Figure 4b shows the cyclic inventory of AR in the harvest sites, which shows that the AR available during the first half of the year is stored at the harvest sites for later processing during the months when it is not available, and storage finished products in the biorefinery. Finally, Figure 6 shows the flow of bio-jet fuel supplied in each month of the year continuously and stably, unlike the availability of feedstock that shows constant fluctuations, which do not have an impact on the production of the SC.

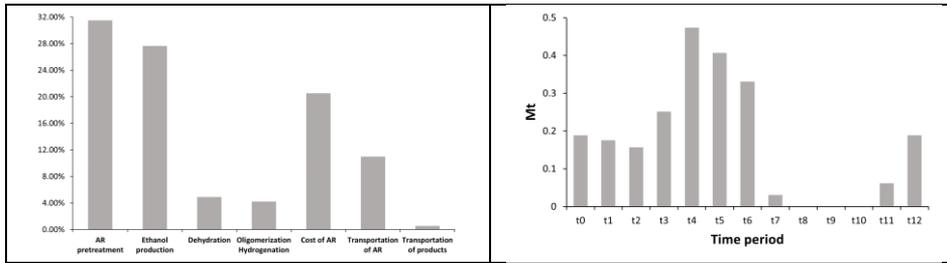

Figure 4. a) SC cost distribution, b) Cyclic inventory of AR

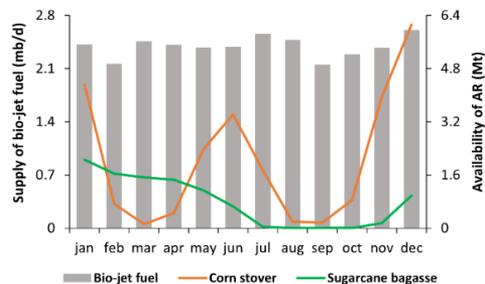

Figure 5. Monthly supply of bio-jet fuel and feedstock availability

5. Conclusions

Agricultural residues are a promising source of raw materials by biofuel production and through the design and optimizing of the SC associated with biofuel production is possible to overcome its geographical and stational dispersion. The proposed model had the purpose of identifying the areas of opportunity in the production of bio-jet fuel from the ATJ process as well as the level of coverage that is possible to achieve with the materials available in Mexican territory today. Based on the results obtained, it has been determined that the main process disadvantages are the first two stages of the process (pretreatment and ethanol production), although despite these disadvantages, the process has an EROI positive, so the improvement of the process will not only bring economic advantages, but also energy and environmental advantages. On the other hand, in this case a centralized configuration was preferred due to the processes carried out in the pretreatment depots are the costliest, and its separation from the other process stages result in a reduction of the effect of the economy of scale, which the transportation cost reduction could not compensate.

Abstract

Integration of process flowsheet simulators and optimization algorithms is a prominent approach to address simultaneous design and optimization of processes, which is represented by a mixed integer nonlinear programming (MINLP) formulation. In this study, DWSIM, a free and rarely used simulator, is used as a black-box function for the evaluation in genetic algorithm in MATLAB. Proposed approach is implemented to a dimethyl ether process, calculating optimum processing conditions in addition to structural decision variables including the feedstock type, reactor, and separation unit selections. Results show that syngas has the major impact on the process economics and is significantly more economical feedstock although high number of additional processing units are required.

Keywords: superstructure optimization; mixed integer nonlinear programming; process synthesis; dimethyl ether process; black-box optimization; DWSIM.

1. Introduction

Chemical processes include complex and integrated pathways combined by several unit operations in which conversion occurs from feedstocks to valuable products. Such a conversion, in general, can be obtained through high number of alternative paths, which hinders the process architecture and operating condition selection under economic considerations and tightly ensured process constraints. Thus, a superstructure optimization problem formulation addressing simultaneously the aforementioned issues has become an important research area over the past decades.

A mixed-integer nonlinear problem (MINLP) is formulated, in general, to obtain a smaller architecture from a larger superstructure that is predefined and includes all alternative units, flows and many other considerations. The resulting MINLP formulation includes integer variables to account for sequences of events, alternative candidates, and the existence of units, whereas the continuous variables represent states. The MINLP problem is flexible and can include various user-defined considerations from economic and environmental aspects (Edgar *et al.*, 2001).

Significant developments in theory and computation have provided substantial capabilities to solve various complex optimization problems over the past decades (Chen and Grossmann, 2017). With many alternatives and modifications, MINLP solvers can be classified roughly into two major groups as rigorous, and heuristic based on solution approach. Rigorous solvers utilize all mathematical tools to exploit optimality through the explicit formulation of all superstructure elements and might ensure global optimality for many cases. As an alternative, black-box or evolutionary algorithms benefit from the patterns from successive function evaluations, rather than focusing on derivative-based iterations, to provide optimality. Evolutionary algorithms, although suffering from significant computational load and local optimality issues, might deliver practical and satisfactory solutions to complex MINLPs once the associated plant models are challenging to derive and requires a priori knowledge due to numerous unknown driving forces and their nonlinearly interacting nature (Mencarelli *et al.*, 2020). In contrast, despite significant computational developments and theoretical advancements, rigorous solvers have scalability problems for large superstructures. In addition, integration of those to process flowsheet simulators which have widespread industrial use is a challenging task, hindering rigorous solver implementations. A significant fraction of superstructure optimization studies focus on commercial software (Ploskas and Sahinidis, 2021). On the other hand, some free alternatives, including DWSIM, might provide similar performance to commercial ones (Tangsrivong *et al.*, 2020). Teerapat and Amata used a DWSIM simulation environment to validate an optimized DME process (Laiwatthanaphaisarn and Anantpinijwatna, 2018).

This study focuses on the simultaneous design and optimization of a comprehensive DME process under several scenarios including different feedstock and unit operation prices using a free process flowsheet simulator, DWSIM, which is automated through Python. The superstructure involves different feedstocks which are processed through different reactors and separation units to be determined by the optimization problem in addition to some operating conditions. A genetic algorithm is used for the evolutionary solution of MINLP problem, which accounts for the existence of the units and plant operating conditions. The case studies show different process configurations are required for profitability based on feedstock and product prices.

2. Superstructure of DME Production Process

Dimethyl ether is one of the prominent candidates for relatively clean and sustainable alternatives to fossil fuels. The increased demand for DME can be met from synthesis gas or methanol from biological waste (Saebea *et al.*, 2019).

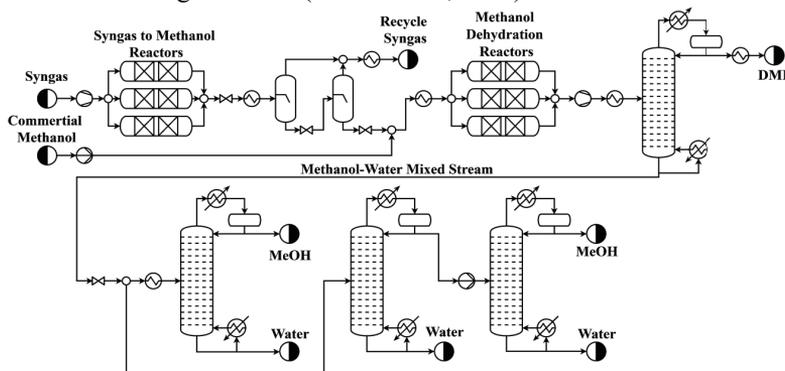

Figure 1. Superstructure of DME production process.

The proposed superstructure in this study is presented in Fig. 1. DME production might be obtained with dehydration of methanol and from various feedstocks, primarily from syngas, as an emerging trend to favor carbon management and biomass utilization. The conditions specified in the kinetic study of Nestler *et al.* (2020) were used for modelling methanol synthesis at three different catalyst density yields high to low conversion (Nestler *et al.*, 2020). Sequential flash units separate syngas from methanol with minimal loss at different pressures. Next, DME is produced with preheated methanol in catalytic dehydration reactor with three conversion preferences. Pressurized and cooled reactor effluent consists of mainly water, methanol and DME, which is obtained using 30 bar distillation column at high purity. Next, unreacted methanol and side product water recovered with two different distillation column arrangements. Side products are marketable/recyclable as well.

3. MINLP Formulation and Solution Method

Superstructure of DME process optimized with MINLP problem formulated as:

$$\begin{aligned}
 & \min_{m,y,T,P} && IC + (OC - S \cdot (1 - f)) \cdot t_f \\
 \text{s. t.} &&& y_1 + y_2 = 1 \\
 &&& y_3 + y_4 + y_5 = 1 \\
 &&& y_6 + y_7 + y_8 = 1 \\
 &&& y_9 + y_{10} = 1 \\
 &&& m_6 = y_6 \cdot (m_1 y_1 + m_{F2} y_2) \\
 &&& m_7 = y_7 \cdot (m_1 y_1 + m_{F2} y_2) \\
 &&& m_8 = y_8 \cdot (m_1 y_1 + m_{F2} y_2) \\
 &&& m_9 = y_9 \cdot m_{T101,B} \\
 &&& m_{10} = y_{10} \cdot m_{T101,B} \\
 &&& y_2 \cdot y_3 \cdot 6 \leq m_3 \leq y_2 \cdot y_3 \cdot 10.5 \\
 &&& y_2 \cdot y_4 \cdot 6 \leq m_4 \leq y_2 \cdot y_4 \cdot 12.5 \\
 &&& y_2 \cdot y_5 \cdot 6 \leq m_5 \leq y_2 \cdot y_5 \cdot 15.5 \\
 &&& y_1 \cdot m_{1,min} \leq m_1 \leq y_1 \cdot m_{1,max} \\
 &&& y_1 \cdot m_{2,min} \leq m_2 \leq y_2 \cdot m_{2,max} \\
 &&& 301 \leq T_1 \leq 308 \\
 &&& 360 \leq T_2 \leq 380 \\
 &&& 46 \leq P_1 \leq 50 \\
 &&& y_j \in \{0, 1\} \quad j = 1 \dots 10
 \end{aligned} \tag{1}$$

where t_f is the project lifetime which is 20 years for this case; f is the tax rate; y_1 and y_2 are binary variables for commercial methanol and syngas feedstock selection, respectively; y_3 , y_4 , and y_5 represent the selection of syngas to methanol reactor with corresponding mass flow rates m_3 , m_4 and m_5 ; y_6 , y_7 , and y_8 methanol dehydration reactor selection variables; m_{F2} is the flash unit effluent; $m_{T101,B}$ is the bottom product of DME distillation column; y_9 and y_{10} are one column and sequential two-column distillation route selection binaries, respectively; S is the income from the products. Equality constraints which include binary variables solely ensure selection of a single path among many. Commercial methanol and syngas stream mass flow rates are represented with m_1 and m_2 . High to low DME reactor inlet stream mass flow rates are m_6 , m_7 and m_8 , respectively. m_9 is 30-stage column and m_{10} is sequential two 15-stage columns mass flow

rates. $m_{F102,B}$ is second flash unit bottom product stream that contains mainly produced methanol, mass flow rate. All produced or purchased methanol fed to DME reactor and this feed stream, $m_{R2,in}$, expressed with fifth equality constraint. $m_{T101,B}$ is bottom product mass flow rate of DME recovery column which fed to selected separation route. T_1 , P_1 are temperature and pressure of flash unit, and T_2 DME recovery column feed stream temperature, respectively. Inequality constraints limit syngas feed mass flow for prevent exceeding equipment sizes which assumed fixed for practical calculation of capital cost investments. The capital cost investment, IC , the operating cost, OC , is calculated from:

$$IC = F_{LANG} \cdot \left(\sum_i C_{BM,i} \cdot y_i + \sum_j C_{BM,fixed,j} \right) \quad (2)$$

$$OC = m_1 \cdot y_1 \cdot C_{MeOH} + m_2 \cdot y_2 \cdot C_{Syngas} + \sum_j Q_j C_{utility,j} \quad (3)$$

where F_{LANG} is the correction for the liquid phase operations; $C_{BM,i}$ is the bare module cost of i^{th} equipment which is related to the y_i ; $C_{BM,j}$ is the bare module cost of j^{th} equipment which exist in the structure independent of the optimization problem; C_{MeOH} and C_{Syngas} are methanol and syngas prices, respectively; Q_j and $C_{utility,j}$ is the quantity and the unit cost of j^{th} utility. Equipment purchases and operational cost calculations performed using (Bailie et al., 2018) and updated to current prices using CEPCI. The distillation column fixed cost provided from ChemSep. Process equipment sizing considers the dimensions that could meet the highest production capacity. For this reason, even if there is a high investment cost in low-capacity production preferences, meeting the upper limit production capacity is ensured.

The MINLP problem in Eq. 1 is solved using Genetic Algorithm (GA) which treats the process flow sheet simulation as a black-box function which is evaluated in DWSIM. Python has a key role in the implementation of the MINLP problem as it provides the communication between DWSIM and MATLAB's GA. A simplified information flow diagram is shown in Fig. 2.

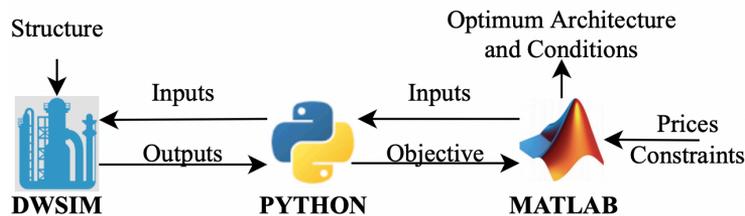

Figure 2. Superstructure optimization information flow diagram

4. Results

MINLP problem in Eq. 1 has been solved using MATLAB R2021a and DWSIM v6 on i5 9400 CPU 8 GB RAM Windows 10 x64 PC. In our case, the commercial methanol feedstock route results in an unprofitable process due to high purchase costs. The non-zero results of the solution are presented in Table 1.

In our case, syngas is selected as the primary raw material thanks to its low cost despite subsequent unit operations and associated operating costs. The resulting architecture proposes the highest conversion reactor for methanol production to favor the DME production and methanol which can be sold as a side product in our MINLP formulation.

Table 1. Non-zero process variables and economic measures of optimal results of Eq. 1

Plant variables									Economic Measures [M\$]		
m_2 [kg/s]	m_4 [kg/s]	m_{10} [kg/s]	$m_{r2,in}$ [kg/s]	$m_{F102,B}$ [kg/s]	$m_{T101,B}$ [kg/s]	T_1 [K]	T_2 [K]	P_1 [bar]	IC	OC	S
10.5	6.4	3.2	6.4	6.4	3.2	301	380	50	92	16	86

Temperature and pressure of flash unit maximize methanol yield while removing unreacted syngas. Produced methanol fed to medium conversion dehydration reactor to balance the DME conversion and related *IC* and *OC*. Sequential two 15-stage columns ensure the removal of high latent heat components while benefiting from the installation of large and single distillation column operations with high costs. The temperature of the feed stream as well as the temperature of the reboiler and condenser affect the efficiency of the separation process. However, feed stream temperature manipulation allows us to tune DME recovery column performance and operational costs. Overall process operation is performed at a maximum raw material rate within the defined operating window.

5. Conclusion

Optimum process design and synthesis under economic and environmental consideration is one of the contemporary challenges of the process systems engineering field. The idea of combining the advantages of process flowsheet simulators to obtain predictions without undergoing a significant modelling approach is useful once it is used in the black-box optimization algorithms which do not need first principal expressions explicitly. Integration of open source DWSIM simulation environment with black-box optimization solver enables us to simultaneously synthesis of process and optimization of conditions, unlike most studies which focus on commercially well-known and widely used software packages on a popular process for the architecture and processing condition calculation which accounts for feedstock selection, unit operation selection, catalysis selection, and related operating regimes. Such a sophisticated integration of high number of process equipment alternatives and feedstocks results in a nonconvex and significantly nonlinear mixed-integer nonlinear optimization problem. As a result, the global optimality of the proposed structure is beyond the scope.

A major decision variable on the plant profitability is determined by the feedstock, which is economically syngas over a wide price spectrum under current economic specifications. Furthermore, the proposed process flow diagram is comprehensive as it enables the selection of different-size unit operations to address the capacity, installation, and operating costs to deliver a realistic evaluation to some extent. Note that, the actual process is more complex than Fig. 1 and requires a more advanced MINLP formulation which also takes uncertainties of plant variables and time-varying prices into consideration in addition to other economic considerations such as inflation and other realistic details including depreciation, land prices, and many other issues. A more detailed process synthesis and the including the impact of the price uncertainties which are characterized by logistic issues and market demands is beyond the scope. Thus, the

simulations are performed for a particular and acceptable price value under marketable feed and product compositions. The architecture is flexible to address those considerations and the impact of those variables on the ultimate plant design and operations conditions can also be calculated using the proposed scheme.

A Comprehensive Evaluation on the COSMO-SAC-dsp Model for Vapor-Liquid Equilibrium Predictions of Refrigerants

Jiayuan Wang, Tongxin Sa, Lingyu Zhu*

College of Chemical Engineering, Zhejiang University of Technology, Hangzhou, 310014, China
zhuly@zjut.edu.cn

Abstract

The performance of the COSMO-SAC-dsp model combining with the Peng-Robinson (PR) equation-of-state (EoS) via several mixing rules is assessed for vapor-liquid equilibrium (VLE) predictions of refrigerants. In particular, the original Huron-Vidal (HVO), the modified Huron-Vidal (MHV1) and the Wong-Sandler (WS) mixing rules are applied. Binary mixture combinations of 51 refrigerants with diverse molecule types are investigated. 447 valid experimental VLE datasets for 233 refrigerant pairs are collected from NIST and by an exhaustive literature search. The results show that the combination of the COSMO-SAC-dsp with the PR yields satisfied and comparable prediction accuracy on VLE in most cases comparing to that from two well established EOS- G^{ex} methods VTPR and PSRK. However, large errors could appear between chlorinated hydrocarbons + hydrocarbons and fluorinated hydrocarbons + chlorinated hydrocarbons. Moreover, errors become more significant and the VLE calculation cannot converge at all for NH_3 and CO_2 including mixtures respectively. The performance of the mixing rules for the studied refrigerant VLE database follows the decreasing order $\text{MHV1} > \text{HVO} > \text{WS}$.

Keywords: refrigerant, mixing rule, COSMO-SAC, Peng-Robinson

1. Introduction

Phase behavior, especially vapor-liquid equilibria, is important in the refrigerant mixture design. Various mixing rules have been developed combining EoS with excess Gibbs free-energy models (i.e. EoS- G^{ex} methods), which enable improved VLE predictions on nonideal mixtures¹. The EoS- G^{ex} methods offer greater extrapolation capability, flexibility and reliability of predictions than the conventional Van Der Waals one-fluid mixing rule and the direct use of G^{ex} models. Because the former typically requires refrigerant pair dependent correction binary parameters and the latter usually fails to describe the phase behavior when approaching the critical region.

G^{ex} models based on group-contribution methods are the most widely used and have been successfully combined with EoS for VLE predictions. Two well-known examples on such group contribution EoS are the VTPR² and PSRK³ methods from Gmehling and his coworkers. However, the G^{ex} models based on group contribution may have limited applicability on refrigerants as 1) many group parameters are missing or only available from commercial sources; 2) group contribution inherently does not work well for small molecules. A more predictive alternative to the group contribution method, is the G^{ex} model based on quantum mechanical conductor-like screening model (COSMO)

calculations. The COSMO models only contain a few universal parameters and do not require a prior knowledge on molecule group assignment. A comprehensive literature review on the development of the COSMO models and implementation details could be found by Bell et al.⁴

An evaluation on phase equilibria of refrigerant systems using COSMO models has recently been reported by Mambo-Lomba and Paricaud⁵. However, the VLE calculation is evaluated based on only 20 binary pairs and one mixing rule. A more systematic and dedicated evaluation using COSMO models on refrigerant VLE is carried out in this work to reach a better understanding on the reliability of predictions. In particular, the COSMO-SAC-dsp model⁶, a state-of-art version of the COSMO models, is combined with the PR EoS as the EoS-G^{ex} method for VLE predictions. As significant extensions to the previous work, 1) a much larger experimental VLE database is constructed and assessed; 2) different mixing rules are applied and discussed; 3) a comparison to the well-established group contribution EoS is added.

2. Methods

2.1 VLE data

51 molecules covering typical types of commonly used refrigerants are selected, which are categorized in to 6 classes: “CH” for hydrocarbons; “Cl”, “F” and “Cl-F” for molecules containing purely Cl, F and both respectively; “Et” for ethers; “In” for inorganics (Table 1). Such classification is mainly based on the consideration that the parameterization in the COSMO-SAC-dsp model is atom type-based.

Table 1. A classification of 51 refrigerant molecules selected in this work.

Type	Chemical Name	Ashrae Number	Type	Chemical Name	Ashrae Number
CH	methane	R50	F	2,3,3,3-tetrafluoro-1-propene	R1234yf
	ethane	R170		1,1,1,3,3-pentafluoropropane	R245fa
	propene (propylene)	R1270		Hexafluoropropylene	R1216
	propane	R290		cis 1,3,3,3-tetrafluoropropene	R1234ze(Z)
	cyclopropane	RC270		trans 1,3,3,3-tetrafluoropropene	R1234ze(E)
	Butane	R600		3,3,3-trifluoroprop-1-ene	R1243zf
	Isobutane	R600a	1,1,1,2,3,3-hexafluoropropane	R236ea	
Cl	dichloromethane	R30	1,1,1,3,3-pentafluorobutane	R365mfc	
	chloromethane	R40	octafluorocyclobutane	RC318	
	1,2-dichloroethane	R150	trichlorofluoromethane	R11	
	chloroethene	R1140	dichlorodifluoromethane	R12	
F	tetrafluoromethane	R14	Cl-F	chlorotrifluoromethane	R13
	trifluoromethane	R23		dichlorofluoromethane	R21
	difluoromethane	R32		chlorodifluoromethane	R22
	fluoromethane	R41		1,1,2-trichloro-1,2,2-trifluoroethane	R113
	hexafluoroethane	R116		1,2-dichloro-1,1,2,2-tetrafluoroethane	R114
	pentafluoroethane	R125		chloropentafluoroethane	R115
	1,1,1,2-tetrafluoroethane	R134a		2,2-dichloro-1,1,1-trifluoroethane	R123
	1,1,1-trifluoroethane	R143a		2-chloro-1,1,1,2-tetrafluoroethane	R124
	1,1-difluoroethane	R152a		1,1-dichloro-1-fluoroethane	R141b
	fluoroethane	R161		1-chloro-1,1-difluoroethane	R142b
	1,1,2,2-Tetrafluoroethane	R134	Et	Dimethyl Ether	RE170
	1,1,2,2-Tetrafluoroethene	R1114		Ethyl ether	-
	octafluoropropane	R218	In	ammonia	R717
	1,1,1,2,3,3,3-heptafluoropropane	R227ea		carbon dioxide	R744
	1,1,1,3,3,3-hexafluoropropane	R236fa			

Valid experimental VLE data for 233 refrigerant binary pairs are collected from NIST and by an exhaustive literature search. Two P-x-y datasets at distinguished temperatures

are taken for each pair if available, which results in 447 datasets with 4387 data points in total. Experimental uncertainties are not considered for model evaluation.

2.2 EoS-G^{ex} method

An overview of the VLE prediction method is illustrated by Figure 1. An improved PR EoS with the Twu α function is adopted⁷. The volume translation is not considered, as it does not affect the VLE calculation. The COSMO-SAC-dsp model⁶ is used as the G^{ex} model, and it is combined with the PR EoS via mixing rules HVO, MHV1 and WS¹. The three resulted EoS-G^{ex} methods are named as PR-HVO-COSMO, PR-MHV1-COSMO and PR-WS-COSMO respectively. VTPR² and PSRK³ methods are implemented as well for comparison.

All group parameters are retrieved from the website “<http://www.ddbst.com/>” (accessed on 08/01). The molecule group assignment is performed using the online tool from the same website as well. Sigma profiles, area and volume parameters for 51 refrigerants are generated using Material Studio conjugated with Python following the steps provided by Bell et.al⁴. The VLE is calculated iteratively in MATLAB with fixed liquid composition and temperature (i.e. bubble-point pressure flash calculation). In case of convergence difficulties, GAMS is applied to solve the VLE in an equation-oriented manner.

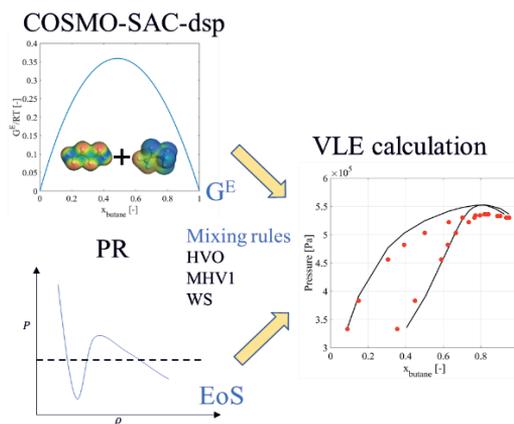

Figure 1. A schematic illustration of the VLE prediction method.

3. Results

Figure 2 provides an overview on the prediction errors from different methods. The number in each block gives the average absolute deviation (AAD) on the pressure and the vapor composition for binary mixtures of corresponding classes, which is defined by Eq 1.

$$AAD = \frac{1}{N} \sum_{i=1}^N \frac{1}{2K_i} \sum_{k=1}^{K_i} \left| \frac{P_{k,i}^{cal} - P_{k,i}^{exp}}{P_{k,i}^{exp}} \right| + \left| \frac{y_{k,i}^{cal} - y_{k,i}^{exp}}{y_{k,i}^{exp}} \right| \times 100\% \quad (1)$$

i is the index for the binary pair from 1 to N . The data point index of the binary pair i is given by k ranging from 1 to K_i . In addition, colors are associated to different ranges for better illustration. The number in the bracket is the number of refrigerant pairs used for error calculation.

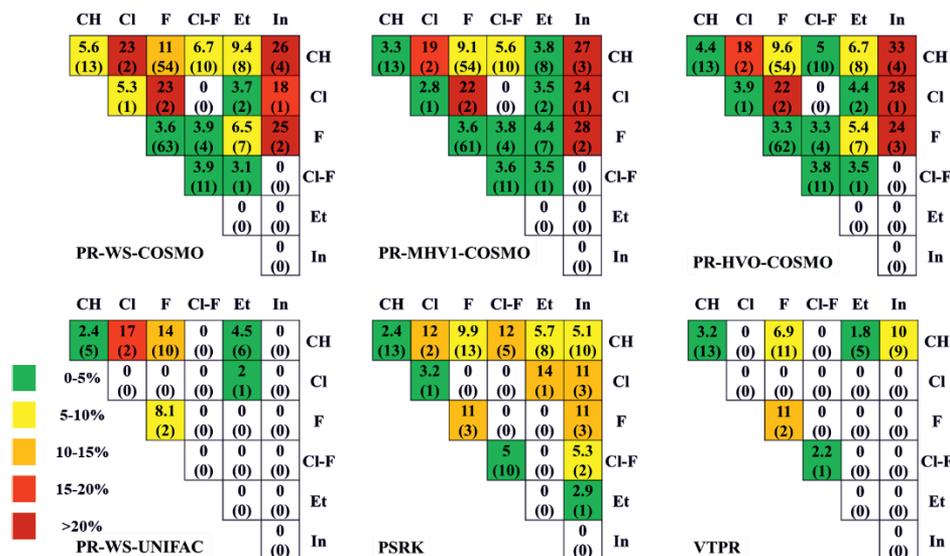

Figure 2. An overview of the prediction errors applying different EoS-G^{ex} methods.

3.1 A comparison between group contribution EoS

PSRK, VTPR and PR-WS-UNIFAC are implemented for the VLE prediction with relative satisfied accuracy (Figure 2). The PR-WS-UNIFAC method combines the PR with the UNIFAC(Do) via the WS mixing rule. Only 26 out of 233 pairs could be calculated due the missing group parameters. Large deviations appear between classes “Cl”+“CH”, “F”+“CH” and “F”+“F”, with three typical examples illustrated in Figure 3. It is clear that azeotropes cannot be well predicted. The group parameters in the UNIFAC(Do) are mainly regressed from the activity information. Dedicated sets of group parameters are proposed later to better fit the EoS-G^{ex} methods in the PSRK and VTPR. However, no significant improvement is achieved, at least on the tested refrigerant VLE database (Figure 2 and 3). The applicability of the group contribution EoS is still very limited due to undefined groups and missing parameters, in particular, on F containing groups. Moreover, proposing groups assignment methods for small molecules like refrigerants to distinguish isomerism is still a challenging task.

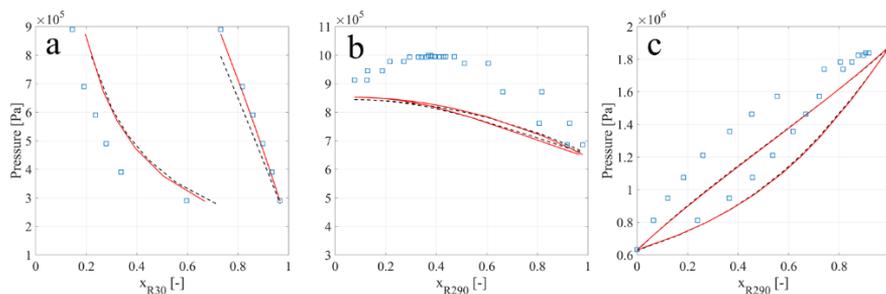

Figure 3. P-x-y plots of a) R30+R1270 at 333 K; b) R290+R143a at 283 K; c) R116+R143a at 273 K. The black dashed lines denote PR-WS-UNIFAC predictions. The red solid lines denote PSRK predictions. The square symbols denote experimental values.

3.2 A comparison between mixing rules

The values in Figure 2 indicate a decreasing order of the mixing rules on the prediction performance: MHV1>HVO>WS. Qualitative differences between three mixing rules cannot be clearly found from P-x-y plots, as exemplified by Figure 4b. The tested refrigerant pairs involving small molecules without association or highly asymmetry, which may not strongly distinguish the weaknesses and strengths of each mixing rule. However, significant improvement on the VLE predictions can still be identified by viewing the AAD values, in particular, at diluted conditions (Figure 4a).

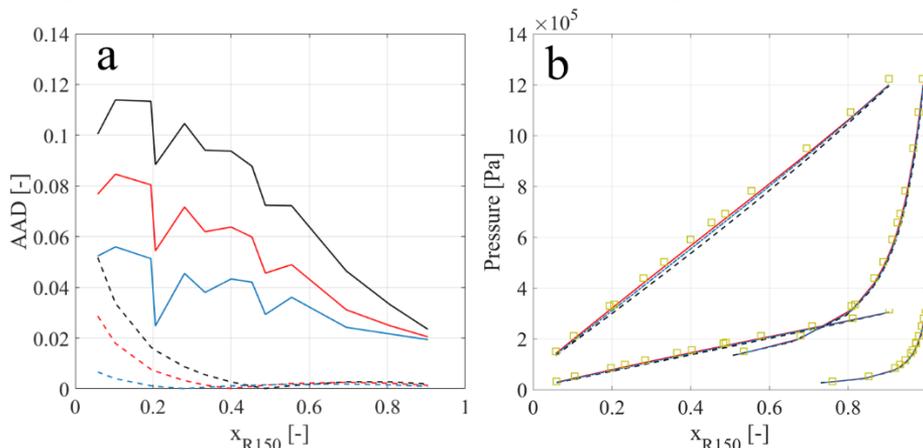

Figure 4. VLE prediction results on the R150+R1140. a) AAD on the pressure (solid lines) and vapor composition (dashed lines) at 364 K (black: WS, red: HVO, blue: MHV1); b) P-x-y plots at 293 K and 364 K (symbols: experimental values, black dashed lines: WS, red solid lines: HVO, blue dotted lines: MHV1).

3.3 A comparison between group contribution and COSMO methods

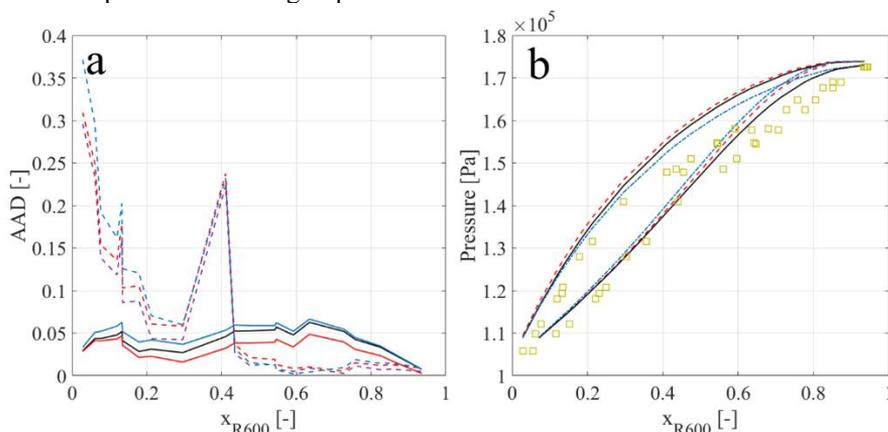

Figure 5. VLE prediction results on the R600+R1140. a) AAD on the pressure (solid lines) and vapor composition (dashed lines) at 273 K (black: WS, red: HVO, blue: MHV1); b) P-x-y plots at 273 K (symbols: experimental values, black solid lines: WS, red dashed lines: HVO, blue dotted lines: MHV1).

The EoS-G^{ex} methods based on the COSMO-SAC-dsp model outperform the group contribution EoS in terms of the extrapolation capability. The VLE of all pairs can be calculated using the COSMO-SAC-dsp, but the majority are not applicable for the group contribution EoS. This is attributed to the atom-based parameterization scheme in the COSMO models, which helps to avoid ambiguities in group assignment and to reduce the adjustable parameters. The COSMO-SAC-dsp model enables comparable prediction accuracy for most combinations of 6 molecule classes, or even better for some cases. However, large errors could appear for “Cl”+“CH”, “Cl”+“F”. Although the P-x-y shapes can be well approximated, significant errors can be found at diluted conditions (Figure 5). The large deviation around $x = 0.4$ may due the experimental data error in Figure 5. Prediction errors above 20% are typically identified for pairs including NH₃. Moreover, infeasible solutions always appear when CO₂ is involved. Convergence on VLE calculations could be achieved only when the dispersion term of the CO₂ is neglected.

4. Conclusions and outlooks

The COSMO-SAC-dsp model is combined with the PR EoS via several mixing rules for VLE predictions on 233 refrigerant pairs, the results show that:

1. The performance of the mixing rules generally follows the order of MHV1>HVO>WS, but without a significant difference.
2. The predictive performance using the COSMO-SAC-dsp model is comparable to that of group contribution EoS in most cases, but not for NH₃ and CO₂ involving mixtures.

A revision on the dispersion parameters for atoms Cl, F, N and O would possibly improve the COSMO-SAC-dsp model performance on the VLE calculation, which is still in progress and would be published separately.

Abstract

Renewable energy sources that involve the use of Concentrated Solar Power systems (CSP) are receiving increased attention due to many of the prominent features that it can provide. Most importantly, the simultaneous production of thermal and electrical energy that can be achieved via CSP systems is of great value and constitute many cogeneration processes. Moreover, CSPs have been proven to be an effective source of energy for industrial applications that require high amounts of clean energy, such as desalination. Hence, combining water production activities together with thermal and electrical energy production options via CSP technologies results in novel hybrid tri-generation systems. The possibility of locating such tri-generation systems on the eastern shore of the Mediterranean Sea is investigated in this paper. As such, several different design aspects such as the effect of direct normal irradiance (DNI) on the production freshwater via desalination has been studied. The daily and seasonal intermittency of sunlight, which consists a major challenge for CSP, necessitates the implementation of hybrid systems to ensure a continuous supply of energy for desalination purposes. This paper studies the design of a hybrid trigeneration system under different weather conditions, including four different seasons. The trigeneration system consists of a CSP plant as the main energy source. The system is usually coupled with a conventional fuel source, mainly natural gas, which serves as a backup energy source in the absence of solar energy. A desalination plant comprising of both thermal and membrane technology options for freshwater generation is also included. The design problem is translated into a Mixed Integer Non-Linear Program (MINLP) that can be solved for the optimal network structure based on appropriately selected technologies for steam, power and freshwater production. The environmental aspect of the system has also been studied by quantifying the total amount of carbon dioxide emissions. As such, the integration of a carbon capture technology to regulate those emissions has been also studied, subject to an appropriate value for the overall net carbon reduction target of the tri-generation system.

Keywords: Concentrated Solar Power, desalination, design, hybrid, trigeneration system

1. Introduction

The global energy sector is currently in a transitional phase towards achieving a higher energy share from renewable sources. Concentrated Solar Power (CSP) is one of the

renewable energy technologies with a high potential for deployment in many countries, especially those located in the MENA region, due to the high availability of direct normal irradiance (DNI). Therefore, studying the factors affecting its performance has been extensively addressed in literature (Klaimi et al., 2021). However, the incorporation of CSP in developing countries apparently faces many challenges, such as high capital investment costs, and the lack of supporting regulations. Moreover, any financial incentives are against the low cost of fossil fuels (Elmorsy et al., 2020). Therefore, the hybridization of CSP plants using conventional energy sources provides more flexibility and reliability by gearing it away from solar intermittency problems. Many have studied the integration of CSP into different industrial applications. For instance, Elmorsy et al. (2020) have worked on a novel natural gas-fired integrated solar-combined cycle power plant in Egypt, where the levelized cost of electricity (LCOE) was found to be 40 \$/MWh. Rashid et al. (2020) have presented a dynamic simulation of a CSP plant incorporating both thermal energy storage and natural gas. The hybrid plant with storage resulted in a higher LCOE value (86.32 \$/MWh) when compared to a single natural gas plant (74.92 \$/MWh). Abdelhay et al. (2020) have proposed a solar driven poly-generation system of CSP coupled with a backup natural gas heater for power, desalination and cooling. Their proposed system resulted in a relatively low unit water price of 1.247 \$/m³. Hybrid energy systems are also associated with greenhouse gas (GHG) emissions which must be taken into consideration while studying the environmental impact of cogeneration and tri-generation processes. Moreover, there exist very few studies that focus on hybrid tri-generation systems. Therefore, this paper studies the effect of solar availability on the performance of a novel CSP-trigeneration system coupled with a natural gas boiler for the production of three different pressure levels of steam, power and freshwater. The novelty of this paper lies in the multiperiod approach presented to study the performance of the CSP-desalination system across different seasons, in addition to the incorporation of carbon capture option and imposing taxation on uncaptured CO₂ which allows the estimation of associated environmental costs.

2. Methodology

The proposed CSP-natural gas hybrid tri-generation system is shown in Figure 1. First, a boiling feed water (BFW) stream is split into two streams: BFW-b that enters a utility boiler and BFW-sg entering a solar steam generator. A natural gas stream is fed into the utility boiler and undergoes combustion, which in turn results in heat transfer to the BFW-b stream. As a result, high pressure (HP) steam at 41 bars (S-b) is generated, in addition to a blowdown stream. On the other hand, the HP steam produced by the steam generator (S-sg) is due to the heat exchange between a molten salt stream circulating in the CSP plant and boiling feed water. A portion of the HP steam produced (S-ms) is utilized by the molten salt system to maintain a temperature above molten salt freezing point. The two HP streams are then mixed into one stream (S-d) that enters the shaft and electric power generation block which consists of several energy generation options (turbogenerators, drivers and throttle valves). This results in the production of low pressure (LP) steam at 2 bars and electric power to be utilized for desalination, in addition to very low pressure (VLP) steam at 0.12 bar to be condensed, deaerated and pumped to HP steam pressure in order to obtain boiling feed water. Any excess in electricity can be exported to the grid. Two different desalination technologies are available in the system for the generation of freshwater, which is the main source of revenue. As for GHG emissions from natural gas combustion, a carbon capture unit with a specific efficiency is incorporated in the system, and the uncaptured CO₂ will be released to the atmosphere.

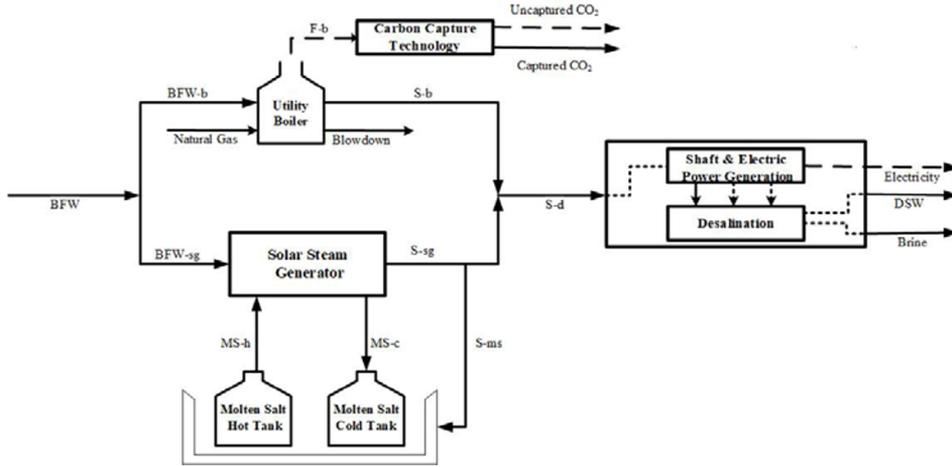

Figure 1: Hybrid Tri-generation System Structure

3. Mathematical Formulation

The proposed hybrid tri-generation system has been converted into a Mixed Integer Non-linear Problem (MINLP) that aims at minimizing the total cost of the system. The objective function is shown in Eq. (1) below, where $Cost^{CSP,energy}$ and $Cost^{NG,energy}$ are the energy production costs from CSP and natural gas respectively, $Cost^{CO_2}$ is the carbon related cost which includes carbon capture cost and taxes on the uncaptured CO_2 , $Cost^{Desal}$ is the desalination cost and Rev^{Water} is the total revenue earned from selling the freshwater produced.

$$\text{minimize } Cost^{CSP,energy} + Cost^{NG,energy} + Cost^{CO_2} + Cost^{Desal} - Rev^{Water} \quad (1)$$

Equality constraints have been added to the model to ensure the satisfaction of mass and energy balances around all the units in the system. Eq (2-5) represent the mass balances on the utility boiler and solar steam generator, where the variable G is the mass flowrate, and the subscripts S , b , sg , d and ms refer to steam, boiler, steam generator, desalination and molten salt respectively. The mass flowrate of steam required for the molten salt system G_{S-ms} and the amount of CO_2 emitted from the boiler G_{F-b} can be calculated using Eq. (6) and (7), respectively, where ω_{ST} is the fraction of HP steam produced by the generator and allocated to the storage tanks heating system, and ε_{NG} is a parameter corresponding to the amount of CO_2 emitted per unit mass of HP steam produced using natural gas. The energy balances around the boiler and steam generator are described in Eq. (8) and (9), respectively, where the variables H and Q are the specific enthalpy and thermal energy, respectively, while HV , η_b and η_{sg} are the parameters corresponding to the calorific value of natural gas, boiler and steam generator efficiencies, respectively.

$$G_{BFW} = G_{BFW-b} + G_{BFW-sg} \quad (2)$$

$$G_{BFW-b} = G_{S-b} + G_{blowdown} \quad (3)$$

$$G_{BFW-sg} = G_{S-sg} \quad (4)$$

$$G_{S-d} = G_{S-b} + G_{S-sg} - G_{S-ms} \quad (5)$$

$$G_{S-ms} = \omega_{ST} G_{S-sg} \quad (6)$$

$$G_{F-b} = \varepsilon_{NG} G_{S-b} \quad (7)$$

$$(G_{BFW-b} H_{BFW-b} + G_{NG} H_{NG}) \eta_b = G_{S-b} H_{S-b} + G_{blowdown} H_{blowdown} \quad (8)$$

$$Q_{absorbed} = \eta_{sg} Q_{released} \quad (9)$$

The inequalities of the model, described in Eq. (10-13) below address the limitations on certain aspects of the system, such as the capacities of the embedded technologies, land and solar availability, in addition to the minimum production of HP steam. In these equations, b represents a binary variable, $A_{SF,t}$ and, $A_{SF,max}$ are the required and available solar field areas in season t , DNI_t is the daily average direct normal irradiance in season t , and G_{S-dmin} is the minimum required amount of HP steam to be produced depending on the amount of energy required to generate a specific flowrate of freshwater.

$$b_i G_{min} \leq G_{BFW-i} \leq b_i G_{max} \quad \forall i \in b, sg \quad (10)$$

$$A_{SF,t} \leq A_{SF,max} \quad (11)$$

$$G_{S-sg} (H_{S-sg} - H_{BFW-sg}) \frac{24}{3600} \leq DNI_t A_{SF,t} \quad (12)$$

$$G_{S-dmin} \leq G_{S-d} \quad (13)$$

It should be noted that the nonlinearities of the model lie in the costing of some of the equipment incorporated within the system, the constraint preventing temperature cross-over in solar steam generator and the utilization of energy generation ratios of CSP and natural gas in some of the equations. Moreover, although the equations of the proposed multiperiod problem seems simple, the actual model is large and complex, consisting of 88 decision variables (80 continuous, 8 binaries) and more than 80 constraints.

4. Case Study

The proposed model was implemented on a tri-generation system located near the Mediterranean Sea in a region whose direct normal irradiance is similar to that of Beirut city in Lebanon. Since the aim of the model is to minimize the total cost of HP steam production that will be used for electricity and freshwater generation, the same selection of optimal technologies, in the shaft and electric power generation and desalination blocks, reported in the optimal case scenario in Klaimi et al. (2021) will be considered. This scenario corresponds to a large-scale desalination plant having a capacity of 100,000 m³/d with an inlet seawater salinity of 35 g/L and HP steam requirement of 7,748 t/d. Thus, the decision variables are mainly the mass flowrates of inlet boiling feed water streams, natural gas, molten salt and the land area of CSP facility. Consequently, the costs associated with the power block and desalination in the objective function were kept constant. Moreover, the daily averaged DNI values for the four seasons, which in turn were divided into four different time periods, are 146.9, 101.2, 170.2 and 229.6 kWh/m²d for fall, winter, spring and summer, respectively (Solar Atlas), whereas the maximum solar field area available for the CSP facility has been set at 20,000 m². The MINLP optimization problem has been implemented using “Whats’Best 17.0” LINDO Global Solver for MS-Excel 2016 via a laptop with Intel Core i5 Duo processor, 8 GB RAM and a 64 bit operating system. Figure 2 below shows the flowrates of HP steam produced from each source of energy, in addition to the amount of CO₂ emissions resulting from the utilization of natural gas, by the optimal solutions attained.

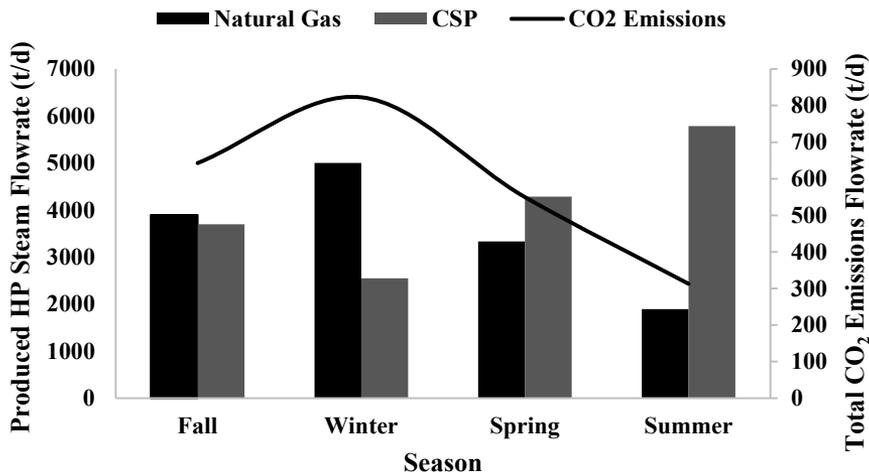

Figure 2: HP steam and CO₂ flowrates in different seasons

The obtained results confirm that the amount of HP steam generated from each energy source is highly dependent on solar availability. The highest DNI in summer resulted in the highest deployment of CSP which generates 5,785 t/d of HP steam in this period with a generation of 1,895 t/d of steam from natural gas. As DNI decreases to 146.9 kWh/m²d in fall, a lower amount of energy could be generated per unit surface area, which explains the reduction in the amount of steam generated from CSP to 4,288 t/d and the increase in the amount of steam generated from natural gas to 3,332 t/d. Winter season witnesses the lowest DNI value among all seasons of the year, which necessitates a high requirement for natural gas, in order to compensate for the reduction in the capacity of the CSP facility. This resulted in the production of around 66.23% of the total required amount of steam from natural gas in winter compared to 24.67% in summer. However, the DNI value increased again in spring, which also increased the share of renewable energy in steam production. It was also very important to quantify the amount of carbon dioxide emissions that resulted from the utilization of natural gas. Since the highest and lowest consumption of natural gas occur in winter and summer, respectively, Figure 2 shows that carbon emissions are indeed the highest in winter (with a flowrate of 823 t/d). This amount decreased when a reduction in natural gas consumption was realized in subsequent seasons, achieving 313 t/d in summer. Although CSP is known for its high capital cost, it has been selected in all seasons, even in winter which has the lowest solar availability. Despite this, a continuous selection of CSP technology was attained throughout the year. In order to further explain this aspect, Figure 3 shows a breakdown of water production cost across the four different time periods.

According to Figure 3, total water production cost from the hybrid system ranges from 1.25 USD/m³ in summer to 1.47 USD/m³ in winter. Moreover, the fraction of steam generation cost from CSP is greater than that of natural gas in all seasons, except in winter when the contribution of natural gas for energy production is much higher than that of CSP. In fact, this was expected due to the high capital cost of CSP compared to the low cost of natural gas in developing countries. However, when serious regulations regarding the environmental impacts of energy production are implemented, such as the use of carbon capture and carbon taxation on CO₂ emissions, the scenario will definitely change.

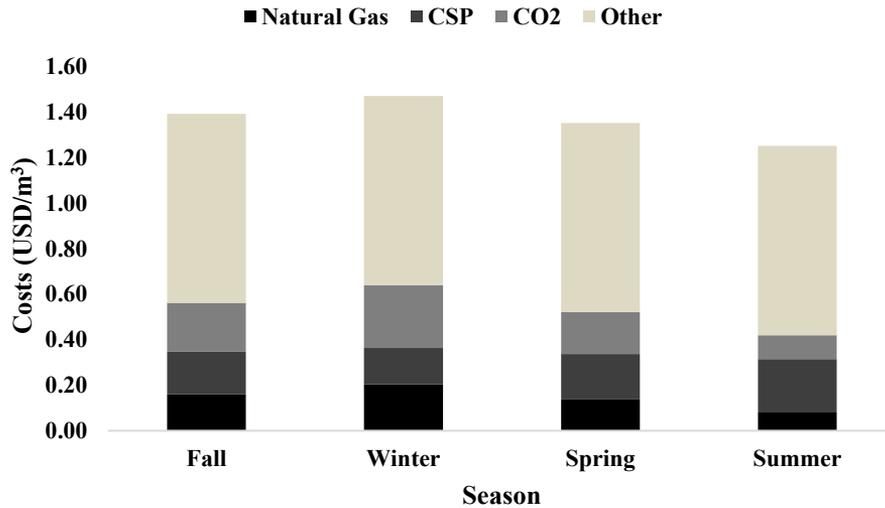

Figure 3: Water production cost breakdown

When comparing the costs related to carbon capture and taxation in winter which has the highest CO₂ emissions (0.28 USD/m³) to the cost of steam generation from CSP in summer (0.24 USD/m³), it was noted that the cheapest energy source is not always the best candidate, as the costs associated with its impacts might be higher than the cost of other options. In addition, the results showed that the available solar field area has been totally invested in all four cases, which means that when a higher area is available, the contribution of CSP could be higher, resulting in a lower total water production cost.

5. Conclusion

In this study, a mathematical model that minimizes water production cost of a hybrid tri-generation system using different seasons has been presented. A minimum water cost of 1.25 USD/m³ was attained in summer. Moreover, significant financial incentives for investing in CSP were realized.

Abstract

Reverse Osmosis is considered today as the best available technology at industrial scale for desalination as an alternative process to conventional thermal technologies. Nevertheless, there is still opportunity to evaluate and optimize other membrane technologies like membrane distillation. Vacuum membrane distillation has been studied at pilot scale and it is a promising technology to treat seawater in areas with un-expensive heat sources. This study presents a modified method of superstructure optimization to evaluate key performance indicators of reverse osmosis and vacuum membrane distillation. To achieve this objective, Computer aided process simulation is deployed; mathematical model was coded in FORTRAN and added to a superstructure defined in a process simulation software (ProSimPlus). Geometry and material parameters are set according to the commercial module Dow SW30HR-380 data. Finally, superstructure's operational conditions (pressure and in-process temperature) and specific number of modules in series and parallel are optimized within an ant colony algorithm (MIDACO).

Keywords: Process synthesis, optimization, desalination

1. Introduction

Desalination processes are important for different industries and for fresh water supply. Multiple stage flash (MSF) is the most deployed thermal technology at industrial scale according to Subramani and Jacangelo (2015). However, Reverse Osmosis (RO) has been implemented as an alternative process to improve the energy performance (EP). Nevertheless, there is still opportunity to evaluate and optimize other membrane technologies regarded as an alternative to MSF and RO. Membrane distillation (MD) has not been tested at industrial scale yet. Pagliero et al. (2021) identifies a growing interest on these technologies due to the capacity to treat high concentration brines, but there are still some technical challenges related to the EP. Vacuum membrane distillation (VMD) has been tested at pilot scale for desalination. VMD research has been focused on new membrane materials and geometries for contactors. Nevertheless, simulation tools to gather the material characteristics, module geometries and operating conditions at industrial scale remains a challenge.

This work presents a modified method of Zhao et al. (2018), to identify a membrane process (VMD and RO) adapted to desalination based on process simulation, taking into account the mass and thermal transfer modelled in previous researches. Besides, this method can be deployed as a tool to evaluate membrane technologies giving an estimation of the energy and/or heat resources needed to accomplish a production objective at industrial scale. A plot for key process indicators of two membrane technologies is presented as a main result.

2. Methodology

Computer-aided process simulation is the main tool used in the present work, based on the optimization of a superstructure following the methodology presented by Zhao et al. (2018). The resultant method is composed of three blocks: a FORTRAN code to simulate each module, the industrial scale process simulation and an optimization block.

2.1. RO and VMD Modelling

Modelling of mass transfer through the membrane is coded in FORTRAN according to previous published works e.g Li et al. (2021), resolution of the mass balance for a module is based in the calculation of differential equations over the membrane area. The FORTRAN subroutine solve the differential equations system giving as a result the retentate and permeate composition, flowrate, temperature and pressure.

Mass transfer through a membrane is modelled as a gradient in the chemical potential between two homogenous phases at each side of the membrane (retentate and permeate). For RO, this driving force is due to a pressure difference. In addition, pressure drop is included into the mathematical model following the work of Lian et al. (2018).

For VMD, chemical potential difference is due to the vapour pressure at each side of the membrane. Mathematical model is based on the work done by Mendez et al. (2019); it calculates a water vapour flux through the membrane (hydrophobic membrane is assumed, thus there is not liquid phase flux). Besides, temperature polarisation effects are evaluated following the thermal balance proposed by Ibrahim and Alsahy (2013) calculating the heat transfer through the membrane.

For both technologies, concentration polarisation effect is calculated based on the fluid hydrodynamic. The commercial module simulated is spiral wound type used for brackish seawater desalination. Boudinar et al. (1992) presents a mathematical model for a commercial spiral module (Filmotec) validated in the range of flowrate, pressures and temperatures used in this work. These effects have an effect on the mass transfer coefficient modelled according to Kim and Hoek (2005), this model also allows to calculate the NaCl concentration at the wall side, then evaluate risk of fouling. Physical and chemical properties are calculated using the commercial software Simulis Thermodynamics. Vapour- liquid equilibrium (VLE) is modelled using an equation of state approach corrected by NRTL model.

2.2. Process modelling

To achieve a comparison between membrane technologies at industrial scale, it has been set a fresh water flowrate to be produced (constraint). Then, a superstructure is defined to simulate different scenarios governed by design and operational variables. These variables affect directly in the process synthesis, therefore, in the key process indicators. Table 1 present a summary of inputs, variables and key indicators used for the optimization problem.

Superstructure conception and evaluation were done with the commercial process simulation software (ProSimPlus). Heat exchangers, pumps, flash and mixers were taken directly from the library (ProSimPlus). Logic switch units, to control the number of stages, were set according to Zhao et al. (2018). VMD and RO FORTRAN subroutines were added as an external module (external DLL). Product salinity is not set as a constraint, the importance of this parameter depends on the industry; nevertheless, it is evaluated as a process indicator for RO, and it is reported as the ratio between NaCl concentration at the product and the feed.

RO superstructure is an adaptation of the process presented by Alsarayreh et al. (2021). It simulates a process structure containing up to four stages for RO and six stages for VMD. A process stage includes a pump (for RO) or heat exchanger (for VMD) to set fluid's conditions and a configuration of modules in parallel. Then, the number of modules in parallel is evaluated in a wide

Table 1: Summary inputs, variables and key indicators for optimisation problem. RO material information from Alsarayreh et al. (2021), VMD material information from Mendez et al. (2018). AA – Active area per module, WP – Water permeability, WS- salt permeability, PVDF- Polyvinylidene fluoride, NMP – modules in parallel, NMS – stages

		RO	VMD

Feed pressure	20 – 80 bar		
Key Process indicators (KPI)	Electricity	X	X
	Heat		X
	Membrane Area	X	X
	Product salinity	X	

range for each step independently. Fig. 1 shows the superstructure to simulate RO and VMD processes.

Superstructures contains three user scripts corresponding to the following calculation:

“Power”: Calculate total electricity in MW and heat in MW(thermic) resulting from the pumps and heat exchangers requirements.

“Area”: Calculate the total membrane area (*m*²) according to each simulated scenario.

“Polarisation”: Verify risk of precipitation inside the modules due to the increase of the concentration above the solubility of NaCl in water. In case of exceeding the limit concentration, this script acts as a constraint for the process, then the solution is excluded.

This superstructure allows the evaluation of different process configuration while changing the key variables into the ranges defined in the table 1. The KPIs are calculated as a result of each simulated scenario.

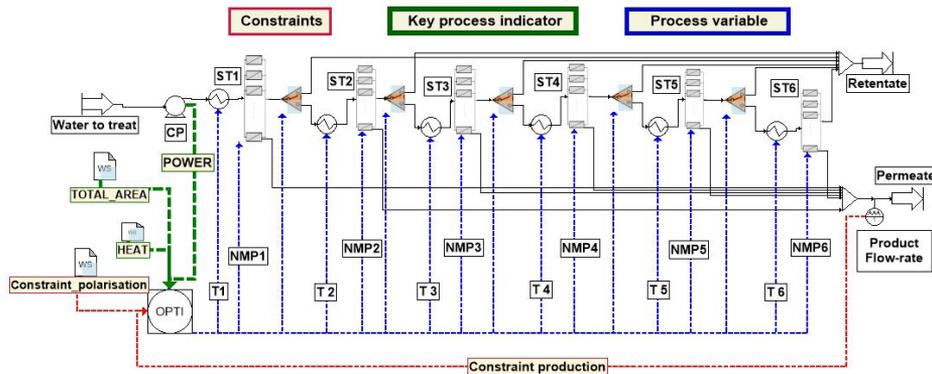

Figure 1: Superstructure for RO and VMD processes. ST - Stage, CP - Centrifugal pump, T - Temperature.

2.3. Process optimization

Optimization of the superstructure is deployed in two steps:

2.3.1. Sensitivity analysis

This analysis is evaluated using the “spec” module of ProSimPlus, which it generates an action over the inlet pressure (RO) or the inlet temperature (VMD) to accomplish the production constraint. Simulated cases are defined by uniform experiment plan to evaluate different module configurations.

2.3.2. Optimization

Parameters of superstructures are optimized using an ant colony algorithm (MIDACO). For this optimization, a multi-objective problem is defined according to the results of the sensitivity analysis. Then, a front-Pareto is obtained in function of the KPI.

3. Results and discussion

Results from the sensitivity analysis are sorted by the value of the performance indicators for each technology. Results for EP are plotted in function of the stages (x-axis) and the average modules in parallel (y-axis) for RO and VMD. As seen in the figure 2, there are configurations for RO being able to accomplish the required production in one or two stages; however, these configurations require more electrical power due to high operational pressure requirements.

For VMD, result of the sensitivity analysis does not show an optimal structure to increase EP when sorting the results by heat as presented in figure 2, however heat required increases at low number of modules in parallel. Besides, to get the production constrain is needed at least a two stages process.

This partial result validates ranges and limits defined in the optimization problem. In addition, it shows a difficulty to identify a group of desired structures while having two objectives. Then the figure 3 shows the resultant front-Pareto solutions for the multi-objective optimization.

For RO, it is obtained a front-Pareto covering a range of values for key process indicators that can

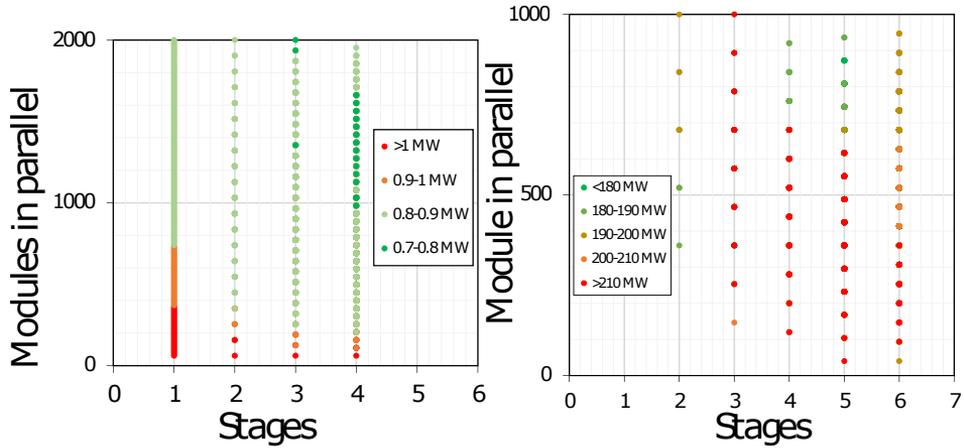

Figure 2: Effect of process structure over total electricity required for RO (left) and over total heat required for VMD (right)

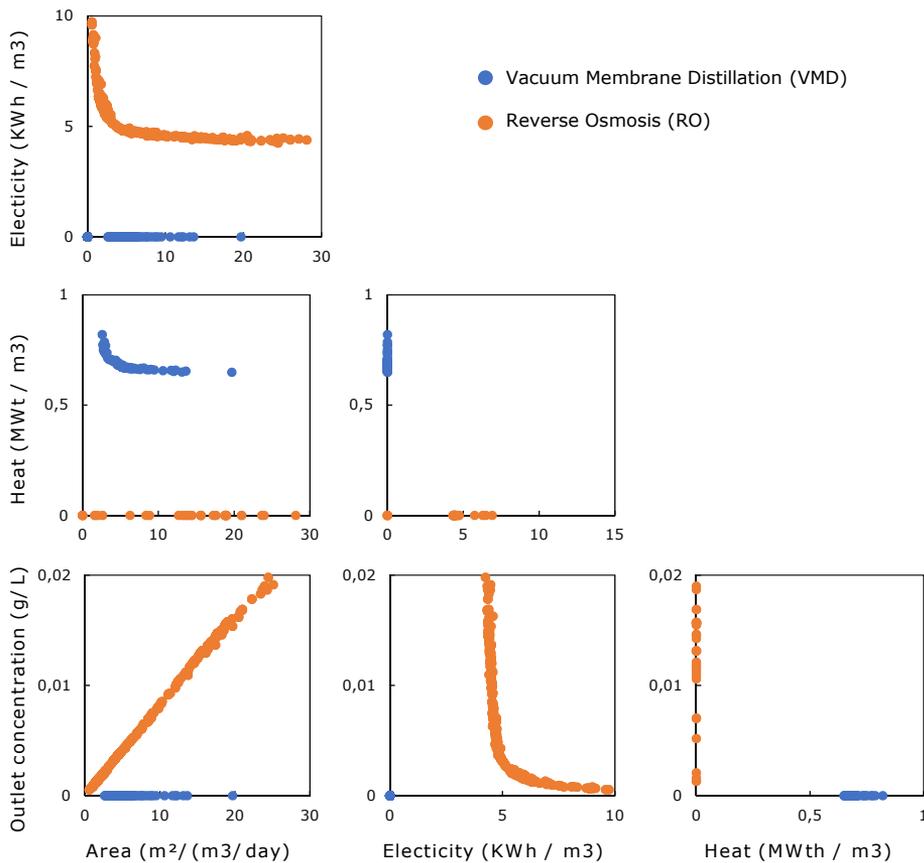

Figure 3: Pareto-front obtained from the superstructure optimisation for RO and VMD

be post-treated to balance the impact of each indicator and identify an optimal structure. Besides, the output concentration is proportional to the area. For VMD, the resultant front-Pareto shows the effect of the area over heat as EP, electricity consumption remains constant for all the cases with lower consumption than RO.

This result can be an input for an economical model allowing the identification of process and operating parameters according to the available sources (heat and electricity). VMD presents a potential over RO due to its low electricity requirement, VMD potential to treat seawater increases in case of product salinity requirements and it can be capitalised if there is a source of heat available at low cost.

Figure 3 provides a tool aimed to guide process synthesis by presenting the expected key parameter for each technology according to the salinity constraints. Besides, this methodology can be deployed with other operating conditions limited to available resources. Associated results will support the selection of one technology in particular.

As a perspective, this evaluation can provide a baseline for the technologies comparison at industrial scale. The suggested post-treatment is the addition of prices for electricity, heat and membrane area according to the industry; in this way, this work can be used as an aid to decision tool providing a more detailed OPEX and CAPEX calculation.

4. Conclusion

The modified method for superstructure optimizations applied to membrane technologies links phenomena models with process synthesis. This tool allows the user to have a deep understanding of the KPI at industrial scale but taking into account the local effects like concentration and temperature polarization and material characteristics.

This work can be used as a tool for technical and economical evaluation adapted to real prices and financial aspects to guide the process synthesis based in membrane technologies. Then, results can support the potential of membrane distillation in certain industrial cases.

Abstract

Various optimization-based process synthesis approaches exist to propose a process structure and associated parameters, which have been applied on many applications. The goal of this work is to provide a comparison of methods on a common process synthesis problem.

Three methods are compared on an identical test problem, they differ in the synthesis approach (based on a superstructure or generative without predefined structures), process modelling (equation- or simulator-based), optimization algorithms (global NLP, MINLP, evolutionary) and implementation (dedicated or commercial programs). Results especially highlight the importance of the search space definition, and the need for accurate process models during the synthesis step.

