stockpiling process shows a lack of resources utilisation. Increasing the level of automation by integrating technology solutions has the power of speeding stockpiling, maximising performance, improving safety, and reducing overall costs. The I4 elements can be implemented with a hybrid SCA dynamic control cycle to relocate feeding positions within seconds, increasing feeding performance, efficiently utilising resources, and performing multi-stockpile feeding. In the broader context of CE, healthy and safe working conditions are among the first expectations for sustainable development.

Abstract

Millions of tonnes of rice husk (RH) are produced annually as an agricultural waste. One area of interest for RH valorisation is to use rice husk ash (RHA, a by-product of RH combustion) as a replacement for mineral-derived synthetic amorphous silica (M-SAS). However, little information is available on the environmental benefit of this approach. This study details the first evaluation of the environmental benefits of producing RH-derived synthetic amorphous silica (RH-SAS). This is done by describing the life cycle of RH-SAS in terms of stages for which existing life cycle inventories can be linked and aggregated in a modular way. It is then shown how the physical meaning of linkages between modules are governed by both the characteristics of the RH feedstock and efficiencies of processes across the life cycle. To provide more robust findings, the sensitivity of predictions to model uncertainty are also considered. Finally, a case is provided for the benefit of RH-SAS production within the Asia-Pacific (APAC) SAS market.

Keywords: Silica, Rice Husk, Life Cycle Assessment, Uncertainty, Global Warming Potential

1. Introduction

An estimated 2.8 million-tonnes of synthetic amorphous silica (SAS) are produced per year by the “wet” industrial process Industry Experts (2019). This process commonly involves the reaction of a mineral-derived sodium silicate (SS) precursor following the stoichiometry in Equation 1 European Commission (2007).

However, many experimental investigations have now also been made into the potential of recovering SS and SAS from wastes produced by the construction and agriculture industries. Among these, a large subset consider the valorisation of rice husk ash (RHA) due to its high silica content Hossain et al. (2018). RHA is a product of the combustion of rice husk (RH), which is itself a by-product of rice grain agriculture. Yet, there is a gap in the literature with regards to understanding the environmental impact of RH-derived SAS (RH-SAS).

Consequently, this work develops models to compare the environmental impact of producing mineral-derived SAS (M-SAS) and RH-SAS via the wet method. This is done by the Life Cycle Assessment (LCA) of production methods for each feedstock case independently. To ensure robust comparisons, sensitivity of predicted impacts to LCA model uncertainty is also considered. This leads to the visualisation of a design space in which the demand for RH feedstock ($\text{kg}/\text{kg}_{\text{SAS}}$) and recoverable bioenergy ($\text{MJ}/\text{kg}_{\text{SAS}}$) of the RH-SAS life cycle can fall. Finally, a case study for the benefit of producing RH-SAS within the Asia-Pacific (APAC) region is provided. In all cases, comparisons are made in terms of the 100-year global warming potential (GWP).

2. Life Cycle Assessment

2.1. Scope, Functional Unit and Inventories

As illustrated in Figure 1, a cradle-to-gate scope has been used to develop inventories in this work. This has been done based on a functional unit of 1 kg of SAS.

For the M-SAS model, an inventory was developed based on the average inventory reported for the EU-15 region by the European Commission (2007). For the RH-SAS model, an inventory was developed by modifying the M-SAS model. This was done by representing the RH-SAS life-cycle in terms of four stages that are strongly linked to pre-existing industries. These were: Rice Grain Agriculture (RGA), RH combustion (RHC), SS production (SSP) and SAS production (SASP). For each stage, a relevant inventory was then selected from the EcoInvent Database (2019). The functional unit of each inventory was also converted to be consistent with 1 kg of SAS as illustrated in Figure 1 (see also Section 2.2). As RH is considered a waste of RGA, no environmental burdens of the RGA stage have been allocated to RH-SAS, following an economic allocation approach. Models and modifications used for each RH-SAS stage are shown in Table 1.

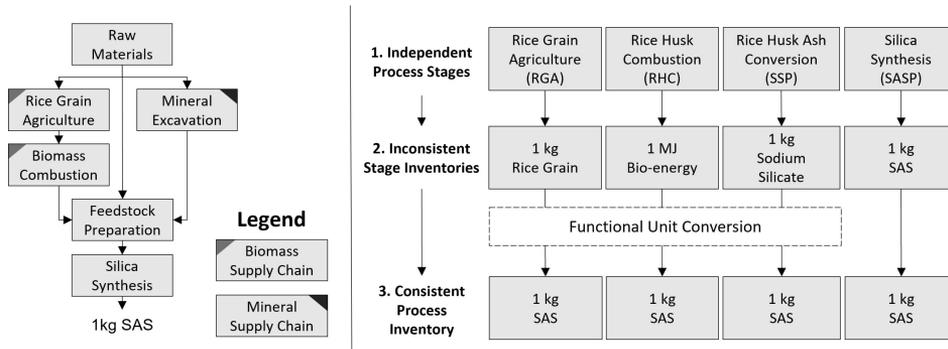

Figure 1: A summary of life cycle scopes considered for M-SAS and RH-SAS during impact assessment (left) and the method for specifying the entire RH-SAS inventory (right)

Table 1: Summary of inventory source associated with RH-SAS models

Stage	Inventory Source	Functional Unit	Modification
RGA	N/a (economic allocation = 0)	1 kg _{biomass}	N/a (economic allocation = 0)
RHC	Bauer (2007) ¹	1 MJ _{bioenergy}	references to biomass use removed
SP	Hirschier (2010) ²	1 kg _{silicate}	references to mineral use removed
SS	European Commission (2007) ³	1 kg _{silica}	references to mineral use removed

¹ "biomass combustion" process; ² "hydrothermal" process; ³ based on the M-SAS model in this work.

2.2. Life Cycle Impact Assessment

The total environmental impact of each independent life cycle model (M-SAS, RGA, RHC, SSP and SASP) was calculated using Equation 2. Impact assessment was carried out for GWP using the ReCiPe (H) method (v1.13) of Goedkoop et al. (2009). A cut-off value of 0.1% was applied.

$$EI_{kpi} = \sum_r \sum_s C_{r,kpi}^{in} F_{r,s}^{in} + \sum_c \sum_s C_{c,kpi}^{out} F_{c,s}^{out} \quad (2)$$

Where EI is the total impact with regards to some key performance indicator, kpi ; $C_{r,kpi}^{in}$ is the characterisation factor (impact/amount) for a resource, r ; $C_{c,kpi}^{out}$ is the characterisation factor (im-

fact/amount) for a compound, c ; $F_{r,s}^{in}$ is the amount of resource, r , arising from process step, s ; $F_{c,s}^{out}$ is the amount of compound, r , arising from process step, s .

The overall environmental impact of RH-SAS, EI_{kpi}^{RH-SAS} (impact/kg_{SAS}), was then calculated by making the individual impact predictions for each associated life cycle stage (RGA, RHC, SSP and SASP) consistent with the 1 kg of SAS functional unit - as shown in Equation 3.

$$EI_{kpi}^{RH-SAS} = EI_{kpi}^{RGA} \hat{M}^{RGA} + EI_{kpi}^{RHC} \hat{Q}^{RHC} + EI_{kpi}^{SSP} \hat{M}^{SSP} + EI_{kpi}^{SASP} \quad (3)$$

Where EI_{kpi}^{RGA} is the environmental impact of the RGA stage (impact/kg_{RH}); \hat{M}^{RGA} is the demand for RH-biomass from the RGA stage (kg_{RH}/kg_{SAS}); EI_{kpi}^{RHC} is the environmental impact of RHC stage (impact/MJ); \hat{Q}^{RHC} is the bioenergy recovered as electricity from the RHC stage (MJ/kg_{SAS}); EI_{kpi}^{SSP} is the environmental impact of the SSP stage (impact/kg_{feedstock}); \hat{M}^{SSP} is the amount of SS required for the SASP stage (kg_{SS}/kg_{SAS}); EI_{kpi}^{SASP} is the environmental impact of rice husk combustion stage (impact/kg_{SAS}) Note: RH mass (kg_{RH}) is considered on a dry basis.

Values of \hat{M}^{RGA} , \hat{Q}^{RHC} and \hat{M}^{SSP} were derived from process and biomass characteristics as:

$$\hat{M}^{RGA} = 1 / (\eta^{SSP} \eta^{SASP} x^{SiO_2} [1 - x^{H_2O}]) \quad (4)$$

$$\hat{Q}^{RHC} = (\eta^{RHC} / [\eta_p^{SSP} \eta_p^{SASP}]) \times \left(\left[\hat{Q}^{LHV} (1 - x^{H_2O}) - \lambda x_b^{H_2O} \right] / [x^{SiO_2} (1 - x^{H_2O})] \right) \quad (5)$$

$$\hat{M}^{SSP} = (1 + n) / \eta^{SSP} \quad (6)$$

Where η^i is the conversion efficiency of process stage, i (no units); \hat{Q}^{LHV} is the lower heating value of RH (MJ/kg_{RH}, dry basis); x^{H_2O} is the moisture content of RH (no units, mass basis); x^{SiO_2} is the silica content of RH (no units, mass basis); and n is the silicate number (no units) of SS (reported as $2 \leq n \leq 4$ by the European Commission (2007)). Values for each variable were taken as the midpoint of ranges reported in Section 2.5. Finally, the contribution of biogenic carbon emissions (arising from the RHC stage) to GWP was assumed to be zero due to the cyclical harvest and short crop rotation period typical of RGA.

2.3. Benefit of RH-SAS and Bioenergy Recovery

The benefit of RH-SAS has been quantified in two ways. Firstly, the benefit of RH-SAS when directly compared to M-SAS, B_{kpi}^{RH} (impact/kg_{SAS}), was calculated as shown in Equation 7. Secondly, the benefit of RH-SAS when using co-recovered bioenergy to offset grid-electricity use, B_{kpi}^{offset} (impact/kg_{SAS}), was calculated as shown in Equation 8.

$$B_{kpi}^{RH} = EI_{kpi}^{RH-SAS} - EI_{kpi}^{M-SAS} \quad (7)$$

$$B_{kpi}^{offset} = EI_{kpi}^{RH-SAS} - \hat{Q}^{RHC} EI_{kpi}^{grid} \quad (8)$$

Where EI_{kpi}^{M-SAS} is the environmental impact of M-SAS (impact/kg_{SAS}); EI_{kpi}^{grid} is the environmental impact of grid electricity (impact/MJ). Evaluation of EI_{kpi}^{grid} was done using the global medium voltage electricity model available within the EcoInvent Database (2019) (v3.6).

2.4. Uncertainty in Inventory Models

The sensitivity of impact evaluations to uncertainty in data quality was quantified by the pedigree matrix approach - in which, the quality of inventory data was rated against five criteria: reliability, completeness, and temporal, geographic and technological representativeness. Ratings were quantified as log-normal probability distributions based on the method of Frischknecht et al. (2004). Monte-Carlo simulations were used to estimate prediction uncertainty (sample size = 100,000).

2.5. Uncertainty in Feedstock and Process Characteristics

The sensitivity of \hat{M}^{RGA} and \hat{Q}^{RHC} to uncertainty in feedstock and process characteristics was derived from typical ranges reported in literature (see Table 2). It was assumed that the uncertainty for each variable was uniformly distributed. Values for each characteristic were randomly sampled 100,000 times (numpy package v 1.20.1 in python v3.7) to complement simulation of uncertainty from data quality (see Section 2.4). Following this, a further 900,000 random samples (i.e. 1-million total) were taken to visualise the feasible domain of \hat{M}^{RGA} and \hat{Q}^{RHC} .

Table 2: Uncertainty in Feedstock and Process Characteristics within the RH-SAS life cycle

Variable	Value	Ref(s).
RHC Stage Efficiency, η^{RHC} (%)	15-30	Bain (1993); Kawahara (2016)
SSP Stage Efficiency, η^{SSP} (%)	73-91	Pijarn et al. (2010); Kalapathy et al. (2000)
SASP Stage Efficiency, η^{SASP} (%)	95 ¹	European Commission (2007)
RH Heating Value, Q^{LHV} (MJ/kg _{GRH})	13 - 16	Natarajan et al. (1998)
RH Moisture Content, x^{SiO_2} (%)	10-14	Webb (1979); Van Hung et al. (2020)
RH Silica Content, x^{H_2O} (%)	15-20	Siddique and Cachim (2018)

¹ Data from European Commission (2007) implies certainty in the conversion efficiency of the SS stage

3. Results

3.1. Impact Evaluations and the Estimated Benefits of RH-SAS

Figure 2 illustrates the predicted GWP of M-SAS and RH-SAS as well as uncertainty in the benefits of RH-SAS (see Section 2.3). Single-value estimates (Figure 2 (left)) identify RH-SAS as having a lower GWP than M-SAS (2.05 vs. 1.77 kg CO₂-eq/kg_{SAS}). However, probability distributions in Figure 2 (right) suggest that the single-value estimate of B_{GWP}^{RH} is not significantly different from zero to any reasonable level of confidence. Consequently, the method could benefit from further minimising model uncertainty - either via data quality or processes and feedstock characteristics. This is also the case for B_{GWP}^{offset} , though this metric has a higher likelihood of being net GWP-negative. The lack of certainty in benefits being net-negative can also be related to the low contribution of feedstock to the GWP of both life cycles.

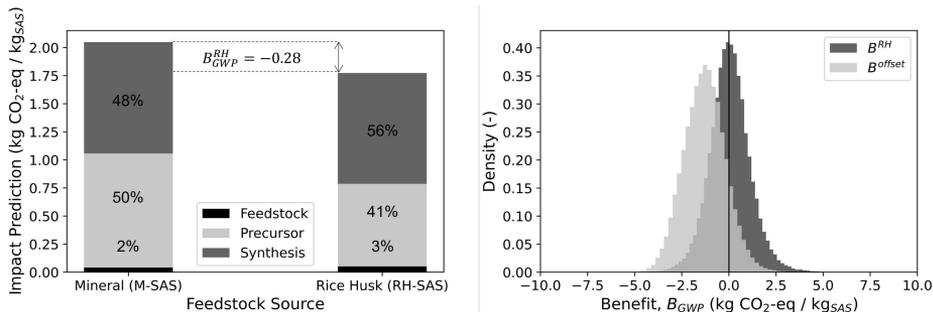

Figure 2: Global Warming Potential of SAS (left) and uncertainty in benefit of RH-SAS (right)

3.2. Uncertainty in Biomass Demand and Bioenergy Recoverable

Figure 3 illustrates the feasible design region for RH-SAS in terms of \hat{Q}^{RHC} and \hat{M}^{RGA} . Differences in the size of dotted regions illustrate the extent of importance in the absolute value of individual

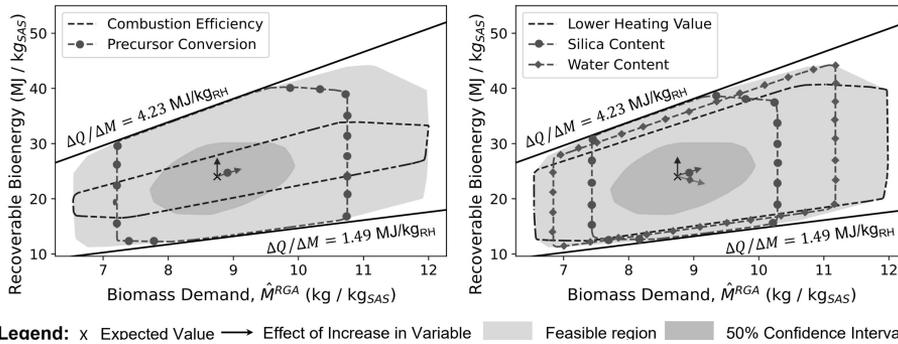

Figure 3: Feasible regions for Biomass Demand and Recoverable bioenergy (RH model)

Table 3: Summary of statistics relevant to potential production of RH-SAS within APAC.

Country	BD	CN	IN	ID	VN
RH Production (Mtonne/year) ¹	10.92	42.28	35.53	10.92	8.70
SAS Capacity (Mtonne/year)	1.30	5.04	4.23	1.30	1.04
Proportion of Market Demand ² (%)	81.63	316.14	265.66	81.66	64.97
Market Benefit, B_{GWP}^{RH} (Mtonne CO ₂ -eq/year)	0.36	0.44 ²	0.44 ²	0.36	0.29
Market, B_{GWP}^{offset} (Mtonne CO ₂ -eq/year)	2.12	2.58	2.58	2.12	1.69
Market GWP Reduction, B_{GWP}^{RH} (%/year)	11	13	13	11	9
Market GWP Reduction, B_{GWP}^{offset} (%/year)	65	79	79	65	52

¹ Based on rice paddy statistics for 2019 from the Food and Agriculture Organization of the United Nations (2020) and assuming 20 wt% of Rice Husk per mass of rice paddy Hossain et al. (2018), ² benefit limited to 100% of APAC market demand for consistency with real-world market

variables when held at their midpoint value. Therefore, smaller dotted regions reflect variables which the process is more sensitive to. Results show that \hat{Q}^{RHC} is most sensitive to changes in electrical efficiency of the RHC stage (i.e. η^{RHC}), while \hat{M}^{RGA} is most sensitive to the silica content of RH feedstock. Minimum and maximum gradients (4.23 and 1.49 MJ/kg_{RH}) observed also indicate the relatively low amount of energy recoverable per kg of RH as received, which is due to energy losses caused by the water content of the RH feedstock. Importantly, Figure 3 acts as a heuristic for understanding the effects of process design and feedstock selection on life cycle performance.

3.3. Implications for Asia-Pacific

A summary of key metrics for the use case of RH-SAS within the APAC region (based on top 5 producers of rice paddy by mass - Bangladesh, BD; China, CN; India, IN; Indonesia, ID; and Vietnam, VN) is provided in Table 3. Results indicate that each country produces RH in amounts which could serve SAS demand equivalent to more than 800% of the current APAC market. Moreover, it is estimated that the benefits from bioenergy co-recovery (within the RH-SAS life cycle) could lead to reductions of as much as 80% (i.e. 2.58 Mtonne/year) of the APAC SAS industry’s annual GWP footprint. However, as predictions rely on the values for B_{GWP}^{RH} and B_{GWP}^{offset} (Section 3.1), the uncertainty in values being significantly different from zero also applies here. Further refinement of each regional prediction will be achieved by using more specific regional models for energy use in future work.

4. Conclusion

This study details the first attempt to evaluate the GWP of RH-SAS. By comparing impacts with that of current industrial methods (M-SAS), our results suggest that RH-SAS may offer a pathway for reducing the GWP of SAS industry, including large reductions in APAC regions. However, high variability in the impact of both processes considered mean that certainty in the benefit of RH-SAS is low. This reflects the small contributions that RH and minerals make to the impact of RH-SAS and M-SAS respectively as well as the sensitivity of models to variability in process implementation in the wider life-cycle shared by each product. Thus, while areas for model refinement is discussed, it is believed that our findings are likely to provide a reliable answer to the question posed - i.e. "bio" is not generalisably "better". Further model refinement will be considered in future work. Finally, the methods described are generalisable for the study of alternate biomass feedstocks and impact metrics.

Economic Analysis of Novel Pathways for Recovery of Lithium Battery Waste

Khalid Amao, Bogdan Dorneanu, Harvey Arellano-Garcia

LS- Prozess- und Anlagentechnik, Brandenburgische Technische Universität Cottbus-Senftenberg, Cottbus D-03044, Germany

Abstract

Using the Umicore process, a current state-of-the-art recycling in the metal recovery industry for lithium battery waste, as a baseline, this contribution examines economic and environmentally friendly solutions for effective metal recovery from spent LIBs. At the same time, possible synergies between existing resource use from other manufacturing and waste treatment industries are considered as valuable input to metal recycling, while also reducing the amount of atmospheric carbon. This further presents a case for possible integration of various waste management approaches as a single business unit for economic incentive and profitability for possible investment.

Keywords: Lithium-ion battery, Waste recovery, e-Waste, Circular economy.

1. Introduction

Waste Management has become one of the most rapidly growing pollution problems globally as new technologies are increasingly exceeding millions of analogue techniques, which in turn result into their disposal in prescribed landfills with possible environmental consequences. Both landfilling and incineration are highly unsustainable remedies since they use large areas of land resulting to the release of significant environmental pollutants, including the greenhouse gases (GHGs) such as carbon dioxide (CO₂) and methane (CH₄) as the waste dissociates thereby causing health and environmental threats to developing countries (The World Bank, 2019). Waste electric and electronic equipment (WEEE/EEE) no longer suitable for their intended use are known as e-waste. TVs, telephones, radios, computers, printers, fax machines, DVDs, CDs, washing machines, refrigerators, dryers, vacuum cleaners, and other electronic devices are examples of e-waste. The composition of typical e-waste is depicted in Table 1. Approximately 50 million metric tons (Mt) of e-waste were produced globally in 2018 alone, compared to 44.7 Mt in 2016 and expected to rise in the future.

Due to a variety of factors such as technological challenges, implausible economic burdens, high environmental impact, complex chemical reactions, and so on, the optimum nature of the Lithium-Ion Batteries (LIBs) recovery process and technologies has yet to be determined (Azpagic, 1999). Creating a circular economy for e-waste could lower manufacturing costs, increase revenue streams, and provide tax advantages. Jobs could be created as a result of new and expanding markets. The Circular Economy (CE) is a regenerative strategy to waste reduction that aims to ensure the environmental sustainability of post-use items. For LIBs, a CE strategy is the central issue of more than 3,000 studies completed in the previous ten years, all of which have focused on the exploration of its primary steps (Yun et al., 2018). By enhancing a company's reputation and consumer confidence through environmentally responsible activities, a CE approach could improve market competitiveness. Reduced waste, energy use, and GHG emissions,

as well as the preservation of raw resources, could all be part of the greater environmental benefits. The goal is to develop a more sustainable e-waste recovery process that aligns with the global vision of reducing the amount of carbon dioxide emission and increase energy efficiency.

The Umicore process, a state-of-the-art commercial recycling process flow in the metal recovery industry for LIBs (Georgi-Maschler et al. 2012), is a global leading solution in environmentally friendly precious metal recycling and processing. It uses an integrated metals smelter and refining procedure to recover metals such as gold, silver, and the platinum group metals (PGMs: palladium, platinum, rhodium, iridium, ruthenium), special metals (selenium, tellurium, indium), secondary metals (antimony, tin, arsenic, bismuth), and base metals (antimony, tin, arsenic, bismuth). Sulphuric acid (from off gas-purification) and a depleted slag, which is used as a building material and in the concrete industry, are two other by-products of the factory.

In the following, environmentally friendly metal recovery from the spent LIB waste is explored using the Umicore process as a baseline. The introduction of solutions such as: anaerobic digestion of organic waste to produce methane, a biogas which can be sold for profit, mineralization of the recovered metals to form stable carbonates, through utilization of the carbon dioxide produced from the digester, as well as possible integration of captured carbon dioxide from energy intensive industries, are considered.

2. Methodology

This paper aims to provide understanding towards the development of an economically and environmentally feasible, efficient, and sustainable LIB recycling system for adoption in Europe. The stages of the Umicore process that fall within this scope are also represented schematically in Fig.1. The analysis, using data from the open literature (Li et al. 2018; Sommerville et al. 2021), was divided into 2 stages: firstly, an economic assessment of the state-of-the-art recovery process, broken down into its major stages, is performed, and secondly, an improved process is proposed, for which a similar study on the economics is carried out.

2.1. Economic analysis of current state-of-the-art LIB recovery process

For the purpose of this analysis, the Umicore process is broken down into its major sub-processes and the cost of each individual component is evaluated to establish the overall cost. Investment, operation and maintenance costs are not considered. All calculations are done on a yearly estimate, assuming a recycling capacity of 7,000 tons/year of LIB waste. The process involves the smelting of the LIBs in a smelter which recovers two main categories of high and low value metals. The high value metals are extracted as an alloy from the smelter, which would later be separated into individual pure components through leaching and solvent Extraction. The low value metals are extracted from the smelter as slag.