Keywords: Process Synthesis, superstructure, generative approach, separation processes

1. Introduction

In the field of process synthesis, various methods have been proposed to select a set of equipment with their operational conditions and interconnection in a process flowsheet. These methods may vary from empirical approaches using expert judgment or heuristics to simulate a few configurations, towards optimization-based approaches where the process synthesis problem is posed as a mathematical problem, allowing to cover a wider search space than tedious manual iterations with process simulators. In the literature, numerous algorithms and application fields are reported. A common approach is to use a superstructure (Mencarelli et al., 2020), i.e. a postulated set of flowsheet alternatives, and to perform optimization among structural and design variables. Other approaches are *generative*, meaning that process structures are directly proposed from a set of available unit operations, using evolutionary or machine/deep learning algorithms (Nabil et al., 2022), instead of choosing among a predetermined set of structures.

This work is therefore a first attempt at comparing synthesis approaches on a common process synthesis problem. Three approaches are used on an identical test problem. At this stage, performance indicators are mainly: found process solutions, computational efficiency, and ease of use for a process engineer.

2. Synthesis approaches and their comparison

Three approaches (denoted here A, B and C), developed by the paper's authors, are selected for the comparison, summarized here. Main highlights of each approach are also reported in the Table 1, and will be discussed in §3 based on the case study.

Method A (superstructure - GO ; Ramírez-Santos et al., 2018) is superstructure-based using continuous splitter for flow alternatives. Modelling is equation-oriented, as all governing process equations are posed as constraints in the optimization problem. The continuous global optimization (GO) problem is solved with an algorithm combining multi-start strategy, monotonous Basin Hopping and local search. Implementation is performed in AMPL language with KNITRO commercial solver for local searches.

Method B (superstructure - MINLP ; Zhao et al., 2018) is also superstructure-based, using here integer *switches* for flow alternatives. Modelling is simulator-based using a commercial simulator, coupled to an optimization solver (*feasible path or unfeasible path*). The resulting Mixed Integer NonLinear Programming (MINLP) problem is solved by an Ant Colony Optimization algorithm. The graphical process simulator ProSimPlus is used, in communication with MIDACO solver.

Method C (ab-initio - EP ; Neveux, 2018) is a generative approach. Modelling is also simulator-based using an in-house simulator. The optimization problem relies on a two-level decomposition of the process synthesis problem, an upper level for designing the topology (i.e. the process flowsheet) using Evolutionary Programming (EP) and a lower level for evaluating the flowsheet (optimizing the degrees of freedom for a given structure). Implementation is performed in Fortran 2008, with calls to nonlinear optimization solvers for process evaluation (e.g. MIDACO, SLSQP).

While these methods do not represent the entirety of existing approaches, they cover various definitions of the search space (superstructure, generative), system modelling (equation- or simulator-based), optimization algorithms (continuous global optimization, mixed integer) and associated solvers, and software ergonomics (programming language, graphical interfaces).

The comparison procedure is summarized as follows: definition of the synthesis problem (common to all approaches), problem formulation to fit each method's requirements (approach-specific), optimization runs to isolate optimal solutions (approach-specific), validation of the solutions within a common process simulator (all approaches). The results are then compared on the basis of various criteria such as: found solutions and their exclusivity (process structure and parameters), computational time, ease of use for a process engineer, etc.

3. Case study: production of N₂ from air using membrane gas permeation

3.1. Definition of process synthesis problem

The production of N₂ from air using membrane gas permeation is chosen due to the numerous possible stages, recycling and design variables, with non-linear and non-convex economic objective and constraints. Industrial solutions are also known for commercial membrane materials, and prospective solutions can be assessed with other materials. The comparison is done for 90%, 95% and 99.9% N₂ purity, for given materials using fixed permeability, as well as variable materials using permeability as degrees of freedom. This case has already been treated using the method A, refer to Bozorg et al. (2019) for results and process assumptions.

The synthesis problem can be summarized as follows (see Figure 1): produce enriched nitrogen from air at the lowest levelized cost of production (objective function), with given N₂ purity and process outlet pressures (production constraints). Arising degrees of freedom occur at various level: at structural level, the choice of unit operations (membrane stages, compressors, vacuum pumps, mixers and splitters) and their connections (sequences, by-passes, recycling etc.); at unit operation level, each design or operational parameter (e.g. pressures, membrane areas); at 'product' level, the membrane permeability which could be kept fixed to given known values (e.g. commercial membranes) or be optimized within a known region for N₂/O₂ separation.

The basis for membrane calculation is the *MEMSIC* code (Bounaceur et al., 2017), a CAPE-OPEN unit operation software for multicomponent membrane gas separations, validated against a large set of chemical mixtures and membranes. All operations are assumed isothermal (i.e. cooling after compression, and Joule-Thompson effect neglected in membrane) and without pressure drop.

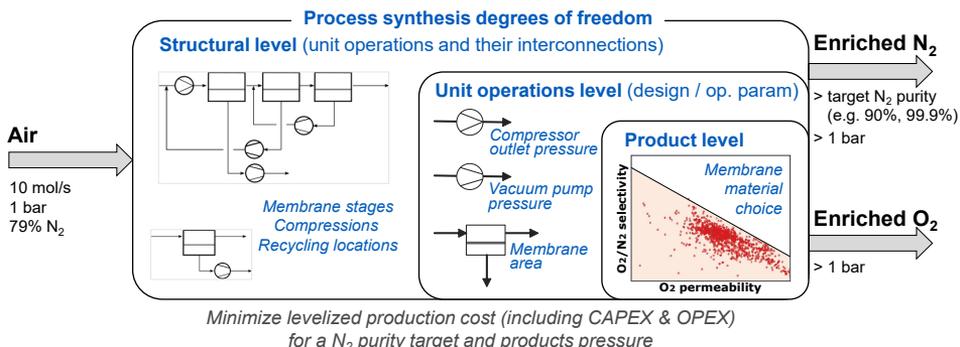

Figure 1: Overview of the process synthesis problem, and associated degrees of freedom

The following bounds are chosen for the design variables: vacuum levels (pressure on the permeate side of membrane) between 0.2 and 1 bar; compression ratio between 1 and 20 for gas compressor; membrane stage-cut (ratio of permeate to feed flowrates) between 0.05 and 0.95 (the required membrane area is calculated by the MEMSIC code knowing this design specification, inlet stream, membrane permeability and pressure ratio around the membrane).

3.2. Problem formulation: approach-specific implementation

Once the process synthesis problem is defined, it needs to be transposed for each approach to fit the method's requirements. We overview here the main particularities, please refer to the original papers for implementation details.

In terms of search space, methods A and B both require a superstructure, taken from Bozorg et al. (2019), allowing between 1 and 3 membrane stages, where all membrane stage outlets (retentate or permeate side) could be mixed and fed to the inlet of a module upstream (by-pass) or downstream (recycle) the current stage. In method C, only the process inlet (air) and outlets (enriched N_2 and O_2) are mandatory, the evolutionary algorithm can use unit operations from a given library (compressor, vacuum pump, membrane stage, mixer, splitter) to construct flowsheets.

In terms of system modelling, methods B and C are simulator-based (feasible path), meaning that the simulator is in charge of calling the membrane MEMSIC code and solving the flowsheet (tear streams) to provide required information to the optimizer (current objective function and process constraints, for the given set of action variables provided by the optimizer). Method A being equation-based, all the process equations are posed as optimization constraints, including flow conservation and unit operation equations. The membrane stage is therefore discretized into a finite number of 'cells' to get an algebraic system of equations from a differential one. This introduces a difference in physical modelling, whose influence will be discussed in §3.4.

In terms of optimization, the type and size of the problem will depend on the method. For method A, the size will depend on the discretization level. For a binary gas mixture (N_2/O_2) and 3 stages, the number of process variables and nonlinear equality constraints is between 748 and 18028 (for, respectively, 20 and 500 discretization cells per membrane stage), in addition to 17 continuous decision variables (splitters, pressures and membrane areas). For methods B and C, only the three production inequalities constraints are required (N_2 purity \geq target, and pressure of both outlets \geq 1 bar), as all process equations (governing unit operation equations and flowsheeting) are solved by the process simulator. For method B, 7 continuous (one design variable per unit operation with a degree of freedom) and 10 integer (switches for flow path) variables are required. For method C, the size will be different for each process evaluation as the topology is designed by the evolutionary algorithm, in this case 1 continuous variable per unit operation.

3.3. Optimization results: found solutions

In this section, we discuss the results obtained by fixing the permeability to 200 GPU (gas permeation unit) for O₂ and 44 GPU for N₂, i.e. values for commercial poly(p-phenylene oxide) membranes (PPO), in order to compare with industrial processes. Obtained results are presented in Figure 2. For each case, the best process structure is drawn as well as main process parameters (upstream and downstream pressure, P_{up} and P_{down} for each membrane stage) and overall process indicators (total membrane surface area A_{tot} , and levelized cost of production).

	Method A (superstructure – GO)	Method B (superstructure – MINLP)	Method C (ab-initio – EP)
90% N₂		$F_{up} = 1.0$ bar $F_{down} = 0.2$ bar $A = 2750$ m ²	13.8 €/t_{N₂} $A_{90\%}$ $B_{90\%}$ $C_{90\%}$
95% N₂	 $P_{up} = 1.0/1.0$ bar $P_{down} = 0.2/0.2$ bar $A_{tot} = 5290$ m ² 31.7 €/t_{N₂}	 $P_{up} = 1.0/1.0$ bar $P_{down} = 0.2/0.2$ bar $A_{tot} = 5112$ m ² 31.1 €/t_{N₂}	 $P_{up} = 1.0/1.0/1.0$ bar $P_{down} = 0.2/0.2/0.2$ bar $A_{tot} = 4915$ m ² 30.4 €/t_{N₂}
99.9% N₂	 $P_{up} = 2.9/2.9/2.9$ bar $P_{down} = 0.2/0.2/0.2$ bar $A_{tot} = 4335$ m ² 161.6 €/t_{N₂}	 $P_{up} = 2.7/2.7/2.7$ bar $P_{down} = 0.2/0.2/0.2$ bar $A_{tot} = 3668$ m ² 145.6 €/t_{N₂}	 $P_{up} = 1.0/2.4/2.4$ bar $P_{down} = 0.2/0.2/0.2$ bar $A_{tot} = 5611$ m ² 142.5 €/t_{N₂}

Figure 2: Found solutions for PPO membranes - $X_{yy\%}$ denotes the solution of the process synthesis approach X for the target of yy% N₂ purity

First, results exhibit high similarities with known industrial practices (Prasad et al., 1994), such as: an increasing number of membrane stages (and process complexity) with target N₂ purity, from one stage for 90% to three stages for 99.9%; an extraction of O₂ at the first stage(s) permeate; a recycling of other permeates at the 'N-1' stage; and an economic preference for vacuum operation when possible, without use of compressors up to 95% targeted purity.

More specifically, for 90% purity, all methods find the same simple solution (same flowsheet and design parameters). For 95% purity, both superstructure-based methods provide also identical solutions ($A_{95\%}$ and $B_{95\%}$) with a two-stages flowsheet and very closed design parameters. However, method C provides a better solution ($C_{95\%}$) with a three-stages flowsheet with same pressure levels, leading to a 4% lower membrane area and 2% lower production cost. It is worth mentioning that the flowsheet of solution ($C_{95\%}$) was indeed included in the superstructure of methods A and B, but not found by the optimization algorithms. This result will be validated and discussed in the validation section (§3.4).

For 99.9% purity, all methods propose three-stages flowsheets, with variations in flowsheets. Solution $A_{99.9\%}$ recycles the second stage permeate at the process inlet, whereas $B_{99.9\%}$ and $C_{99.9\%}$ mix with the O₂ process outlet. The best solution ($C_{99.9\%}$) is found by method C that was *not* included in the superstructure of methods A and B, with a flowsheet similar to solution $B_{99.9\%}$, simply consisting in pressurizing the retentate between stage 1 and 2, instead of at the process air inlet. This variant is comprehensible as no additional driving force (total pressure) may be required where the driving force is already high (O₂ partial pressure in retentate side). Putting the compressor after the first stage therefore lower the energy cost, further superstructure should therefore consider retentate recompression as options between each stage. Finally, solution ($A_{99.9\%}$) is significantly worse than $B_{99.9\%}$ and $C_{99.9\%}$, it will also be validated and discussed in the validation section (§3.4).

3.4. Validation: highlighting the importance of model accuracy and search space definition

The purpose of the validation step is to verify that the found solutions are actually retrieved within a common environment, different from the one used for optimization, here the COCO process simulator using the CAPE-OPEN MEMSIC code for membrane calculations.

From the simulations, it appears that all solutions found with various approaches and problem definition (N_2 target purity and membrane material) are validated, except the solution $A_{99.9\%}$ found by method A since the targeted 99.9% purity is not achieved. This is due to low deviation between rigorous and simplified models in the majority of the operating domain, but higher deviations in small regions with high-purity. This point is verified in Figure 3, where optimization runs are performed with increasing number of discretization cells for the simplified membrane model. As the discretization is more precise, both flowsheet and prediction of cost evolve until stabilizing to the same optimum as the one obtained with the rigorous membrane model.

For simplified models (e.g. physic, numeric, metamodel etc.), attention must therefore be placed in the regions of interests in addition to the overall domain. It highlights the need for accurate unit operation models, even for the exploration of the process structure (large) search space.

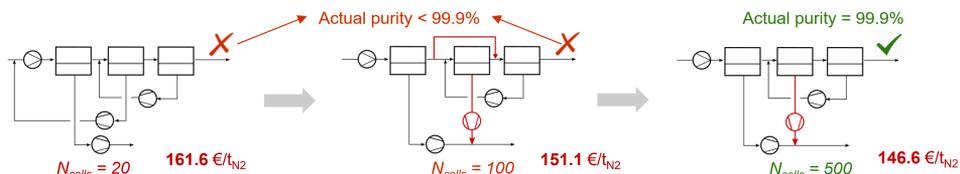

Figure 3: Effect of membrane discretization on synthesis results for method A (simplified model) and validation with the rigorous model under COCO simulator

Regarding solutions found by the method C, the fact that solution $C_{99.9\%}$ is validated confirms the interest of generative methods as this solution was not included in the superstructure of methods A and B. In addition, it is surprising to see that the solution $C_{95\%}$ is validated and that it was included in the superstructure, but was not found by any of the superstructure-based methods, despite various optimization approaches, system modelling and solvers. One possible explanation is on the way the various approaches explore the search space. In a superstructure-based approach, the entirety of the structural search space is explored at once as all foreseen alternatives are transposed into an optimization problem. Generative approaches usually work in two-levels, with an upper level being in charge of the flowsheet, and a lower level of the optimization of a (small) flowsheet. Each sub-optimization problem is therefore smaller and easier to solve.

3.5. Overall comparison

The Table 1 attempts to summarize found solutions, computational efficiency and ergonomics; in addition to details of the methods previously mentioned.

Regarding the found solutions, superstructure-based approaches (methods A and B) provide identical flowsheets and similar design parameters, if a sufficient discretization level is used when using the method A. The interest of the *ab-initio* method (generative) is highlighted as a better structure is found, which were not included in the superstructure of the other two methods, without the need to define a superstructure.

In terms of computational time, implementation differences makes it difficult to assess. It is here estimated based on the number of process evaluations (averaged over 10 random seeds, including constraint calculations for method A and flowsheet convergence for B and C) required to reach the reported solutions in Figure 2 for 99.9%. Superstructure based methods naturally need fewer evaluations than the *ab-initio* method, whose search space is wider.

Finally, in terms of ergonomics, implementations within commercial simulators allow chemical engineers to use familiar tools (graphical process simulators) instead of programming languages, which could promote acceptance of these methods.

Table 1: Overall comparison of synthesis approaches for the case study

	Method A (superstructure - GO)	Method B (superstructure - MINLP)	Method C (ab-initio - EP)
Synthesis approach / search space	Superstructure-based (choice among a postulated set of alternatives)	Superstructure-based (choice among a postulated set of alternatives)	Generative (available unit operations without postulate)
System modelling	Equation-oriented	Simulator-based	Simulator-based
Optimization	Continuous Global Optimization (Monotonic Basin Hopping + local NonLinear Programming)	Mixed Integer NonLinear Programming (solved by Ant Colony Optimization)	Evolutionary Programming (structure generation) + NonLinear Programming (evaluation)
Software tools	Programming (AMPL + KNITRO solver)	Graphical (commercial simulator ProSim + MIDACO solver)	Programming (in-house simulator + MIDACO/SLSQP solvers)
Membrane model	Simplified discretization of MEMSIC equation	Rigorous (direct call to MEMSIC)	Rigorous (direct call to MEMSIC)
Found solutions	+ (if adequate discretization in membrane model)	+ (similar as method A)	++ (similar as methods A and B + new ones not in superstruc.)
Computation time (N° of evaluations)	++ ($\simeq 2 \times 10^6$)	+ ($\simeq 3 \times 10^6$)	\simeq ($\simeq 10 \times 10^6$)
Ergonomics	\simeq (programming)	+ (graphical)	\simeq (programming)

4. Conclusion

From this case study, it is observed the importance of accurate models for unit operations, as simplified models lead to different optimal structures and associated parameters. By extension, the use of surrogate models for process synthesis should be done carefully, with efforts put during the validation of the surrogate in the whole operating domain.

Also, the definition of the structural search space is crucial, as postulating a superstructure restricts the search space. Meaning that if the optimal solutions are not in the superstructure, the optimizer cannot find it. *Generative* methods are therefore less biased and can explore a wider search space. As each approach exhibits various advantages, future works could include hybrid methods, for example using a generative approach for the definition of a restricted search space, then treated by a superstructure-based approach. This comparison can also be extended beyond the present case study to more constrained separation problems, meaning a smaller feasibility region, and more complex systems (multicomponent mixtures, multi-products, reactions, heat integration etc.).

Abstract

Granulation in fluidized beds is an important unit operation in chemical engineering, finding widespread use in the production of food, fertilizer and pharmaceuticals in particulate form. The main particle size-enlargement mechanisms during this process are layering growth and agglomeration. Regarding the former, the possible occurrence of self-sustained oscillations during continuous operation with sieve-mill-cycle is well known. For agglomeration such phenomena have not been observed yet. The goal of this contribution is to investigate process stability for simultaneous layering growth and agglomeration. Therefore in this contribution a population balance based bifurcation analysis is conducted. It can be shown that for a wide range of process conditions an increased partition of agglomeration has a stabilizing effect on the process dynamics.

Keywords: fluidized bed, granulation, agglomeration, layering growth, bifurcation analysis

1. Introduction

Spray agglomeration and spray granulation (layering growth) in fluidized beds are size-enlargement unit operations, which are applied frequently during the production of goods in particulate form, e.g. in the chemical, food or pharmaceutical industry. Due to high mass and heat transfer rates in the fluidized bed both processes are highly efficient. Furthermore desired product particle properties can be influenced by multiple adjustable process conditions (Strenzke et al., 2020; Neugebauer et al., 2020). The mechanisms of size-enlargement are presented schematically in Fig. 1 for both processes, having in common that a liquid solution is sprayed onto the fluidized particle bed. During layering growth, the liquid is deposited on the surface and dried by the fluidization medium, resulting in continuous particle growth of an onion-like particle structure (Fig. 2). During an agglomeration process however the liquid solution on the

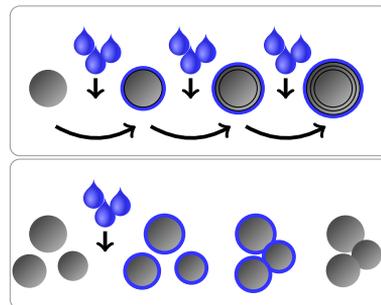

Figure 1: Schematic representation of the layering growth process (top) with continuous addition and drying of a liquid solution and agglomeration process (bottom) with solution addition, collision and drying.

particle, after collision with another particle and drying, acts as a binder, permanently connecting both particles, resulting in a blueberry-like cluster.

In general both layering growth and agglomeration can occur simultaneously in a spray fluidized bed, depending on the operation conditions. A variety of research contributions aims at identifying the dominant size enlargement mechanism under different process conditions (Villa et al., 2016; Rieck et al., 2020), which is important since the final particle properties depend on it. For example agglomerates usually are more porous than granules obtained by layering growth and therefore possess less mechanical strength. Besides of differences in the product particle properties, the dynamical behavior of the two processes differs drastically with respect to time constants and stability. From theoretical investigations (Radichkov et al., 2006) which were confirmed experimentally (Neugebauer et al., 2019) it is known that the particle size distribution in layering growth processes with sieve-mill-cycle as presented in Fig. 3 can exhibit self-sustained oscillations under certain process conditions. These oscillations are highly undesired from a production point of view and can be suppressed using suitable process control algorithms (Neugebauer et al., 2020; Palis and Kienle, 2014). To the author's best knowledge such behavior was not observed in agglomeration processes, a bifurcation analysis for a generic process did not reveal unstable regions (Bück et al., 2016). This leads to the question whether and under which circumstances oscillations can occur in a process where both agglomeration and granulation occur simultaneously. Vesjolaja et al. (2020) presented a process model for a drum granulation process, incorporating both growth mechanisms. They found oscillatory behavior, however a thorough bifurcation analysis was not conducted. This contribution aims at shedding light on the question of stability for the fluidized bed process by conducting a multi-parameter bifurcation analysis using a generic population balance process model containing a layering growth and an agglomeration term.

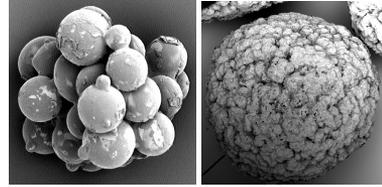

Figure 2: A blueberry-like agglomerate (left) and a spherical granule from layering growth (right).

2. Process Description and Model

In this contribution a generic, continuous fluidized bed spray process with external sieve-mill-cycle as presented in Fig. 3 is considered. Particles are fed to and withdrawn from the fluidization chamber, where the liquid solution is sprayed onto the particle surface and the size-enlargement occurs. The outlet particles are separated into three fractions by sieving according to the desired product size specifications. While the oversized particle fraction is ground up and recycled together with the undersized fraction, the product fraction is removed from the process.

For describing the evolution of a particle size distribution, the population balance equation is an established modeling framework (Ramkrishna, 2000). Here the evolution of a *volume*-based number density distribution $n(t, v)$ is described by the following partial differential equation

$$\frac{\partial n(t, v)}{\partial t} = \dot{n}_{\text{growth}}(t, v) + \dot{n}_{\text{agg}}(t, v) + \dot{n}_{\text{feed}}(t, v) - \dot{n}_{\text{out}}(t, v) + \dot{n}_{\text{mill}}(t, v) + \dot{n}_{\text{fines}}(t, v) \quad (1)$$

where the left-hand side describes the size-dependent accumulation of particles and the right-hand side accounts for the respective number fluxes. Typically the agglomeration term \dot{n}_{agg} is given in the following volume-based formulation (Hulburt and Katz, 1964)

$$\dot{n}_{\text{agg}} = \frac{1}{2} \int_0^v \beta(t, u, v-u) n(t, u) n(t, v-u) du - \int_0^\infty \beta(t, v, u) n(t, v) n(t, u) du. \quad (2)$$

The second-order agglomeration kinetics are described by the so-called agglomeration kernel $\beta(t, u, v)$ which describes the rate at which particles with volumes v and u collide and form a new particle. In this contribution we separate the kernel into a size-independent particle collision rate β_0 and a size-dependent coalescence probability $\beta_c(u, v)$ with values between 0 and 1, i.e. $\beta(u, v) = \beta_0 \beta_c(u, v)$. This kernel model is equally simple and flexible due to its generality. In a fluidized bed process the coalescence probability is a function depending on a variety of process and material specific conditions. To keep the model simple, we choose a generic two-parametric function $\beta_c = (u + v)^a / (uv)^b$ known as the Kapur kernel, which allows us to simulate different types of coalescence by varying the parameters (Otto et al., 2021). In order to keep values of β_c between 0 and 1, the kernel is normalized.

In contrast to this the layering growth term is introduced depending on the particle diameter (Mörl et al., 2007)

$$\dot{\tilde{n}}_{\text{growth}}(t, d) = -G \frac{\partial \tilde{n}(t, d)}{\partial d} = -\frac{\dot{m}_{\text{spray}}}{\rho A_{\text{tot}}} \frac{\partial \tilde{n}(t, d)}{\partial d}. \quad (3)$$

Here $\tilde{n}(t, d)$ describes the *diameter*-dependent number density distribution. In this contribution we assume that all particles are approximately spherical, i.e. $v = \pi/6d^3$, so that all *diameter*-based number density distributions $\tilde{n}(t, d)$ can be transformed into volume-based distributions $n(t, v)$ and vice-versa using the conservation of particle number in an infinitesimal class $n(t, v) dv = \tilde{n}(t, d) dd$.

The layering growth kinetics are described by the growth rate G which depends on the total particle surface A_{tot} and the liquid spray rate \dot{m}_{spray} as well as the liquid density ρ .

Previous studies have shown that the particle mill and especially the size of milled particles play a major role in the emergence of oscillations. Thus, the milling model is presented

$$\tilde{n}_{\text{mill}}(t, d) = \frac{\tilde{q}_{0, \text{mill}}(t, d)}{\mu_3(\tilde{q}_{0, \text{mill}}(t, d))} \mu_3(\tilde{n}_{\text{over}}(t, d)),$$

where $\tilde{q}_{0, \text{mill}}$ is the normalized number density distribution of particles after milling, \tilde{n}_{over} is the oversized particle size distribution and μ_3 is the third moment which is proportional to the total volume (Radichkov et al., 2006). For simplicity $\tilde{q}_{0, \text{mill}}$ is assumed to normalized Gaussian with the milling diameter μ_{mill} and standard deviation σ_{mill} . It is assumed that the milling diameter can be adjusted (Neugebauer et al., 2019).

The terms in Eq. (1), that are not described until now are part of the process model, they do however not play a major role with respect to this bifurcation analysis. Therefore we refrain from describing them explicitly in this contribution and refer the reader to Neugebauer (2020) for detailed information including parameters. We want to stress that the process model presented here is the same as presented in Neugebauer (2020) with exception of the additional agglomeration term. The volume-based formulation here can be transformed into the diameter-based formulation without any approximations and are therefore equivalent. Therefore the results are indeed comparable.

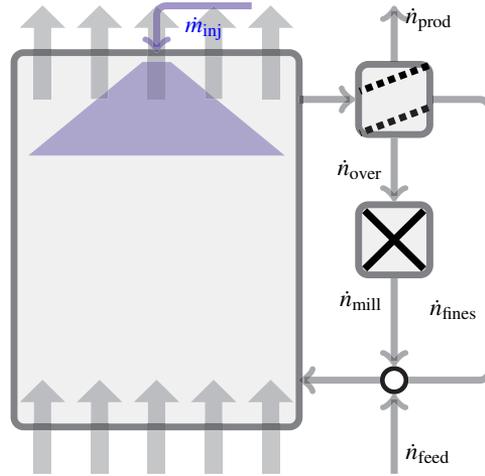

Figure 3: Schematic representation of the fluidization chamber and the sieve-mill-cycle.

3. Bifurcation Analysis

In order to generate stability maps for the variation of two general process parameters a simple prediction-correction scheme is used. To this end steady states are computed by optimization on a fixed, equidistant parameter grid. At every grid node (i, j) the minimization problem

$$n_{\text{cor}}^{(i,j)} = \arg \min_n \left\| \frac{\partial n}{\partial t} (v, \mathbf{p}^{(i,j)}) \right\|_1 \quad (4)$$

s.t. $n(v) \geq 0$

is solved (correction) using a steady state distribution from the adjacent grid point $(i-1, j)$ as initial guess (prediction).

The initial distribution predictions at $(0, j)$ in the stable area are generated by solving the PDE numerically over a long time horizon. The local stability is obtained by linearizing around the steady states and computing eigenvalues. In order to compute the minimization and for the numerical solution of the PDE the volume coordinate in the population balance is discretized using a finite volume method on a geometric grid with $N = 200$ classes. For the agglomeration term the discretization algorithm presented in Singh et al. (2015) is applied. The discretization of the other terms in Eq. 1 is straight forward. For the minimization of the L_1 -residuals of the time-differential, the Matlab built-in trust-region gradient-descent algorithm is utilized.

4. Results

Previous contributions (Radichkov et al., 2006; Neugebauer et al., 2020) have identified the milling grade μ_{mill} as primary influence on the stability of the layering growth process. Based on this we choose

μ_{mill} as the first bifurcation parameter. In order to investigate the influence of an increased rate of agglomeration events, we choose $\beta_0 \in [10^{-14}, 10^{-12}]$ as second bifurcation parameter, where the lower interval bound accounts for a negligible amount of agglomeration events compared to the growth by layering. Therefore the stability results for $\beta_0 = 10^{-14}$ are the same as in Neugebauer (2020). The influence of additional process parameters is investigated by conducting the parameter continuation for selected values.

The influence of an increased amount of injected solution \dot{m}_{inj} is investigated, since it influences the growth rate G proportionally. The results presented in Fig. 5 indicate an increased region of instability for larger values of \dot{m}_{inj} , which is in qualitative accordance with Radichkov et al. (2006). A change of the coalescence kernel β_c is modeled by varying the kernel parameter

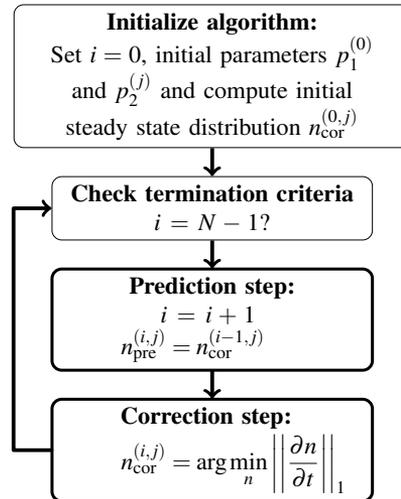

Figure 4: Parameter Continuation Scheme for one parameter.

Name	Symbol	Value	Unit
Bed mass	m_{bed}	100	kg
Mill grade	μ_{mill}	[0.1, 0.8]	mm
Collision rate	β_0	$[10^{-14}, 10^{-12}]$	s^{-1}
Injection rate	\dot{m}_{spray}	100	kg h^{-1}
Kapur parameters	a	0	
	b	0	
Feed rate	\dot{m}_{enuc}	72	kg h^{-1}

Table 1: Nominal process parameters.

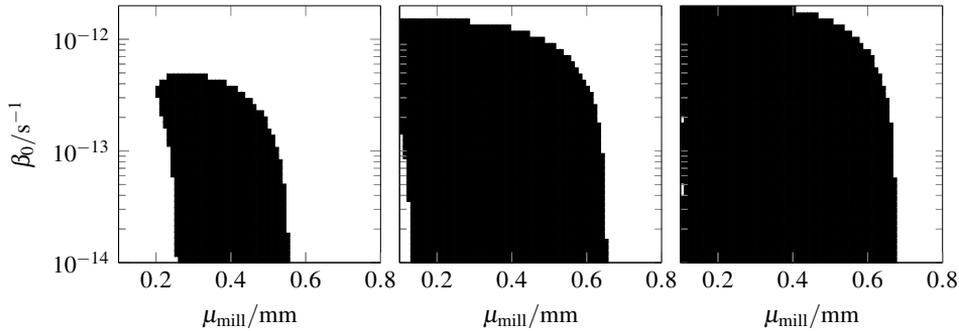

Figure 5: Stability map for a variation of the binder injection rate. Left: $\dot{m}_{\text{spray}} = 80 \text{ kg/h}$, middle: $\dot{m}_{\text{spray}} = 150 \text{ kg/h}$, right: $\dot{m}_{\text{spray}} = 200 \text{ kg/h}$. The region of instability is colored black.

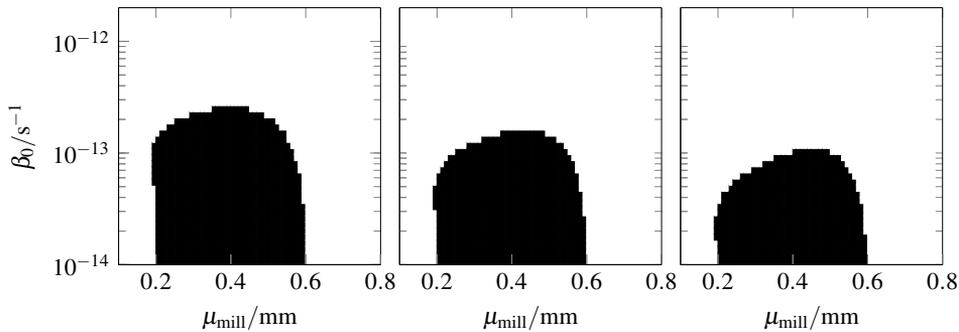

Figure 6: Stability map for a variation of kernel parameters: $b = 0.1$ (left), $b = 0.2$ (middle) and $b = 0.3$ (right). The region of instability is colored black

b . Increasing it results in preferential coalescence of smaller particles compared to coalescence of larger particles. As depicted in Fig. 6 increasing b from 0.1 to 0.2 to 0.3 reduces the region of instability slightly. Furthermore, the influence of the external nuclei feed rate is investigated and presented in Fig. 7. The region of instability is reduced significantly by increasing the feed rate, which is again in accordance with Radichkov et al. (2006).

The transitions from white to black areas in Figs. 5-7 represent supercritical Hopf bifurcation points, i.e. transition from a stable fixed point to a stable limit-cycle (Seydel, 1998).

5. Conclusion and Future Work

In this contribution a model based bifurcation analysis was presented for a fluidized bed spray process with layering growth and particle agglomeration. The process stability was investigated for different plant and kinetic parameters. The results generally indicate that self-sustained oscillations in the particle size distribution are dampened with an increasing number of agglomeration events taking place. This result is in agreement with previous observations on the stability of agglomeration processes.

Future contributions will be concerned with a more detailed bifurcation analysis for an extended process model including the thermal process conditions such as fluid temperature and moisture as

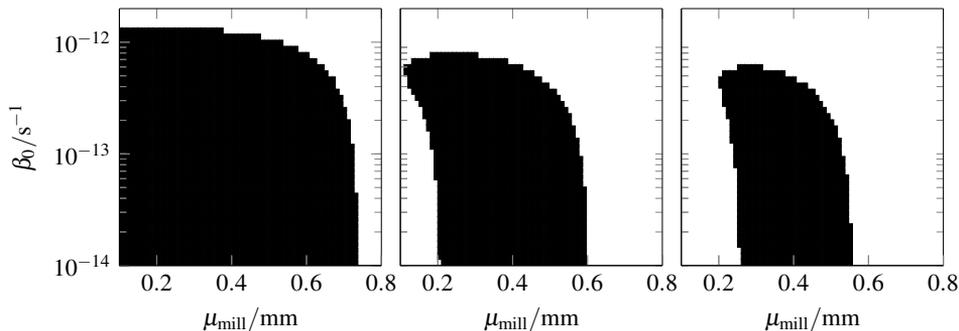

Figure 7: Stability map for variations of the external feed rate: $\dot{m}_{\text{enuc}} = 0 \text{ kg/min}$ (left), $\dot{m}_{\text{enuc}} = 1.2 \text{ kg/min}$ (middle) and $\dot{m}_{\text{enuc}} = 1.5 \text{ kg/min}$ (right). The region of instability is colored black

well as considering the particle porosity.

Abstract

Reverse Osmosis (RO) desalination capacity has been increasing steadily over the years. However, the necessity of developing more efficient designs has become more crucial due the increased demands for freshwater. This study shows the development of a conceptual design of an efficient energy medium-scale RO brackish water desalination plant of the Arab Potash Company (APC) located in Jordan. In this regard, a photovoltaic (PV) solar farm has been combined with the original RO process to generate electricity in a sustainable way and decrease the overall energy consumption. To obtain an accurate estimation of the process performance, this work shows the utilisation of an efficient process model for the spiral wound RO process. Also, an accurate model for the photovoltaic system was obtained from the literature to conduct preliminary calculations of the proposed new configuration. The simulation results of the proposed RO design are compared to the original ones of APC and showed a considerable energy saving.

Keywords: Brackish water; Reverse osmosis; Photovoltaics; RO-PV system; energy consumption

1. Introduction

Reverse Osmosis (RO) membrane desalination systems are considered to be the most superior technology for desalinating brackish water and producing high-quality water with relatively low energy consumption (Alsarayreh et al., 2020). For medium sized RO desalination systems, the energy consumption is estimated to be about 3.5-4 kWh/m³ and 19 kWh/m³ for larger scale desalination system (Abdelkareem et al., 2018). However, there is an increased interest to promote the overall performance of RO system with an alleviated energy consumption. In this regard, the utilisation of renewable energy, especially solar energy, to power RO system desalination has proved to be one of the most viable and economic options to mitigate the overall energy consumption. The integration of solar energy systems with RO system is mainly to drive the high-pressure pumps (Nayar et al., 2017). An integration of RO systems and photovoltaic (PV) is one of the most successful and cost-effective desalination hybrid systems (Filippini et al., 2019). Several researchers have evaluated the feasibility of installing small and medium scales RO seawater and brackish water desalination systems powered by a PV system.

A small scale PV and brackish water two-stage configuration RO desalination system has been constructed by Alghoul et al. (2016). They concluded that RO system can produce 5.1 m^3 of freshwater during 10 hours a day at a specific energy consumption of 1.1 kWh/m^3 . The viability of using PV solar energy for brackish water RO desalination process in Jordan valley has been studied by Alsarayreh et al. (2017). They confirmed that employing PV systems for brackish water desalination is cost-effective with reduction of more than 20% in the initial cost.

While many renewable energy-powered RO units have been developed for seawater and brackish water desalination systems, only a few attempts have been made to investigate the feasibility of combining PV solar energy to an industrial medium scale- brackish water RO desalination system of multistage, multi pass configuration. Thus, it is feasible to test such integrated system and explore the maximum energy saving. Unarguably, this would introduce a reliable and cost-effective desalination system especially for coastal areas of intense sun radiation. Thus, this research focuses on installing PV solar farm to be integrated to the multistage multi-pass brackish water RO system of the Arab Potash Company (APC), located in Jordan.

The assessment of the hybrid system will be carried out based on intensive simulation based models developed for RO (developed by the same authors) and PV (available in the literature) systems. In this regard, the total energy consumption of RO desalination system will be firstly determined as a base case and the required number of PV panels and associated energy saving will be investigated for three different selected PV types.

2. Description of RO desalination plant powered by PV system

The layout of a brackish water RO powered by solar energy for the APC plant with capacity $1200 \text{ m}^3/\text{day}$ is shown in Fig. 1. It comprises of two passes with permeate and retentate reprocessing designs. The 1st pass has two stages of pressure vessels organized in the following order: (4:2). The 2nd pass contains three stages of pressure vessels organized in the following order: (2:1:1). The 1st pass's permeate is sent into the second pass for additional polishing. The 1st pass's high-concentration stream is drained. The low-concentration streams of the 2nd pass are gathered to make the high-quality water with salinity of 2 ppm. The 2nd pass's high-concentration stream is returned to the 1st pass's raw feed water. As shown in Fig. 1, a photovoltaic (PV) solar farm is integrated with a RO system to provide the necessary amount of power to drive the pumps.

3. Design of PV system

This study will determine the number of panels required to supply the RO system for each type of PV system with evaluating the generated power and associated construction area. The RO plant feed characteristics are 1098.62 ppm, $74 \text{ m}^3/\text{h}$, $25 \text{ }^\circ\text{C}$, and 9.22 atm of brackish water salinity, flow rate, temperature and pressure, respectively.

According to the simulation-based model developed by Al-Obaidi et al. (2018) based on the above feed conditions, the total energy consumption of the original RO plant was 0.837 kWh/m^3 for a water productivity rate of $48.6 \text{ m}^3/\text{h}$ ($1166.4 \text{ m}^3/\text{day}$). In this study, three type of solar panels were selected to be integrated to the RO plant. The first type is made by Monocrystalline, Sun-Power 315-SOLAR PAN, with an efficiency of 19.3% and 315 W, as maximum power (Al-Najideen and Alrwashdeh (2017). The second type is made by the TopSun Energy Ltd with an efficiency of 17.2% (Filippini et al. (2019). The third type is made by the FSM-155 W- Mono-crystalline, with an efficiency of 16% (Abd Elbar and Hassan, 2020). The inverter type GermanPV TRIO-27.6-TL-OUTD-S2X manufactured by GermanPV Inc has been used in this study and has a high value of CEC

efficiency of about 98% (Al-Najideen and Alrwashdeh, 2017). Tables 1, and 2 show the characteristics of selected types of solar panel and inverter device, respectively.

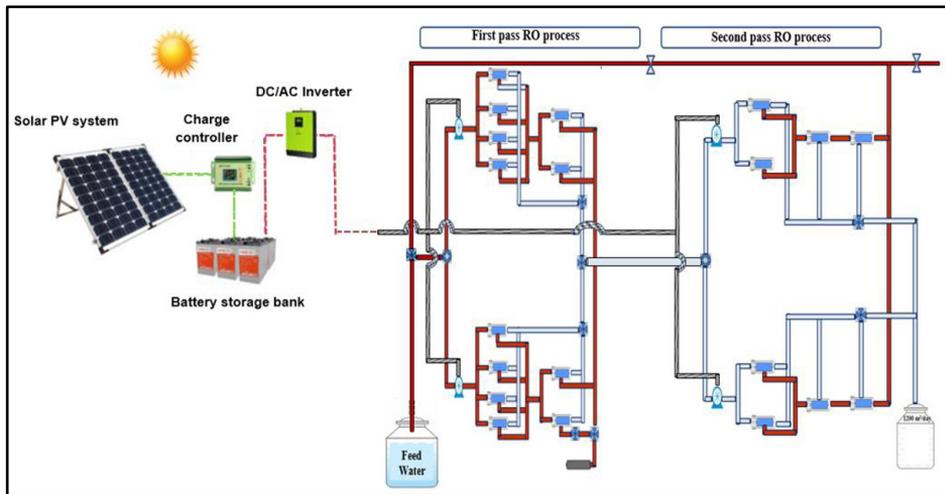

Fig. 1. A schematic representation of a PV-RO system of APC

Table 1. Technical features of the photovoltaic solar panel (Al-Najideen and Alrwashdeh, 2017, Filippini et al., 2019, Abd Elbar and Hassan, 2020)

Properties of the PV module	Sun power315-SOLAR PAN	TopSun Energy Ltd	FSM-155 W-Mono-crystalline
Maximum power output (P_m)	315 W	440 W	155 W
Maximum system voltage	1000 V	1000 V	1000 V
Module efficiency (η)	19.3%	17.2%	16%
Rated current at maximum power (I_m)	5.76 A	8.86 A	8.15 A
Rated voltage at maximum power (V_m)	54.7 V	49.67 V	30.7 V
Module length (L)	1.559 m	1.960 m	1.482 m
Module height (h)	1.046 m	1.308 m	0.676 m
Module depth (d)	0.046 m	0.040 m	0.035 m
solar radiation (G) at 25 °C	1000 W/m ²	1000 W/m ²	1000 W/m ²

Table 2. Inverter specifications (Al-Najideen and Alrwashdeh, 2017)

Properties for Input DC	Value	Properties for Output AC	Value
Max. recommended PV power	30 kW	Maximum efficiency	98 %
Max. DC voltage	1000 V		
Rated MPPT voltage range	252- 970 V	Nominal AC rated power	27.6 kW
Nominal DC rated power	28.6 kW	Maximum AC output power	30 kW
Number of MPP tracker inputs	2	Nominal AC rated line voltage	400 V
Max. input current / per MPP tracker input	64 A / 32 A	AC voltage rang	320–480 V
Number of DC input pairs (parallel connection)	5	AC maximum output current	45 A

4. Modelling of RO-PV system of APC

Al-Obaidi et al. (2018) developed a steady-state model for the APC medium-scale brackish water RO desalination system. The detailed model was validated against actual APC data before being used to study plant performance under variable operating conditions. For the convenience of the reader, it is recommended to revise Al-Obaidi et al. (2018) for the model's details of the RO system. This model was recently upgraded by including a specific sub model to measure the power generated by the PV system.

5. Modelling of Photovoltaic System

The required energy power of RO desalination $E_{Power Des.}$ is estimated using Eq. 1, (Filippini et al., 2019).

$$E_{Power Des.} = M_{RO} \times E_{Cons. RO} \quad (1)$$

where M_{RO} , and $E_{Cons. RO}$, are the productivity of freshwater of RO process (m³/day), and energy requirement for RO (evaluated in kWh/m³), respectively.

The on-grid type is the most basic PV installation system model in which the load is supplied by the user and the suggested inverter is simply equal to the nominal array power. However, the energy produced by the array equivalent to the energy available to the grid in MWh and can be calculated by the following equation

$$E_{grid} = E_{Power Des.} \times \eta_{inv.} \quad (2)$$

where $\eta_{inv.}$, is the inverter efficiency.

Based on the grid configuration, the grid may not be able to absorb all the supplied energy. In this regard, the actual amount of energy delivered can be calculated using Eq. 3 (Al-Najideen and Alrwashdeh, 2017).

$$E_{actual} = E_{grid} \times \eta_{absorbed} \quad (3)$$

where $\eta_{absorbed}$, is the efficiency grid absorption rate

The energy power for PV module $E_{Power Module}$, can be calculated using Eq. 4

$$E_{Power Module} = \eta_{Module} \times A_{Module} \times G \quad (4)$$

where η_{Module} , A_{Module} , and G are the solar panel module efficiency (%), the PV module area (m²) and the solar radiation in (kW/m²), respectively.

The required number of PV panels is calculated as follows:

$$NPV, Panels = \frac{E_{Power Des.}}{E_{Power Module}} \quad (5)$$

Eq. 6 can also be used to calculate the hourly total power generated by the PV system, measured in kW and based on the value of the PV array (Mokheimer et al., 2013);

$$Power_{PV} = N_{PV, Panels} \times V_{pv} \times I_{pv} \quad (6)$$

where $N_{PV, Panels}$, V_{pv} , and I_{pv} are the number of the PV modules, the voltage of each PV module and current of each PV module, respectively.

6. Evaluation of PV-RO system for various types of solar panels

As stated in section 3, the required power of RO desalination $E_{Power Des.}$ is estimated from Eq. 1 to be 976.28 kWh/day (40.67 kW), and annually about 356.34 MWh at the selected operating conditions. Using Eqs. 2 and 3, the annual energy available to the grid is estimated to be 349.2 MWh and the actual energy delivered annually is 345.7 MWh, with an inverter efficiency of 98% and grid absorption rate of 99%. The power of three PV modules, was estimated based on Eq. 4: (Sun power315-SOLAR PAN), (TopSun Energy Ltd), and (FSM-155 W-Mono-crystalline) and are 0.31 kW, 0.44 kW, 0.16 kW, respectively.

At standard test conditions for SOLAR PAN module, the rated voltage for each panel is 54.7 V and the rated current is 5.76A, whereas the maximum system voltage is 1000 V, according to the solar panel data sheet and Table 1. Dividing the maximum system voltage by the panel rated voltage gives the number of panels in series orientation; that is $18.3 = 18$ panels in series. Therefore, 7 parallel lines are required each with 18 panels connected in series (5.67 kW, 984.6 V, 5.76A). According to the panel data sheet in Table 1, the panel area with its frame is 1.63 m². Thus, the required area is 210.4 m².

For the TopSun Energy module, the rated voltage for each panel is 49.67 V and the rated current is 8.86 A, whereas the maximum system voltage is 1000 V. The number of panels in series orientation is $20.1 = 20$ panels. Therefore, 4.5 parallel lines are required each with 20 panels connected in series (8.8 kW, 993.4 V, 8.86 A). Thus, the panel area with its frame is 2.56 m² with required area of 235.8 m².

For the W-Mono-crystalline module, the rated voltage for each panel is 30.7 V and the rated current is 8.15 A, whereas the maximum system voltage is 1000 V. The number of panels in series orientation is $32.6 = 33$ panels, and therefore, 7.7 parallel lines are required each with 30 panels connected in series (5.12 kW, 1013.1 V, 8.15 A). Finally, the panel area with its frame is 1.002 m² and therefore 254.5 m² is required to construct this type of solar panel.

Using Eq. 5, the number of PV panels required for the Sun power315-SOLAR PAN, TopSun Energy Ltd and FSM-155 W-Mono-crystalline modules are 129, 92 and 254, respectively.

Table 3 shows the calculations of total power generated by the three selected PV systems in kW and based on the value of the PV array. The calculations of the generated power are also based on 100% energy saving. For the convenience of the plant operator, Table 3 shows the calculation of the power generated of three PV modules with 90%, 80%, 70%, 60% and 50% of energy saving. Also, the required construction area and the number of panels are calculated for each option. Logically, the reduction of energy saving implies lesser required construction area and panels. Using Eq. 6, the PV power required based on the number of panels for three selected types of PV modules are 40.674 kW, 40.677 kW, and 40.672 kW.

Table 3. The energy saving and construction area of three types of PV of different number of panels

Sun power315-SOLAR PAN				TopSun Energy Ltd Module type				FSM-155 W-Mono-crystalline			
No. panels	Power PV (kW)	Energy saving (%)	Area (m ²)	No. panels	Power PV (kW)	Energy saving (%)	Area (m ²)	No. panels	Power PV (kW)	Energy saving (%)	Area (m ²)
129	40.67	100	210.4	92	40.67	100	236.5	163	40.67	100	163
116	36.6	90	189.4	83	36.6	90	213	146	36.6	90	147
103	32.5	80	168.3	74	32.5	80	189	130	32.5	80	130
90	28.4	70	147.3	65	28.5	70	166	113	28.5	70	114
77	24.4	60	126.2	55	24.4	60	142	98	24.4	60	98
64	20.3	50	105.2	46	20.3	50	118	81	20	50	82

Most importantly, the PV module type TopSun Energy Ltd is the most feasible and favorable option to generate the required power of RO desalination process with the least number of panels compared to the other tested modules (Table 3). However, the

construction area required to install the Sun power 315-SOLAR PAN Module type is the lowest one compared to the other tested ones.

7. Conclusions

This paper presents the integration system of PV and RO brackish water desalination plant of Arab Potash Company. The simulation of the proposed PV-RO system is carried out based on a developed model of subsystems. The simulation results confirm the possibility of gaining full energy saving for three types of PV modules. The calculations have determined the number of panels and construction area required for each PV system. More specifically, the PV module of TopSun Energy Ltd has been selected as the most feasible option. This study therefore lays the foundation for further improvement to lowering the overall freshwater production cost of the RO desalination plant of APC.

Abstract

Global carbon emissions are continuously increasing, clean and sustainable technologies are needed to utilize fossil fuels. Methanol is a clean fuel that can enable a smooth transition between fossil fuels and renewables. This work explored the production of methanol through two different fossil fuels, i.e., natural gas (case I) and vacuum residue (case II). Aspen Plus has been utilized to simulate the two processes for the methanol production capacity of 90 t/h with 99.9 wt. % purity. The two methanol production processes are compared in terms of energy, environmental and economic factors. The important reactive sections of the two processes are validated with the design data to ascertain the accuracy of the results. The results show that case II has a process efficiency of 49.5 % which is 1.6 % higher compared to the case I. From an economics point of view, case II design can produce methanol at a unit cost of \$317/t CH₃OH, which is 14% less than the case I design. As a result of the environmental analysis, the case I design releases fewer carbon emissions than case II. Despite this, the case II design offers CO₂ captured with high purity that can be used for another application which can further reduce the production cost of methanol.

Keywords: vacuum residue gasification; carbon capture and utilization; methanol; process simulation

1. Introduction

The high emission of greenhouse gases (GHGs) is attributed to the increase in energy demand. Carbon dioxide is considered as one of the main contributors to carbon emissions. Therefore, several technologies have been developed to reduce CO₂ emissions such as carbon capture, utilization and storage (CCUS) (Alibrahim et al., 2021). The utilization and conversion of CO₂ to clean fuels or other added-value chemicals is one of the potential approaches to reduce carbon emission in the chemical industry. Therefore, the conversion of CO₂ to methanol is one of the key routes. Methanol is also an important feedstock downstream to produce many valuable chemicals. Moreover, methanol blending with gasoline provides clean combustion characteristics. Besides, methanol has a wide-ranging of uses in painting, anti-freezing agents, production of biodiesel, and denitrification of wastewater (Khalafalla et al., 2020). Based on all these applications, methanol demand has rapidly increased in the global market. Currently, China is the largest consumer of methanol, accounting for around 58% of methanol usage. It is also

predicted to grow at a compound annual growth rate (CAGR) of 5.66 % from 2019 to 2027 due to the methanol-to-olefin industry (Inkwood Research, 2020). Most of the methanol is produced via the catalytic reaction of the synthesis gas. Recently, methanol production technologies utilize CO₂ as a feed source. Many studies have been conducted on CO₂ direct hydrogenations to methanol. Battaglia et al. (Battaglia et al., 2021) studied the techno-economics parameters for methanol synthesis through direct hydrogenation of CO₂ captured from power plants with hydrogen from water electrolysis. They also performed heat integration and utilization between different sections and reported savings of cooling and heating loads as high as 47% and 81% respectively. Ahmed (Ahmed, 2021) also performed a techno-economics analysis for the co-production of methanol and hydrogen. He reported an increase in efficiency compared to the standalone technologies.

Gasification, another synthesis gas production technology, converts heavy carbon-based feeds to synthesis gas as an intermediate for many useful chemicals. Choi et al. (Choi et al., 2007) studied the composition of the synthesis gas produced through gasification of the vacuum residue. They concluded optimal operating conditions for the temperature and pressure are 1200 – 1250°C and around 1 bar respectively. Al-Attas et al. (Al-Attas et al., 2021) studied operational parameters of co-gasification of vacuum residue and biomass. They stated that oxygen content in the biomass increases the activation energy for the gasification reaction.

Saudi Arabia produces over 200,000 barrels per day (BPD) of vacuum residue used in asphalt production. Its massive production capacity rises environmental concerns in addition to environmental regulations of sulfur content in asphaltene (Al-Rowaili et al., 2021). In this study, the conversion of vacuum residue through gasification is proposed to reduce its carbon emissions. Both conventional steam methane reforming to methanol and vacuum residue gasification to methanol processes have been simulated using Aspen Plus® V11. Moreover, comparative analysis has been performed based on equal production rate and the purity of the methanol.

2. Process design

2.1. Methanol production from natural gas (Case I)

This process consists of five major units; sulfur removal unit, steam reforming, gas compression, methanol synthesis, and methanol purification unit. Toxic sulfur components harm the catalysts of both syngas reforming and methanol synthesis; thus, it is removed to a trace level less than 1 ppm. Natural gas (NG) is fed to the desulfurization unit which utilizes a fixed-bed reactor at high operation conditions of temperature and pressure, about 300 – 400°C and 30 – 130 bar respectively. The sweet NG stream is sent to the steam reforming unit where methane is converted to syngas as mentioned in Eq.1. The hot syngas is utilized to heat the feed of the reformer through a network of heat exchangers. The reactor effluent stream contains CO, CO₂, H₂, unreacted CH₄, and some amount of water.

The produced syngas is then compressed to operation conditions of the methanol synthesis block. Methanol synthesis is an exothermic process and happens in a commercial fixed-bed reactor operating at pressure and temperatures between 50 to 100 bar and 230 to 270°C, respectively. The crude methanol produced from the synthesis reactor is sent to the purification unit which consists of two distillation units to produce

90 t/h of methanol with a purity of 99.9 wt.%. Figure 1 shows a simplified block flow diagram of the steam reforming process of natural gas to methanol. This process has been simulated using Aspen Plus using the Peng-Robinson equation of state (PR-EOS).

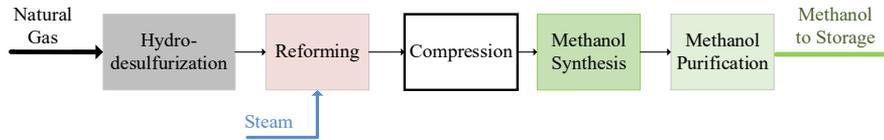

Figure 1: Block diagram of methanol production from natural gas (Case I)

2.2. Methanol production from vacuum residue (Case II)

Vacuum residue (VR) is utilized for syngas production via gasification technology. The composition and heating value for the VR is adapted from the literature (Al-Rowaili et al., 2021). PR-EOS has been selected as a method for the thermodynamic models to predict the thermodynamic properties. The block flow diagram for the case II design is illustrated in figure 2.

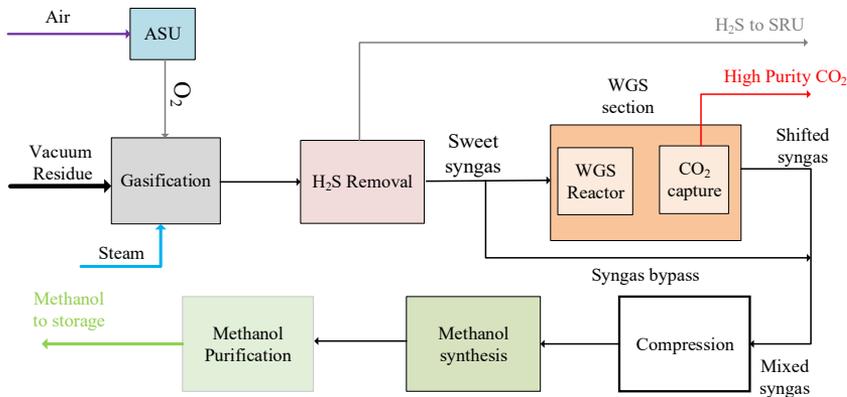

Figure 2: Block diagram of methanol production from vacuum residue (Case II) – sweet shift

The vacuum residue is assumed to be supplied from the refinery vacuum distillation unit (VDU). The vacuum residue along with oxygen and steam are fed to the gasifier. The raw syngas leaves the gasifier at 1300°C, which is utilized in the heat recovery steam generation unit (HRSG) to produce high-pressure steam and power. The raw syngas contains a mixture of gaseous products including CO, CO₂, H₂, H₂O, H₂S, and minor quantities of other gases. Methanol has been used as a physical solvent in the absorber for removing more than 99.9% of the sulfur components in the raw syngas. The sweet gas has a low syngas ratio that is not suitable for methanol production. Hence, 38% of the total syngas is sent to the water-gas shift reactor unit (WGS) where most of CO is converted to H₂ by the reaction with steam as Eq. 2. This step is key to meeting the H₂ deficiency in the sweet syngas ratio which requires a stoichiometric number (SN) from 2 as depicted in Eq. 3. Excess CO₂ is produced due to the water gas shift reaction and it is captured by methanol absorption to fix the stoichiometric number.

$$SN = \frac{[H_2] - [CO_2]}{[CO] + [CO_2]} \quad (3)$$

The mixed syngas is compressed and heated to 100 bar and 230°C respectively to meet the methanol synthesis reactor conditions as shown in figure 3. Methanol synthesis reactor is modelled as an adiabatic quenching reactor with five stages due to the exothermic nature of methanol synthesis as shown in Eq. 4 – Eq.6.

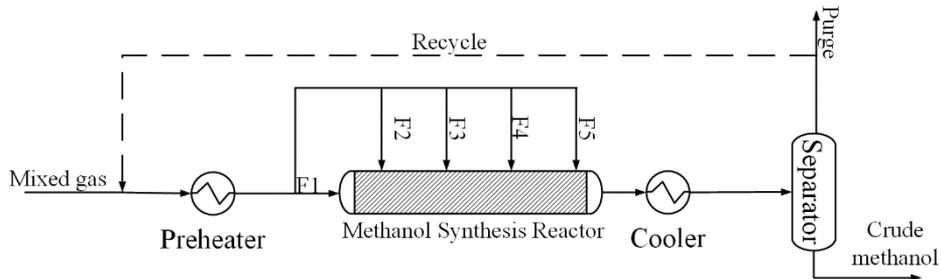

Figure 3: Process flow diagram for Methanol synthesis unit

The crude methanol produced from the synthesis reactor is sent to the purification unit that consists of two distillation units to produce 90 t/h of methanol with 99.9 wt.% purity.

3. Results

3.1. Model Validation

The simulation results have been validated for the main units such as the gasifier and the steam reformer as shown in figure 4-a. The nature of the feedstock used to produce syngas directly affected the quality of the syngas and their composition. The raw syngas produced from steam reforming technology has a higher H_2/CO ratio compared to VR gasification. Moreover, methanol synthesis is also validated with design data as illustrated in figure 4-b. The result shows well agreement between both the simulation results and design data.

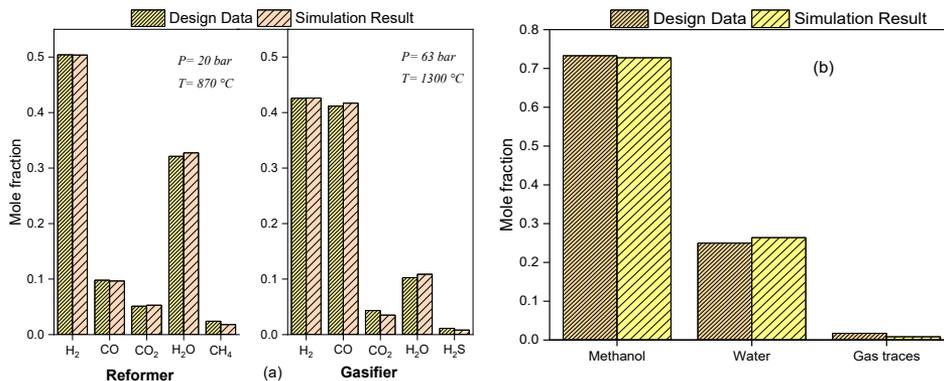

Figure 4: Model validation results: a) for reforming and gasification reactors respectively. b) for methanol reactor.

3.2. Techno-economic and Environmental Analysis

Energy analysis has been performed for both the proposed design and conventional steam reforming to estimate the energy consumption in these processes. Table 1 presents a summary of the energy consumption of various units in case I and case II designs.

Table 1: Energy consumption of various sections in case I and case II designs

Case I (MW)		Case II (MW)	
Steam reforming	208.9	VR Gasification	6.1
Compression	34.6	Cleaning unit	52.9
Methanol synthesis	225.4	WGS	190.8
Methanol Purification	149.9	Compression	31.1
		Methanol synthesis	188.4
		Methanol Purification	84.6

The findings illustrate that the case I process has a 14.9% higher total energy consumption compared to case II. Moreover, the energy efficiency has been calculated for the two processes and the result shows that the case I process has 47.9% which is 1.6% lower than the case II process. On the other hand, based on the environmental impact carbon emission has been calculated for both processes. Case I design is more environmentally sustainable compared to case II because it has a lower CO₂ emission per unit of methanol produced. Furthermore, economic analysis has been studied for both scenarios. The unit cost of methanol product from the case II process is \$317/tCH₃OH which is 14% lower compared to the case I process as shown in figure 5.

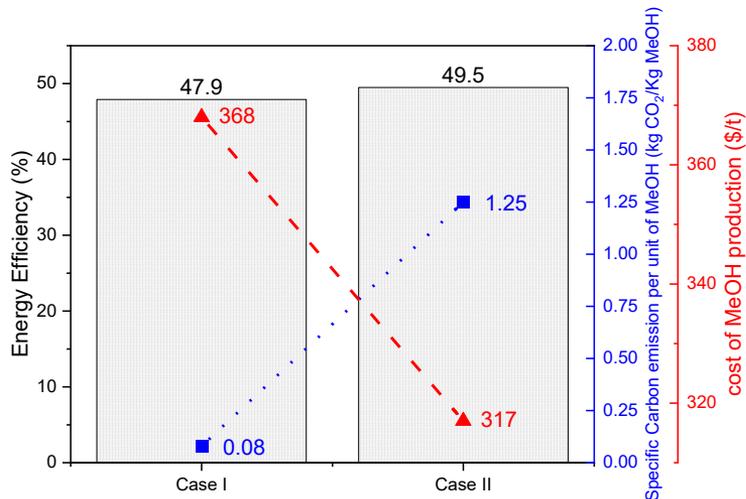

Figure 5: Techno-economic and environmental analysis.

4. Conclusion

In order to minimize the emissions of CO₂, the conversion of heavy vacuum residue to green fuel is proposed. In this study, comparative analysis between conventional

methanol production from natural gas and vacuum residue feed has been studied to produce 90 t/h with 99.9 wt. % purity. The overall results show that the proposed case II process has a lower energy consumption as compared to the conventional case I design. Moreover, case II is more economical compared to the natural gas-based case I since it has a lower cost of production. On the other hand, the proposed design has a higher specific carbon emission compared to the conventional steam reforming process.

Abstract

Process intensification has been widely researched in recent years because of its possibility of reducing process capital/operating cost and carbon emissions. It has been shown that implementing intensified/hybrid unit operations into the process industry can significantly improve the process performance. This work aims to develop an integrated process synthesis framework, which includes reaction synthesis for the reaction pathways selection and process intensification in the early stages of process synthesis-design. So, given the product one needs to produce, this framework could identify the optimal reaction pathway with its best separation route, which includes both traditional and hybrid/intensified equipment. The framework was applied to a dimethyl carbonate (DMC) production case study. Eight potential reaction pathways are identified, and three of them are further analyzed in separation synthesis.

Keywords: process synthesis, intensification, reaction synthesis.

1. Introduction

Process intensification is defined as a set of innovative solutions, which aims to improve the whole process performance, such as lower capital/operating costs, minimizing waste, and carbon emissions. As a potential method for process improvement, identifying and applying process intensification will be critical. Lutze *et al.* (2013) proposed a phenomena-based methodology to identify and incorporate intensified equipment options into process synthesis. Tula *et al.* (2017) further integrated the phenomena-based methodology into a process synthesis framework to identify sustainable process flowsheets, including hybrid/intensified unit operations. Furthermore, researchers have evaluated different hybrid distillation configurations, and the results show potential energy savings up to 30% and capacity enhancement of 20%. Bhargava *et al.* (2019) indicated that the intensified equipment, e.g., dividing wall column, has 20-30% lower capital cost than conventional distillation systems. Applying intensification in the early stages of process design, e.g., separation synthesis, is one potential way to generate sustainable process flowsheets with higher energy efficiency and lower environmental impact. However, this method is usually applied for generating sustainable processes with a given reaction pathway without considering the possibilities of different raw materials. Generally, to produce a given target product, multiple reaction pathways are available, and each reaction pathway leads to different downstream processes. To identify the best process to produce the target product, not only process intensification but also different feasible reaction pathways should be considered. In this work, an integrated process synthesis framework including reaction synthesis and separation synthesis is proposed to identify the best processing route for chemical production.

2. Framework

The three-stage integrated process synthesis framework is shown in Figure 1. In stage 1, reaction synthesis is applied to identify novel reaction pathways with potential lower environmental impact and separation cost. Here, the input is either raw materials or target products so that the forward synthesis or retrosynthesis model can be used to generate multiple novel reaction pathways. In stage 2, with different identified novel reaction pathways, the downstream separation synthesis is applied to find its corresponding optimal process flowsheets. In stage 3, the identified process is designed and verified using rigorous models. A detailed description of reaction synthesis and separation synthesis is provided in the following sections.

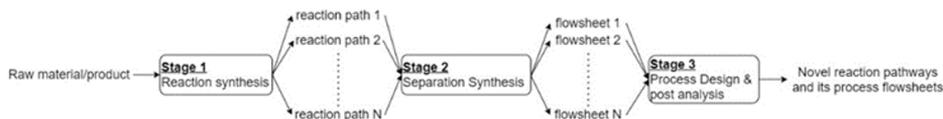

Figure 1. Integrated framework for process synthesis problem

2.1. Reaction Synthesis

Reaction synthesis was initially developed to assist organic chemistry and pharmaceutical research. The task of reaction synthesis is to identify an optimal reaction path to produce a product (retrosynthesis) or utilize the raw material (forward synthesis). Given the target product, the retrosynthesis model can reversely identify different starting materials. Generally, reaction synthesis methods can be classified into logic-centered approach, direct associative approach (Nishida *et al.*, 1981), and data-driven approach (Coley *et al.*, 2017). In this work, a data-driven approach-based reaction synthesis framework is used, which is shown in Figure 2. First, a specific target product or material is given to the reaction synthesis model. In step R1, a constructed retrosynthesis or forward synthesis tool is applied for reaction path prediction. The tool uses a neural network to find the reaction template where the product/reactant has the highest structural similarity to the input molecule. Then, these identified templates are used to predict the reaction pathways. In this way, multiple feasible reaction pathways, including the predicted and external literature pathways, are generated. In step R2, based on the identified reaction pathways, a rule-based screening method is applied to select the optimal reaction pathways. The screening method includes the following rules/conditions:

- 1) Viable reactants that have a good production pipeline.
- 2) Reactions that have lower absolute reaction enthalpy values are preferred.
- 3) Toxicity for reaction i : $LC50_i = \min\{LC50_{i,j}\}$, j represents component j . Reactions that have higher LC50 are preferred.
- 4) Separation driving force of reaction i : $DF_i = \prod_{j,k} DF_{i,jk}$, jk represent binary components j and k . Reactions with a higher DF value are preferred as they may be easier for separation.
- 5) Economic viability.

2.2. Separation Synthesis

The separation synthesis framework utilizes the thermodynamic insight-based process synthesis method by Tula *et al.* (2015). It has six steps (Figure 3): problem definition, problem analysis, feasible separation techniques identification, process alternative generation, process ranking, and design/verification. In step 1, the raw materials,

products, inlet conditions, and product purity specifications are specified. In step 2, azeotropic/eutectic analysis is performed, and binary ratios of pure component properties are calculated. In step 3, based on the data from the analysis step and predefined selection rules, all feasible separation techniques are identified. Here, conventional unit operations and recently developed hybrid/intensified separation techniques, including distillation-membrane, distillation-adsorption, distillation-crystallization, and membrane-crystallization, dividing wall column, are considered in identifying the feasible separation techniques. In step 4, based on the identified superstructure of separation techniques, all the feasible process alternatives are generated. In step 5, a ranking algorithm is applied to evaluate all the process alternatives. Here, all the processes are ranked based on their process energy indices, which is the summation of the estimated energy consumption of each unit operation. For example, the energy consumption for distillation and hybrid distillation is estimated based on first principle-based models (Lange, 2017) as shown in Equations (1) and (2). Energy consumption for the other unit operations is based on enthalpy balances (Equation (3)). After the evaluation step, the processes with lower process energy indices are selected. Finally, these top processes are further evaluated using rigorous models. In this way, the method identifies the best process alternatives and their optimized design/operating conditions.

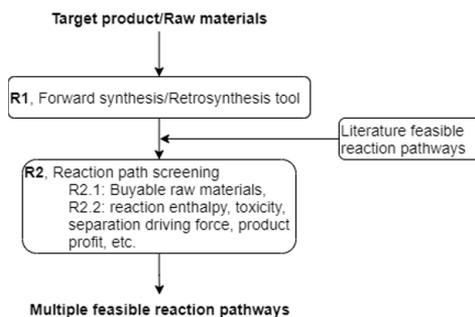

Figure 2. Framework for reaction synthesis.

$$Q_d = 57 \times \sum_i \frac{w_i}{\Delta T_i} \quad (1)$$

$$Q_{dhs} = \eta \times Q_d \quad (2)$$

$$Q_{hs} = H_{out}N_{out} - H_{in}N_{in} \quad (3)$$

Where Q_d is the reboiler duty; w_i is the inlet mass fraction of component i ; ΔT_i is the atmosphere boiling point different between component i and $i + 1$ (ranked based on boiling point); Q_{dhs} is the reboiler duty for distillation hybrid separation techniques; η is an constant coefficient; Q_{hs} is the heat duty for the other separation techniques; H_{out} and H_{in} are the enthalpy at outlet and inlet conditions; N_{out} and N_{in} are the outlet and inlet flowrates.

3. Case Study

The developed framework is applied to a DMC production case study. This case study aims to find the best reaction pathway and its separation route for DMC production. First, reaction synthesis (Section 3.1) is applied to generate and select the top reaction

pathways. Next, the selected top reaction routes are given to the separation synthesis (Section 3.2) step to determine the optimal separation flowsheet.

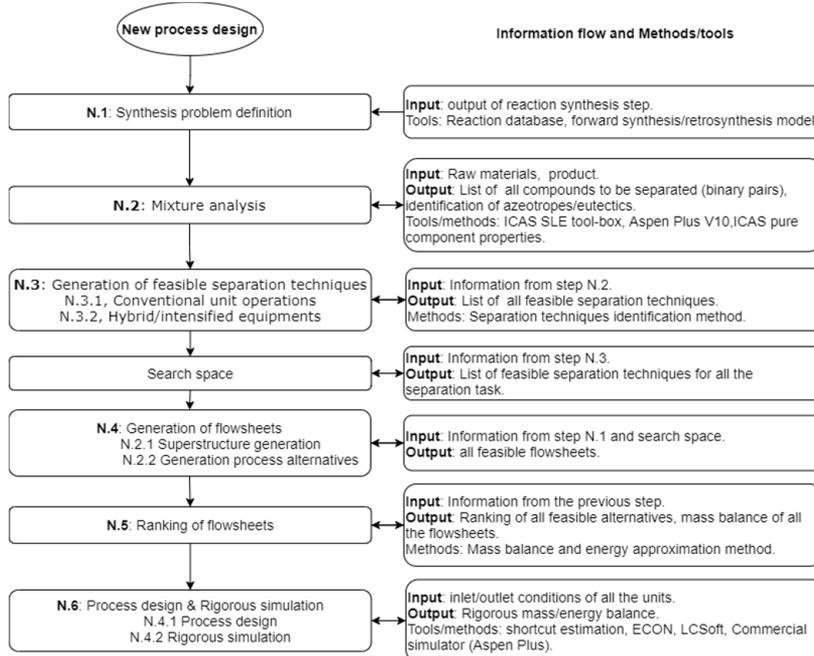

Figure 3. Framework for separation synthesis.

3.1. Reaction Synthesis

In this step, the retrosynthesis tool ASKCOS is applied to generate different feasible reaction pathways (github.com/ASKCOS). To maintain good prediction accuracy, default settings are used to generate these potential reaction pathways. A total of eleven reactions are generated, including eight reactions from ASKCOS and three from literature (Kongpanna *et al.*, 2015). After applying the rule-based approach, three of these reactions routes violate the first rule, which leads to eight reactions pathways for further screening. Table 1 shows the eight reactions and calculated/estimated reaction enthalpy, toxicity, and separation driving force. Based on the criteria in Section 2.1, the top three are reaction routes 3, 4, and 5, which are sent to separation synthesis for further analysis.

Table 1. Potential feasible reactions for DMC production.

No.	Reactants		Products		ΔH	LC50	DF
1	CH ₃ OH	C ₂ H ₃ ClO ₂	C ₃ H ₆ O ₃	HCl	0.88	47.46	0
2	CH ₃ OH	CH ₄ N ₂ O	C ₃ H ₆ O ₃	NH ₃	109.99	129.51	0
3	CH ₃ OH	CO ₂	C ₃ H ₆ O ₃	H ₂ O	-22.9	129.51	0
4	CH ₃ OH	C ₃ H ₄ O ₃	C ₃ H ₆ O ₃	C ₂ H ₆ O ₂	-22.05	129.51	0
5	CH ₃ OH	C ₃ H ₆ O ₃	C ₃ H ₆ O ₃	C ₃ H ₈ O ₂	26.67	129.51	0
6	CH ₃ OH	CO ₂	C ₃ H ₆ O ₃	H ₂ O	-305.7	129.51	0
7	CO	CH ₃ ONO	C ₃ H ₆ O ₃	NO	-189.6	63.67	1
8	CH ₃ OH	CCl ₂ O	C ₃ H ₆ O ₃	HCl	-70.75	128.14	0

3.2. Separation Synthesis

Separation synthesis is performed to produce 56.4 kmol/h of DMC using the identified three mechanisms. The raw materials requirements, inlet conditions, and product specifications are shown in Table 2. In the mixture analysis step, DMC/methanol and

DMC/water are identified as binary azeotropes. Based on pure component and mixture analysis, all feasible separation techniques are identified. Table 3 shows an example of all the feasible separation techniques for reaction 3.

Table 2. Inlet conditions for separation synthesis.

		Reaction 3	Reaction 4	Reaction 5
CH ₃ OH	kmol/h	56.4	56.4	56.4
C ₃ H ₆ O ₃	kmol/h	46.8	56.4	56.4
H ₂ O	kmol/h	46.8	-	-
C ₃ H ₄ O ₃	kmol/h	-	18.2	-
C ₂ H ₆ O ₂	kmol/h	-	46.8	-
C ₃ H ₆ O ₃	kmol/h	-	-	18.2
C ₃ H ₈ O ₂	kmol/h	-	-	46.8
Pressure	bar	10		
Purity specification	mol%	CH ₃ OH, C ₃ H ₆ O ₃ : 99.5 mol%		

Table 3. Feasible separation techniques for methanol/DMC and DMC/water.

Binary Mixture	Feasible Separation Techniques
Methanol/DMC	Membrane, adsorption, distillation-membrane, distillation-adsorption, extractive distillation
DMC/water	Azeotropic distillation, membrane, adsorption, distillation-membrane, distillation-adsorption

A total of 16, 127, and 166 process alternatives are generated for reactions 3, 4, and 5, respectively. All the alternatives are ranked based on their process energy indices. For each reaction pathway, the top two process alternatives are selected for rigorous simulation. Figures 4 and 5 show the flowsheets of these top selected process alternatives. Figure 6 compares the simulation results of all the top alternatives with respect to utility/capital cost and process environmental factors like carbon footprint and global warming potential (GWP). From Figure 6, the process alternative from reaction pathway 4 has the lowest utility, capital cost, and environmental impact compared to the top alternatives from other pathways. Reaction pathway 3 has two azeotropes, which leads to higher separation cost and carbon emissions.

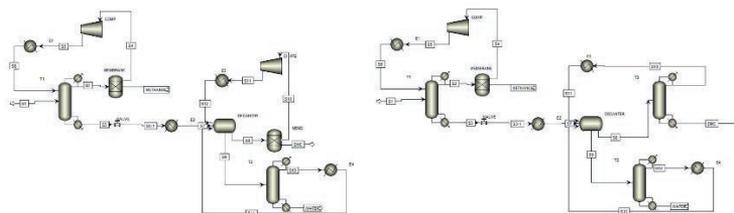

Figure 4. Top two separation configurations for reaction 3 (from left to right R3_P1, R3_P2).

4. Conclusions

An integrated process synthesis framework is developed to identify the best process flowsheet, including both reaction synthesis and separation synthesis. Given the product compound, the reaction synthesis generates multiple feasible reaction pathways, while the separation synthesis identifies the best downstream separation flowsheet, including intensified/hybrid separation techniques. The framework was applied to a DMC production case study. The results show that the best pathway for DMC production is using propylene carbonate and methanol as reactants with distillation-membrane and

dividing wall column for separation, which has 20% lower operating cost than the conventional extractive distillation process.

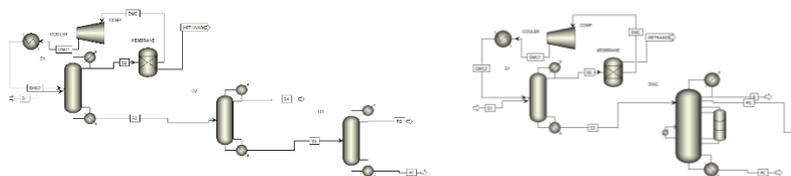

Figure 5. Top two separation configurations (from left to right R4(5)_P1, R4(5)_P2) for reaction 4 and 5 (similar reactants and byproducts, which leads to the same top two separation flowsheets).

Macroalgae-based integrated biorefinery for hydrocolloids, chemicals and advanced biofuels production

Andrés I. Casoni, Alejandro H. Pedrozo, Fernando D. Ramos, Vanina Estrada,
M. Soledad Diaz*

Planta Piloto de Ingeniería Química- PLAPIQUI (UNS-CONICET), Camino la Carrindanga km. 7, Bahía Blanca (8000), Argentina

sdiaz@plapiqui.edu.ar

Abstract

In this work, we address the simultaneous design of an integrated macroalgae-based biorefinery and its heat exchanger network for the production of alginates, high added-value chemicals and advanced biofuels. We apply a superstructure approach, which is formulated as a mixed integer nonlinear programming (MINLP) model. The resulting MINLP model has more than 53000 constraints and continuous variables and 14000 discrete variables. Net present value is the objective function. Numerical results show that heat utility costs are reduced by 41 % due to heat integration, as compared to a base case, and the production of alginates and dimethyl-isosorbide (DMI) via sorbitol, as well as methane as biofuels are selected in the optimal scheme.

Keywords: MINLP, Heat Exchanger Network, Macroalgae biorefinery.

1. Introduction

The use of macroalgae in the biorefinery concept is known to positively contribute to the environmentally friendly production of bioproducts (Zapata-Boada et al., 2021). Despite recent contributions (González-Gloria et al., 2021; Kostas et al., 2021), there is still a gap in the understanding of using macroalgae species to obtain chemical products industrially (Sudhakar et al., 2019).

Alginates are a family of polysaccharides composed of mannuronic and guluronic which constitute the main commercial product from brown macroalgae with a wide range of applications in the food, cosmetic, pharmaceutical and nutraceutical industries. Currently, alginate is commercially produced in USA, Japan, China, France, and Norway (Gomez et al. 2009). The giant kelps *Macrocystis pyrifera* and *Lessonia* sp. (Laminariales, Phaeophyceae) are brown macroalgae widely distributed throughout the cold water of the Argentinean Patagonia, with great potential to be sustainably exploited (Zaixso and Boraso, 2015) for hydrocolloids, materials, chemicals and biofuels integrated production (Pedrozo et al., 2021; Ramos et al., 2021).

In this work, we propose a mixed-integer nonlinear programming (MINLP) model for the simultaneous plant design and heat exchanger network synthesis of a macroalgae-based integrated biorefinery for alginate, chemicals and advanced biofuels. In previous work, we formulated a biorefinery model (Casoni et al., 2020) for the production of the platform molecule isosorbide, biogas and fertilizers from the brown macroalgae. Isosorbide is used to obtain several final products that include a flame retardant, a biopolymer, a biosolvent

(dimethyl isosorbide) and a drug for heart disease (isosorbide dinitrate). In the present work, the potential production of alginate and the sequential production of hydrogen and methane through two-stage anaerobic digestion is included, to enhance macroalgae biomass valorisation and advanced biofuels production.

2. Process Description

We consider an integrated biorefinery potentially based on two species of macroalgae, alternatively, on corn starch that can be raw materials for sorbitol production by acid hydrolysis. Also, sorbitol can be directly bought from the market. This compound is subsequently transformed into isosorbide, a platform molecule. This molecule may be converted into different products: a biopolymer, a flame retardant, a drug for heart disease and a biosolvent (further details can be found in Casoni et al., 2020). Alginate can also be produced from macroalgae biomass. Figure 1 shows a simplified scheme with the different process alternatives embedded within the superstructure presented in this paper.

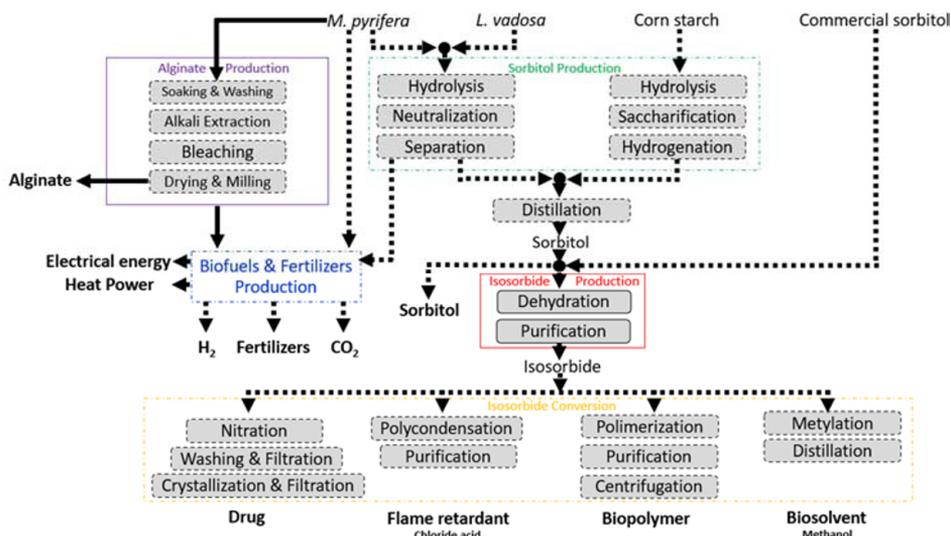

Figure 1. Simplified superstructure of process alternatives showing the five considered sections: Alginate Production, Sorbitol Production, Isosorbide Production, Isosorbide Conversion, and Biofuels and Fertilizers Production. Potential products of the integrated biorefinery are shown in bold. Chloride acid and methanol are byproducts.

A detailed description of Alginate Production Section is described hereunder. As a first step, macroalgae are treated with formaldehyde (FAL) 0.1% wt. in a 0.086 algae-to-FAL ratio in a soaking reactor. Then, the mixture is filtered to recover macroalgae biomass, which is washed using HCl 0.38 % wt., in a 0.038 HCl-to-algae ratio and subsequently filtered. The pre-processed biomass is mixed in an extraction reactor with a hot alkali solution (80 °C) of Na₂CO₃ 10 % wt. in a 0.91 algae-to-Na₂CO₃ ratio. A water stream is fed to this unit to dilute the solution to reach an 18.68 water-to-algae ratio. The stream containing sodium alginate (Na(alg)) is diluted in a reactor with water at 70 °C in a 141.15 water-to-Na(alg) ratio. The outlet stream is filtered in a rotating vibrating filter using expanded lava as filter aid in a 0.94 perlite-to-Na(alg) ratio. The residual algae biomass is sent to the Biofuels and Fertilizers Production Section, while the process stream composed of Na(alg) and water is fed to a CaCl₂ reactor. In this reactor, a solution of

CaCl₂ 10 % wt., is fed in a 1.81 Na(alg)-to-CaCl₂ ratio to transform sodium alginate into calcium alginate (Ca(alg)). This stream is then filtered to separate NaCl with water and the Ca(alg) is fed into a bleaching reactor to bleach it using NaClO 5 % wt. in a 0.0076 NaOCl-to-Ca(alg) ratio. Next, the stream is fed to an acid reactor where it is mixed with HCl 3.6 % wt. in a 0.195 HCl-to-Ca(alg) ratio. In this reactor, the calcium alginate is transformed into acid alginate (H(alg)), which is fed into a belt press unit to separate as much water as possible. The stream containing H(alg) and water is fed into a Na₂CO₃ reactor where it is mixed with Na₂CO₃ 10 % wt. in a 0.29 Na₂CO₃-to-H(alg) ratio. This treatment converts the H(alg) into Na(alg), which is dried at 50 °C and milled to obtain the final product: 90% sodium alginate.

3. Mathematical Model

We formulate a Mixed-Integer Nonlinear Programming (MINLP) model to address the simultaneous optimal design of the integrated macroalgal based biorefinery and its heat exchanger network through a superstructure representation as shown in Eqs. (1.1)-(1.2). The objective function is net present value maximization (NPV) (Eq. (1.1)), to consider a detailed economic evaluation. Equation (1.2) is the set of linear equations corresponding to process design and includes mass balances of reactive and nonreactive units, power consumption of process units, and Big-M constraints to model conditional units. Equation (1.3) refers to the set of nonlinear constraints of process synthesis, for instance, equipment design calculations and capital cost correlations. In this work, we have also embedded the potential matches between process streams and utilities to synthesize the heat exchanger network within the proposed superstructure, following Yee and Grossmann (1990), to simultaneously address the optimal heat exchanger network (HEN) design within the biorefinery design problem. Equation (1.4) is the set of linear equations, which includes global overall heat balances for hot and cold streams, temperature assignments, and logic constraints for stream matches and temperature differences. Equation (1.5) represents HEN nonlinear equations, such as heat balances at temperature stages, and capital cost correlations. Finally, Eq. (1.6) is the set of connection equations to link process design variables with HEN variables. It should be noted that the HEN model requires process flowrates from which determines utility and capital costs of heat exchanger units.

$$\max NPV = f(x) \tag{1.1}$$

$$\text{Process design} \left\{ \begin{array}{l} A_1x + A_2y \leq a \end{array} \right. \tag{1.2}$$

$$g(x, y) \leq 0 \tag{1.3}$$

$$\text{Heat exchanger network} \left\{ \begin{array}{l} B_1w + B_2z \leq b \end{array} \right. \tag{1.4}$$

$$h(w) \leq 0 \tag{1.5}$$

$$\text{Connection eqns.} \left\{ \begin{array}{l} C_1x = C_2w \end{array} \right. \tag{1.6}$$

$$x \in \mathbb{R}^n, y \in \{0,1\}^m$$

$$w \in \mathbb{R}^{n'}, z \in \{0,1\}^{m'}$$

where x and w are continuous variables associated with process and heat exchanger network design, respectively; y are binary variables related to the technology selection; and z are binary variables to model heat exchanger matches.

4. Numerical Results

A fixed production of 920 t/y of sorbitol and 300 t/y of alginate has been considered, taking into account current market demand. The resulting MINLP model is formulated in GAMS 35.2 (McCarl et al., 2017). The mathematical model for the simultaneous process and heat exchanger network design includes 53423 constraints, 53554 continuous variables, 13988 discrete variables. As initialization procedure, we first solve mass balances, and then, a model that includes heat balances, temperature assignments, and logic equations for stream matches and temperature differences. It should be noted that these equations are already linear, then no linearization procedures are required. This framework provides a suitable initial guess, which allows solving the MINLP problem in 26 seconds. We use DICOPT, with CONOPT and CPLEX as nonlinear and linear sub solvers, respectively (Grossmann et al., 2003). The optimal scheme includes the co-production of dimethyl-isosorbide (DMI) via sorbitol and alginate from the macroalgae *M. pyrifera*. Table 1 shows the main economic indicators for the optimal solution, and a base case where DMI is produced as sole product (no alginate production). The NPV of the optimal solution is 52.24 MM\$, representing an improvement of 17 %, with respect to the base case. Although the total capital cost increases by 57 % for the optimal design, it allows for producing alginates, improving the revenues by 28 %. These results show the benefits of co-producing alginates DMI and advanced biofuels.

Table 1. Main economic indicators.

	DMI and alginate	DMI
NPV (MM\$)	52.239	44.575
Investment (MM\$)	22.375	14.252
Revenues (MM\$/y)	22.232	17.409
Raw material cost (MM\$/y)	3.241	2.698

Regarding the heat exchanger network, numerical results indicate that utility costs are reduced by 41 % due to heat integration. The network includes 25 heat exchanger units. It is highlighted that the number of matches does not increase with respect to the case of using only utilities to satisfy energy requirements, and the optimal solution only requires cooling water as cooling utility. Furthermore, as the Alginate Production Section has a process stream that is fed to the Biofuels and Fertilizers Production Section, the energy production in this section increases in 133 %, with respect to the base case (no alginate production).

Due to uncertainties in alginate market demand, we performed a sensitivity analysis on the optimal technological route to assess the influence of the alginate plant capacity over the biorefinery NPV. In this sense, we compare the value of the economic objective function for the integrated biorefinery (alginate and DMI co-production) to a base case scenario in which alginate production is not included.

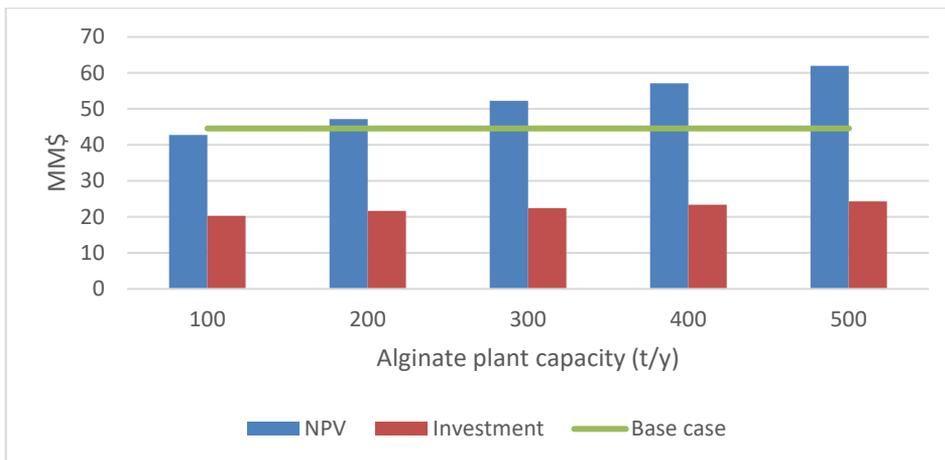

Figure 2. Sensitivity analysis of the alginate plant capacity.

As it can be seen in Fig. 2, alginate production is economically attractive if the alginate section capacity is higher than approximately 180 t/y due to the economies of scale (Roldán-San Antonio et al., 2021).

5. Conclusion

In the present work we propose an MINLP model for the sustainable production of alginates, chemicals and advanced biofuels based on macroalgae. The superstructure includes different process alternatives, as well as alternative process streams and utility streams matches for the simultaneous design of an integrated biorefinery and its heat exchanger network. The proposed model size increases more than two orders of magnitude with the inclusion of the design of its heat exchanger network and provides a decrease in energy consumption of 41% due to heat integration, with respect to a base case. The optimal configuration for NPV maximization includes alginates and DMI via sorbitol production, as well as energy production, which increases 133% due to the inclusion of the biofuels production section.

Abstract

This work details the development of a five-step workflow for design space determination of mesenchymal stem cell (MSC) cultivation. The workflow employs mechanistic models to represent system dynamics of MSC cultivation processes while introducing stochastic simulations to capture uncertainties. The developed workflow was applied to an MSC cultivation case study where seeding density and medium change ratio were selected as critical process parameters (CPPs), while the number of cells cultivated was specified as the sole critical quality attribute (CQA). Monod kinetics based modelling and stochastic simulation were used to determine a dynamically evolving probabilistic design space. The results were then visualized on a 2D map with probability contours. In the presented calculations, the optimal batch termination time was identified as Day 10, given a probability preference of 90 %. The results illustrated the need to account for both raw material and process/operation uncertainties and dynamics in design space determination for MSC cultivation.

Keywords: Cell therapy, stochastic simulation, quality by design, decision support.

1. Introduction

Mesenchymal stem cells (MSCs) are a promising cell therapy candidate due to their multipotency, self-renewability, and ethical compliance (Ullah et al., 2015). Today, MSCs are used in several cell therapies, creating a need to produce MSCs at scale while guaranteeing product quality. Despite ongoing research and developments into producing MSCs at scale, many challenges remain in ensuring the quality manufacturing of MSCs. In Lipsitz et al. (2016), managing the influence of raw material and process variability was identified as the key aspect in ensuring quality MSC manufacturing. Figure 1 provides a schematic representation of MSC cultivation where dynamic cell expansion and metabolism are performed under raw material and process/operation uncertainties.

One strategy that can be employed to ensure product quality at scale is the use of Quality by Design (QbD) framework (European Medical Agency, 2017). The core concept in the QbD framework is developing a systematic and science-based understanding of how materials and processes affect the final product quality. Once all relationships are established, an operation envelop can be identified where the product is guaranteed to be of acceptable quality. This operation envelope is also referred to as the design space

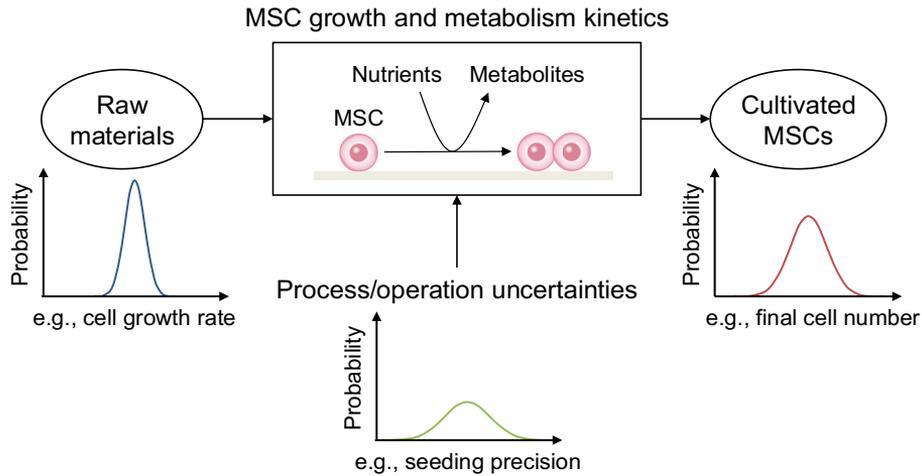

Figure 1. A schematic of an MSC cultivation process where cell expansion and metabolism occur under both raw material and process/operation uncertainties.

(García-Muñoz et al., 2015). In other words, the design space represents an operational envelope where critical process parameters (CPPs) satisfy all critical quality attributes (CQAs).

To apply the QbD framework for design space determination in MSC cultivation, the following aspects must be considered: 1) the time-dependent nature of the MSC cultivation, 2) the influence of raw material and process/operation uncertainties, 3) the lack of experimental data and the high cost of experiments. Inspiration can be drawn from Process Systems Engineering (PSE) to address these needs. For example, mechanistic models, often based on Monod kinetics, have been applied to describe the dynamics of cell growth and metabolism in therapeutic protein production (Badr et al., 2021). These models have also been used to describe MSC cultivation processes (Jossen et al., 2020). Combining stochastic simulations with mechanistic models can generate time-dependent data sets that capture raw material and operation uncertainties (Andersen et al., 2020). While the use of mechanistic models can also reduce the need for experimental data in determining a design space (García-Muñoz et al., 2015). To this end, a workflow that integrates these types of PSE tools with the QbD framework can address the specific needs for design space determination in MSC cultivation.

2. Proposed workflow

Figure 2 represents the proposed five-step workflow for design space determination in MSC cultivation.

2.1. STEP 1: CPP and CQA specification

This step specifies the CPPs and CQAs that are relevant to quality MSC cultivation. Ideally, the CPPs and CQAs should be specified based on fundamental relationships (e.g., stoichiometry). In practice, CPPs and CQAs will be based on expert opinion backed by available literature or experimental data. This is because the fundamental understanding that connects CPPs and CQAs in MSC cultivation is generally lacking, while literature data are sparse.

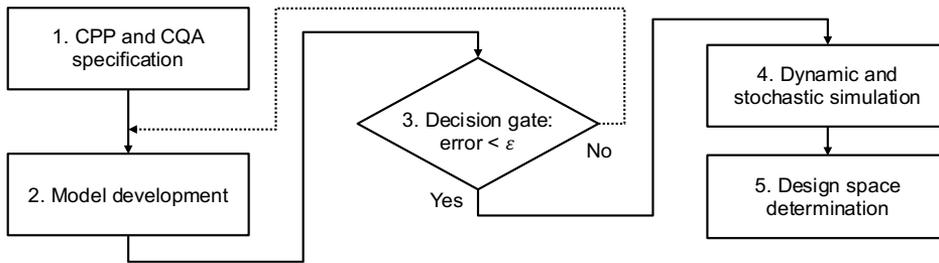

Figure 2. The applied workflow consisted of five steps to determine a design space and the optimal cultivation time.

2.2. STEP 2: Model development

In this step, the identified CPPs and CQAs are connected using a mechanistic model. In the context of cell cultivation, a mechanistic model will consist of a set of ordinary differential equations (ODEs), where empirical relationships such as Monod cell growth kinetics are used to describe state key relationships.

2.3. STEP 3: Decision gate

Through parameter estimation, the model is fitted to the available process data. The parameter estimation is performed by minimizing the error between the model output and the process data. The calculated error is then compared to a user-specified accuracy criterion (ϵ). If the error is less than ϵ , the workflow proceeds. Otherwise, the workflow reverts to Step 2.

2.4. STEP 4: Dynamic and stochastic simulation

Information required to determine a time-dependent probabilistic design space is produced in this step. First raw material and process/operation uncertainties are identified based on literature, experiments, or expert opinion. These uncertainties are then linked to specific parameters in the model developed in Step 2. Once the parameters are identified, the type of probability distribution they follow must be determined. This workflow assumes that all uncertain parameters follow a normal distribution, which is a typical assumption made in probabilistic design space determination (Ochoa et al., 2021). A stochastic simulation is then conducted by iteratively executing the model with the identified parameter sets. Each run will use a randomly sampled parameter set from the defined distribution, capturing the expected uncertainty. The time-dependent output generated by the stochastic simulations can then be compared against the CQAs to determine the probability that a given run satisfies all CQAs. Repeating this process for all combinations of CPPs enables the generation of time-dependent probability information required for design space determination.

2.5. STEP 5: Design space determination

The information from Step 4 is then used to determine and visualize a dynamic and probabilistic design space. If the number of CPPs is limited to two, then a contour map is used for design space visualization. In this case, the X-Y axes are the two given CPPs, and the contours represent the predicted probability that a given batch meets all CQAs. This visualization is performed for each day of cell cultivation. A decision-maker can make an informed decision about the ideal combination of CPPs and cultivation time based on their probability preference. If the number of CPPs is greater than two, geometric projection could be used to visualize the design space (García-Muñoz et al., 2015).

3. Case Study

The proposed workflow was applied to an MSC cultivation process described by Jossen et al. (2020). The source MSCs were derived from the abdomen of a healthy and post-chemotherapy donor and cryopreserved, respectively. The frozen MSCs were thawed and precultured before carrying out the main culture. The main cultivation was performed on a T₂₅-flask as a batch operation for 11 days. An initial culture media volume of 5 mL was used with two partial medium changes of 40 % and 60 % carried out on days 4 and 8, respectively.

3.1. STEP 1: CPP and CQA specification

Based on literature observations and expert opinion, the following CQAs and constraints were specified. The final viable cell number was specified as the sole CQA as this variable was linked to cell therapy product quality (Redaelli et al., 2012). The lower cell limit was specified as 1.4×10^6 cells to meet the product requirements, while the upper limit of 1.7×10^6 cells was set to prevent genome instability due to excessive cell expansion (Redaelli et al., 2012). In addition, a maximum ammonia concentration of 2.0 mmol/L was specified as a constraint (Schop et al., 2009). MSC seeding density was specified as a CPP based on previous experimental observations (Kino-oka, 2000). Medium change ratio was identified as the other CPP as medium change both replenished nutrient (e.g., glucose) needed for cell growth and removed metabolic products (e.g., lactate, ammonia).

3.2. STEP 2: Model development

An ODE based mechanistic model was developed to represent the MSC cultivation process. The model described the cell growth based on the Monod equation, which was modified to consider growth inhibition due to excessive cell-cell contact. The overall ODEs were formulated as follows:

$$\mu = \mu_{\max} \cdot \frac{C_S}{K_S + C_S} \cdot \frac{K_P}{K_P + C_P} \cdot \frac{X_{\max} - X_A}{X_{\max}} \quad (1)$$

$$t_{\text{lag}} = \beta \cdot \ln\left(\frac{X_0}{X_0^*}\right) + \gamma \quad (2)$$

$$\frac{dN_A}{dt} = \mu \cdot N_A \quad (t \geq t_{\text{lag}}) \quad (3)$$

$$V \frac{dC_X}{dt} = \frac{Y_{X/S}}{Y_{\text{cell}/S}} \cdot \mu \cdot N_A + p_X \cdot N_V \quad (4)$$

where β and γ , empirical parameters; μ , specific growth rate; μ_{\max} , maximum specific growth rate; C_X , metabolite concentration; K_X , Monod constant; N_A , attached cell number; N_V , viable cell number; P , metabolic product (i.e., lactate, ammonia); p_X , specific metabolite consumption/production rate; S , nutrient (i.e., glucose); t , time; t_{lag} , lag time; V , working medium volume; X_0 , seeding density; X_0^* , 1 cell/cm²; X_A , cell density on a bottom surface; X_{\max} , maximum cell density on the surface; $Y_{\text{cell}/S}$ and $Y_{X/S}$, nutrient consumption coefficients for cell mass production and metabolite consumption/production, respectively.

3.3. STEP 3: Decision gate

This step ensured the developed model adequately described cell number (i.e., CQA) and ammonia concentration (i.e., constraint). The model was fitted by parameter estimation, where the Nelder-Mead method was used to minimize the normalized root mean square error (NRMSE) between the predicted values and the literature observations (Jossen et al., 2020). The accuracy criterion (ϵ) was set as 10 % and 20 % for the cell number and

ammonia concentration, respectively. The NRMSE was calculated to be 5.8 % and 17 % for the cell number and ammonia concentration, respectively. As such, the workflow was able to proceed to the next step.

3.4. STEP 4: Dynamic and stochastic simulation

Based on literature, maximum specific growth rate (μ_{\max}) and maximum cell density (X_{\max}) were identified as model parameters that could vary due to raw material and process/operation uncertainties (Jossen et al., 2020; Schop et al., 2009). The maximum specific growth rate was determined as 2.71×10^{-2} /h (based on the parameter estimation in Step 3), while the standard deviation was set to 1.59×10^{-3} /h based on literature (Higuera et al., 2009). For the maximum cell density, the average (6.5×10^4 cells/cm²) and standard deviation (2.0×10^3 cells/cm²) were identified from the literature (Jossen et al., 2020).

The model developed in Step 2 was then executed 1,000 times using uncertain model parameters randomly sampled from their respective probability distributions. The model generated time-dependent profiles of the viable cell number (i.e., CQA) and the ammonia concentration (i.e., constraint). The time-dependent outputs of the 1,000 runs were then compared to the CQA and constraint requirements between days 8 and 11 to identify the time-dependent probability that a given run would meet all requirements (CQA and constraint). This process was repeated on 10,000 CPP combinations that uniformly covered the CPP ranges (i.e., the seeding density range: 6.0×10^3 – 1.0×10^4 cells/cm², medium change ratio range: 0.2–1.0).

The default *scipy.integrate.solve_ivp* solver with the BDF method was used for solving the ODEs, and the algorithm was implemented in Python 3.8. The total CPU time for the design space determination was ca. 15 h using an Apple M1 processor with 16 GB RAM.

3.5. STEP 5: Design space determination

Figure 3 visualizes the probabilistic design space between days 8 to 11 on a 2D map, where seeding density and medium change ratio (CPPs) are the X-Y axis, respectively, while contours are the predicted probability. The acceptable minimum probability of 90 % was adopted in this case study, in line with literature (García-Muñoz et al., 2015). Figure 3 shows that Day 10 provides the broadest design space for the adopted probability preference. Further investigation found that before Day 8, no CPP combination resulted in at least 90% of the batches producing 1.4×10^6 cells (lower bound of the CQA). In fact, most CPP combinations resulted in no batch reaching this criterion (visualized as a black region). On Day 9, CPP combinations with high seeding densities and medium change ratios resulted in over 90 % of the batches producing more than 1.4×10^6 cells (visualized as a white region). The underlying reason for this observation is that 1) high seeding densities provide a head start, and 2) a high change ratio accelerates cell growth due to the removal of inhibitors. However, as the cultivation progressed, the same high seeding

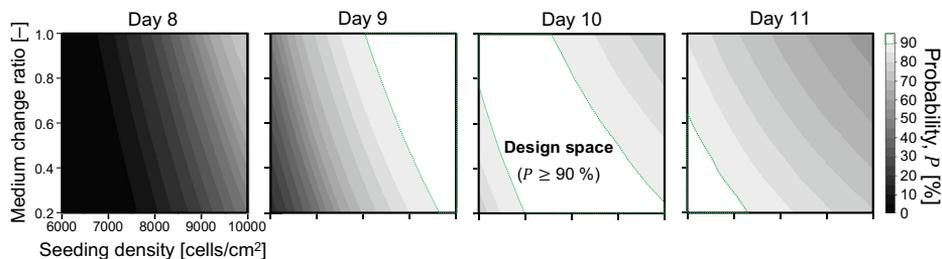

Figure 3. Visualized time evolving probabilistic design space between on days 8–11.

density and medium change ratio combinations resulted in batches exceeding 1.7×10^6 cells, which was the upper bound of the CQA requirement. This effect was observed as an enlarging grey area on the top righthand side of the design space on Days 10 and 11. To this end, Day 10 was the ideal cultivation termination date where the broadest set of CPP combinations produced at least 90 % of the batches between the 1.4 – 1.7×10^6 cells. In this design space determination, the ammonia constraint was found to be non-bounding.

4. Conclusions

This work detailed the development and application of a workflow that determined a dynamic and probabilistic design space for MSC cultivation. In the case study, the proposed workflow captured the dynamics of the MSC cultivation process by a Monod kinetic based mechanistic model. Raw material and process/operation uncertainties were then incorporated into the model by linking these uncertainties to the model parameters (maximum specific growth rate and maximum cell density). A dynamically evolving probabilistic design space was then determined using the QbD framework. The design space was then visualized over days 8–11 of the cultivation with the aid of an X-Y contour map. The contour map was then used as an early-stage decision support tool to determine the optimal cultivation time. In the future, this workflow can be further expanded to incorporate more realistic probability estimations and be developed into a detailed methodology applicable to a more complex case study.

Abstract

This case study considers the deterministic global optimization of a multistage separation process using melt crystallization. A detailed model of the crystal growth process is replaced by a computationally more efficient data-based surrogate trained on simulation data from the detailed model. The resulting optimization problem is solved with the deterministic global solver MAiNGO using a reduced space formulation. The results demonstrate that this is a feasible approach for identifying globally optimal designs for this complex separation process.

Keywords: deterministic global optimization, layer melt crystallization, surrogate modeling, reduced space formulation, multistage crystallizer network

1. Introduction

Layer melt crystallization is a thermal separation process with very high theoretical selectivity in case of eutectic mixtures, lower required energy for the phase change than e.g. distillation, and the ability to treat heat sensitive substances (Ulrich et al., 1996). Crystal layers that grow on a cooled surface incorporate impurities from the melt if the growth rate is not extremely small (Wintermantel, 1986), which may necessitate additional recrystallization steps in a multistage process to achieve a desired purity. The layer growth process determines the separation efficiency of each stage and can be described by complex dynamic models. However, including differential equations in mathematical process optimization is computationally unfavorable, and using strongly simplified correlations for the separation efficiency could lead to significant prediction errors and suboptimal design decisions. Instead, an artificial neural network (ANN) that reproduces the separation efficiency accurately is used here as a surrogate for a dynamic model adapted from (Beierling et al., 2014). The surrogate model is trained on simulation data from the dynamic model and combined with mechanistic equations to create a hybrid overall process model that is used for the optimization of multistage crystallizer networks. In order to obtain certified globally optimal designs, the deterministic global solver MAiNGO (Bongartz et al., 2018) is used to solve a reduced space formulation of the optimization problem, i.e. a formulation in which the dimensionality of the problem is not increased by intermediate variables, in particular those appearing in ANNs. The structure of the following sections is as follows: The original model, the surrogate approach, and the optimization problem are presented in Section 2, results are summarized in Section 3, and a conclusion is given in Section 4.

2. Methods

2.1. Melt crystallization model

The layer melt crystallization model used here is adapted from the model presented in (Beierling et al., 2014). Beierling et al. (2014) consider a falling film crystallization process. In this process, the liquid mixture, i.e. the melt, continuously flows down the cooled inner surface of a tube and is pumped back to the top. A crystal layer grows on the cooled inner surface of the tube until a desired layer thickness is achieved and the remaining liquid is removed from the tube. In the next step, the crystal layer is melted by increasing the temperature of the tube and collected separately. Beierling et al. (2014) consider systems with eutectic solid-liquid equilibria, for which no impurities are embedded in the crystals themselves. However, if the growth rate is not extremely small, the crystal layer will incorporate impurities from the melt through liquid inclusions.

In a mixture containing components A and B, where A is the crystallizing component, the distribution of component B between melt and crystal layer is described by the following set of equations (Wellington and Wintermantel, 1991; Beierling et al., 2014).

$$\frac{\partial m_B^{\text{cr}}}{\partial m^{\text{cr}}} = k_{\text{diff}} w_B^{\text{m}} \quad (1)$$

$$k_{\text{diff}} = e \phi^f \quad (2)$$

$$\phi = \frac{w_B^{\text{m}}}{1 - w_B^{\text{m}}} \left(e^{\frac{v \rho^{\text{cr}}}{\beta \rho^{\text{m}}}} - 1 \right) \quad (3)$$

Here, $\frac{\partial m_B^{\text{cr}}}{\partial m^{\text{cr}}}$ is the differential increase of mass of the impurity B in the crystal layer m_B^{cr} per increase of total mass of the crystal layer m^{cr} , $k_{\text{diff}} \in [0, 1]$ is the differential distribution coefficient, and w_B^{m} is the mass fraction of B in the melt. For $k_{\text{diff}} = 0$ there are no liquid inclusions in the crystal layer and for the theoretical limit case $k_{\text{diff}} = 1$, the crystal layer contains only liquid inclusions. The dimensionless number ϕ is used to correlate the properties of the melt with the differential distribution coefficient k_{diff} , using parameters e and f . The crystal growth rate is denoted by v , the mass transport coefficient at the crystal surface by β , and the densities of the crystals and the melt by ρ^{cr} and ρ^{m} , respectively.

Equation (2) is a heuristic expression introduced in (Beierling et al., 2014) and should only be used in a range that is supported by experimental data. Otherwise, it may produce non-physical values, e.g. values of k_{diff} larger than one for large values of ϕ and positive parameters e, f .

Using dimensionless variables Y^{m} and Y_B^{m} relating to the liquid phase

$$m^{\text{m}} := Y^{\text{m}} m_0^{\text{m}}, \quad m_B^{\text{m}} := Y_B^{\text{m}} m_{B,0}^{\text{m}}, \quad (4)$$

with total initial melt mass m_0^{m} and mass of B in the initial melt $m_{B,0}^{\text{m}}$, the model Equations (1)-(3) are rewritten as

$$\frac{\partial Y_B^{\text{m}}}{\partial Y^{\text{m}}} = e \left(\frac{w_B^{\text{m}}}{1 - w_B^{\text{m}}} \left(e^{\frac{v \rho^{\text{cr}}}{\beta \rho^{\text{m}}}} - 1 \right) \right)^f \frac{Y_B^{\text{m}}}{Y^{\text{m}}}, \quad w_B^{\text{m}} = w_{B,0}^{\text{m}} \frac{Y_B^{\text{m}}}{Y^{\text{m}}}, \quad Y_B^{\text{m}}(Y^{\text{m}}=1) = 1, \quad (5)$$

where $w_{B,0}^{\text{m}}$ is the mass fraction of B in the initial melt. Note that the classical freezing rate is obtained by $Y^{\text{cr}} := \frac{m^{\text{cr}}}{m_0^{\text{m}}} = 1 - Y^{\text{m}}$.

In the present study, an operating mode with constant crystal growth rates v is considered. Additionally, the constant values for $e, f, \rho^{\text{cr}}, \rho^{\text{m}}$ and β provided in (Beierling et al., 2014) for a mixture of n-dodecanal/iso-dodecanal are used, see Table 1.

Instead of using the solution of Equation (5) directly as a melt crystallization model, we introduce an effective differential distribution coefficient $k_{\text{diff}}^{\text{eff}}$ with

$$Y_B^{\text{m}} := (Y^{\text{m}})^{k_{\text{diff}}^{\text{eff}}}, \quad (6)$$

in analogy to layer melt crystallization with a constant differential distribution coefficient. The effective differential distribution coefficient is then a function $k_{\text{diff}}^{\text{eff}} = f(Y^{\text{m}}, w_{\text{B},0}^{\text{m}}, v)$ of the final liquid yield, the initial mass fraction of B, and the crystal growth speed. This function is approximated by a data-based surrogate $k_{\text{diff}}^{\text{eff}} \approx \hat{f}(Y^{\text{m}}, w_{\text{B},0}^{\text{m}}, v)$ as described in the subsequent sections. This strategy removes the differential equation (5) from the model in order to be able to apply deterministic global optimization for a multi-stage separation process, at the cost of introducing some approximation error.

2.2. Crystallizer network model

With the results from the previous section, the model for each melt crystallization stage $n = 1, \dots, N$ reads

$$\dot{m}_n^{\text{m}} = Y_n^{\text{m}} \dot{m}_{0,n}^{\text{m}}, \quad \dot{m}_{\text{B},n}^{\text{m}} = Y_{\text{B},n}^{\text{m}} \dot{m}_{\text{B},0,n}^{\text{m}}, \quad \dot{m}_n^{\text{cr}} = \dot{m}_{0,n}^{\text{m}} - \dot{m}_n^{\text{m}}, \quad \dot{m}_{\text{B},n}^{\text{cr}} = \dot{m}_{\text{B},0,n}^{\text{m}} - \dot{m}_{\text{B},n}^{\text{m}}, \quad (7)$$

$$Y_{\text{B},n}^{\text{m}} = (Y_n^{\text{m}})^{k_{\text{diff},n}^{\text{eff}}}, \quad k_{\text{diff},n}^{\text{eff}} = \hat{f}\left(Y_n^{\text{m}}, \frac{\dot{m}_{\text{B},0,n}^{\text{m}}}{\dot{m}_{0,n}^{\text{m}}}, v_n\right) \quad (8)$$

where \dot{m} -variables are time-averaged mass flows for the batch-operated stages. Each stage has two output flows: one for the remaining melt after crystallization $\dot{m}_n^{\text{m}}, \dot{m}_{\text{B},n}^{\text{m}}$ and one for the melted crystal layer $\dot{m}_n^{\text{cr}}, \dot{m}_{\text{B},n}^{\text{cr}}$.

The feed mass flows $\dot{m}_{0,n}^{\text{m}}, \dot{m}_{\text{B},0,n}^{\text{m}}$ for each stage $n = 1, \dots, N$ are calculated as

$$\dot{m}_{0,n}^{\text{m}} = \dot{m}_0 \beta_n^{\text{feed}} + \sum_{l=1}^N \dot{m}_l^{\text{m}} \beta_{l,n}^{\text{m}} + \sum_{l=1}^N \dot{m}_l^{\text{cr}} \beta_{l,n}^{\text{cr}}, \quad (9)$$

$$\dot{m}_{\text{B},0,n}^{\text{m}} = \dot{m}_{\text{B},0} \beta_n^{\text{feed}} + \sum_{l=1}^N \dot{m}_{\text{B},l}^{\text{m}} \beta_{l,n}^{\text{m}} + \sum_{l=1}^N \dot{m}_{\text{B},l}^{\text{cr}} \beta_{l,n}^{\text{cr}}, \quad (10)$$

and the overall network product flows $\dot{m}^{\text{m}}, \dot{m}^{\text{cr}}$ as

$$\dot{m}^{\text{m}} = \sum_{n=1}^N \dot{m}_n^{\text{m}} \beta_n^{\text{m,out}}, \quad \dot{m}^{\text{cr}} = \sum_{n=1}^N \dot{m}_n^{\text{cr}} \beta_n^{\text{cr,out}}, \quad (11)$$

$$\dot{m}_{\text{B}}^{\text{m}} = \sum_{n=1}^N \dot{m}_{\text{B},n}^{\text{m}} \beta_n^{\text{m,out}}, \quad \dot{m}_{\text{B}}^{\text{cr}} = \sum_{n=1}^N \dot{m}_{\text{B},n}^{\text{cr}} \beta_n^{\text{cr,out}}. \quad (12)$$

Here, $\beta_n, \beta_{l,n}$ are binary parameters that determine mass flow connections in the crystallizer network and $\dot{m}_0, \dot{m}_{\text{B},0}$ is the overall feed of the network.

Individual crystallizer network configurations, i.e. parameter sets for $\beta_n, \beta_{l,n}$, are selected from the superstructure depicted for $N=3$ stages in Figure 1. This results in 4 unique configurations for $N=2$ stages and 31 unique configurations for $N=3$ stages.

The product specifications are given as lower and upper bounds of the mass fraction of B in each product flow.

$$\dot{m}_{\text{B}}^{\text{m}} \geq w_{\text{B},\text{lo}}^{\text{m}} \dot{m}^{\text{m}} \quad (13)$$

$$\dot{m}_{\text{B}}^{\text{cr}} \leq w_{\text{B},\text{up}}^{\text{cr}} \dot{m}^{\text{cr}} \quad (14)$$

Table 1: Parameter specifications for the crystallizer model.

parameter	value	unit
ρ^{cr}	938.6 ^a	kg m ⁻³
ρ^{m}	844.24 ^a	kg m ⁻³
e	0.4903 ^a	1
f	0.3493 ^a	1
β	3.67 · 10 ⁻⁶ ^a	ms ⁻¹

^a(Beierling et al., 2014)

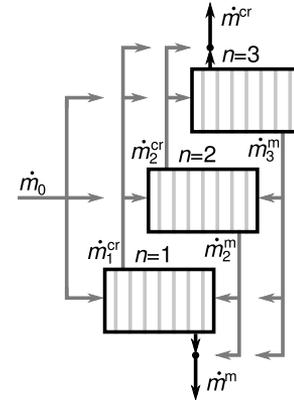

Figure 1: Superstructure for the crystallizer network for $N=3$ stages.

The crystallization model is valid only in a limited range for ϕ , i.e. in the range of measurement data for the original model in (Beierling et al., 2014), and for the mass fraction of B in the melt, i.e. for values sufficiently far away from the eutectic composition. These additional constraints are added to the model for each stage $n = 1, \dots, N$ as

$$\dot{m}_{B,n}^m \leq w_{B,\text{up}}^m \dot{m}_n^m \quad (15)$$

$$\dot{m}_{B,n}^m \left(e^{\frac{v_n \rho^{\text{cr}}}{\beta \rho^{\text{m}}}} - 1 \right) \leq \phi_{\text{up}} (\dot{m}_n^m - \dot{m}_{B,n}^m), \quad \dot{m}_{B,n}^m \left(e^{\frac{v_n \rho^{\text{cr}}}{\beta \rho^{\text{m}}}} - 1 \right) \geq \phi_{\text{lo}} (\dot{m}_n^m - \dot{m}_{B,n}^m) \quad (16)$$

Additionally, the crystal growth speeds on each stage $n = 1, \dots, N$ are limited by

$$v_n \in [v_{\text{lo}}, v_{\text{up}}]. \quad (17)$$

The objective function, taken from (Kunde et al., 2016), represents total annualized cost comprising storage tanks for each crystallization stage, a heat exchanger as the actual crystallizer vessel, as well as energy costs for cooling. Parameters are updated to the current case study and the objective function is adapted for mass flows and a variable crystal growth speed. The resulting objective function can be written in a condensed form as

$$J = \left(a_1 J_1^{0.65} + a_2 N J_1^{0.32} + a_3 J_2 \right) \text{€ year}^{-1}, \quad (18)$$

$$J_1 = \sum_{n=1}^N \dot{m}_n^{\text{cr}} v_n^{-1} \text{kg}^{-1} \text{m}, \quad J_2 = \sum_{n=1}^N \dot{m}_n^{\text{cr}} \text{kg}^{-1} \text{s}. \quad (19)$$

The model parameters used in the following case study are listed in Table 2.

Table 2: Additional parameter and domain specifications for the case study, $n = 1, \dots, N$.

parameter	value	unit	variable	domain	unit
$(\dot{m}_0, \dot{m}_{B,0})$	(0.3, 0.0234)	kg s^{-1}	Y_n^m	[0.05, 0.99]	1
$(w_{B,\text{up}}^{\text{cr}}, w_{B,\text{lo}}^{\text{m}})$	(0.01, 0.4)	1	$\dot{m}_{0,n}^m, \dot{m}_n^{\text{cr}}$	$[10^{-9}, 10]$	kg s^{-1}
$w_{B,\text{up}}^m$	0.90	1	$\dot{m}_{B,0,n}^m, \dot{m}_{B,n}^{\text{cr}}$	[0, 10]	kg s^{-1}
$(\phi_{\text{lo}}, \phi_{\text{up}})$	(0.01, 0.45)	1	v_n	$[0.01\beta, 0.5\beta]$	m s^{-1}
a_1	$1.030049 \cdot 10^1$	1			
a_2	$4.744830 \cdot 10^1$	1			
a_3	$1.273072 \cdot 10^5$	1			

2.3. Data generation and surrogate training

The data required for the training of the surrogate model $k_{\text{diff}}^{\text{eff}} \approx \hat{f}(Y^m, w_{B,0}^m, v)$ is obtained by numerical solution of Equation (5) using “ode45” in MATLAB 2019b and Equation (6). Data points are calculated on a grid for $Y^m \in \{0.01, 0.012, \dots, 0.99, 1\}$, $v \in \{0.005\beta, 0.01\beta, \dots, 0.5\beta, 0.501\beta\}$, and $w_{B,0}^m \in \{10^{-6}, 10^{-5}, 10^{-4}, 10^{-3}, 0.01, 0.02, \dots, 0.99\}$. In the crystallization model, feasible input values of f are constrained by bounds on $w_{B,0}^m$, ϕ , and v , see also Equations (15)-(17). In order to improve the data support on the boundary of this feasible region, an extended feasible region is defined by relaxing the corresponding constraints by a small amount. All data points that lie inside the extended feasible region are used for the surrogate training.

An ANN $\hat{f}(Y^m, w_{B,0}^m, v) = b^{[2]} + W^{[2]} \sigma(b^{[1]} + W^{[1]}(Y^m, w_{B,0}^m, v)^\top)$ comprising a single hidden layer with 20 neurons is used as a surrogate, where the activation function σ is the element-wise hyperbolic tangent. The surrogate is trained using the function “train” in MATLAB 2019b, with Levenberg-Marquardt backpropagation minimizing the mean squared error (MSE) and default options except for the minimum gradient set to 10^{-16} and the regularization parameter set to 10^{-11} .

The final MSE for all data points inside the feasible region is $2.0603 \cdot 10^{-08}$. Additionally, the corresponding regression results for the mass fraction of B in the melted crystal layer are shown in Figure 2. The relative error of predictions \hat{w}_B^{cr} for w_B^{cr} using the trained ANN is less than 1% for data points in the feasible region, including for values close to zero.

2.4. Optimization

In order to minimize the cost J of the process such that the model constraints Equations (7)-(19) are fulfilled, the optimization problem is solved as a reduced space formulation in the deterministic global solver MAiNGO (Bongartz et al., 2018). The general structure of the optimization problem is

$$\begin{aligned} \min_{x \in X = [x_{\text{lo}}, x_{\text{up}}]} \quad & J(x, y) \\ \text{s. t.} \quad & h(x, y) = 0, \\ & g(x, y) \leq 0, \\ & y = h_y(x), \end{aligned} \quad (20)$$

where $h_y(x)$ are explicit functions or sequences of functions of the selected optimization variables x that are used to substitute dependent variables y . The resulting optimization problem has a much smaller dimension compared to a problem where y are included in the optimization variables. In particular, this avoids introducing a large number of intermediate variables for the activations of the neurons in an ANN. MAiNGO solves reduced space formulations using automated methods for calculating relaxations for $h_y(x)$ in a branch-and-bound framework, as well as tailored relaxations for specific expressions such as the hyperbolic tangent appearing in ANNs (Schweidtmann and Mitsos, 2019). The optimization variables and bounds that are used in this case study are listed in Table 2. The optimization problem is solved as a non-linear program for each individual configuration selected from the superstructure in Figure 1. The problem is solved in MAiNGO v0.4.0 with subsolvers IPOPT and CLP with default options except for the absolute optimality gap, which was reduced to 10^{-6} such that the algorithm terminates at the default relative optimality gap of 1%. Additionally, for all configurations with $N=3$ stages, the target lower bound is set to the best known upper bound for configurations with $N=2$ stages rounded up to two significant digits in order to save computation time, since the latter case is much faster to solve.

3. Results

The optimal crystallizer network configuration is shown in Figure 3. This configuration comprises a pre-treatment stage ($n=2$) that separates the mixture to below specification for the melted crystal product and two purification stages ($n=1, 3$) that are connected in series and separate the remaining mixture to above product specification. By mixing both product flows, \hat{m}^{cr} is exactly at specification. For the considered case study, the mixture has to be processed by at least two stages in a countercurrent fashion to achieve the product specifications. By including the pre-treatment stage, a smaller amount of the mixture has to be processed in that way, thereby reducing overall cost. The optimal cost for the process is $1.22680 \cdot 10^5 \text{€} \cdot \text{year}^{-1}$. This is compared to the optimal cost of $1.26504 \cdot 10^5 \text{€} \cdot \text{year}^{-1}$ when limiting possible configurations to countercurrent cascades of crystallizers. Note that, in order to allow for comparability, the parameter values were chosen such that constraints due to model validity (15)-(17) were not active and no variable was at their bound

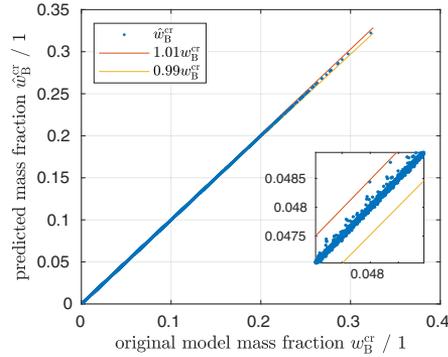

Figure 2: Regression results for the mass fraction of B in the crystal layer $w_B^{\text{cr}} = \frac{1-(y^m)^{\text{diff}}}{1-y^m} w_{B,0}^m$. The inlay shows a magnification of the value with the largest relative error.

at both optimal solution points.

We observed computation times of up to 1300s for configurations with three stages on a standard desktop computer. The overall computation time for all configurations with two or three stages was 6500s. The additional effort for data generation and surrogate training was in the order of 200s.

4. Conclusions

This case study demonstrates the applicability of deterministic global optimization to multistage melt crystallization processes by replacing the computationally expensive dynamic crystal growth model with a static surrogate. The approach can be extended to more detailed crystallization models provided sufficient input-output data is available. This includes operating modes other than constant crystal growth rates as long as the operating mode can be described by a limited number of parameters.

Local optimization approaches might also benefit from surrogates for crystallizer models by trading some model accuracy for computationally more efficient models.

The same optimal configuration as in the current case study was identified before for a simplified crystallization model with constant differential distribution coefficient and equal crystal growth rate on each stage in (Kunde et al., 2016), with cost reductions up to 25% compared to countercurrent cascades in a large parameter region. It was also found that countercurrent cascades are optimal in most of the remaining parameter space. An analogous parameter study could show whether those results can be transferred to the current model and how much improvement over the countercurrent cascade can be achieved.

Abstract

As demand for biopharmaceuticals rises, manufacturers are required to meet multiple competing key performance indicators (KPIs) such as process sustainability, efficiency and product efficacy and quality. Advanced process optimisation and control in biopharmaceutical manufacturing is challenged by the lack of online Process Analytical Technologies (PAT). This results in processes relying heavily on wet-lab experimentation, which may be costly and inefficient. In this work, a novel methodology for evaluating process robustness and alternative operating strategies using design space identification is proposed to accelerate process design and optimisation. The focus in this work is on the initial separation step for the purification of monoclonal antibodies (mAbs) separating the majority of process impurities generated upstream using affinity (protein A) chromatography. A high fidelity process model is used to computationally explore the multi-dimensional design space. The performance and robustness of the process under three different resin properties and a variety of input conditions are evaluated using the framework. Three scenarios for each of the resins are considered resulting in a total of nine design spaces. The results indicate that using a higher column protein A density resin can increase operational flexibility.

Keywords: computing and systems engineering, process design and development, process optimisation, biopharmaceutical manufacturing

1. Introduction

Biopharmaceuticals is the fastest growing sector of the pharmaceutical industry (Walsh, 2018; Philippidis, 2019). As demand for biopharmaceuticals rises and there is a drive towards sustainable processes, now manufacturing needs to meet multiple competing key performance indicators (KPIs) (Nasr et al., 2017). The Quality by Design (QbD) initiative was started to address inefficient, out-of-date and wasteful practices to process development and manufacturing. QbD encourages systematic decision making and deep understanding of pharmaceutical development and manufacturing in contrast to the traditional statistical experimentation approach (Rathore and Winkle, 2009). This initiative encourages manufacturers to design quality into the product from the early phases of drug development instead of treating it as a secondary objective. Monoclonal antibodies (mAbs) are the most popular biologics as they can be manufactured to target almost any substance. However, the implementation of QbD for biopharmaceuticals, specifically therapeutic proteins, faces three main challenges: product heterogeneity, limited measurements for process monitoring and lack of online process control strategies due to lack of online Process Analytical Technologies (PAT) (Papathanasiou and Kontoravdi, 2020). In this work, a novel methodology for evaluating process robustness and process optimisation using model-based design space is proposed to accelerate process design and optimisation. The methodology is intended to be applied

during the process design phase within the QbD framework to act as a virtual experimentation platform to reduce reliance on resource-intensive experimentation. The capture step of the mAb production process is the main focus in the case study of this work.

2. The Framework

Evaluating robustness and performance of a process under different parameters and conditions is vital for designing optimal and robust processes. In this section, the framework for model-based design space identification is presented. A schematic of the framework is shown in Figure 1.

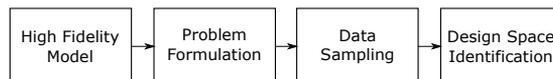

Figure 1: Model-based design space identification framework.

Step 1. High Fidelity Model. First, a high fidelity model is developed and validated using experimental data to ensure accurate description of the system. The validity of the findings observed from the framework is highly determined by the quality of the model. Therefore, ensuring that the model is validated across the range of parameters which will be sampled from is important.

Step 2. Problem Formulation. Next, the problem is formulated starting with identifying what are the objectives of this study. What are the key performance indicators (KPIs) of interest and what are the parameters/variables (e.g., design variables, process parameters) that the design space need to cover. It is also possible to introduce constraints to the problem such as target minimum yield.

Step 3. Data Sampling. The choice of the sampling method used can affect the computation time, accuracy and the coverage of the space. In this work, the quasi-random Sobol sequence (Sobol and Shukman, 1993) is used to sample the multi-dimensional design space with good coverage. For application in process design and development within the QbD paradigm, it is crucial to ensure good accuracy, hence, the high fidelity model is used directly for data sampling.