The following steps are considered in the analysis of the Umicore process:

- a) Breaking down the process into its main stages of Smelting, Leaching and Solvent Extraction.
- b) Calculate the cost of each stage using a functional unit of 1,000kg of LIB waste as input to establish an overall recovery cost.
- c) Calculate the carbon tax related to the smelting the processes.
- d) Calculate the mass of each high value metal and slag recovered.
- e) Calculate the market value of recovered metals and slag as revenue for the process.

- f) Calculate the profit from the difference between the cost of the process and revenue generated from the market value of the recovered metal and slag.
- g) Calculate the improved profit after a predicted 25% decrease in cost due to economies of scale at a recycling capacity of 7,000 tons of LIB per year.

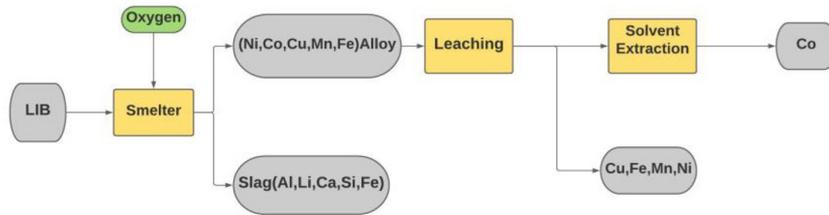

Figure 1. Flowsheet of the Umicore process

2.2 Economic analysis of improved process

In the second step, an improved and sustainable LIB recovery process is designed conceptually (Fig.2). New stages, such as mineralization, utilize CO₂ from an anaerobic bioreactor or absorption from the atmosphere for the conversion of the recovered metals and the slag to products which can be sold (e.g., Portland cement). In the case an anaerobic reactor is used, methane is also produced as biogas. Furthermore, the carbon tax acquired from the utilization of the CO₂ can also be sold as carbon credit. Thus, the recovery process creates new revenue streams, apart from the metals and LIB waste, by applying Circular Economy concepts, and creating new pathways for the reduction of atmospheric CO₂ emissions.

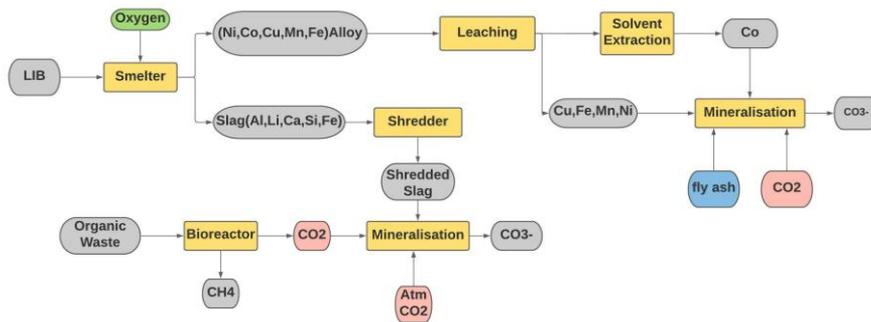

Figure 2. Flowsheet of the improved LIB recovery process

Once the process flowsheet is available, the following steps are followed to evaluate its efficiency and use the results for the comparison with the baseline:

- a) Calculate the cost of operating the anaerobic bioreactor and the shredder through their energy consumption.
- b) Calculate the cost of mineralization of the recovered metals and slag.
- c) Calculate the total cost of the overall improved process.
- d) Calculate the revenue generated from the sale of methane produced from the bioreactor as biogas.

- e) Calculate the revenue generated from the sale of slag Portland cement produced during the mineralization.
- f) Calculate the total carbon tax on the total CO₂ consumption for the whole processes which is to be sold as Carbon Credit.
- g) Calculate the total revenue of the overall improved process.
- h) Calculate the profit of the improved process after a 15% predicted reduction in cost due to economies of scale.

3. Results and Discussion

The recovery of the metals is divided into precious and non-precious metals, according to their market value. All precious metals are recovered through leaching and solvent extraction, while the non-valuable metals are extracted as slag during the smelting stage as. From the costing of the stages of the Umicore process (Table 1), the leaching contributed approx. 94% to the total recovery cost of \$19,858.16, while the solvent extraction and smelting contributed approx. 6.5 and 0.15%, respectively.

Table 1. State-of-the-art subprocess cost breakdown

Process	Cost (\$)	%
Smelting	1,266.28	6.38
Leaching	18,565.69	93.49
Solvent extraction	26,20	0.13
Total	19,858.16	100

The revenue generated from the recycling processes is comprised of the following streams: the selling of the recovered precious metals, the selling of the slag and the tipping fee (Table 2).

Table 2. State-of-the art subprocess revenue breakdown

Revenue breakdown	Valuation (\$)	%
Valuable metals	10,266.79	51.36
Slag resell value	223.02	1.16
Recycling fee per tonne	9,500	47.52
Total	19,989.81	100

As a commercial recycling process, it is predicted that a 25% reduction in recycling cost is expected due to economies of scale after the processing of 7,000 tons/year of LIB waste, which is the current operating capacity of the Umicore Process. This results in a profit of \$35,343,248 per year (Table 3).

The major cost of the improved process is the cost of mineralization, with a percentage of 99.81% for the cost of mineralizing the slag (0.04%) and the high value metals (99.77%), while the cost of the mechanical treatment by shredding contributes 0.15%.

Table 3. Cost-Revenue breakdown of current state-of-the-art process

	Value (\$)
25% Cost reduction	34,861,757
Improved cost	104,585,272
Revenue	139,928,701
Profit	35,343,428

Table 4. Cost breakdown of the improved process flow

Process	Cost (\$/year)	Percentage (%)
Bioreactor	61,205.76	0.04
Shredding	205,920.00	0.15
Slag mineralisation	52,992.92	0.04
Metals mineralisation	140,132,160.00	99.77
Total Cost	140,452,278.68	100
Reduction due to economy of scale (15%)	21,067,841.80	
Total	119,384,436.87	

Table 5. Revenue breakdown of the improved process flow

Revenue breakdown	Valuation (\$/year)	%
Carbon tax	1,414,011.40	1.50
Methane	19,225,728.00	20.38
Digester tipping	1,647,360.00	1.75
Mineralised metals	71,867,558.52	76.16
Slag Portland cement	203,218.02	0.22
Total	94,357,875.94	100

Table 6. Cost-Revenue breakdown of the improved process

Process economic parameters	Valuation (\$/year)
Total revenue	94,357,875.94
Cost	119,384,436.87
Loss	25,026,560.93

The total revenue from the improved metal recovery process focuses on applying a Circular Economy approach and the introduction of new revenue streams from the production of methane and slag Portland cement, in addition to the sale of stable

mineralized metals and the carbon credit achieved. As shown in Table 5, a total revenue of \$94,357,876 per year is achieved for the proposed process.

From Table 5, the revenue generated from methane and mineralized metal contributes 20.38% and 76.16%, respectively to the total revenue of the improved process. Additionally, the cost of mineralizing the metals contributes 99.77% to the total cost of the improved process (Table 4). This results in a loss of \$25,026,560 per year compared to a profit of \$35,343,428 from the Umicore process, as illustrated in Table 6. However, the improved process is able to use 46,270.01 metric tons of carbon dioxide per year.

4. Conclusion

This work analyzes the current state-of-the-art for the LIB recycling process from an economical perspective, by estimating its cost and revenue generated from the sale of the recovered metals. The results are used as a baseline to propose an improved conceptual pathway for the metal recovery process from both an environmental and economic perspective, with the introduction of new technologies that use carbon dioxide as input and improve the recovery efficiency.

This improved pathway for the recovery of metals from spent LIBs is efficient in recovering metals and recycling of organic waste which could have ended up in the landfill causing degradation of soil and water and increasing toxic and microbial levels in the environment. The mineralization of the recovered metals in the improved process uses up all the CO₂ from the digester, with captured carbon dioxide hypothetically making up for the deficit, with a total consumption of 46,270.01 metric tons per year. This serves as an environmental advantage in reduction of possible anthropogenic CO₂ released to the atmosphere compared to the current Umicore process.

Nonetheless, the new recovery pathway is more expensive compared to the commercially implemented process, with the mineralization of the high value metals taking up a huge percentage of the total cost. The revenue created by Circular Economy from the production of secondary materials (slag Portland cement) and reselling of the high value metals is not able to offset this high cost, which results in a loss of the overall proposed process. The high cost of mineralization can be reduced with improved investment in the integration of the chemical process into current carbon capture and storage technologies of current industrial processes.

Sensitivity Analysis and Risk Assessment for the In-Silico Design and Use of Optimized Cell Factories in a Xylitol Biorefinery

Nikolaus I. Vollmer,^a Krist V. Gernaey,^a Gürkan Sin^a

^a*Process and Systems Engineering Center (PROSYS), Department of Chemical and Biochemical Engineering, Technical University of Denmark, Søtofts Plads, Building 228A, 2800, Kongens Lyngby, Denmark*

Abstract

This work presents the results of investigating the design and use of optimized cell factories in a biorefinery. Based on a base-case process design created in an optimization-based framework, the cell factory models are analyzed through a sensitivity analysis to define and implement engineering targets. With the engineered cell factory models, flowsheet simulations are performed for a risk-based uncertainty analysis. The results show significantly improved economics of the biorefinery. A future outlook about integrating cell factory optimization into process design and optimization is given.

Keywords: Biorefinery, Mechanistic Modelling, Monte Carlo, Cell Factory Optimization

1. Introduction

Second-generation biorefineries are a key element in the transition towards more sustainable production processes and bio-based value chains. Despite harboring this immense potential, second-generation biorefineries are consensually hardly economically feasible (Ubando et al., 2020). Compared to first-generation biorefineries, the second generation commonly utilizes lignocellulosic biomass as feedstock, requiring an additional biomass pretreatment unit. This implies several challenges: firstly, the related capital and operational expenditures for the pretreatment unit directly affect the key performance indicators (KPIs) of the plant and, furthermore, both the sugar yield, as well as the yield of undesired inhibitor compounds created in the pretreatment influence the yield of the conversion processes and the downstream processing of the whole process (Vollmer et al., 2021b). Consequently, this also has a mediate effect on the KPIs, which often results in a poor overall economic performance.

On another note, there has been immense progress in cell factory optimization in the last decade. Firstly, rational design approaches in synthetic biology and genetic and metabolic engineering allow for optimizing yield, titer, and productivity of existing cell factories by manipulating metabolic pathways through, e.g., the overexpression or knockout of genes. Moreover, new cell factories can be created by inserting heterologous pathways by tools like, e.g., CRISPR-Cas9. This potential is currently unfolding and will further revolutionize biotechnology in the coming years. Secondly, irrational design approaches, e.g., adaptive laboratory evolution, can be employed to optimize cell factories by fast-forwarding the natural evolution process towards more robust or adapted cell factories for different operating conditions. Nonetheless, the translation of this paramount progress to bridge the gap into the process engineering domain for the design and optimization of

entire biotechnological processes is complex and highlights the need to integrate these approaches over different scales (Straathof et al., 2019)

In the scope of this work, a base-case process design for the production of xylitol and succinic acid is taken as the basis for investigating the potential of optimized cell factories in a second-generation biorefinery. For this, different tools from process systems engineering are used: Based on wild-type cell factories for the fermentation processes for both products, a sensitivity analysis is performed on both mechanistic models of the cell factories to identify targets for optimization in the cell factories to increase yield, titer, and/or productivities. Based on the results of the sensitivity analysis, the mechanistic models are redesigned accordingly to resemble the optimized cell factory. With these, a risk-based techno-economic analysis with a whole process model for the biorefinery is performed in order to investigate the economic potentials of the optimized-case process design. Ultimately, the conclusions of the analysis highlight potential future directions for the in-silico design of optimized cell factories and biotechnological processes to accelerate the transition towards bio-based value chains.

2. Methodology

2.1. Xylitol Biorefinery

2.1.1. Base-Case Process Design

The mentioned xylitol biorefinery was designed by Vollmer et al. (2021c) in an optimization-based framework – S3O – and assessed through a techno-economic analysis: The framework employs mechanistic unit operation models through surrogate models in the optimization procedure. The biorefinery involves a pretreatment unit for the lignocellulosic biomass, where the hemicellulosic fraction is separated and depolymerized. The resulting hydrolysate is upconcentrated in an evaporation unit. Subsequently, the sugars are used as substrate in a fermentation unit to produce xylitol. The downstream process involves an evaporation unit and two crystallization units. The solid residue of the pretreatment is subjected to enzymatic hydrolysis to separate the cellulosic fraction and depolymerize the sugars. These are used as substrate in a second fermentation process to produce succinic acid. The downstream process for succinic acid also involves an evaporation unit and two crystallization units. Lastly, the lignin fraction is combusted for steam and electricity generation to be integrated with the downstream processes (Vollmer 2021a, c). The flowsheet of the process is illustrated in Figure 1.

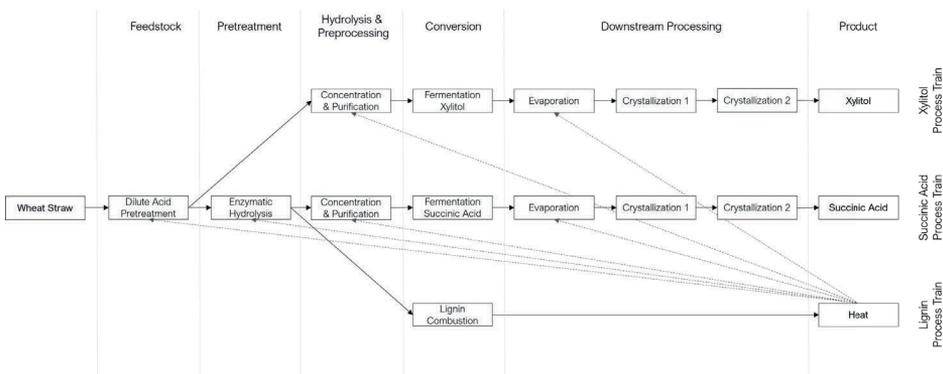

Figure 1: Flowsheet of the Base-Case Process Design of the Xylitol Biorefinery (adapted from Vollmer et al. 2021c)

2.1.2. Fermentation Models and Cell Factory Design

Both fermentation models are mechanistic models and based on a so-called black-box approach, referring to the reduction of intracellular reactions into three essential reactions, as depicted by Heijnen (2009): The first reaction describes the substrate uptake into the cell factory as shown in equation (1):

$$q_s = q_s \cdot \frac{C_s}{K_s + C_s} \cdot 1/I_s \cdot 1/I_p, \quad (1)$$

Here, q_s denotes the rate of substrate uptake, C_s the substrate concentration, K_s the substrate affinity constant of the cell factory and I_s and I_p terms for substrate and product inhibition. The second reaction is a Herbert-Pirt substrate distribution relation, summarizing the intracellular metabolism. Mathematically, this is described by equation (2):

$$q_s = a \cdot \mu + b \cdot q_p + m_s. \quad (2)$$

Here, a and b describe the yields of biomass and product over the substrate and μ the cell growth rate, q_p the product formation rate and m_s the cell maintenance rate.

Lastly, the third reaction is a Luedeking-Piret equation describing the product formation, given with equation (3):

$$q_p = \alpha \cdot \mu + \beta. \quad (3)$$

Here, α and β are fitted parameters, describing the product formation as a function of the cell growth (Heijnen, 2009). For the base-case process design, the model is fitted to wild-type strains of cell factories that naturally produce xylitol or respectively succinic acid. The reader is referred to the original work for a detailed description of the models and the fitted parameters (Vollmer et al., 2021c).

2.2. Monte Carlo Methods

2.2.1. Sensitivity Analysis

Sensitivity analyses attribute uncertainty in a model output to the different model inputs. In this work, we apply a variance-based sensitivity analysis based on Monte Carlo Simulations and implemented in the easyGSA package (Al et al., 2019). Both the first-order as well as the total sensitivity index are calculated. While the prior describes the sensitivity of the model output to uniquely this parameter, the latter describes the sensitivity of the output to the model parameter when considering all interactions with other input parameters (Vollmer et al., 2021b).

2.2.2. Uncertainty Analysis

The complementary to sensitivity analyses are uncertainty analyses trying to quantify the model output with varying model input. The methodology applied in this work is equally based on Monte Carlo Simulations. After defining input uncertainties and ranges, a sampling method is chosen, and Monte Carlo simulations are performed. The results are subsequently analyzed.

3. Results

3.1. Sensitivity Analysis of Cell Factory Model

As a first step, sensitivity analyses for both fermentation models are performed to determine the model parameters with the highest sensitivities. Each parameter can uniformly vary by $\pm 50\%$, equivalent to downregulating or overexpressing genes for specific pathways in the microorganism. For the xylitol model, $N = 8192$ and for the succinic acid model $N = 4096$ Monte Carlo samples are performed, using Sobol sampling. The results for the total sensitivity indices are shown in Figure 2.

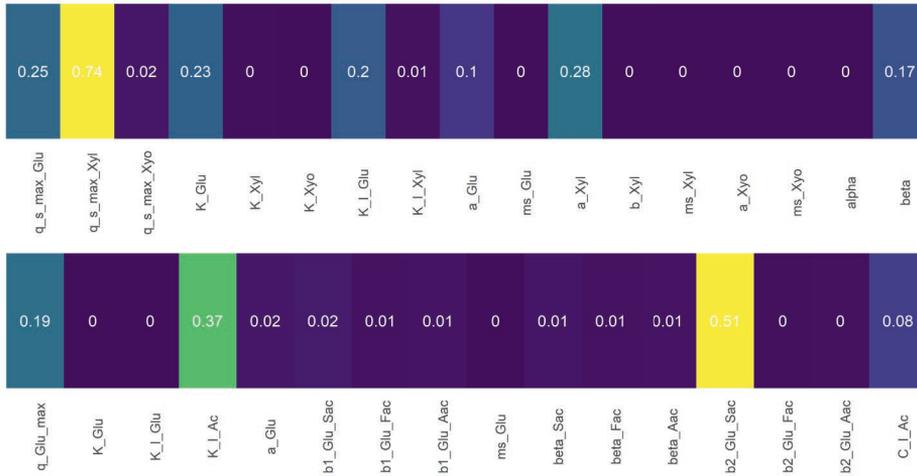

Figure 2: Heatmap of the total sensitivity indices for the fermentation model parameters.

For the xylitol cell factory, the most sensitive parameter is the substrate uptake rate of xylose. An increased uptake rate directly influences the productivity of the cell factory as the throughput through the cell factory increases as a function of the uptake rate. Secondly, also the operational yield of biomass over xylose a_{xyl} and the constant parameter of the product formation equation β influence the output, increasing the biomass growth and thus indirectly increasing the yield of xylitol over xylose. Lastly, the parameters related to the glucose uptake and growth on glucose influence the output, as the uptake of xylose is catabolically repressed by the glucose uptake, which influences productivity. For the succinic acid cell factory, the most influential parameters are the operational yield of succinic acid over glucose, increasing the yield of succinic acid directly, and the inhibition constant for the acids, which induces product inhibition in the cell factory. Secondly, the glucose uptake rate influences the output as increased substrate uptake also increases productivity.

3.2. Risk Assessment of Economic Feasibility

Based on the results presented in section 3.1, the following cell factory design is conceptualized and translated into the model parameters for retrofitting the fermentation models to engineered cell factories: The cell factory optimization for both models aims at increasing the yield of the respective product over the respective substrate. The product yields over substrate for both wild-type cell factories lie around 40 – 55%. The engineering strategy for the xylitol cell factory targets the growth metabolism on xylose, e.g., by overexpressing genes of relevant enzymes and the excretion of xylose out of the cell factory, e.g., by overexpressing the genes for the transporter. Mathematically, this is done by increasing the value of a_{xyl} and β by 75%. This translates to a new product yield of around 80% for the microorganism. The engineering strategy for the succinic acid cell factory targets the acid tolerance I_p to decrease the product inhibition, e.g., by performing adaptive laboratory evolution in media with low pH. Furthermore, the operational yield of succinic acid over glucose b_{Suc} is increased by e.g. knocking out respective genes for enzymes through a metabolic engineering approach. Mathematically, this is done by decreasing the value of I_p and increasing the value of b_{Suc} by 20%. This translates to a new product yield of around 80% for the microorganism. Both engineering strategies

have been proven to be realistic in different laboratory studies by the mentioned or similar engineering strategies (Hernández-Pérez et al., 2019 and Mancini et al., 2020).

Employing both retrofitted models in the S3O framework, an updated-case process design can be simulated to perform a new techno-economic analysis. Based on the results from Vollmer et al. (2021c), the four most promising candidate process topologies are investigated. Equally to the original study, uncertainties in the capital and operational expenditures (CAPEX and OPEX), including all equipment and utilities considered, and the product prices are assumed. The CAPEX varies in the interval $[-50, +100]\%$ and the OPEX varies in the interval $[-20, +50]\%$, assuming a triangular distribution for both. The product price of the xylitol varies between $4.29 \text{ \$/kg}$ and $5.42 \text{ \$/kg}$, and the succinic acid price between $3.18 \text{ \$/kg}$ and $3.24 \text{ \$/kg}$, assuming a uniform distribution for both. When performing an uncertainty analysis with these, $N = 1000$ Monte Carlo simulations and analyzing the net present value of the xylitol biorefinery as, the failure rates of investment result as $R_f = 48.9\%$, 86.9% , 92.4% and 55.5% (Vollmer et al., 2021c). Repeating the same uncertainty analysis with the engineered cell factory models and otherwise unaltered parameters, the metrics change significantly, as illustrated in Figure 3.

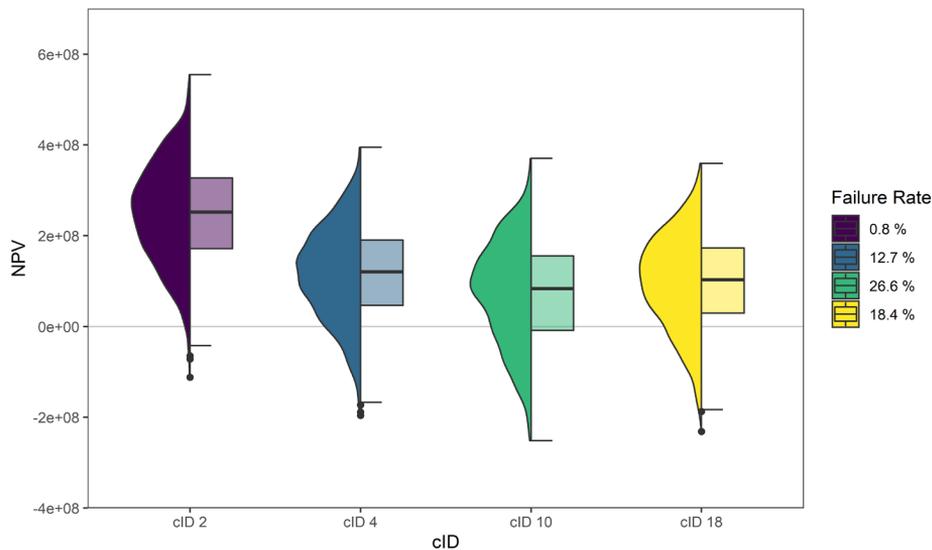

Figure 3: Results from the uncertainty analysis of the net present value of the xylitol biorefinery with engineered cell factories

Prominently visible is the increased economic feasibility for all four candidate process topologies. In particular, process configuration cID 2 shows an outstandingly low failure rate. This directly correlates with the increased yields of the engineered cell factories, consequently increasing the product sales without altering CAPEX or OPEX.

4. Conclusions

In this work, we showcased the potential in-silico design of cell factories based on mechanistic models for the use in a second-generation biorefinery. Based on a sensitivity analysis, the most sensitive model parameters of the cell factories were defined, and based on approaches in cell factory optimization, engineering targets were defined to increase

the product yield of the cell factories. The retrofitted cell factory models were used in flowsheet simulations to perform a risk-based uncertainty analysis on the net present value of the biorefinery to analyze the failure rate of the investment. Compared to the base-case process design, the optimized-case process design shows minimal failure rates, indicating a profitable investment.

Directions for future work could be the actual optimization of the model parameters by mathematical methods to guide potential cell factory optimization efforts. Ultimately, the used mechanistic models of the cell factories should be replaced by full genome-scale metabolic models, containing detailed information about the metabolism and potentially even information about transcriptional, metabolic, and other constraints. In Systems Biology, such models are constantly developed and improved and used for dynamic flux balance analysis to simulate fermentation processes (Sánchez and Nielsen, 2015). Integrating these models in full process models in a framework like the S3O framework would allow the simultaneous optimization-based design of cell factory, process, and value chain in a multi-scale approach. Ultimately, this approach allows bridging the gap between cell factory optimization and process design to accelerate the transition towards more bio-based processes and value chains for more sustainable industrial production.

Abstract

This work develops a multi-product MILP vaccine supply chain model that supports planning, distribution, and administration of viral vectors and RNA-based vaccines. The capability of the proposed vaccine supply chain model is illustrated using a real-world case study on vaccination against SARS-CoV-2 in the UK that concerns both viral vectors (e.g., AZD1222 developed by Oxford-AstraZeneca) and RNA-based vaccine (e.g., BNT162b2 developed by Pfizer-BioNTech). A comparison is made between the resources required and logistics costs when viral vectors and RNA vaccines are used during the SARS-CoV-2 vaccination campaign. Analysis of results shows that the logistics cost of RNA vaccines is 85% greater than that of viral vectors, and that transportation cost dominates logistics cost of RNA vaccines compared to viral vectors.

Keywords: SARS-CoV-2 vaccines, vaccination campaign, mathematical programming, economic analysis, vaccine availability.

1. Introduction

The COVID-19 pandemic has accelerated the research and development of new platform technologies for the production of vaccines against infectious diseases, including the novel corona virus, also known as Severe Acute Respiratory Syndrome Corona Virus 2 (SARS-CoV-2). Platform technologies such as viral vectors (Voysey et al., 2021) and RNA (Walsh et al., 2020) have been used to develop vaccine candidates to combat COVID-19. However, these new vaccines pose both logistics and distribution challenges. For example, unlike conventional vaccines, certain RNA-based vaccines require ultra-low temperature throughout the distribution network to avoid loss of potency.

Vaccine supply chain is a complex network that facilitates the transport of vaccines from manufacturing plants to administration points, such as GP surgeries, hospitals, pharmacies, clinics, and mass vaccination centers. The storage and transport conditions required by vaccines determine the type of cooling technology (e.g., fridge, freezer, or ultra-low freezer) to be installed at storage locations. During transportation, ultra-low temperature is maintained using thermal shipper loaded with dry ice (liquified CO₂).

The structure of a typical vaccine supply chain comprises manufacturing plants or import locations, fill-finish plants, warehouses/central stores, regional stores, and administration points. A manufacturing plant, aka primary manufacturing, consists of several unit operations used in the production of drug substance, which is the main ingredient in vaccines, while a fill-finish plant, also known as secondary manufacturing, inserts

vaccines (drug substances and excipients) into sterile glass vials or bags that are further packaged into cartons.

The design and planning of vaccine supply chains addresses the following: optimal selection of storage locations, production planning at manufacturing and fill-finish plants, inventory management/storage capacity planning, distribution planning, selection of routes and transport types, etc. In the recent past, Lee and co-workers (2014; 2015, 2016) have applied a simulation-based analytical tool, known as HERMES–Highly Extensible Resource for Modeling Supply Chains, to assess and re-design vaccine supply chains in low- and middle-income countries. However, HERMES does not support optimisation of supply chains, leading to solutions that could be suboptimal. Cavalho et al. (2019) developed a mixed-integer linear programming (MILP) model for optimal design and planning of a sustainable vaccine supply chain. The key performance indicators used to assess candidate supply chains are related to economic, environmental, and social performance. Kis et al. (2019) developed a supply chain model for the distribution of vaccine candidates such as RNA vaccines, outer membrane vesicle vaccines with genetically customizable membrane antigens virus-like particle vaccines with genetically configurable epitopes, and humanized yeast-produced vaccines. The model optimizes both supply-chain configuration and delivery type. Recently, Georgiadis & Georgiadis (2021) developed a MILP model for the distribution of COVID-19 vaccine and proposed an efficient method to solve the complex model. Nevertheless, the model does not account for quality control checks, fill-finish plants, production planning, selection of transport mode, and more importantly, management of vaccine thermal shippers.

This work develops a multiple-product MILP supply-chain model that supports the planning and distribution of viral vectors and RNA-based COVID-19 vaccines, from manufacturing plants to vaccination centers where vaccines are administered to targeted individuals. Unlike previous work, the proposed optimisation-based supply chain model comprises of five echelons, including manufacturing plants, fill-finish plants, imports, warehouses, regional stores, and administration points. A recycle loop for vaccine thermal shippers from warehouses to administration points and back to warehouses is implemented to ensure efficient management of vaccine thermal shippers. Including these entities within the supply-chain model allows efficient distribution of viral vectors and RNA-based vaccines, in addition to setting production targets at manufacturing and fill-finish plants. The performance of candidate supply chains is assessed using relevant key performance indicators such as vaccine availability, logistics cost, logistics cost per fully immunized patients, etc.

2. Methodology

2.1. Vaccination scheduling

Vaccination campaigns against infectious diseases are mostly preceded by scheduling of targeted individuals as well as healthcare personnel needed to administer vaccines. For the COVID-19 vaccination campaign, targeted individuals are selected according to risk of mortality and hospitalization when exposed to the highly contagious disease. Next, the targeted individuals are stratified, giving rise to cohorts to be schedule for the vaccine administration. The cohorts are prioritized according to risk-factors and vulnerability to COVID-19. Based on the COVID-19 vaccine regimen, the total number of doses required is estimated, and hence the vaccine demand profiles. By dividing the daily/weekly number of vaccinations by workload, it is possible to estimate the number of healthcare

workers that should be schedule on daily/weekly basis in order to ensure a successful vaccination campaign. This calculation may be carried out separately or embedded within the supply-chain model described in Section 2.2.

2.2. Design and planning of vaccine supply chains

The proposed vaccine supply-chain model supports the distribution and administration of vaccine candidates developed using various platform technologies, including viral vectors and RNA-based vaccines. The proposed supply chain comprises five echelons: manufacturing plants/imports, fill-finish plants, central stores, regional stores, and administration points (see Figure 1). Vaccines flow from manufacturing plants to vaccination centers via transportation modes, which can be a refrigerated van, a refrigerated truck, or an airplane. For vaccine candidates requiring ultra-low cooling temperatures, vaccine “thermal shippers” are used to ensure that the recommended temperature is not compromised during transportation. A recycle loop from warehouses to clinics and back to warehouses is implemented to enable efficient management of thermal shippers. The model inputs and outputs are summarised in Table 1.

Table 1. Vaccine supply chain inputs and outputs

Inputs	Outputs
i. vaccine demand profile	i. optimal supply chain configuration
ii. proposed supply chain structure (optional)	ii. transport mode per route
iii. minimum and maximum inventories (manufacturing and fill-finish, warehouses, regional stores, and administration points)	iii. backlog in each time period
iv. minimum and maximum capacities of manufacturing plants, fill-finish plants, and import rate	iv. vaccine availability and vaccine wastage at administration points
v. minimum and maximum capacities of transportation modes	v. vaccine supplied to administration points per time period
vi. operating cost and capital cost factors (manufacturing and fill-finish, warehouses, regional stores, and administration points)	vi. vaccine import rate and production rates in manufacturing and fill-finish plants
vii. travel distances and times	vii. capacity of quality control facilities
	viii. capital cost, operating cost, and total annualised cost of supply chain facilities
	ix. total transportation cost and transport cost per route
	x. inventories of vaccines in manufacturing, fill-finish, warehouses, regional stores, and administration points
	xi. inventories of vaccine thermal shippers (full and empty) in warehouses, regional stores, and administration points

Note that thermal shippers are needed only for vaccines stored and transported at ultra-low temperature. Also, constraints are included in the supply chain model to ensure that vaccines stored at clinics do not stay longer than their shelf-life. The objective function used to assess the performance of candidate supply chains include logistics cost, logistics

cost per fully immunized patient, and total cost of supply chain components. The model is built in GAMS, where the solver CPLEX is used to optimise the MILP model.

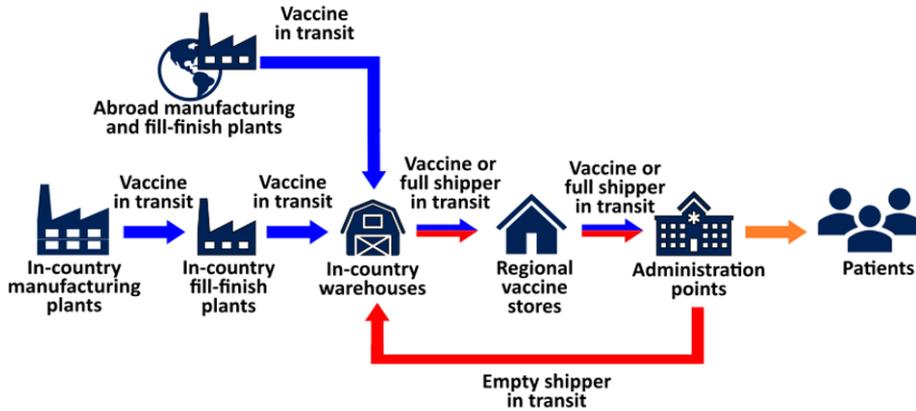

Figure 1. Schematic of the proposed vaccine supply chain comprising internal and external manufacturing and fill-finish plants, in-country warehouses, regional vaccine stores and administration.

3. Application

This section illustrates the capabilities of the proposed multi-product vaccine supply-chain model against COVID-19 in the UK, considering both viral vectors (AZD1222) and RNA vaccines (BNT162b2). The targeted individuals, as recommended by the UK Joint Committee on Vaccination and Immunization (JCVI), includes: care home residents, residential care workers, age 80 plus, health care workers, social care workers, age group 75-79, age group 70-74, clinically extremely vulnerable (under 70), age group 65-69, at risk (under 65), age groups 60-64, 55-59, and 50-54. For both vaccines, individuals are required to take two doses to be fully immunized. Vaccine doses are administered at least three weeks apart, leading to a vaccination timeframe of 38 weeks. The optimal supply chain distribution network is determined by the supply-chain model together with production targets at manufacturing and fill-finish plants, as well as vaccine inventory at storage locations, distribution planning, selected transportation mode, number of shippers and quantity of dry ice needed, etc. The total logistics cost and cost of supply chain components for viral vectors and RNA vaccines are shown in Figure 2 and Table 2, respectively.

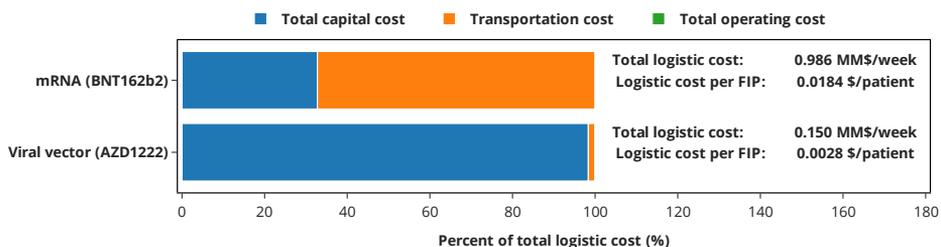

Figure 2. Total logistics cost required to deliver vaccines from manufacturing plants to administration points in England, Scotland, Wales, and Northern Ireland. The costs of precuring AZD1222 and BNT162b2 are not included, since logistics cost is the sum of total annualized capital cost, transportation cost, and total operating cost.

Figure 2 compares the logistics cost and logistics cost per fully immunized patient (FIP) for viral vectors and RNA-based vaccines. Note that there is no inventory of vaccines at warehouses and regional stores throughout the vaccination campaign, leading to zero operating cost, as shown in Figure 2. In this case study, vaccine inventory accumulates at administration points only. Note that this work considers a fixed supply chain structure in order to mimic the existing vaccine distribution network in the UK. Therefore at the design level, the supply chain model selects the transport type between echelons and their corresponding delivery frequency, which are discussed below.

From the results, the logistics cost of RNA vaccines is 6-fold larger than that of viral vectors. Similar trend is observed for logistics cost per FIP. Logistics cost is the sum of total annualized capital cost, transportation cost, and total operating cost. The high logistics cost observed for RNA vaccines is due to the large delivery frequency required to deliver sufficient vaccines to administration points during the vaccination campaign. RNA vaccine candidate, BNT162b2, has a shelf life of five days when stored at 2-8°C or kept in thermal shippers (without re-icing) and two hours at room temperature. Hence vaccine inventory can be kept to satisfy demand for five days only in order to avoid loss of potency and vaccine wastage. On the contrary, viral vector candidate, AZD1222, have a shelf life of six months at 2-8°C, thus warehouses, regional stores, and administration points can hold vaccine inventory for a longer period, consequently reducing the delivery frequency, but increasing the total annualized capital cost (see Figure 2). The increase in total annualized capital cost is due to the larger cold chain storage facility required to hold vaccine inventory. Another factor that leads to high transport cost for RNA vaccines is that BNT162b2 is produced in Pfizer-BioNTech manufacturing plant in Puur, Belgium, and have to be transported using an expensive transport mode (airplane) to warehouses in London, Edinburgh, Cardiff, and Belfast. On the other hand, viral vector candidate, AZD1222 is produced in the UK transported using refrigerated truck.

In addition to logistics cost and logistics cost per (FIP), the supply-chain model estimates the cost of other vaccine supply- chain components (see Table 2), including thermal shipper, dry ice, vaccinator wages, vaccine procurement, and quality control checks.

Table 2. Total cost of vaccine supply chain components such as vaccine thermal shippers, dry ice, vaccinator wages, vaccine procurement, and quality control checks.

Item (in million \$)	AZD1222	BNT162b2
Cost of vaccine shipper	-	7.72
Cost of dry ice	-	20.30
Cost of vaccinating individuals	1880.0	1880.0
Cost of vaccinating individuals at care home	24.10	24.10
Cost of vaccine procured	450.0	2000.0
Cost of quality control checks	59.90	59.90
Total cost	2420.0	3990.0

In Table 2, the total supply chain components cost for AZD1222 and BNT162b2 are \$2.42 and \$3.99 billion respectively. The selling price of BNT12b2, \$18 per dose, is higher than that of AZD1222, \$3 per dose, leading to 78% increase in the procurement cost of vaccine needed to vaccinate the entire UK target population of approximately 53 million individuals with two doses. AZD1222 does not require ultra-low cooling during

transportation, hence no thermal shipper and dry ice are required. Apart from the recycle loop for vaccine thermal shippers, the supply chain structure for ADZ1222 and BNT162b2 is similar. Also worth mentioning is that the storage technology for the two supply chains differs, i.e., refrigerators (2-8°C) for AZD1222 and deep freezers (-80°C) for BNT162b2. Deep freezers lead to high operating cost as a result of energy consumption needed for ultra-low temperature cooling.

4. Conclusions

A multi-product MILP vaccine supply chain model has been developed considering the essential features of a typical vaccine supply chain. The model can be used to design, plan, and optimize the distribution and administration of vaccine candidates developed using the most advance platform technologies, i.e., viral vectors and RNA. A case study compared the logistics costs when either viral vectors or RNA-based vaccines are used during a vaccination campaign against COVID-19 in the UK. The results show that the logistics cost of RNA-based vaccines (BNT162b2) is far greater than that of viral vector (AZD1222). Transportation cost dominates logistics cost of RNA-based vaccines as a result of high delivery frequency needed to supply sufficient vaccines to administration points. The long shelf life of viral vectors allows this vaccine type to be stored at administration points for a period of up to 6 months, consequently increasing capital cost related to storage facility.

Abstract

The paper focuses on three different modeling approaches to describe the dynamic evolution of an epidemic. These models have been extensively tested in the field and applied to Italy, one of the countries that most suffered from Covid-19.

Keywords: Covid-19, pandemic, modeling, early-warning, vaccination policies.

1. Introduction

Covid-19 pandemic with its prolonged and iterated waves has caused emergencies at the hospital and political levels calling for responsible and prompt decisions. The “every day counts” saying is meaningful when one has to make choices and resolutions that have an impact on human lives. At the very beginning of Covid-19, there was no knowledge of the outbreak dynamics and rather simple questions about the expected allocation of resources for hospital wards and intensive care units (ICU) were difficult to answer. If one was able to answer those questions, the replies shocked both medical doctors and general managers of hospitals because the exponential growth of the pandemic phenomenon had never been experienced before in most continents of the world. The doubling time of infected, hospitalized, intubated, and dead individuals were unprecedented and often as short as two-three days.

Similar questions about the time evolution and intensity of the outbreaks were raised by local and central government representatives who were interested in making timely decisions to contain the spreading and relieve the pressure on all the organs responsible for the health and safety of citizens. Finally, the world of information focused most of its attention on the pandemic and on any news capable of predicting, quantifying, and assessing fragments of the whole framework. Mass media urged insistently on ever updated and critically analyzed pandemic data.

Most of the questions focused on what-if scenarios and resource allocation, pressure, and duration. The queries were first formulated for short-term horizons but quickly expanded towards medium- and long-term perspectives. The short-term horizon involved decisions for the allocation of hospital resources such as beds, wards, resuscitation personnel, and scarce material. The medium-term horizon called for decisions about non-pharmaceutical protective actions such as masks, swabs, social distancing, and lockdowns. These decisions had to find a balance between health/safety/treatment and economy/security/freedom of the population. Finally, both hospitals and governments called for a quantitative prediction of the pandemic on a long-term horizon to psychologically start seeing the light at the end of the tunnel (i.e. hope, perseverance, and resilience), to dynamically (re)allocate hospital means to elective medicine rather than

emergency treatments, and to loosen the strict lockdown rules in favor of a progressive return to normality. In the meanwhile, there were new requests for a quantitative prediction of pandemic-related themes when the first wave came almost to an end but suddenly a second outbreak caught most of the countries unprepared. Afterward, there have been further pandemic waves and some nations have experienced the fourth and fifth waves with the onset of new virus variants. What it was deemed to be understood became suddenly new and unknown. The lessons learned were no more sufficient and a new call for quantifying the ever-changing and multifaceted pandemic became evident and compelling. In the meanwhile, the first vaccines were released. Initially, for several months, the doses were few and the fragile population was exposed to more infectious and lethal virus variants (e.g., alpha, beta, delta, omicron to cite the most circulated). The vaccination problem was hyper-constrained as several categories claimed the right to be vaccinated first and every government adopted different sanitary policies. These governments chose different criteria to vaccinate the population and to inject the vaccine with different time intervals between doses. There was a new call for understanding the optimal vaccination policy and finding a suitable compromise between population coverage in number and category to reduce both the overall pandemic risk and mortality, as well as achieve more robust sanitary and public force systems. The paper shows how the PSE community with its tools, algorithms, models, and methods can cover, analyze, and quantify the different topics and issues that were listed above.

2. Short-term pandemic models

At the very beginning of the Covid-19 outbreak, the hospital heads of resuscitation wards were overwhelmed by SARS-CoV-2. The most stringent resource in hospitals was ICU beds. Resuscitation heads had often to double and even increase three-, four-, five-folds the number of beds in a few days alongside the resources connected (e.g., air-breathing lines, respiratory devices, monitors, space allocation, dirty and clean areas/paths). Human resources were the determining step, which called for specialized ICU doctors and nurses. Indeed, these specialized operators can be neither increased nor hired in the characteristic time of an epidemic. It calls for years of planning and formation. Regarding the dynamics of Covid-19 ICU beds, they start from zero at the very beginning of an epidemic (or from a positive known value in case of subsequent waves) and they increase steadily up to a maximum value. In the following, the ICU wards begin emptying and they reach either a final null value at the end of the epidemic or a minimum nonzero plateau before a new outbreak triggers the inversion of deflation with a new inflation trend. Similar qualitative behavior occurs also for daily positives, hospitalized, healed, and dead. Conversely, the total cumulated values of those quantities are curves that are monotonically increasing and reach either temporary or permanent plateaus between two waves or at the end of the epidemic respectively. Manca *et al.* (2020) proposed three different curves that describe the inflation trend of a pandemic wave: the exponential, the logistic, and the Gompertz functions (Eq.s 1-3). The mathematical description of the exponential model is:

$$y = a10^{bt} \quad (1)$$

The mathematical description of the logistic model is:

$$y = \frac{a}{1 + b \exp(-ct)} = \frac{a}{1 + b e^{-ct}} \quad (2)$$

The mathematical description of the Gompertz model is:

$$y = a \exp(-b \exp(-ct)) = a e^{-b e^{-ct}} \quad (3)$$

The adaptive parameters of Eq.s 1-3 can be evaluated through a nonlinear regression of real values that are periodically measured at both regional and national levels. For the sake of clarity, the logistic curve performs comparably and sometimes worse than the Gompertz model, which is the preferred one. Equally, the exponential model is very compact and effective at the very beginning of each outbreak but it soon overpredicts the epidemic dynamics. Hence, Gompertz is the most robust model and its analytical features allow also evaluating the inflection point, $t_{infl} = \ln(b)/c$, and the halfway point, $t_{halfway} = -\ln(\ln(2)/b)/c$. In addition, a is the asymptote of the dynamic inflation phenomenon. Once the plateau is reached, the curve starts decreasing and the reverse Gompertz function (Eq. 4) describes the deflation region:

$$y = a \left(1 - e^{-b e^{-c(t-t_0)}} \right) \tag{4}$$

Equally, the around-the-maximum period is well described by Eq. 5 which is an exponentially modified Gaussian (EMG) curve:

$$y = 10^{at^2+bt+c} \tag{5}$$

Figure 1 shows the typical dynamic behavior of both direct/reverse logistic and Gompertz functions, and the EMG curve for the ICU patients of Lombardy (the most populated region of Italy with over 10 million citizens) during the first pandemic wave.

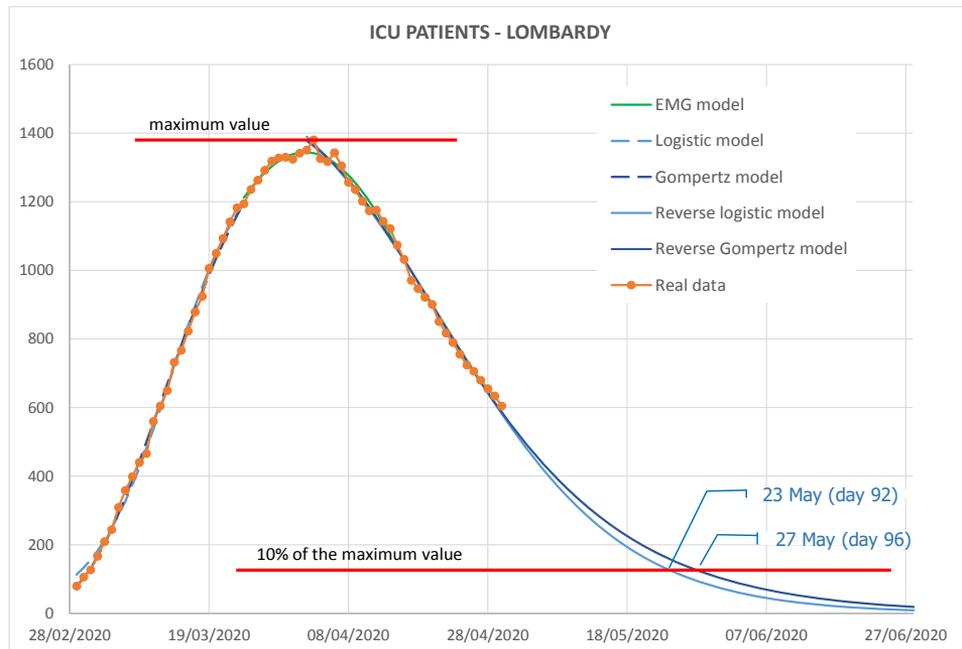

Figure 1: ICU patients in Lombardy and parametric models during the first Covid-19 wave.