Step 4. Design Space Identification. Finally the design space is visualised and identified from the collected computational data samples. The constraints are applied to find out which sample points do not satisfy the desired performance constraints.

The multi-dimensional design space can be used to evaluate the robustness of the process by identifying acceptable disturbance ranges. This information can also be used to identify the optimal design given a range of disturbance expected. The case study in the next section presents how the framework can be applied to the capture process of mAb production.

3. Case Study: Monoclonal Antibody Capture Process

The capture process is the first step in downstream separation of mAbs. The objective of this process is to concentrate the Harvest cell culture fluid (HCCF) from upstream reactor removing the bulk impurities. In this process, the mAb concentration from upstream is treated as a disturbance as there can be fluctuations. This variation in feed mAb concentration can impact the separation performance of the process. Model-based design space identification (DSI) can be used to design a process which is able to handle the variation in feed mAb concentration.

3.1. The System

For the purposes of this work, the two-column capture process model as presented in Steinebach et al. (2016) is adapted. The two-column system consist of three major steps: A – interconnected

loading, B – interconnected wash, and C – batch operation (washing, elution, and regeneration). As shown in Figure 2, in the first step, column 1 is loaded beyond its dynamic binding capacity and the breakthrough is fed onto column 2. In step B, column 1 is washed and the breakthrough which may contain some mAb is mixed with the fresh feed and loaded onto column 2. In the last step the operation is in batch mode, column 1 is washed further and then the products are eluted and the column regenerated while column 2 is being loaded. Then the column positions are swapped, and the process is repeated.

3.2. Problem Formulation & Data Sampling

The objective for the DSI study is to investigate the performance and robustness of the process under different resin properties and conditions to find the optimum resin which satisfy the performance constraints of $Yield \geq 99\%$ and $Productivity \geq 15 \text{ mg mL}^{-1} \text{ h}^{-1}$. $Yield$ is the percentage of mAb recovered to the amount fed, while $Productivity$ is amount of mAb produced per time taken per resin volume used. The constraints are chosen based on the nominal performance reported by Steinebach et al. (2016). The resins used in this study are summarised in Table 1. The column protein A density is the density of protein A ligands per volume of the column. It was calculated based on the reported values of the protein A ligand density in the solid phase of the resin and both the bed and particle porosity (Hahn et al., 2005; Liu et al., 2015; Steinebach et al., 2016). Three scenarios of design spaces for each of the three different resins are considered and summarised in Table 2.

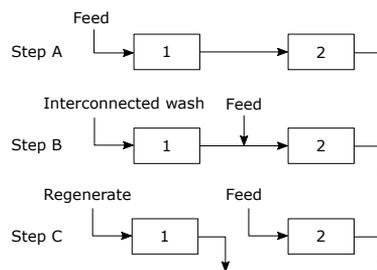

Figure 2: Schematic of the two-column capture process

CaptivA PriMAB	31.25

Table 2: Design space problem scenarios.

Scenario	Type	Parameters Varied
1	Column Dimension	D_c, HD_c
2	Switching Time	$T_{load}, T_{wash C}$
3	Process Parameters	$c_{feed}, Q_{feed}, T_{load}, T_{wash C}$

In the first scenario, only the column diameter, D_c , and column height to diameter ratio, HD_c , are varied. The height to diameter ratio is varied to ensure the shape remains like a column. In this scenario, the design space can be used to size the column for process design. In scenario two, only the loading time, T_{load} , and the interconnected washing time, $T_{wash|C}$, are varied (the times combined together is the switching time of the column). The switching time is one of the most important design variable which determines how long the column is loaded before the products are eluted and collected. In this scenario, the design space can help to choose the appropriate switching time which satisfies our production constraints. Finally, in the last scenario, the design space is a four-dimensional design space where the feed mAb concentration, c_{feed} , feed volumetric flowrate, Q_{feed} and the switching time parameters are varied simultaneously. The volumetric flowrate is a control variable of the process. When a disturbance in the form of fluctuations in mAb feed

concentration occurs, the volumetric flowrate can be adjusted to keep the mass flowrate of mAb going into the column within the designed range. The design space in the last scenario can identify ranges of c_{feed} and Q_{feed} which satisfies the performance constraints. Lastly, the quasi-random Sobol sequence (Sobol and Shukman, 1993) was used to sample the parameter space directly on the high fidelity model.

4. Results and Discussion

First, the design spaces of the resin MabSelect SuRe is shown and discussed in detail. The resin MabSelect SuRe is the nominal resin used in the study by Steinebach et al. (2016).

4.1. MabSelect SuRe Design Space

The design space of all three scenarios for the MabSelect SuRe resin is shown in Figure 3. A total of 128 samples are used to construct each design space.

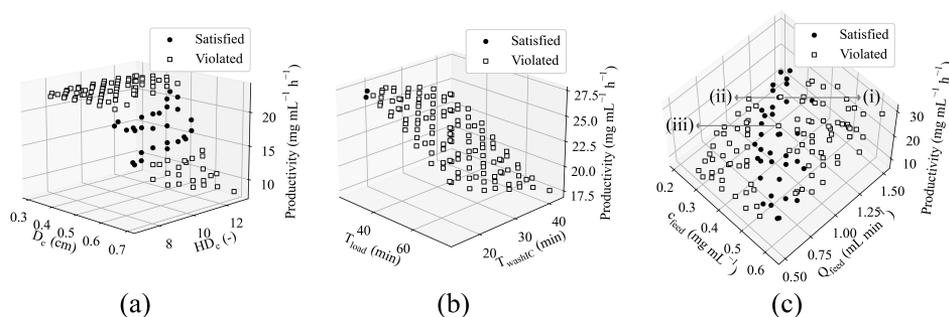

Figure 3: Design space of all scenarios for the MabSelect SuRe resin. Scenario 1, 2, and 3 are shown in (a), (b), and (c) respectively. Solid black circle markers indicate that the constraints are satisfied and white square that they are violated.

The design space for the first scenario is shown in Figure 3 (a) plotted in 3D (diameter, height to diameter ratio and productivity). A region of samples which satisfied both constraints can be seen. This information can be used to design a column which is able to satisfy both performance constraints. From Figure 3 (a), it can be seen that the majority of the samples satisfied the productivity constraint ($\geq 15 \text{ mg mL}^{-1} \text{ h}^{-1}$), while only a subset of samples shown in solid black circles satisfied both constraints. The yield constraint proves to be the limiting one for this design space.

Shown in Figure 3 (b) is the design space of scenario two. From Figure 3 (b) it can be seen that the yield is again the limiting constraint as all of the sample were able to satisfy the productivity constraint. Furthermore, the design space here is very narrow with only two samples which satisfied both constraints. This results aligns with the work by Steinebach et al. (2016) as the process was optimised using the MabSelect SuRe resin. The results also indicate that at lower switching times, higher productivity and yield is achieved. This is because when the switching time is reduced, the column is prevented from becoming saturated with mAb. Therefore, by lowering the switching time, the driving force for separation can be maintained at a higher value. Although lower switching time can give better performance in terms of yield and productivity, a lower loading time can result in a higher buffer consumption. Therefore, there is a trade-off between economic and environmental performance.

The four-dimensional design space from the last scenario is shown in Figure 3 (c). Looking at the design space in Figure 3 (c) it is clear that there are samples, marked (i) and (iii), which

violated one or more of the constraints despite the fact that it is very near to another sample, marked (ii), which satisfied both constraints. This is due to the fact that the design space here is a four-dimensional space represented in a two-dimensional space.

Table 3: Parameter and KPI values of samples (i), (ii), and (iii) in the design space of scenario three.

Sample	c_{feed}	Q_{feed}	T_{load}	T_{washIC}	Yield	Productivity
(i)	0.32	1.25	62.50	35.50	98.84	18.58
(ii)	0.31	1.25	43.36	28.62	99.17	18.33
(iii)	0.39	1.05	56.23	30.40	98.51	19.37

The labelled samples from Figure 3 (c) are shown in detail in Table 3. The samples (i) and (iii) did not satisfy the constraint due to violation in the yield constraint. On the other hand, sample (ii) satisfied both constraints. From Table 3, it can be seen that the value of T_{load} for both violated samples are significantly higher than that of sample (ii). From the design space in scenario two it was found out that to achieve higher yield, lower switching time is preferable. It is further evident here where samples (i) and (ii) are very close in the values of c_{feed} and Q_{feed} but having a larger T_{load} resulting in violation of the yield constraint. Using a lower switching time can reduce loss of products achieving higher yield. However, by doing so more buffer is consumed during washing, elution and regeneration as they are performed more often. There is, therefore, a trade-off which needs to be considered when designing the process.

4.2. Comparison of Resin Performance

Shown in Figure 4 is the design spaces of all three resins.

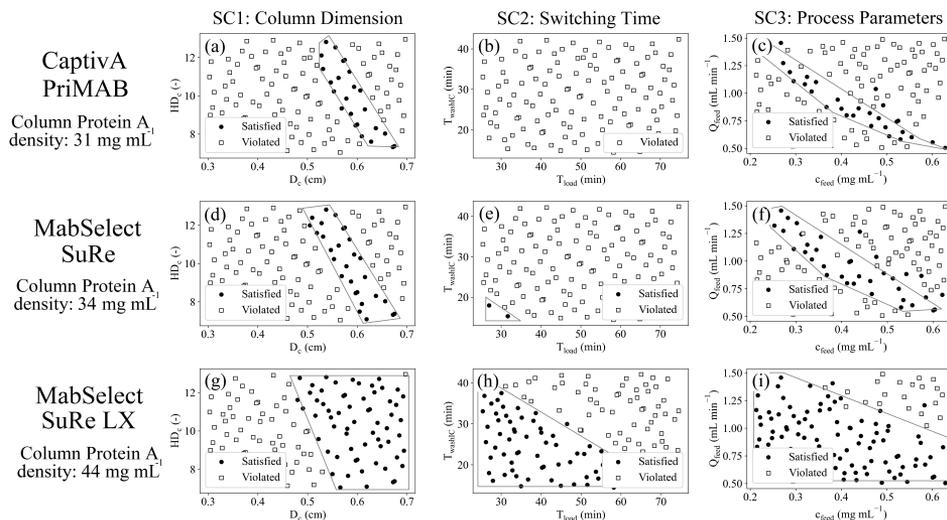

Figure 4: Comparison of the design spaces (as columns: scenarios 1, 2, and 3) for three different resins (as rows: Captiva PriMAB, MabSelect SuRe and MabSelect SuRe LX)

The Captiva PriMAB resin has the lowest column protein A density out of the three resins. From Figure 4 (c), it is shown that it does not have a single sample which satisfies both of the constraints. The column protein A density is directly correlated with how much mAb can be adsorbed onto the column. Hence, the lower the column protein A density the lower the yield is. From Section 4.1, it

was shown that the yield constraint is harder to satisfy than the productivity constraint. This leads to wider design spaces seen in resins with larger column protein A density shown in Figure 4.

Using the design spaces, the robustness of the process under different resin properties can be evaluated. For example, given a case where it is known that the upstream process produces a feed stream with mAb concentrations of between $0.35 - 0.45 \text{ mg mL}^{-1}$. Then, using the design spaces from Figure 4 (c), (f), and (i) it is possible to figure out what value of Q_{feed} that can satisfy the performance constraints. In this case, the CaptivA PriMAB resin can operate at between $0.85 - 0.90 \text{ mL min}^{-1}$, the MabSelect SuRe resin can operate between $0.85 - 1.00 \text{ mL min}^{-1}$, and the MabSelect SuRe LX resin can operate between $0.55 - 1.30 \text{ mL min}^{-1}$. This information can also be used in the opposite way. For instance, if the process has a nominal volumetric flowrate of 1.00 mL min^{-1} , the design spaces from Figure 4 (c), (f), and (i) shows that the CaptivA PriMAB resin can process feed streams containing c_{feed} of about $0.32 - 0.43 \text{ mg mL}^{-1}$ satisfying both constraints. On the other hand, the MabSelect SuRe and MabSelect SuRe LX resin can operate in the range of $0.31 - 0.45 \text{ mL min}^{-1}$ and $0.20 - 0.52 \text{ mL min}^{-1}$ respectively. Therefore, using the design spaces, an optimal resin that can satisfy the performance constraints and be robust against disturbance from the upstream process can be selected.

5. Conclusion

In this work, the framework for DSI within the QbD paradigm has been presented and applied in a case study. As shown in the case study, the proposed framework offers the opportunity to evaluate process robustness which is crucial for manufacture of biopharmaceuticals with stringent quality standards. Model-based DSI can be used to identify the range of operation conditions which satisfies a set of constraints. The case study has shown how model-based DSI can evaluate process robustness of protein A affinity chromatography for mAb capture under different resin properties and identify the optimum resin for a robust process. It was found out that resin with higher column protein A density has greater operational flexibility. This information is also important for process integration where it is vital to ensure compatibility between units to design a robust and optimal process. The approach can be transferred to other types of process operations (e.g., tangential flow filtration, bioreactor). It can be tailored to meet different types of study objectives (e.g., glycosylation in mAbs, buffer consumption) and to address other parameters (e.g., temperature, pH). Current and future work is focused on combining more advanced modelling techniques such as multi-parametric programming (mp-P) and data driven/hybrid models to accelerate data sampling in an effort to increase the framework's capabilities for online use.

Sustainable Energy Systems Design with Heat Pump Technologies for Meeting Peak Heating Demand

Xueyu Tian,^a Fengqi You^a

^a *Cornell University, Ithaca, New York, 14853, USA*
xt93@cornell.edu

Abstract

This study tackles the sustainable design of carbon-neutral energy systems with electrified peak heating systems, namely heat pump technologies for meeting electricity, heat, and cooling demand. We first propose a superstructure of the carbon-neutral energy systems for electricity, heat, and cooling generation. A multi-period optimization model with a predefined time horizon and temporal resolution is developed based on the proposed superstructure for total annualized cost minimization. The objective is to determine the optimal design of the carbon-neutral energy systems in the investigated region, seasonal operations, energy mix, and corresponding capacity of each technology while meeting the electricity, heat, and cooling demand. The applicability of the proposed modeling framework is illustrated through a case study using Cornell University as the living laboratory, explicitly considering the electrification of the peak heating systems.

Keywords: carbon neutrality; energy systems; decarbonization; electrification; mixed-integer nonlinear programming.

1. Introduction

The Paris Agreement sets a goal to curb global greenhouse gas (GHG) emissions, driving vast penetration of renewable energy worldwide. Extensive research on deep decarbonization of energy systems is conducted at the community-level (Tian et al., 2019), city-level (Wiryadinata et al., 2019), state-level (Zhao and You, 2020), and country-level (Vaillancourt et al., 2017). Electrification of heat and cooling generation and decarbonization of electricity generation is identified as a promising lever to address the ambitious climate goals (de Chalendar et al., 2019). However, heat and cooling generation stand a chance to affect the stability of the power system due to the surge in electric load involved (Sun et al., 2021), if they are electrified in an uncontrolled way. Therefore, it seems to be a reliable and promising decarbonization option by exploring renewable heat and cooling generation technologies rather than simply using electrified counterparts (Sánchez-Bautista et al., 2017). Among the vast array of renewable heat and cooling generation technologies (Gong et al., 2015), geothermal energy and deep water source cooling system show great potentials for the decarbonization transition of energy systems (Lee et al., 2019). Recent research efforts have also identified the values of green hydrogen (Dodds et al., 2015), large-scale heat pumps (Bach et al., 2016), biomass and biogas (Kassem et al., 2020), and thermal energy storage (Ochs et al., 2020) for decarbonizing the heating system. There is a lack of studies addressing the sustainable design of energy systems toward carbon neutrality by simultaneously exploring renewable electricity, heat and cooling generation, and electrified heating and cooling

options in the region with a humid continental climate, such as New York State (NYS) (Zhao and You, 2021). To bridge the knowledge gap, this paper aims to develop a modeling and optimization framework to handle the optimal design of carbon-neutral energy systems. In this paper, a multi-period optimization model, given a time horizon and a temporal resolution for total annualized cost (TAC) minimization, is built. The aim is to determine the optimal design of the carbon-neutral energy systems in the investigated region, seasonal operations, energy mix, and corresponding capacity of each base-load and peak-load technology involved. A tailored global optimization algorithm is applied to circumvent the computational challenges induced by separable concave terms in the objective function. The applicability of the proposed modeling framework is illustrated through a case study developed using the real data from the main campus of Cornell University, located in Ithaca, NYS.

2. Problem Statement and Model Summary

We are given a superstructure of carbon-neutral energy systems, including a set of renewable electricity generation technologies and a set of renewable and electrified heating and cooling options, as shown in Figure 1. To capture the optimal design, seasonal operations, energy mix, and corresponding capacity of each base-load and peak-load technology in the carbon-neutral energy systems, a time horizon and a set of time periods are specified to improve the temporal resolution of the model. The multi-period optimization problem of the proposed carbon-neutral energy system with earth source heat, lake source cooling (LSC), on-site electricity generation, and peak heating options for the total annualized cost minimization is formally defined in this section. The aim is to determine the optimal design of the carbon-neutral energy systems in the target region, seasonal operations, energy mix, and the corresponding capacity of each base-load and peak-load technology involved while fulfilling the seasonal demand for electricity, heat, and cooling.

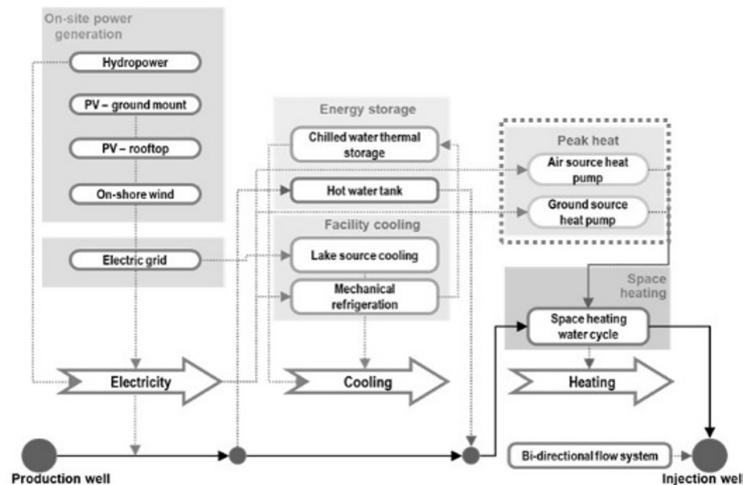

Figure 1. Overview of the superstructure of the proposed carbon-neutral energy systems with earth source heat, lake source cooling, on-site electricity generation, and peak heating technologies.

The general multi-period optimization model is subjected to the mass balance and configuration constraints, energy balance constraints, logic constraints, and techno-economic evaluation constraints (Gong and You, 2018). The integer decision variables

represent the selection of technologies. The number of geothermal well-pairs is an integer decision variable. Other essential decision variables such as the mass flow rates, energy flows, and capacities are continuous variables. The objective function, total annualized cost, includes integer variables such as the numbers of production wells and injection wells and thus is a mixed-integer function. The nonlinear terms mainly come from the separable concave terms induced by the economy of scale. Therefore, the resulting problem is a mixed-integer nonlinear programming (MINLP) problem. The general form of this MINLP problem is summarized as follows.

$$\begin{aligned} \min \quad & TAC = AIC + AOC + RE & (1) \\ \text{s.t.} \quad & \text{mass balance and configuration constraints;} \\ & \text{energy balance constraints;} \\ & \text{logic constraints;} \\ & \text{techno-economic evaluation constraints;} \end{aligned}$$

where AIC , AOC , and RE refer to the annualized investment cost, annual operating cost, and replacement cost, respectively.

The resulting MINLP problem includes integer and continuous variables embedded in nonlinear functions. For the global optimization of this problem, general-purpose global optimization solvers could be intractable. A global optimization strategy is developed to solve this non-convex MINLP problem. Specifically, we substitute the separable concave functions for capital cost model with successive piecewise linear functions for a relaxation of the original MINLP. The resulting MINLP problem is solved iteratively following the branch-and-refine algorithm (You and Grossmann, 2011).

3. Application to Sustainable Design of Campus Energy Systems

The proposed multi-period optimization modeling framework for energy systems decarbonization is applied to address the optimal design of the carbon-neutral energy systems using the main campus of Cornell University located in Ithaca as the living laboratory. Based on the optimization results, the optimal configuration of the carbon-neutral energy system in the target region, seasonal operations, energy mix, and corresponding capacity of each base-load and peak-load technology involved are determined while accommodating the seasonal demand for electricity, heat, and cooling across the main campus of Cornell University located in Ithaca, NYS. The case study aims to obtain the global optimal solution of the multi-period optimization problem with a monthly model resolution for the proposed carbon-neutral energy system with earth source heat, LSC, on-site electricity generation, and peak heating options, namely heat pump technologies. The maximum monthly average demand for cooling and heating are 46.7 MW and 68.0 MW, respectively. In 2020, there are 23,094 students, 9,907 non-faculty staffs, and 1,530 faculties on campus.

3.1. Systems Configuration

Herein, we demonstrate the peak heating options with different base-load capacities, where only ground source heat pumps are employed with no thermal energy storage. Specifically, 2,037, 1,265, and 493 ground source heat pumps with a typical capacity of 19 kW for each (Tian et al., 2020) in the North American region are deployed to handle the peak-load heat demand for the cases with two, three, and four base-load earth source heat pumps, respectively. We note that deploying thousands of geothermal heat pumps

across the campus could be a significant challenge in practice. This result helps inform the technology limitations and practice needs.

The selection of cooling technologies, peak heating systems, and the corresponding operating levels vary from month to month. The block flow diagram in Figure 3 reflects the technology selection in cold winter days when the heat demand is large and exceeds the capacity of base-load earth source heat systems. The column chart shows the breakdowns of electricity used to accommodate the building demand across the campus and drive all the electrical appliances for cooling and heating purposes, including the LSC, auxiliary chiller, air source heat pump, and ground source heat pump. The ground source heat pump provides extra heat as the peak heating option on cold winter days when the base-load earth source heat cannot fulfill all the heat demand. On the contrary, the base-load LSC occasionally fails to satisfy the peak cooling load on hot summer days. Thus mechanical chillers are utilized to generate additional chilled water during the night, which is warmed by the campus cooling load during the day, as shown in Figure 4.

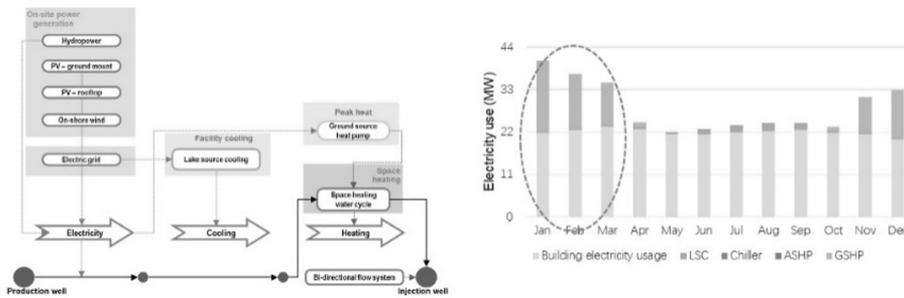

Figure 3. Technology/process configuration on cold winter days.

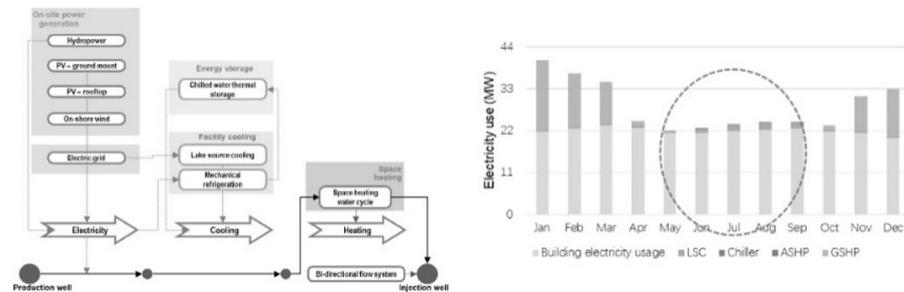

Figure 4. Technology/process configuration on hot summer days.

3.2. Techno-economic analysis

For a better understanding of the optimal design from an economic perspective, the breakdowns of the total annualized cost are given in Figure 6. The total annualized cost sums up the annualized investment cost and annual operating cost, calculated with a 15-year project lifetime (from 2021 to 2035) and a 5% discount rate. Because the capacity of base-load earth source heat systems has significant impacts on the selection of peak-load technologies and the corresponding capacity, the sensitivity of the base-load capacity is systematically analyzed. The number of geothermal well-pairs is chosen as the investigated input parameter, ranging from two to five. This case study considers at most five geothermal well-pairs because five well-pairs are sufficient to satisfy base-load heat

demand for the main campus of Cornell University located in Ithaca. We note that as the number of geothermal well-pairs increases from two to five, the annualized investment cost increases from \$93.62 MM/yr to \$95.64 MM/yr, while the annual operating cost decreases from \$31.56 MM/yr to \$28.20 MM/yr. In terms of capital investment, solar panels (58%-59%), wind turbines (23%), and hydroelectric power plant (8%-9%) are the major contributors. When the base-load earth source heat capacity is low, the operating cost associated with the ground source heat pump is more pronounced. The remaining annual operating cost is mainly sourced from the operations of solar and wind farms. We find that the number of base-load geothermal well-pairs shows little impact on the total annualized cost.

We note that all the techno-economic analysis results are obtained based on the current electricity price, which is volatile in the future. We perform breakeven analysis to gain insights and justify the need for earth source heat over the heat pumps. For the earth source heat-based systems, we consider five well-pairs based on the optimization results, and we consider all the electricity driving the heat pumps is sourced from the local grid. The results show that if the electricity price is higher than \$0.0202/kWh, the earth source heat system outperforms the ground source heat pumps from an economic perspective.

3.3. Energy Flow

The Sankey chart in Figure 5 shows the annual energy flow profile for the case with only two geothermal well-pairs as the base-load heat supplier. We find that 65.3% of the total electricity is sourced from the local grid, with an annual consumption of 160,812 MWh during the on-peak time and 393 MWh during off-peak hours. 0.13% of the total electricity is consumed to drive the geothermal pumping systems, the ground source heat pump utilizes 19%, and 3% are attributed to LSC assisted by mechanical chillers. It is also found that the ground source heat pumps provide approximately one-third of the building heat demand across the campus, and the base-load geothermal well-pairs fulfill the remaining heat demand. Finally, 99% of the cooling is provided by the LSC (with COP of around 30) and only 1% from the mechanical chiller.

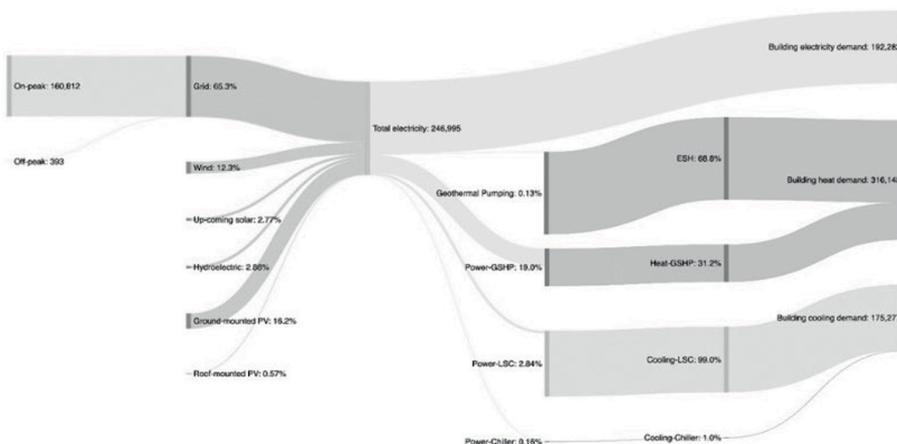

Figure 5. Annual energy flow profile with two base-load geothermal well-pairs (unit: MWh/yr).

4. Conclusion

A multi-period optimization model, given a time horizon and a temporal resolution for total annualized cost minimization, was built. The aim was to simultaneously determine

the optimal design of the carbon-neutral energy systems in the investigated region, seasonal operations, energy mix, and corresponding capacity of each base-load and peak-load technology involved while fulfilling the seasonal demand for electricity, heat, and cooling. The applicability of the proposed modeling framework was illustrated through a case study considering electrified peak heating options, namely heat pump technologies, which was developed by leveraging the real-world data from the main campus of Cornell University, located in Ithaca, New York.

Isopropanol/ n -Butanol/ Ethanol separation from diluted fermentation broth by distillation. Process optimization using MILP techniques

Eszter Toth^a, Gianluca Mancino^a, Ludovic Raynal^a

^a*IFPEN, Rond-point de l'échangeur de Solaize, BP 3, 69360 Solaize, France*

Abstract

This work has been performed in the framework of the development of the bio-based fermentation process to produce IBE (isopropanol/ n-butanol/ ethanol). The so-called IBE fermentation is indeed an interesting sustainable alternative to produce fossil-based products. However, product inhibition in fermentation leads to dilute fermentation broths in water (15-25 g IBE/L) which implies high energy demand for products/water separation. In the present study focus has been put on ready-to-industrialize downstream processes for Isopropanol/ n-Butanol/ Ethanol separation from dilute fermentation broth, using conventional distillation and shell-and-tube heat-exchanger technologies. A reference process scheme, using 5 distillation columns, as well as an IFPEN patented distillation sequence with 3 columns only were optimized using an in-house tool. The tool allows to simultaneously optimize the heat exchanger network configuration and the distillation columns' operating pressures for a given material balance, using Mixed Integer Linear Programming (MILP) optimization techniques. When comparing to the reference process, the optimized heat exchanger network leads to significant vapor consumption reduction and to also significant total separation cost reduction, when both investments and utilities costs are considered. The IFPEN patented scheme even without optimization is found to be more interesting than the reference scheme and is shown to be even more interesting after optimization. The tool can be applied to any distillation process, leading to significant cost savings.

Keywords: Isopropanol/ n-Butanol/ Ethanol fermentation, Distillation, Optimization, Mixed Integer Linear Programming

1. Introduction

N-butanol is used as a solvent and could be used as a fuel. It reached 4.1 million tons consumption in 2015. Isopropanol, a 1.9 million tons market in 2015, can also be used as a solvent and has also shown its interest as an additive in fuels. Finally, isopropanol can also be transformed into propylene, a major chemical intermediate today.

N-butanol and isopropanol are currently produced by petrochemical routes, but new technological routes are under development including bio-based technologies. Their production can be carried out by fermentation, e.g. ABE production (acetone, n-butanol, and ethanol) or IBE production (isopropanol, n-butanol, ethanol). The ABE process using *Clostridium*-type bacteria was one of the first large-scale industrial microbial process for chemical production, as well as the largest fermentation process under sterile conditions (Ni, 2009; Köpke, 2011). Initially, acetone was the main compound of interest for its use in the production of cordite during World War I and its use in the production of other chemicals. Nowadays, acetone is sometimes considered as an undesirable by-product due

to its low properties as a biofuel or chemical. The reduction of acetone into isopropanol is possible using different bacteria belonging to the genus *Clostridium*. The production process of IBE is therefore based on the ABE fermentation process and uses strains of the genus *Clostridium* capable of fermenting simple sugars and reducing a large part of the acetone into isopropanol. However, a small part of acetone is still produced during IBE fermentations.

N-butanol production by *Clostridium*-type strains, for both ABE and IBE fermentations, is limited by its impact towards microbial growth, typically when its concentration is between 7 and 15 g/L. This greatly limits the final alcohol concentration of the fermentation broth, to approximately 10 to 30 IBE g/L. Let's note at this point that some aspects of ABE process can easily be used for IBE process: for example, n-butanol inhibition in fermentation leads to the same issues of diluted broth separation.

Such low concentrations imply high energy demand for products/water separation and therefore high separation costs. Several solutions have been reviewed in literature to achieve cost reduction (Kujawska, 2015; Vane, 2008). A part of them concerns the downstream process, i.e. alcohol/water and alcohol/alcohol separations. Hybrid distillation/liquid-liquid extraction processes using solvents have been proposed, mesitylene has been considered by Kraemer (2010, 2011)–, and ethylene glycol by Zhang (2020). Mesitylene appears to be an interesting solution as far as energy demand is concerned, but capital cost investment is not given. Moreover, after alcohol separation, the vinasses are meant to be recycled to the fermenter, and the residual mesitylene's toxicity to micro-organisms must be investigated. For ethylene glycol, the authors use n-butanol in higher concentration of about 4.46 wt %, which further implies low energy demand for separation but is hard to achieve with ABE/ IBE fermentation. Another way to achieve separation cost reduction is to increase alcohol concentration in broth. In order to limit n-butanol inhibition on bacteria, In Situ Product Recovery Techniques (ISPR), consisting in removing n-butanol from the fermenter during its production, have been considered (Outram, 2016). A part of these techniques, such as perstraction, are at research level and would need significant development before industrial level. Gas stripping (Xue, 2012) or two-phase fermentation (González-Peñas, 2020) in the presence of a biocompatible solvent in the fermenter are two types of techniques nearer to industrial scale. However, those techniques are relatively expensive and there is no evidence that the cost of ISPR techniques is offset by the decrease in separation costs as several parameters must be considered. It would then be important to properly estimate the cost/benefit ratio of ISPR techniques.

In the present study focus has been put on ready-to-industrialize downstream processes for isopropanol/ n-butanol/ ethanol separation from dilute fermentation broth, using conventional distillation and shell-and-tube heat-exchanger technologies. The originality of the work consists here in a thorough process study including both process flow scheme optimization and an associated techno-economic estimation.

2. Methods

As aforementioned, the IBE process is close to the ABE process. For the downstream separation part, the main difference is that, unlike acetone, isopropanol forms an azeotrope with water which makes infeasible the complete dehydration of isopropanol by conventional distillation: for example, at atmospheric pressure, the isopropanol-water azeotrope contains 12 wt % of water. . Moreover, that little amount (approx. 0.2 - 0.6 g/L)

of acetone is still being produced, which represents an undesirable impurity to be eliminated from the main products.

2.1. Process description. 5 columns distillation process – reference case.

The reference distillation process was adapted from the ABE literature (van der Merwe, 2013) and is shown in Fig. 1. It involves five distillation columns to perform the separation of the various components. The Beer column recovers IBE at the top and eliminates 98.7 % of water at the bottom. The Acetone column allows the elimination of undesired acetone. With the IPA column, it is possible to separate the isopropanol/ water azeotrope and the small amount of ethanol at the top. The Water and Butanol columns are the last two columns used to break the water/n-butanol heterogenous azeotrope and recover the n-butanol at the bottom of the Butanol column.

2.2. Process description. 3 columns distillation process – base case

Another way to achieve the required separation is to use the sequence adapted from an IFPEN patent (Mikitenko, 1983) discussed by Pucci (1986) and shown in Fig. 2. This sequence consists only of a Beer column and a second column to separate the butanol from the other components. These are finally sent to a third column which separates isopropanol/water azeotrope and ethanol from the undesired acetone. The particularity of this scheme is in the second column. This column provides a three-phase area (two liquid and one vapor) on some trays. The aqueous phase is subtracted from the three-phase zone and is recycled and mixed with the feed of the first column.

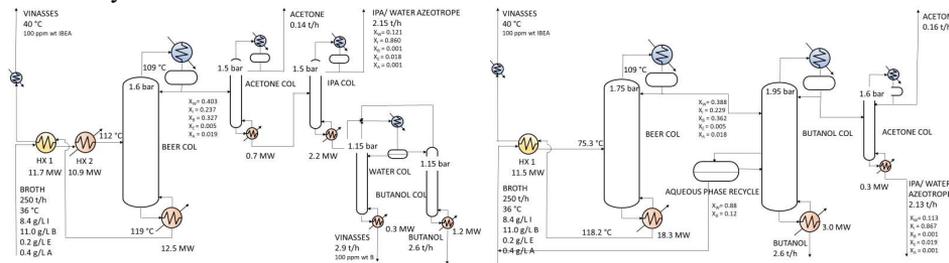

Fig 1. Flowsheet of the 5 columns reference case

Fig 2. Flowsheet of the 3 columns base case

2.3. Flowsheet simulation

The flowsheets were simulated using SIMSCI’s PRO/II v 10.2 software. The base thermodynamic method used was SRK-Simsci (SRKS). The unary and binary, both for vapor/liquid and liquid/liquid equilibria, were adjusted based on literature and in-house experimental data.

2.4. Process optimization using Mixed Integer Linear Programming (MILP) techniques

To achieve separation cost reduction, including both investments and utilities, the two process schemes were optimized with an in-house optimization tool, based on Mixed Integer Linear Programming (MILP) techniques. Fig 3. shows the general optimization procedure.

The global material balances, as shown in Fig. 1. and 2. are kept constant for the whole study. First, data are generated using PRO/II v 10.2 process simulation software. A linear equation set, including temperature vs. enthalpy curves for process streams at different pressures, energy consumption vs pressure with different number of trays for columns and utility consumption is coded into GAMS Studio V 25.1.2 after equation parameter fitting using Microsoft Excel. The novelties of the model stay in the fact that on the one

hand streams can either give or receive heat, i.e. they are not mandatorily defined as hot or cold streams, and on the other hand the column's operating pressures are simultaneously optimized with the heat exchanger network, i.e., the pressures of some of them are adapted in order to allow reboiler/condenser integration between columns. Some extra features, such as steam and electricity generation are also enabled by the model but not used in the current study. The goal is to maximize process/process energy integration, thus minimizing utility consumption while considering penalties for extra investment costs due extra heat exchangers or extra number of trays for columns. The objective function thus corresponds to a global optimum expressed in €/h, taking into account operational and capital expenditures. Calculations are based on an IFPEN internal data base with utility and investments costs, 2019 being the reference year. The objective function is then minimized using CPLEX 12.10 solver provided by GAMS Studio V 25.1.2. As a result, we get an optimized heat exchanger network and column's operating pressures and an idea of optimum number of trays. To end with, the resulting heat exchanger network is integrated in the flowsheet and used to determine real utility consumption, equipment are sized, and investment cost determined to end up with total separation cost, in €/t of IBE.

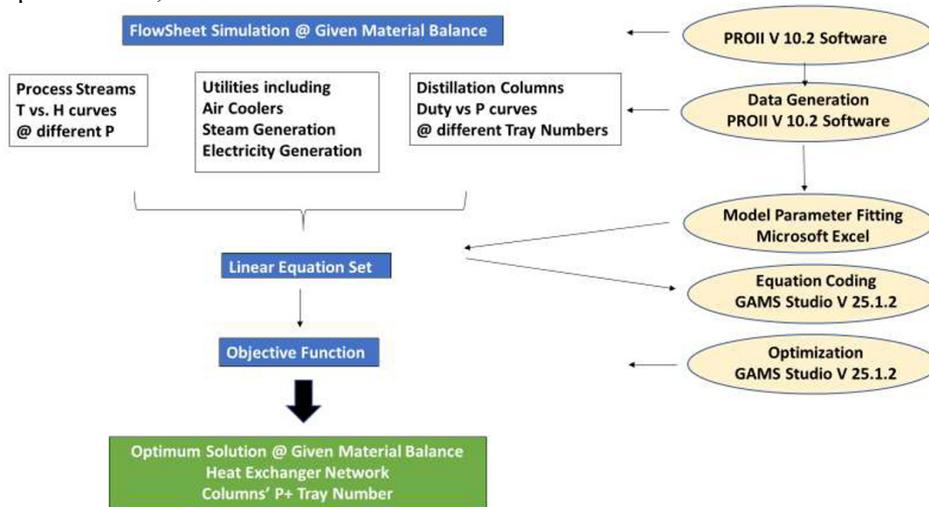

Fig 3. Optimization procedure

3. Results and discussion

3.1. Optimized process with 5 distillation columns. Energy demand.

The resulting flowsheet is shown in Fig. 4. The optimized scheme consists in an integration between IPA and Butanol columns. The operating pressure of the first is raised to 5.5 bars, further increasing the condenser temperature, and allowing its heat of condensation to be recovered for the Butanol column's reboiler. Moreover, liquid-liquid demixing is no longer present at this level of pressure in the IPA column, leading to cheaper column internals and easier operation.

Optimization mainly impacts the pre-heating of the fermentation broth and the Beer column's reboiler duty. Indeed, heat can be recovered not only from the bottom effluent of the column (the so-called vinasses), but also from the top, requiring two additional

exchangers. The broth is divided into two streams, one stream recovers heat from the vinasses and the other from the top stream. After mixing those two streams, extra 1.9 MW can be recovered from the top. In the reference case a total of 23.4 MW of low-pressure steam was necessary to achieve the required separation (10.9 MW and 12.5 MW respectively for the HX 2- pre-heater and the Beer column reboiler, as shown in Fig.1). In the optimized case 13.9 MW are sufficient. The Beer column operating pressure was slightly increased compared to the reference case to compensate extra pressure drop from the extra heat exchangers.

3.2. Optimized process with 3 distillation columns. Energy demand.

The resulting flowsheet is shown in Fig. 5. The main idea is roughly the same than for the 5 columns process. Extra heat can be recovered from the top of the Beer Column. The vinasses transfer heat to the broth in two heat exchangers (HX 6 and HX 1) and recover heat from the top in heat-exchanger HX7. Low-pressure steam consumption falls from 18.3 MW down to 15.4 MW, requiring two extra heat exchangers.

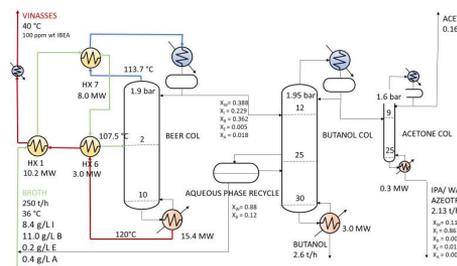

Fig 4. Optimized 5 columns flowsheet

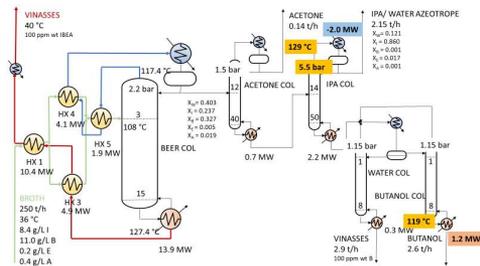

Fig 5. Optimized 3 columns flowsheet

3.3. Total separation cost

For both distillation sequences, hot utility demand remarkably decreases when optimized. The total separation cost, including total utilities consumption and investment costs has further been calculated. The results, given in normalized to 100 base are shown in Fig 6. The 3 columns optimized process ends up being 34% cheaper than the reference case. Because of the liquid-liquid demixtion zone in the Butanol column of this process, it may however be hard to operate. In that view, the more classical, optimized 5 columns process, with 28 % lower separation cost compared to the reference case can be considered as the best solution.

3.4. Alternative solutions

Vapor recompression of the Beer column's top stream to provide heat to the bottom could be an option, considering the 10 °C temperature difference between the top and bottom tray temperatures. Nevertheless, after total separation cost calculation, even if this solution is interesting from utility consumption point of view, the investment cost of the compressor appears to be too high, as it is shown in Fig. 6.

To end with, aforementioned ISPR processes could lead to broth concentrations above 25 g IBE /L. Fig 7. shows that the relative gain on separation tends to decrease in this concentration region.

4. Conclusions

The IFPEN process optimization tool allowed to identify process flow scheme with heat exchanger integration with significant decrease in the IBE fermentation downstream

process cost. It is shown here that up to 30% reduction in production cost can be achieved. Such approach and tool can be applied to any distillation process to lead to economically interesting distillation processes which is especially of great importance for bio-based processes.

Abstract

Solvent-based separation processes, such as liquid-liquid extraction are important options for the separation of aqueous mixtures with low relative volatilities, tangent pinches or azeotropes, for which distillation is either infeasible or energy intensive. As the choice of solvent is of utmost importance, various methods for solvent screening have been proposed, focusing either on properties like solubility and capacity, or the minimum solvent requirement. While some do evaluate the energy for solvent recovery, they assume a fixed process structure, based on the integration of an extraction and a distillation column. Therefore, additional constraints restrict feasible solvents to those that do not form azeotropes and show specific boiling points. While such constraints are oftentimes reasonable, overcoming this limitation requires the identification of solvent-specific process configurations, which is a complex task usually performed by graphical analysis or trial and error. For this purpose, the current work introduces a novel algorithmic synthesis approach and illustrates its application for the separation of a ternary mixture of acetone, acetic acid and water using chloroform as solvent.

Keywords: process synthesis, azeotropic multi-component mixtures, extraction-distillation hybrid processes.

1. Introduction

The separation of aqueous non-ideal mixtures continuously gains importance, while low relative volatilities or azeotropes limit a direct and energy-efficient application of distillation for these systems. Solvent-based separation processes, such as liquid-liquid extraction are of special interest, as the addition of a suitable mass separating agent (MSA) that introduces immiscibility in the system, allow for the separation of the target product even from complex mixtures. Thereby, depending on the choice of a suitable MSA, liquid-liquid extraction can be a very efficient means of separation with very little energy requirements, which primarily result from the recovery of the MSA. For this reason, various methods for solvent screening and computer-aided molecular design have been proposed (Gertig et al., 2020).

Solvent recovery is required to keep the solvent in the loop. Although regeneration strategies such as back-extraction are of interest for non-volatile solvents, this is usually accomplished using distillation or simply stripping and accounts for the major energy requirement in the process (Sprakel & Schuur, 2019). While many studies screen solvents

based on distribution coefficients (at infinite dilution) or the minimum required solvent flowrate, which correlates with the energy required to regenerate it, the latter also depends on the complexity of the individual separation. Solvent screening is therefore usually focusing on the selection of a suitable solvent for a specific process configuration, usually limited to homogeneous distillation, posing constraints on the solvent (e.g. Gertig et al., 2020). Such constraints can only be dropped if process synthesis is performed, and for each solvent the most promising flowsheet is selected. This is especially necessary for the separation of multi-component mixtures, where multiple separation steps are required to recover the solvent and constituent components from the extract and raffinate phases. Kraemer et al. (2011) have demonstrated the combined approach of solvent screening and process synthesis for the separation of butanol from fermentation broth, whereas each process configuration was manually designed. Kaul et al. (2018) also combined solvent screening and flowsheet synthesis, building on expert knowledge for the generation of process variants. For a systematic approach, it is necessary to automate the synthesis method. Expert systems developed in the 90s such as SPLIT by Wahnschafft et al. (1992) and PROSYN by Schembecker & Simmrock (1997) demonstrated the synthesis of separation processes including extraction and distillation. The former is a blackboard-based synthesis method where the separation problem is divided into so called *binary separation tasks*, which effectively oversee the non-idealities in the multi-component space, the latter is a combined heuristic-numeric approach where the separation process is designed using heuristic rules and the physical properties are estimated numerically. While such expert systems can systematically guide process synthesis, they require subsequent simulation to validate the feasibility of the developed process configurations and cannot easily be automated for an effective evaluation of different solvent candidates. To overcome this limitation, the current approach proposes a thermodynamically-sound method for an algorithmic process synthesis of hybrid extraction-distillation processes. The method generates process alternatives solely based on a thermodynamic model of the chemical system. It extends our previously developed algorithmic framework, for the synthesis of homogeneous and heterogeneous distillation processes (Sasi & Skiborowski 2020a, Sasi et al. 2020b) introducing liquid-liquid extraction as an alternative unit operation that is evaluated by means of the pinch-based shortcut method of Redepenning et al. (2017), which determines the minimum required solvent flowrate for a pre-defined recovery. The synthesis approach can be applied to azeotropic mixtures as well, thereby allowing the use of azeotrope-forming solvents for extraction, which require a more complex process configuration for solvent recovery. The subsequent sections summarize the extended synthesis method and illustrate the application of the method for the separation of a ternary mixture of acetone, acetic acid and water using chloroform as solvent.

2. Methodology

The overall process synthesis framework extends our previously presented algorithmic framework (Sasi & Skiborowski 2020a, Sasi et al. 2020b), which can broadly be divided in the three consecutive steps shown in Figure 1. The method builds on the topological analysis of the mixture to identify the distillation regions and compartments as well as miscibility gaps. Based on this initial knowledge potential process sequences are generated in a tree structure before they are finally converted to process configurations with closed recycles. The application of the method only requires the specification of a thermodynamic model for VLE and LLE computations, as well as a problem definition

with feed composition and flowrate, desired products and the definition of a potential solvent. The method is implemented in MATLAB, whereas property data can be extracted from literature or directly from the property database of a process simulator, such as Aspen Plus.

2.1. Mixture topology

In order to evaluate the feasibility of individual splits by means of distillation, first the topology of the mixture, which includes the determination of homogeneous and/or heterogeneous azeotropes (Skiborowski et al. 2016) and the identification of distillation regions and compartments (Rooks et al. 1998) is performed. For liquid-liquid extraction, a necessary phase separation is evaluated by means of the homotopy continuation method of Bausa & Marquardt. (2000).

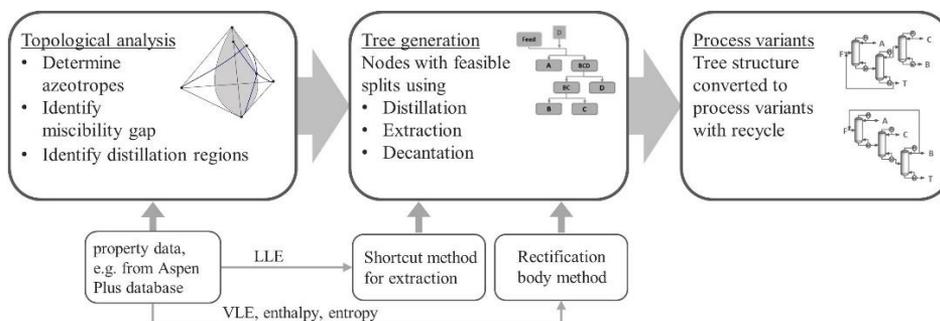

Figure 1: Illustration of the framework of the synthesis methodology

2.2. Generation of process sequences in a tree structure

Process sequences are generated through the evaluation of individual splits, creating a tree structure. The process starts from the initial feed mixture and adds feasible splits as new branches of the tree. Each node is further split until all desired products are reached. For each node, distillation, decantation and extraction are considered, with a potential subcooling to a predefined operating temperature being considered for the latter options. In case the product specification cannot be reached immediately, the program evaluates if recycling of individual products can improve the recovery or shift a feed stream to a different distillation region.

2.2.1. Feasibility test for distillation

For a separation by means of distillation the maximum recovery of individual splits is determined by means of a general feasibility criteria, which evaluates if both product compositions are located in the same distillation region. This is achieved by evaluating the terminals of product residue curves and pinch lines with respect to the topological distillation regions. Thus, if a sharp split is not feasible due to the intersection of the mass balance line with a distillation boundary, the highest possible purity of the limiting product is determined by means of a simple bisection. Through application of the rectification body method (Bausa et al. 1998) it is furthermore checked if both products are located in the same compartment, furthermore providing an estimate of the minimum energy demand (MED) for the specific separation. Thus, this combined procedure evaluates split feasibility without an explicit computation of the distillation boundaries, considers potential boundary crossing for finite reflux distillation and provides an estimate of the MED.

2.2.2. Feasibility test for extraction

For the evaluation of a separation by means of extraction, a pinch-based shortcut method for an isothermal counter-current liquid-liquid extraction column (Redepenning et al. 2017) is applied to determine the feasibility of extraction and the minimum solvent flowrate for the separation of a given feed composition. For the application the solvent composition and the desired purity of the key component in the raffinate phase must be defined a-priori. The shortcut method builds on the identification of the saddle-node pinch that governs the minimum solvent operation. The computations build on a rigorous thermodynamic model for LLE computation and exploit continuation methods for a robust and computationally efficient evaluation of the minimum solvent flowrate.

2.3. Generation of variants including recycle

While potential recycle streams are already introduced during the generation of the tree structure, the recycle streams are not closed in this initial synthesis phase. In case such recycle streams are used the recycles are closed in a subsequent step. Furthermore, individual nodes that are not desired products or pure components are also recycled to suitable destinations. If the recycle cannot be converged due to topological restrictions, an additional pure component stream is introduced with the recycle.

3. Case Study

For illustration of the methodology the separation of a ternary mixture of acetone, acetic acid and water using chloroform as solvent is considered. Although the ternary mixture is zeotropic at ambient pressure, separation by means of distillation is energy-intensive due to a rather low relative volatility of acetic acid and water and a tangent pinch near pure water. Acetone and water also exhibit low relative volatility at high acetone purity. Previous studies have shown the use of chloroform as a suitable solvent for liquid-liquid extraction (Minotti et

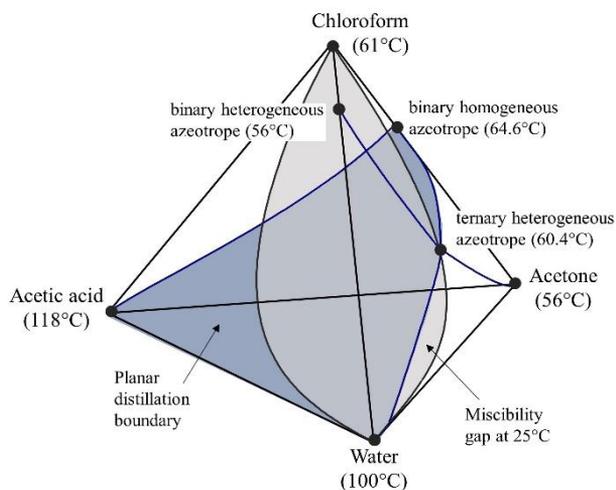

Figure 2: Topology of the quaternary mixture of acetone, acetic acid, water and chloroform at 1 atm including the miscibility gap at 25°C

al. 1996, Caballero & Grossmann 2009, Redepenning et al. 2013). Figure 2 illustrates the topology of the quaternary mixture, including chloroform, which introduces two binary and a ternary azeotrope at 1 atm pressure, and a miscibility gap between water and chloroform, which extends into the quaternary region. The thermodynamic model builds on the UNIQUAC parameters obtained from Aspen Plus. The azeotropes induce a distillation boundary, which divides the quaternary composition space into two distillation regions with acetone and chloroform being the unstable nodes of the individual distillation regions. Note that the ternary sub-space of acetone-chloroform-water is even more complex, with four individual distillation regions.

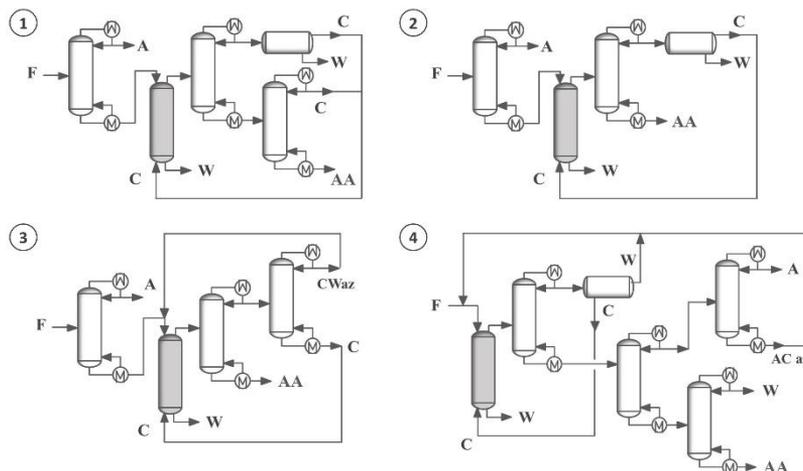

Figure 3: Process variants for the separation of a ternary mixture of acetone (A), acetic acid (AA) and water (W) using chloroform (C).

For process synthesis a feed stream of 10 mol/s with 70 mol-% water and 15 mol-% each of acetone and acetic acid is to be separated in the individual components. For decantation and extraction an operating temperature of 25°C is assumed. Application of the methodology results in overall six feasible process variants, including the direct split (DS) and indirect split (IS) sequence for the separation of the initially zeotropic ternary mixture. The computations for the generation of these variants take less than 5 min of computational time on a desktop PC. Figure 3 illustrates the four variants that utilize chloroform as a solvent and incorporate an extraction column with a closed solvent recycle. Due to the azeotropes formed with chloroform, solvent recovery is more complex. Variants 1-3 first remove acetone from the feed in a distillation column, followed by extraction of the binary acetic acid-water mixture using chloroform. Variant 4 starts with liquid-liquid extraction and requires the most unit operations. The MED of all process variants is illustrated in Figure 4. For streams leaving an extraction column or decanter at subcooled conditions, additional heating duty is accounted for in the MED if such streams are further processed using distillation. Compared with the DS and IS sequences only variant 1 and 2 offer the potential for energy savings. These process variants require 22% and 26% less energy than the DS sequence respectively. Variant 2 offers the lowest MED and requires one distillation column less than variant 1. The two streams from the decanter have a purity of 99.4 mol-% chloroform and 99.88 mol-% water respectively. Based on the comparison of variant 2 and 3 it becomes apparent that the chloroform water separation is much more efficient by decantation than distillation. Variant 4 does not only require the most number of equipment, but also the highest MED, which is also caused by a large water recycle stream that needs to be mixed with the acetone-chloroform azeotrope prior to recycling to the extraction column.

4. Conclusion

Given the selection of a suitable solvent, hybrid extraction-distillation processes present an important option for the energy-efficient separation of complex non-ideal mixtures. Yet, depending on the choice of solvent a more complex process design may be required, which so far had to be manually designed. In order to overcome this limitation and allow

for an algorithmic generation of integrated process flowsheets the algorithmic framework for the synthesis of homogeneous and heterogeneous azeotropic distillation processes has been extended to include liquid-liquid extraction. The application of the extended methodology to the separation of acetone, acetic acid and water with chloroform illustrates the capability of the method to synthesize hybrid separation processes for a solvent that introduces additional azeotropes and distillation boundaries. The results further illustrate the potential energy savings of such solvent-based processes, even for close-boiling systems that do not experience azeotropes. The extended synthesis method provides the basis for a solvent screening that considers tailored process configurations for each individual solvent. Such evaluations will be the focus of future work, which will also consider processes with alternative unit operations such as heteroazeotropic distillation and extractive distillation.

Abstract

The modern design of chemical processes should involve holistic objective functions as well as the consideration of uncertainty sources. This work presents an optimization framework for flexible design combining stochastic programming with metaheuristic algorithm as solver, the 4E analysis as objective functions, and the integration of a decision-making criterion based on statistical fundamentals, applied in optimal distribution designs under uncertainty (80 % value of cumulative distribution functions (CFD)). The framework was applied to a separation and purification scheme (SPS) based on hybrid configurations and evaluating four extracting agents to separate an ABE mixture. The results show that the use of 80 % value of CFD is an adequate indicator for decision-making in multi-objective optimization under uncertainty. The similarities of the final designs using different extracting agents allows to conclude that a unique flexible and adaptable SPS design can be selected.

Keywords: Optimization under uncertainty, MOGA, Flexible design, 4E analysis.

1. Introduction

In the past decades, the objectives for optimal designs were focused on simple targets, because the standard metrics for chemical plants consisted of the assessment of the operational aspects and comparison of their performance through common targets (*e.g.* economy, heat duty, CO₂ emissions, etc.). These optimal designs are strictly related to steady-state operating conditions, and therefore, they are not naturally capable to respond to external perturbations and internal unexpected behaviors. In this sense, the introduction of the flexibility concept and multi-objective optimization are some of the principal and attractive challenges in Process System Engineering (Pretoro *et al.*, 2019).

Particularly, the design of chemical processes that involves multiple conflicting objectives and uncertainties, are identified as relevant and interesting optimization challenges, where the combination of two mathematical and solution strategies can be applied to tackle those issues: multi-objective optimization and optimization under uncertainty. Both strategies allow to obtain a final reliable and robust design (Zhang & Taflanidis, 2019). Regarding to flexible design, this generally involves system oversizing with respect to the nominal design, which represents major investment and operational costs, as well as better energy manipulation to compensate the variability and keep the final product specifications (Pretoro *et al.*, 2021).

Based on the actual state of the art, the metrics of modern process design must gradually adapt and consider internal and external perturbations, besides the fast-changing market demand, and the resources availability, without neglecting sustainability aspects and optimal operating conditions. Therefore, the objective of this work is to develop and implement a conceptual framework for optimal and flexible schemes design, associated to uncertainty sources using a computational platform based on the use of statistical indicators as decision-making criteria for the selection of the final design.

2. Case study

The production of biofuels and bio-bulk commodities is still an attractive path to satisfy a partial global market demand, in this sense, the acetone-butanol-ethanol production via *Clostridia* microorganism is an interesting bioprocess to contribute to this goal, which naturally has diverse sources of uncertainties; but due to the nonidealities in the mixture, high dilution ratio, multiple products and variable yields, the design of ABE separation and purification schemes (SPS) is a complex system to model and optimize (Grisales & Olivar, 2017). In previous works, liquid-liquid extraction (LLE) and conventional distillation were employed as separation and purification techniques for the ABE mixture, getting satisfactory energy results, and showing the relevance of suitable selection of extracting agents (EA) through computer-aided molecular design (Sanchez-Ramirez *et al.*, 2018). Based on the previous statements, the framework was evaluated using the hybrid SPS for ABE mixture.

3. Methodology

The framework for optimal and flexible schemes design under uncertainty & sustainable aspects involves the main idea to combine the stochastic programming fundamentals (wait-and-see strategy) but replaces the conventional solvers by a metaheuristic algorithm to solve the problem statement. This framework includes four steps illustrated in Figure 1 and are described below.

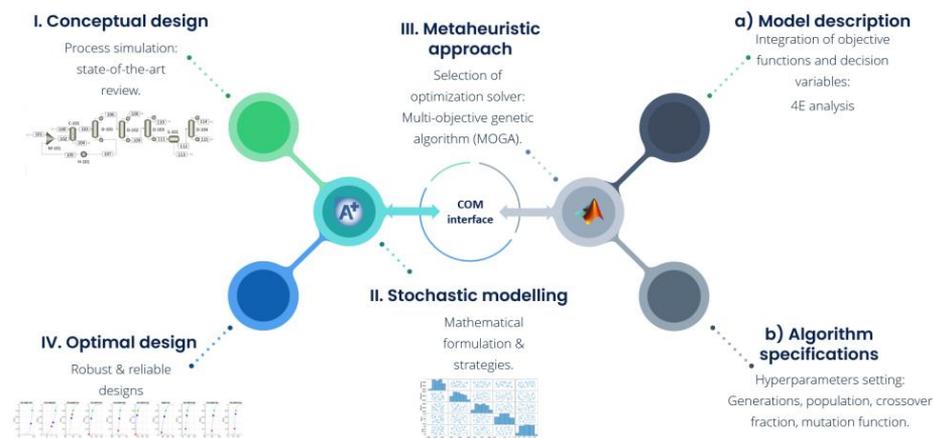

Figure 1. Framework for optimal and flexible design under uncertainty & sustainable aspects.

3.1. Conceptual design: Thermodynamic description

Aspen plus was employed for the conceptual design of the SPS (illustrated in Figure 2), including one LLE column (C-101) to remove ABE from the aqueous phase, evaluating four EA: heptyl acetate (HEP), hexyl acetate (HEX), heptyl-hexyl acetate mixture (HEP-

HEX), and 2-ethyl-1-hexanol (2-ETH-1-OL). Four conventional distillation columns (D-101, D-102, D-103, and D-104) were used to recover and purify the extracting agent, acetone, ethanol, and butanol, respectively. Phase equilibria was calculated employing the NRTL thermodynamic model and the equation of state Hayden-O'Connell (Ponce Rocha, 2021).

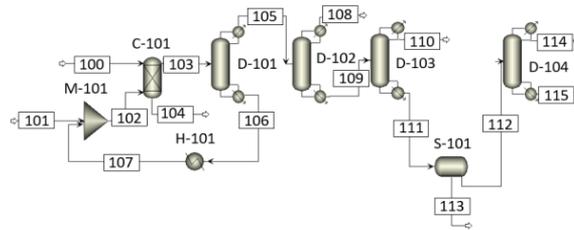

Figure 2. Case study employed to evaluate the MOOUU framework.

3.2. Stochastic modelling: MOOUU

The multi-objective optimization under uncertainty (MOOUU) employed in this work was formulated as following (1):

$$\underset{x}{\text{Min}} \quad \underline{Z} = [Z_k(\underline{x}, \theta^*)] \quad \text{s. t.} \quad \mathbf{h}(x, \theta^*) = 0 \quad \mathbf{g}(x, \theta^*) \leq 0 \quad x \in \mathbf{X}, \theta^* \in \Theta^* \quad (1)$$

Where \underline{Z} , describes the vector of k objective functions under uncertainty (Exergy, energy, economy, and environment), \underline{x} represents the vector of n-dimensional states associated with structural and operational specifications (FMAEX: extracting agent mass flowrate, NS: number of stages, FS: feed location, RR: reflux ratio, DF: distillate flowrate, or BF: bottom flowrate), θ^* is the vector of s-dimensional uncertainties present in the selected variables. \mathbf{h} & \mathbf{g} represent the vectors of equality and inequality constraints associated with operational and structural limitations.

3.2.1 Objective function definition: 4E-analysis

The combination of energetic, exergetic, economic, and environmental analysis (4E analysis) has been reported as a useful tool to design and optimize energetic intensive processes (Ponce Rocha, 2021). In the present work, this 4E functions are calculated as follows:

a) Exergetic analysis

The exergy losses (σT_0) can be obtained as illustrated in Equation (2), where $\Delta \dot{E}x_{In}$ represents the exergy input, and $\Delta \dot{E}x_{Out}$ is the exergy output, of each stream in the analyzed system, which includes the heating, cooling, and concentration changes effects.

$$\sigma T_0 = \Delta \dot{E}x_{In} - \Delta \dot{E}x_{Out} \quad [kW] \quad (2)$$

b) Energetic analysis

A common metric to validate the feasibility of biofuels separation is the ratio of the energy requirements and product throughput, as illustrated in equation (3).

$$ER = \frac{\text{Energy consumption [MJ]}}{\text{Product [kg]}} \quad (3)$$

c) *Economic analysis*

The total annual cost (TAC) is one of the more important indicators that includes the capital cost, operating cost, and the payback period (4).

$$TAC = \frac{\text{Capital cost}}{\text{Payback period}} + \text{Utilities} \quad (4)$$

d) *Environmental analysis*

A simple metric to evaluate the environmental impact is the use of the E factor, this indicator is the ratio between waste and products generated in the process.

$$E_{factor} = \frac{\text{Waste [kg]}}{\text{Product [kg]}} \quad (5)$$

3.2.2 *Uncertainty identification and propagation*

The feed flow stream (100) was identified as one of the principal uncertainties sources in the system since this is coming from the fermentation section. Therefore, the propagation of the uncertainty in the feed composition was generated using the following values: acetone (A) 2,275±112 kg/h, butanol (B) 5,931±276 kg/h, ethanol (E) 1,592±135 kg/h, water (W) 10,479±498 kg/h, carbon dioxide (CO₂) 82±5 kg/h. The Latin hypercube sampling (LSH) method was used for the generation of seventy-five random scenarios using a uniform distribution function.

3.3 *Metaheuristic algorithm: simulation-optimization approach*

In this section, a computational interface (COM) was used to integrate Aspen Plus and Matlab. This interface involves three main steps: 1) Matlab generates random vector values using the LSH, 2) The vector values are used by Aspen Plus to evaluate each scenario under uncertainty, 3) The optimal operating and design results are returned to matlab to calculate the objective function values. This step is performed according to the hyperparameters definition. The optimal values are saved to be used in the next step for graphical, statistical and feasibility analysis. The Matlab suite: gamultiobj, a multi-objective genetic algorithm (MOGA) and a variant of NSGA-II were used for metaheuristic optimization. Each optimization employed the following hyperparameters: 50 generations, 200 individuals, and a crossover fraction of 0.8 and an adaptative feasible mutation function. The mass purity (P) and mass recovery (R) constraints are specified for equations (6) and (7).

$$[P_{HEP}, P_A, P_B, P_E] \geq [0.999, 0.950, 0.995, 0.900] \quad (6)$$

$$[R_{HEP}, R_A, R_B, R_E] \geq [0.999, 0.995, 0.000, 0.992] \quad (7)$$

3.4 *Optimal distribution designs: decision making for flexible design*

After the evaluation of each uncertain scenario employing the evaluated EA, a set of optimal designs was obtained, which can be analyzed employing statistical indicators as tool for establishing a robust and reliable design in uncertainty scenarios. Three criteria were evaluated: mean, mode, and the 80 % of the cumulative distribution function (CDF).

4. Results

Figure 3 shows the distribution designs for each EA, using the mean (blue dot), mode (red dot) and 80 % of CFD (green dot). Then, the minimum, average, and maximum flowrate vectors were evaluated in the final optimal design obtained for each statistical indicator for each extracting agent. In this sense, the 80 % of CFD indicator showed better results

assuring the robustness of the design through the convergence analysis of the average value and the lower and upper boundaries of the feed flowrate vectors.

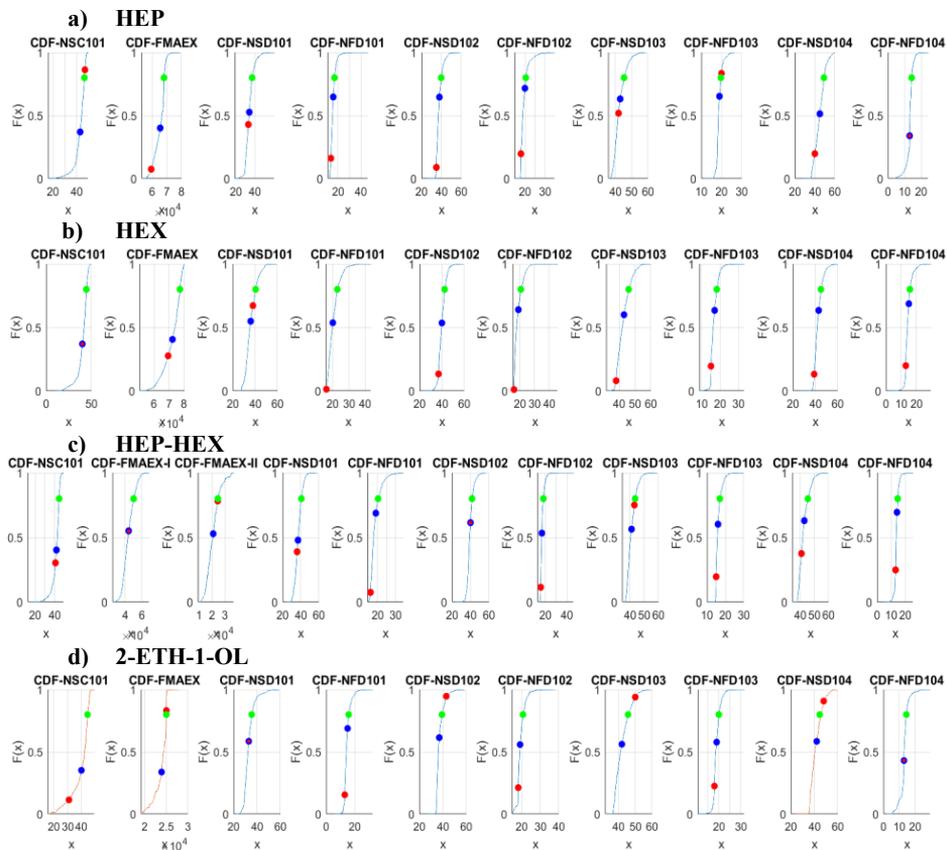

Figure 3. CFD for optimal distribution structural designs for each EA. FMAEX: extracting agent mass flowrate, NS: number of stages, FS: feed location.

Table 1 illustrates the optimal design results summary obtained for the 80 % of CFD indicator, employing the evaluated EA. In Table 1 is possible to observe similar structural designs specification such as, number of stages and feed locations for each equipment.

Table 1. Comparative structural designs for each design and operating variables.

Variable	N _S	F _{MAEX}	N _S	N _F	N _S	N _F	N _S	N _F	N _S	N _F
	C ₁₀₁	kg/h	D ₁₀₁	D ₁₀₁	D ₁₀₂	D ₁₀₂	D ₁₀₃	D ₁₀₃	D ₁₀₄	D ₁₀₄
HEP	47	68,080	37	17	40	20	46	20	49	14
HEX	44	77,292	41	23	43	21	46	18	45	16
HEP-HEX	45	24,753-50,418	41	20	42	18	44	17	46	15
2-ETH-1-OL	45	25,000	36	16	39	21	46	20	46	15

Table 2 shows the average results and standard deviations of the objective functions values for each extracting agent, employing the average values and the lower and upper boundaries of the uncertain values of the feed flowrate vectors. The use of HEP as EA gives the best results in three criteria (exergy, energy and environmental). The second option was the use of the HEP-HEX mixture as EA, followed by 2-ETH-1-OL and HEX.

Table 2. 4E objective functions values

	σT_0 [MW]	ER [MJ/kg ABE]	TAC [MUSD/year]	E _{factor}
HEP	2.00±0.06	12.19±0.42	8.34±0.22	0.24±0.01
HEX	2.28±0.09	17.33±0.35	10.96±0.29	0.44±0.01
HEP-HEX	2.29±0.07	14.88±0.49	9.86±0.33	0.32±0.02
2-ETH-1-OL	2.03±0.07	16.50±0.45	7.87±0.29	0.80±0.02

5. Conclusions

In this framework, a novel strategy to optimize under uncertainty a complex SPS was applied. The implementation of 4E analysis and MOGA showed satisfactory results in the stochastic problem solution. The 80 % of the CFD indicator was validated as a satisfactory indicator to select reliable and robust designs. Due to the identical targets in separation and purification tasks, each optimal final design for each EA has similar structural specifications, in this sense, a single design can be proposed and identified with adaptable and flexible characteristic, where EA flowrate is variable due to their physicochemical properties. Regarding to the EA, HEP showed the best performance results, but the idea of a flexible and adaptable design would allow to use other EA considering market availability.

Abstract

Carbon capture and utilization for fuel production is one of the attractive and effective solutions addressing climate change and energy security. In which captured CO₂ is considered as raw materials for high-energy-density products (e.g., methanol, dimethyl ether, Fischer-Tropsch fuel, gasoline) via different technologies (catalytic conversion, thermochemical energizing, electrochemical reduction). This study developed an optimization-based framework to analyze and assess CO₂ utilization strategies for fuel products regarding technical, economic, and environmental performance. To achieve this goal, we first generated a superstructure involving a series of technologies (carbon conversion and separation) to produce value-added fuels from captured CO₂ as a feedstock. We then simulated all the involved processes and estimated the technical and economic parameters (mass and energy flow, and sizing and costing data) that were further adopted into the optimization model. The optimization models were developed to identify the optimal CO₂ utilization strategies with different criteria: energy efficiency, production cost, profit, and CO₂ reduction. As a result, we can determine the best CO₂ utilization strategy over various technological pathways to produce different targeted fuels, which makes CO₂-based fuels economically and/or environmentally viable.

Keywords: Process design; CO₂ utilization superstructure; Optimization.

1. Introduction

Carbon capture and utilization is one of the attractive and effective solutions addressing global warming and energy security. This action supports reducing CO₂ emission by capturing and utilizing CO₂ as a raw material for high-value fuels and chemicals such as methanol (MeOH), dimethyl ether (DME), Fischer-Tropsch fuel (FT fuel), and gasoline. Besides mitigating emission, the CO₂-based fuels can share the burden on fossil fuels by replacing (e.g., FT fuels, gasoline) or blending (e.g., MeOH, DME) with conventional fuels.

Recently, the literature has found much research on CO₂ utilization technologies such as catalytic conversion, electrochemical reduction, and thermochemical energizing (Kim et al, 2012, and Mevawala et al., 2017). While some work on the high performed catalyst or thermochemical/electrochemical materials, others study process design and optimization, techno-economic and environmental analysis of CO₂ utilization to fuels (Do et al., 2019 and 2020). Also, many studies conduct a technological superstructure and optimization-based framework for fuels and chemicals from various feedstock materials. Kim et al.

developed a superstructure of fuels from biomass and assessed the conversion strategies with different evaluation criteria, the uncertainty, and sensitivity analysis (Kim et al., 2013). Han et al. developed an assessment framework for optimal strategies to utilize industrial residue gas (Han et al., 2019).

This study developed an optimization-based assessment framework to analyze and assess CO₂-to-fuel utilization strategies with different evaluation criteria: energy efficiency, economic, and environmental friendliness. The problem statement and methodology are presented in Section 2. The generation of the technological superstructure, including various carbon conversion and separation technologies, which aim to produce CO₂-based fuels: MeOH, DME, FT fuels, and gasoline, are discussed in Section 3. Then, the process simulation of possible CO₂-to-fuels pathways among the superstructure was developed and the techno-economic parameters (e.g., mass and energy flow, and sizing and costing data) were further obtained and presented in Section 4. In section 5, the optimization models were developed to identify the optimal CO₂ utilization strategies with different criteria: energy efficiency, production cost, and CO₂ reduction. Finally, the best CO₂ utilization strategy over various technological pathways for different targeted fuels is discussed in Section 6.

2. Methodology

This study aims to propose and develop an optimization-based assessment framework of CO₂ utilization to fuels, which supports identifying the optimal strategies for specific CO₂-based fuels, as shown in Figure 1. We first define the problem by selecting captured CO₂ as the main feedstock, selecting final products and technologies, and developing the superstructure by integrated technologies to convert CO₂ forward to final products. The process simulation of all possible production pathways is then developed and the technical (mass and energy flow), and economic data (sizing and costing data) are obtained. The optimization model is developed based on the generated superstructure framework and the associated techno-economic data. The model identifies the optimal CO₂-to-fuel strategy for a given problem and given final products, such as: maximizing energy efficiency (EEF), minimum unit production cost (UPC), and net CO₂ emission (NCE).

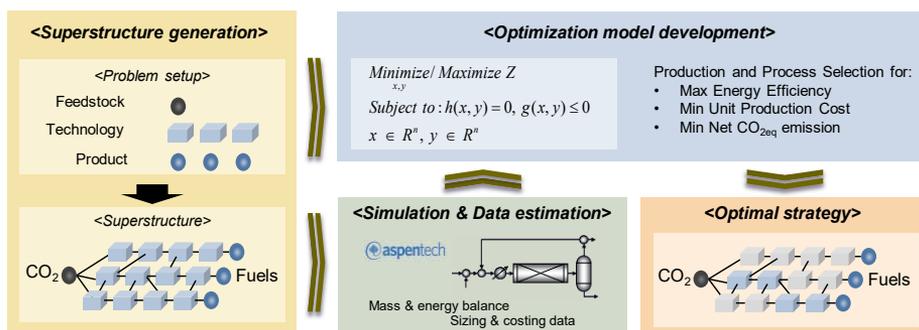

Figure 1. Methodology for the assessment of CO₂ utilization strategy for liquid fuels

3. Superstructure

In this study, the compounds were classified into three groups: feedstock (i.e., captured CO₂), intermediates (e.g., syngas, raw fuels), and final products (e.g., MeOH, FT fuel, DME, and gasoline). The technologies including reaction/conversion technology (e.g.,

direct CO₂ hydrogenation, reverse water-gas shift, thermochemical CO₂ energizing, electrochemical CO₂ reduction, methanol/DME/FT synthesis from syngas, methanol-to-gasoline, methanol dehydration) component separation (e.g., CO₂ absorption, CO adsorption), and product purification (e.g., flash drum, distillation). Note that a single technology includes various operating equipment.

The CO₂ utilization superstructure was developed by connecting compounds and multiple techniques for targeted products, as presented in Figure 2. Here, there are many production pathways for a specific product. For example, FT fuels can be produced via direct CO₂ hydrogenation or FT synthesis from syngas (indirect pathway), in which, the intermediate syngas can be converted through reverse water-gas shift or thermochemical splitting, or electrochemical reduction.

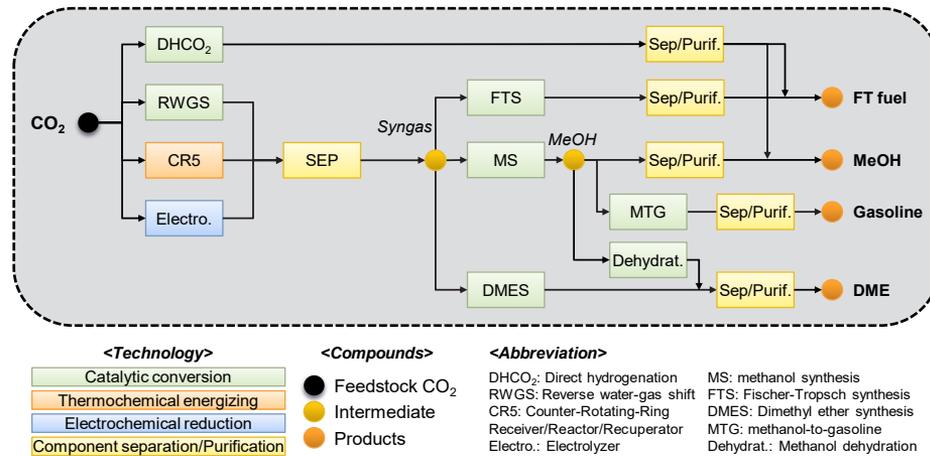

Figure 2. Superstructure of CO₂ utilization to fuels

4. Simulation and parameter estimation

In this study, CO₂ feedstock is assumed to be captured from the flue gas of coal-powered electric utility (500 MW), which is about 3.1 million ton of captured CO₂ per year. Each process was simulated using Aspen Plus V.11. More detailed process simulation and modeling could be found in the literature (Do et al., 2022). The mass flow, energy flow, sizing and costing data were then obtained for further model input and analysis. Table 1 summarizes major technical and economic parameters.

^a Yield: calculated based on the material input and production output.

^b TCI (M\$): total capital investment cost.

^c TOC (M\$/y): total annual operating cost

^d ER (MWh): energy requirement for process.

^e DCE (ton/h): direct CO_{2eq} emission (vent-out gas, purge gas) from process.

^f EO (10³ GGE/h): Energy flow of products.

Abbreviations: RWGS: Reverse water-gas shift, DH: Direct CO₂ hydrogenation, CR5: Counter-Rotating-Ring Receiver/Reactor/ Recuperator, ELECZ: Electrochemical reduction, MS: Methanol synthesis, FTS: Fischer–Tropsch synthesis, DMES: dimethylether synthesis, DEH.: Methanol dehydration, MTG: methanol-to-gasoline, COSEP: CO separation by adsorption, CO2SEP: CO₂ separation by absorption, SEP: separation and purification.

5. Optimization model

To identify the optimal strategy for CO₂ utilization to fuels, we develop optimization models using a mixed-integer linear programming (MILP) technique to identifies the optimal CO₂-to-fuel pathway for each CO₂-based fuel type. Eq. (1) uses to identify the maximum energy efficiency strategy, which is maximum energy stored in product with a certain input energy to process. Eq. (2) seeks for the most economic strategy, which is minimum unit production cost for a fixed amount of product. Other, minimum net CO₂ emission strategy is identified vis Eq. (3), which emits as producing a certain amount of product.

$$MaxEEF_s = \sum_j \rho_i P_{ij} \quad (1)$$

$$MinUPC_s = \sum_j \alpha_j + \sum_j \psi_j + \sum_{i \in I^F} \xi_i F_{ij} + \sum_{i \in I^U} \varpi_i U_{ij} \quad (2)$$

$$MinNCE_s = \sum_j \lambda_j + \sum_{i \in I^F} \varepsilon_i U_{ij} - \sum_{i \in I^P} \tau_i F_{ij} \quad (3)$$

Where ρ_i is the heating value of final product $i \in I^P$. F_{ij} , U_{ij} , P_{ij} , is the the amount of feestock $i \in I^F$, utilities $i \in I^U$ and product of pathway j , respectively. α_j is the

total capital investment cost of pathway j , ψ_j is the fixed operating cost factor of pathway j . ϖ_i and ξ_i are the unit costs for utilities $i \in I^U$ and feedstock $i \in I^F$, respectively. λ_j is the amount of CO₂ directly emitted by technology j . ε_i is the amount of indirect CO₂ emission by using utility $i \in I^U$, and τ_i is the CO₂ inventory for feedstock $i \in I^F$.

The optimization model was constrained by the demand satisfaction and feed availability and minimum feed purchase, as expressed in Eqs. (4) – (5).

$$P_i \geq \beta_i \tag{4}$$

$$\gamma_i \leq F_i \leq \delta_i \tag{5}$$

Where β_i is the demand of product. γ_i and δ_i are the minimum purchase and feed's availability, respectively.

6. Results and discussion

With the proposed models, we can identify the optimal strategy to utilize CO₂ to different fuels objecting to max EEF, min UPC and min NCE. Figure 3 presented the optimal strategies, including CO₂-to-fuel technological pathways and three main evaluated criteria for the production of MeOH, FT fuel, DME and gasoline.

Target Fuels	Problem	Optimal Strategy	Description
Methanol (MeOH)	(a) Max EEF	CO ₂ → CR5 → SEP → MS → Sep/Purif. → MeOH	<ul style="list-style-type: none"> • EEF: 82.7% • UPC: 18.13 \$/GGE • NCE: -0.93 kgCO₂/GGE
	(c) Min UPC	CO ₂ → DHCO ₂ → Sep/Purif. → MeOH	<ul style="list-style-type: none"> • EEF: 71.2% • UPC: 3.60 \$/GGE • NCE: -1.01 kgCO₂/GGE
	(d) Min NCE	CO ₂ → DHCO ₂ → Sep/Purif. → MeOH	<ul style="list-style-type: none"> • EEF: 71.2% • UPC: 3.60 \$/GGE • NCE: -1.01 kgCO₂/GGE
Fischer-Tropsch (FT fuel)	(a) Max EEF	CO ₂ → DHCO ₂ → Sep/Purif. → FT fuel	<ul style="list-style-type: none"> • EEF: 58.2% • UPC: 4.46 \$/GGE • NCE: 3.22 kgCO₂/GGE
	(c) Min UPC	CO ₂ → DHCO ₂ → Sep/Purif. → FT fuel	<ul style="list-style-type: none"> • EEF: 58.2% • UPC: 4.46 \$/GGE • NCE: 3.22 kgCO₂/GGE
	(d) Min NCE	CO ₂ → DHCO ₂ → Sep/Purif. → FT fuel	<ul style="list-style-type: none"> • EEF: 58.2% • UPC: 4.46 \$/GGE • NCE: 3.22 kgCO₂/GGE

	(c) Min UPC	CO ₂ → DHCO ₂ → Dehydrat. → Sep/Purif. → DME	<ul style="list-style-type: none"> • EEF: 58.4% • UPC: 4.01 \$/GGE • NCE: 0.18 kgCO₂/GGE
	(d) Min NCE	CO ₂ → DHCO ₂ → Dehydrat. → Sep/Purif. → DME	<ul style="list-style-type: none"> • EEF: 58.4% • UPC: 4.01 \$/GGE • NCE: 0.18 kgCO₂/GGE
Gasoline	(a) Max EEF	CO ₂ → DHCO ₂ → MTG → Sep/Purif. → Gasoline	<ul style="list-style-type: none"> • EEF: 81.3% • UPC: 3.71 \$/GGE • NCE: -1.86 kgCO₂/GGE
	(c) Min UPC	CO ₂ → DHCO ₂ → MTG → Sep/Purif. → Gasoline	<ul style="list-style-type: none"> • EEF: 81.3% • UPC: 3.71 \$/GGE • NCE: -1.86 kgCO₂/GGE
	(d) Min NCE	CO ₂ → CR5 → SEP → MS → MTG → Gasoline	<ul style="list-style-type: none"> • EEF: 72.3% • UPC: 21.92 \$/GGE • NCE: -2.78 kgCO₂/GGE

Figure 3. Optimal strategy for CO₂-based fuel production using different criteria

The optimal strategy with the highest process energy efficiency for MeOH is through thermochemical CO₂ energizing subsequent methanol synthesis, at 82.7%. However, it is challenged with extremely high production cost at 18.13 \$/GGE (GGE – gallon gasoline equivalent). The direct CO₂ hydrogenation to MeOH is the most economic and eco-friendly pathway at 3.6 \$/GGE and reduces 1.01 kgCO₂/GGE (NCE<0), respectively.

For production of FT fuel, the direct hydrogenation of CO₂ is also the optimal strategy over other pathways and over three examined problems. Compared to MeOH, FT fuels is less energy efficient (58.2 %), higher cost (4.46 \$/GGE), and emit 3.22 kgCO₂/GGE (NCE>0). Here, FT is indicated as an unfavorable choice for eco-hydrocarbon synthesis. Similar to MeOH, the CO₂-to-DME pathway of thermochemical CO₂ energizing subsequent DME synthesis is the optimal strategy for maximum EEF. The optimal strategy for cost and environmental problems is through direct CO₂ hydrogenation to MeOH subsequent MeOH dehydration to DME, which results in 4.01 \$/GGE and 0.18 kgCO₂/GGE emission.

The direct CO₂ hydrogenation to MeOH followed methanol-to-gasoline is the optimal gasoline production strategy regarding max EEF (81.3%) and min UPC (3.71 \$/GGE). This strategy also performs good environmental performance, which reduces CO₂_{eq} at NCE of -1.86 kgCO₂/GGE. However, the optimal eco-friendly strategy is through thermochemical energizing technology for methanol synthesis subsequent methanol-to-gasoline, at -2.78 kg CO₂/GGE with the trade-off of extremely high production cost.

7. Conclusion

In this study, we proposed and developed an optimization-based assessment framework for CO₂ utilization to fuels strategies. The framework is based on the CO₂-to-fuels superstructure includes a number of conversion and separation technologies for desired fuel production. Then, the optimization model enables us to assess CO₂ utilization strategies with evaluation criteria regarding energy efficiency, unit production cost, and process eco-friendliness. Thereby, the framework determines the best CO₂ utilization strategy over various technological pathways to produce different targeted fuels, which makes CO₂-based fuels economically and/or environmentally viable. It can also support the policymaker or company identify a suite of strategic solutions to utilize captured CO₂ for fuels.

Abstract

This contribution introduces a combined liquid chromatography purification designed for a continuous and resource-efficient process, integrating the rotating columns and the simulated bed principles. The approach is demonstrated and validated based on bisabolol oxides A and B, which are effective ingredients with anti-inflammatory and spasmolytic effects, prepared from chamomile essential oil. The results show superior efficiency to the traditional selective methods for isolating ingredients from multicomponent mixtures, as well as reduction in resources and costs.

Keywords: Essential oil; Preparative chromatography; Simulated moving bed (SMB).

1. Introduction

Bioactive ingredients from plant extracts are the basis of many innovative products in the food, cosmetics, or the pharmaceutical industries. However, at present, mainly diluted products are extracted as complex mixtures, as a large amount of by-products accumulates as waste at the end of the process, and can only be recovered with increased effort. Essential oils are complex volatile substances composed of many ingredients with broad spectrum of bioactivity and, therefore, subject to extensive research (Chouhan et al. 2017). Various processes have been used to extract these ingredients: harvesting as plant materials, washing, extraction of phytonutrients, or purification of the components of interest (Belwal et al. 2020). Traditional techniques consist of liquid-liquid extraction, solid-liquid extraction, or solid phase micro-extraction. Modern techniques include ultrasound-assisted extraction, pressurised liquid extraction, supercritical fluid extraction, microwave-assisted extraction, or instant controlled pressure drop extraction (Yahya et al. 2018). Often, for the same plant, extraction conditions may vary in terms of extraction time or amount of solvent used. Conventional methods suffer from some serious disadvantages, such as excessive solvent, time and energy requirements, which demand the development of new techniques that are more efficient, less expensive and least hazardous (Abbas et al. 2021). Modern techniques show significant improvement over the traditional ones in terms of less extraction time, greater extraction yield and lower solvent consumption, but depend on parameters such as solvent composition, amount of solvent, and plant material loading (Bagade et al. 2021). Moreover, green extraction technologies come with their own shortcomings: high capital investment, high running

cost, complex configuration, training, maintenance cost, which limit their large scale application (Picot-Allain et al. 2021).

Using the example of bisabolol oxides A and B (BOA, BOB), effective ingredients with anti-inflammatory and spasmolytic effects, prepared from the essential oil of a bisabolol oxide-rich chamomile (Schilcher et al. 1987), a combined liquid chromatographic purification is designed and implemented in the following sections up to their complete separation.

2. Materials and methods

The developed procedure is implemented using a system for continuous liquid chromatography (Wissenschaftliche Gerätebau Dr.-Ing. Knauer GmbH, Berlin; Type: CSEP®9116) with a 64-port multifunction valve (100 bar pressure-resistant). Up to 16 separation units (columns) can be combined in parallel or in series. In the present work, (semi-)preparative columns (C18H, 10 μ m 8x120mm) are used. The active ingredients were detected using a photo diode array (PDA) detector (Knauer Smartline S2800).

2.1. Materials

The chamomile oil produced by steam distillation is separated from the paraffins (long-chain, branched and unbranched n-alkanes) contained in it using a simple crystallization method. Subsequently, the oil could be prepared by distillation in such a way that the low-volatility components (β -farnesene, germacrene D, elemene) are largely depleted and only present in traces (remaning low-volatility compounds < 2 wt. %). The concentration of the valuable active ingredients increases during this step, and a pre-fractionated oil is produced with the composition presented in Table 1.

Table 1: Chamomile oil content

Ingredient	Mass fraction
β -farnesene	1.68 wt.%
Bisabolol oxide A	45.52 wt.%
Bisabolol oxide B	28.51 wt.%
Chamazulene	9.55 wt.%
Rest	14.74 wt.%

To avoid policy hurdles during a possible product development, the process design is limited to a solvent mixture of ethanol/water (mobile phase – MP), which is pharmacologically harmless.

The modular structure of the simulation toolbox offers flexibility in adding new modules for improved representation of the internal geometries as well as of the different phenomena (*e.g.*, holdup, fluid flow, kinetics, etc.) taking place inside the TBR, as well as expansion to energy balance to move away from the isothermal assumptions.

2.2. Analysis

Gas chromatography systems are used to analyse the starting, intermediate, and end products. Their structure is elucidated and identified using a GC-MS system (Shimadzu QP2010S), and then transferred to a GC-FID system for quantification (Shimadzu 2010Plus).

2.3. The rotating columns principle

Bauer et al. (1996) introduced a continuous chromatographic process based on a rotating multifunctional valve in which individual fractions can be separated spatially from a multifunctional mixture. In principle, the process can be compared with annular chromatography (Brozio et al. 2004), whereas the annular gap built up with the stationary phase (SP) is divided into discrete units and, thus, replaced by traditional (semi-)

preparative chromatography columns. The columns connected in parallel are filled with the MP in the direction of the flow, whereby the feed is introduced at a fixed point. A significant disadvantage of the process is the mandatory isocratic loading of the MP across all pillar positions. In the case of a heterogeneous feed consisting of components with different adsorption-desorption mechanisms, this leads to long processes, high cycle frequency and high consumption. To overcome this, in the first stage of the extraction process, the task of the MP is divided into position segments, which allow the gradient elution and ultimately a cleaning of difficult-to-elute components with equilibration of the columns for the subsequent cycle. The two components considered, BOA and BOB, are difficult to separate by liquid chromatography using the ethanol-water combination, and sometimes elute at the same time under the desired high feed concentrations. To circumvent this problem, the two eluents are first fractionated together.

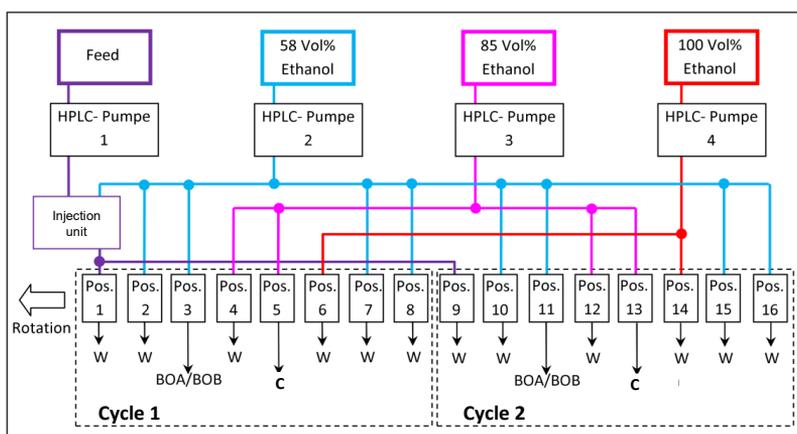

Figure 1: Fractionation system for BOA and BOB

Figure 1 shows the schematic interconnection of the system for the continuous fractionation of the bisabolol oxides as a binary mixture.

2.4. The simulated moving bed (SMB)

Counter current chromatography also offers the possibility of a continuous process management and is characterised by high efficiency compared to other alternatives, but it is limited to binary mixture. For the procedure developed here, both the SP and MP are moved in counter current to one another. The structure of the SMB used in the separation considers a four-zone configuration. A true moving bed (TMB) model (Charton & Nicoud, 1995) is used to define the parameters for the SMB. The residence time of the compounds in a chromatographic system results from the distribution equilibrium. The distribution coefficient is determined as the concentration quotient between the MP and the SP and is to be established via the retention time (t_R), taking into account the dead time (t_0) and the porosity (ϵ) of the packed column, based on the following equation:

$$K_i = \frac{t_R - t_0}{t_0 \frac{1 - \epsilon}{\epsilon}} \quad (1)$$

The selectivity between substances is defined as:

$$\alpha = \frac{t_{R(A)} - t_0}{t_{R(B)} - t_0} \quad (2)$$

The triangular theory developed by Ruthven & Ching (1989) for linear adsorption isotherms are used for the design of the simple SMB process. A system of equations is set up for the respective volume flows in each of the zones as follows:

$$\dot{V}_{MP(I)} = \dot{V}_{Elu} + \dot{V}_{MP(IV)} \quad (3)$$

$$\dot{V}_{MP(II)} = \dot{V}_{MP(I)} - \dot{V}_{Ex} \quad (4)$$

$$\dot{V}_{MP(III)} = \dot{V}_{MP(II)} + \dot{V}_F = \dot{V}_{MP(I)} - \dot{V}_{Ex} + \dot{V}_F \quad (5)$$

$$\dot{V}_{MP(IV)} = \dot{V}_{MP(III)} - \dot{V}_{Ra} = \dot{V}_{MP(I)} - \dot{V}_{Ex} + \dot{V}_F - \dot{V}_{Ra} \quad (6)$$

Where \dot{V} is the volume flow, in ml/min.

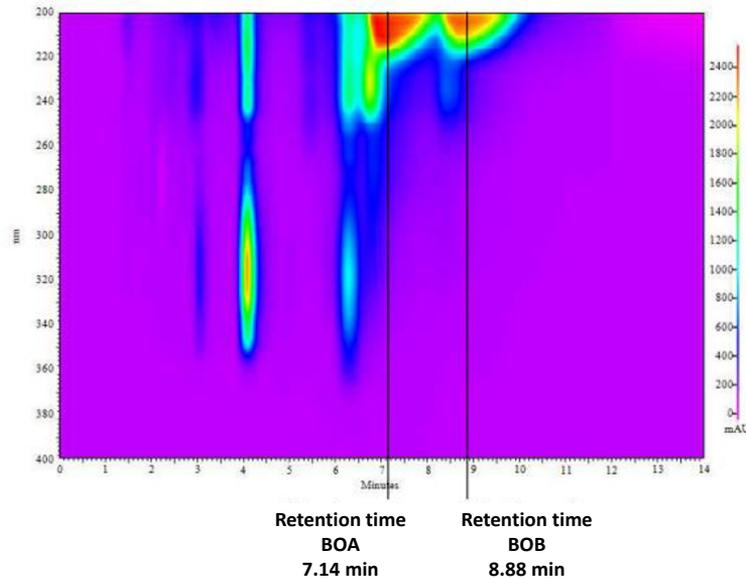

Figure 2: Retention times for the bisabolol oxides

The substance-specific retention times for the bisabolol oxides to be separated using the SMB method are determined in an optimized batch method. For this purpose, the most efficient separation of the components, with the lowest possible MP consumption is implemented. Due to the ethanol-water mixture used as MP, a relatively low maximum selectivity is set. Figure 2 shows the underlying chromatogram for the determination of the retention times as the basis for establishing the operating point for the TMB model. The following user-specified constraints are defined further:

- a) The permissible minimum flowrate ratio in Zone I must be increased by approximately 25% to ensure complete elution in the extract. Furthermore, if the flowrate increase, the eluent consumption increases as well

- b) The permissible maximum flowrate ratio in Zone IV must be reduced by approximately 25% in order to prevent carryover into Zone I. However, too great reduction is equivalent with an inefficient utilization of the SP
- c) For Zones I and II, an operating point within the range from Points 1 and 2 must be fixed ($m_{II} \leq m_{III}$)

For the operating conditions of the TMB model, the flowrate ratios in Zones I and IV were thus fixed, whereby the separation area for a practical operating point is spanned (triangle). From this, the flowrate for Zones II and III can be determined.

Table 2: Parameters for the SMB stage

Stationary phase (SP)	
Flowrate	0.1944 ml/min
Cycle rate	14.26 min
Mobile phase (MP) zone flow rates	
MP Zone I (Fixed)	1.500 ml/min
MP Zone II	1.084 ml/min
MP Zone III	1.162 ml/min
MP Zone IV	0.808 ml/min
Input and Output flows	
Eluent flow (Zone I – Zone IV)	0.692 ml/min
Feed flow (Zone III-Zone II)	0.078 ml/min
Extract flow (Zone I – Zone II)	0.416 ml/min
Raffinate flow (Zone III – Zone IV)	0.354 ml/min

The parameters determined for the SMB are summarised in Table 2. When assessing the test with a fixed operating point from this table, the concentration of the extract (BOB) at the extraction point is assessed as too low. The MP flowrate in Zone I should therefore be corrected downwards to 1.3 ml/min (instead of the value of 1.5 ml/min resulted from the

modelling) in order to cause a shift in the concentration profile of this component in the direction of Zones I and II (increase in the concentration at the extraction point). The eluent flowrate is consequently reduced to 0.492 ml/min, while the extract flow is only 0.216 ml/min.

3. Results and discussion

The rotating column stage is compared with a discontinuous batch application. According to the GC-FID analysis, BOA is detected to 91.3 wt. %, while BOB to 93.8 wt. % in their respective fractions. The losses are carried out via the respective column Positions 2 and 10 (BOA) and 4 and 12 (BOB) via the waste (W).

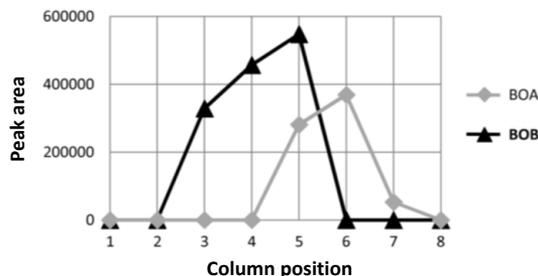

Figure 3: Profile concentration of the SMB application for the bisabolol oxides separation

The SMB-method for the subsequent separation of the binary fraction is developed based on linear adsorption isotherms. Figure 3 shows the concentration profile (GC-FID) after the iterative optimisation at steady state (Cycle 7). The subsequent SP overloading and the system approaching the efficiency limits took place by continuously increasing the feed concentration. The decrease in

the raffinate (BOA) purity due to increasing contamination by BOB is used for the evaluation of the process. Under an essential oil feed of 5µl/ml·cycle, a purity of 98.1% is achieved for BOA, and > 99.0% for BOB, according to the GC-FID analysis.

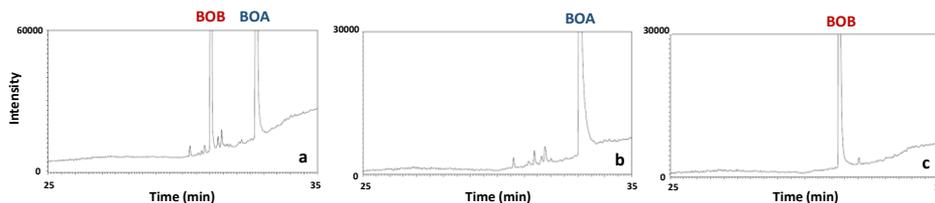

Figure 4: GC-FID of: a) Feed; b) Raffinate as BOA; c) Extract as BOB

The GC-FID for determining the fractions' purity also show that the impurities contained in the feed fraction are almost completely separated via the Raffinate, whereas the Extract almost exclusively contains the target component (Figure 4).

4. Conclusions

In the present work, a coupled method strategy for the isolation of valuable active ingredients is developed based on the example of an essential oil as a starting mixture. The approach integrates the rotating columns and the simulated moving bed principles. During the first stage (the rotating column stage), a binary mixture target (bisabolol A and B oxides) are fractionated at the same time. The oxides are then separated in the second stage (the SMB stage). The combination of the two processes shows superior results in terms of efficiency to the traditional selective methods for isolating different ingredients from multicomponent mixtures (e.g., batch chromatography), with the additional reduction in resources and costs.

The proposed procedure is intended to provide practical solutions for the continuous chromatographic extraction of ingredients from heterogeneous multicomponent mixtures. Through subsequent processing steps, possible co-elutions of valuable active ingredients can be achieved, which have to be further purified.

Abstract

This work investigates the digital design of a continuous pharmaceutical plant comprising a continuous three stage reaction, liquid-liquid extraction, multistage cooling and antisolvent crystallization, and wash-filtration. Firstly, the mathematical models were developed and validated in conjunction with the available experimental data obtained from the literature and research partners. The resulting digital twin was used for steady state optimization to deliver optimal options for plant design and operation, including process capacities and number of crystallization stages. After the identification of the optimal design and optimal steady state operation, the digital twin was used to perform uncertainty propagation and global sensitivity analysis to identify the Critical Process Parameters (CPP) and Critical Material Attributes (CMA) and deliver robust and cost-effective methods for a systematic implementation of Quality-by-Design (QbD). This approach is aimed at demonstrating that the plant can be operated within the robust quality bounds which provide a built-in quality assurance for the final product. Several Critical Quality Attributes (CQA) which impact drug safety and efficacy were considered which includes the average crystal size, crystal size distribution, coefficient of variation and product purity were considered as the CQA.

Keywords: Integrated continuous pharmaceutical plant, Continuous multistage crystallization, Global Sensitivity Analysis, Uncertainty Analysis, Digital Twin, Quality-by-Design.

1. Introduction

Continuous manufacturing has been identified as a pivotal technology in overcoming the inherent limitations of current batch manufacturing methods used within the pharmaceutical sphere. New research in process analytical technologies and real-time control strategies have made continuous pharmaceutical manufacturing (CPM) feasible for wider use alongside its capacity to surpass quality compliance of former batch processing methods (Mascia et al., 2013). Despite the progress in research, technical hurdles remain before the wider adoption of CPM. One such hurdle is developing systematic and economic methods to design, optimize and operate integrated continuous pharmaceutical processes (ICPP) due to the complexity of integrating the synthesis and purification steps to produce the active pharmaceutical ingredient (API), formulations and final dosage forms (Benyahia, 2018). The advent of digital transformation opened new opportunities for computer aided optimal design, operation and decision making using digital twins (Ramin et al., 2018). However, successful use of digital twins requires the development of more robust mathematical models and systematic methodologies to understand and quantify the impact of the process and design parameters, material attributes and technology selection on drug product safety and efficacy. Besides the traditional objectives above, an effective digital twin should allow reliable identification of the critical process parameters (CPP) and critical material attributes (CMA) which influence the critical quality attributes (CQA) of the drug product. The last decade has seen a wider adoption of a range of process simulators in the pharmaceutical sector, including high fidelity models, surrogate models, flow sheet models, and plant-wide dynamic models (Benyahia et al., 2012; Maloney et al. 2020). There is clear evidence of the benefits of these process models and digital twins in the development and optimal operation and control of the world's first ICPP

and the kilogram scale continuous upstream plant for Prexasertib Monolactate Monohydrate (Mascia et al., 2013; Cole et al., 2017; Lakerveld et al., 2015). More recently, dynamic models of ICPPs were used for the design of a carfilzomib process (Maloney et al. 2020) and optimize steady state and dynamic performance such as start-up and shut down (Liu and Benyahia, 2021). The impact of recycles have not yet been investigated along with the impact of uncertainties that these present. A significant challenge in the implementation of Quality-by-Design (QbD) is the identification of the CPP and CMA which are commonly addressed by combining human expertise and expensive designs of experiments (e.g., Factorial DoE). The development of predictable and reliable mathematical models or digital twins may provide a systematic tool to understand the influence of the different factors and design parameters on the CQA's of the final product. In this paper, a dynamic simulator of an integrated upstream process comprising reactions, liquid liquid extraction, crystallization and wash-filtration was developed and used to optimally design and operate an ICPP. The digital twin was then used to perform uncertainty propagation and global sensitivity analysis (Fysikopoulos et al., 2019) to help identify more reliably the CPPs and CMAs which are essential in the subsequent implementation of QbD. This approach is aimed at demonstrating that the plant can operate with a built-in quality and safety assurance for the final product. The average crystal size, crystal size distribution, coefficient of variation and purity were considered as the CQA's, and all simulations were performed using gPROMS formulated products 2.0.1 which specializes in process simulation and optimization.

2. Methodology

2.1. Process description

The digital twin of the upstream continuous pharmaceutical process for the synthesis and purification of ibuprofen was created in gPROMS 2.0.1 and consisted of a sequence of three tubular reactors, a continuous liquid-liquid extractor, a three-stage continuous crystallization and finally a filtration step (Figure 1). The parameter estimation of the mathematical model of the reaction step was based on a continuous flow synthesis performed by Bogdan (Bogdan, 2009) which consists of three plug flow reactors where a sequence of three reactions takes place: a Freidel-Crafts acylation, a mediated aryl migration and a saponification reaction which finally produces ibuprofen as a potassium salt. The reaction is followed by a liquid liquid extraction (LLE) used as a preliminary purification step followed by a three-stage continuous crystallization process. The solubility and kinetic data of growth and nucleation for the antisolvent crystallization of ibuprofen were obtained from the literature (Afrose. 2017). In addition, a combined wash and wash-filtration step was considered to separate the crystals from the mother liquor and reduce the impurities and residual solvents in the final product. The intensified plant was designed for a productivity of 6.58 g/hr at an assumed efficiency of 70%.

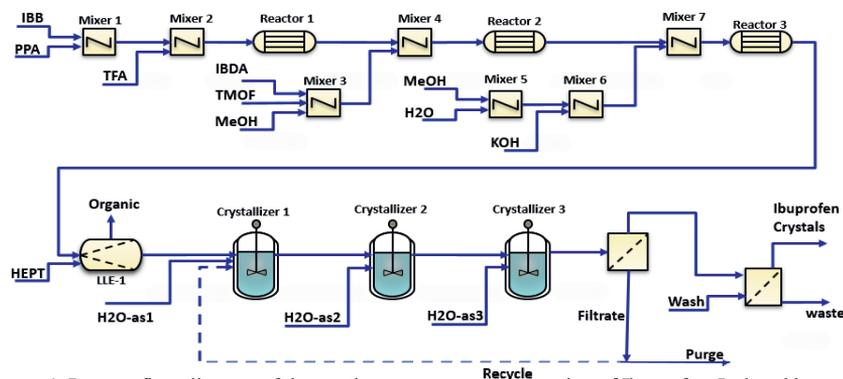

Figure 1. Process flow diagram of the continuous upstream processing of Ibuprofen. Isobutyl benzene (IBB), Propanoic acid (PPA), triflic acid (TFA), Iodobenzene diacetate (IBDA), Trimethyl orthoformate (TMOF), Methanol (MeOH), Potassium Hydroxide (KOH), Heptane (HEPT).

2.2. Optimization

The objective is to optimize the design features and operating conditions to maximize productivity of the final product at steady state, here the crystals obtained after wash-filtration, under a set of quality and efficiency constraints (e.g., Mean Crystal Size, purity, yields) and operation constraints (e.g., Maximum process capacity, maximum flow rates etc.). The mathematical formulation of the optimization problem is described below.

$$\begin{aligned}
 & \underset{F_{as,i}, T_i, V_i, \tau_i, F_{org}, V_{LLE}, P_{filt}}{\text{Max}} \quad \text{Pr} \\
 \text{s.t.} \quad & \dot{x} = f(x, y, u, p, t) \\
 & 0 = g(x, y, u, p, t) \\
 & \bar{d} \geq 200 \mu\text{m} \\
 & w_{T,TA} \leq 0.01 \text{ kg/kg} \\
 & w_{T,KOH} \leq 0.01 \text{ kg/kg} \\
 & 0 \leq F_{AS,i} \leq 200 \text{ mL h}^{-1} \\
 & 283 \text{ K} \leq T_i \leq 313 \text{ K} \\
 & 20 \text{ min} \leq \tau_i \leq 100 \text{ min} \\
 & 0 \text{ mL h}^{-1} \leq F_{org} \leq 100 \text{ mL h}^{-1} \\
 & 0.5 \text{ Bar} \leq P_{filt} \leq 2.0 \text{ Bar} \\
 & S_i \geq 1 \\
 & i = 1, 2, 3
 \end{aligned}$$

Where \bar{d} is the average crystal size (D [4,3]), $w_{T,TA}$ and $w_{T,KOH}$ are the residual mass fraction of triflic acid and potassium hydroxide impurities in the product, left after the wash-filtration stage. $F_{AS,i}$ is the flowrate of the anti-solvent fed to each mixed suspension mixed product removal crystallizer (MSMPR), T_i, τ_i, S_i are respectively the temperature, the residence time and the relative supersaturation in each MSMPR, F_{org} is the flowrate of the organic solvent to the LLE stage, and P_{filt} is the pressure of the filter. The optimization problems were solved using a Control Vector Parameterization (CVP) technique which converts the dynamic optimization problems into nonlinear programming problems solved using an efficient SQP (Successive Quadratic Programming) solver built into gPROMS.

2.3. Global Sensitivity Analysis

Upon completion of the optimization, the optimal results were used as nominal values to develop global system analysis which included a variance based global sensitivity analysis, using a quasi-random (Sobol) sampling technique. The objective is to identify the most influential CPPs and CMAs. The CQAs, used here as the outputs or responses were the mean crystal size, crystal purity or total mass fraction of the impurities and productivity. Process and material parameters include the reactant flowrates, the operating temperatures of the MSMPRs, the antisolvent streams for the MSMPRs, the residence times of the MSMPRs, and the wash flowrate.

3. Results and discussion

3.1. Optimization

The optimization results correspond to the set of optimal decision variables including the operating conditions and design options along with their upper and lower bounds and are summarised in table 1. Two scenarios are considered, the base case with no recycle and the second with a 50% recycle after the filtration stage. Table 1 shows that the organic solvent flowrate remains the same because the LLE is prior to the crystallization where the recycle stream is being fed. However, the steady state crystallization temperatures dropped at each crystallizer to help address the dilution effect inherent to the recycle stream which contains significant amounts of solvent and antisolvent. The optimal residence times associated with the scenario at 50% recycle has also significantly increased as shown in table 1 which suggests that larger capacities are required to achieve effective crystallization under the recycle conditions. The key performance indicators of each case are summarized in table 2 including the attainable maximum production mass flow rates in both scenarios, considered here as the

objective functions, as well as the CQAs and key performance indicators. Overall, the scenario considered in presence of 50% recycle shows improved productivity and yields. Both cases met the required impurity contents however the recycle scenario exhibits as expected a slightly higher impurity content due the accumulation of the impurities in the system. To better control the level of impurities our future work will consider the recycle ratio as a decision variable. The dynamic simulations of the integrated process using the optimal steady state conditions are presented in Figure 2.

Table 1. The optimal values of the input factors from the optimization simulation for both non-recycle and the 50% recycle case.

Variables	Units	Optimal values		Lower Bound	Upper Bound
		Base case	50% Recycle		
Organic Solvent flowrate	mL/h	95.96	95.96	0	400
MSMPR 1 temperature	K	309	305.330	283	313
MSMPR 2 Temperature	K	304	309.088	283	313
MSMPR 3 Temperature	K	305	283.615	283	313
Anti-solvent flowrate MSMPR 1	mL/h	170.4	188.0	0	100
Anti-solvent flowrate MSMPR 2	mL/h	11.2	5.0	0	150
Anti-solvent flowrate MSMPR 2	mL/h	3.6	6.0	0	200
Mean residence time MSMPR 1	Min	16.0	76.4	0	100
Mean residence time MSMPR 2	Min	35.5	120	0	120
Mean residence time MSMPR 3	Min	19.7	120	0	120
Pressure filter flowrate set point	kg/hr	0.0078	0.0088	0	1
Pressure drop filter	bar	1.6	1.7	0.5	2.0

Table 2. CQA and key performance indicators for the base case and the recycle scenario.

	Units	Base case	50% Recycle
Mass flowrate	g/hr	7.41	8.4
Overall Process yield	%	65%	73%
Impurity content- Triflic acid	kg/kg	0.0025	0.0032
Impurity content- KOH	kg/kg	0.0036	0.0046

(c) Coefficient of variation in each of the MSMPRs. (d) Mass fraction of impurities in the final crystal product after filtration then after the wash-filtration.

Table 3. The global sensitivity analysis total order factor sensitivities table of the CQA's and CPP's.

		Mass Flowrate Crystal	Average Particle size D43	Coefficient of variation	Impurity Triflic acid KOH	
Reactant Mass flowrate	Prop acid	0.007	0.008	0.008	0.000	0.000
	IBB	0.007	0.009	0.009	0.000	0.000
	IBD	0.007	0.008	0.007	0.001	0.000
	KOH	0.027	0.022	0.021	0.006	0.913
	TMOF	0.003	0.003	0.003	0.001	0.000
RDT	MSMPR_1	0.000	0.000	0.000	0.000	0.000
	MSMPR_2	0.000	0.000	0.000	0.000	0.000
	MSMPR_3	0.000	0.000	0.000	0.000	0.000
Temp	MSMPR_1	0.000	0.047	0.047	0.000	0.000
	MSMPR_2	0.010	0.121	0.124	0.001	0.000
	MSMPR_3	0.199	0.050	0.051	0.008	0.001
Anti-Solvent	MSMPR_1	0.647	0.573	0.571	1.112	0.109
	MSMPR_2	0.000	0.000	0.000	0.001	0.000
	MSMPR_3	0.000	0.000	0.000	0.001	0.000
Flowrate Wash		0.000	0.000	0.000	0.000	0.000

At the optimal production, the final production rate of the reaction step is 9.39 g/hr. After the first purification step which occurs in the LLE, a three-stage crystallization process is used to purify the API and recover ibuprofen as a crystalline form. The manipulation of temperature and anti-solvent flowrate help achieve the required supersaturation levels across the three MSMPRs which results in increased mean crystal size from one stage to the other.

As shown in Figure 2b, the final mean crystal size obtained in the last MSMPR stage is 325 μ m. The coefficient of variation has a sharp increase in all MSMPRs due to the higher initial rates of nucleation. When steady state is reached, all coefficients of variation stabilize. The slurry leaving the final crystallization stage, goes through a filtration then a wash-filtration step to reduce the residual solvent and impurities content in the final crystal product. The wash stage reduces the mass fraction of the main impurities, triflic acid and potassium hydroxide, to below 0.005g/g as indicated in Figure 2d. The dynamic simulations of the integrated process using the optimal steady state conditions are presented in Figure 2. At the optimal production, the final production rate of the reaction step is 9.39g/hr. After the first purification step which occurs in the LLE, a three-stage crystallization process is used to purify the API and recover ibuprofen as a crystalline form. The manipulation of temperature and anti-solvent flowrate help achieve the required supersaturation levels across the three MSMPRs which results in increased mean crystal size from one stage to the other. As shown in Figure 2b, the final mean crystal size obtained in the last MSMPR stage is 325 μ m. The slurry leaving the final crystallization stage, goes through a filtration then a wash-filtration step to reduce the residual solvent and impurities content in the final crystal product. The wash stage reduces the mass fraction of the main impurities, triflic acid and potassium hydroxide, to below 0.005g/g as indicated in Figure 2d.

3.2. Global Sensitivity Analysis

The results of the global sensitivity analysis are used to identify the hierarchy of CPPs for the integrated process. This is a critical step in the implementation of QbD for process operation. The total order sensitivities factors can be seen in table 3. The most influential three parameters of each CQA are highlighted in grey with the most influential being the darkest. The crystal quality was most influenced by the antisolvent flowrate into MSMPR 1, temperature of MSMPR 3 and the mass flowrate of the reactant potassium hydroxide. The Anti-solvent flowrate into MSMPR 1 had a dominating effect on the solubility curve in the following crystallizers. Of the three antisolvent streams it is over 10 times the amount of the other factors thus the comparative impact is respective of this. Regarding the triflic acid impurity in the

residue on the crystals, the antisolvent stream again had the highest impact due to its diluting effect reducing the overall amount within the residue of the intermediate from the filtration stage. With respect to the KOH impurity, the reactant mass flowrate is the most influential factor as unreacted KOH will remain in the liquid phase. More unreacted KOH will result in a higher proportion left in the residue. Further investigation is required on the wash phase as this has zero effect on any of the impurity factors. This could be due to the low comparative impact to the other CPPs or other unknown factors.

4. Conclusions

A dynamic mathematical model of a continuous pharmaceutical plant comprising a continuous three stage reaction, liquid-liquid extraction, multistage cooling and antisolvent crystallization, and wash-filtration was developed using data from the literature. This resulting process simulator used a digital twin for steady state optimization to deliver optimal options for plant design and operation and maximize productivity. To enhance cost-efficiency and environmental performance of the plant, an additional optimization scenario was conducted under 50% recycle of the mother liquor obtained from the filtration stage without further purification. The results showed that the scenario associated with 50% recycle increases the startup time and impurity content, which in turn required reoptimized crystallization and wash-filtration conditions. However, the 50% recycle was also shown to improve the overall productivity of the process. The GSA identified that the antisolvent flowrate into MSMPR 1, the temperature of MSMPR 3 and the mass flowrate of the reactant KOH had the most impact on the CPP's. The future work will be focused on the optimization of recycle to purge ratio and the incorporation of downstream processes in the design and optimization.

This work was conducted as part of the EPSRC CMAC HUB (EPSRC EP/P006965/1). The authors would like to thank PSE Enterprise for their support and for providing the licenses for gPROMs Formulated Products.

Abstract

A multi-objective optimization framework is proposed to design single-mixed refrigerant natural gas liquefaction processes considering the conflicting goals of minimizing both power consumption and heat transfer area utilization. In the present approach, the black-box process simulation is embedded into a nonlinear programming (NLP) problem via kriging surrogate model. To deal with the conflicting objectives, the ε -constraint methodology is applied. The surrogate NLP problems with fixed ε are solved in GAMS using CONOPT to determine a non-dominated solution candidate of the original multi-objective problem. The Pareto Front achieved with the present framework dominates recent single-objective result from the literature. The non-dominated solutions have power consumption that ranges from 0.2800 to 0.4060 kW/(kg NG) and heat transfer area utilization multiplied by overall heat transfer coefficient varying from 0.0699 to 0.1852 kW/°C. A trade-off solution can be achieved by increasing 5.29 % of power consumption to save 31.8 % of heat transfer area.

Keywords: Multi-objective optimization, Kriging surrogate model, Natural gas liquefaction, Simulation optimization, Process simulation.

1. Introduction

The natural gas liquefaction process design presents a clear trade-off between energy consumption and equipment size (Khan et al., 2016). The concern of achieving high energy efficiency and diminished equipment size is further emphasized in offshore processes, where the plant site size is significantly restricted. These liquefaction processes consist of cryogenic refrigeration cycles to cool down the natural gas to about -160 °C to liquefy, store, transport, and commercialize it safely as liquefied natural gas (LNG). Optimization has been successfully used to determine refrigerant composition and thermodynamic cycle conditions in natural gas liquefaction processes to improve power consumption, exergy efficiency, or total annual cost (Austbø et al., 2014). Despite the vast literature on single-objective optimization, the evaluation of the natural gas liquefaction processes optimal trade-offs has been timidly addressed in the literature. Khan et al. (2016) investigated the optimization of the dual-mixed refrigerant LNG process under cold and warm ambient conditions. The authors used NSGA-II algorithm to trade-off between the minimization of specific compression energy and the area of heat exchangers in terms of overall heat transfer coefficient times the area (UA). Ghorbani et

The final pre-refrigeration temperature is considered to be $-24.0\text{ }^{\circ}\text{C}$. The pressure drop in the multi-stream heat exchangers (MSHEs) is 100 kPa for hot streams, 10 kPa for cold streams, and 50 kPa for water inter-stage coolers. The intermediate pressures are determined to guarantee a constant compression ratio in all four compressors, and the intermediate cooling temperature is $30\text{ }^{\circ}\text{C}$. The temperature of hot streams leaving the MSHEs is considered to be the same, $-24.0\text{ }^{\circ}\text{C}$ for the first and $-157.2\text{ }^{\circ}\text{C}$ for the second to achieve the desired LNG condition of $-160.0\text{ }^{\circ}\text{C}$, 110 kPa, and 3.7 % of vapor fraction. The process design problem is formulated as a multi-objective optimization model, considering the minimization of specific power consumption and UA. The process constraint is that a minimum temperature approach of $3\text{ }^{\circ}\text{C}$ must be assured throughout the MSHEs. To overcome the issue of this constraint not being smooth for kriging modelling (Santos, 2021), Santos et al. (2022) proposed to discretize the MSHEs 1 and 2 in K sections. The optimal process design can be formulated as the following multi-objective optimization problem

$$\begin{aligned} \min_{\mathbf{x} \in \mathcal{D}} \quad & \mathbf{f}(\mathbf{x}) = \left[\sum_{p \in \text{PM}} \frac{W_p(\mathbf{x})}{\dot{m}_{NG}}; \sum_{ex \in \text{HE}} UA_{ex}(\mathbf{x}) \right] \\ \text{s. t.} \quad & \mathbf{g}_{\kappa}(\mathbf{x}) = 1 - \frac{\min_{k \in \Omega_{\kappa}} \{Th_{\kappa,k}(\mathbf{x}) - Tc_{\kappa,k}(\mathbf{x})\}}{3} \leq 0, \kappa = 1, \dots, (2K) \end{aligned} \quad (1)$$

In Eq. (1) $W_p(\mathbf{x})$ is the work consumption of the pressure manipulator unit p in the set of compressors and pumps PM , and $UA_{ex}(\mathbf{x})$ is the global heat transfer coefficient multiplied by the area of the heat exchanger ex in the set of all heat exchangers HE . $Th_{\kappa,k}(\mathbf{x})$ and $Tc_{\kappa,k}(\mathbf{x})$ are the temperature of hot and cold composite curves in the κ section of the MSHEs, and Ω_{κ} is the set of the k points from composite curves calculations that belongs to section κ (Santos et al., 2022). $\mathcal{D} = [\mathbf{x}^{lb}, \mathbf{x}^{ub}]$ is a box constraint for the decision variables bounded by \mathbf{x}^{lb} and \mathbf{x}^{ub} as proposed in Qyyum et al. (2020), and \dot{m}_{NG} is the mass flow rate of the natural gas stream.

3. Kriging-based multi-objective optimization

To solve the multi-objective simulation optimization problems as in Eq. (1), the proposed framework is presented in Algorithm 1. The computer code to compute \mathbf{f} and \mathbf{g} at given $\mathbf{x} \in \mathcal{D}$ is a function written in MATLAB connected to the process simulator Aspen HYSYS. First, m_0 samples of \mathbf{X} is generated by a Latin Hypercube algorithm to maximize the minimum distance between points in the search space \mathcal{D} . The value of \mathbf{f} and \mathbf{g} are calculated in the simulation for each $\mathbf{x} \in \mathbf{X}$. The initial data is defined as $D_0 = [\mathbf{X} \ \mathbf{Y}]$. Given D_0 , m_f , and D , the single-objective optimization for each \mathbf{f}_i objective is solved using the framework for constrained black-box optimization proposed in Santos et al. (2022). In the case of Eq. (1), the objective function \mathbf{f}_1 is the specific power consumption and \mathbf{f}_2 is the overall UA. The above-mentioned approach consists of using the data in D_0 to fit kriging models for the objectives and constraints. These models are implemented in an NLP problem and solved in GAMS with multi-start local optimization with CONOPT local solver. The solution, which is promising a minimizer candidate, is evaluated in the simulation and the values are appended to the data. This process is repeated until convergence or simulation evaluation budget m_f . The values of \mathbf{f}_1 at each single-objective solution, $\mathbf{f}_1(\mathbf{x}_1^*)$ to $\mathbf{f}_1(\mathbf{x}_2^*)$, bound the ε vector. The ε -constraint vector is defined as the equally distributed n_{ε} -vector from $\mathbf{f}_1(\mathbf{x}_1^*)$ to $\mathbf{f}_1(\mathbf{x}_2^*)$. The single-objective solutions are appended to the data, D_2 . For the other entries of ε , the ε -constrained single-objective optimization is solved using the same framework for constrained black-box

optimization proposed in Santos et al. (2022). Each optimization solution is appended to the data so that $D_{ite} = D_{ite-1} \cup [\mathbf{x}_{ite}^*, \mathbf{f}(\mathbf{x}_{ite}^*), \mathbf{g}(\mathbf{x}_{ite}^*)]$. The last step of the proposed framework is to eliminate dominated and infeasible solutions from D_{n_ε} to form the set of Pareto solution, P , found by the algorithm.

Algorithm 1: Kriging-based multi-objective optimization framework

Input: Initial sample size $m_0 \in \mathbb{N}_+$, maximum number of samples $m_f \in \mathbb{N}_+$, box-constrained design space $\mathcal{D} \in \mathbb{R}^{2 \times n}$, the computer code to compute \mathbf{f} and \mathbf{g} at given $\mathbf{x} \in \mathcal{D} \subseteq \mathbb{R}^n$, and the number of ε -constrait values $n_\varepsilon \in \mathbb{N}_+$

- 1) Generate m_0 samples \mathbf{X} with respective simulation output values $\mathbf{Y} = [\mathbf{f}; \mathbf{g}]^\top$ and define $D_0 = [\mathbf{X} \ \mathbf{Y}]$;
- 2) Solve the single-objective optimization problem for each \mathbf{f}_i using the framework proposed in Santos et al. (2022) to determine \mathbf{x}_1^* and \mathbf{x}_2^* , with D_0, m_f, \mathcal{D} ;
- 3) Define ε as the equally spaced n_ε -vector from $\mathbf{f}_1(\mathbf{x}_1^*)$ to $\mathbf{f}_1(\mathbf{x}_2^*)$;
- 4) Append to the data: $D_2 = D_0 \cup [\mathbf{x}_1^*, \mathbf{f}(\mathbf{x}_1^*), \mathbf{g}(\mathbf{x}_1^*)] \cup [\mathbf{x}_2^*, \mathbf{f}(\mathbf{x}_2^*), \mathbf{g}(\mathbf{x}_2^*)]$;

for $ite = 3, \dots, n_\varepsilon$ **do**

- 5) Solve the ε -constrained single-objective optimization

$$\begin{aligned} \min_{\mathbf{x} \in \mathcal{D}} \quad & \mathbf{f}_2(\mathbf{x}) \\ \text{s.t.} \quad & \mathbf{f}_1(\mathbf{x}) \leq \varepsilon_{ite-1} \\ & \mathbf{g}(\mathbf{x}) \leq 0, \end{aligned}$$

using the framework proposed in Santos et al. (2022) to determine \mathbf{x}_{ite}^* , with $D_{ite-1}, m_f, \mathcal{D}$;

- 6) Append the solution to the data: $D_{ite} = D_{ite-1} \cup [\mathbf{x}_{ite}^*, \mathbf{f}(\mathbf{x}_{ite}^*), \mathbf{g}(\mathbf{x}_{ite}^*)]$;

end

- 7) Eliminate dominated and infeasible solutions from D_{n_ε} to form P , the set of Pareto solutions;

Output: Set of non-dominated solutions, P .

4. Results

The proposed multi-objective, kriging-based optimization framework is applied to the design of SMR natural gas liquefaction processes considering power consumption and heat exchanger area utilization objectives. The considered parameters of the optimization approach are initial sample size $m_0 = 10n$, function evaluation budget $m_f = 20n$, number of decision variables $n = 8$, number of sections into which each MSHE is divided $K = 10$, and number of non-dominated solution $n_\varepsilon = 18$.

Figure 2 presents the Pareto Front determined by the non-dominated solutions of the present approach. It also includes the best result from the literature to this liquefaction process with the given specifications (Qyyum et al., 2020). This figure shows that the present approach was able to determine an energy-optimal solution that is better than the literature, with energy saving of 1.51 %, from 0.2843 to 0.2800 kW/kg of natural gas. Also, given the present Pareto Front, the literature solution is a dominated one. It means that, for the same specific power consumption, the present approach would design a liquefaction process with reduced UA. The proposed Pareto Front ranges from 0.2800 to 0.4046 kW/(kg NG) for power consumption and 0.0699 to 0.1852 kW/°C for UA. The shape of this Pareto curve shows that the increase in heat exchanger area is more pronounced as the power consumption approaches low values. Based on this insight, one can choose non-dominated solutions that better balances high energy efficiency and heat exchanger area utilization as the solutions that presents the smallest ℓ^2 and ℓ^1 norm. These solutions are highlighted in Figure 2 in the blue square and magenta hexagram, respectively. The best trade-off based on the ℓ^2 norm presents an increase in power consumption of 5.29 % and 31.80 % UA decrease compared to the energetically-optimum solution. The ℓ^1 norm-based solution presents an increase in power consumption of 10.61 % and 44.65 % UA decrease compared to the energy-optimum solution.