3. Medium-term pandemic models

Another family of epidemic models can describe the contagion dynamics on a medium-term horizon. These models are based on interconnected compartments that summarize the condition of individuals in a given population. The simplest compartmental model for

an outbreak is the SIR model that is based on three compartments (susceptibles, infected, and removed) that describe the evolution of a population plagued by the epidemic. The population features N individuals, whose number is assumed constant (this hypothesis holds if N is sufficiently large and one assumes that the number of newborns equals that of fatalities and the prediction horizon is not too prolonged). Initially, $N-1$ individuals are susceptible (*i.e.* they belong to the S compartment of those vulnerable to the virus) and one person is infected and belongs to the I compartment of those who can transmit the contagion with a reproduction number, β . Once an infected individual either recovers or dies, they move to the R compartment, with a rate proportional to γ . Eq. 6 summarizes the SIR model based on an ordinary differential system with suitable initial conditions:

$$\begin{cases} \frac{dS}{dt} = -\beta \frac{I}{N} S & \frac{dI}{dt} = \beta \frac{I}{N} S - \gamma I & \frac{dR}{dt} = \gamma I \end{cases} \quad (6)$$

The adaptive parameters of the model (β, γ) can be identified by a nonlinear regression that minimizes the distance between the real data and the model predictions. The continuing availability of periodically measured real data allows improving the quality of the model and better predicting the dynamics of the pandemic. The complexity of the SIR model can be increased (Giordano *et al.*, 2020) by introducing further compartments (*e.g.*, those infected but not yet contagious, those who died) or contributions (those who have recovered but may lose their immunity and move back to the susceptible compartment). The adaptive parameters may change in time according to virus mutations, improved capacity of treating the infection, and different behavior of the population induced by nonpharmaceutical measures such as lockdowns, curfews, and social distancing. For the sake of simplicity, Eq. 7 shows some modifications to the adaptive parameters that account for lockdown measures and modification of the healing rate. These modifications call for the evaluation of additional adaptive parameters that pave the way to further simulations of what-if scenarios in case of government decisions such as non-pharmaceutical interventions.

$$\beta(t) = \begin{cases} \beta_0, t < t_{\text{lockdown}} \\ \beta_0 \exp\left(-\frac{t - t_{\text{lockdown}}}{\tau_\beta}\right) \end{cases} \quad \gamma(t) = \gamma_0 + \frac{\gamma_1}{1 + \exp(-t + \tau_\gamma)} \quad (7)$$

Compartmental models can be effective in predicting the expected dynamics of an epidemic. The so-called parametric runs allow quantifying the effect of different measures on the outcomes in terms of infected, recovered, and fatalities. Understanding the role played by adaptive parameters enhances the quality of decision-making aimed at prompt and effective resolutions for the health safety of citizens. Equally, compartmental models do not show a high degree of precision, rather they indicate the trend of the epidemic. However, their predictive capability usually increases towards the end of an outbreak once a good amount of real data allows refining the adaptive parameters.

A further differential equation can account for the vaccination of the population, which for most of the industrialized countries started in the middle of the second/third Covid-19 pandemic wave: $dV/dt = V_d M$. The first differential equation of system (6) must be modified accordingly to account for the individuals that once vaccinated are assumed not to be susceptible anymore and therefore neither recover nor die but move directly to the V compartment: $dS/dt = -\beta S \cdot I/N - V_d M$. V_d is the vaccination rate and M is the

fraction of individuals who were not infected and are vaccinated. V_d is a dynamic input value that measures the capacity of the system (either regional or national) to daily inject the vaccine and decrease (after one or two doses) the number of susceptible individuals (Figure 2). Again, the model can be improved by removing some oversimplifications and accounting for reinfections and partial protection from infection as a function of the number of doses and vaccine maker. Parametric runs can quantify the effect of increasing the rate of vaccination and population coverage by computing the number of saved lives.

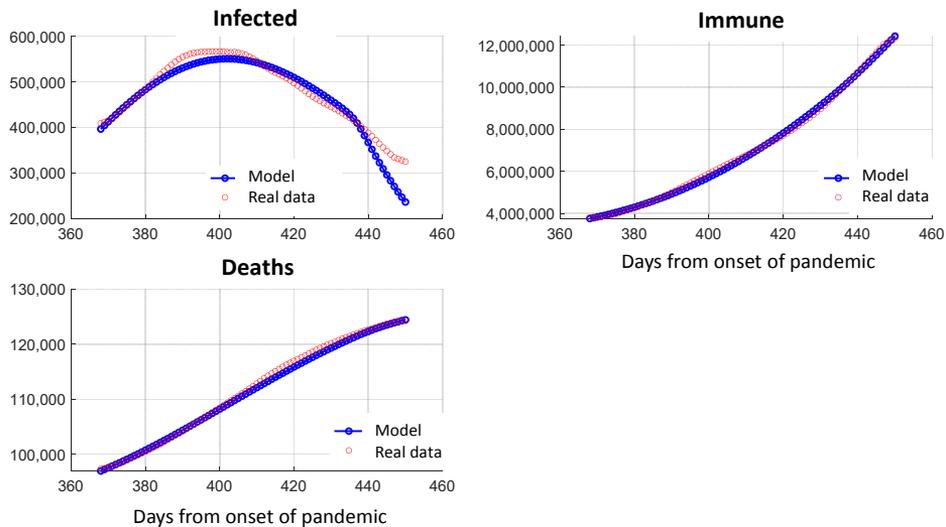

Figure 2: SIRDV model based on susceptible, infected, recovered, dead, and vaccinated compartments. The immune diagram collects both recovered and vaccinated individuals. Italy, third Covid-19 wave.

4. Long term predictions

Equations (2-5) can be extrapolated to long-term horizons to determine when the asymptotic condition for a maximum or minimum plateau is reached. Equally, it is possible to determine the time taken to reach and overtake a given threshold for both the inflation and deflation phases. These last bits of information are valuable when hospital managers have to either prepare for emergencies (during the inflation period) or progressively allocate resources to return to elective medicine (during the deflation period). Likewise, Equation (6) allows evaluating the asymptotic condition for rather long integration times. However, the user should be aware of the risks connected to the extrapolation of long-term models that depend heavily on adaptive parameters.

5. Alternative vaccination policies

In the case of a vaccination campaign against an epidemic, initially, the available doses are limited and a suitable vaccination policy should be chosen and implemented. The most effective indicator to account for is the number of fatalities. If the decision-makers try to minimize the fatalities toll then the pressure on the limiting resources of hospitals such as ICU beds and Covid-19 wards gets relieved and both medical doctors and nurses can cure the patients more efficiently, which results in a synergistic reduction of mortality. In the case of Italy, the first available doses (January 2021) were reasonably administered

to high-priority categories (such as hospital operators, health doctors, and fragile subjects). Nonetheless, it is well-known that Covid-19 mortality follows a monotonically increasing curve with age. In Italy, almost 99% of the officially documented 133,000+ victims of Covid-19 (as of November 2021) were people aged 50 and older. Unfortunately, the following doses did not strictly respect a reverse-order of age policy aimed at minimizing the fatalities. There were some diversions to lower priority categories that, thanks to their health status and age, were less exposed to either serious or fatal consequences (e.g., school and university personnel, armed forces, lawyers, scientific informants, social workers, customs and airport personnel, and funeral home staff).

An *in silico* vaccination simulator can quantify the difference between real fatalities and what might happen if an alternative vaccination procedure were adopted. That simulator relies on the immunization degree after injection (Creech *et al.*, 2021) and the death distribution curve, which both allow assessing the expected number of saved lives. After having covered the high-priority categories, if one implements a rigid approach to vaccination based on the reverse order of age ranges (i.e. the elderly first, the young last) every dose can be injected to individuals in the following decreasing sequence of 90+, 80-89, 70-79, 60-69, 50-59, 40-49, 30-39, 20-29, and 12-19 years old. The rate of injected doses is available daily and the optimal reallocation of doses allows evaluating the number of lives that would be saved. In addition, the simulator can solve what-if scenarios such as what would happen if (i) the daily delivered doses increased by some percent, or (ii) the vaccination campaign to the elderly were anticipated of a few days, or (iii) some doses were diverted from lower priority categories to the elderly, or (iv) the interval between first and second dose were increased or decreased. Table 1 reports some results of different vaccination policies on the expected number of saved lives.

Table 1: Saved lives in Italy by alternative vaccination policies. Rows report the expected saved lives under the hypothesis of administering the same amount (100%) or 10% and 20% more daily doses than those injected in reality. The columns report the calculated saved lives under the three hypotheses of 0, 10, and 20 days anticipation with respect to reality (which started on 18-Feb-2021). The numbers in brackets quantify the increase over the basic case study of 18-Feb at 100% administrations. The assessment was carried out at the end of May 2021.

Saved lives – ITALY	Start on 18-Feb-2021	Start 10 days before	Start 20 days before
100% of the real administrations	3969	4465 (+12.50%)	5317 (+33.96%)
110% of the real administrations	4905 (+23.58%)	5414 (+36.41%)	6311 (+59.01%)
120% of the real administrations	5712 (+43.92%)	6245 (+57.34%)	7083 (+78.46%)

Abstract

Considering the growing need for alternative and cleaner fuels to replace the ones based on fossil energy sources, and to reduce the environmental impacts associated, this work aims to present a novel process that replaces natural gas (NG) as a source of hydrogen (H₂) in the production of ammonia (NH₃). The generated CO₂ is fed to the urea synthesis unit, which reduces the greenhouse gas (GEEs) emissions through an integrated ethanol-ammonia-hydrogen-urea plant. To achieve these goals, an integrated plant was designed where the H₂ from NG was replaced by the H₂ from the ethanol reform ("moss hydrogen") and electrolysis process (green H₂) where it receives electricity from the co-generation ethanol system. The capturing process of the CO₂ produced during the fermentation and bagasse burning is carried out in the sugarcane photosynthesis. Besides, part of the CO₂ emitted during the ammonia section (in the ethanol reform stage) is used as feed in the urea plant, supplying all the demand for the urea production from the outputs of the process itself and minimal carbon emission to the atmosphere ($\approx 44\%$). Finally, after an evaluation performed in the Aspen Plus process simulator and based on metrics used in green chemistry associated with sustainability, it was concluded that the proposed plant can be considered sustainable with great potential, especially in regions rich in biomass.

Keywords: Ammonia, Ethanol, Urea, Green hydrogen, CO₂ emission.

1. Introduction

The path to a low carbon economy involves the development of new processes and the use of new raw materials to produce all the necessary products to maintain a modern standard of living, meeting the sustainability tripod. Thus, in addition to fuels and other chemical products that used to come from fossil sources, new routes to produce fertilizers, such as NH₃ and urea, must be developed. (Konig, et al. 2015)

A renewable source of chemicals and energy is biomass, where Brazil is one of the world leaders in the use it, especially sugarcane, used in the production of ethanol, sugar and electricity through the burning of bagasse and vinasse. Cogeneration of energy in sugarcane mills plays a fundamental role in the sustainability of the production process, which remains independent of external fuels. On the other hand, electricity is often generated in excess, and sold to the local energy distributor. (Mehmeti, et al. 2018)

Currently, according to Mehmeti, et al. (2018), the ammonia and urea feedstocks are natural gas, CO₂ and air. Developing new technological routes, with sustainable sources of CO₂ and hydrogen, is necessary for a cleaner and more sustainable process. This work aims to present a new route to produce green ammonia and green urea from clean energy sources widely available in Brazil, (biomass energy and sugarcane ethanol). (Erdemir & Dincer, 2020)

The hydrogen sources come from the electrolysis of water, using the excess of electrical energy generated in the plant, and ethanol, which undergoes a steam reforming process. The source of CO₂ is ethanol (EtOH), also through steam reforming, implementing the capture and storage process within the plant. Nitrogen continues to come directly from air. This new concept plant was modeled and simulated in Aspen Plus v.12. (Erdemir & Dincer, 2020)

2. Methodology

In this work, the methodology consisted, firstly, in carrying out the plant simulation of the proposed process, which integrates the stages of production of ethanol, green H₂, ammonia and urea and whose main objectives are to change the source of H₂ to a more sustainable one and the reduction of CO₂ emission. Then, an analysis was carried out to assess and quantify the proposed plant's capability to reduce CO₂ emissions.

The simulation only includes the ammonia, green H₂ and urea production sections (figure 1). As for the ethanol section, it was considered a plant with the capacity to process 1150 ton/h of sugar cane, producing 1766 kmol/h of ethanol and 287.5 ton/h of bagasse. In the following topics, the step-by-step performed to simulate the green H₂, ammonia and urea production sections will be elucidated. (Wirti, 2016)

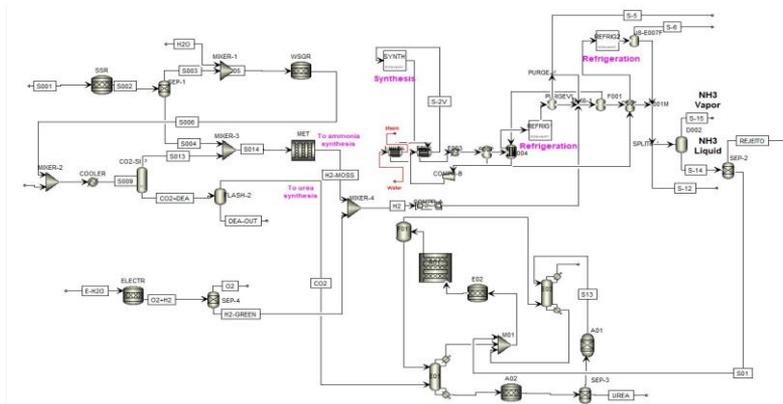

Figure 1. Integrated process flowsheet

2.1. Green H₂ Unit - Simulation

Green H₂ is produced through the alkaline electrolysis of water which, in this case, was simulated using an RSTOIC (Stoichiometric Reactor Module), named "ELECTR" and an SEP (Component Separation Module), named SEP-4.

In the reactor, the reaction shown in equation 1 was added and the yield attributed to the fractional conversion of H₂O into H₂ and O₂ was 99.9%, according to Faria (2018). In addition, the reaction temperature and pressure conditions were 80°C and 1 bar and the electricity consumption required by the electrolyzer (ELECTR) per Nm³ of H₂ produced is around 4.3 kWh.

2.2. Ammonia Unit - Simulation

According to Garcês (2021), ammonia is produced from the Haber-Bosch reaction (equation 2), which consists of reacting H_2 and N_2 to form NH_3 . However, on an industrial scale, some additional steps are necessary for this synthesis.

In this plant, different from the technologies commonly found in the literature ammonia production (BASF (1910), Kellogg (1960), KBR (Kellogg modified by Braun), Haldor Topsoe), the hydrogen source is the green H_2 process – produced from the electrolysis of water – and “moss” H_2 – produced from the reform of ethanol. (Pattabathula et al., 2016)

Therefore, to explain the ammonia section simulation process, the explanation will be divided into two parts: ethanol reforming and ammonia synthesis.

2.2.1. Ethanol Reforming

The ethanol reforming process consists of generating H_2 from ethanol to produce ammonia and, in addition, capturing and recovering the produced CO_2 , so that it can be used to in urea production plant.

The process basically takes place in two stages (SSR and WSGR), where the reactions shown in equations 3 and 4 occur, respectively, the first at high temperatures ($650^\circ C$) and the second at relatively lower temperatures ($200^\circ C$). Furthermore, according to Teixeira (2016), the fractional conversions for both reactions are, respectively, 93.7% and 99.5%.

The stream rich in CO_2 , H_2 and H_2O is sent to the CO_2 capture and recovery, as carbon dioxide is extremely poisonous to the ammonia production catalyst and needs to be separated from H_2 . (Sunny et al., 2016)

The stripping strategy adopted in the work was the capture of CO_2 by alkaline amine, more specifically DEA (Diethanolamine). The process was simulated in a “Hierarchy” block, composed of two RSTOICS and a FLASH, as seen in figure 2.

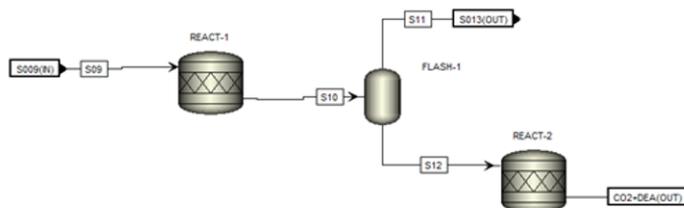

Figure 2. CO_2 Removal

As mentioned by Oh et al. (2010) and Mendieta (2011), in the first reactor (REACT-1), at low temperature and pressure conditions, the reaction between water, carbon dioxide and diethanolamine occurs (eq. 5), followed by a flash drum that separates H_2 from the other product components and, finally, in the REACT-2, the inverse reaction of the one

described above occurs (eq. 6), due to the high established temperature and pressure conditions.

Next, the separation of CO₂ from the DEA takes place, so that it can be directed to the urea plant, in addition, due to the residues of carbon oxides in the H₂ stream (S014), it goes to a methanation step, where the concentrations of CO₂ and CO are drastically reduced to the order of 0.2% and 0.02% (mol/mol), respectively. The reactions of the step can be seen in equations 7 and 8. (Sunny et al., 2016)

2.2.2. Ammonia Synthesis

As previously mentioned, the main reaction that occurs in the synthesis step is the Haber-Bosch (eq. 2), reacting the H₂ - obtained in the ethanol reforming and in the production section of Green H₂ - and N₂ removed from the atmosphere. This step uses Haldor Topsoe's S-250 ammonia conversion strategy, which consists of a two-bed radial flow converter with indirect heat exchange between the two beds. In this way, efficient use of the converter volume, low pressure drops, and high conversion occurs - due to indirect cooling. In these reactors, the NH₃ formation reaction was defined through the subroutine "NH3SYN", found in the software files. (Sunny et al., 2016)

Finally, the ammonia fed into the refrigeration unit is liquefied and goes direct to its intended purpose, whether it is for storage or, in this case, for feeding the urea plant.

2.3 Urea Section - Simulation

Finally, the urea synthesis step starts, simulated from the example flowsheet present in the Aspen Plus files. However, some changes were made to this flowsheet, such as: considering the formation of reactor biuret (unwanted by-product); add pure component - using the NIST database - and binary interaction parameters - defined as the same as urea - for biuret, in addition to DHFORM and DGFORM data; add vapor pressure data - PLDTDEP - for urea and biuret; finally, define the urea and biuret formation reactions as "POWERLAW", placing their kinetic data according to Chinda (2019).

3. Results

Having carried out all the methodology previously presented, obtaining the simulation of all the steps of the proposed process, an evaluation of the achieved results was carried out.

As mentioned, the ethanol production plant used as a base a processing capacity of 1150 ton/h of sugarcane, producing around 1766 kmol/h of ethanol and 287.5 ton/h of bagasse. All the bagasse was used to generate energy, first to supply the plant itself and then to produce Green H₂ by electrolysis. It is noteworthy that the produced CO₂ released into the atmosphere at this stage - from the fermentation and burning of bagasse - does not

enter the final balance, since the sugarcane manufacture itself will absorb it. (Oh et al., 2010)

After burning the bagasse and supplying the ethanol plant, 172.5 MW of energy were directed to the electrolyzer, being able to produce, with this amount of energy, 1790.8 kmol/h of green H₂ - entirely directed to the synthesis of ammonia. (Faria, 2018)

The ethanol produced is directed to the reform, so that the moss H₂ is produced. The table 1 shows the main composition data for this section, prior to ammonia synthesis.

Table 1. Streams composition – Ammonia section

Comp.	Flow – kmol/h								
	SRR		WSGR		CO ₂ - SEP			MET	
	In	Out	In	Out	In	Top	Bottom	In	Out
Ethanol	1766,0	111,3	-	-	-	-	-	-	-
H ₂	-	6619,0	-	3292,9	3292,9	3276,0	16,9	9895,0	9194,7
CO	-	3309,5	3309,5	16,5	16,5	16,2	0,3	16,2	1,8
CO ₂	-	-	-	3292,9	3292,9	182,5	2999,2	182,5	18,3

Then, all hydrogen produced - approximately 11000 kmol/h, adding the streams of "green H₂" and "moss H₂" - is sent to the ammonia synthesis, where it reacts with the N₂ removed from the atmosphere and, through the Haber-Bosch reaction, it forms NH₃, which is then sent to the synthesis of urea. At the end of the process, the ammonia section releases 2624.92 kmol/h of NH₃ and 2999.25 kmol/h of CO₂. (Garcês, 2021)

Due to the integration of the ammonia and urea sections, the amount of carbon dioxide that would be released into the atmosphere is reduced, since part of the CO₂ produced is transferred so that urea is produced. Considering that the NH₃ feed from the urea section is 2624.92 kmol/h, the simulated plant is capable of processing about 1317 kmol/h of greenhouse gas, reducing its emission by approximately 44%. The table below shows the overall balance of the proposed integrated plant.

Table 2. Overall Balance

Green H2 Section		Ammonia Section		Urea Section	
H ₂ O	In	EtOH	In	NH ₃	In
	1790,8 kmol/h		1766,0 kmol/h		2624,9 kmol/h
Energy	In	CO ₂	Out	CO ₂	In
	172,5 MW		2999,2 kmol/h		1316,9 kmol/h
H ₂	Out	NH ₃	Out	UREA	Out
	1790,8 kmol/h		2624,9 kmol/h		1312,0 kmol/h

Furthermore, it is worth noting that, in the ethanol steam reforming step, approximately 8300 kmol/h of water were processed, used both in the SSR and WSGR steps and in the capture of CO₂ by DEA. Besides, simultaneously with the production of urea fertilizer, there is also the production of $8.5 \cdot 10^{-3}$ kmol/h of biuret which, although low, must be considered (given the harmful character of the by-product for plants).

4. Conclusion

Finally, it can be concluded that, from the data found in the literature (operational conditions, reaction yield, mass, and energy balances of existing plants), it was possible to carry out the simulations of the proposed plant that integrated the production sections

of green H₂, green ammonia - produced from hydrogen from the reform of ethanol - and urea. As a result, it is observed that the results were satisfactory, showing the possibility of a plant with an alternative source of hydrogen (moss H₂) for the ammonia production, in addition to being able to reduce 44% of the CO₂ emission of this step and use the waste from the ethanol plant (bagasse) as an energy source to produce green H₂.

A methodology based on social life cycle assessment for social hotspots identification

Andreia Santos,^a Madalena Veloso,^a Ana Carvalho,^a Ana Barbosa-Póvoa^a

^a*Centre for Management Studies of Instituto Superior Técnico, Av. Rovisco Pais, 1049-101 Lisboa, Portugal*

Abstract

Although there are studies where the economic and environmental impacts of different cork supply chains were assessed, no study exists where the social impacts of these supply chains have been analyzed. The main goal of this study is to narrow this research gap by assessing the social performance of the Portuguese natural cork stoppers' supply chain, using the social life cycle assessment methodology. Furthermore, this study provides suggestions on how this social performance can be improved based on the processes and regions where the most relevant potential social impacts are likely to arise (i.e., social hotspots). Five social issues were recognized as relevant and one hotspot, Cork harvest in Portugal, was identified for these issues. Based on these results, a set of industry-specific recommendations is provided for Portuguese cork suppliers to improve their social performance. If implemented, these recommendations will contribute to three Sustainable Development Goals, namely Goal 4 – Quality Education, Goal 8 – Decent Work and Economic Growth, and Goal 16 – Peace, Justice, and Strong Institutions.

Keywords: Sustainable supply chain management; Social life cycle assessment; Social hotspots; Sustainable Development Goals; Natural cork stoppers supply chain.

1. Introduction

The economic and environmental dimensions of sustainable development have been comprehensively covered in the field of sustainable supply chain management (SSCM), while the social dimension is addressed in a fairly simplified manner (Seuring, 2013). Similarly, a recent review found that the social dimension of sustainability is the most overlooked in assessment studies applied to forest wood supply chains (Santos, et al., 2019). While some studies have attempted to narrow this research gap, including the study conducted by Santos et al. (2020) where the social impacts of a Portuguese pulp and paper supply chain were quantified, there is still work to be done. For example, no study has been conducted where the social performance of a cork product supply chain has been assessed. Hence, the main goal of this study is to assess the social performance of the Portuguese natural cork stoppers' supply chain since the cork industry is one of Portugal's biggest industries and natural cork stoppers (NCS) are the most manufactured product in this industry (ICNF, 2018). Social life cycle assessment (LCA) was chosen in this study to assess the social performance of the selected supply chain because it has been identified as a promising approach to assess the social performance of forest wood supply chains (Santos, et al., 2019). Furthermore, this study also provides suggestions on how the social performance of the Portuguese NCS supply chain can be improved by identifying the social hotspots associated with this supply chain. Social hotspots are processes in a region where the most relevant potential social impacts are likely to arise (UNEP, 2020). Thus, identifying these hotspots allows determining where changes need to be made to reduce

the most critical social issues associated with a supply chain. The suggestions provided will assist natural cork stoppers' manufacturers and other supply chain partners dealing with the relevant social issues highlighted in improving their social performance and, as a result, the social performance of their supply chain. By implementing these suggestions, the different NCS supply chain partners will address critical social issues and help achieve specific Sustainable Development Goals (SDGs) (United Nations, 2021).

2. Social Life Cycle Assessment

The social LCA methodology is used to analyze the potential social impacts associated with the life cycle of a system (i.e., the specific object under analysis). This methodology is comprised of four steps (ISO, 2006): Goal and Scope Definition, Life Cycle Inventory (LCI), Life Cycle Impact Assessment (LCIA), and Results Interpretation. These steps are explained below together with an explanation of how they were applied to the supply chain under analysis.

2.1. Goal and Scope Definition

The first stage of this step is to establish the goal of the social LCA. In this study, the goal was to assess the social performance and identify the social hotspots associated with the supply chain of natural cork stoppers manufactured in Portugal.

The second stage of this step is to establish the scope of the social LCA which requires establishing the functional unit and system boundary. The functional unit is a representative element of the system(s) under analysis (EC-JRC-IES, 2010). One ton of natural cork stoppers was the functional unit selected in this study. The system boundary defines which part of the supply chain and respective processes will be considered (EC-JRC-IES, 2010). Given the goal previously defined (i.e. social hotspots identification), it is very important to select a boundary that considers the entire supply chain since choosing a restrictive system boundary could prevent the social hotspots from being identified if these were located outside the boundary. Hence, the system boundary chosen was cradle-to-grave, which includes four distinct life cycle stages: Raw materials' extraction, Products' manufacture, Products' distribution, and Products' end-of-life.

2.2. Life Cycle Inventory

The purpose of the second step is to collect a list of social flows (e.g., number of worker hours in bad working conditions) which will be converted into potential social impacts in the following step. To determine these flows, the system(s) under analysis must be modeled using foreground (i.e., specific) and background (i.e., generic) data related to the different life cycle stages included within the system boundary previously defined. Foreground data refers to data that has been collected for the specific system under analysis (UNEP, 2020) and it usually includes information on (Norris, et al., 2019):

- Materials (i.e., raw materials, utilities, and transports) used in the different life cycle stages included within the system boundary;
- Economic sectors (GTAP, 2019) to which the materials belong to;
- Region (e.g., country) from which the materials are sourced from;
- Cost of the materials.

Background data refers to data that has not been collected for the specific system under analysis (UNEP, 2020) and it can be found, for example, in databases such as the Social Hotspots Database (SHDB) which includes information on (Norris, et al., 2019):

- Supply chain composition – Using the Global Trade Analysis Project (GTAP) global economic equilibrium model version 9, which contains information on the trade flows between 57 economic sectors (GTAP, 2019) from 140 regions

for the reference year 2011, the SHDB database can provide information on supply chain composition. Based on the economic sector, origin, and cost of each material identified in the foreground data collection, the SHDB determines the trade flows (in US dollars) from other sectors/regions involved;

- Labor intensity – Using GTAP data on total wage payments (US dollars) per US dollar of output by the sector/region average wage (US dollars/hour), the SHDB database can determine the worker hours involved per dollar of output for the reference year 2011 for each of the 57 economic sectors in each of the 140 regions previously mentioned;
- Social risks – Using data obtained from different sources such as country statistics, academic papers, and intergovernmental databases (e.g., the International Labor Organization database), the SHDB has information on over 160 social impact indicators for 244 regions and 57 sectors.

In this study, the foreground data was collected considering the four life cycle stages included within the system boundary (see subsection 2.1) and the background data was collected using the Social Hotspots Database. The collected foreground and background data were used to model the Portuguese natural cork stoppers supply chain using the SimaPro 8.4.0 software. The developed model is presented in Figure 1.

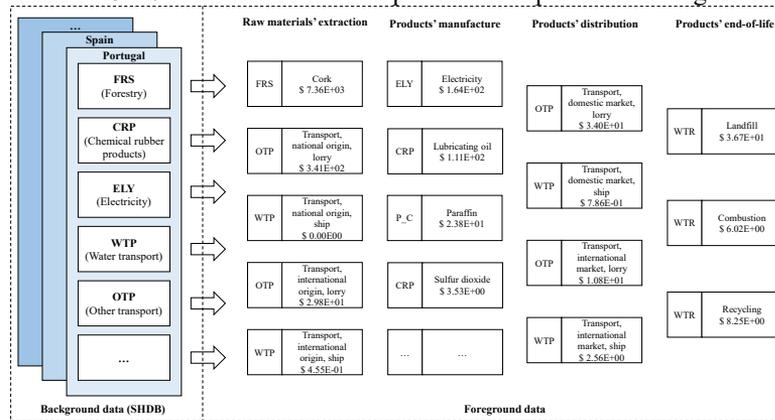

Figure 1 - Portuguese natural cork stoppers supply chain model.

The output of the model presented in Figure 1 is a list of social flows associated with the Portuguese natural cork stoppers supply chain.

2.3. Life Cycle Impact Assessment

The third step of a social LCA consists of converting the social flows collected in the previous step into potential social impacts. The Reference Scale Approach is the most developed impact assessment approach (UNEP, 2020). This approach assesses the potential social impacts based on reference scales typically comprised of 1 to 5 levels (i.e., performance reference points). Therefore, a reference scale with clearly defined levels needs to be developed for each social inventory indicator collected in the previous step (UNEP, 2020). One impact assessment method that uses the Reference Scale Approach is the Social Hotspots Index (SHI) available in the SHDB. This was the method chosen in this study to convert the inventory collected in the previous step into potential social impacts. The SHI method considers 25 impact subcategories (e.g., Child Labor, Occupational Toxics and Hazards, and Gender Equity) (Norris, et al., 2019). These impact subcategories are assessed using the 160 social impact indicators mentioned in subsection 2.2, with some being assessed using only one indicator, while others are assessed using

several indicators. Each indicator has a clearly defined reference scale of four risk levels (very high, high, medium, and low). A characterization factor is attributed to these levels (10, 5, 1, and 0.1, respectively), representing the relative probability of an adverse situation (Norris, et al., 2019). By combining these characterization factors with the social flows obtained in the LCI step, it is possible to quantify the potential social impacts in medium risk hours equivalent (MRH eq.). These impacts can be added together to determine the overall potential social impact (i.e., single score) of the system(s) under study after normalized and weighted using normalization and weighting factors, respectively.

2.4. Results Interpretation

The fourth and last step of a social LCA consists of examining and interpreting the results of the LCA study to accomplish the goal defined in Step 1. Since the goal of this study is not only to assess the social performance of the Portuguese natural cork stoppers supply chain but also to provide suggestions on how this performance can be improved, the interpretation of results will focus on social hotspots identification. According to the definition provided in the Introduction, social hotspots are processes in a region (e.g., cotton production in India) where the most relevant potential social impacts are likely to arise (UNEP, 2020). Following this definition, the first step to identifying social hotspots is to determine the most critical potential social impacts. In this study, the most relevant social impacts were identified using the “80/20” rule which asserts that 80% of outcomes (i.e., total social impact) result from 20% of all causes (i.e., impact subcategories). Hence, the 25 impact subcategories were sorted in decreasing order of normalized and weighted results and the top 20% (i.e., the five impact subcategories with the highest normalized and weighted results) were chosen. The next step to identifying social hotspots is to determine the most relevant processes and regions. In this study, for each relevant impact subcategory identified, the most relevant processes and regions were determined by sorting the processes and regions in decreasing order of characterized results and selecting the top result.

The results of applying the social LCA to the Portuguese natural cork stoppers supply chain are presented in the next section. These results will be used to provide informed suggestions on how the social performance of this supply chain can be improved.

3. Results Analysis and Discussion

From the normalized and weighted results obtained for the Portuguese natural cork stoppers supply chain, it is possible to conclude that the most relevant impact subcategories (i.e., highest normalized and weighted results) associated with the supply chain under analysis are Injuries and Fatalities, Occupational Toxics and Hazards, Corruption, Migrant Labor, and Children Out of School. The same social hotspot, Cork harvest in Portugal, was recognized for the five relevant impact subcategories identified since this is the process and region with the highest characterized results in these subcategories. Given this information, Portuguese cork suppliers are key to improving the overall social performance of the Portuguese NCS supply chain. Due to the background data available in the SHDB, it is possible to determine which economic sector and region is most responsible for the bad social performance of Cork harvest in Portugal (Figure 2). The results presented in Figure 2 can assist in providing suggestions on how the social performance of the Portuguese NCS supply chain can be improved. In the case of the two most relevant social issues, Injuries and Fatalities and Occupational Toxics and Hazards, the social hotspot identified was Cork harvest in Portugal. The sector/region most responsible for this result is the Forestry sector in Portugal (Figure 2) which

indicates that it is the activities/behaviors of the Portuguese cork suppliers the main responsible for the bad social performance of Cork harvest in Portugal in the two aforementioned subcategories. Consequently, to improve the social performance of the Portuguese NCS supply chain, Portuguese cork suppliers should improve their working conditions by implementing different strategies such as (1) identifying where common accidents occur and which health hazards may be present in the workplace; and (2) defining measures to minimize occupational accidents and prevent employers from being exposed and harmed by occupational hazards (ILO, 2021). If implemented, these measures will contribute towards achieving *SDG 8 – Decent Work and Economic Growth*.

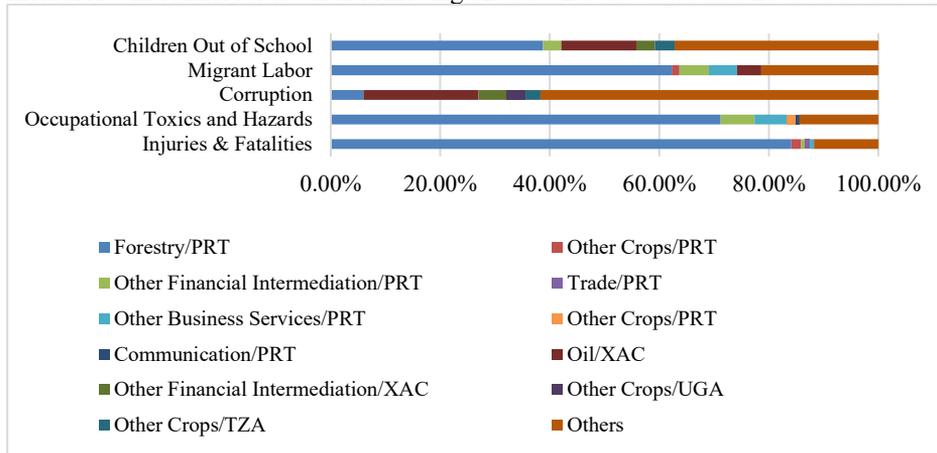

Figure 2 – Contribution of different sectors/regions to the characterized result of “Cork, Portugal” in the five relevant impact subcategories.

In the case of Corruption, the social hotspot identified was Cork harvest in Portugal and the sector/region most responsible for this result is the Oil sector in the South Central Africa (i.e., XAC) region (Figure 2). This result indicates that it is not the activities/behaviors of the Portuguese cork suppliers the main responsible for the bad social performance of Cork harvest in Portugal in the Corruption subcategory but activities/behaviors of oil providers from South Central Africa with whom the Portuguese supply chain partners deal with. To improve the social performance of the Portuguese NCS supply chain, Portuguese cork suppliers should contact the oil providers from South Central Africa and make sure they implement different measures such as (1) publishing financial accounts for each country of operations, including what is paid to each government in taxes and other contributions, and (2) disclosing and regularly monitoring anti-corruption systems throughout all operations and those of subsidiaries (Transparency International, 2017). If implemented, these measures will contribute towards achieving *SDG 16 – Peace, Justice, and Strong Institutions*. Similar to the conclusion reached for the two most relevant impact categories, the social hotspot identified for Migrant Labor was Cork harvest in Portugal and the sector/region most responsible for this result is the Forestry sector in Portugal (Figure 2). Portuguese cork suppliers should implement measures to support the migrant workers employed by them such as (1) developing policies and procedures that promote equality of opportunity in the workplace; and (2) providing equality and diversity training for all workers and having a suitable induction process that includes introducing the new workers to their team and touring the workplace (NiBusinessInfo, 2021). If implemented, these measures will contribute towards achieving *SDG 8 – Decent Work and Economic Growth*. In the case of Children Out of

School, the social hotspot identified was Cork harvest in Portugal and the sector/region most responsible for this result is the Forestry sector in Portugal (Figure 2). Portuguese cork suppliers should implement business actions such as (1) creating programs (e.g., internships) that give students early access to the corporate environment, which could reduce the number of students that drop out of school (SDG Compass, 2015). If implemented, these actions will contribute towards achieving *SDG 4 – Quality Education*.

4. Conclusion

In this study, the social performance of the Portuguese natural cork stoppers' supply chain was assessed and the social hotspots of this supply chain were identified using the social life cycle assessment methodology. Based on the hotspots recognized, a set of suggestions were provided to assist natural cork stoppers' manufacturers and other supply chain partners in improving their social performance and, as a result, the social performance of the Portuguese NCS supply chain. If implemented, these suggestions will contribute to three Sustainable Development Goals: *Goal 4 – Quality Education*, *Goal 8 – Decent Work and Economic Growth*, and *Goal 16 – Peace, Justice, and Strong Institutions*.

Abstract

The paper presents a game-theoretical approach for the analysis of waste management and circular economy networks. Players include waste producers, competitive technologies, and the governing authorities. The variables include interactions of the players, choices for valorization technologies and different cost models. In search of Nash equilibria, an interesting conclusion has been that the players often converge at errant and deviant equilibria unless waste valorization is involved. In other words, circularity brings stability. In the case where valorization is involved, bilevel optimization has been applied to evaluate the dependence of profit share on market elasticity, options to subcontract waste upgrade to third parties, the cost of processing technologies, and the choices of products. Results indicate a strong dependence of the profit share on market conditions and player interactions. Solutions include cases where leaders choose to subcontract followers, cases that indicate the impact of controls to divert profit share, and the impact of cost and process efficiency in the network development.

Keywords: circular economy, game theory, bilevel optimization, waste management

1. Introduction

Circular economy is emerging as a sustainable alternative to clean and waste management technologies in that waste is upgraded as a resource with a purpose to further use it as feedstock either to the same or to other industries. Major drivers include consumer needs, resource shortages, and technological breakthroughs. Other than materials and energy though, circular economy involves different stakeholders who have similar or different roles and entertain a different level of interactions with each other; the state, as government or municipality, is a major stakeholder and a player assigned with a role to incentivize or manipulate interactions. To understand the development of interactions, the use of game theory can be both insightful and powerful. Traditional applications in game theory typically follow Stackelberg formulations that feature players in open markets, with identical or similar roles. They compete each other on how they can access markets, by means of cost or market functions that dictate their profits. Approaches involve mathematical formulations produced as bilevel optimization problems optimized to determine the profit share of each player. Quite often, mathematical models take the form of multi-objective optimization approaches in which one optimization function balances trade-offs with another competitive function.

Game theory can be applied to address interactions and roles in emerging and circular economy networks. Torres and Stephanopoulos [1] have been among the first to illustrate the use of game theoretical methods to analyze interactions in chemical engineering. Palafox-Alcantar et al. [2] have specifically pointed the significance of game theory in circular economy networks. These are cases where markets are shaping up, and are not

ideal. Indeed, many researchers ignore the fact that profits are primarily made at the purchase of raw materials (waste) rather than the production of marketable products. As the ownership of value chains involves many actors, partner payoffs depend not only on the choices of a single actor but on the choices of others. Research by Y Jin et al [3] indicates that compensation policy may promote cooperation between players. D Salmon et al point [4] out instead that unqualified government subsidy to recyclers may not be sufficient to shift choices; instead, a more targeted approach should benefit recyclers that engage honestly with downstream material or resale markets. Drivers other than competitive advantage include a better management of threats, social and environmental benefits, and policies to establish a fair share of profits. Parlar et al [5] use mathematical programming to model the networks for control and on-line decision purposes. Instead, this paper addresses strategic decisions in the problem. Nash equilibria rather than Pareto optimal constitute more attractive and sensible objectives. Both in waste management and circular economy networks, there are two profit lines to consider: one at the receiving end and, potentially, a second one at the production as based on the valorization path that is selected. While in the context of a classical Stackelberg approach the competition relates to the product, in circular economy networks the competition is mainly for the feedstock; products may diversify with the players' choice to valorize feedstock. Moreover, while the profit share is important to study, it is equally important to study the equilibrium of the overall system in the context of Nash as the network are subjected to several threats and opportunities from the players involved.

The paper presents a game-theoretical approach for the analysis of waste management and circular economy networks. Players include waste producers, competitive technologies, and the governing authorities. The variables include interactions of the players, choices for valorization technologies and different cost models. In search of Nash equilibria, an interesting conclusion has been that the players often converge at errant and deviant equilibria unless waste valorization is involved. In other words, circularity brings stability. In the case where valorization is involved, bilevel optimization has been applied to evaluate the dependence of profit share on market elasticity, options to subcontract waste upgrade to third parties, the cost of processing technologies, and the choices of products. Results indicate a strong dependence of the profit share on market conditions and player interactions. Solutions include cases where leaders choose to subcontract followers, cases that indicate the impact of controls to divert profit share, and the impact of cost and process efficiency in the network development.

2. Games in extensive forms with complete information

Let us use game theory to model a typical problem of a waste producer (A) and a contractor (B). The model is formulated in extensive form with complete information. Let us use backward induction under the assumption that both players are rational and that each player is trying to maximize her/his own payoff. For each unit of waste, Player A

(A.1) is required to dispose waste to the contractor at a gate fee α (€/t) and receive a receipt

(A.2) may discharge his waste without receipt at a gate fee α' (€/t)

(A.3) may risk and dump his waste without cost

Besides, Player B is required to process waste and this would cost β' (€/t)

(B.1) will be taxed on his profits by $\gamma\%$

(B.2) may risk dump the waste he/she received without processing

The backward induction tree for the game is shown in Fig. 1. Table 1 is the payoff matrix of the game; x_1 and x_2 represent possible government subsidies for A and B.

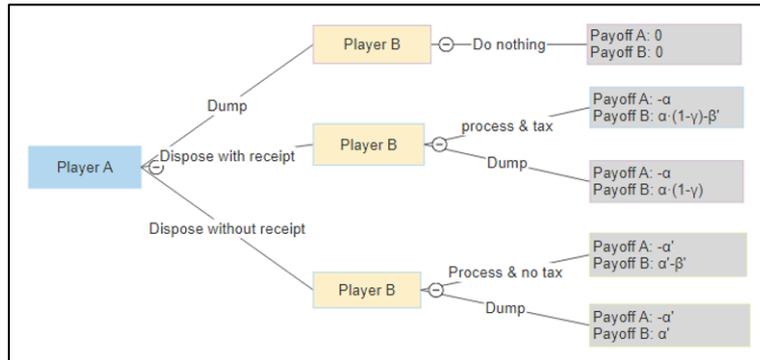

Figure 1. Backward induction tree for the game

Based on Table 1, without any government subsidies, the lawful and desirable choice is (A.1, B.1). However, payoffs for Player A are best for A.3; A.2 is the second-best choice. Similarly, payoffs for Player B are better for B.2; B.1 is the worst choice. In other words, based on game theory payoffs, both players are inclined for errant and unlawful choices. Provided payoffs are available, (a) player A would choose A.1 over A.2 & A.3 once $x_1 > a - \alpha'$ & $x_1 > a$, and (b) Player B would choose B.1 over B2 once $x_2 > \beta'$. Such conditions imply that, lawful choices are ensured once the government is prepared to take up all the costs of waste management.

		Player B	
		B.1	B.2
Player A	A.1	$-\alpha + x_1, \alpha \cdot (1 - \gamma) - \beta' + x_2$	$-\alpha + x_1, \alpha \cdot (1 - \gamma)$
	A.2	$-\alpha', \alpha' - \beta'$	$-\alpha', \alpha'$
	A.3	0, 0	0, 0

Table 1. Payoff matrix of the game

3. Continuous games with multiple players

The previous section considered games with players featuring different roles (e.g. waste producers, contractors) and a finite number of choices (e.g. select legal or lawbreaking action). This section considers players featuring similar roles and continuous choices as this often happens in open markets. More precisely, we consider games with two players as have been extensively studied already in Stackelberg's models of duopoly. Our incentive would be to assess whether game theoretical models for waste management and circular economy are straightforward extensions of Stackelberg problems or they feature differentiating aspects.

Let A and B be respectively leaders and followers in a context of Stackelberg duopolies. A and B compete in collecting waste, Q ; they may further valorize waste (circular economy) to increase revenues at a cost, C , that depends on technology and downstream markets. A and B profit by selecting waste (probably more profitably) and/or in processing waste. *A and B subsequently compete in two markets:* in the first market (waste) they compete against each other; in other markets they may compete, but they may also cooperate instead (e.g., subcontracting waste discharge on behalf of the other). Assume A and B share Q in capacities q_1 and q_2 . Instead of processing waste, A may opt to discharge all or part of q_1 , as q_{12} , over to B (at a lower price so he can profit). Once B

is prepared to process the waste, the total capacity would be then q_2+q_{12} . Another difference over the conventional Stackelberg, is thus that *A and B have a clear incentive to eventually cooperate*.

Fig. 2 illustrates the interactions between A and B. Let p be the collection price of waste; p_1, p_2 sale prices of end products from waste; p' the resale price of waste; c_1, c_2 the costs to process waste to products.

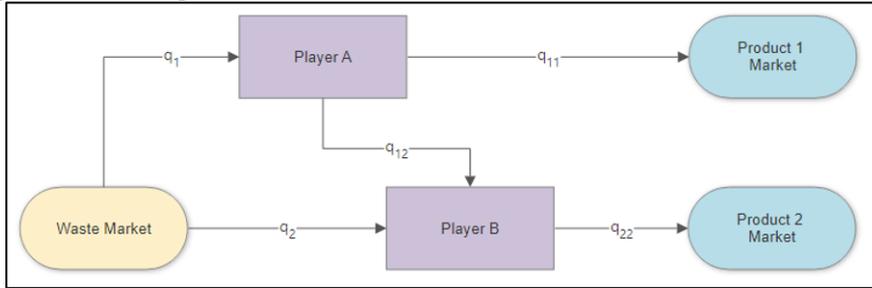

Figure 2. Player interactions in continuous game

Let us further assume linear markets for waste collection and treatment (M_W) as well as those valorizing products to markets (M_A and M_B respectively for A and B). The prices in M_W, M_A and M_B are set by

$$p = a - b \cdot Q \quad (1); \quad p_1 = \alpha_1 - b_1 \cdot q_{11} \quad (2); \quad p_2 = \alpha_2 - b_2 \cdot q_{22} \quad (3)$$

Where α, β are market parameters. Mass balances in Fig 1 translate to

$$Q = q_1 + q_2 \quad (4); \quad q_{11} = q_1 - q_{12} \quad (5); \quad q_{22} = q_2 + q_{12} \quad (6)$$

Economic balances subsequently translate to

$$P_1 = p \cdot q_1 + p_1 \cdot q_{11} - C_1 \quad (7); \quad P_2 = p \cdot q_2 + p_2 \cdot q_{22} + p' \cdot q_{12} - C_2 \quad (8)$$

$$C_1 = c_1 \cdot q_{11} + p' \cdot q_{12} \quad (9); \quad C_2 = c_2 \cdot q_{22} \quad (10)$$

The solution to the game-theoretical model that is set up by A and B results in a bilevel mathematical formulation with one leader and one follower that takes the form

$$\begin{aligned} & \max_{q_{11}, q_{12}} P_1(q_{11}, q_{12}) \\ & \text{s.t. Eqs. (1), (2), (4), (5), (7), (9)} \\ & q_2, q_{12} \text{ solves } \max_{q_{11}, q_{12}} P_2(q_2, q_{12}) \\ & \text{s.t. Eqs. (1), (3)-(6), (8), (10)} \end{aligned}$$

The bilevel optimization problems has been formulated and solved using the Extended Mathematical Programming (EMP) of GAMS and solvers JAMS and BARON.