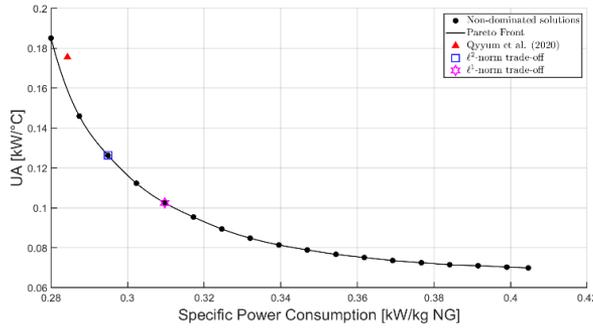

Figure 2: Pareto Front and comparison with Qyyum et al. (2020).

Table 1 presents the values of the decision variables and objective functions for the base case (Qyyum et al., 2020), energy-optimum, UA-optimum, ℓ^2 -norm trade-off, and ℓ^1 -norm trade-off solutions. The energy-optimum result presents a refrigerant composition that is reduced in propane and i-pentane in comparison with the literature result. The UA-optimum result shows that for reducing the heat exchangers area utilization high compression ratio and refrigerant with more contents of light-components are preferred. Differently from what one would expect, the trade-off solutions are complex and unique, i.e., not mere interpolations of the single-objective ones. Therefore, the use of multi-objective optimization approach is justified as a means to derive complex solutions that trades-off optimally between conflicting objectives to the process design.

The computational time is dominated by simulation evaluation, which takes around 4.7 s. The mean elapsed time for the multi-objective optimization algorithm was 143 min. The advantage of the present approach over the well-established population-based metaheuristics is the reduced budget of time-consuming simulation calculation, in the present case $10n \times n_\varepsilon = 1440$. The circumstances that the present approach would no longer be efficient is when the surrogate models do not capture the true functions behavior. That is often the case for high-dimensional problems or stiff functions.

Table 1: Multi-objective optimization results for SMR natural gas liquefaction processes

Optimization Results	Qyyum et al. (2020)	Energy-optimum	UA-optimum	ℓ^2 -norm trade-off	ℓ^1 -norm trade-off
m_N [kg/h]	0.2210	0.2426	0.2620	0.1871	0.1500

UA [kW/°C]	0.1759	0.1852	0.0699	0.1263	0.1025

5. Conclusions

This paper presented a multi-objective optimization framework to the SMR natural gas liquefaction process design problem, considering the trade-off between energy efficiency and heat exchanger area utilization. Kriging surrogate model, ϵ -constraint methodology, and gradient-based solver in GAMS are used in the proposed approach to determine candidates of non-dominated solutions of the original black-box optimization problem. The Pareto Front determined by the present approach shows that the recent literature result of energy-efficient SMR process is a dominated solution. The objective functions of non-dominated solutions range from 0.2800 and 0.4046 kW/(kg NG) for power consumption and 0.0699 and 0.1852 kW/°C for UA. Two trade-off solutions were analyzed and the results showed that 5.29 % and 10.61 % increase in the power consumption can lead to 31.80 % and 44.65 % heat exchanger area decrease, respectively. The trade-off solutions are complex process configurations instead of interpolations of the single-objective optima, which justifies the use of multi-objective optimization approach to tackle competing objectives.

Abstract

To address the urgent need to transform the current economic paradigm towards a more circular one, this contribution proposes a framework for assisting the selection of the most promising waste-to-resource alternatives. An ontology-based approach is used to manage and centralize the knowledge across the different stages of this methodology. Feasible combinations of operations lead to processing routes connecting waste with products and the paths are assessed to pre-select the most suitable ones. Then, the network is optimized, and a set of configurations are obtained in order to maximize economic profit and minimize environmental impact. The performance of the proposed framework is illustrated through a case study for the treatment of mixed plastic waste. Results show how pyrolysis-based treatments lead to suitable options according to some specified objectives but also reveal the main drawbacks and conditions that these treatments should improve. The work also demonstrates how to efficiently assess a large number of options, and discusses how to build and improve new processing networks.

Keywords: circular economy, pyrolysis, plastic waste, integrated modeling, sustainable development

1. Introduction

Numerous processes/product design strategies are being proposed towards the new circular economy paradigm. Among them, it should be emphasized the line based on improved design of products to reduce waste generation and maintain resources within the material cycles as long as possible, as well as promoting the use of renewable or better-performing resources to reduce environmental impacts as much as possible (Ellen MacArthur Foundation, 2015) and improve overall sustainability.

A considerable number of technologies are now being developed to achieve such objectives. Consequently, the number of available alternatives is set to grow exponentially. Decision-makers need to assess these alternatives and select the best ones for each kind of waste or material cycle and optimize them attending to all three main pillars of sustainability: maximizing economic performance, minimizing environmental impacts, and promoting social benefits (Sillanpää and Ncibi, 2019). However, traditional optimization methods are very complex and not efficient enough when the number of structural alternatives is very large (Yang et al., 2013).

To address this challenge, this contribution proposes a way to integrate several models and procedures to generate, assess, and optimize the most promising alternatives for the treatment and revalorization of a generic waste stream, providing a systematic and fully

integrated tool to support decision-making towards the circular economy. The resulting framework (Figure 1) encompasses interoperable modules, which exchange the necessary information to perform a comprehensive route generation and assessment, as well as the optimization of a waste-to-resource network considering the best options.

1.1. Problem Statement

- Given an ontology filled with relevant information of processes suitable to treat a specific waste source.
- Obtain a set of promising treatment pathways and an optimized process network attending to environmental and economic objectives.

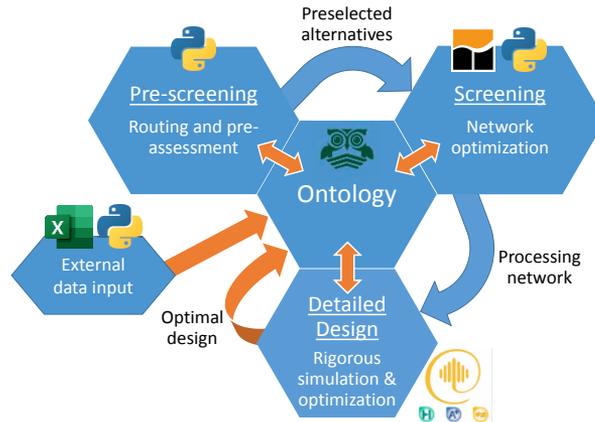

Figure 1. Schematic representation of the proposed framework.

2. Methodology

The proposed framework is structured into four main stages:

- The first one corresponds to knowledge management, where many single process steps are characterized as specific instances, including all the corresponding attributes that hold specifications such as properties, process parameters, and relationships with other instances such as process states and other process steps. Such information is managed through an ontology-based system. Ontologies have proven to be an efficient repository of information that allows establishing versatile relationships between different entities and storing parameters flexibly.
- The second one uses the information from the ontology to implicitly generate all the feasible routes (e.g. using short-path algorithms). Different criteria may be used to limit this generation based on usual branch and cut procedures. Once the routes are generated, they are sorted according to a proposed Global Performance Indicator (GPI) and the most promising ones are selected (Pacheco-López et al., 2021).
- The third one starts with this pre-selection of alternatives, where a more extensive process screening is performed. To do so, a superstructure with the most promising alternatives is assessed and optimized to select the most suitable processing networks based on different objectives, such as maximizing economic profit and minimizing the three endpoint life cycle assessment indicators (Somoza-Tornos et al., 2021).
- The fourth stage corresponds with the design and simulation of the process steps that are introduced in the ontology to be used by the other modules. It can be used as a preliminary step to fill up the ontology with new alternatives or afterward to further optimize selected alternatives and therefore enrich the ontology.

3. Case Study

The integrated decision-making framework performance is illustrated through a case study that consists of mixed plastic waste (MPW) treatment to obtain valuable products and reduce its environmental footprint. The chosen feedstock corresponds to a simulated MPW sample from sorting plants where packaging plastic is separated from municipal solid waste. It is composed of 40% of polyethylene (PE), 35% of polypropylene (PP), 18% of polystyrene (PS), 4% of polyethylene terephthalate (PET), and 3% of polyvinyl chloride (PVC) as proposed by Adrados et al., 2012.

The used ontology is an extended version from the one proposed previously (Pacheco-López et al., 2021), which was adapted from OntoCAPE (Marquardt et al., 2010) and filled with extra processes found in the literature to increase the number of alternatives available. For the pre-screening stage, all estimations were made and unified as presented in previous works, such as monetization of environmental impacts, maturity evaluation, and unitary costs calculation. The separation steps were simulated to split the gas and oil phases into all their components as commercial grade products. Pyrolyses were simulated and validated with experimental data from different studies. Market prices were updated to 2019 from the Prodcom database (Eurostat - European Commission and Eurostat, 2021). For the screening stage, all the estimations and assumptions for the needed parameters are as presented by Somoza-Tornos et al., 2021, such as the gate-to-gate approach for the life cycle assessments. The volume of plastic waste to treat is the amount collected in the EU28 (9.4 MT; PlasticsEurope, 2020) and escalated to a city of around 3 million inhabitants such as the Metropolitan Area of Barcelona, leading to a throughput of 5.72 tons of MPW per hour. Specific products demand satisfaction has been obviated in this case and all obtained products are assumed to be potentially sold at market price. For simplicity, only a deterministic model is used, although a stochastic model can be implemented in future developments to deal with cost estimation uncertainties.

4. Results and Discussion

Once the ontology is filled with the corresponding process steps and state specifications, the algorithm is run selecting the chosen starting material as mentioned above. The results for the pre-screening and screening stages are then obtained systematically. Figure 2 shows the graph obtained as a previous step to the route generation and assessment in the pre-screening stage, where all possible connections among the processes available in the ontology are shown. When the routing is implicitly performed, a total of 45 tentative processes are considered and 136 alternative paths are generated, assessed, and sorted according to their GPI. For simplicity, Table 1 shows a partial list of the sorted paths where it can be appreciated that the pyrolysis at 500°C with and without catalysts appear as the most promising, as opposed to landfilling and incineration. Once a representative set of the most promising processes are selected, the network optimization is performed in the screening stage, where a multi-objective optimization is performed using the ϵ -constraint method. By doing so, different configurations and results are obtained depending on the objectives trade-off. Figure 3 shows the optimal configuration when the objective is to maximize profit. Applying the ϵ -constraint for each one of the three environmental endpoint indicators, the corresponding Pareto optimal solution curves are obtained, as illustrated in Figure 5. The points in these plots are color-coded according to the different configurations, which are shown in Figure 4.

As envisaged in the previous stage, pyrolysis reactors that operate at 500°C with and without catalysts appear as the most profitable options from economic and environmental points of view in the screening stage as well. Involving these processes, the procedure

obtained four different configurations. The gray configuration (Figure 3) is obtained for the maximized economic performance and the green one when the objective is to minimize the impacts on the three endpoints. The first configuration consists of the pyrolysis at 500°C without catalyst and separation of the liquid and gas phase into their pure components to be sold. When minimizing environmental impacts, the configuration consists only of the pyrolysis using zeolite as catalyst (green configuration) and selling the pyrolytic gas and oil fractions for other uses (fuels for instance). In between the two-abovementioned anchor points, two more configurations could serve as a trade-off between the four objectives, blue and orange, which entail several pyrolyses with and without catalysts along with separation of some of their products (see Figure 4). As observed in Figure 5, the more separations are included in the configurations, the higher the environmental impact on all categories, and the higher the profit. This can be explained by the higher added value of the products when separated against the separation cost, which is the opposite case for environmental indicators due to energy requirements.

Table 1. Sorted paths obtained in the pre-screening stage according to the proposed GPI.

N°	Path composition	GPI
1	Pyrolysis MPW 500°C + Separation	779
2	Pyrolysis MPW 500°C /red mud/ + Separation	707
3	Pyrolysis MPW 500°C /ZSM5/ + Separation	509
7	Sorting + Pyrolysis PE 740°C + Separation	158
...
132	Sorting + Pyrolysis PS 425°C + Separation	28
134	Sorting + Pyrolysis PE 450°C	19
135	Incineration	0
136	Landfill	0

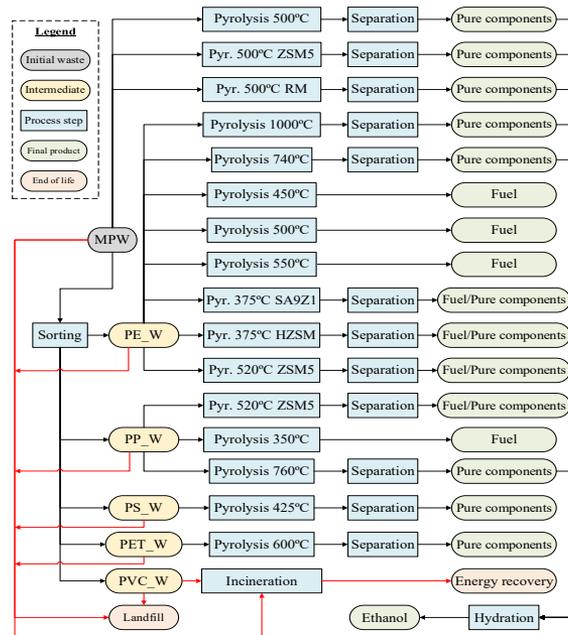

Figure 2. Implicitly generated graph in the pre-screening stage with tentative connections.

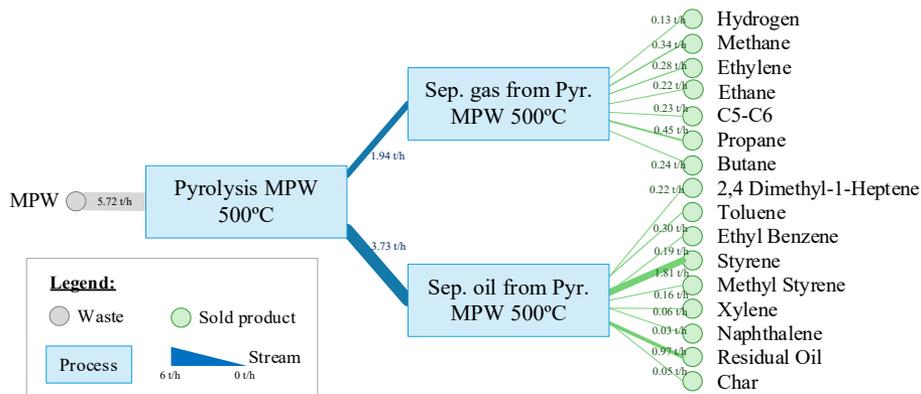

Figure 3. Configuration obtained for maximized profit. Color-coded as gray in Figure 5.

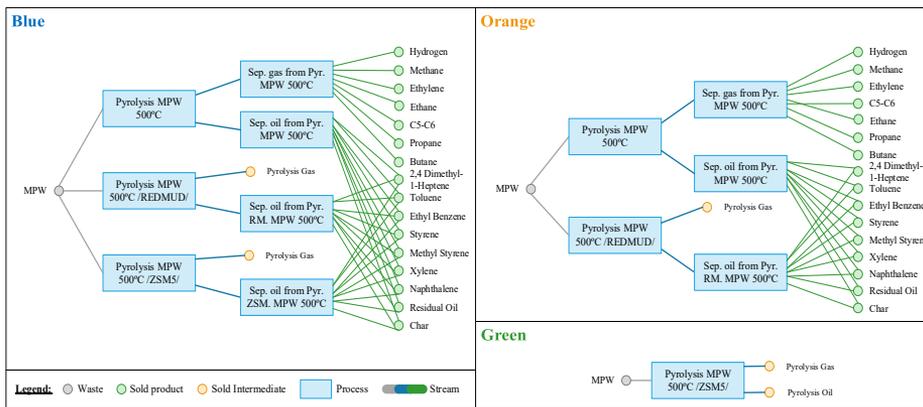

Figure 4. All possible configurations are color-named to ease their identification in the Pareto fronts in Figure 5.

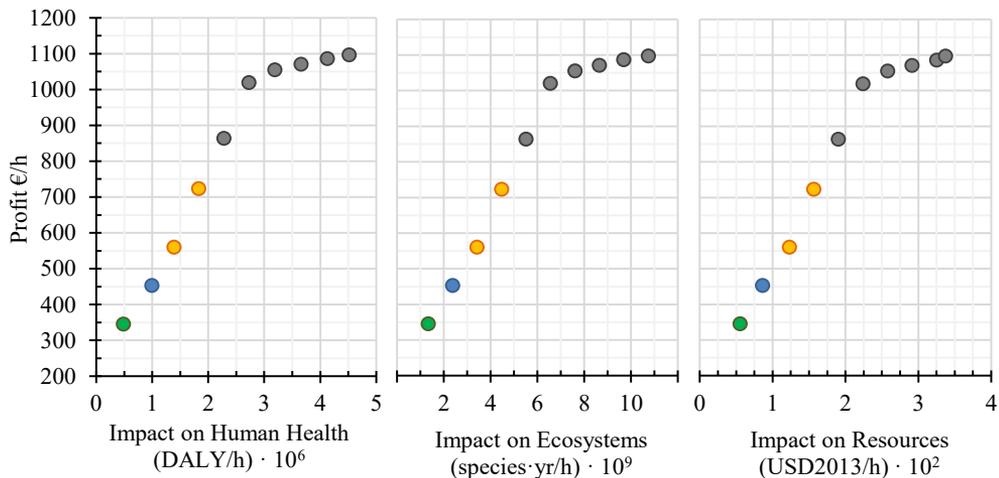

Figure 5. Pareto points for the trade-off between profit and the three environmental endpoint indicators. The points are color-coded to represent different configurations, as shown in Figure 4.

5. Conclusions

This work presents an integrated and systematic tool to generate feasible processing routes using short-path algorithms and assess them with different performance indicators, including a newly proposed one, that simultaneously accounts for economic, environmental, and maturity objectives. The best routes obtained at this stage are then stored back and enriched through their integration in an ontology and passed forward to a third stage where a network multi-objective optimization is performed and different network configurations are obtained and classified according to their performance, attending to different Pareto fronts. The presented case study illustrates the identification and assessment of opportunities in the recycling of plastic wastes. These opportunities are shown to be potentially profitable not only environmentally but also from the economic point of view. Additional developments should entail a more in-depth design of the selected configuration, along with energy integration, and optimization of equipment parameters (e.g. sizing, operating conditions...), including results, feedback to enrich the ontology. Future work will focus on this part as well as on further integrating other useful tools, such as automated information extraction and flowsheet development.

Abstract

The optimal synthesis of work and heat exchange networks (WHENs) is deeply important to achieve simultaneously high energy efficiency and low costs in chemical processes via work and heat integration of process streams. This paper presents an efficient MINLP model for optimal WHENs synthesis derived from a superstructure that considers unclassified streams. The derived model is solved using BARON global optimization solver. The superstructure considers multi-staged heat integration with isothermal mixing, temperature adjustment with hot or cold utility, and work exchange network for streams that are not classified *a priori*. The leading advantage of the present optimization model is the capability of defining the temperature and pressure route, *i.e.* heating up, cooling down, expanding, or compressing, of a process stream entirely during optimization while still being eligible for global optimization. The present approach is tested to a small-scale WHEN problem and the result surpassed the ones from the literature.

Keywords: Work and heat exchange networks, Mixed-integer nonlinear programming, Unclassified streams, Process synthesis, Global optimization.

1. Introduction

Recovering work and heat in chemical processes is fundamental for achieving high energy efficiencies, and it can be performed through the optimal synthesis of work and heat exchange networks (WHENs). This synthesis problem can be approached with superstructure-derived mixed-integer nonlinear programming (MINLP). The main challenge of WHENs synthesis is the lack of predefined pressure and temperature change routes of process streams, which hampers *a priori* stream classification. In other words, differently from heat integration and because of temperature variation in compression and expansion, a stream may change its thermal identity from hot to cold or vice-versa, making it difficult to target energy demands. The resulting MINLP models are intrinsically difficult to solve due to nonconvexity and combinatorial complexity that scales up quickly with the size of the problem, *i.e.* with the number of streams and superstructure stages (Santos et al., 2020b).

This problem has been addressed via either thermodynamic analysis (pinch variations to account for work and heat) or mathematical programming. The latter approach has shown promising results in the literature. Wechsung et al. (2011) proposed a superstructure with fixed thermodynamic routes for process streams that were classified as hot or cold, and

with fixed or variable pressure. To further simplify the MINLP problem, heuristics were considered for the appropriate placement of pressure manipulators. The optimization problem aimed to minimize the WHEN irreversibility.

Onishi et al. (2014a) proposed a WHEN superstructure based on Wechsung et al. (2011), except that the well-known heat exchanger network (HEN) superstructure from Yee and Grossmann (1990) was introduced for heat integration, and mathematical programming was used for placing the pressure manipulators. The MINLP formulation was developed to minimize the network total annualized cost (TAC). Onishi et al. (2014b) elaborated a multi-stage superstructure considering high-pressure streams as cold streams and low-pressure as hot streams. Huang and Karimi (2016) presented some modifications to the work of Onishi et al. (2014b), like the decision of the final device to adjust stream temperature based on the stream need instead of its identity.

Onishi et al. (2018) developed an innovative WHEN superstructure to deal with streams that are not classified *a priori*. Generalized disjunctive programming (GDP) was used to deal with the pressure manipulator selection and the classification of the stream. The problem had an MINLP formulation that was a convex hull reformulation of the GDP. It was incorporated with a Pinch-based optimization model for heat integration to minimize the TAC. Nair et al. (2018) added to the model of Onishi et al. (2018) the possibility of phase change, variable heat capacity, as well as compression and expansion of streams with no net pressure change (cycles).

Differently from previous authors that relied on mathematical programming, some interesting results used meta-heuristics to deal with the WHEN synthesis problem. Pavão et al. (2019) proposed a new approach to WHEN synthesis considering non-isothermal mixing and utilities in every HEN stage in parallel with the other heat transfer devices. The solution approach comprised Simulated Annealing (SA) for the combinatorial level and Rocket Fireworks Optimization for the continuous one. Santos et al. (2020a) proposed a new superstructure-derived MINLP model with a reduced number of decision variables. Change of variables and inner-level optimization were considered to diminish the combinatorial size of the optimization problem. The solution approach consisted of a two-level meta-heuristic optimization, using SA in the combinatorial problem and Particle Swarm Optimization in the nonlinear problem. Lin et al. (2021) proposed a two-piece WHEN synthesis framework composed of a targeting phase followed by the detailed HEN synthesis. The former was performed by optimizing a model of thermodynamic paths of process streams using hybridization of genetic algorithm and golden section method. The latter was performed using mathematical programming to minimize TAC.

A major challenge in this synthesis problem is dealing with streams classification. Some authors considered energy targeting or fixed temperature and pressure routes based on thermodynamic insights. Other authors included the classification of the stream as binary decision variables in the optimization problem. The objective of this paper is to present a WHEN superstructure and a derived MINLP model that deals with streams classification without binary decision variables or thermodynamic heuristics. That is achieved by introducing the novel reciprocal heat exchangers in the heat integration superstructure.

2. WHEN model

2.1. Problem definition

The WHEN synthesis problem can be defined as determining a set of electric turbines and compressors, single-shaft turbine-compressors, helper motors, electric generators, heat exchangers, heaters, and coolers that perform the required temperature and pressure

changes of process streams with minimum operating and capital costs. Therefore, for the set of S streams ($s = 1, \dots, S$), it is given their initial and final states (T_{in} , P_{in} , T_{out} , and P_{out}), heat capacity flow rates (CP) and heat exchange coefficients (h). Hot and cold utilities are available with known inlet and outlet temperatures (TS_{in} , TW_{in} , TS_{out} , and TW_{out}), individual heat exchange coefficients (h_s and h_w) and costs (CHU and CCU). The prices of purchase and selling electricity (CE and PE) are given as well as economic capital cost equations ($capC$, $capT$, and $capA$), polytropic coefficient (κ); and compression and expansion efficiencies (η_c and η_e).

2.2. Superstructure

The superstructure is based on Santos et al. (2020a), but without a classification section (Figure 1). The proposed superstructure has three sections: heat integration, temperature adjustment, and work exchange network. The heat integration section is based on Yee and Grossmann (1990), updated to deal with unclassified streams with reciprocal heat exchangers. This superstructure artifact consists of using the notation of s, n, ss, nn, k for a heat exchanger between hot stream (s, n) and cold stream (ss, nn) in heat integration stage k for the hot stream and $K - k - 1$ for the cold one, where s is the stream number, n is the WHEN superstructure stage and K is the total number of heat integration stages. The temperature adjustment section allows using a hot or cold utility to achieve the desired cooling or heating task. The work exchange network section is based on Onishi et al. (2018), which uses convex hull reformulation of a GDP model to deal with the selection of compressors and turbines.

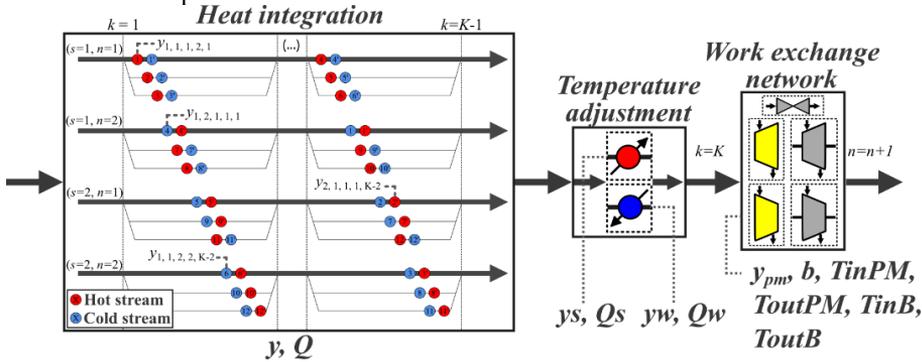

Figure 1. Proposed WHEN superstructure.

2.2.1. MINLP Model

In the heat integration section, Eqs. (1) – (6), the binary variable $y_{s,n,ss,nn,k}$ stands for the existence (1) or inexistence (0) of a heat exchanger between hot stream (s, n) and cold stream (ss, nn) in heat integration stage k for the hot stream and $K - k - 1$ for the cold one. In addition, Q , T , dTh , dTc , and A are the heat load, temperature, temperature difference at the hot and cold end, and area of a heat exchanger, respectively, considering their subscript index. CP , h , and the upper and lower limits of temperature (T^{up} and T^{lo}) are parameters given by the problem statement. Note that to deal with pre-classified streams one might just fix to zero the heat load and binary variable of the heat exchangers that regard streams with opposite thermal identity.

$$\forall s, n, ss, nn, k < K - 2: \quad T_{s,n,k+1} = T_{s,n,k} - \sum_{ss,nn \in he} \frac{Q_{s,n,ss,nn,k}}{CP_s} + \sum_{ss,nn \in he} \frac{Q_{ss,nn,s,n,K-k-1}}{CP_s} \quad (1)$$

$$Q_{s,n,ss,nn,k} \leq y_{s,n,ss,nn,k} Q^{up} \quad (2)$$

$$dT h_{s,n,ss,nn,k} \leq T_{s,n,k} - T_{ss,nn,K-k} + (T^{up} - T^{lo})(1 - y_{s,n,ss,nn,k}) \quad (3)$$

$$dT c_{s,n,ss,nn,k} \leq T_{s,n,k+1} - T_{ss,nn,K-k-1} + (T^{up} - T^{lo})(1 - y_{s,n,ss,nn,k}) \quad (4)$$

$$y_{s,n,ss,nn,k} + y_{ss,nn,s,n,K-k-1} \leq 1 \quad (5)$$

$$A_{s,n,ss,nn,k} \left(dT h_{s,n,ss,nn,k} dT c_{s,n,ss,nn,k} \frac{dT h_{s,n,ss,nn,k} + dT c_{s,n,ss,nn,k}}{2} \right)^{\frac{1}{3}} \geq Q_{s,n,ss,nn,k} \frac{h_s + h_{ss}}{h_s h_{ss}} \quad (6)$$

In the temperature adjustment section, Eqs. (7) – (16), it is possible to place a heater ($y_{s,n} = 1$), a cooler ($y_{w,n} = 1$), or none ($y_{w,n} + y_{s,n} = 0$) at stream s in stage n . Q_s , Q_w , $dTsh$, $dTsc$, $dTwh$, $dTwc$, A_s , and A_w are the heat load of the heater and cooler, temperature difference at the hot and cold end for the heater and cooler, and heat exchange area of the heater and cooler, respectively, considering the subscript index referred to streams and stages. The upper limit of heat load (Q^{up}), $TSout$, $TSin$, $TWout$, $TWin$, h_s , and h_w are parameters given by the problem statement.

$$\forall s, n, k = K - 2:$$

$$T_{s,n,k+1} = T_{s,n,k} + Q_{s,n}/CP_s - Q_{w,n}/CP_s \quad (7)$$

$$Q_{s,n} \leq y_{s,n} Q^{up} \quad (8)$$

$$Q_{w,n} \leq y_{w,n} Q^{up} \quad (9)$$

$$y_{w,n} + y_{s,n} \leq 1 \quad (10)$$

$$dTsh_{s,n} \leq TSout - T_{s,n,k} + (TSin - T^{lo})(1 - y_{s,n}) \quad (11)$$

$$dTsc_{s,n} \leq TSin - T_{s,n,k+1} + (TSin - T^{lo})(1 - y_{s,n}) \quad (12)$$

$$dTwh_{s,n} \leq T_{s,n,k} - TWout + (T^{up} - TWin)(1 - y_{w,n}) \quad (13)$$

$$dTwc_{s,n} \leq T_{s,n,k+1} - TWin + (T^{up} - TWin)(1 - y_{w,n}) \quad (14)$$

$$A_{s,n} \left(dTsh_{s,n} dTsc_{s,n} \frac{dTsh_{s,n} + dTsc_{s,n}}{2} \right)^{\frac{1}{3}} \geq Q_{s,n} \frac{h_s + h_s}{h_s h_s} \quad (15)$$

$$A_{w,n} \left(dTwh_{s,n} dTwc_{s,n} \frac{dTwh_{s,n} + dTwc_{s,n}}{2} \right)^{\frac{1}{3}} \geq Q_{w,n} \frac{h_s + h_w}{h_s h_w} \quad (16)$$

The work exchange network (WEN) section is based on Onishi et al. (2018). The cost calculation is based on Santos et al. (2020a), in which the TAC is the sum of operating and capital costs of WEN and HEN. The resulting MINLP model is implemented in GAMS 37.1.0 and solved with the global optimization solver BARON 21.1.13 (Tawarmalani & Sahinidis, 2005) to minimize the TAC.

3. Case study

This two-stream problem was proposed by Onishi et al. (2014a) and later approached by Lin et al. (2021). Table 1 and Table 2 present the stream and cost data, in which Wc , Wt , Qs , and Qw are given in kW, and A is given in m^2 . Notice that the problem statement contains several considerations to simplify mathematically the synthesis task. Some other parameters from the problem statement include T^{lo} and T^{up} of 350 and 750 K, minimum temperature approach ($dTmin$) of 5 K, polytropic coefficient of 1.352, compressor and turbine efficiencies of 100 %, and annualization factor of 0.18. Notice that $dTmin$ is the lower limit of all dT variables. For this case study, the authors disregarded the use of single-shaft turbine-compressors. The model size for this small-scale case study was 397 equations, 397 variables (80 discrete ones), and the best solution is found in about 5 s.

The results of solving this WHEN synthesis problem with the proposed MINLP model are illustrated in Figure 2.

Table 1. Stream data for the case study.

Stream	T_{in} [K]	T_{out} [K]	P_{in} [MPa]	P_{out} [MPa]	CP [kW/K]	h [kW/m ² K]
s1	650	370	0.1	0.5	3.0	0.1
s2	410	650	0.5	0.1	2.0	0.1
HU	680	680				1.0
CU	300	300				1.0

Table 2. Cost data for the case study.

Operation	Capital cost	Unit	Operating cost	Unit
Compressors	$capC = 30.317(Wc)^{0.62}$	(k\$)	$CE = 0.45504$	(k\$/kW _y)
Turbines	$capT = 1.5338(Wt)^{0.81}$	(k\$)	$PE = 0.0$	(k\$/kW _y)
Heat exchangers	$capA = 21.778 + 3.4467(A)$	(k\$)	$UT = 0.377Q_s + 0.1Q_w$	(k\$/y)

The TAC of this solution is 834.7 k\$/year, a value that surpassed the literature results of 1207 in Onishi et al. (2014a) and 837 k\$/year in Lin et al. (2021). This shows that strategies of energy targeting and fixing thermodynamic routes can simplify big-size WHEN problem at the price of potentially disregarding the global optimum.

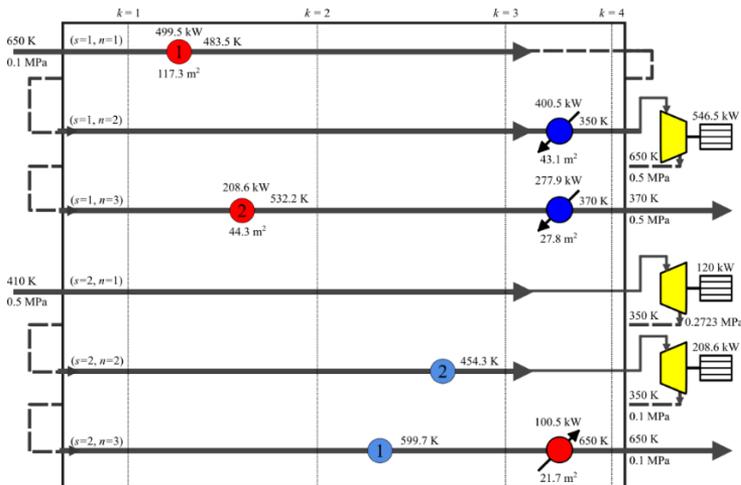

Figure 2. WHEN result for the case study.

Compared to the result of Lin et al. (2021), the proposed solution for this small-scale WHEN synthesis problem has one less heat exchanger recovers 2.2 kW more heat, consumes 2.1 kW less net work, and consumes 2.2 kW less cold utility. The main advantages of the present WHEN are achieving a higher inlet temperature to the second turbine, producing more work, and the increased heat integration, which saved utility. For future work, one might consider using the idea of reciprocal heat exchangers and the present MINLP model for medium or big-sized WHEN problems. For solving such problems efficiently with global optimization solver, such as BARON, improving the model to provide tighter bounds might be required.

4. Conclusions

An efficient MINLP model for optimal WHENs synthesis was proposed from a superstructure that considers unclassified streams via reciprocal heat exchangers. A small-scale WHEN case study from the literature was used to test the developed model. It was solved using the BARON global optimization solver in GAMS. The leading advantage of the present optimization model is the capability of defining the temperature and pressure route of a process stream entirely during optimization, instead of relying on energy targeting or fixed thermodynamic routes. Results surpassed the ones from the literature from 837.0 to 834.7 k\$/year of total annualized cost. For future work, the present MINLP model should be tested to medium or big-sized WHEN problems and be modified to tighten the bounds for global optimization.

Abstract

Carbon capture and utilization (CCU) has attracted growing interest to potentially curb CO₂ emissions while generating valuable chemicals. These emerging technologies will coexist with their fossil analogs soon, creating opportunities to combine both. In this context, flue gas valorization from power plants can play a role in this transition. The success of CCU technologies will ultimately depend on its environmental sustainability, which should be evaluated based on global indicators such as the Planetary Boundaries (PBs). Here we assessed the absolute sustainability level of an integrated facility producing ammonia (NH₃) and synthetic natural gas (SNG) using hydrogen (H₂) from water electrolysis, and nitrogen (N₂) and CO₂ from flue gas from a combined-cycle natural gas power plant. The LCA-PBs assessment showed that the alternative technologies could contribute to operating the Planet safely by significantly reducing the impact on the climate change and ocean acidification Earth-system processes, compared to the fossil Haber-Bosch (HB) and conventional steam reforming processes. Overall, the investigated process could smoothen the transition towards low-carbon technologies. More broadly, the application of the PBs to quantify the environmental performance of the integrated system opens up new avenues for the absolute sustainability assessment of emerging low-carbon technologies within the chemical sector and beyond.

Keywords: flue gas valorization, planetary boundaries, life cycle assessment, circular economy

1. Introduction

The phasing out of fossil fuels for power generation is a key step in the sustainable transition of the energy and chemical sectors. However, during this transition, greenhouse gases (GHG) emissions from power plants still under operation will have to be reduced, possibly following a circular economy approach. This could be accomplished by using natural resources more efficiently and combining them with the valorization of side outputs into valuable materials that can re-enter the economy. In this context, carbon capture and utilization (CCU) is gaining increasing traction (Kätelhön et al., 2019). Recent work by Castellani et al. (2018) proposed an integrated process that separates flue gas from power plants into its main components: carbon dioxide (CO₂) and nitrogen (N₂). These streams are then upgraded into synthetic natural gas (SNG) and ammonia (NH₃) through the Sabatier and the Haber-Bosch (HB) process, respectively, using electrolytic hydrogen (H₂). This concept shows several advantages. First, what was originally a waste stream could be upgraded into promising low-carbon energy vectors. Second, the produced SNG could reduce the consumption of natural gas power plants, in line with circular thinking. Third, by producing H₂ from intermittent energy sources such as wind

or solar power, part of the excess electricity during peak power generation times could be absorbed, avoiding curtailment (Staffell et al., 2019).

The environmental impact of these emerging technologies has been estimated through life cycle assessment (LCA), evaluating their sustainability along the whole supply chain. Several works applied LCA on NH_3 and SNG production through many alternative pathways to the business as usual (BAU) (Castellani et al., 2018). However, these studies often focus on carbon footprint solely while neglecting other impact categories.

In recent times, absolute sustainability assessments gained broad interest. Among these, the recently proposed planetary boundaries (PBs) concept (Rockström et al., 2009) establishes a set of critical thresholds on key Earth-system processes that enable comprehensive absolute sustainability assessments. Transgressing the PBs could shift the Planet's current state, challenging the Earth's resilience. These limits, all together, define a safe operating space (SOS) within which anthropogenic activities should lie. Despite their relevance in sustainable development, studies incorporating the PBs in chemicals and fuels assessments are scarce.

In this work, we apply a PB-LCA methodology to evaluate valorization pathways of flue gas from a natural gas power plant to produce NH_3 and SNG using renewable H_2 . In particular, we quantify the transgression levels relative to the SOS, focusing on a plant located in Germany and comparing the results with the fossil-based analogs. To the best of the authors' knowledge, this is the first time that such a novel methodology of environmental assessment is applied to the proposed process.

2. Methodology

2.1. Process description

The block flow diagram of the process is presented in Figure 1. It encompasses four main stages: membrane separation, water electrolysis, the Sabatier process, and the HB process. The plant is designed to use 10% of the electricity produced by wind in Germany for electrolytic H_2 production. Given an annual wind energy production of 131.7 TWh in 2020 (Burger, 2021) and an annual plant operating time of 8000 h, this represents an average consumption of 1.65 GW, corresponding to about 136 kt h^{-1} of flue gas (see also Table 1). Flue gas was assumed to contain exclusively N_2 (80 mol%) and CO_2 (20 mol%), approximating the average flue gas composition for a combined-cycle natural gas power plant (Al Hashmi et al., 2018; Castellani et al., 2018).

H_2 production is modeled in Aspen Custom Modeler[®] using the proton exchange membrane (PEM) technology (Ni et al., 2006) since it is currently considered the most suitable for intermittent operation (Staffell et al., 2019).

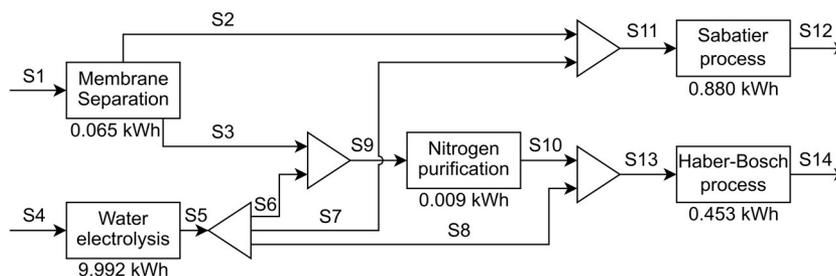

Figure 1. Block diagram of the case study. See Table 1 for the corresponding streams table. The electricity consumption, per kg flue gas, is shown below each process step.

Table 1. Selection of streams from the studied process. All the values are mass flows, in kt h^{-1} . The values denoted with a * correspond to water that is assumed to be immediately flashed.

Comp.\Stream	S1	S2	S3	S4	S6	S7	S8	S10	S12	S14
N ₂	97.67	1.16	96.52	0	0	0	0	96.52	1.16	0
CO ₂	38.36	34.53	3.84	0	0	0	0	0	0.19	0
H ₂	0	0	0	0	0.07	6.63	21.07	0	0.33	0
CH ₄	0	0	0	0	0	0	0	1.40	12.52	1.40
NH ₃	0	0	0	0	0	0	0	0	0	115.77
H ₂ O	0	0	0	248.12	0	0	0	3.14*	28.11*	0

The flue gas (S1 in Figure 1) is fed to a two-stage membrane separation, which provides a CO₂-rich stream (S2) and a N₂-rich stream (S3). A CO₂ recovery of 90% and a CO₂ purity of 95 mol% can be achieved in S2 (Castellani et al., 2018). The Sabatier process is tolerant to N₂ impurities, since N₂ behaves as an inert gas. In contrast, it is not possible to feed CO₂ impurities to the HB process. Consequently, as for the industrial standard, a small purification step that converts all the CO₂ to methane in the N₂-rich stream through methanation is assumed (D'Angelo et al., 2021). Accordingly, H₂ is fed in stoichiometric ratio to CO₂ to consume it entirely.

For the Sabatier reaction step (S11 to S12 in Figure 1), the process was modeled here assuming a CO₂ conversion of 99.5% (Castellani et al., 2018). To reach industrial grade, the SNG needs to be further purified from the N₂ impurity, which can be easily performed with a pressure swing adsorption unit using zeolites, for instance, at a low energy expense (Jayaraman et al., 2004). In the current study, this step was omitted for simplicity.

Furthermore, the water generated from the N₂ purification and Sabatier reaction (streams S10 and S12) is assumed to be separated using a flash at ambient conditions.

Finally, for NH₃ (S13 to S14 in Figure 1), a detailed model in Aspen HYSYS[®] was designed, based on D'Angelo et al. (2021) and considering an N₂ conversion of 98.6%.

2.2. Environmental Assessment

The LCA was performed following the ISO 14040 (ISO, 2014).

Three different scenarios were considered differing in the electricity source. All three scenarios assume that electricity powering the membrane separation, N₂ purification, Sabatier process, and HB process must be non-intermittent to ensure a smooth operation of the compressors. Accordingly, these steps are powered by the German 2020 power grid mix (Burger, 2021). At the same time, the first scenario (Sc1) assumes that PEM electrolysis is powered by the same mix, while the second (Sc2) uses offshore wind energy for the water-splitting step, and the last (Sc3) onshore wind instead.

A cradle-to-gate study was adopted to quantify the absolute sustainability level of three alternative flue gas valorization routes and an equivalent functional unit for the BAU. Further conversion of the products SNG and NH₃ is considered out of the work's scope. The selected functional unit was 1 kg of flue gas valorized for the three alternative scenarios. For the BAU, a system expansion approach was used. Notably, we considered the direct emissions from venting the flue gas, plus the impact of the BAU (fossil analogs) associated with the equivalent amount of natural gas and NH₃ produced from flue gas valorization. An attributional approach was selected.

In the second LCA phase, the life cycle inventories (LCIs) are modeled. The foreground system includes all the subprocesses depicted in Figure 1 and Table 1. At the same time,

the underlying energy and raw materials suppliers belong to the background system, here modeled with Ecoinvent v3.5, accessed through SimaPro v9.2. All the inventories, wherever possible, were regionalized for the German or European (RER) region. The H₂ inventory was obtained by combining results from Aspen Custom Modeler[®] with literature data, assuming H₂ storage in salt caverns (D'Angelo et al., 2021). The oxygen by-product obtained from water splitting was considered vented.

In the third phase, we used the characterization factors proposed by Ryberg et al. (2018) to estimate the impact on the control variables of the PBs. Nine Earth-system processes characterized by 11 control variables were considered, but two of them, atmospheric aerosol loading and novel entities, are yet to be quantified so they were omitted from this analysis. Since any of the PBs, if trespassed, could lead to catastrophic events, their joint ensemble defines the SOS for human anthropogenic activities. The same methodology described in D'Angelo et al. (2021) was used to quantify the levels of transgression (LTs). However, a different downscaling method was applied. Notably, the SOS was scaled down to the German market using a non-egalitarian approach involving the share of global GDP in 2019 covered by Germany. At the same time, the production plant was scaled up to cover the valorization of all the flue gas produced from natural gas power plants in the country (BEDW, 2020).

Finally, in step 4 of the LCA methodology, the results are interpreted, and potential recommendations are drawn. Here, we analyzed the impacts of the indicators exceeding the SOS to identify the main hotspots.

3. Results

The results of the selected scenarios (Sc1, Sc2, Sc3, and BAU) are shown in Figure 2.

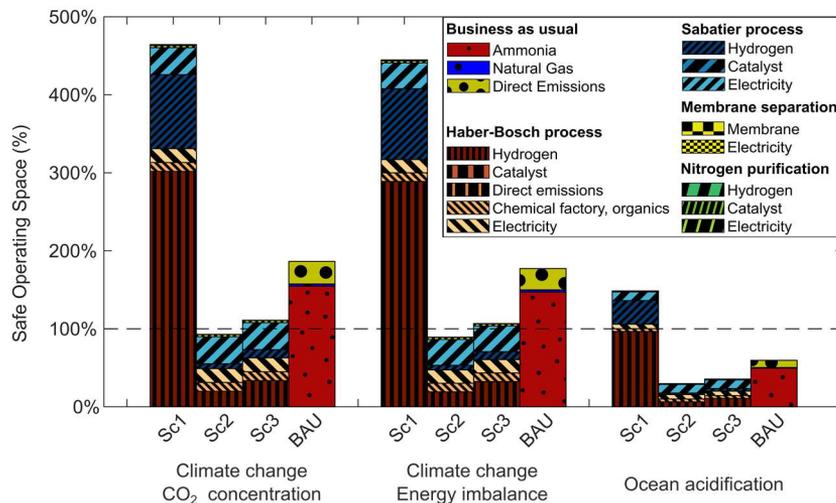

Figure 2. Impacts on the PBs control variables, and breakdown, for the four scenarios considered, quantified in terms of share of the SOS. Only the impacts exceeding the limit of 100% SOS are here shown.

Only the indicators exceeding the full SOS in at least one scenario are here presented, namely, climate change – CO₂ concentration (CC-CO₂), climate change – energy imbalance (CC-EI), and ocean acidification (OA). This is not surprising since these three

indicators are strictly associated with GHG concentration in different Earth compartments, i.e., the atmosphere for the first two and marine waters for OA.

The first key result is that the sustainability ranking witnesses Sc2 dominating for all the three selected control variables (29.7%-92.8% among the three indicators in focus), followed by Sc3 (35.5%-110.9%), BAU (59.6%-186.4%), and finally Sc1 (148.5%-464.4%). Sc2 is the only scenario that does not transgress any PB.

Moreover, the performance of the three valorization scenarios is strictly linked to the sustainability of the electricity employed for H₂ production. In fact, H₂ causes most of the impact in Sc1, with around 85.6% of the total contribution for all three indicators. Conversely, the H₂ contribution to the total impact shrinks down to around 28.1-28.2% for Sc2, where the electricity from the grid powering the rest of the facility plays the greatest role (49.6-49.9%). This fact is due to the remarkably high electricity consumption of water splitting (see also Figure 1) and the carbon intensity of the German power grid. In fact, more than a third (36.5%) of this energy mix relies on coal and natural gas power plants (Burger, 2021). Moreover, H₂ consumption explains the different magnitude of the impact of the various sub-processes in the valorization scenarios. The dominating role of the NH₃ production section is clearly highlighted, with a contribution to the overall alternative scenarios' impacts in the range of 52.76%-71.28%. Continuing along with the ranking, the second-highest contribution to the total impacts is SNG production, with a share of 27.9%-44.0% of the total impact.

On the contrary, the impacts associated with the very energy-efficient membrane separation are negligible. As anticipated, the power consumption associated with each part of the process dictates the overall performance. As highlighted in Table 1, the HB process requires the highest amount of H₂, almost 3.2 times as much as for SNG production. This is due to the fact that the N₂ feed to the HB process is much larger than the CO₂ feed that is meant to react through the Sabatier reaction. However, the latter needs more direct electric energy input, excluding H₂, than the HB process (see Figure 1), and a higher stoichiometric ratio H₂-to-substrate is required to convert CO₂ (4) with respect to N₂ (3). Finally, shifting the focus on the BAU, NH₃ production dominates the impact with about 83.0% of the share, followed by the emissions from venting the flue gas (15.4%-15.5%) and natural gas extraction and transport (about 1.6%). The lower relevance of the natural gas extraction compared to the SNG production can be explained by the much higher energy intensity of the Sabatier reaction and the very optimized extraction and transport of natural gas.

4. Conclusions

This work assessed an integrated process valorizing flue gas from natural gas power plants into NH₃ and SNG through using electrolytic H₂. The absolute environmental impact exerted on the Earth's biophysical limits was quantified through the PBs framework. For the first time, this novel LCA methodology is applied to such a process, to the best of the author's knowledge.

We found that the proposed process could perform more sustainably than the current fossil analog when using H₂ from renewable power sources such as wind. This fact can be true even in a country with energy mixes yet to be decarbonized, such as Germany, which still relies heavily on fossil coal and natural gas. However, the final feasibility of the proposed process will be strongly dependent on its economic affordability, which in the long run should be favored by the energy transition to renewables and lower capital costs for the electrolyzers.

For future studies, a comparison with an approach using the same membrane module to separate CO₂ from the flue gas, but assuming at a later stage the use of carbon capture and storage, could shed further light on the competitiveness of such a process relative to other environmentally promising approaches.

Abstract

The Middle East and North Africa region (MENA) is the largest global producer of dates, with an annual production of more than 8 million tonnes. The date palm has been an iconic part of this region's culture since 3000 BC and played a key role in its development over the centuries. Incidentally, date pits account for approximately 10% of the fruit, representing a vital biomass resource due to its high carbon and low ash contents. Several studies investigated the valorisation of date pits into biochar via pyrolysis and the product applications as solid fuel, adsorbents, or soil enhancers. However, few have evaluated the economics of pyrolysis using date pits as feedstock. As such, this study presents a techno-economic assessment of biochar production from date pits. Proximate and elemental analyses of date pits samples are conducted in the laboratory, while a 500 tonne/day biorefinery is designed and evaluated using adapted pyrolysis prediction models. In addition, the process is evaluated in two modes: slow pyrolysis at 250 °C and fast pyrolysis at 400 °C. The obtained results are promising, where slow pyrolysis yielded 50 wt.% of biochar with 62 % elemental carbon content. Besides, it achieved a return on investment of 19% and a 5-year payback period. Whereas fast pyrolysis yielded 24 wt.% of biochar with 77 % elemental carbon content, while the return on investment is 17% with a 6-year payback period. Both modes of pyrolysis using date pits proved to be feasible in the MENA region for the production of high-quality biochar.

Keywords: Date pits, Pyrolysis, Biochar, Biocrude, MENA.

1. Introduction

The date palm (*Phoenix dactylifera*) is a tropical tree that has been cultivated in the MENA region for over 7000 years (Sarraf et al., 2021). Nearly 8 million tonnes of date fruits were produced in the MENA region in 2019 (Dates, Crops and livestock products., 2021). The date fruit is very rich in carbohydrates, salts, minerals, dietary fibers, vitamins, fatty acids, amino acids, and proteins. The fruit contains a large seed known as date pit which is generally used as animal feeds and soil conditioners. It is also used as a functional food and an adsorbent for removing pollutants from water. However, the usage of date pits for the aforementioned applications is little considering its massive availability in the MENA region, which is approximately 800,000 tonnes. It is mostly treated as a waste material. As both landfilling and burning of date pits, cause serious environmental problem, an environmentally benign route of valorising the date pits need to be explored. The valorisation of date pits for the production of biochar and bio-oil through pyrolysis has been found as a potential and sustainable solution for the date pits

accumulation issue by many researchers. Hence, in this study, the pyrolysis method of valorising date pits is considered.

Pyrolysis prediction models are commonly used to forecast pyrolysis product distribution. The models are based on the reactions that take place during the pyrolysis process. Many pyrolysis regulating parameters, such as heating rate and pyrolysis temperature, are considered during the simulation. In this way, several models have been developed by researchers to predict the pyrolysis process (Neves et al., 2011; Sharma et al., 2006). The pyrolytic kinetics model proposed by Song (Song, 2016) has been adapted in this study to predict the yields of bio-oil, biochar, and syngas yields. The model uses empirical equations to satisfy the mass and energy balances, and empirical relationships to represent the overall patterns of product distribution as a function of temperature.

The objective of the current prediction model is to predict product composition of date pits by two pyrolysis modes: slow and fast pyrolysis. Besides, the study investigates the economic feasibility of the two process' modes to produce a cost-effective biochar from date pits.

2. Materials and methods

2.1. Date pits preparation

The date pits are obtained from a local syrup producer and rinsed twice in water to eliminate dirt and impurities. The moist stones are then dried for around 24 hours at 323.15 K. The date pits are then crushed into powder in a blender and stored in an airtight container for subsequent analyses. An SDT-650 Thermogravimetry analyser is used for the proximate analysis, while a Euro-vector Euro EA 3000 CHN elemental analyser is used for the ultimate analysis. The proximate and ultimate analyses are carried out using ASTM D7582-12 and ASTM D 3176-8 standards, respectively.

2.2. Model development

A simplified process flow diagram of date pits pyrolysis is illustrated in Figure 1. The following assumptions guide the development of the prediction model. Date pit samples are pyrolysed in an isothermal reactor with a nitrogen inert environment. The drying of samples occurs at the start of the reaction, and the samples are pyrolysed and converted into water, bio-oil, ash, biochar, and volatile gases such as CO₂, CO, CH₄, and H₂ in the first stage of pyrolysis, as specified in equations 1, 2, and 3 (Swagathnath et al., 2019). The bio-oil is further cracked into volatiles again in the second step, which occurs as the temperature rises. Depending on the biomass composition, the generated gas products split into different gaseous substances during this phase.

$$\text{Total liquid yield} = Y_{\text{bio-oil},F} + Y_{\text{H}_2\text{O},F} + \text{Moisture content of samples} \quad (1)$$

$$\text{Total volatile gas yield} = Y_{\text{H}_2,F} + Y_{\text{CO},F} + Y_{\text{CH}_4,F} + Y_{\text{CO}_2,F} \quad (2)$$

$$\text{Total char yield} = 0.106 + 2.43 * \exp(-0.66 * T * 10^{-2}) \quad (3)$$

The composition of carbon, hydrogen, and oxygen in biochar is calculated using the following equations.

$$\text{Carbon content} = 0.93 - 0.92 * \exp(-0.42 * T * 10^{-2}) \quad (4)$$

$$\text{Hydrogen content} = (-0.41 * 10^{-2}) + (0.10 * \exp(-0.24 * T * 10^{-2})) \quad (5)$$

$$\text{Oxygen content} = 0.07 + 0.85 * \exp(-0.48 * T * 10^{-2}) \quad (6)$$

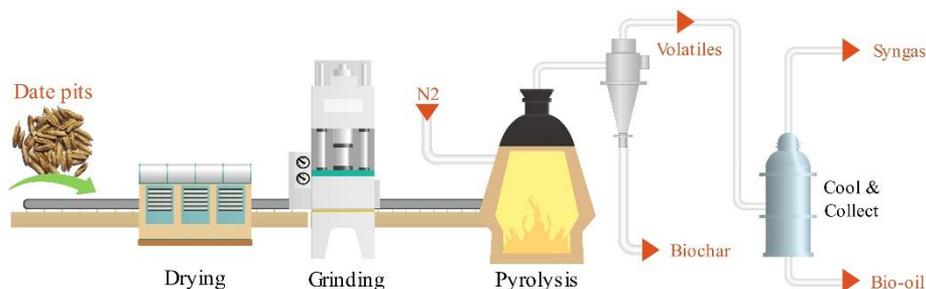

Figure 1: A simplified process flow diagram of date pits' pyrolysis.

2.3. Techno-economic assessment

The economic feasibility of date pits pyrolysis is conducted for a plant feed capacity of 20 tonne/hr and the assumptions highlighted in Table 1. The key pyrolysis equipment costs and labour requirement are adapted from earlier technical reports (Humbird et al., 2011; Wright et al., 2010). All prices are scaled up and inflated to the year 2019 using the Chemical Engineering Plant Cost Index (CEPCI).

Table 1: Assumptions for the techno-economic analysis.

Parameters	Values
Location of the proposed plant	Qatar
Analysis year	2019
Plant lifespan (years)	25
Discount rate (%)	20
Plant capacity (t/h)	20
Annual operating hours (h/y)	8000
Biomass price (\$/t)	100

3. Results and discussion

3.1. Date pits attributes

The proximate and ultimate attributes of the date pit samples are presented in Table 2.

Table 2: Proximate and ultimate analyses result of the date pit samples (this study).

Analysis	Composition (wt. %)
Proximate analysis (adb.%):	
Moisture	7.73
Volatile matter	68.11
Fixed carbon ^d	20.41
Ash	3.75
Ultimate analysis (daf.%):	
Carbon	46.30
Hydrogen	6.70
Nitrogen	0.83
Oxygen ^d	46.17
Sulphur	0.00
Chlorine	0.00

*adb.- air dried basis; ^d-calculated by difference; *daf- dry and ash-free basis

The date pit samples have a relatively high volatile content (68%) and a very low ash content (4%), indicating that the date pit could be an ideal feedstock for the pyrolysis process. Because of the low levels of nitrogen (~1%), and sulphur (~0%), NO_x and SO_x emissions from date pit pyrolysis are unlikely to exert any significant environmental burden.

3.2. Effect of pyrolysis type on pyrolysis products distribution

The effect of pyrolysis type on the pyrolysis products distribution of date pit samples is illustrated in Figure 2. Whereby, the slow pyrolysis produced a bio-oil yield of 19.6% while the fast pyrolysis generated a bio-oil yield of 37.7%. With respect to biochar yield, the slow and fast pyrolysis produced 50.2% and 24.6% yield, respectively. Both processes produced low syngas yields of 1.0% and 6.7%, respectively. The increased production of bio-oil and syngas in fast pyrolysis is due to its high temperature and heating rate as high temperatures and heating rates promotes secondary cracking of products leading towards more bio-oil and syngas production. A higher yield of biochar in slow pyrolysis is due to the process' low temperature, during which a significant amount of the biomass' volatile matter remains in solid state. Encinar *et al.* (Encinar et al., 2000) and Karaosmanoğlu *et al.* (Karaosmanoglu et al., 1999) also noted a similar trend of products distribution, whereby, an increased biochar production at low temperatures and increased bio-oil and syngas generation at higher temperatures have been reported.

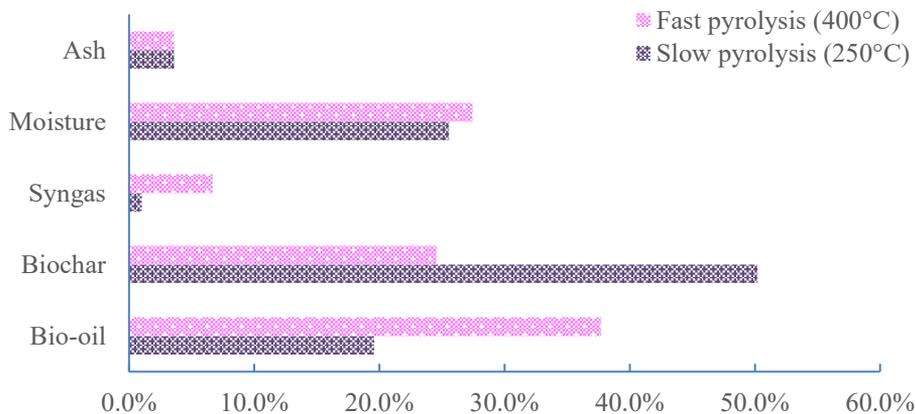

Figure 2: Slow and fast pyrolysis' product distribution of date pit samples

3.3. Effect of pyrolysis type on the biochar composition

The effect of pyrolysis type on the biochar composition of date pit samples is presented in Figure 3.

With the increase in temperature, an increase in the carbon content and at the same time a decrease in the hydrogen and oxygen contents can be observed. The increase in the carbon content is due to carbonisation or enrichment of char which is favoured at high temperatures. The decrease in the hydrogen and oxygen contents of char is attributed to the devolatilisation reactions which are dominant at temperatures between 350 and 600°C. The effect of temperature on the composition of biochar was also studied by Duman et al. (2011) and Bonelli et al. (2003). The aforementioned studies also indicated a similar increase in the carbon content and a decrease in the hydrogen and oxygen contents of char with the increase of operating temperature.

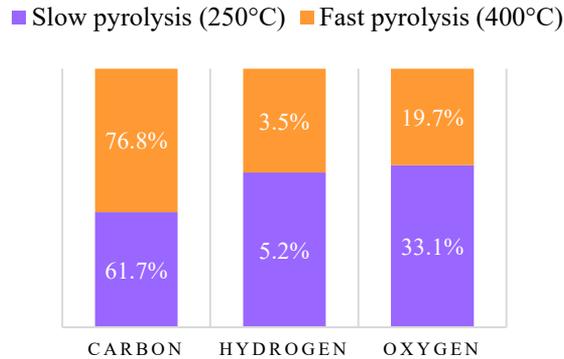

Figure 3: The effect of pyrolysis type on the biochar composition of date pit samples.

3.4. Techno-economic assessment

A summary of the technoeconomic assessment of both pyrolysis processes is presented in Table 3. Capital expenses (CAPEX) of fast pyrolysis is higher due to the need for bio-oil and syngas handling equipment (i.e. condensor, liquid and gas separator, liquid and gas filters, etc.), as fast pyrolysis produces higher quantities of bio-oil and syngas. Similarly, the operating expenses (OPEX) of fast pyrolysis is also higher, which is due to higher utility, labour, and maintenance cost associated with the handling of bio-oil and syngas. With respect to biochar production, slow pyrolysis offers a return on investment (ROI) of 17% as compared to an ROI of 16% for fast pyrolysis. In addition, the slow pyrolysis is offering a payback period of 5.3 years, whereas fast pyrolysis is offering 5.8 years to payback the capital investment.

Table 3: Summary of technoeconomic assessment of slow and fast pyrolysis.

Economic parameter	Slow pyrolysis (250°C)	Fast pyrolysis (400°C)
CAPEX (M US \$)	41.66	65.06
OPEX (M US \$/year)	21.09	21.67
Annual sales (M US \$/year)	29.00	32.86
Annual profit (M US \$/year)	7.91	11.19
Return on investment (%)	19%	17%
Payback period (Years)	5.3	5.8
Bio-oil LCOF (US \$/kg)	0.416	0.432
Biochar LCOF (US \$/kg)	0.206	0.249
Syngas LCOF (US \$/kg)	0.365	0.238

Conclusion

The availability of date pits in the Middle East and North Africa region (MENA) is enormous. The current study employed a prediction model to study the feasibility of pyrolysis of date pits considering the MENA scenario. The study considered two pyrolysis modes; slow (at 250°C) and fast (at 400°C) and investigated the effect of temperature on the product distribution of both pyrolysis processes. Besides, this study presented a techno-economic assessment of the two processes. The outcome of the study

is encouraging, indicating that pyrolysis of date pits is quite feasible in the MENA region. The techno-economic analysis indicates that slow pyrolysis is more ideal as far as biochar production is concerned, where it offers 19% return on investment and a 5-year payback period while the fast pyrolysis is offering 17% return on investment with a 6-year payback period. The outcome of this study provides an insight for the planning, design, and commercialisation of date pits-based pyrolysis plants in the MENA region.

Abstract

Global warming is one of the main environmental problems affecting the world. The continuous emissions of Carbon Dioxide (CO₂) released into the atmosphere have generated a critical environmental situation worldwide. It is reported that 70% of CO₂ emissions are related to electricity production. For this reason, if there is an increase in energy demand therefore it is expected to increase CO₂ emissions. Globally, different alternatives have been sought to reduce the environmental footprint related to CO₂ emissions, highlighting the implementation of capture and storage plants as a promising alternative. In this work it is presented the multiobjective optimization for the simulation of a CO₂ capture plant coupled to a power plant considering a stochastic optimization having as objective function the minimization of the environmental implications (Ecoindicator 99), the control properties (Condition Number), as well maximize the economic indicator (Return on investment). The analysis considered the most used fuels in the power plant. From the results, the design with the best overall performance is when natural gas is burned. Presenting the lower environmental impact with 22549.43kEcopoints and a return on investment of 73.24%. This results in a sustainable process with less environmental impact.

Keywords: CO₂ Capture Plant, biogas, coal, natural gas, associated gas.

1. Introduction

Electricity production from the burning of fossil fuels, is one of the main sources of CO₂ emissions. Moreover, it is projected the growth of electricity demand. With this scenario, it is necessary to develop sustainable alternatives for power generation, as well as alternatives to mitigate CO₂ emissions. Due to global environmental problems, it is imperative to seek industrial processes in accordance with the United Nations Organization sustainable development goals for green chemistry and sustainability. An alternative to convert electricity production into a sustainable process is the implementation of CO₂ capture and storage plants (CCS). Studies on post-combustion capture technologies focus mainly on chemical absorption using aqueous mono-ethanolamine (MEA) solution. MEA is considered as a good choice of solvent due to its great capacity to capture CO₂ (Nagy, T. et al., 2013) and also because its properties are well

known which facilitates modeling studies (Wagner et al., 2013). Despite its high efficiency, MEA is considered highly toxic so that its implementation entails a high environmental impact. Moreover, no studies report a full design considering environmental impact and the process economies as a sustainable indicator.

In this work aims to present a novel proposal for the simulation of a CO₂ capture plant coupled to a power plant. In which it is presented the optimum design from a sustainable point of view, considering a stochastic optimization having as objective function the minimization of the environmental implications of capture plants using MEA as solvent (Ecoindicator 99), the minimization of Condition Number (CN) as an indicator of the control properties of the system, as well maximize the return on investment (ROI) as an economic indicator. The analysis considered the most used fuels in the power plant: biogas, coal, natural gas, and associated gas. All the cases were standardized to recover at least 95% of the CO₂ produced. The results indicate that for a fuel feed flow of 1000 kmol/h it was necessary to vary the air ratio to achieve the CO₂ recovery objective.