4. Results

The bilevel optimization model of the previous section is applied to evaluate typical cases in waste management (primal) markets with gate fees closely regulated by the state and serviced by two contractors without upper bounds on the amount of waste they collect and process (typical to larger markets). The purpose would be to evaluate: (a) the split of profit and the market share, and (b) the emerging interactions and exchanges that differentiate the game from conventional cases. Sets of parameters are selected accordingly for low elasticity in primal markets (small $b, b_1 = b_2 = 0.005$), large gate fees (large a as compared to α_1 and α_2), and competitive processing costs $c_1 = c_2 = 10$. The impact of parameters is outlined in Fig 3-5.

(i) Fig. 3 illustrates the impact of waste management economics, namely the impact of gate fee on market shares. As expected, A holds the largest share in all cases, either picking up all waste ($a < 120$), or share with B (once $a > 120$). Without exception, A

makes use of B as a subcontractor profiting by diverting his waste to B. Subcontracting peaks as B enters the primal market; thereafter it decreases to lower volumes.

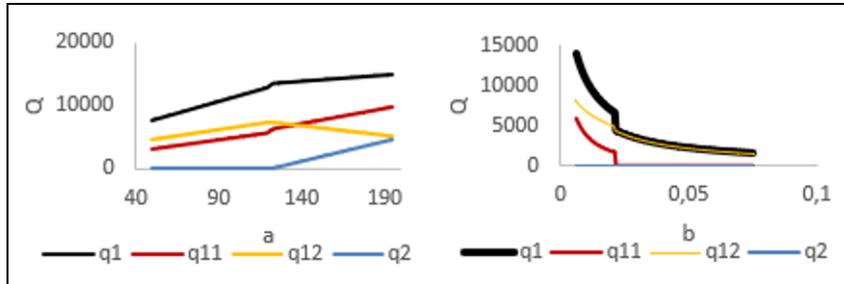

Figure 3. The impact of gate fees on market shares.

- (ii) Fig. 4 illustrates the impact of circular economy choices as made by players, namely the product types selected for valorization. Quite naturally, A increases his/her share as higher value products are selected. A continues to subcontract to B with a rate that increases with the product value (but at lower rate than the increase of his share in A. As the product value of B increases, the gap in the market share initially decreases ($a1 < 25$) but then increases again as A picks up waste for resale purposes (essentially A gradually transforms into a trader, processing no waste and profiteering by his position as a leader).

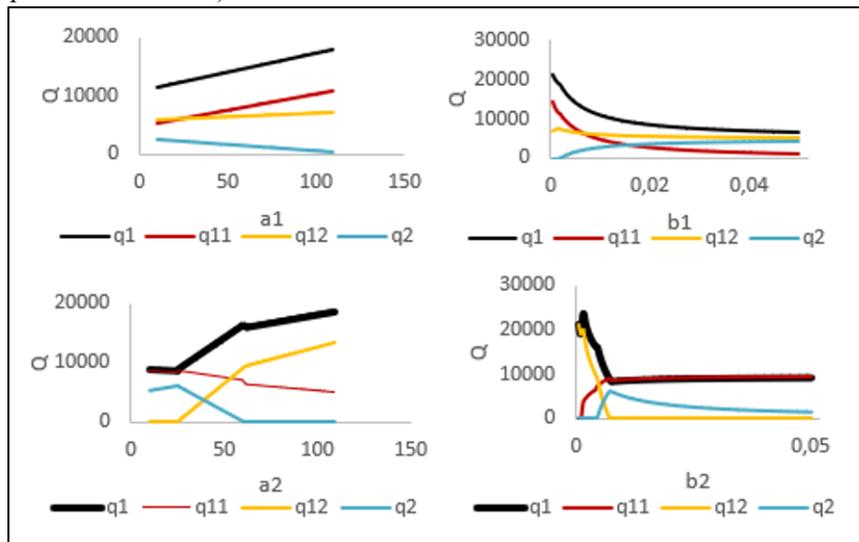

Figure 4. Impact of circular economy choices made by the players, namely product types selected for valorization the market.

Fig. 5 illustrates the impact of process technology costs. As expected, with an increase in the processing costs of A, the share of B in the primal market increases. Reversely, as the processing costs of B increase, both the market share of A and B decrease since the scope of A to use B as a subcontractor also decreases.

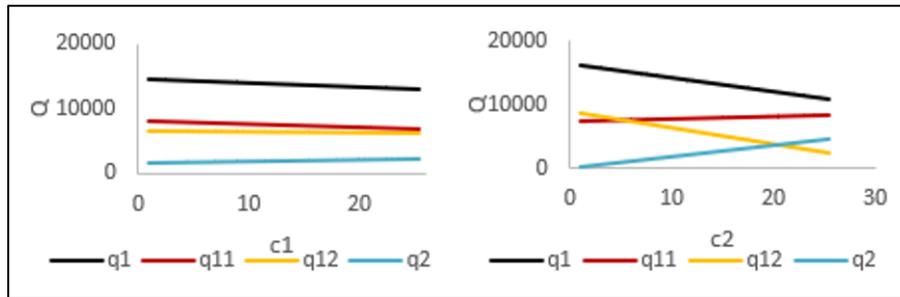

Figure 5. Impact of process technology costs on market share and interactions.

5. Conclusions

The paper applied a game theory in an extensive form using a backward induction model (discrete decisions, complete information) as well as a bilevel optimization problem exploring similarities and differences with a conventional Stackelberg approach. The discrete decision model has revealed that, unless there is an incentive to valorize waste, players are encouraged to bypass the law. Waste management can only be possible through full subsidies by the government. Contrary to the claims by Jin et al. [3] and more aligned to the conclusions of Salmon et al. [4], subsidies are not providing incentives unless with a scope to install circular economy models. The bilevel optimization formulation has similarly revealed important differences that characterize circular economy and waste management problems from conventional market problems: (a) economics are reversed as feedstocks make profits instead of products; (b) competitors are naturally and fully entitled to cooperate (as one is encouraged to subcontract for another), and (c) the type of products produced and the technologies used could have a significant impact.

Abstract

Our two-part paper investigates the current status and future trends and suggests a framework for teaching of Process Systems Engineering (PSE) topics that addresses *what* should be taught and *how* these topics should be taught effectively in a classroom setting. This first part concerns the “what” – i.e., which specific key PSE topics should constitute the core requirement of chemical engineering education – either a BSc, but in many cases, an MSc, and which application areas should be included. We surveyed existing courses on novel aspects of PSE applications, as well as polling PSE stakeholders to ascertain their opinion of what is taught and the degree to which graduates skills match their expectations. Existing gaps and interesting prospects have been revealed by the surveys leading to suggestions for the future.

Keywords: PSE education, curriculum, active learning

1. Rationale and Background of the Work

Process Systems Engineering (PSE) is the branch of the chemical engineering discipline that exploits computational methods and tools for the analysis, design, control, optimization, and effective operation of processing systems, and the design of products, across different scales and dimensions. The field of Process Systems Engineering (PSE) in the context of Chemical Engineering (CE) has been active for more than 50 years. Prof. Roger Sargent, founder and pioneer of the PSE field, defined it in the mid-60’s as the development of systematic techniques for process modelling, design and control. Subsequently, a large number of academics and researchers have made significant developments and contributions to advance and expand PSE principles in many directions. Recently the interest in PSE education has increased with the development of comprehensive works, as described in Section 2.

Several inspiring works have been recently published that highlight prospects and critical points that need attention for the future of PSE education. Grossmann and Harjunkski (2019) describe in detail the current status, discuss the future academic and industrial perspectives of PSE, and summarize the results of their survey on the standing of PSE in academia and industry. The authors also outlined critical issues such as the disconnect between academia and industry with regards to the appreciation of PSE and the role of stakeholders to disseminate the crucial role of PSE in the academic content and the profession of graduates. In a recent work, Pistikopoulos et al (2021) analyzed the needs of PSE for the next generation in terms of basic principles, research, practical implementation as well as education. Their work adopts a hierarchical model representing the education needs, starting from the core and proceeding to the outer layers. The authors consider the Circular Economy as the framework for future PSE expansion and developments. Cameron et al (2019) have expressed - possibly for the first time so clearly - the relevance of PSE to the so-called Grand Challenges that require holistic approaches. Their work provides the insight of PSE as an integrative discipline in chemical and process engineering. The authors suggest an integrated framework for the design of PSE curriculum, mainly aiming at the development of technical knowledge as well as the mindset to approach problems in the PSE way.

This increased interest in educational needs for PSE highlights the need to match educational activities to a rapidly changing engineering world as well as the recognition of the impact PSE may have in all the great challenges in the years to come. In that respect, the present work should not be considered as just one more contribution. It supports the ideas in play and takes the discussion one step further. The methodology that has been followed in the present paper consist of: (a) a comprehensive survey of the actual topics and application areas covered in the courses taught in academia, and (b) an online survey that received responses from PSE stakeholders around the world (developers, researchers, and management) that map the education perceptions of PSE.

2. Current Status and Contents in PSE Education

This section surveys the PSE related modules being taught in some selected undergraduate and postgraduate courses in Europe, Asia, USA, and Canada. Clearly, there are Chemical and Biochemical Engineering courses with a strong presence of PSE related content without the presence of PSE modules as such. As pointed out by Cameron et al (2019), the presence, breadth and depth to which PSE is included in the curriculum of a Chemical and Biochemical Engineering program depends strongly on the number of faculty members with a background or research focus on PSE. Other relevant parameters may be the presence of a strong process industry, the attitude and focus of academics and industrials to cooperate (e.g. forms of industry – academia cooperation, e.g. in Imperial College), the recognition of PSE expansion in other strong areas such as the energy field (e.g. Texas A&M, USA), and the creation of, and local activity in, computer science and technology capacity. The modules present in almost all undergraduate Chemical and Biochemical Engineering undergraduate curricula that have PSE content are the ubiquitous courses covering integrated process design, process dynamics and control, and often courses in process modelling, simulation as well as in process optimization. While it has been widely recognized that process integration is key for the successful operation of chemical systems (Baldea and Harjunkski, 2014), this aspect is still missing in most of the chemical engineering curriculums, i.e., offer courses that integrate fundamental PSE tasks such as process design, control, scheduling and planning strategies.

In a few universities, PSE focused postgraduate studies are also carried out in dedicated MSc Courses, also including research dissertations in the PSE field. These PSE dedicated MSc courses have started appearing in universities programs during the last decade, clearly revealing the strong interest in the field and its expansion in other areas. However, it should be emphasized that the relevant PSE education content in the key societal issues such as energy, environment, water, pharmaceuticals, water-energy-food-environment nexus is often lagging behind the relevant focus of PSE research in these fields. A number of courses have also been found, mainly in MSc programs, such as big data methods and modelling in CE, supply chain planning and scheduling, process and energy integration, energy systems optimization and process intensification, knowledge based systems and AI, process safety and operations integrity, advanced environmental engineering; transition to a low carbon economy, modelling of biological systems, advanced bioprocess engineering, multivariate statistics in CE. These courses are found mainly in postgraduate courses since the capacity of undergraduate courses is usually limited to more basic subjects.

3. Survey Content and Methodology

As a complement to the review of actual teaching practice, we carried out an online survey to obtain the opinions from PSE stakeholders (developers, researchers, users) to map the education perceptions of PSE around the world. The survey asked the respondents to establish their position regarding the content of PSE education and its response to current and future needs. This questionnaire was termed the “WHAT” survey, delivered using Google Forms, and distributed via email links to the global PSE community. The second part of our contribution analyses the methods and tools (the HOW issues) to educate engineers more efficiently to respond to present and future needs (Lewin et al, 2022 The “WHAT” survey consisted of 16 questions and was organized into three main categories:

- A. Information about the responder (Q1-Q3 on the nature and size of business, geographic location, Q4 on how responder views PSE skills as critical)
- B. Questions relating to the responder’s position on aspects of the PSE and CE in general curriculum outcomes.
- C. Questions relating to how the respondents’ organizations use PSE methodology.

To collect as many responses as possible, we reached out to the following communities: the EFCE CAPE Working Party members, EURECHA members, the Energy Section of the EFCE, the AIChE CAST Division, the CACHE Corporation, the master list used to promote PSE 2018, the Systems and Control Division from Canada and the Japanese PSE community. The total number of respondents was 142: 92 from academia and research and 50 from a wide range of industries (i.e., process industry, software development, and consulting companies). The respondent’s geographical distribution is: 40% Europe, 21% USA, 27% Asia, 10% Central and South America, 2% Australia/New Zealand. About 50% of the responses were from very large organizations (more than 5,000 employees, with a further 25% from large organizations (500-5,000).

4. Survey Results

The responses to the 16 questions establishing the positions of respondents in Parts A, B and C of the survey were distributed on a 5-point Likert scale, where 1 indicated strong disagreement, 3 indicated a neutral position and 5 indicates a strong agreement. Tables 1-3 summarize the average and standard deviation of the received responses to the 16 position questions.

Table 1. Statistics and response distributions of the received responses to the position questions of the “what” survey, Part A: Your position on the importance of PSE.

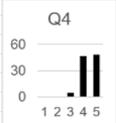

Question	Question statement	Ave	STD	Histogram
Q4	To what extent do you consider PSE skills as useful in developing a career as a chemical engineer?	4.42	0.62	
<p>Not surprisingly, given the PSE-related organizations who were polled, 94% of the respondents considered PSE skills as either important or vitally important to developing a career in chemical engineering. Some respondents made comments related to the reliability of the results due to the very wide nature of questions. One comment is quoted due to its significance: <i>“The students have high critical thinking, but it is not only due to PSE... We are very familiar here with ‘advanced’ tools and methods from PSE, but this area lost some way in some sense. Even with Optimization, Design and Cyber Physical Fusion, the real sense is very important. All computer aided design tools must be used with some discretion and engineering judgment on the part of the designer. This judgment mainly comes with experience. The art and practice of design cannot be learned from books. The intuition and judgment necessary to apply theory to practice will come only from practical experience.”</i> (G. Towler)</p>				

Table 2. Statistics and response distributions of the received responses to the position questions of the “what” survey, Part B: Your position on aspects of PSE curriculum outcomes.

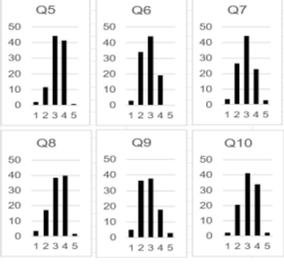

Question	Question statement	Ave	STD	Histogram
How close to your expectations are the skills of freshly-graduated chemical engineers in the following areas:				
Q5	Fundamentals of chemical engineering	3.27	0.76	
Q6	Practical engineering design capabilities	2.79	0.78	
Q7	Critical thinking	2.95	0.87	
Q8	Mastery of process analysis and synthesis software packages	3.18	0.86	
Q9	Computer programming skills	2.77	0.90	
Q10	Professional and personal skills (group work, presentation, writing)	3.13	0.84	
The last question in this part of the survey refers to the impact of teaching innovations on skills				
Q11	Do you see a positive effect of innovative teaching methods on the capabilities of freshly-graduated chemical engineers?	3.23	0.97	

Table 3. Statistics and response distributions of the received responses to the position questions of the “what” survey, **Part C: How your organization uses PSE methodology.**

Question	Question statement	Ave	STD	Histogram
To what extent is your industry/research involved in/using computation tools in:				
Q12	Enhancing sustainability or addressing climate change	3.39	1.25	
Q13	Production planning, scheduling or supply chain management	3.20	1.22	
Q14	Safety and risk management	2.87	1.17	
Perceived value of PSE				
Q15	How do you value of PSE in driving business?	3.52	1.03	
Q16	Extent of in-house capability to conduct PSE projects	3.72	1.09	
Q17	Degree of in-house development or implementation of Industry 4.0 projects	3.19	1.20	
Q19	Would you consider bringing in experts from outside to address PSE-related questions?	2.96	1.07	

5. Discussion of the results

The responses to the specific questions are presented in Tables 1-3. One of the interesting issues of this part of the survey is that it has been answered by respondents from both academia and industry, and thus, are weighted averages from both communities. However, separate analysis for the two groups indicates that there is no significant difference between them. The responses from industry in general avoid extreme opinions (i.e., “not at all” and “very much”). Almost all the respondents (94%) believe that PSE is a key factor that contributes to the knowledge and capabilities of freshly graduated chemical engineers. The respondents certainly are PSE experts or with PSE knowledge and this affects the survey’s outcome. But the general opinion is that young graduates appear to be rather moderate in chemical engineering fundamentals, practical engineering knowledge, personal and professional skills, and particularly low in design, critical thinking, and programming skills. On the other hand, it is very clear from the respondents that they have been using PSE methods and tools to face climate change and sustainability issues but to a lesser extent, supply chain management and planning/scheduling problems. In general, PSE is considered very important for their activities, and they are much interested in hiring specialised graduates to accomplish the PSE related projects.

The above results indicate serious issues not only for PSE related education but more generally for the ability and knowledge of graduates to understand the complexity of today’s industry and professional environment. Indeed, paraphrasing Pistikopoulos et al (2021), there is no chemical engineer that does not utilize PSE every day, everywhere. Therefore, PSE education needs to be totally integrated into the entire CE undergraduate curriculum to gain depth in different areas of application of chemical engineering and provide cases and expansion to all the relevant fields at a later stage. Courses in engineering computational tools, numerical methods, statistics and engineering

economics, essential in the PSE field, should be integrated to the engineering core of each curriculum.

To perform successfully, the chemical engineer must be able to design, analyse, operate and control processes to produce useful and desirable products from less valuable raw materials in an efficient, economic, and socially responsible way. The integrated approach of PSE and its focus on modelling and systems thinking make a very important framework and it is not only a matter of separate modules but a way of thinking and a mindset that should be introduced straight from the beginning in the Chemical Engineering curriculum.

6. Conclusions

Our two-part contribution suggests a framework for academic activity in preparing the next generation of engineers and researchers to be better aligned with the needs of academic research, industry, and society. This first part presents surveys of current practice and the perceptions of practitioners in both academia and industry, concerning the appropriate content of PSE education that would provide prospects and professional advancement to graduates as well as significant added value to industry for the most sustainable solution of their crucial problems. Outcomes of the research and suggestions for the future include the encouragement of the PSE community to expand to fields related to novel challenges in classical problems such as sustainable supply chains or the societal issues of circular economy, water, food, energy engineering, where the PSE approach has a lot to offer, and PSE-specialised engineers will find new professional prospects. Following the principal conclusion of Part 2 of this contribution, which refers to active learning enabled by novel teaching methods, perhaps the time has come for educational modules to be developed to facilitate the introduction of these new areas into the PSE curriculum worldwide, for the benefit of both students and the PSE community.

More work should follow on the investigation of the real PSE needs from the side of the demand and the users. It is believed that this will provide a much more complete insight where we should go. Furthermore, the accommodation of new PSE applications – expansion in the great social challenges will further enhance its role and contribution amongst industry and society in general.

You have nothing to lose: Worry-free flipping for PSE

Daniel R. Lewin

Chemical Engineering, Technion, Israel Institute of Technology, Haifa, Israel
Email for correspondence: dlewin@technion.ac.il

Abstract

Even though the COVID-19 pandemic forced all PSE instructors to move their teaching completely online, this has largely not changed most teaching practice, which has retained face-to-face lecturing as the main activity during contact between lecturers and students. This paper presents the case for shifting teaching to active learning by students, most effectively accomplished using the flipped classroom. With the advantages of adopting the flipping approach clear, one is left with two issues to resolve, both of which are the focus of the contributions of this paper: (a) how to effectively produce the necessary supporting materials (recorded lectures, online quizzes, and class activities), and (b) how to continuously foster engagement by the students. These contributions are supported by examples from the authors' extensive experience of successful applications of active learning approaches relying on the flipped classroom in process design and process control courses.

Keywords: PSE education, active learning, flipped class

1. Introduction

All topics taught under the PSE umbrella benefit from more time-on-task made available for students to learn by class discussion, experimentation, and cooperative solution of open-ended problems – basically by “getting their hands dirty” – as a key component of their own learning process. Courses taught using the conventional teacher-centered, lecture-based approach have less time available for these crucial activities, and thus may achieve lower levels of learning outcomes.

The flipped format moves the lecture material online, to be completed by students as homework. Thus, the main justification to move to flipped format is the desire to increase the proportion of the student-staff contact time in which students are actively learning, rather than just listening to lectures (Crouch and Mazur, 2001; Felder and Brent, 2015). This makes better use of the shared time between teacher and students, which has a huge impact on students' engagement, as does aiming to maximize the degree to which students are participating actively with the teacher and with each other, rather than passively listening to lectures. There are many existing studies that provide quantitative evidence that active learning improves course outcomes (e.g., Freeman et al, 2014, Velegol et al, 2015; Lewin and Barzilai, 2021). In an extended study involving secondary and post-secondary education, van Allen et al. (2019) found that the flipped classroom has a small effect of learning outcomes, but uncertain effect of student satisfaction, noting that the results depend strongly on how flipping is implemented.

Since the COVID-19 pandemic forced all teaching to move completely online, one would have thought that this would have motivated the transition to active methods in teaching. In fact, teaching pedagogy has largely not been affected by the potential of

technology, with much online teaching still teacher-centered, relying on synchronous lectures delivered over Zoom. Lewin et al. (2022) ran a survey that received 82 responses, mostly from veteran lecturers on PSE topics, which found that the main obstacles to change are the following: time taken away from research activities (65%), lack of available institutional funding (46%), and student dissatisfaction with new forms of teaching (32%). Teachers are clearly discouraged both by the significant investment of time and effort required to prepare quality online materials (prerecorded lectures and online exercises), and by the initial resistance of some students to active learning. Not surprisingly, there is reduced outcomes performances from the non-participants/non-engagers; Quantifiable lower outcomes are attained by students who engage less with the online materials and with class activity (Lewin, 2022).

The paper next discusses the link between active learning and learning outcomes. Next, in Section 3, the components of the proposed flipped class approach are presented, as well as details of what is required from the point of view of the lecturers and the benefits for students, with a focus on guidelines for practice that works. Next, working experience is shared regarding evidence for the contribution of the proposed teaching methodology to learning outcomes (exam results), followed by conclusions.

2. The Link Between Active Learning and Learning Outcomes

PSE topics are challenging to teach and to master since they all address the three top tiers in Bloom's Taxonomy (Bloom, 1956): analysis, synthesis, and evaluation. Ideally, a combination of examinations and group project assignments are the vehicles for teaching and assessing students' knowledge and competencies in all PSE topics. The utilization of project outcomes for assessing individual assessment requires careful checking to ensure all team members are truly contributing. For example, most process design courses also include a competitive design project component, calling for a demonstration of team-effort in addition to individual mastery. While both team and individual capabilities are important, examinations provide a reliable measure of the crucial mastery of individual students (Turton et al., 2013). Bloom (1968) postulated that the degree to which students achieve mastery depends on four conditions:

1. *Clear definition of what constitutes mastery.* It is the responsibility of the course instructor to clearly state the learning objectives in a manner that defines precisely what students need to achieve to demonstrate mastery.
2. *Systematic, well-organized instruction focused on student needs.* Our approach is based on pre-prepared, clear presentations of the course materials in which online lectures are composed of short video segments interspersed with practice activities, to enable students to actively control their initial acquisition of the basic materials. Then in the class meetings and active tutorials, students practice on more complex and advanced example exercises, first in cooperation with the course staff, and then on their own and with their peers. This sequence of actions leads to weekly cycles of systematic learning.
3. *Assistance for students when and where they experience difficulties.* The active tutorials are the ideal vehicle to aid students when they need it most: the first time when they attempt to solve example problems for themselves. This increases the likelihood that mastery will be achieved in less time.
4. *Provision of sufficient time for students to achieve mastery.* This implies the need to increase the time allotted to active tutorials at the expense of time expended in teacher-centered lectures and demonstrations. This is the reason for the shift

to switch lectures to online homework activities, which is the basis of the flipped classroom.

Bloom (1968) reports the modes of learning that improve outcomes, with the most significant obtained by personal tutoring, which increases the degree of mastery as exhibited by exam grades up to two standard deviations higher than for students taught by a conventional lecture-based approach. Amongst other factors indicated by Bloom (1984) as having significant positive effects on achieving learning mastery, are positive reinforcement and praise from the instructors, student classroom participation and time on task. Bloom reports that all these factors improve results by approximately one standard deviation higher than achieved by conventional lecture-based instruction.

The main justification to move to flipped format was the desire to increase the proportion of the student-staff contact time in which students are actively learning rather than just listening to lectures. This format makes better use of shared time between teacher and students to significantly impact students' engagement, as does aiming to maximize the degree to which students are participating actively with the teacher and with each other, rather than passively listening to lectures.

3. Flipped-class Enabled Active Learning

This section describes the three phases of the flipped approach, the demands on teachers who choose to adopt it in their courses, and the benefits to their students.

3.1. The recommended flipped approach

Three PSE topics, process design, process control and plant design, have been taught annually at the Technion using a three-phase flipped approach, the first of which since 2015, and all three online since the COVID-19 pandemic struck. In this approach a weekly cycle consists of three steps:

- (a) Asynchronous assignments in which pre-recorded video lessons are completed in advance of the week's activity by students as homework. Moodle *lessons* (<https://moodle.org>) are used as a framework for these, with each lesson being composed of a series of questions in which short video segments of lecture material are embedded.
- (b) Synchronous class meetings, using Zoom or in F2F/hybrid sessions, in which students interact with the lecturer and with each other. Typically, these involve review of concepts from the online lesson, discussions generated by quiz questions, and open-ended problem solving.
- (c) Synchronous active tutorials, using Zoom, in which students solve example problems for themselves. These usually begin with a brief review by the teaching assistant followed by problem solving by students working separately or in groups, utilizing breakout rooms. Our experience is that active tutorials run in Zoom breakout rooms are more effective than tutorials in regular F2F settings.

3.2. Requirements from the lecturer

The flipped format implemented imposes significant effort on the part of the lecturer:

- (a) Online materials, namely, the prerecorded lectures involving 5-15 minute video segments and associated quiz questions need to be prepared, most effectively using a video editor such as Camtasia® (<https://www.techsmith.com>). Each course typically requires of the order of 100 of each, which constitutes a huge investment. However, this effort is only invested once: the author prepared the materials for the process design course in 2015, for the process control course in 2017, and for the plant design course in 2020. No additional preparatory materials have been required for either course since then.

- (b) The lecture time freed by moving lectures to online homework tasks for students to do on their own needs to be occupied by suitable activities. The main difficulty for many teachers, especially those who are used to just lecturing, is the required change in their mind-set, which shifts the contact time between lecturer and student from being teacher-centered to being student-centered. This means that class materials should be designed to support open-ended problem solving performed by the lecturer but stressing class participation, the use of pop-quizzes to generate class discussion on their solutions, and any other activity that will enhance students' understanding. The development of these activities will take time to get right, and will likely evolve over time, as teachers become more accustomed to this mode of instruction.
- (c) The active tutorials could be as simple as just having students solve what used to be homework exercises working in teams in recitation time, or more involved and specially designed exercises. The main objective is to ensure that the students are doing most of the work for themselves.
- (d) It is important to continuously monitor the activity of each student, and follow-up on those students who are less active. This task is facilitated by a myriad of tools that are available in learning support systems.¹

3.3. Benefits to the students

Low-performing students typically do not significantly engage during the semester, leaving most of their effort for cramming just before final exams. This behavior is unlikely to achieve mastery of the taught materials. In each week of a course taught in flipped format, students need to prepare for class meeting and active tutorials by covering the pre-prepared materials ahead of time. They then benefit from participating effectively in the class meetings, by responding to the pop-quizzes, contributing to class discussion and brainstorming during the open-ended problem solving. Finally, they participate in active tutorials where they solve exercises for themselves, mentored by the course staff. This combination of activities increases the performance of the entire class, as will be described next.

4. Class Experience with the Teaching Method

As a teacher of process design for more than 20 years, I have taught using the full spectrum of possible approaches. This began with a traditional teacher-centered instruction, in which the course materials were transmitted via lectures and demonstration-recitations to my students, termed Phase I. The first transition was to active tutorials, where at least students were actively engaged in problem-solving for themselves, termed Phase II. The last major change, Phase III, was the move to the flipped classroom paradigm in 2015, which freed even more time for students to get to grips with the course material for themselves. I also teach process control and plant design, both of which are now also taught in the flipped format as previously described.

As described in Lewin and Barzilai (2021), the outcomes achieved by the students of the process design course have incrementally improved over the last 15 years, as illustrated in Figure 1, which shows a bubble plot showing disks whose diameters are in proportion to the fraction of the high-performing students in each year's class, p , centered on coordinates, whose ordinate and abscissa are the average grades of the high- and low-

¹ For more implementation details about our flipped classrooms, see the YouTube video: https://www.youtube.com/watch?v=O3hoSIYaGo4&list=PLW3u28VuDAHIOHECm8Vq30_Et_2chWFyO (13.5 min)

performing subsets of the class in each year, μ_1 and μ_2 respectively. These parameters are determined by fitting a bimodal distribution to actual exam grade distributions using the approach of Lewin (2021). Note that as $\mu_1 \geq \mu_2$ by definition, all disks have to be centered under the dashed line $\mu_1 = \mu_2$ indicated in Figure 1. The best performing classes would be those represented either by disks of any diameter in the top right of the plot (high average exam grades of both high- and low-performers, irrespective of their proportions), or lower on the right with large diameters (high average exam grade of high-performers, whose proportion dominates the population). Conversely, classes represented by disks on the left would be characterized by low average exam grades of the high-performers, and even lower average grades of the low-performers. As can be seen in Figure 1, in Phase I, the class disks, shown in black, are on the left. The transition to Phase II indicates a shift to the right, maintained after the transition to the flipped class in Phase III.

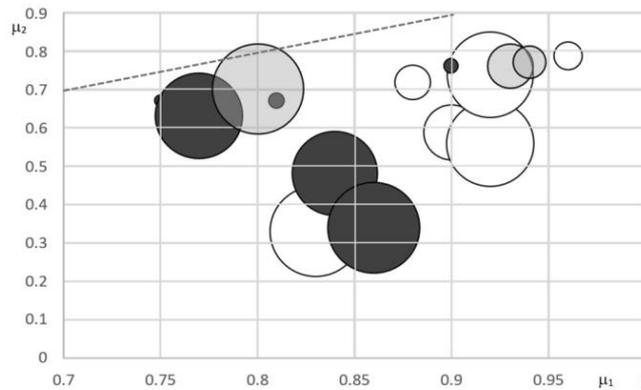

Figure 1. Bubble chart summarizing binomial distribution diagnosis (adapted from Lewin and Barzilai, 2021). The statistics for each year are centered on the $\mu_1 - \mu_2$ plane, with the disk diameter proportional to p . The disks are color-coded according to period: black – Phase I: 2005-2010 (before active tutorials), grey – Phase II: 2011-2013 (before flipping), white – Phase III: 2015-2020 (after flipping). The dashed line indicates $\mu_1 = \mu_2$.

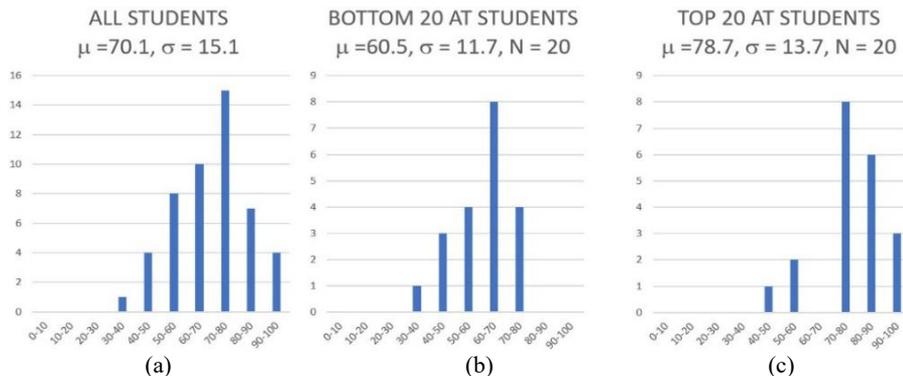

Figure 2. (a) 2021 Process control course outcome distribution for the entire class and separate distributions for (b) the 20 students that attended active tutorials the least and (c) the 20 that attended the most, out of a total of 50 students examined. In the histograms, abscissae indicate numbers of students, plotted against exam grade bins.

What is the cause of the bimodal distribution present in all exam grade histograms? As discussed in Lewin (2021), these could be inherent heterogeneous capabilities of the students in the class, or the consequence of the degree of engagement in the course materials. Certainly, there is evidence for the link between engagement and final exam grades, as shown in the example data in Figure 2 in which the exam grade distribution in the final exam of the process control course in 2021 is shown in comparison with separate distributions – one for the 20 students that attended active tutorials the least, and other distribution for the 20 that attended the most. Note that whereas the average exam grade for the entire course was about 70.1%, the average grade of the 20 students that attended the most tutorials was 78.7%, while that for the 20 least attending students was 60.5% -- more than one standard deviation lower than that achieved by the most attending students.

5. Conclusions

This paper advocates a change in teaching practice of PSE – from teacher-centered to student-centered instruction. It is worthwhile to consider moving much of the teaching materials from the lecture room to an online setting and require students to cover these materials on their own in preparation for class and tutorial activities. The effort is worthwhile in the long run, as better-prepared students will learn more effectively with the instructors and TAs, especially if they are expected to take an active part in the problem-solving sessions in class. The paper has provided evidence of the outcome improvements that can be expected.

Abstract

This study is the second part of a contribution addressing the appropriate content of process systems engineering (PSE) curriculum (the “what”) and how best it should be taught, so that our graduates are equipped to effectively apply their knowledge (the “how”). The two-part contribution presents the collective views and perceptions of the responders from all over the world to surveys as well as the collective view of the authors. This paper presents the “how” – how best to instruct our students in all matters PSE, given the availability of teaching technologies, and the time available to effectively train our students.

Keywords: PSE education, curriculum, active learning.

1. Introduction

This two-part paper proposes a “game plan” for effective teaching of process systems engineering (PSE) topics that addresses *what* should be taught and *how* these topics should be taught effectively. We base our recommendations on: (a) A survey of the teaching methods used by professors teaching PSE concepts and tools in universities around the World (the “how”), and (b) Surveys of the actual topics and application areas covered in the courses taught in academia (the “what”). This second part concerns the “how” – the most effective methods that should be used to achieve learning objectives that enable graduates of the first degree in chemical engineering – either a Bachelor’s, but in many cases, a Master’s degree. In particular:

- Students should be taught fundamental concepts in detail, ideally self-paced. This is achieved more efficiently using prerecorded materials.

- Students need to be exposed to computer programming packages ranging from those solving chemical process flowsheets to those specialized in data analysis, optimization, and spreadsheets.
- Students need to understand why some software or computer packages may not provide accurate answers in some instances. The fact that they run and converge to a solution does not necessarily mean that the solution is correct.
- Students should become familiar with optimization tools earlier in their academic career, so that they can use them to solve practical problems in their senior years.
- Students should apply multivariate statistical and artificial intelligence tools for solving real problems.
- Students should be required to develop critical thinking skills, i.e., to question their solutions/methods and ask themselves if other (attractive) approaches could be used to tackle a particular problem.
- Students should develop professional and personal skills such as teamwork, communication, project management.

This study consists of a survey of teaching practices aimed to assess the degree to which active methods are used in practice, to understand their benefits, limitations, and potential reasons as to why they are not implemented, and to identify circumstances or the conditions under which these methods may be more effective. The two-part paper provides a working plan for academic activity in preparing the next generation of engineers and researchers to be better aligned with the needs of both academic research, industry, and society, without requiring additional time-on-task beyond that allocated currently for the coverage of PSE topics.

2. Teaching PSE using Active Learning

For students to attain mastery in the critical understanding and application of the PSE core materials, time needs to be allocated for them to experiment, get things wrong and understand why; thereby, repeating this process as many times as needed. Such student-centered, active approaches to learning require time, which in a conventional teacher-centered approach is often allocated to lecturing. Several methods have been advocated that free class time for students to engage in active learning such as project-based learning, blended teaching, and flipped class approaches. The flipped class paradigm, detailed by Lewin (2022), moves the transmission of basic information to online preparatory tasks, which students complete in advance of class activities. This freed class time enables the four key agile values to be incorporated into the class environment, i.e.,

1. Student-centered flipping inherently focuses on the learner rather than following traditional teaching processes, which are teacher-centered.
2. Student-staff contact time is mostly used to work problems cooperatively and for project work, rather than for the transmission of information.
3. The contact time is largely reserved for collaborative work between staff and students and transforms the staff member to take on the role of mentor and motivator.
4. Staff can respond to the feedback and needs of students.

3. Method

3.1. Design

We used a survey to map the teaching perceptions of PSE academic teachers around the world. The survey asked the responders to establish their position regarding the application of active teaching methods, and then describe the extent to which active

methods are used in one of the courses taught by the responder. Moreover, the responders were asked to discuss how they see their teaching will evolve, and to define barriers to future evolution of their teaching approaches. This questionnaire was termed the “HOW” survey, delivered using Google Forms, and distributed to the global PSE community.

3.2. Material

The survey consisted of 26 questions organized into five main categories:

- A. Information about the responder (i.e., geographical location, teaching experience)
- B. Questions regarding the responder’s position on aspects of the PSE curriculum
- C. Questions regarding the responder’s position on how teaching should be carried out and, to the degree to which active learning should be applied.
- D. Questions regarding the responder’s teaching practice, and to what extent active learning is employed.
- E. Questions regarding the responder’s future adaptation of teaching methods.

3.3. Participants

To cover as many individuals as possible, we reached out to the following communities: the EURECHA members, the Energy Section of the EFCE, the AIChE CAST mailing list, the CACHE mailing list, the master list used to promote PSE 2018, the Canadian Systems and Control Division mailing list, and the Japanese PSE community.

3.4. Procedure

On 15th October 2021, a request for feedback with a link to the survey was emailed to all potential responders on the mailing lists described above, with a reminder sent on 22nd October. We received 82 responses from academic lecturers from all over the world, with the following geographical distribution: 47.6% Europe, 20.7% North America, 15.9% Asia and 13.4% Central/South America. Most of the responders (83%) had more than 10 years of experience teaching PSE courses, with an additional 10% having between 6 and 10 years of experience.

4. Analysis

The responses to the 18 questions establishing the positions of responders in Parts B-E (see Section 3.2) were distributed on a 5-point Likert scale (1 indicates strong disagreement, 3 indicates a neutral position and 5 indicates strong agreement). Tables 1-4 summarize the averages and standard deviations and presents histograms of the received responses to the position questions.

Table 1. Statistics and response distributions of the received responses to the position questions of the “how” survey, **Part B: Your position on aspects of the PSE curriculum.**

Question	Question statement	Ave	STD	Histograms
Q3	Enrich Courses should be enriched with external sources or guest lecturers	4.17	0.83	
Q4	Should offer courses using open access software	3.94	0.93	
Q5	Should offer courses on advanced statistics	4.13	0.84	
Q6	Should offer courses on AI and ML	4.02	0.75	
<p>Summary: There is general agreement about the need to enrich PSE courses using external sources (Q3), and to maintain curriculum up-to-date with regards to the usage of open-access software (Q4), and the introduction of courses in advanced statistics, artificial intelligence, and machine learning (Q5 and Q6).</p>				

Table 2. Statistics and response distributions of the received responses to the position questions of the “how” survey, **Part C: Your position on how should teaching be carried out in practice.**

Question	Question statement	Ave	STD	Histograms
How course materials should be transmitted to students, and how best to utilize contact time				
Q7	Classes should be organized so teachers mostly lecture, and students listen	3.16	1.18	
Q8	Lecture materials should be reviewed by students on their own as homework in preparation for class activity	3.52	1.00	
Q9	Most of the contact time between teachers and students should be used for student activity	3.56	1.03	
The responses indicate ambivalence regarding face-to-face lecturing as the main transmission vehicle (Q7). There is slightly more support for moving materials online for students to cover on their own (Q8) and for class time to be used more for student activity (Q9). However, it is fair to indicate that this support was not overwhelming.				
How should most of recitation time be best utilized?				
Q10	Instructors demonstrating solutions and students listening	2.68	1.01	
Q11	Students solving problem sets with staff providing hints/motivating	4.04	0.80	
If responses are consistent, the two questions should have response distributions that are mirror images. The responses to Q10 are bimodally distributed, with more disagreement than agreement – more responders do not approve of student passivity, but clearly many are comfortable with it. Moreover, Q11 indicates that there is strong support of student activity in recitations. However, the distributions are clearly not inversed, as they should be for consistency.				
How should PSE course outcomes be assessed?				
Q12	Include a significant portion of project-based learning (teamwork)	4.35	0.62	
Q13	Students should do individually graded homework exercises	3.79	0.96	
Q14	Using one or more exams involving open-ended problem solving	3.51	0.89	
The need for project-based assessment (Q12) received strongly positive response. There were mixed feelings about the other two issues – while there is a slightly positive position regarding the need to check individual students’ formative abilities by grading homework (Q13), the position does not have overwhelming support. The support for summative assessment (exams, Q14) is moderate. The main issue is which kind of formative/summative assessment methods are the most appropriate given students’ time limitations. What proportion of assessment should be team or individual is crucial. That is likely to be more significant than the methods.				

Table 3. Statistics and response distributions of the received responses to the position questions of the “how” survey, **Part D: How do you teach?**

Question	Question statement	Ave	STD	Histograms
Q16	Graduate (G) or undergraduate (UG) course: 28% UG, 53% Combined, 19% G			
Q17	Subject taught: 48.5% Process design, 33.3% Process control, 15.2% Optimization, 3% Numerical methods			
Q18	Class size: : 8.6% <10, 58% 10-50, 25.9% 51-100, 7.4% >100			
Slightly more than half of the responders teach mixed classes of graduate and undergraduate students, with 28% teaching only undergraduates and 19% teaching only graduates. Most responders are teaching either process design (49%) or process control (33%). Most class sizes are either medium-sized with 10-50 students (58%) or large with 51-100 students (26%).				
The following questions were directed at the type and mode of learning environment that exists in the responders’ institution.				
Q19	Student-centered (>50% of contact time is student activity).	3.16	1.10	
Q20	Teacher-centered (>50% of contact time, students are listening to me).	3.02	1.06	
Q21	Students are required to work independently and not in groups.	2.74	1.07	
Q22	Student activities are included into the lectures and recitations.	3.70	1.02	
The responses to Q19 and Q20 regarding how responders run their lectures are very similar and are both bimodally distributed. The responses are almost split 50/50 between those who teach in the traditional teacher-centered method (teacher talks – students listen) and those who apply student-centered, active learning in their classes. More detailed analysis indicates that much of the support for student-centered activity was by teachers of process design, and independent of the class size. Q21 discloses the responders’ views on the need for students to work independently rather than in groups. The majority of the responders disagree with this statement, indicating there is some application of group effort in many of the responders’ courses. However, many of them (27%) still consider it important for students to spend time working problems on their own. Q22 discloses the responders’ choice to include student activities into lectures and recitations. The responses to this question are somewhat in conflict with the responses to Q19 and Q20. On the one hand, about 50% of the responders adopt teacher-centered classes, yet here there appears to be more than 50% support for student-centered class activities. Perhaps the question was poorly posed as it refers both to lectures and recitations.				

Table 4. Statistics and response distributions of the received responses to the position questions of the “how” survey, **Part E: Your position on adaptation of teaching methods.**

Question	Question statement	Ave	STD	Histograms
Q23	I regularly investigate the engineering education literature	3.63	0.94	
Q24	It is important that I increase my use of real-world situations	4.12	0.87	
The surprising response to Q23 indicates relative support for keeping in touch with state-of-the-art engineering education literature, while Q24 indicates strong support for increasing use of real-world situations in the classroom.				
Q25	Most important barriers for me to innovate in my teaching role	65%	Time taken away from research activities	
		46%	Lack of available institutional funding	
		32%	Student dissatisfaction with new methods	

5. Responder Opinions Summarized and Conclusions

Lecturers are ambivalent concerning whether teacher-centered instruction is appropriate (Q7) but tend to support the idea of students reviewing materials to prepare for class (Q8) as well as the use of contact time to enable student activity (Q9). Regarding recitations, the responders largely disagreed that staff should run them in demonstration mode (Q10), and strongly supported the idea of active tutorials, where students do the problem-solving themselves (Q11). Regarding outcomes assessment, there was high agreement that project-based learning (PBL) should be employed (Q12), agreement that individually graded homework should be assigned (Q13), and that open-ended exams should be used for formative assessment (Q14). Note that requiring both preparation before classes, as well as individual homework and project work may overload students, and this needs to be considered. When it comes to their own teaching practice in lectures, the responders were more ambivalent, with responses almost evenly split between those taking teacher- and student-centered approaches (Q19 and Q20). Regarding student activities, there are more instances of group work than individual work (Q21), and a majority of the responders include student activities in lectures and recitations (Q22). Furthermore, the responders indicated that a majority regularly update their teaching materials (Q23), and a large majority indicated the importance of using real-world situations in their teaching, which links to the importance of PBL indicated by Q12. Finally in addition, the main obstacles to teaching innovation (Q24) are identified as the lack of time (65%), followed by the lack of institutional support (46%), but it also appears that not all students are welcoming innovative teaching methods (32%). In addition to the above, the survey also included two questions (Q15 and Q26) giving responders the opportunity to make general remarks. Because of space limitations, these are not being addressed in this paper, but will be summarized in the full version, as will summaries of interviews with leading members of the worldwide PSE community.

The survey disclosed that there is a gap between the technological capabilities that can be harnessed to the teaching of PSE and practice for many of the responders, most of whom see this as a burden since research time is sacrificed to perform this activity. Perhaps additional incentives are required to promote the move to more active teaching. In conclusion, the objectives of our studies are to provide information and suggestions to improve learning outcomes (i.e., the “what”) but also their efficient transmission to students (i.e., the “how”). The process systems engineering community needs to openly share best practices and resources, otherwise we will be back talking on this subject in 5- or 10-years' time (Cameron and Lewin, 2009, Cameron et al., 2019, Kiss and Grievink, 2020).

bmenezes@hbku.edu.qa

Abstract

The recent pandemic events have significantly affected people and institutions worldwide. Multiple issues and difficulties arise, with an increasing number of challenges. In this work, we address the impact of pandemic events on educational resilience, and we provide guidelines for addressing such concerns by using a structured framework assisted by data-driven and decision-making capabilities. The educational resilience framework is comprised of five steps: data collection, data analysis, gaps formulation, solution development, and implementation planning. First, a data-driven strategy collects data from the internet, literature, surveys, and previous knowledge. Second, analyses are carried out to draw patterns and insights that can serve as indicatives of potential improvements. Third, the most critical gaps are analysed and classified according to a cost-effectiveness criterion. Fourth, guidance is provided to handle these gaps, whereby proper solutions are developed considering the availability of resources (time, effort, money) and outcomes (benefits, accomplishments, profit). Finally, a deployment plan is built using the structured solution. From the proposed guidelines, educational resilience improvements can be achieved for people, academia, industry, and society, in a wide variety of problems and applications and with multiple significant benefits. The results and conclusions derived from this work illustrate how a decision-making framework can be effectively and interestingly employed towards easier and more efficient educational strategies, methodologies, and policies.