2. Study Case and Methodology

The study case presents a power plant coupled to a post-combustion CO₂ capture process (see Figure 1) considering the most used fuels for electricity production. The simulation was carried out in the software ASPEN PLUS. For the power plant it was considered a single-stage air compressor system as a simplified model for electricity production. According to Luyben (2013) it is possible to represent the electricity production in this simplified model considering the operating parameters as compression ratio, etc. As well, it is considered a fuel feed flow of 1000 kmol/h and a molar ratio of fuel and air of 1:30 to achieve the total combustion for all the fuels used in this study (Luyben, 2013). To describe the thermodynamic properties involved in the combustion, the Peng-Robinson method was used (Hasan, M. et al., 2012). For the CO₂ capture plant, a chemical absorption using an aqueous solution of Monoethanolamine (MEA) at 30% by weight as solvent was considered (Nagy, T. et al., 2013). The proportion of 30 wt% it is important to take in consider because MEA is strongly corrosive in high concentrations. As well, the viscosity also increases affecting the efficient of capture (Kohl, 1985).

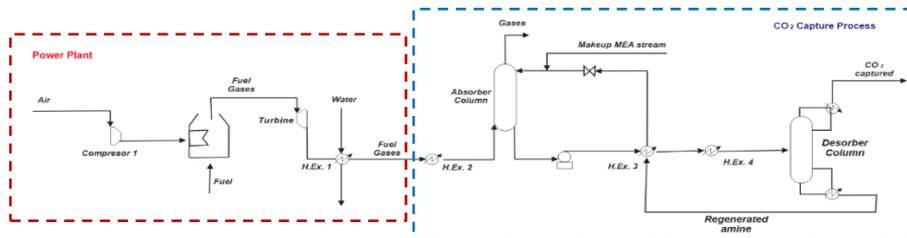

Figure 1. Scheme of a power plant coupled to a post-combustion CO₂ capture process using MEA 30wt% as solvent.

The capture process includes two columns, the absorption and desorption units. In the absorption the flue gases enter at the bottom of the column and the MEA at the top. Therefore, there is an interaction between the liquid and gas phases, driving the CO₂ to the liquid phase at the bottom of the absorber column. In the desorber column it is important to regenerate the solvent and make the desorption of the CO₂, which strongly depends on the reboiler duty. The capture process, is complex because the chemical absorption includes several dissociation reactions (Wagner et al., 2013). In order to model

this electrolyte behavior, it is important to consider all the kinetics as well as the binary interaction parameters. Likewise, the thermodynamic model Electrolyte Non-Random Two Liquids was implemented to consider the dissociation of ionic species. For the combustion process, the main design aspects are related to finding the amount of air to be fed and the optimum combustor pressure because of the trade-off between compressor work and turbine power (Luyben, 2013). The amount of air used to complete the combustion is very important. This factor directly influences the capture, as it is stated that the capture efficiency depends on the composition of flue gases. To ensure high capture efficiency, flue gases must be high in CO₂. For the capture process, some design aspects related to the process configuration and operational conditions should be taken into consideration to reduce the energy consumption and use of MEA. For the desorber column, in order to capture the maximum amount of CO₂ from the flue gas obtained from the power plant, it is necessary to manipulate the distillate flow and the reflux ratio. All the cases were standardized to a purity of 99 mol% CO₂ and at least 95% recovery of the CO₂ produced during the combustion. This directly affects the energy requirements of the process and therefore directly influences environmental and cost indicators.

The proposed model, has a significant number of variables to be optimized to have an optimal design and operation conditions, by aiming a maximum capture of CO₂, the best control criteria, maximum return on investment and lowest environmental impact. In this context, due to the electrolytic behaviour present in the liquid phase, the CO₂ capture process represents a highly non-linear model. With a certain number of discrete and continuous variables, the CO₂ capture model is suitable for optimizing. The design variables and the operation range, where chosen through a sensibility analysis of the process. The design variables for the study case are shown in Table 1.

Table 1. Design variables for the multi-objective optimization

Process	Variables	Type of Variable	Symbol	Range	Units
Combustion	Air Flow	Continue	Air	10 000-35 000	kmol/h
	Pressure Ratio	Continue	P _{com1}	1 – 8	---
	Compressor Combustion	Continue	P _{react}	4.5 – 9	atm
	Reactor Pressure	Continue	P _{turbine}	1 - 8	atm

2.1. Optimization Methodology

For the multi-objective optimization, it was employed the method of Differential Evolution with Tabu List (DETL) proposed by Srinivas and Rangaiah (2003). This technique works as a combined system between the biological evolution from Differential Evolution technique and the random search method from the Tabu search technique. The objective function involves three important axes to analyze: Return on Investment (ROI) as an indicator of the economy of the process by calculating return on investment due to the coupling of a capture plant to an existing power plant. Condition Number (γ^*) as an indicator of the dynamic behavior of the process considering low condition number for systems with good controllability and Eco-indicator 99 (EI99) to quantify the environmental impact derived from the coupling of the capture process, use of MEA as a solvent. According to Jiménez-González et al. (2011), these axes are needed in the optimization of a process to evaluate green chemistry. It is hoped that the analysis framework developed in this paper can contribute to the use of indices that can assess more than one aspect of green chemistry, in order to be easily integrated into a green process-based optimization. Similar works have been reported by Sánchez-Ramírez et al. (2017) and Contreras-Zarazúa et al. (2019) applying these indexes for distillation columns. The objective function is expressed in function of the variables described in Table 1 as is shown in Eq. (1).

$$\text{Min}[-ROI, \gamma^*, EI99] = f(\text{Air}, P_{\text{com1}}, P_{\text{react}}, P_{\text{turbine}}, N_{i,j}, NF_{i,j}, D_{i,j}, \text{MEA}, RR, Q) \quad (1)$$

Subject to:

$$\begin{aligned} y_{i,f} &\geq x_{i,f} \\ w_{i,f} &\geq u_{i,f} \end{aligned} \quad (2)$$

The objective function is restricted to satisfy the recuperation of at least 95% of the CO₂ produced during the combustion and also to achieve a purity of 99% mol of CO₂. Where $y_{i,f}$ represents the CO₂ recovered in the desorber column and $x_{i,f}$ represents the 95% of the CO₂ produced during the combustion. As well $w_{i,f}$ represents the purity achieved at the desorber column and $u_{i,f}$ represents the purity expected of at least 99% mol of CO₂. The optimization process was done through a visual basic hybrid platform in a Microsoft Excel macro. Where initially the values of the input vector are chosen randomly and sent to ASPEN PLUS. Where it is performed the simulation of the process and register that data as initial value in Excel. Then, the output vector data is sent to Matlab where, according to the methodology presented by Skogestad (2007), the value of the condition number is obtained. After that, the data is sent to Excel to obtain the ROI and EI99. Finally, the results are stored and it is generated a new vector. The values of parameters required by DETL method are: Population size: 120 individuals, Generation number: 1000, Tabu list size: 60, Tabu radius: 0.0001, Crossover fractions: 0.9, Mutation fractions: 0.3.

3. Results

In this section are presented the result obtained from the optimization. In order to analyze the operating conditions for each design it is important to highlight the composition of the flue gases obtained for each fuel used for the simulation. With a CO₂ molar fraction for Biogas, Coal, Natural Gas and Associated Gas of: 0.054, 0.124, 0.050 and 0.042

respectively. It is possible to observe that the flue gasses with the highest concentration of CO₂, is the one that is obtained from burning Coal, Biogas and Natural Gas. This concentration directly affects the parameters related to operational conditions as: solvent requirement and reboiler duty, which impact on economic and environmental indexes. Table 2 shows, the impact of some design parameters on the process performance. For the absorption, when the CO₂ concentration is low, the efficiency in the capture is affected. In order to capture a bigger amount of CO₂, the solvent requirement increases. Moreover, the reflux ratio is directly related to the energy requirements. As higher is the reflux ratio the energy requirements for the capture will increase.

Table 2. Design parameters for the best scenario of CO₂ capture for each fuel

Process	Variables	Biogas	Coal	Natural Gas	Associated Gas
Combustion	Air [kmol/h]	17133.95	20519.78	19602.76	24221.83
	P _{com1} [atm]	3.72	3.9	3.64	4.60
	P _{react} [atm]	5.13	6.46	7.46	6.79
	P _{turbine} [atm]	4.8	2.73	6.89	5.53
Absorber	N _{abs}	39	34	29	33
	NF _{abs}	3	3	3	3
	D _{abs}	3.2	1.18	2.59	2.76
	MEA [kmol/h]	43681	43258.06	43504.63	43509.26
Desorber	N _{des}	33	24	24	22
	NF _{des}	3	3	3	3
	D _{des} [m]	2.36	1.33	2.04	1.45
	RR	3.53	2.24	2.32	3.67
	Q[GJ/h]	470.08	210.50	364.45	491.86
	CO ₂ recovered [ton/h]	67.57	32.72	65.84	70.40
	Q/CO ₂ [GJ/ton]	6.9	6.4	5.5	6.9
CO ₂ Purity [%mol]	0.99	0.99	0.99	0.99	
Objective Function	ROI [%]	64.25	40.86	73.24	77.83
	γ*	20.17	2.39	6.7	34.82
	EI99 [kEcopoints]	28920.05	22615.53	22549.43	30369.51

For the analysis of the sustainability indexes, it can be observed that the better return on investment when implementing a capture process is when associated gas and natural gas are used as fuels, this trend is related to the topology of the process. For these two fuels, the process configuration is smaller impacting directly on construction costs. Also, as the flue gasses for those fuel have a bigger concentration in CO₂, the solvent requirements will be less in comparison with the other two fuels. It is possible to see that the least environmental impact occurs when natural gas is used as a fuel. This can be explained due to several factors, first of all it is the process the highest recovery of CO₂ decreasing the environmental food print related to CO₂ emissions. Likewise, the reduction in environmental impact can be explained because it is the process that has the lowest energy requirements and uses of solvents; these factors have a significant impact on the environmental weighting. On the other hand, it can be observed that the process where coal is used has an environmental score approximate to that obtained with natural gas. However, it is the process with the highest use of solvent, due to the low concentration of CO₂ in its flue gases. As well as the process in which there is a lower recovery of CO₂. About the control properties, it can be seen that the processes where coal and natural gas are used, are those that present best control properties by presenting lower condition

numbers. However, through the optimization process it is possible to obtain the best combination of design variables generating the design that meets the lowest environmental impact, highest return on investment and the best control properties for each fuel studied. The results obtained show that the process in which natural gas is used globally presents a balance in the three objectives of costs, environmental and control properties.

Conclusions

Implementing the CO₂ capture process in power plants has been considered the most mature technology to reduce flue gas emissions associated with electricity production. Although capture plants help to reduce the environmental footprint of CO₂. It is important to consider the type of fuel that is used for electricity production. Due to the CO₂ concentration contained in the flue gasses there will be variations on the design specifications of the capture process. However, before implementation, it is necessary to analyze the environmental implications that arise from the implementation, use of solvents and energy consumption. From the results obtained it can be concluded that the type of fuel is a high weight variable during the capture process, impacting directly on solvent and energy requirements. As the CO₂ concentration decreases; CO₂ recovery and capture efficiency decreases, but solvent and energy requirements are increased. There is also a huge area of opportunity in the study of new solvents; such as ionic liquids and deep eutectic solvents, to improve the efficiency of CO₂ capture, to replace the use of MEA as the main solvent for CO₂ capture and minimize the environmental impact that entails the use of such a toxic solvent.

Abstract

A two-level MINLP model is used for water network optimisation of large sites, composed of several independent plants. At the lowest level, the water consumption within a given plant is first minimised, considering feasible connections between the units of this plant, using a predefined set of interplant connections and capacities. During the second step, the water needs and wastewater emissions of each plant are coordinated, to minimise the network costs for the entire complex.

This strategy was applied to the water network of the Petrogal Sines refinery, with significant reductions in the network operating cost and freshwater consumption, using a mixture of local and global numerical solvers available in the GAMS system.

Keywords: Water networks, Process synthesis, Process design, Total site integration

1. Introduction

Water is of utmost importance in several sectors of the society, and industry consumption accounts for a substantial fraction of this resource's usage. Substantial work has therefore been conducted towards rationalising the design and operation of industrial water networks. Takama et al. (1980) introduced non-linear programming to achieve the optimal design of an oil refinery's total water network. More recent examples are Karuppiah and Grossmann (2006); Ahmetović and Grossmann (2011), introducing nonlinear and mixed-integer nonlinear programming formulations, to account for several particularities of these problems. Interplant designs were also proposed by Chew et al. (2008); Lv et al. (2018); Rubio-Castro et al. (2012); Azmi et al. (2020).

2. Problem statement

The problem of a multi-site industrial water network optimisation can be described by a set of freshwater sources ($a \in AS$), contaminants ($c \in CS$), plants ($f \in FS$), operations ($p \in PS$) and treatment units ($t \in TS$), and a set of discharge effluents ($e \in ES$). A typical design problem consists of devising a network which minimises the total or operational costs involved, considering all interconnections, flow rates and contaminant concentrations. Typical industrial networks include a large number of such units and specifications, and may result in computationally challenging problems. Using a common site arrangement as a set of multiple plants, the existing operations can be further classified as belonging to individual plants or common to the industrial complex. The proposed strategy divides the problem in two instances: first the optimal water network of each

plant is achieved separately (P1), and then the total site network is later optimised, to minimise the network costs for the entire complex (P2).

3. Mathematical formulation

3.1. Model P1 — individual plant network

Model P1 is the optimisation block for each individual plant, described by Eqs.(1–6) and illustrated in Figure 1. The objective function Eq. (1) in P1 is comprised by the expenses related with the utilisation of water from the different sources ($\text{cost}_a^{\text{FW}}$ — cost of freshwater from source a , and F_a^{FW} — total freshwater flow from source a). Eqs. (2–4) correspond to the plant's units total flow (units inlet f_p^{in} and outlet f_p^{out}), from source a ($F_{a,p}^{\text{W}}$), reused from unit p' ($F_{p',p}^{\text{RP}}$), unit discharge (F_p^{D}) and contaminant mass balances (inlet and outlet concentrations: $C_{p,c}^{\text{in}}$, $C_{p,c}^{\text{out}}$), with the possibility of water use from all sources and from the same plant's units outlet, although recycle to-and-from the same unit is not allowed ($p' \neq p$). Nonlinearities will arise in these equations, as flows (continuous variables) are multiplied by concentrations (continuous variables). In Eq. (5) operations are modelled as having a contaminant mass discharge, the possibility of an indissociable treatment section (process units' contaminant removal ($\text{rr}_{p,c}$), and an upper limit in the inlet concentration — Eq. (6). In the present formulation, f_p^{in} and f_p^{out} are fixed parameters; however, they can also be treated as variables, as there may be water consumption or formation during the operations. The solution of P1 for each individual plant provides updated inlet flow water needs for the total site problem considered by model P2.

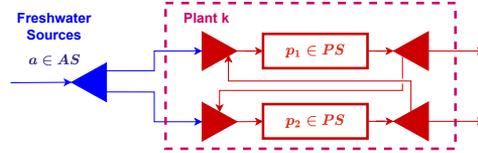

Figure 1: Superstructure of model P1.

$$\min \text{cost}_a^{\text{FW}} F_a^{\text{FW}} \quad (1)$$

$$\text{s.t.} \quad \sum_a F_{a,p}^{\text{W}} + \sum_{p' | p' \neq p} F_{p',p}^{\text{RP}} = f_p^{\text{in}}, \quad \forall p \in \text{PS} \quad (2)$$

$$f_p^{\text{out}} = \sum_{p' | p' \neq p} F_{p,p'}^{\text{RP}} + F_p^{\text{D}}, \quad \forall p \in \text{PS} \quad (3)$$

$$\sum_a F_{a,p}^{\text{W}} C_{a,c}^{\text{W}} + \sum_{p' | p' \neq p} F_{p',p}^{\text{RP}} C_{p',c}^{\text{out}} = f_p^{\text{in}} C_{p,c}^{\text{in}}, \quad \forall p \in \text{PS}, \quad \forall c \in \text{CS} \quad (4)$$

$$f_p^{\text{in}} C_{p,c}^{\text{in}} (1 - \text{rr}_{p,c}) + I_p = f_p^{\text{out}} C_{p,c}^{\text{out}}, \quad \forall p \in \text{PS}, \quad \forall c \in \text{CS} \quad (5)$$

$$C_{p,c}^{\text{in}} \leq C_{p,c}^{\text{in,max}}, \quad \forall p \in \text{PS}, \quad \forall c \in \text{CS} \quad (6)$$

3.2. Model P2 — total site network

Model P2 considers the entire complex, with plants, individual operations not belonging to plants, treatment units and multiple discharge effluents. The plants residual needs and wastewater specifications result from the solution of P1. Figure 2 represents the problem superstructure, and all the possible connections. This second model also reuses some equations from model P1.

Eqs. (7–9) correspond to the processes' total flow (from and to treatment units, $F_{t,p}^{\text{TP}}$ and $F_{p,t}^{\text{PT}}$), and flow to the final discharge ($F_{p,e}^{\text{PD}}$) and contaminant mass balances (here $C_{t,c}^{\text{out}}$ is the outlet concentration from treatment t). Note that reutilising water from the same unit, plant, as well as water from

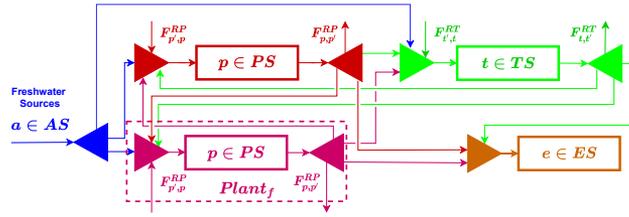

Figure 2: Superstructure of model P2.

the discharges, is not permitted. A new set MP contains the allowed process matches, accordingly to the plant arrangement. As in P1, nonlinearities are present in the contaminant mass balances, as flows are multiplied by concentrations.

$$\sum_a F_{a,p}^W + \sum_{p'|(p,p') \in \text{MP}} F_{p',p}^{\text{RP}} + \sum_t F_{t,p}^{\text{TP}} = f_p^{\text{in}}, \quad \forall p \in \text{PS} \quad (7)$$

$$\sum_a F_{a,p}^W C_{a,c}^W + \sum_{p'|(p,p') \in \text{MP}} F_{p',p}^{\text{RP}} C_{p',c}^{\text{out}} + \sum_t F_{t,p}^{\text{TP}} C_{t,c}^{\text{out}} = f_p^{\text{in}} C_{p,c}^{\text{in}}, \quad \forall p \in \text{PS}, \quad \forall c \in \text{CS} \quad (8)$$

$$f_p^{\text{out}} = \sum_{p'|(p,p') \in \text{MP}} F_{p,p'}^{\text{RP}} + \sum_t F_{p,t}^{\text{PT}} + \sum_e F_{p,e}^{\text{PD}}, \quad \forall p \in \text{PS} \quad (9)$$

Operations are modelled as having a contaminant mass discharge and an embedded treatment section, as in model P1, in Eqs. (5–6).

Similar to process units, Eqs. (10–12) formulate the flows of the treatment units (flow from treatment to discharge, $F_{t,e}^{\text{TD}}$) and mass balances (inlet concentration in treatment, $C_{t,c}^{\text{in}}$). Reutilisation from and to the same treatment is restricted ($t \neq t'$). Contaminant removal ($\text{rr}_{t,c}$), in the treatment units, is achieved through the units' inlet concentration and the units' removal rate — Eq. (13). Effluent flow (F_e^D) and mass balances are inserted for each discharge e in Eqs. (14–15), and the resulting concentration $C_{e,c}^D$ is limited to an upper bound $C_{e,c}^{D,\text{max}}$.

$$\sum_a F_{a,t}^W + \sum_{t'} F_{t',t}^{\text{RT}} + \sum_p F_{p,t}^{\text{PT}} = F_t, \quad \forall t \in \text{TS} \quad (10)$$

$$F_t = \sum_{t'} F_{t,t'}^{\text{RT}} + \sum_t F_{t,p}^{\text{TP}} + \sum_e F_{t,e}^{\text{TD}}, \quad \forall t \in \text{TS} \quad (11)$$

$$\sum_a F_{a,t}^W C_{a,c}^W + \sum_{t'} F_{t',t}^{\text{RT}} C_{t',c}^{\text{out}} + \sum_p F_{p,t}^{\text{PT}} C_{p,c}^{\text{out}} = F_t C_{t,c}^{\text{in}}, \quad \forall t \in \text{TS}, \quad \forall c \in \text{CS} \quad (12)$$

$$C_{t,c}^{\text{in}} (1 - \text{rr}_{t,c}) = C_{t,c}^{\text{out}}, \quad \forall t \in \text{TS}, \quad \forall c \in \text{CS} \quad (13)$$

$$\sum_p F_{p,e}^{\text{PD}} C_{p,c}^{\text{out}} + \sum_t F_{t,e}^{\text{TD}} C_{t,c}^{\text{out}} = F_e^D, \quad \forall e \in \text{ES} \quad (14)$$

$$\sum_p F_{p,e}^{\text{PD}} C_{p,c}^{\text{out}} + \sum_t F_{t,e}^{\text{TD}} C_{t,c}^{\text{out}} = F_e^D C_{e,c}^D, \quad \forall e \in \text{ES}, \quad \forall c \in \text{CS} \quad (15)$$

$$C_{e,c}^D \leq C_{e,c}^{D,\text{max}}, \quad \forall e \in \text{ES}, \quad \forall c \in \text{CS} \quad (16)$$

Effluent costs can be defined accordingly to the discharge concentrations, partitioned into several class intervals ($\delta_{e,c,k}^{\text{cls}}$), with $k \in \text{KS}$, and tarified accordingly to the highest activated concentration. That instance is modelled by defining a subset, corresponding to the special effluent $\text{SES} \in \text{ES}$ — Eq. (17). The highest activated class is multiplied by the discharged flow, resulting in that effluent cost cost_e , in Eq. (18). To avoid nonlinearities, Eq. (18) is further reformulated and linearised.

Eq. (19) computes the network costs, to be minimised similarly to Eq. (1).

$$C_{e,c}^D - (C_{e,c}^{D,\max} + \varepsilon) \delta_{e,c,k}^{\text{cls}} \leq C_{e,c,k}^{\max}, \quad \forall e \in \text{SES}, \quad \forall c \in \text{CS}, \quad \forall k \in \text{KS} \quad (17)$$

$$\text{cost}_e \geq \text{cost}_k \delta_{e,c,k}^{\text{cls}} F_e^D, \quad \forall e \in \text{SES}, \quad \forall c \in \text{CS}, \quad \forall k \in \text{KS} \quad (18)$$

$$\text{cost}^{\text{net}} = \sum_a \text{cost}_a^{\text{FW}} F_a^{\text{FW}} + \sum_t \text{cost}_t F_t + \sum_{e|e \notin \text{SES}} \text{cost}_w F_e^D + \sum_{e|e \in \text{SES}} \text{cost}_e \quad (19)$$

4. Initialisation

A good initial guess is frequently of major importance for local optimisation of nonlinear problems (NLP) and mixed integer non-linear problems (MINLP). To initialise the full network problem P2, two distinct procedures were tested: solving a simpler NLP for the entire network or a linear programming (LP) sequence strategy, where each section of the problem is analysed separately (Figure 3).

Figure 3: LP sequence initialisation strategy.

4.1. NLP initialisation strategy

This technique considers a simpler NLP, by removing the constraint inequalities from the original formulation and replacing the objective with a new function — Eq. (20), minimising the network infeasibilities resulting from a crude network initialisation. Eq. (20) can then be reformulated using suitable smoothing approximations (e.g., based on complementarity analysis (Gopal and Biegler, 1999)). The solution reached is then used as an initial solution for the original MINLP.

$$\min \sum_{c,p} \max\{0, C_{p,c}^{\text{in}} - C_{p,c}^{\text{in},\max}\} + \sum_{e,c} \max\{0, C_{e,c}^D - C_{e,c}^{D,\max}\} \quad (20)$$

$$\text{s.t.} \quad \text{eqs. (5,7–15)} \quad (21)$$

Note that during the application of this strategy, local NLP solvers may not reach an objective value of zero, even when the original problem is feasible. In either case, the solution obtained is considered as the initialisation for the subsequent MINLP solvers.

4.2. LP sequence initialisation strategy

The proposed strategy implies solving each of the following subproblems with LP models.

4.2.1. Water Usage Network (WUN) initialisation

Teles et al. (2008) suggest a combinatorial LP approach to initialise WUN problems. Each operation is dealt individually within an LP block, considering information from the previous units. Zhao et al. (2016) use this methodology, but instead of a combinatorial arrangement they consider the concentration potentials concept (CPDs) (Liu et al., 2009), to select the LP blocks sequence (Figure 4).

4.2.2. Discharge allocation

In order to initialise the water treatment network (WTN) section of P2, the strategy of Castro et al. (2009) was employed.

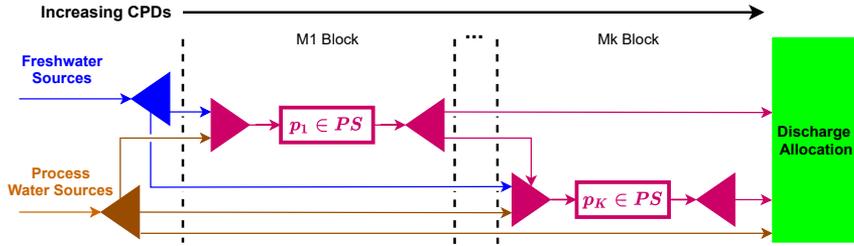

Figure 4: WUN initialisation strategy, based on Zhao et al. (2016).

This method has a limited capacity of dealing with multiple discharges and respective constraints. A LP was designed to allocate wastewater sources ($s \in \text{WWS}$) resulting from the WUN initialisation to the effluent e , accordingly to the discharge constraints and costs, in Eq. (22). The routine has the possibility of diluting the effluents with freshwater ($F_{a,e}^{\text{WD}}$) to eliminate infeasibilities — Eq. (23). Eq. (24) ensures that the wastewater sources allocated to the effluents ($F_{s,e}^{\text{WW}}$). Eq. (25) ensures that the discharge is within the allowed constraints. This equation is particularly relevant as $T \in \text{ES}$, requiring a previous match of the treatments ($t \in \text{TS}$) with each effluent ($e \in \text{ES}$).

$$\min \sum_e \text{cost}_e F_e^D + \sum_{(a,e)} F_{a,e}^{\text{WD}} \quad (22)$$

$$\text{s.t. } f_s^{\text{WW}} = \sum_e F_{s,e}^{\text{WW}}, \quad \forall s \in \text{WWS} \quad (23)$$

$$\sum_s F_{s,e}^{\text{WW}} + \sum_a F_{a,e}^{\text{WD}} = F_e^D, \quad \forall e \in \text{ES} \quad (24)$$

$$\sum_a F_{a,e}^{\text{WD}} C_{a,c}^W + \sum_s F_{s,e}^{\text{WW}} C_{s,c}^{\text{WW}} \prod_t (1 - \text{rr}_{t,c}) \leq F_e^D C_{e,c}^{\text{env}}, \quad \forall e \in \text{ES}, \quad \forall c \in \text{CS} \quad (25)$$

4.2.3. Water Treatment Network (WTN) initialisation

Castro et al. (2009) employ a sequence of LP blocks, each one handling a different treatment unit, and utilising information relative to the previous LPs and the subsequent ones; that strategy can be used to initialise WTN problems. All operations sequences are tested (using a combinatorial procedure), and the arrangement with the minimum objective value is selected. This method becomes prohibitive for medium-large problems. Instead, as recommended by Fan et al. (2019), for WTN problems, units were sorted by decreasing treatment cost, and the resulting sequence was inserted into the method of Castro et al. (2009). This strategy was applied independently for each effluent e , considering the treatment units allocated to that effluent line.

5. Application example

The Galp Sines refinery is an industrial complex located in the south of Portugal, with a production cap of 220 kbpd, accounting for approximately 70% of the country's refining capacity. The existing water network was optimised, employing several initialisation methods: using a reference refinery network configuration, and the previous sections techniques (Table 1). The version of the problem considered used 5 classes of contaminants, 3 individual plants involving 21 operations, one source of raw fresh water, and 2 discharge lines, with dynamic tariffs. The local MINLP solver SBB, and the global MINLP solver ANTIGONE were used with GAMS 33.2, in a AMD Ryzen 7 4800H computer with 16 GB of RAM, considering a maximum limit of 3600 s of CPU time.

Method	Fixed initialisation solution (€h ⁻¹)	MINLP local solver solution (€h ⁻¹)	MINLP global solver solution (€h ⁻¹)	Optimality gap (%)
No initialisation	—	Infeasible		11.4
Reference network	950.9	812.8	800.2	4.9
NLP initialisation	1591.1	1151.3		11.7
LP sequence initialisation	916.7	800.2		4.7

Table 1: Application results to the Sines refinery network.

The procedure resulted in reductions of 15.8% and 7% in cost and freshwater consumption respectively, increasing the environmental sustainability of the complex. Due to the extra effort incurred during the initialisation phase, the LP sequence initialisation displayed one of the lower gaps in the final solutions reached among the techniques utilised.

6. Conclusion

The application of methodology developed provided an efficient method for the optimisation of the industrial example considered. Within this problem, the impact of the initial solution considered is noticeable in the final results, both from the local MINLP solver and in the final global optimality gap. These results stress the importance of the availability of good initialisation techniques for the efficient solution of similar problems of comparable complexity.

Optimal design of solar-aided hydrogen production process using molten salt with CO₂ utilization for polypropylene carbonate production

Wanrong Wang, Nan Zhang, and Jie Li*

Centre for Process Integration, Department of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK

Abstract

In this work, optimal design for solar steam methane reforming using molten salt (SSMR-MS) with CO₂ capture and utilisation is investigated by employing a machine-learning based optimisation framework. The results obtained show that a 65.77 % reduction can be obtained compared with the existing SSMR-MS. The optimal Levelised Cost of Hydrogen Production (LCHP) is 1.26 \$ kg⁻¹ which represents about half of the LCHP in the existing SSMR-MS. The captured CO₂ can produce around 485.73 kt polypropylene carbonate annually.

Keywords: Hydrogen production; solar energy; CO₂ utilization; Machine learning; Optimization

1. Introduction

Global warming has been considered as the biggest environmental problem in this fast developing world. Anthropogenic CO₂ emission by using fossil fuel plays a key role in the global temperature rise as seen today. Therefore, it is urgent to shift to low-carbon technologies. To achieve this target, using renewable energies, clean fuels such as hydrogen are considered as longer-term solutions and carbon capture, utilization and storage is considered as short- to mid-term solution. Among all these solutions, hydrogen shows off excellent potentials as a commercial clean fuel. Furthermore, it is also an essential feedstock in many chemicals such as ammonia (Ohs et al., 2019). In 2020, the European Commission have stated that hydrogen economy is an important part for the economy recovery after COVID-19. However, conventional hydrogen production primarily utilizes natural gas and oil-based feedstock for steam reforming which contributes to large amount of CO₂ emissions. To reduce CO₂ emission, using renewable energy and carbon capture and utilisation in hydrogen production process should be investigated significantly (Alper et al., 2017).

Among the renewables, solar hydrogen production has received great attention in recent years due to its high capability to fulfill global energy demands (Koumi Ngoh et al., 2012). Wang et al. has studied the optimisation of solar steam methane reforming using molten salt (SSMR-MS) to reduce TAC and CO₂ emissions (Wang et al., 2021). In their work, it is shown that the optimal LCHP is still higher than the conventional methane steam reforming. What's more, the CO₂ removal model is designed at a constant separation efficiency, which could lead to inaccurate cost and utility calculation for this unit. Considering the coke formation in process, the lower bound of steam to methane ratio should also be adjusted. Therefore, an integrated rate-based CO₂ removal model in

SSMR-MS along with CO₂ utilization for polypropylene carbonate production is investigated in this work. This is the main novelty of this work.

In this work, the employment of machine learning in process optimisation from (Wang et al., 2021) is extended for optimal design of SSMR-MS with integration of CO₂ capture and utilization. The artificial neural network (ANN) is used to address this problem by obtaining functions that approximates the deterministic functions of TAC, hydrogen production rate, molten salt duty and gas flowrate from CO₂ capture unit with process variables in SSMR-MS. Then the problem is solved using a hybrid optimisation technique. The solution is then validated in Aspen Plus V8.8 and SAM. The most striking result is that there is a significant reduction in TAC by 65.77 % and CO₂ emissions by 68.97 % compared to the existing SSMR-MS process. With 485.73 kt polypropylene carbonate annually, the profit is considerable. The Levelised Cost of Hydrogen Production (LCHP) reduces from 1.26 \$ kg⁻¹ to 2.40 \$ kg⁻¹ compared to the optimal case in Wang et al. (2021).

2. Problem description

As shown in Figure 1, the SSMR-MS integrated with rate-based CO₂ capture model and polypropylene carbonate production process is developed in this work. There is a detailed description of SSMR-MS can be found in Wang et al. (2021). The pre-reforming process is non-adiabatic with a co-current flow mode. Solar energy is delivered using molten salt as media to the hydrogen production process. Methyl diethanolamine (MDEA) is used for CO₂ absorption and solution regeneration has the same equations as those in Moiola et al. (2016). Polypropylene carbonate is produced using the captured CO₂.

The objective is to minimize total annualized cost (TAC) of the integrated system.

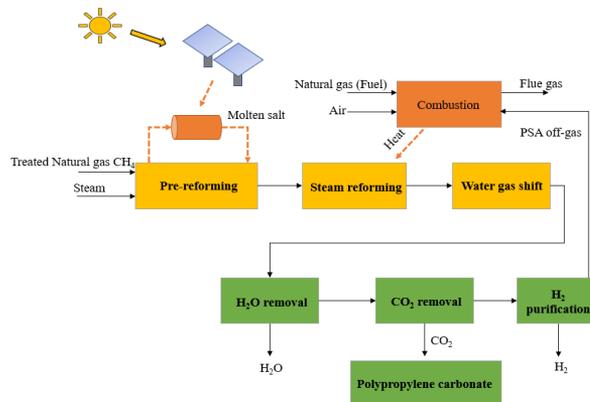

Figure 1: Block diagram of the integrated system (revision from Wang et al., 2021)

3. Mathematical formulation

The integrated system using rigorous models is modelled in Aspen Plus V8.8. However, the evaluation of the objective in this model as well as constraints is computationally expensive. To reduce complexity, surrogate model is applied to obtain a function $\hat{f}(X)$ that approximates the function f . ANN is employed as surrogate model for optimisation. ANN is particularly effective for modelling high-dimensional and highly non-linear

problems, because of its ability to learn and its usefulness in nonlinear processing compared with other techniques (Ibrahim et al., 2018).

In this work, a rigorous rate-based CO₂ removal model for CO₂ capture is firstly developed in Aspen Plus V8.8. To integrate the CO₂ removal model to SSMR-MS process, a surrogate model using ANN is constructed because of the difficulty in convergence in CO₂ removal model. To construct the ANN surrogate model, input variables and output variables should be selected to describe the rigorous CO₂ removal process precisely. The input variables include stream component flowrate of for CH₄, H₂O, CO, CO₂, H₂ which are denoted as $F_{in,CH_4,MDEA}$, $F_{in,H_2O,MDEA}$, $F_{in,CO,MDEA}$, $F_{in,CO_2,MDEA}$ and $F_{in,H_2,MDEA}$, respectively and stream temperature ($T_{in,MDEA}$). The input variables are organised as below,

$$\mathbf{z} = [F_{in,CH_4,MDEA}, F_{in,H_2O,MDEA}, F_{in,CO,MDEA}, F_{in,CO_2,MDEA}, F_{in,H_2,MDEA}, T_{in,MDEA}]^T.$$

The output variables include the outlet stream flowrates of CH₄, H₂O, CO, CO₂ and H₂ in the CO₂ removal process which are predicted using individual ANN surrogate models, as shown in Eqs. 1-5.

$$F_{out,CH_4,MDEA} = ANN_1(\mathbf{z}) \quad (1)$$

$$F_{out,H_2O,MDEA} = ANN_2(\mathbf{z}) \quad (2)$$

$$F_{out,CO,MDEA} = ANN_3(\mathbf{z}) \quad (3)$$

$$F_{out,CO_2,MDEA} = ANN_4(\mathbf{z}) \quad (4)$$

$$F_{out,H_2,MDEA} = ANN_5(\mathbf{z}) \quad (5)$$

These constructed ANN surrogate models are implemented in the rigorous SSMR-MS process by using the user model in Aspen Plus through Excel Link (Fontalvo, 2014). Then, this new SSMR-MS process is used to construct a new surrogate model for optimisation through extending the optimisation framework of Wang et al. (2021). Latin hypercube sampling method is used for sample generation.

In the integrated system, the independent input variables including molar flowrate of natural gas into pre-reformer F_{NG} , steam to methane ratio $\gamma_{S/C}$, operating temperature of reformer T_R , high-temperature water gas shift (HWGS) reactor T_{HWGS} , low-temperature water gas shift (LWGS) reactor T_{LWGS} , tube length of pre-reformer L_{PR} , reformer L_R , HWGS reactor L_{HWGS} and LWGS reactor L_{LWGS} , tube number in pre-reformer N_{PR} , reformer N_R , HWGS reactor N_{HWGS} and LWGS reactor N_{LWGS} vary between lower and upper bounds. The input variables are organised as a vector \mathbf{x} as below,

$$\mathbf{x} = [F_{NG}, \gamma_{S/C}, T_R, T_{HWGS}, T_{LWGS}, L_{PR}, L_R, L_{HWGS}, L_{LWGS}, N_{PR}, N_R, N_{HWGS}, N_{LWGS}]^T.$$

$$\mathbf{x}^L \leq \mathbf{x} \leq \mathbf{x}^U \quad (6)$$

The objective function TAC can be calculated as follows,

$$TAC = C_{capital} \cdot ACCR + C_{production} \quad (7)$$

where $C_{capital}$ is total capital investment. $ACCR$ is annual capital charge ratio. $C_{production}$ is the total production cost per year.

The optimization problem using the surrogate models is stated as follows,

$$(PS) \quad Min \quad TAC = TAC_1 + TAC_{solar}$$

$$\begin{aligned}
 \text{s.t.} \quad & TAC_1 = ANN_6(\mathbf{x}) + ANN_7(\mathbf{x}) \\
 & TAC_{solar} = f(Q_{MS}) \\
 & Q_{MS} = ANN_8(\mathbf{x}) \\
 & F_{H_2} = ANN_9(\mathbf{x}) \geq F_{H_2}^{TA} \\
 & \text{Eq. (6)}
 \end{aligned}$$

where TAC_1 is non-solar related cost, TAC_{solar} is the solar related cost. $ANN_6(\mathbf{x})$ is CO_2 removal process related cost. ANN_7 is the non-solar related cost excluding MDEA unit. \mathbf{x} is the set of independent variables in hydrogen production process, Q_{MS} is molten salt duty. The relationship of solar-related equipment cost, and molten salt duty is described using an algebraic linear function $f(Q_{MS})$. The surrogate model comprises 4 artificial neural networks as indicated above in the optimization problem and a linear regression model $f(Q_{MS})$. F_{H_2} denotes the predicated flowrate of hydrogen.

4. Solution algorithm

As illustrated in Figure 2, a hybrid optimisation algorithm is employed to solve the optimisation problem PS (Wang et al., 2021). Three platforms are employed in this work to reduce the computational complexity. During sample generation process, Matlab is used to generate the sample points and import the sample points to Aspen Plus. The output variables are collected from Aspen Plus simulation results. For each sample generation, the new SSMR-MS process in Aspen Plus would call Visual Basic Application (VBA) in Excel (Fontalvo, 2014) to transfer data from the ANN surrogate model constructed for CO_2 removal model. The hybrid solution algorithm is implemented in MatLab R2019a.

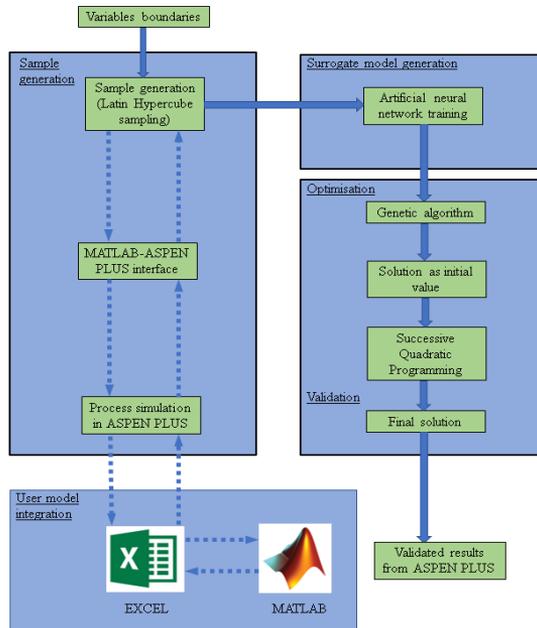

Figure 2: Flowchart of the extended design methodology

5. Computational studies

The results obtained using the extended optimisation framework are shown in Table 1. The required hydrogen production rate is 2, 577 kmol h⁻¹ with 99.9 vol% hydrogen purity. Other data can be referred to Wang et al. (2021). It can be observed that the optimal TAC is 166.52 M\$ y⁻¹. The optimal steam to methane ratio is 2.7.

Table 1: Optimization results from the surrogate models

Item	Optimal value
$Y_{S/C}$	2.7
T_R (°C)	963.0
T_{HWGS} (°C)	379.1
T_{LWGS} (°C)	199.1
L_{PR} (m)	11.1
L_R (m)	11.9
L_{HWGS} (m)	4.6
L_{LWGS} (m)	4.5
N_{PR}	4,021
N_R	50
N_{HWGS}	2159
N_{LWGS}	2036
F_{NG} (kmol h ⁻¹)	786.6
Q_{MS} (MW)	14.61
F_{H_2} (kmol h ⁻¹)	2,577
TAC (M\$ y ⁻¹)	166.52

The optimal results of the independent variables from surrogate models are used as inputs in Aspen Plus V8.8 to calculate all dependent variables for validation. The validated results for Q_{MS} , F_{H_2} and TAC are 14.37 MW, 2577.6 kmol h⁻¹, 165.46 M\$ y⁻¹ respectively. After comparison, it shows that the largest difference between validation results and predicted results from surrogate models is within 1 %. That means the ANN surrogate model has high accuracy for prediction.

Heat integration is conducted for heat recovery in hydrogen production process. The final results are provided in Table 2. After heat integration, a 6.7 % reduction on TAC (155.33 M\$ y⁻¹) is obtained. With integration of poly production, TAC is further significantly reduced to 41.86 M\$ y⁻¹ because of the high profit of poly production.

As shown in Table 2, a comparison is also made between optimal results in this work and the best results from Wang et al. (2021) and the conventional steam methane reforming (SMR). Without poly production, TAC in this work is 33.03 M\$ y⁻¹ higher than that from Wang et al. (2021). The reason is that with the integration of rate-based CO₂ removal model, the cost related to the CO₂ capture unit is increasing. However, with poly production, the TAC decreases 65.77 % which is significantly lower than that in Wang et

al. (2021). As a consequence, LCHP reduces 47.50 % along with the reduction on TAC. CO₂ emission drops from 423.90 kt y⁻¹ to 131.53 kt y⁻¹ and the captured CO₂ can produce 485.73 kt polypropylene carbonate annually.

What is the most striking is that the LCHP in this work is 37.00 % lower than the conventional SMR and CO₂ emissions decreases from 502.90 kt y⁻¹ to 131.53 kt y⁻¹. Through integrating solar energy and CO₂ utilisation into the hydrogen production process, it indicates that the hydrogen can be used in a renewable, sustainable and economical manner.

Table 2: Comparative optimization results

Item	Optimal Case	Wang et al. (2021)	Conventional SMR
Q_{MS} (MW)	14.37	10.20	20.00
F_{H_2} (kmol h ⁻¹)	2,577.6	2577.30	2,577.0
TAC without poly production (M\$ y ⁻¹)	155.33	122.30	90.90
TAC with poly production (M\$ y ⁻¹)	41.86	-	-
LCHP (\$ kg ⁻¹)	1.26	2.40	2.00
CO ₂ emission (kt y ⁻¹)	131.53	423.90	502.90
Polypropylene carbonate (kt y ⁻¹)	485.73	0.00	0.00

6. Conclusion

In this paper, the optimisation-based framework using machine learning techniques is extended for optimal design of SSMR-MS integrated with CO₂ capture and utilization for large-scale hydrogen production. The computational results demonstrate a significant reduction in TAC by around 65.77 % can be achieved compared with the existing SSMR-MS (Wang et al., 2021). Captured CO₂ can produce around 485.73 kt yr⁻¹ polypropylene carbonate. The LCHP is 37.00% lower than the conventional SMR. In the future, more process options for different pre-reformer operating conditions are expected to evaluate.

Abstract

Chemical recycling allows upcycling of polymers into their monomers and/or other valuable chemicals and contributes to a resource-efficient future. This demands selective depolymerization of a particular fraction from a mixed waste stream and thereby, necessitates the use of appropriate solvents. The solvent not only governs the effective depolymerization of the polymer but also influences the sustainability of the process. Conventionally, the tendency of the solvent to dissolve the polymer is considered as the only selection criterion. However, careful consideration should also be given to its interaction with other process reagents and its sustainability. This research proposes a systematic approach to identify potential solvents suitable for a particular recycling strategy. The hierarchical approach begins with identifying potential solvents using computer-aided molecular design based on the Hansen Solubility Parameters (HSPs) of the target polymer. Further, their interactions with other process reagents are also considered. Subsequently, they are screened for their sustainability through a comprehensive life-cycle assessment and some short-listed systems are further evaluated using process simulation. The application of this methodology for developing a recycling strategy for PLA is illustrated.

Keywords: chemical recycling, solvent selection, sustainability

1. Introduction

Fossil-based plastics have gained immense importance because of their durable performance and versatile properties. However, based on their production and subsequent waste management, it is estimated that 12000 Mt of plastic waste will be disposed in landfills and/or oceans by 2050 (Meys et al., 2020). About 50% of this waste originates from the packaging sector (Meys et al., 2020). According to the EU Directive 2019/852 on Packaging and Packaging Waste, the targeted recycling rate is ca. 55% by 2030. While both mechanical and chemical recycling contributes towards a circular economy, the latter represents an infinite strategy as it can effectively depolymerize different grades of polymers from varied value chains. Possible routes for chemical recycling include gasification, pyrolysis and solvolysis. Gasification involves combustion of plastic waste in the presence of oxygen to produce syngas. During pyrolysis, plastic waste is combusted

in the absence of oxygen to produce basic platform chemicals such as benzene, toluene and xylene. These strategies can handle heavily contaminated, mixed waste streams. Solvolysis results in the production of constituent monomers and/or other valuable chemicals. It is suitable for different addition and condensation polymers such as polycarbonate (PC), polyethylene terephthalate (PET), poly-lactic acid (PLA), etc. and has a potential to further reduce the greenhouse gas (GHG) emissions in comparison to other waste-management strategies (Meys et al., 2020).

Though circularity is commonly implemented in process engineering through recovery of excess reagents and/or heat integration, the use of process systems engineering in transforming a linear economy into a sustainable circular economy is quite rare (Avraamidou et al., 2020). Further, research directed towards chemical recycling is primarily focused on optimizing its economy and lack a systematic guideline to incorporate sustainability (Glavič et al., 2021). For instance, previous efforts directed towards solvolysis considered the ability of the solvent to dissolve the polymer as the only criterion for solvent selection (Sherwood, 2020). However, careful consideration should also be given to its sustainability and the energy required for its recovery (Vollmer et al., 2020). Different computer-aided molecular design (CAMD) methods based on thermodynamic predictions are proposed for appropriate solvent selection in several applications (Austin et al., 2016). Recent efforts directed towards integrating CAMD in conventional process development incorporate different scales, ranging from molecular design to process optimization (Gertig, et al., 2020). In addition, integration of predictive life-cycle assessment (LCA) tools in a single multi-scale system has also been strongly advocated (Fleitmann et al., 2021; Gertig et al., 2020; Glavič et al., 2021). With a similar objective, the current work proposes a hierarchical approach for solvent selection in efforts directed towards chemical recycling (solvolysis), involving successive refinement through incorporation of multiple criteria.

2. Methodology

The proposed hierarchical approach involves three steps. Firstly, an appropriate CAMD method is used to identify potential solvents, which are further screened for their interaction with other process reagents. The sustainability of promising candidates is assessed by a comprehensive LCA in accordance to the principles of green chemistry. Further, the performance of some potential candidates is evaluated by process simulation.

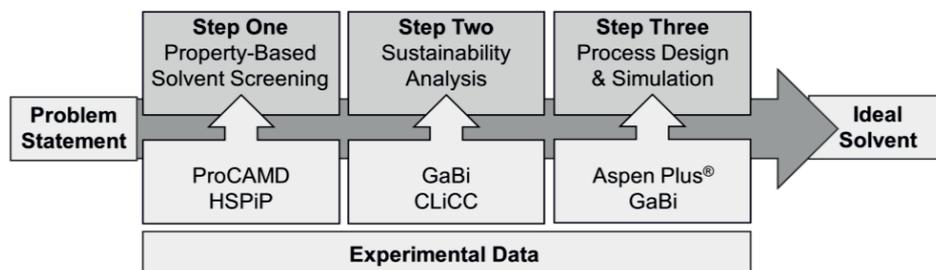

Figure 1: Proposed Hierarchical Approach for Solvent Selection in Circular Economy

2.1. Solvent Screening based on Hansen Solubility Parameters (Step One)

CAMD is an analytical tool aimed at guiding solvent selection for target applications such as liquid-liquid extraction and/or refrigerant and polymer design (Austin et al., 2016). In this approach, the preliminary solvent screening was performed in ProCAMD v1.41 from

PSE for SPEED¹ with the help of a well-established method ("generate-and-test") based on group-contribution methods (Harper & Gani, 2000). During this screening, different alcohols, aldehydes, amines, esters, ethers, ketones and molecules containing chlorine with a boiling point higher than and a melting point lower than 303 K were identified. The generated molecules have a minimum number of two and a maximum number of six groups with two functional groups. Subsequently, these candidates were further evaluated based on their HSPs (δ_D^S , δ_P^S , δ_H^S) relative to that of the polymer ($\delta_D^{PLA} = 18.9$, $\delta_P^{PLA} = 7.6$, $\delta_H^{PLA} = 4.6$) at 298 K (Esmacili et al., 2019). These predictions were further validated with the experimental data obtained from HSPiP v5.3.07. The most promising solvents were evaluated on the basis of the distance between the polymer and the solvent (D_{s-PLA}) relative to the interaction radius of PLA ($R_{o,PLA} = 9.74$) (Agrawal et al., 2004).

$$D_{s-PLA} = \sqrt{4 \times (\delta_D^{PLA} - \delta_D^S)^2 + (\delta_P^{PLA} - \delta_P^S)^2 + (\delta_H^{PLA} - \delta_H^S)^2} \dots\dots (1)$$

Analysis of the interaction of these solvents with other process reagents is a subsequent pre-requisite for further process development. Thus, potential candidates screened on the basis of their relative energy difference ($RED = D_{s-PLA}/R_{o,PLA}$) were analyzed for the possibility of an azeotrope. This was based on vapor-liquid equilibrium predictions performed in ProCAMD v1.41 using the UNIFAC approach and was validated with the help of available experimental data.

2.2 Life-Cycle Assessment of Short-Listed Solvents (Step Two)

LCA is the most common method to assess environmental impacts of products and processes (Monsiváis-Alonso et al., 2020a). Prior to process analysis, the sustainability of the short-listed candidates was evaluated by a comprehensive LCA, in accordance to the ISO 14040 and ISO 14044 standards. Datasets for life-cycle inventory were obtained from commercial databases (ecoinvent v3.7) for some solvents while others were analyzed through predictive life-cycle impact assessment (LCIA) using the Chemical Life Cycle Collaborative (CLiCC) tool. This tool employs artificial neural networks to predict the impact of different organic molecules based on their chemical structure (Song et al., 2017). Environmental impact of these solvents was primarily considered in four categories, namely, acidification potential, climate change, cumulative energy demand (resource use) and human toxicity (human health).

2.3 Evaluation of Process Performance and Sustainability (Step Three)

Based on the afore-mentioned screening, one or more solvents with preferential properties were selected for further experimental investigation. In order to estimate the energy required for solvent recovery, an appropriate down-streaming concept was analyzed through process simulation in Aspen Plus[®]. In addition to this, the sustainability of the down-streaming strategy was also assessed by a preliminary LCA (primarily considering energy-related emissions).

3. Case Study – Chemical Recycling of PLA

Amongst other bio-plastics, PLA is the most promising polyester and is often regarded as a sustainable alternative to petro-chemical plastics (Majgaonkar et al., 2021). However, its production from first-generation biogenic feedstock requires repurposing of land and thus, presents a direct competition to the rising food demand (Atiweh et al., 2021). Further, converting natural landscapes to cultivate feedstock for bio-plastics can lead to higher net GHG emissions than the current GHG savings achieved by replacing fossil-based plastics (Piemonte & Gironi, 2011). Therefore, bio-plastics will only be sustainable

¹ <https://www.pseforspeed.com/> (accessed on 06.02.2022; 13:00)

if non-food crops or waste residues are used for their production and if they are duly recycled at their end-of-life. In the past decade, several efforts have been directed towards chemical recycling of PLA (McKeown & Jones, 2020). As opposed to other attempts, alcoholysis of PLA to produce lactate esters in the presence of primary alcohols such as ethanol or methanol represents an economically and environmentally sustainable recycling strategy (Majgaonkar et al., 2021). However, the insolubility of PLA in alcohols necessitates an appropriate solvent, which was assessed with the help of the proposed hierarchical approach. In an initial screening, about 4200 different primary molecules (excluding isomers) were identified. From these candidates, a compact yet comprehensive list of solvents capable of dissolving PLA was obtained (listed in the Table 1). In addition to conventional solvents, acetyl acetone and ethyl lactate are two new potential candidates identified by the CAMD approach. These candidates were further evaluated to identify the possibility of forming azeotropes with ethanol and methanol. It was observed that, MEK, DCM and chloroform form an azeotrope with both ethanol as well as methanol.

Table 1: Results of the Solvent Screening by ProCAMD v1.41 and HSPiP v5.3.07

Source	Solvent	Solubility Parameters			D_{S-PLA}	D_{S-PLA}/R_o
		δ_D^S	δ_P^S	δ_H^S		
CAMD Screening	acetyl acetone	17	11	6.8	5.52	0.586
	methyl ethyl ketone (MEK)	15.6	7.8	5.5	6.54	0.671
	acetone	15.7	9.1	6.5	6.79	0.697
	ethyl lactate	16.7	7.7	13.1	9.49	0.974
HSPiP Database	cyclohexanone	17.8	8.4	5.1	2.39	0.246
	butyl benzoate	20	5.1	5.2	3.38	0.347
	N-methyl pyrrolidone (NMP)	18	12.3	7.2	5.66	0.580
	tetrahydrofuran (THF)	16.8	5.7	8	5.87	0.603
	N,N-dimethylformamide (DMF)	17.4	13.7	11.3	9.54	0.980
Literature	dichloromethane (DCM)	18.2	6.3	6.1	2.67	0.275
	chloroform	17.8	3.1	5.5	5.09	0.522

Comprehensive LCA of potential solvents, summarized in Table 2 and Table 3, serve as an indicator to assess their sustainability. It can be observed that, acetone, acetyl acetone and ethyl lactate have the most attractive environmental performance. However, acetone outperforms acetyl acetone and ethyl lactate in all impact categories. Further, it has been experimentally demonstrated that, acetone is a better solvent as compared to ethyl lactate with regards to the dissolution of PLA (Gironi et al., 2016). Thus, acetone was chosen as the preferred solvent for further experimental investigation and subsequent process evaluation.

Majgaonkar et al. demonstrated the use of acetone in solvent-assisted depolymerization of PLA for the production of ethyl lactate. The ternary mixture thus obtained contains acetone, ethanol and ethyl lactate, which can be easily separated in a series of two distillation columns. The system was represented by the NRTL equation and the resulting

process sequence was simulated in Aspen Plus[®]. The energy required for this separation amounts to 4.89 MJ/kg_{product}.

Table 2: Heat Map of the Results of LCA from GaBi using EF 3.0

Impact Category	Unit	Solvents				
		acetone	cyclohexanone	DMF	NMP	THF
Acidification	[mole H ⁺ eq./kg]	0.0026	0.0047	0.003	0.006	0.046
Resource Use	[MJ/kg]	55.4	88.1	37.5	93.3	115
Climate Change	[kg-CO ₂ -eq./kg]	1.58	3.65	1.98	4.52	6.86

Table 3: Heat Map of the Results of LCA from the CLiCC tool using predictive LCIA (CED = Cumulative Energy Demand; GWP = Global Warming Potential)

Impact Category	Unit	Solvents		
		acetyl acetone	butyl benzoate	ethyl lactate
Acidification	[mole H ⁺ eq./kg]	1.24	1.23	0.0515
CED	[MJ/kg]	143	121	83.3
GWP	[kg-CO ₂ -eq./kg]	5.32	8.27	3.61

As opposed to the afore-mentioned process, Zeus Industrial Products Inc. developed a chemical recycling strategy for PLA employing chloroform as a solvent and methanol as the depolymerizing agent. The resulting ternary system required a series of three distillation columns, including a pressure-swing distillation sequence, which escalated the energy demand by ca. 20% (5.9 MJ/kg_{product}). The sustainability of these distinct approaches for chemical recycling of PLA was further analyzed in a comparative LCA, wherein the former process outperformed the latter in almost all impact categories (Aryan et al., 2021).

4. Conclusion and Outlook

This study proposes a hierarchical approach for solvent selection to compliment efforts directed towards a circular economy. About 4200 potential solvents were screened based on their ability to dissolve PLA to identify the most promising candidates. Further, integration of LCA and subsequent process simulation allows for the development of a competitive yet sustainable concept with minimal experimental efforts, as illustrated with regards to chemical recycling of PLA. The approach is efficient and flexible and can be extended to other polymers with further introduction of additional constraints.

Abstract

The consequences of investment decisions regarding a chemical plant's distribution and utilities system can be crucial for the operability, and thus the success of a chemical plant. This work presents a novel framework for investment decision making regarding the distribution and utilities systems of a chemical plant, based on multi-stage infrastructure planning and production scheduling, incorporating all relevant process and material timescales. The literature has classically investigated industrial distribution systems only for a single material or energy system and utilities systems only in terms of heat or work exchange networks and their respective integration. However, the evaluation of several relevant material streams holistically within the distribution system of one chemical plant together with several interconnected utilities, and the incorporation of different timescales has not yet been presented in a decision making framework. To do so, a mixed-integer linear programming (MILP) problem is formulated to investigate decision making regarding future investment decisions based on multi-stage infrastructure and maintenance planning for chemical plants. The applicability and capabilities of the developed framework are demonstrated through an application to the distribution and utilities system of a chemical plant in South-East Texas.

Keywords: infrastructure planning, production scheduling, multi-scale modeling.

1. Introduction

Investigating the feasibility and economic implications of a chemical plant's distribution and utilities system is of utmost importance for generating revenue, improving energy use and plant resilience, reducing material losses, and consequently staying competitive within a global economy. Especially, the consequences of investment decisions regarding these systems can be crucial for

the operability and thus the success of a chemical plant.

The optimization of distribution and utilities systems of chemical plants have been examined in the literature for over 30 years (Sahinidis et al. (1989), Papoulias and Grossmann (1983)). However, distribution systems have traditionally only been investigated for a single distribution process material or energy system (Pena et al. (2019)). Regarding the utilities system, it can be observed that optimization has mostly been done in terms of heat or work exchange networks and their respective integration (Pavão et al. (2020)). Recently, integrated planning and scheduling solution strategies have been applied to chemical process systems (Beykal et al. (2022)). Further, the optimization of process integration within a plant and potentially for industrial symbiosis based on different scales has been investigated by Kantor et al. (2020). In addition, multi-stage infrastructure planning and production scheduling, incorporating all relevant process and material timescales, can be utilized to analyze the implications of possible process modifications and future industrial investment decisions (Bi et al. (2020)).

Thus, this work introduces a generic decision making framework which can be applied to a chemical plant's utilities and distribution system. One of the main novelties of the proposed approach is the generic nature of the tool, enabling fast and efficient analyses of competing process and investment alternatives for chemical production facilities. Further, it allows the investigation of various process objectives depending on the facility's goals, i.e. minimizing investment costs or maximizing produced energy. Therefore, various plant operational setpoints can be simulated and automatically visualized.

In Section 2, a general overview of the developed framework and possible applications are given, while in Section 3 the mathematical model is described in detail. In Section 4, the framework is applied to a representative steam utilities system case study to illustrate the capabilities. Lastly, the conclusion and a brief future outlook is stated.

2. Framework Overview

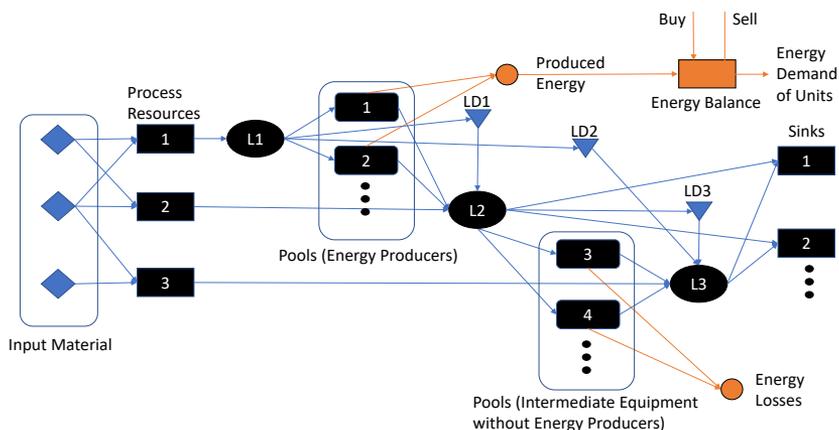

Figure 1: Superstructure of a representative utilities process.

To illustrate to what kind of processes the framework can be applied, a representative utilities superstructure is shown in Figure 1. In this case, input materials (blue diamonds) are used to generate process resources of different quality (black rectangles). These resources are of different quality levels (L1 to L3) and can consequently be used for various purposes. Higher quality resources can be letdown (LD - blue triangles) for lower quality usage if needed or used in intermediate

equipment, e.g. for energy generation purposes (rectangles with rounded corners). All generated resources are used to satisfy material demands at process sinks (black rectangles). Comparing the overall produced energy with the energy demand of all units results in an overall energy balance which shows whether there is excess energy to be sold or additional energy to be bought. If the process involves equipment which requires energy in the form of a material flow, i.e. turbine driven pumps, the energy used to power this type of equipment is summarized as an energy loss, since this material flow cannot be used for energy production. In case of distribution systems, the given superstructure can be further simplified since material transformation or energy production does not occur throughout these systems. In this case, our main goal is to fulfill the material sink demands, while considering an applicable storage system and scheduling of the incoming material from various suppliers through different means of transportation, e.g. by pipeline or truck. Thus, for distribution systems it is essential to consider a time dependency of variables during the mathematical modeling, whereas for utilities steady-state assumptions are applicable. The developed framework can handle time dependent systems of equations. However, for simplicity and since the developed case study is based on a steam utilities system the time index has been neglected in the mathematical modeling equations. By adding an additional time index to all material and energy flows the given system of equations can be modified to a time dependent system.

To derive a generic decision making framework which is capable of optimizing the distribution and utilities system of an industrial chemical plant, a mathematical model is developed in the Python Pyomo environment. All process specific information, such as the involved units and materials, are defined in an Excel data exchange file, which is loaded into the optimization program. Thus, historic plant data is processed to define relevant process data in terms of identifying the correct equipment classification as well as equipment specific constraints and the relevant material and energy conversions of the respective units. This data is automatically processed and assigned in the optimization model. After solving the model, the feasibility of the solution is checked. Further analyses in terms of relevant material and energy streams and their respective implications for the obtained solution can also be conducted. It is important to note that the tool is capable of automatically visualizing the generated solution in a superstructure summarizing all material and energy streams.

3. Mathematical Modeling

The basis of the decision making tool are mass and energy balances based on a set notation, which results in a more compact system of equations. To this end, various sets for all available units and material flows are introduced as follows. All available units of a process (set called *Units*) are separated into material producers or suppliers (*P*), intermediate equipment (*EQ*) and material sinks (*S*). Additionally, all energy producing units are summarized in a set called energy producers (*EP*), whereas units with an energy demand are classified in the set called energy sinks (*ES*). For further analysis of solutions and trade-offs additional sets are introduced which consist of all material producing and intermediate equipment (EQ_2), as well as one consisting of EQ_2 excluding all energy producing equipment (EQ^*). Material flows are generally classified as the set of resources (*Res*), which can be divided into the subsets key resources (*Key*) and other resources (*NK*). In this case, key resources describe the focus of the process, e.g. for steam at various steam pressure levels, whereas other resources summarize all non steam resources like natural gas, air or boiler feed water and include the subset of inputs (*In*), $In \subseteq NK$.

Apart from the set notation, energy and material conversion factors are introduced. These conversion factors can be deduced from actual plant data or from ASPEN simulations. These conversion factors are equipment and material specific and summarized in the previously mentioned Excel file, which therefore enables fast and easy modifications, if necessary. The definition of the material and energy conversion factors are given in Eq. 1 and 2.

Conversion Factors

$$f_{EQ,i,j} = \frac{\text{Output flow } j \text{ of } EQ}{\text{Input flow } i \text{ of } EQ} \forall EQ, i \in Res, j \in Res, i \neq j \quad (1)$$

$$ef_{EQ,i} = \frac{\text{Energy produced or consumed in } EQ}{\text{Input flow } i \text{ of } EQ} \forall EQ, i \in Res \quad (2)$$

The material conversion factors are derived for all equipment and respective input and output flows. The energy conversion factors are calculated for all equipment and respective input flows. The key idea of the generic tool is to introduce artificial resource pools to which generated material throughout the process can be booked and from which consumed material throughout the process can be taken. Therefore, book-keeping variables for all resources are introduced as x_{Res} . Generally, in the case of key resources this variable has to be zero for generated solutions. For other resources the amount produced or needed can be deducted from the variable value. Further, material flows from equipment to the resource pools can be introduced as $x_{EQ,Res}$ and flows from resource pools to equipment as $x_{Res,EQ}$ in $\frac{klb}{h}$. Based on these definitions the following mass balance equations can be introduced (Eq. (3) overall balances of *Key*, Eq. (4) fulfill all demands at *S*, Eq. (5) supply of *Key*, Eq. (6) conversion of *Key* in *EQ*, Eq. (7) overall balances of *NK*):

Mass Balancing

$$\sum_P x_{P,Key} + \sum_{EQ} x_{EQ,Key} = x_{Key} + \sum_S x_{Key,S} + \sum_{EQ} x_{Key,EQ} \forall Key \quad (3)$$

$$x_{Key,S} = x_s^{Demand,Key} \forall S, Key \quad (4)$$

$$x_{P,Key} = f_{P,In,Key} \cdot x_{In,P} \forall P, In, Key \quad (5)$$

$$f_{EQ,i,j} \cdot x_{i,EQ} = x_{EQ,j} \forall EQ, i, j \in Res, i \neq j \quad (6)$$

$$x_{NK} = \sum_{EQ_2} x_{EQ_2,NK} - x_{NK,EQ_2} \forall NK \quad (7)$$

For the energy balance, additional variables are introduced. The energy produced or consumed in a unit is given by n_{Units} . Further, n_{Sell} and $n_{Purchase}$ can be introduced as variables for selling a surplus of energy generated in the plant or buying energy in the case of an energy deficiency throughout the system. Thus, the energy balances can be summarized as follows (Eq. (8) overall energy balance, Eq. (9) overall energy demand, Eq. (10) energy needed for production of *K*, Eq. (11) energy produced):

Energy Balancing

$$\sum_{EP} n_{EP} - n_{ES} + n_{Purchase} - n_{Sell} = 0 \quad (8)$$

$$n_{ES} = \sum_P n_P + \sum_{EQ} n_{EQ}^{Demand} \quad (9)$$

$$n_P = ef_{P,In} \cdot x_{In,P} \forall P \quad (10)$$

$$n_{EP} = ef_{EP,Key} \cdot x_{Key,EP} \forall EP \quad (11)$$

$$n_{EQ^* \setminus P} = ef_{EQ^* \setminus P,Key} \cdot x_{Key,EQ^* \setminus P} \forall EQ^* \setminus P \quad (12)$$

Further, Eq. (12) derives the energy needs for all units summarized in EQ^* without key resource producing units. This special set includes units which require energy in the form of material flows, e.g. turbine driven pumps. Therefore, $\sum_{EQ^* \setminus P} n_{EQ^* \setminus P}$ specifies energy lost for energy generation due to equipment specific choices and can be understood as an opportunity to increase energy efficiency throughout the system by trying to reduce this value.