Keywords: Educational resilience, Education in PSE, Learning capabilities, Decision-making framework, Modelling and optimisation, Pandemic events, COVID 19

1. Introduction

Resilience can be understood as the potential of adaptation, or the ability to maintain or regain healthy status when experiencing adversity (Herman et al., 2011). Within a community, resilience measures the ability of responding to and recovering from adverse situations. This allows adaptation and growth after disaster strikes (Magis, 2010). In this work, we address the topic of educational resilience, defined as the likelihood of success in the educational life accomplishments, despite environmental adversities brought by traits, conditions, experiences, and unforeseen events (Waxman et al., 2003). This concept focuses on dynamic variables such as motivation, smart-work (rather than just hard-work), and learning environment (McMillan and Reed, 1994).

The literature on the topic of educational resilience has been extensively addressed (Downey, 2008; Torsney and Symonds, 2019), but only a few works have focused on

scenarios of crisis (Annarumma et al., 2020; Zamfir, 2020; Naidu, 2021) such as the COVID-19 pandemic that has affected the society worldwide. This is a novel topic that has emerged due to the current pandemic scenario and which presents several gaps that require attention. Tackling these gaps represent multiple potential opportunities towards more efficient educational resilience, with several benefits towards real-life educational applications.

This work aims to introduce a decision-making framework to systematically address important and impactful educational gaps derived (or augmented) from times of crisis and to provide guidance towards implementing computational-aided decision-making (e.g., modelling, simulation, optimisation) to achieve enhanced educational resilience. Such decision-making tools have increasingly assisted a wide variety of applications in multidisciplinary areas and provide proper capabilities for improved solutions (Franzoi et al., 2021). The foundation of the proposed framework is twofold and relies on data-driven and solution-driven concepts. Reliable and representative data are required to allow proper analyses, which can be done based on previous knowledge on the topic, literature review, further research, surveys with students, researchers, faculty, workers, etc. Moreover, the development of an efficient educational framework is closely related to solution-driven objectives, which relies on data gathering, data-driven analyses, identification of educational gaps, development of solutions, and implementation of deployment plans required for an enhanced educational system.

This paper is structured as follows. Section 2 discusses educational resilience, including the main drivers, resources, and beneficiaries. Section 3 presents the proposed educational resilience framework. Section 4 provides an illustrative example. Section 5 highlights the main findings and future guidelines derived from this work.

2. Educational resilience

Educational resilience concerns a wide variety of gaps, issues, and improvements required towards a more efficient educational system. Its importance is significantly augmented in times of crisis, with increased difficulties and new challenges. Under the presence of unforeseen pandemic events, which have recently caused significant impacts worldwide, the general concept of resilience becomes particularly important. In this section, we present the: a) main drivers that affect educational resilience of individuals, organisations, and communities; b) resources required for improved resilience; and c) beneficiaries and benefits from a more resilient educational system.

2.1. Main drivers

There are three important drivers that significantly impact educational resilience: investments, learning capabilities, and collective intelligence.

1. Investments are typically funded by the government or partnerships between universities and companies. They concern project and research grants, scholarships, infrastructure, resources, tools, software, etc.
2. Learning capabilities can be described as the mechanisms and management structures that can be implemented to promote better learning environments (Goh et al., 2012). Examples of learning skills include organisational, communication, collaboration, critical-thinking, and creative skills.

3. Collective intelligence arises from a group of individuals acting intelligently towards collective goals, such as in collaborations between postgraduate students (Menezes et al., 2021).

The concepts and some key foundations of those drivers are illustrated in Figure 1.

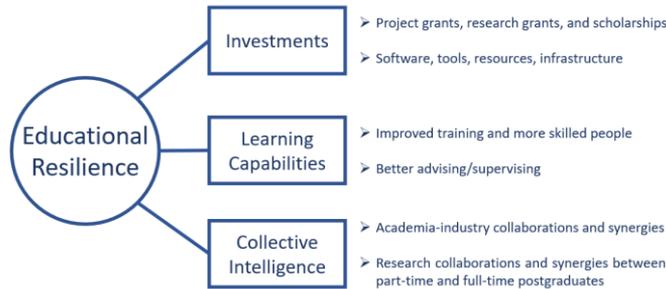

Figure 1: Educational resilience drivers.

2.2. Required resources

Three resources are fundamental to properly improve the educational system. The first are the data to be collected mostly through research and surveys, which provide insights on the most critical educational issues derived from the pandemic, either qualitative (i.e., according to peoples’ opinions) or quantitative (i.e., numerical data and statistical analyses). The second is the effort needed to analyse data, define gaps, propose efficient solutions, and draw implementation plans. The third concerns the capabilities required for implementing the deployment plan (e.g., investments, time, effort).

2.3. Beneficiaries

Improved educational resilience provides benefits for recipients (students, researchers, faculty, staff), academia (schools, research centers, laboratories, universities), industry (companies), and society (people, public system, government), as shown in Table 1.

Table 1: Drivers and outcomes, beneficiaries, and benefits.

Drivers and Outcomes	Direct Beneficiaries	Benefits
Investments: grants, scholarships	People and academia	Resources for studying and developing research, which can be applied for industrial and public sector applications.
Investments: software, resources, infrastructure	People	Resources for developing high-quality research, which also benefits universities.
Learning capabilities: training and skills	People	Better efficiency and accomplishments (also extend to universities).
Learning capabilities: better supervising	People	Improved performance, enhanced learning efficiency, and higher accomplishments.
Collective intelligence: academia-industry synergies/collaborations	Academia and industry	Development of industrial-driven research, scholarships, better environment.
Collective intelligence: research collaborations	People	Exchange knowledge (full-time researchers) and experience (part-time researchers).

3. Educational resilience framework

The educational resilience framework proposed herein is expected to identify the potential gaps that lead to (or augment) educational crisis, and to guide the implementation of efficient solutions seeking enhanced educational resilience. This provides assistance in understanding the importance of the education system, especially under pandemic events that bring many difficulties and impose restrictions worldwide (e.g., remote access, distance learning, educational limitations). Figure 2 illustrates the proposed educational resilience framework.

The framework is comprised of five steps: data collection, data analysis, gaps formulation, solution development, and implementation planning. This data-driven approach employs distinct sources of data: a) surveys to be carried out with students, researchers, faculty, and workers; b) previous knowledge from the research team to provide practical examples where educational gaps exist; c) literature review aiming to collect useful information and data related to the topic; and d) search for recent news and information from reliable sources that indicate real scenarios and examples of impactful educational issues. Multiple procedures and analyses may be carried out on the collected data, including aggregating data to provide quantitative information, drawing insights, performing statistical analyses, and verifying whether the data are accurate and sufficient for the purpose of the research. Then, educational gaps are identified and classified according to a cost-effectiveness criterion, whereby listing for each gap their respective pros and cons, risks and probabilities of success, and expected outcomes. Decision-making capabilities, which may include any simulation- or optimisation-based tools, are employed for properly tackling the gaps. This is fundamental to manage the resources available to be used, and to consider potential issues, risks, and damages that may jeopardise the feasibility and success rate in the implementation phase. Finally, a deployment plan is carefully developed to guide the solution implementation. An efficient implementation is mandatory and can be performed through a structured and organised plan, whereby avoiding delays and minimising risks.

The objective of the proposed framework is to assist in identifying the most impactful educational gaps and leveraging the capabilities required for enhanced educational resilience. Such measures target people, academia, industry, and government, and concern the implementation of strategies such as public sector investments, assistance to people for easier and better adaptation against pandemic events, incentives for companies and universities to build partnerships, etc. From the guidelines provided by such a framework, decision-making based on mathematical modelling, simulation, and optimisation approaches can provide proper capabilities for achieving improved educational resilience, whereby solutions can be implemented in the real-life environment according to requirements, restrictions, and limitations (e.g., availability of people and resources, investments). To illustrate the foundation of such educational resilience framework, we provide an illustrative example that follows the sequence of steps shown in Figure 2.

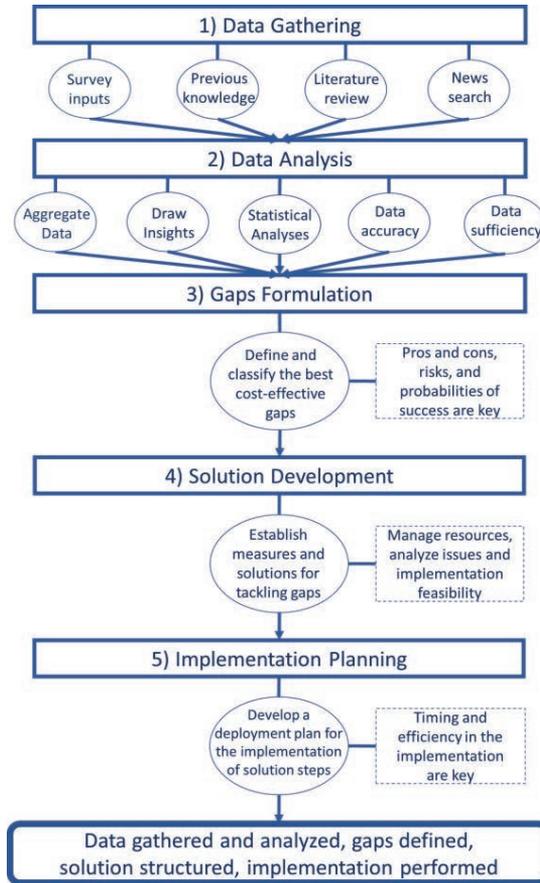

Figure 2: Educational resilience framework.

4. Illustrative example

It is known that the recent pandemic events have introduced several difficulties in the management of classes and resources of schools. Thus, a survey is launched for high school teachers over a significant number of public schools to collect information on the gaps, challenges, and improvements needed in the current educational system. The data gathered is analysed, whereby major gaps are found regarding the availability of materials and resources for laboratory classes (e.g., chemical/physics experimental classes). Those classes have to be in-person to provide a proper experience for the students, but the pandemic restrictions impose reduced classroom occupancy. Then, the laboratory classrooms are divided into multiple sub-groups, which leads to additional requirements of personnel and materials for carrying out the experiments, and hence, an overload of the system with consequent lack of resources. This includes achieving better allocation and distribution of resources to public schools to optimise such educational requirements. To properly address this concern, modelling and optimisation decision-making is employed, whereby building a mathematical model that represents the problem and utilising an optimisation algorithm to find an optimal solution to be implemented in the system. This would provide proper capabilities for systematically identifying and addressing the current and challenging educational needs.

5. Remarks and future guidelines

This work provides guidance for effectively addressing educational gaps through the development of an educational resilience framework assisted by decision-making capabilities. Guidelines are provided in a structured fashion which segments the methodology into five steps, namely, data collection, data analysis, gaps formulation, solution development, and implementation planning. They include identifying the most impactful educational gaps in times of crisis, developing solution methods and strategies that are appropriate and effective for each scenario, and providing practical guidance towards implementing these solutions to mitigate educational gaps.

The framework proposed herein is expected to: a) identify representative and impactful educational gaps and issues, which are insights drawn from the data gathered; b) provide cost-effectiveness or other similar analyses to systematically establish a criterion considering the importance to handle each gap, the cost and effort required, and the potential outcomes; and c) highlight quick and efficient methods, approaches, and solutions to be employed in the implementation steps.

From the proposed guidelines, educational resilience improvements can be achieved for multiple beneficiaries in a wide variety of problems and applications, and with multiple advantages, including better allocation of personnel, materials, and resources; improved teaching/learning; proper capabilities for the learning/development of students, teachers, and staff; more efficient investments from the government (e.g., allocation of financial resources for training, teaching, materials, infrastructure), enhanced resilience of the education system, among others. The results and conclusions derived from this work illustrate a decision-making framework can be effectively and interestingly employed towards easier and more efficient educational strategies, methodologies, and policies.

Abstract

The current pandemic has blatantly affected teaching at all levels. Specifically, in Portugal, for STEM (Science, Technology, Engineering and Mathematics) students attending Universities and taking high learning degrees, it was particularly harsh. Most mandatory courses implied attendance to science laboratory or computational lab lessons that had to be postponed to after lockdown times, rescheduled to late night hours, or simply converted into videoconference sessions. Teachers and researchers had to be very creative and resourceful to keep their students interested and invested in their courses in spite of the disturbing and abnormal situations caused by the pandemic. Operational Research, Simulation, and Actuarial and Financial Mathematics courses were mostly converted to online versions with videoconference lectures supported by e-learning platforms. The courses' heavy usage of computational resources and the physical characteristics of the majority of existing computer labs prevented the possibility of face-to-face classes due to social distancing even after the end of the several lockdowns. Unfortunately, online versions of these very hands-on courses revealed to be really bland and having a low appealing to students, leading to pupils' increasingly dropping out of courses and even quitting their attendance for that particular semester.

In this work the authors will present the adaptations that they decided to implement on their courses during three long semesters to make the teaching and learning experiences engaging, interesting and effective and the assessment activities reliable and efficient. Lectures being recorded (previously or live), small group assignments during classes, the use of a professional video-conferencing software, each course having its Moodle page are some of the experimented adaptations, among others. The main goal was to meliorate and even to cease students' drop-outs. This work will explore the experiments and good practices that worked and the ones that did not correspond to the expected outcomes. Additionally, some framing will be made concerning how Portuguese Government and the authors' teaching institution have supported these experiments and good practices. Some comparisons between the students' performances from the affected semesters and from previous years will also be presented.

Keywords: Virtual Education, Teaching Practices, Pandemics, Active Learning, Peer Instruction

1. Introduction

FCT NOVA (NOVA School of Sciences and Technology) is one of the most important and renowned Sciences and Engineering schools in Portugal. It offers doctorate, master and bachelor degrees in Mathematics, Computer Sciences, Physics, Chemistry, Industrial Management, Geology, Environmental Sciences, Material Sciences, among others. All offered degree programmes are accredited by the national agency for assessment and accreditation of higher education and all Engineering programmes have the EUR-ACE certification. Around 8,000 students, 400 professors, 1,000 researchers and 200 staff (NOVA School of Sciences and Technology, 2021) study, work and live in its campus making it larger than several Portuguese villages. The current CoViD19 pandemic had a tremendous impact in this academic community like it happened across the Globe, slowing down research and teaching activities, leading to students dropping out of their hard earned higher learning opportunities.

From March, 2019 to June, 2020, FCT NOVA lived through total and partial lockdowns. Regular classes were converted into remote versions, whenever possible, affecting the lives of thousands of students and hundreds of teachers. The authors were the Coordinator Professors of a total of nine different courses offered to Mathematics and Engineering degrees' students. Almost 300 students attended to their courses during the mentioned period. Table 1 lists those courses and some of its characteristics.

Table 1 - List of Courses

Course	Year	# students	Type	Level
Decision Sciences	2020/21	2	Mandatory	Doctor.
Decision and Risk	2019/20	9	Optional	Master
Decision and Risk	2020/21	9		
Financial Mathematics	2019/20	77	Optional	Bach.
Financial Mathematics	2020/21	75		
Introduction to OR ¹	2020/21	42	Mandatory	Bach.
Non-Life Insurance	2019/20	17	Mandatory	Master
Non-Life Insurance	2020/21	17		
RM ² Non-Life Insurance	2020/21	11	Mandatory	Master
Simulation techniques in RM ²	2020/21	14	Mandatory	Bach.
Simulation	2020/21	16	Mandatory	Master
Social Security and Pension Funds	2020/21	11	Optional	Master

Decision Sciences is a mandatory course for students attending the doctorate degree in Mathematics – Operational Research. Decision and Risk is offered to the Master in Analysis and Engineering of Big Data Programme. Financial Mathematics is an optional but transversal course available to every FCT NOVA Bachelor students. Introduction to Operational Research is a mandatory course in both Mathematics and Risk Management Applied Mathematics degrees. The course “Simulation techniques in Risk Management” was new and the class of 2020/21 was the first one attending it. The remaining courses are offered to students attending the Applied Mathematics Master Programme.

¹ Operational Research

² RM - Risk Management

In the following the authors will address the various pedagogical approaches implemented on the listed courses.

2. What was tried

During the three mentioned semesters classes were held remotely through a videoconference platform. The authors had to adequate the courses' documents and other pedagogical materials to this format. Additionally several approaches were implemented in order to keep the students interested and invested. Namely:

- (1) Lectures were recorded live and the recordings were later made available to students;
- (2) Lectures were previously recorded and the recordings were available to students before the corresponding remote session;
- (3) Course was supported by a MOODLE³ course page;
- (4) The usual midterm tests were replaced by several smaller and more focused tests during class time;
- (5) Group assignments solved not only during classes but also as homework;
- (6) Students studied some small part of the course syllabus, or solved a more complex problem, and prepared and presented a lecture about it, individually or in group;
- (7) Students rated their peers' works;
- (8) Students were offered additional non-mandatory tasks that could be used to improve their final grade up to a limiting threshold;
- (9) Collections of solved exercises were made available before or after the corresponding classes. Although this was already a common practice during this period it was expanded. More exercises and with a higher variety were added to the collections and it was implemented in more courses.

Table 2 presents which of the listed approaches/techniques were used in each course.

Table 2 - Pedagogical approaches

Course	Years	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Decision Sciences	2020/21					X	X			
Decision and Risk	2019/21	X		X						X

RM in Non-Life Insurance	2020/21			X		X	X			
Simulation tech. in RM	2020/21	X		X	X	X	X	X	X	X
Simulation	2020/21			X		X	X			X
Social Security and Pension Funds	2019/20			X		X				

³ MOODLE is the acronym to Modular Object-Oriented Dynamic Learning Environment. It is a digital learning platform designed to provide an integrated, secure and highly flexible system for teachers, educators and students. (The Moodle Project, 2021). Often used by schools and universities as an e-learning platform.

A typical lesson included some lecturing time where the teacher presented the important theme concepts, deduced the relevant formulae and demonstrated the fundamental theoretical results using digital slides and/or writing on shared digital white boards. Later the teacher would explore practical examples supported by specific digital applications like spread sheets, Geometry software and an adequate programming language.

Afterwards the class would be split into smaller groups and would go into separated videoconference “rooms” and would tackle with simple but consecutively more complex problems and practical case studies on their own under the supervision of the teacher. The lesson ended with the day’s theme being wrapped up with the problems solving or, at least, a possible resolution for the case study and the results’ discussion. The main goal was to emulate a face-to-face experience as close as possible using the videoconference platform and some additional digital means.

3. Some results and comments

At FCT NOVA, at the end of each semester students are obliged to fill an on-line anonymous questionnaire addressing the course and any out of the ordinary happenstance occurring during the semester. Additionally, the Coordinator Professor elaborates a report with his/hers perspectives about the course, discussing the students’ performances and commenting the students’ answers to the questionnaire.

This section presents the overall feeling of the authors concerning the implemented measures from the students’ point of view based on the information collected from the semester report of each course. No serious statistic treatment was made with that information and therefore no numbers will be presented.

3.1. Lectures’ recordings.

They were generally well received although were mostly used by students who missed some of the videoconference sessions. Some students also declared they reviewed the recordings if they were unsure of having fully understood some concept or explanation. Nevertheless, more timid students avoided asking questions knowing they were being recorded in spite of the guarantee that students’ identities were excluded from the recording. Live recordings were usually more messy and chaotic than previously recorded lectures but also realer because they included students’ questions during the lecture. Currently, even after classes went back to the classrooms and computational labs some of these last year’s recordings are still offered as additional studying material.

3.2. MOODLE

This was a no-brainer. Teaching this courses during lockdown without it or a similar platform would not be reasonably possible. The authors kept using it in all the courses they coordinate.

3.3. More evaluation moments

Students really enjoy them. Having short term objectives helped keeping them focused. Nevertheless this situation can easily become a heavy burden for the teachers. In the current school year, the courses referred in Table 2 keep using a diverse and more frequent

evaluation schedule although with some adaptations due to the lighten of the social distancing measures.

3.4. Group assignments

The general consensus is that they work really well even remotely. The current video and sound equipment present in most home computers and internet connections make it totally possible for students to follow their peers even from their bedrooms. Unfortunately, it can become a tricky situation when a student does not have a healthy family environment. Additionally, still not every family in Portugal has a good access to internet, particularly in rural areas.

Another issue arose when the groups were randomly assigned. Some students refused to work with colleagues they did not know. And simply turned off their microphones and cameras and worked alone for the rest of the session. In the current year group assignments are still a part of the courses evaluations.

3.5. Autonomous work with oral presentations

This was a hit or miss. When a student did a good job it was exciting to follow and motivating for the rest of the class. And the students enjoy it tremendously and praised it in the report. But when a student was shy, did not feel comfortable speaking in public or had some difficulties dealing with the videoconferencing technical issues the presentation could become a difficult situation to correct in the heat of the moment, a lost learning opportunity and very penalizing for the involved students. Currently, some of the courses mentioned in Table 2 still have some oral evaluation moment but with some teachers safeguard measures to ensure a higher evaluation equity.

3.6. Students marking their peers' work

It was a partial success. Some students really enjoyed it and discovered they would learn immensely from marking their colleagues' works. They became more aware of what was the teachers' expectations and therefore managed to achieve better results in the following tests. Other students never took it seriously. Additionally this kind of activities demand a tight control from the teacher otherwise it can lead to personal vendettas with a group of less mature students. This measure was kept for the current year.

3.7. Extra tasks for extra grade

As the previous measure, this was a partial success. The majority of students praised it and tried to execute those extra tasks as much as they could. Other students mentioned schedule issues and work overload and not even tried. Nevertheless, most students complained that the reward was sometimes too low for the extra work.

3.8. Collection of solved exercises.

This come to stay. The collections are already made. It is just a matter of adding more every other year.

From the authors' point of view all these implemented measures ensured that students had a good learning experience during the worse part of the pandemic. Not everything had the expected outcome but the general result is positive. Table 3 compares the average students' grades, in the [0 – 20] scale used in Portugal, where a 10 is needed for a student to successfully conclude a course. The grades in bold type and shaded in grey correspond

to the pandemic period. The excluded averages correspond to school years when the course was not being coordinated by one of the authors.

Table 3 - Average Grades

Course	Average Grades				
	2016/17	2017/18	2018/19	2019/20	2020/21
Decision Sciences	-	-	17.0	-	19.0
Decision and Risk	-	-	13.5	16.2	14.2
Financial Mathematics	14.9	-	14.8	13.1	14.6
Introduction to OR	-	-	16.1	15.8	16.9
Non-Life Insurance	-	13.8	13.9	14.0	15.5
RM in Non-Life Insurance	16.6	15.0	14.5	14.2	17.5
Simulation tech. in RM	-	-	-	-	16.3
Simulation	14.5	14.0	-	15.8	16.1
Social Security and Pension Funds	13.8	14.8	-	16.0	15.2

As can be seen, the grades did not suffer much during the lockdowns. On the contrary, in some courses an obvious improvement was noticed. And that led to the maintenance of some of the aforementioned measures even after classes returned, totally or partially, to the campus.

4. Conclusion

Both authors made important, creative and meaningful efforts during the lockdown semesters for keeping the courses they were coordinating engaging and interesting to students attending them. The additional load of work paid off because the main goal of those efforts was achieved. Students generally gave positive feedbacks on their semester questionnaire and the average grades were similar to the ones from recent years.

Additionally, in some courses the students' performance seemed to have improved leading to the maintenance, to some extents, of several of the teaching practices introduced during in the initial phase of the pandemic. Some lessons were learned and they were too good to be discarded!

Acknowledgments

This work was partially funded by national funds through the FCT – Fundação para a Ciência e a Tecnologia, I.P. (National Foundation for Science and Technology), under the scope of the project UIDB/00297/2020.