Originally, binary decision variables have been introduced for equipment and flow decision making. However, since competing equipment or investment decisions are taking resources from the same artificial resource pool, and flows from a resource pool to an equipment can be zero, the introduced binaries were discovered to be redundant. Apart from that, neglecting binary decision variables resulted in better computational performance, while no process information was lost.

4. Case Study

To highlight the capabilities of the developed tool, we apply our framework to the steam utility system of a chemical production plant in South-East Texas. The production plant generates four different steam pressure levels ($P_1 > P_2 > P_3 > P_4$, summarized in *Key*) as byproducts from various processes, such as boiler and reactor systems (*P*). Further, the steam is used to satisfy demands of various material (*S*) and energy sinks (*ES*) using two different sized turbines using different pressure levels of steam as input (*EP*), as well as a set of intermediate turbine driven pumps for various applications in other plant processes ($EQ^* \setminus P$). When necessary, steam from higher pressure levels can be let down to lower pressure levels. Additionally, the steam process requires feed water, air and natural gas (set of *NK*). A representative process operation point is summarized in the top part of Figure 2.

The goal of the case study is to minimize the overall cost by investigating a process alternative denoted by neglecting one steam producer, the turbine operating at a higher pressure level, as well as modifying all turbine driven pumps to motor driven pumps. The energy and material demands are assumed to be constant. For this particular case study, the objective function is introduced based on the investment and maintenance costs of the selected equipment. Linear correlations for the total installed cost (TOC) of equipment dependent on the flow rate have been derived with ASPEN Capital Cost Estimator (AspenTech, 2012). Further, the annual maintenance cost of a unit are estimated based on its TOC. The process visualization for the modified case is given in the bottom part of Figure 2. The selected modification reduced the overall cost by approximately \$7.9 MM. Subsequently, by only investigating this scenario, steps towards a process cost reduction of approximately 70% can be deducted.

Overall, the tool can not only be used to match streams for heat or work exchange, comparable to more conventional methods such as PINCH analysis, but also to evaluate present and future operational set-points as well as influences of investment decisions and process alternatives underlining the multi-stage nature and capabilities. This further enables the transition planning and scheduling for an operational process transition from the current setup to a desired future one. However, one potential drawback to conventional methods is a less rigorous implementation of thermodynamic restrictions.

5. Conclusion

We have presented a comprehensive generic framework with the capabilities of optimizing the distribution and utilities systems of an industrial chemical production plant. Our proposed approach is based on developing a mathematical superstructure model which encompasses the incoming and outgoing material and energy flows, as well as their respective conversions for each unit of the plant. By defining different investment alternatives for the facility based on the demand and costs, we are able to identify and recommend optimal investment opportunities to reduce the overall cost. The effectiveness of our framework was demonstrated through its application to the steam utility system of an industrial chemical plant. The results indicate a significant reduction in overall cost, as well as the plant's energy needs. Our next steps include the possible interconnection of various utility processes, e.g. steam, water and electricity networks and take into account network

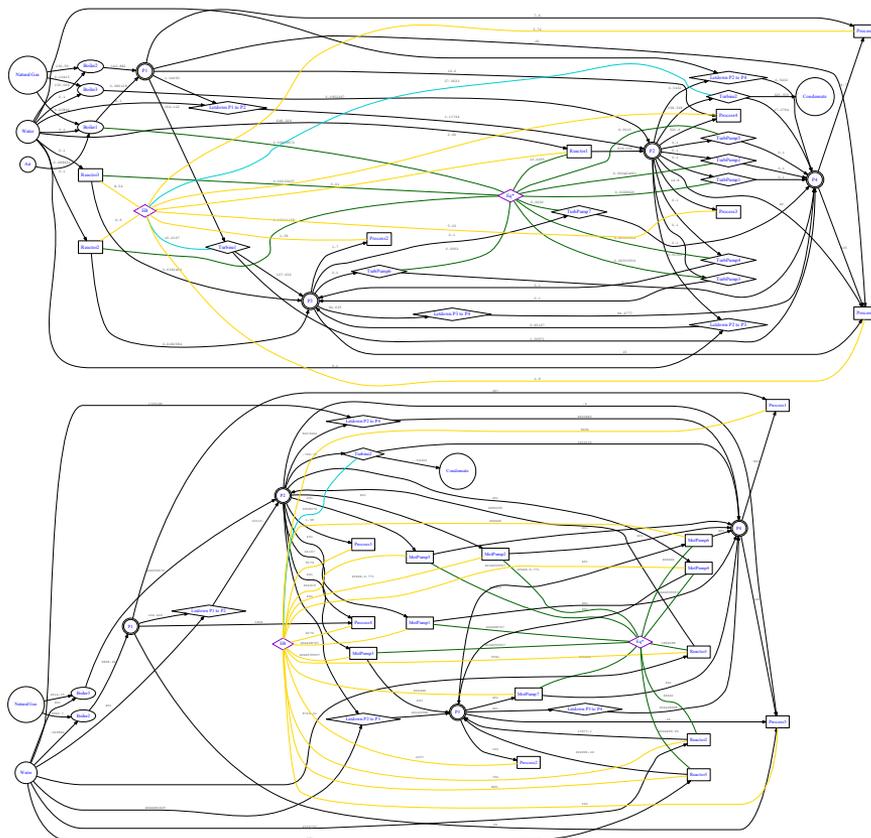

Figure 2: Automatic visualization of process simulation. Top: Standard case; Bottom: Modified case.

disruption scenarios for optimizing plant resilience and respective cost and energy trade-offs.

Abstract

This paper aims to develop an optimization model for the expansion planning of reliable power generation systems. To achieve this goal, we propose an optimization model that minimizes the total cost using Generalized Disjunctive Programming (GDP). Specifically, the model determines both investment decisions (number, size, location, and time of generators to install, retire, and decommission) and operation decisions (number of operating/backup generators, operating capacity, and expected power output) by imposing penalties when the demand is not satisfied, and a system has low reliability. The model is verified through an illustrative example of two regions with four power stations over five operating periods.

Keywords: Reliability, Expansion Planning, Power systems, Optimization

1. Introduction

Expansion planning for power generation systems aims to determine the optimal number, size, location, and time to install and/or retire the power generators, while minimizing the total cost over a given time horizon (Conejo et al., 2016). Expansion planning works have been reported in the literature. For instance, Lara et al. (2018) develop a multi-region and multi-period MILP optimization model by considering short-term operation problems (e.g., unit commitment) and investment decisions. Given the large size of the model, it is solved with a Nested Benders decomposition method. Li et al. (2022) extend the expansion model developed by Lara et al. (2018) by integrating generation and transmission. Although studies on integrating the reliability and expansion planning have been reported (Moreira et al., 2017), there is still modest research that comprehensively accounts for the impact of reliability in expansion planning.

Reliability is the probability that a system or component can perform its required function without failure for a given time (Sherwin & Bossche, 1993). Securing high reliability, or more precisely high availability, in the design and operation of power systems is essential since power generation systems aim to provide uninterrupted electric power to customers. One method to improve reliability at the design phase is to add redundant or backup units, which allows the systems to operate even if one or multiple generators fail (Kim & Kim, 2017). This approach is known as ‘reliability-based design optimization,’ and various studies on this topic have been reported (Ye et al., 2018; Ortiz-Espinoza et al., 2021; Chen et al., 2022). However, since power systems operate dynamically due to time-varying power demand, reliability is also influenced by the operational strategies that power systems use to satisfy the load demand. Specifically, backup units have a dual role in power generation systems. They can remain as backup units in case of low power demand or change to operating units when the power demand is high. This dual purpose of backup

units depending on the load demand must be considered in designing reliable power generation systems.

One of the conventional methods used to evaluate the reliability of power systems is “ $N-1$ reliability”. The $N-1$ reliability assumes that a power system can withstand an unexpected failure of a single component (Ballireddy & Modi, 2019). This implies that power systems may not function properly if multiple units fail simultaneously. The failures of multiple generators may reduce the power output but not necessarily fail the entire system. Hence, a rigorous method anticipating every possible failure state and selecting the proper number and size of the backup generators should be developed to design and plan reliable power generation systems. The specific goal of this work is to develop an optimization model for the expansion planning of reliable power generation systems. The model is formulated using Generalized Disjunctive Programming (GDP) that determines both investment (number, size, location, and time of generators to install, retire, and decommission) and operation decisions (number of operating/backup generators, operating capacity, and expected power production level) to minimize the total cost including unmet demand and low reliability penalties.

2. Problem statement

Given are regions $r \in R$, with power stations $k \in K_r$, parallel generators $j \in J_k$, and discretized capacities of generator $p \in P_k$. There are two types of power stations: existing ($k \in K_r^{EX}$) and potential ($k \in K_r^{NW}$) power stations. A set of power station designs $h \in H_k$ and corresponding operation modes $m \in M_{k,h}$, time periods (year) $t \in T$, and sub-periods (season) in each year $n \in N$ are also given. Specifically, $h = 1$ indicates that one generator is available in power stations k and $h = H$ means all generators that can be installed in power stations k are available. Likewise, $m = 1$ represents one generator is operated, $m = M$ refers to the mode in which all generators are operated. Each power station k has different failure states $s \in S_{m,k,h}$ depending on the design h and operation mode m . The failure states can also be classified into successful operation states ($S_{m,k,h}^F$) and partial operation states ($S_{m,k,h}^P$). ‘Successful operation states’ indicate the operation modes in which the power generation capacity is sufficient to satisfy the load demand, whereas ‘Partial operation states’ refer to the operation modes in which the power generation capacity is insufficient to meet the load demand as it can only produce electric power at a limited level. The major assumptions in this model are: (i) Each power station has a maximum number of available power generators, (ii) Storage systems are not included, (iii) Operational problems such as unit commitment are not included.

3. Model formulation

The model is developed by Generalized Disjunctive Programming (GDP) (Trespalcios and Grossmann, 2014), which can be expressed in terms of Boolean and continuous variables, algebraic constraints, disjunctions, and logic propositions. We also introduce binary variables since several investment decisions are reformulated as algebraic constraints.

3.1. Investment constraints

The binary variable $y_{j,p,k,r}^{EX}$ indicates the existence of unit j with discrete capacity p in power station k of region r . The binary variables $y_{j,p,k,r,t}^{IN}$ and $y_{j,p,k,r,t}^{AV}$ state the installation and availability of unit j in year t , respectively. The binary variables are also represented with corresponding Boolean variables ($Y_{j,p,k,r,t}^{IN}, Y_{j,p,k,r,t}^{AV}$). $IC_{j,k,r,t}, AC_{j,k,r,t}, TAC_{k,r,t}$ are

installed capacity, available capacity, and total available capacity, respectively. There are three different investment decisions for generators such as early decommission, retirement due to lifetime expiration, and lifetime extension. However, equations for the three decisions are not provided here due to space limitation. Eqns. (4) – (6) correspond to the capacity constraints, and Eqn. (7) states that only one capacity p can be selected for each generator j .

$$\begin{aligned}
 & \sum_{p \in P_k} y_{j,p,k,r}^{EX} + \sum_{p \in P_k} \sum_{t \in T} y_{j,p,k,r,t}^{IN} \leq 1 \quad \forall j \in J_k, k \in K_r, r \in R & \text{(1) Generator installation} \\
 & \left. \begin{aligned}
 y_{j,p,k,r,t}^{IN} & \Rightarrow \bigwedge_{q \in [t, t+LT_{j,k,r}]} y_{j,p,k,r,q}^{AV} \quad \forall j \in J_k, p \in P_k, k \in K_r^{NW}, r \in R, t, q \in T \\
 y_{j,p,k,r,t}^{AV} & \Rightarrow \bigvee_{q \in [t-LT_{j,k,r,t}]} y_{j,p,k,r,q}^{IN} \quad \forall j \in J_k, p \in P_k, k \in K_r^{NW}, r \in R, t, q \in T
 \end{aligned} \right\} & \begin{aligned}
 & \text{(2) Generator in potential} \\
 & \text{power stations} \\
 & \text{(3) Generator in existing} \\
 & \text{power stations}
 \end{aligned} \\
 & y_{j,p,k,r,t}^{AV} = 1 \quad \forall (j, p, k, r) \in Pre, t = 1 \\
 & IC_{j,k,r,t} = \sum_{p \in P_k} \delta_{k,p} y_{j,p,k,r,t}^{IN} \quad \forall j \in J_k, k \in K_r, r \in R, t \in T \quad \text{(4)} \quad AC_{j,k,r,t} = \sum_{p \in P_k} \delta_{k,p} y_{j,p,k,r,t}^{AV} \quad \forall j \in J_k, k \in K_r, r \in R, t \in T \quad \text{(5)} \\
 & TAC_{k,r,t} = \sum_{j \in J_k} AC_{j,k,r,t} \quad \forall k \in K_r, r \in R, t \in T \quad \text{(6)} \quad \sum_{p \in P_k} y_{j,p,k,r,t}^{AV} \leq 1 \quad \forall j \in J_k, k \in K_r, r \in R, t \in T \quad \text{(7)}
 \end{aligned}$$

3.2. Operation and system reliability constraints

There are two Boolean variables related to investment and operation decisions. $Z_{k,r,h,t}$ is true if design h is selected for power station k of region r in time t (Eqn. (a)). $W_{k,r,m,h,n,t}$ is true if power station k of region r is in operation mode m during sub-period n in time t for design h (Eqn. (b)). The binary variable $x_{j,p,k,r,n,t}$ indicates the operation of unit j with discrete capacity p in power station k of region r during sub-period n of time t . $OC_{j,k,r,n,t}$ represents an operating capacity, $P_{s,k,r,n,t}$ is the probability of station k of region r being in failure state s during sub-period n of time t , and $EP_{s,k,r,n,t}$ corresponds to the expected power output. $P_{k,r,n,t}^F$ and $P_{k,r,n,t}^P$ are the probabilities of station k being in successful and partial operations.

$$\left[\begin{array}{l} \bigvee_{h \in H_k} \\ \bigvee_{m \in M_{k,h}} \end{array} \left[\begin{array}{l} \sum_{j \in J_k} \sum_{p \in P_k} y_{j,p,k,r,t}^{AV} Z_{k,r,h,t} = i \quad i = 0, 1, \dots, h \\ \sum_{j \in J_k} \sum_{p \in P_k} x_{j,p,k,r,n,t} = i \quad i = 1, \dots, m \\ \sum_{p \in P_k} \varphi_j \delta_{k,p} x_{j,p,k,r,n,t} \leq OC_{j,k,r,n,t} \quad \forall j \in J_k \\ OC_{j,k,r,n,t} \leq \sum_{p \in P_k} x_{j,p,k,r,n,t} \delta_{k,p} x_{j,p,k,r,n,t} \quad \forall j \in J_k \\ P_{k,r,n,t}^F = \sum_{s \in S_{m,h,k}^F} \left\{ \prod_{j \in J_{s,m,h}^O} \lambda_{j,k} \prod_{j \in J_{s,m,h}^N} \gamma_{j,k} \right\} \\ P_{k,r,n,t}^P = \sum_{s \in S_{m,h,k}^P} \left\{ \prod_{j \in J_{s,m,h}^O} \lambda_{j,k} \prod_{j \in J_{s,m,h}^N} \gamma_{j,k} \right\} \\ EP_{s,k,r,n,t} = \sum_{j \in J_{s,m,h}^O} \rho_n OC_{j,k,r,n,t} P_{s,k,r,n,t} \quad s = 1, s \in S_{m,k,h} \\ EP_{s,k,r,n,t} = \sum_{j \in J_{s,m,h}^N} \rho_n x_{j,k,r,n,t} AC_{j,k,r,n,t} P_{s,k,r,n,t} \quad s \neq 1, s \in S_{m,k,h} \end{array} \right] \quad \forall n \in N \quad \left. \begin{array}{l} \text{(a) Investment decision} \\ \text{(8) Number of available unit} \\ \text{(b) Operation \& reliability decision} \\ \text{(9) Number of operating unit} \\ \text{(10) Operating capacity of} \\ \text{available unit} \\ \forall k \in K_r^{TH}, r \in R, t \in T \\ \text{(11) Successful and partial} \\ \text{operation reliability} \\ \text{(12) Expected production by} \\ \text{successful and partial} \\ \text{operation} \end{array} \right\}$$

The objective function is to minimize the total cost (Eqn. (13)), which includes the investment costs $(\theta_{j,p} y_{j,p,k,r,t}^{IN})$, the operating costs $(\varphi_{j,p} x_{j,p,k,r,n,t})$, the feedstock costs

($\kappa_k FS_{k,r,n,t}$), the downtime penalty ($\varepsilon DT_{k,r,n,t}$), and the unmet demand penalty ($PN_{n,t}$). The unmet demand penalty is determined with the disjunction shown in Eqn. (14).

$$\min COST = \sum_{j \in J} \sum_{p \in P_k} \sum_{k \in K_r} \sum_{r \in R} \sum_{n \in N} \sum_{t \in T} (\theta_{j,p})_{j,p,k,r,t}^{IN} + \varphi_{j,p} x_{j,p,k,r,n,t} + \kappa_k FS_{k,r,n,t} + \varepsilon DT_{k,r,n,t} + PN_{n,t} \quad (13)$$

$$\left[\begin{array}{l} \sum_{k \in K_r} \sum_{r \in R} TEP_{k,r,n,t} < \sum_{r \in R} \rho_n D_{r,n,t} (1 + R_t^{min}) \\ PN_{n,t} = (\sum_{r \in R} D_{r,n,t} - \sum_{r \in R} TEP_{r,n,t}) \alpha \end{array} \right] \vee \left[\begin{array}{l} \sum_{r \in R} TEP_{r,n,t} \geq \sum_{r \in R} \rho_n D_{r,n,t} (1 + R_t^{min}) \\ PN_{n,t} = 0 \end{array} \right] \quad \forall n \in N, t \in T \quad (14)$$

where ρ_n is a duration (hours) of sub-period n , $D_{r,n,t}$ is a power demand, and R_t^{min} is a reserve margin related to the peak demand of time t . The GDP given by (1)–(14) can be reformulated into a Mixed-Integer Nonlinear Programming (MINLP) using Big-M (BM) and/or Hull Reformulation (HR) (Trespalcios & Grossmann, 2014). In this paper we use the Big-M method. Also, the MINLP model is reformulated as MILP model by using exact linearization of Eqn. (12) (Garcia-Herreros et al., 2015).

4. Illustrative example

To illustrate the application of the proposed model, we consider a simple case consisting of two regions, each with two power stations (i.e., coal power plants (1 existing, 1 potential), and natural gas power plants (1 existing, 1 potential)) as shown in Figure 1(a). Each power station is assumed to have a maximum of three parallel generators, and there are three capacities for the generators. Note that renewable power generators are not considered in this example. Figure 1(b) displays power demands during five time periods, each with four sub-periods. Table 1 shows the technical and economic parameters.

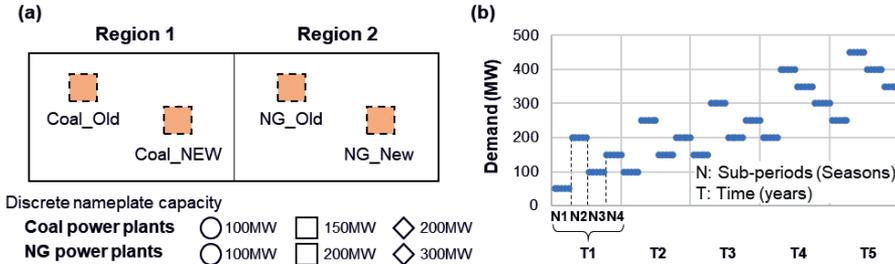

Figure 1. (a) Geographical representation of illustrative example, (b) Power demand

Table 1. Parameters of the illustrative example

Parameters	Symbols	Values	Parameters	Symbols	Values
Nameplate capacity (MW)			Installation cost (k\$/unit)		
Coal plants	$\delta_{k,p}$	100, 150, 200	Coal plants	$\theta_{j,p}$	50, 64, 76
Natural gas plants		100, 200, 300	Natural gas plants		60, 91, 116
Unit reliability			Start-up cost (\$/unit)		
Coal plants	$\lambda_{j,k}$	0.93	Coal plants	$\varphi_{j,p}$	50, 80, 100
Natural gas plants		0.95	Natural gas plants		60, 100, 150

Additionally, the deterministic expansion planning without reliability is obtained, and its expected cost is calculated under the risk of generator failures. Table 2 shows the numerical results of the cases, and the results are obtained with CPLEX in GAMS 32.1.0 on an Intel Core i7-10510U CPU, 1.80GHz. It should be noted that the disjunctive constraints proposed in this paper make the model require longer computational times (almost 2000 sec) than the deterministic model without disjunctions (less 1 sec).

Table 2. Numerical results of the example

	# Binary variables	# Cont. variables	# Constraints	CPU (sec)
Deterministic case (No reliability)	1,363	15,762	62,888	0.203
Reliability-constrained case	1,646	15,773	63,659	1.983

A detailed comparison of the deterministic and reliability-constrained cases can be found in Figure 2. As shown in Figure 2(a), when reliability is not considered, the model newly installs one large coal generator (200MW) in region 1 and one large natural gas generator (300MW) in region 2. On the other hand, the proposed model decides to install three large natural gas generators in region 2 (See Figure 2(c)). Note that both cases are assumed to have two existing coal generators and one natural gas generator. Figures 2(b) and 2(d) show the operation results of the deterministic and the reliability-constrained cases during the last period (T5), respectively. The deterministic case has one backup generator in region 1 during spring (N1) and winter (N4), but all generators participate in power generation during summer (N2) and fall (N3) due to relatively high power demand. On the other hand, the reliability-constrained case has two backup generators (one in region 1 and one in region 2) during all periods. This result is because the system availability can be improved by having more backup generators.

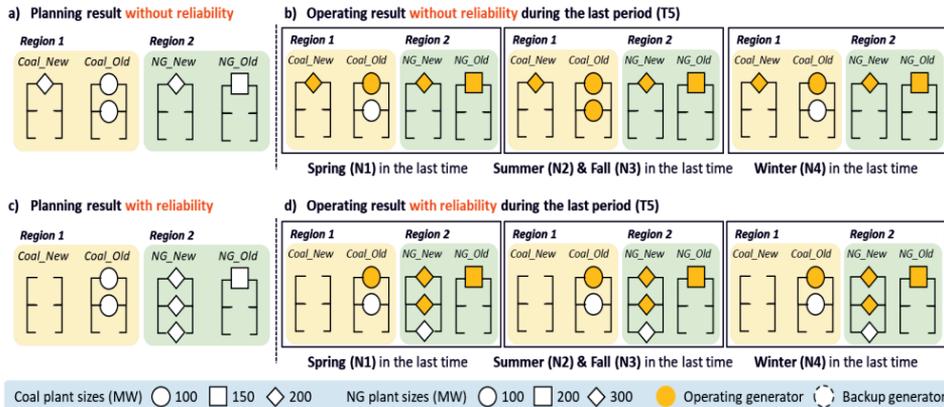

Figure 2. (a) and (b): investment and operation results of deterministic case; (c) and (d): investment and operation results of reliability-constrained cases during period 5 (T5)

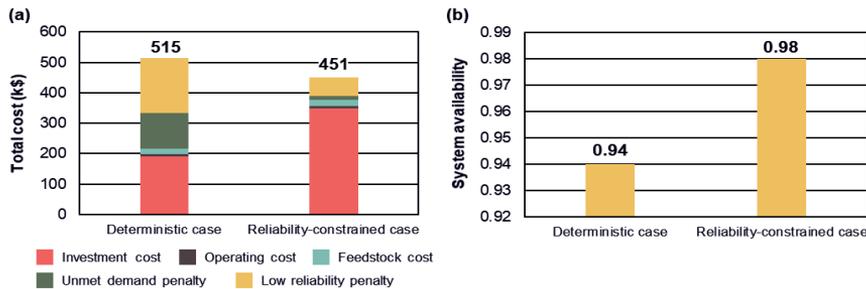

Figure 3. (a) Total cost and (b) System availability of the cases

Figure 3(a) shows the cost contribution of the two cases. Due to backup generators, the reliability-constrained case requires a higher investment cost (\$192,000 vs. \$348,000). The investment cost is compensated by lower penalties (unmet demand penalty: \$115,000 vs. 12,703; low reliability penalty: \$182,774 vs. \$61,807). The deterministic case has a poor performance in the case of generator failure due to a lack of flexibility. On the other hand, the reliability-constrained case has enough slack capacity to reallocate power

demands when the generator failure occurs. Such flexible design of the reliability-constrained case enables the system to have higher availability than the deterministic cases (0.94 vs. 0.98), as shown in Figure 3(b). This example proves that the proposed model is more effective for designing reliable power systems than expansion models in which generator failures are not considered.

5. Conclusions

This paper has presented an optimization model for the expansion planning of reliable power generation systems. The proposed GDP model optimizes investment decisions (number, size, location, and time of generators to install, retire, and decommission) and operation decisions (number of operating/backup generators, operating capacity, and expected power production level). It was identified that the proposed model effectively designed a reliable power generation system. Future work will develop decomposition methods for large-scale problems and involve other operation problems such as economic dispatch and unit commitment to evaluate the reliability more precisely. Moreover, renewable technologies such as wind turbines and solar panels will be included, and Markov chain theory will be applied to enumerate all possible failure states explicitly.

Abstract

The decision-making process for the design of formulated products faces different challenges because of its intrinsic complexity. On the one hand, it is not sequential, but iterative due to the fragmented and heterogeneous nature of available information. On the other hand, there is not a unique design workflow because it changes from company to company according to its context and specific requirements. The lack of structure of knowledge for product formulation requires developing a robust knowledge representation to show coherently and explicitly concepts, models, and data. Furthermore, this representation must allow design teams to use it flexibly and to adapt it to specific design contexts. In view of the above, this work proposes an ontology for formulated products with emphasis on cosmetic emulsions. This ontology integrates concepts from emulsion science, cosmetic formulation, expert knowledge, and design heuristics in a systematic and accessible way. It was done based on the recent work of our research group in Chemical Product Design. This document shows an overview of the ontology and one of its possible applications: verification of the formulation of a skin care cream. As a conclusion, it was found that the ontology enables the access to precise information according to design requirements. It is a versatile and useful information tool for the design of emulsion-based products.

Keywords: Product design, Cosmetic emulsions, Ontology

1. Introduction

Formulated chemical products, such as cosmetics, are complex systems whose properties are defined by a synergistic action of ingredients, composition, and production process. Their design is a scientific and organizational challenge, as it requires the management of heterogeneous information from multiple sources and the application of multidisciplinary knowledge (Zhang et al., 2020). Available information for their design is huge and diverse in nature: there are multiple ingredient databases, property models, heuristics, knowledge from colloidal science, regulations, recommendations, guidelines, etc. Additionally, in the field of Chemical Product Design (CPD), there are several methodologies and computer-aided methods. Examples are as a design methodology for cosmetic formulations incorporating heuristics (Arrieta-Escobar et al., 2020), a methodology for formulated products applying expert knowledge (Serna et al., 2021), and

an integrated framework for formulated products including liquids, solids, emulsions (Zhang et al., 2017), among others. Despite its abundance, the application of the existing information for product formulation of is not straight-forward (Zhang et al., 2020). Design methodologies are not adapted to practical design processes, which are iterative and change according to the design context. Additionally, available information is not centralized, has different forms (qualitative and quantitative), and it is frequently fragmented. Thus, it is necessary to create tools capable of managing real design contexts and available information to solve practical problems. In view of the above, this work proposes OntoCosmetic, an ontology to systematically represent knowledge for the formulation of cosmetic products of the type of homogenous mixture or emulsion. It is proposed to support data storage and analysis, information modeling and decision-making for cosmetic formulation. It is based on the knowledge and information gathered and developed by our design team in CPD (Arrieta-Escobar et al., 2020) (Serna et al., 2021) and it has a structure that can be extended to represent more general information in the field of formulated chemical products. The ontology was developed following the ontology creation methodology described by Gabriel (2019) and formalized using the software Protégé¹. In this document, section 2 presents a short introduction to ontologies and an overview of OntoCosmetic. Section 3 presents an application of the ontology for the verification of a formulation in relation to a heuristic database. Finally, Section 4 highlights some conclusions and perspectives.

2. An ontology for cosmetic product design

2.1. Concept of ontology

Ontology is “an explicit specification of a conceptualization” which is an abstract, simplified view of the world that is represented for some purpose (Gruber, 1993). It is holistic since it contains all relevant concepts and relationships between concepts to model a specific subject or phenomenon (Hailemariam & Venkatasubramanian, 2010). It is also as precise as required because it is normally defined within a specific domain of knowledge and with a clear purpose (Gabriel et al., 2019). In software engineering, ontologies are seen as “a means to efficiently build the knowledge-based necessary to effectively support engineering work processes” (Marquardt et al., 2010).

The main elements of an ontology are: *Classes* which are concepts or sets containing instances (e.g. the class ‘Ingredient’ in a cosmetic formulation). *Relations* which show the relation between classes (e.g., the relation ‘has’, connecting ‘Formulation’ with ‘Ingredient’). *Instances* which are the elements of the classes (e.g., ‘Argan oil’, which belongs to the class ‘Ingredient’). *Rules* which are logical statements that can be used to make inference (e.g., heuristics).

2.2. An ontology for cosmetic product formulation

OntoCosmetic was constructed based on the ontology OntoCAPE (Marquardt et al., 2010), a very elaborated ontology for process design in the field of Chemical Engineering. In OntoCAPE, products and processes are technical systems, which are developed in an engineering design process to meet defined requirements (Marquardt et al., 2010). There, technical systems are represented through five viewpoints: requirements, function, realization, behavior, and performance. OntoCosmetic uses part of this description to define the Product System and adapts it to the application of cosmetic formulation.

Figure 1 shows an overview of OntoCosmetic. It is organized in two interconnected blocks: A) Product System, containing all the relevant concepts describing a cosmetic formulation, B) Product Model, containing a knowledge base of models to support practical decision-making during the formulation process.

¹ <http://protege.stanford.edu/>

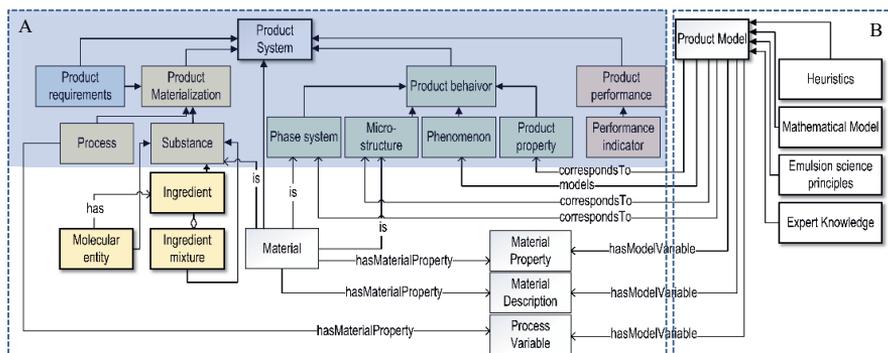

Figure 1. Overview of the OntoCosmetic ontology. A) Product System B) Product Model. The dark area corresponds to the concepts adapted from OntoCAPE

In OntoCosmetic, Product System is divided in four viewpoints:

- Product requirements: It corresponds to the product desired behavior, represented by product specifications and target values. It is a 'to be' relation.
- Product materialization: It corresponds to the decisions that designers can make and implement to achieve product requirements. For example, the selection of ingredients. Product materialization has the modules of process and substances. The latter is a super class of the ingredient class which is connected to a database of cosmetic ingredients.
- Product behavior: It corresponds to the real behavior of the product whether it is expected or not. It can be characterized quantitatively, through product properties, or qualitatively, through a qualitative product description. Product behavior can also be related to a phenomenon, to the micro-structure of the product (in the case of emulsions, microstructure is frequently characterized by particle size and particle size distribution), and to the phase system (which describes the product as a thermodynamic system).
- Product performance: It corresponds to the evaluation of the Product System specifically in relation to product requirements. It indicates whether the product has the desired performance (as described by product requirements) or not. The evaluation is done through target value indicators and sustainability indicators. In this case, in contrast to product requirements, indicators are related to the product system with a 'as is' relation.

The ontology has been developed with focus on cosmetic applications. Thus, it contains concepts and databases specifically related to this subject. In the ontology, ingredients are classified in subclasses that enable their search based on cosmetic related categories. Figure 2 shows some sub-classes of the class Ingredient with their definitions. Figure 3 shows some attributes of the sub-class Emollient with their definitions.

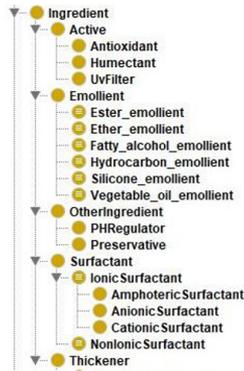

Figure 2. Extract of Ingredient sub-classes in OntoCosmetic

Table 1. Extract of Ingredient sub-classes in OntoCosmetic

Function	Description
Ingredient	Chemical compounds that are part of a formulation
Emollient	Oils used in cosmetic emulsions for several purposes: to make skin and hair softener, to serve as solvents for liposoluble actives. Some of them can act as occlusive ingredients.
Surfactant	Ingredient used in emulsions for three purposes: to decrease the energy required during emulsification, to adsorb rapidly at the interface of recently formed droplets, and to generate a barrier for long-term emulsion stability.

By its part, Product Model contains the models and tools that enable designers to make decisions. Product models are classified in the following classes:

- Heuristic: It is a guideline or rule of thumb expressed in natural language that gives a practical instruction to achieve a product requirement. It can be transformed into an algebraical mathematical model.
- Expert knowledge: It is a qualitative relation between the classes of product behavior and product materialization. They were established with the help of experts in emulsion science. They are used in combination with emulsion science principles.
- Mathematical model: It is an equation that enables a quantitative definition of ingredients in relation to product requirements.
- Emulsion science principles: They are scientific descriptions of emulsion phenomena, which explain some product system behaviors and can be used for decision-making in combination with expert knowledge.

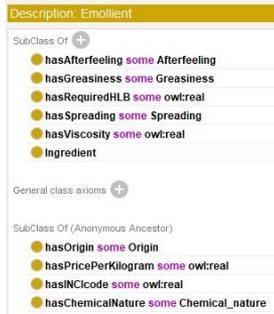

Figure 3. Some attributes of the class emollient

Table2. Some attributes of the class emollient

Function	Type	Description
requiredHLB	Real	It determines the compatibility of oils with the surfactant system
greasiness	String	It that reflects the oiliness of the skin after a lotion is applied. Allowed values: {Very high, High, Medium, Low}
viscosity	Real	It is the is a measure of the resistance of a fluid to deformation.
origin	String	Ingredient source. Allowed values: {natural, from nature raw materials, from natural and synthetic raw materials, synthetic}

As well, Product models are classified into sub-classes according to their applicability (general emulsions, cosmetic emulsions, specific cosmetic applications). Additionally, their implementation is related to the product materialization system (a model can be related to one or more ingredient class, sub-class, or attribute), and their effect is related to the classes of product behavior and product performance systems. Examples of product models and their relations are presented in Table 3.

Table 3. Some product models and their relations

Product model	Description	Application	Relations	System	Range
Heuristic	For a good sensorial, at least one emollient of each spreading type should be used: high, medium, and low.	Cosmetic emulsion	isImplementedBy	Product Materialization	Emollient; Spreading
			hasEffectOn	Product Performance	Performance indicator; Sensorial
Emulsion Science	Emulsion stability is affected by the phenomenon gravitational separation.	General	hasEffectOn	Product Performance	Performance indicator; Stability
		General	isRelatedtoPhenomenon	Product Behavior	PhenomenonGravitationalSeparation
Emulsion Science	Gravitational separation can be controlled with the addition of a thickener.	General	isImplementedBy	Product Materialization	Thickener; Concentration
		General	isRelatedtoPhenomenon	Product Behavior	PhenomenonGravitationalSeparation

3. Application: Checking if a given formulation follows the heuristics

The Ontology was used to verify if a given cosmetic formulation follows or not a group of heuristics, and thus if it is recommended based on them. The verification was done using the Semantic Web Rule Language (SWLR) in Protégé, where heuristics can be written as logic rules involving instances of classes. The formulation checked against the heuristics is shown in Table 4 and the considered heuristics are presented in Table 5. As result, the reasoner classified the formulation as recommended according to selected heuristics (ConformFormulation).

Table 4. Formulation checked against some heuristics

Class	Ingredient	%
Emollient	Ethylhexyl Palmitate	4
Emollient	Olive oil	3
Emollient	Caprylic/Capric Triglyceride	9
Surfactant	Glyceryl Stearate Citrate	2.5
Surfactant	Oleth-3	0.5
Surfactant	Sorbitan Monostearate	1
Preservative	Cosgard	0,7
Antioxidant	Tocopherol	0,5
Humectant	Glycerin	3
Thickener	Xanthan gum	0.1
	Water	To 100

Table 5. Heuristics considered to test the formulation using the ontology

Product model	Description	System	Range
Heuristic	at least one emollient of each spreading type should be used: high, medium, and low	Product Materialization	Emollient; Spreading
Heuristic	Use a minimum level of 2% and up to 5% of surfactants	Product Materialization	Surfactant; SurfactantComposition
Heuristic	At least one ingredient should be of the natural origin	Product Materialization	Ingredient; Origin
Heuristic	surfactant/emollient ratio should be between 1:4 to 1:6	Product Materialization	SurfactantComposition; EmollientComposition
Heuristic	HLB should match the RHLB required	Product Materialization	Surfactant; Emollient; SurfactantComposition; EmollientComposition

As shown in Figure 4, the formulation is introduced to the system as an instance with relations to ingredients (composition) and rules (heuristics that the formulation should

follow). Based on this information, the reasoner activates the required rules and classifies the formulation as *ConformFormulation*, when it follows the rules or as *NonConformFormulation*, when it does not. The formulation must be experimentally validated to verify that it meets the requirements.

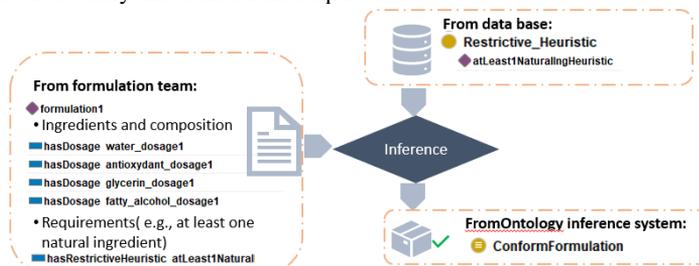

Figure 4. Results of the verification in Protégé

4. Conclusions and perspectives

The article presents a brief overview of *OntoCosmetic*, an ontology for cosmetic product design. Currently, the ontology formalizes concepts of product formulation. It can be used to create information systems with common definitions, to call ingredient and formulation information through a SPARQL² request, to apply heuristics through the activation of rules. The perspective of this ontology is to create an application programmer interface (API) to allow the integration of knowledge into a software. This software would assist the decision-making process during design as well as visualize data and optimize the formulation of cosmetic products considering multiple criteria.

Abstract

This work presents a synthesis problem for the separation and purification of Ethanol using extractive distillation. Glycerol was the chosen solvent to separate the azeotropic mixture. The synthesis problem was based on the Infinite-DimensionAl State-space (IDEAS) approach to discretize the liquid composition space represented by a ternary diagram. Then, a distillation module was assigned to each subspace, and a superstructure representation was used in which all distillation modules connect to generate an optimal distillation structure. The synthesis problem was formulated as a linear programming (LP) problem in which the utility cost was minimized subject to material and energy balances. Furthermore, the optimal structure was derived without the need to set any preestablish distillation structure. After the optimization problem is solved, the best connection between distillation modules is known. Therefore, a realistic and feasible distillation structure was interpreted at a post-optimization step.

Keywords: Process Synthesis, Extractive Distillation, LP, Process Simulation, Ethanol production

1. Main Text

Ethanol obtained from lignocellulosic biomass can be used in the chemical industry as an intermediate material for the synthesis of esters and ethers and as a solvent in the production of paint, cosmetics, sprays, perfumery, medicine, and food, among others. Furthermore, mixtures of anhydrous ethanol and gasoline can be used as fuels, reducing environmental contamination and improving gasoline's octane index (Gil et al., 2014). In order to obtain high-purity ethanol over 99.5 mol%, the water-ethanol azeotrope (89 mol%) must be surpassed.

Conventional distillation fails to obtain high-purity ethanol because as the water-ethanol mixture approaches the azeotrope, their vapor and liquid compositions become the same. Thus, further separation is not possible. However, by adding a third component acting as a mass separating agent (MSA), the vapor liquid equilibrium relationships between water and ethanol change so as to make possible ethanol purification. Therefore, this work deals with the extractive distillation of ethanol using glycerol as solvent.

The water-ethanol separation has been extensively researched in the past decades where the separation alternatives have been mainly related with extractive distillation (Dai et al., 2014), azeotropic distillation (Luyben, 2006), pressure-swing distillation (Mulia-Soto and Flores-Tlacuahuac, 2011), and membrane-assisted distillation (Kunnakorn et al., 2013).

In this work, the synthesis of extractive distillation structures for the purification of ethanol is studied through a low aggregation module-based superstructure framework consisting of the following steps: 1) superstructure representation, 2) modules generation, 3) linear programming (LP) optimization, 4) solution interpretation, and 5) solution validation.

2. Problem statement

Given the feed conditions and product specification for the separation of a water-ethanol mixture, the used solvent, and the operating pressure, a synthesis problem based on distillation modules can be proposed to derive optimal distillation structures.

Synthesis problems can be divided according to their aggregation level. Superstructures of high aggregation level comprise a set of equipment or tasks subject to a preestablished connectivity while superstructures of low aggregation level are based on a phenomenological approach, which combines cooling, heating, mixing, splitting, reaction, etc. (Alcantara-Avila et al., 2021). The use of low aggregation superstructures has been already proposed for the purification of ethanol. Kuhlmann et al., (2018) adopted the Phenomena Building Blocks (PBBs) framework for the synthesis of a membrane-assisted distillation process while Tian and Pistikopoulos, (2019) adopted a Generalized Modular Representation Framework (GMF) for the synthesis of an extractive distillation process. This work is based on the Infinite Dimensional State-space (IDEAS) framework proposed by Drake and Manousiouthakis, (2002) in which a process can be represented by a network of units operations.

2.1. Superstructure representation

The proposed superstructure in this work is composed by five types of modules: a heating module, a cooling module, two feed modules, two product modules, and a set of distillation modules. Figure 1 shows the representation of a distillation module.

Since the liquid composition space of the ternary mixture is discretized in subspaces, by definition, a distillation module is a subspace in which the liquid and vapor compositions and enthalpies are uniquely define given the pressure is known.

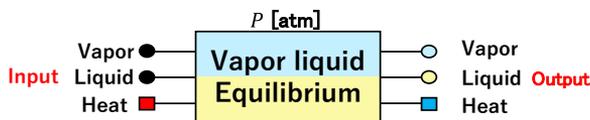

Figure 1. Conceptual representation of a distillation module

For each module i , the liquid molar fraction of component k (x_{ik}), vapor molar fraction of component k (y_{ik}), liquid enthalpy (h_i^L), and vapor enthalpy (h_i^V) are uniquely defined and entered as parameter in the optimization problem. The combination of modules will result in the optimal process.

Figure 2 shows the proposed superstructure representation in this work. The modules in the superstructure contain heat and mass inputs and-or outputs. For example, the heating, feed, and solvent modules have only outputs while cooling and product modules have only inputs, and the distillation module have both. The superstructure considers all possible flow connections between distillation modules and other modules.

3. Mathematical formulation

The minimize utility cost (UC) minimization was taken as objective function because the distillation cost is largely dominated by UC. Equation 1 shows the objective function.

$$UC = \sum_{i \in S_M} (c_H Q_i^H + c_C Q_i^C) \quad 1$$

where S_M the set of distillation modules, c_H and c_C are the cost of heating and that of cooling per unit amount of energy. Q_i^H and Q_i^C are the heating amount entering a module i and that of cooling leaving a module i .

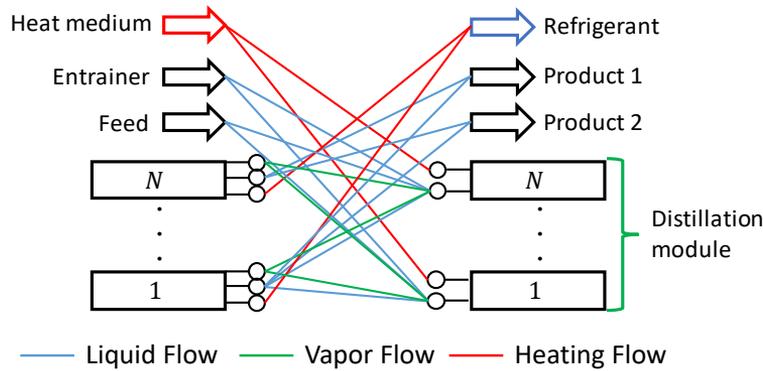

Figure 2. Conceptual representation of the module-based superstructure

Equation 2 shows the overall mass balance while Eq. 3 shows the component mass balance for the two products in each distillation module

$$\sum_{i \in S_M} (L_{ji} + V_{ji}) + L_{Fi} + L_{Si} - \sum_{j \in S_M} (L_{ij} + V_{ij}) - \sum_{p \in S_p} L_{ip}^P = 0 \quad 2$$

$$\sum_{i \in S_M} (L_{ji} x_{jk} + V_{ji} y_{jk}) + L_{Fi} x_k^F + L_{Si} x_k^S - \sum_{j \in S_M} (L_{ij} x_{ik} + V_{ij} y_{ik}) - x_{ik} \sum_{p \in S_p} L_{ip}^P = 0 \quad 3$$

where L_{ij} and V_{ij} are the liquid and vapor molar flows from module i to module j , L_{Fi} is the feed molar flow to module i , L_{Si} is the liquid solvent molar flow to module i , L_{ip}^P is the product molar flow amount from module i . x_k^F is the liquid molar fraction of component k in the feed, and x_k^S is the liquid molar fraction of component k in the solvent, respectively.

Equation 4 shows the overall heat balance in each distillation module

$$\sum_{j \in S_M} (L_{ji} h_j^L + V_{ji} h_j^V) + L_{Fi} h^F + L_{Si} h^S + Q_i^H - \sum_{j \in S_M} (L_{ij} h_i^L + V_{ij} h_i^V) - h_i^L \sum_{p \in S_p} L_{ip}^P - Q_i^C = 0 \quad 4$$

where h^F and h^S are enthalpy of feed, and the solvent, respectively.

Equations 5 and 6 are additional equations for the connectivity between the feed module and distillation modules, and between distillation modules and product modules, respectively.

$$\sum_{i \in S_M} (L_{Fi}) - L^F = 0 \quad 5$$

$$x_k^P \sum_{j \in S_M} (L_{jk}^P) - \sum_{j \in S_M} (L_{jk}^P x_{jk}) \geq 0 \quad \{k = 1, 2\} \quad 6$$

where L_{Fi} is the liquid feed flow to module i , and x_k^P is the molar purity target of component k . Moreover, since all the proposed equations in this section are linear, the optimization problem can be solved as a linear programming (LP) problem.

3.1. Case study

The feed flow rate of the water-ethanol mixture is 100 kmol/h, and its liquid molar fraction of ethanol is 0.894 and that of water in 0.106. The molar fraction specifications for ethanol, water and glycerol must be more than 0.95. The pressure in all modules is 1 atm. The feed and the product flows are saturated liquid. The heating cost is 10 \$/GJ and the cooling cost is 0.5 \$/GJ.

As for the discretization of the liquid compositions for the distillation modules, each of ethanol, water, and glycerol molar composition was discretized with the width of 0.02.

The vapor liquid equilibrium and each phase enthalpy were calculated by using NRTL model. The calculations done in Aspen Plus V10®. The optimization was done by IBM ILOG CPLEX Optimization Studio 12.8.0.

4. Results and Discussion

Figures 3 and 4 show the plot of the connectivity of liquid and vapor flows between distillation modules in a ternary diagram.

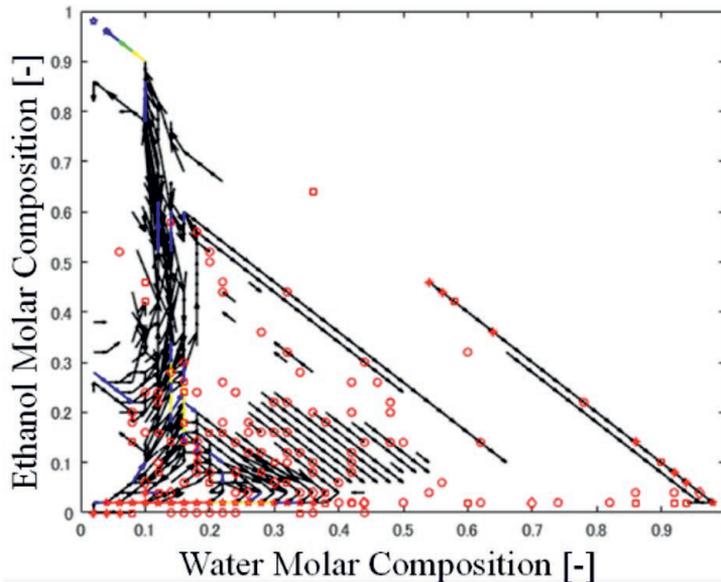

Figure 3. Liquid flow path of the optimal solution

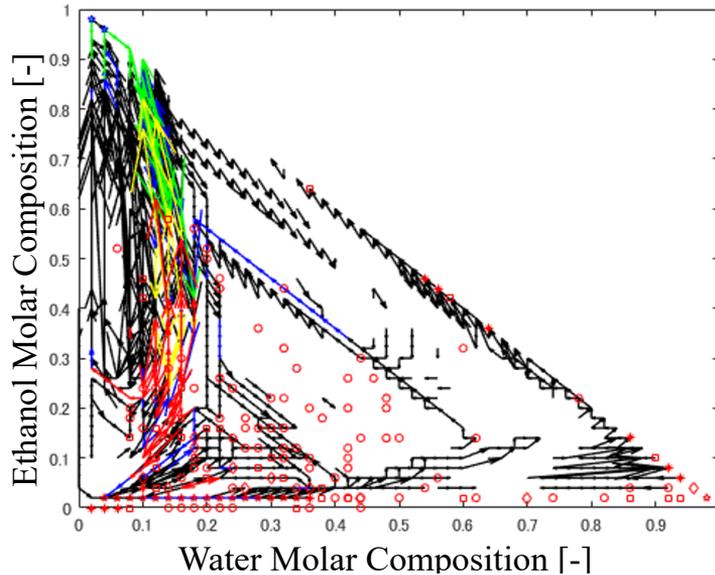

Figure 4. Vapor flow path of the optimal solution

The utility cost of the optimization result was 9.36 \$/h. Table 1 shows the description of colors and shapes for the ternary diagrams in Figures 2.

Table 1. The colors and shapes of modules and flows in Figs. 3 and 4

Shapes and colors	explanation	amount
→	Flow direction	More than 1 kmol/h
→	Flow direction	Less than 17 kmol/h
→	Flow direction	Less than 25 kmol/h
→	Flow direction	Less than 33 kmol/h
→	Flow direction	More than 33 kmol/h
○, ○	Amount of heating or cooling	More than 0 kJ/h
□, □	Amount of heating or cooling	Less than 5000 kJ/h
◇, ◇	Amount of heating or cooling	Less than 10000 kJ/h
*, *	Amount of heating or cooling	Less than 30000 kJ/h
★, ★	Amount of heating or cooling	More than 30000 kJ/h

It can be seen from Figs. 3 and 4 that cooling is necessary to separate Ethanol while heating is necessary to separate Water and Glycerol. Also, most of liquid flows are less than 1 kmol/h. However, modules with low molar fraction of water have liquid flows less than 17 kmol/h. On the other hand, there are large flows of vapor in the region with low molar fraction of water.

Figure 5 shows the interpreted solution of the optimization results in Figs. 3 and 4. The interpreted solution exhibits several features: 1) there is no need to use a condenser in the first column, 2) water is separated in second column, 3) thermal coupling between stages makes possible to increase the internal flow of vapor streams, and 4) there is no need to cool the recycled solvent streams since the process will use this energy directly when mixed with the feed steam. The utility cost of the interpreted solution is 60.8 \$/h.

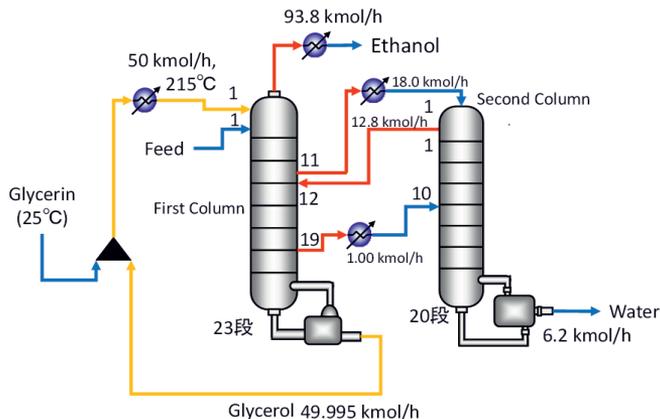

Figure 5. Interpreted distillation structure

5. Conclusions

This work presented a module-based framework for the synthesis of extractive distillation column. The modules are collected and represented in a ternary diagram. The interpreted solution showed an intensified distillation column with a cost much higher than the cost obtained after solving the LP problem. The derived solution was done without any preestablished connectivity. Further improvements at the interpretation step must be done.

Optimal design for flexible operation with multiple fluctuating input parameters

Bastian Bruns^{a,*}, Marcus Grünewald^a and Julia Riese^a

^a*Ruhr University Bochum, Universitätsstraße 150, 44801 Bochum, Germany

Abstract

Feasibility is a crucial aspect when dealing with flexible operation of processes, as it is, e.g., the case when incorporating renewable energies. Process design and operation should thus account for the operational fluctuations. When flexible operation with multiple fluctuating input parameters is required, a design that increases the feasible region spanned by these parameters can be advantageous. In this paper, we study the optimal design of a fixed bed reactor for the CO₂ hydrogenation to methanol that is operated under variable capacities. We introduce a design approach to optimize the multidimensional operating window of the process. Dynamic optimization is used as an overarching framework to adapt the design of the fixed bed reactor, increasing the flexibility of the process in terms of H₂ and CO₂ feed capacity.

Keywords: Design optimization, flexibility, power-to-x, dynamic operability, methanol production

1. Introduction

Chemical process plants are constantly subject to disturbances and need to respond appropriately in order to meet safety, environmental or operational constraints. Early works found that these disturbances should be considered as uncertainties during the design phase of processes. Mathematical tools for steady-state (Swaney and Grossmann (1985)) and dynamic analysis (Dimitriadis and Pistikopoulos (1995)) were developed to provide processes able to overcome operational flexibility limitations. These tools are able to determine flexibility of a process system by means of a hyperrectangle that is centered at the nominal point in the space of uncertain parameters. The length of the sides of the hyperrectangle are defined by the nearest boundary. This measure can then be used to adapt design parameters to provide feasibility in uncertain conditions. Most of the studies analyzing flexibility under uncertainty are, however, based on open loop processes.

Therefore, there have been efforts towards the consideration of design and control actions of processes subject to disturbances. Early research showed that an integrated approach to design and control processes is superior to a sequential one when dealing with these disturbances during operation (Swartz and Kawajiri (2019)). However, these integrated design and control strategies were usually developed to maintain an optimal operation around a nominal steady-state operating point.

Due to recent developments in chemical engineering such as the increasing incorporation of renewable energies, flexible operation of chemical plants has received considerable interest (e.g. Caspari et al. (2019); Otashu and Baldea (2019); Fischer and Freund (2020)). Flexible operation implies significant deviations from steady-state operating conditions and requires that process design, and operation account for these fluctuations in advance. This includes that control actions are found that allow a feasible and fast transient behavior. When these fluctuations are the main

concern, a system that can compensate for larger deviations in its operating conditions is advantageous. However, there are few design approaches (e.g. Cao et al. (2015)) that consider the size of the operating window of a process.

In this work, we introduce a design approach that considers the multidimensional operating window of a process. The aim of the design optimization is to provide a process design that is highly flexible towards multiple fluctuating input parameters. We demonstrate the approach on the production process of green methanol, as this is a realistic process scenario for flexible operation (Mbatha et al. (2021)). We consider that CO₂ is produced by absorption in a fossil power plant, operated for frequency regulations. Hydrogen required by the process is produced by a water electrolysis that operates with renewable energies. Although there is an optimum in the H₂ and CO₂ ratio, we assume that each flow rate varies independently, neglecting possible storage capacities.

2. Design Problem

During flexible operation, certain intended variables undergo significant deviations from their nominal operating conditions. These fluctuating variables are limited by process boundaries and thus span the operating window of the process. Boundaries can be, e.g., process performance, or environmental, and safety issues. In the space of uncertain parameters the operating window corresponds to the feasible region of the process. The size of the operating window determines the feasible combinations of the intended fluctuating variables. Thus, increasing the size of the operating window, increases the feasible deviations of the corresponding variables. It becomes evident that flexible operation benefits from an increased size of the operating window, as it allows for more feasible operating points.

We consider the load ξ of a process or its equipment as an auxiliary variable that determines the operating point in accordance with the intended changing variables (flexibility dictating parameter β) during flexible operation. The definition of the operating window considered here follows the approach proposed recently in Bruns et al. (2021). The load is then a function of the vector of design d and operational variables x , and the flexibility dictating parameters:

$$\xi = f(d, x, \beta) \quad (1)$$

Consequently, the operating window is the space of all feasible loads bounded by all considered process limitations. To optimize the operating window of the process, we determine the maximum ranges over which each flexibility dictating parameter may vary, while remaining in the operating window. The size of the operating window ξ^{ow} is then characterized by the product of the difference between the maximum and minimum deviation of each parameter:

$$\xi^{\text{ow}} = \prod_{i=1}^n (\xi_n^{\text{max}} - \xi_n^{\text{min}}) \quad (2)$$

where n is the number of flexibility dictating parameters, and ξ_n^{max} and ξ_n^{min} are the farthest loads on the process boundaries. This results in a multidimensional rectangle, where the length of its sides correspond to the difference between maximum and minimum deviation of parameters β .

This representation of the operating window can be incorporated into design optimization by means of dynamic optimization. By considering a time horizon τ , in which the flexibility dictating parameters represent the degrees of freedom that are available during operation, the farthest loads on the process boundaries can be determined.

3. Methanol Synthesis Modeling

The investigated green methanol synthesis process is shown in Figure 1. Fresh feed of H₂ and CO₂ enters the process and is then mixed with the recycle stream. Before entering the methanol reactor,

the gas mixture is preheated to 498 K. Methanol is then formed in the tube bundle reactor over a commercial Cu/Zn/Al₂O₃ catalyst at an inlet pressure of 55 bar. In the tube bundle reactor 150 tubes with a length of 8 m and a tube diameter of 0.058 m are assembled in parallel. The catalysts particle diameter is 0.006 m with a density of 1175 kg m⁻³. The void fraction in the reactor is 0.4. The tubes are surrounded by a shell where an isothermal heat exchange fluid regulates the temperature in the reactor. The produced gas mixture is then condensed after the reactor in a separator in order to remove and recycle unreacted gases from methanol and water. 10 % of the recycled gases are purged from the process.

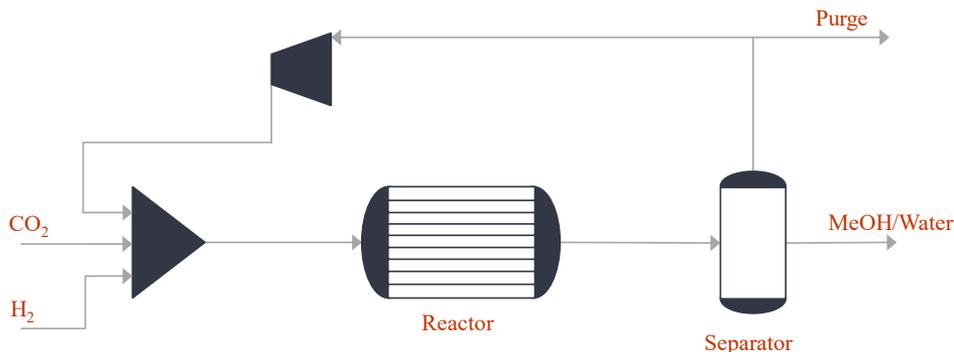

Figure 1: Methanol synthesis process.

The tube bundle reactor is represented by a one dimensional plug-flow model, considering heat capacities and weight of the catalyst bed, and the reactor material. The model consists of component material balances and an energy balance in the form of partial-differential equations. Reaction rates, pressure drop correlation and heat transfer are considered in the form of algebraic equations. We employed reaction kinetics by Bussche and Froment (1996) to calculate the reaction rates of each component over the length of the reactor. The overall heat transfer coefficient considered in the model between reactor wall and heat exchange fluid is 1000 J s⁻¹ m⁻².

The separator is modeled by a set of differential-algebraic equations, calculating the vapor-liquid equilibrium, while considering liquid and gas hold-up in the vessel. Valves and the compressor in the process are modeled to represent the typical behavior of the process equipment by efficiency relationships and pressure drops. The entire process is solved pressure-driven in Aspen Custom Modeler v10.

4. Optimal Process Design

The design decision variables for the methanol reactor are the length of the reactor ($l \in [7, 9]$ m) and the diameter of the tubes ($d_t \in [0.02, 0.065]$ m). Operational decision variables are the heat exchange fluid temperature ($T_{cw} \in [473.15, 543.15]$ K) and the reactor inlet temperature ($T_{in} \in [473.15, 543.15]$ K). Process constraints are: 1) minimum productivity of 1000 kg h⁻¹, 2) minimum CO₂ conversion of 0.1, 3) maximum split fraction of the purge of 0.15, 4) maximum pressure drop of 1.5 bar, and 5) maximum hot spot temperature of 543.15 K. Due to the pressure-driven simulation of the methanol synthesis process, the split fraction of the purge is not a fixed value, but rather calculated according to the pressure in the system. The split fraction is thus a value that changes during operation and should not exceed a certain value to prevent excessive loss of reactant.

We want to design the methanol reactor such that its operating window in the space of the considered flexibility dictating parameters is optimized. The flexibility dictating parameters for this case

are the H₂ feed flow rate $\beta_1 = \dot{n}_{H_2}$ and the CO₂ feed flow rate $\beta_2 = \dot{n}_{CO_2}$. The objective function is thus defined as follows:

$$\begin{aligned} \xi^{\text{ow,MeOH}} &= \prod_{i=1}^2 \left(\xi_n^{\text{upper}} - \xi_n^{\text{lower}} \right) \\ &= \prod_{i=1}^2 \left(\mathbf{f}(\mathbf{d}\mathbf{v}, \mathbf{x}, \beta_n^{\text{upper}}, \tau + \Delta t) - \mathbf{f}(\mathbf{d}\mathbf{v}, \mathbf{x}, \beta_n^{\text{lower}}, \tau) \right) \end{aligned} \quad (3)$$

where \mathbf{f} represents all model equations considered in the methanol synthesis process and ξ_n^{upper} and ξ_n^{lower} are the upper and lower load depending on the respective flexibility dictating parameter value. At the process boundaries ξ_n^{upper} and ξ_n^{lower} equal ξ_n^{max} and ξ_n^{min} . $\tau + \Delta t$ is the time horizon, where the time step Δt considers the dynamic behavior of the process and needs to be sufficiently large so that steady-state is reached again. For the methanol synthesis process we chose $\Delta t = 500$ s. β_1 and β_2 are degrees of freedom in addition to the design and operational decision variables that are optimized at $t = \tau$. We thus maximize the rectangle resulting from the farthest loads in the feasible region in the space of β_1 and β_2 . The dynamic optimization is performed by means of scripts integrated in the simulation software.

We investigate two scenarios: first, solely the design decision variables are optimized and second, both design and operational variables of the reactor are optimized. Dynamic feasibility is assessed for both scenarios by means of path constraints. We also use the dynamic optimization framework to test the investigated operational variables to be adapted as advanced control strategy during operation to satisfy the path constraints. Both scenarios are compared to the base case, which was described in Section 3.

5. Results and Discussion

The optimization results for both scenarios and for the base case are shown in Table 1. The process model is highly nonlinear so that various initial guesses were required to find the optimal solution for each scenario. In the base case no decision variables were considered, and by that we just evaluate the size of the operating window. The maximum and minimum deviation for both H₂ (318.39 kmol h⁻¹ and 96.22 kmol h⁻¹) and CO₂ (106.19 kmol h⁻¹ and 30.44 kmol h⁻¹) feed flow rates are determined. The resulting scaled operating window size is 16.83. We performed the same optimization with reactor length and tube diameter as decision variables in scenario 1. The optimal design has a reactor length at the lower design boundary and a tube diameter at the upper design boundary. The size of the operating window increases by 54.03 %. By additionally considering the inlet temperature and the thermal fluid temperature during the design optimization, as in scenario 2, the determined operating window can be further enhanced compared to the base case (60.56 %). The optimal inlet temperature changed only insignificantly, while the thermal fluid temperature has increased by 7.99 K.

For both considered scenarios, we can observe an increase of the determined operating window size. However, because the size of the operating window is approximated by the rectangle drawn by the farthest feasible operating points, we must evaluate the actual operating window, since the shape of the operating window may differ significantly from a rectangle. By sampling the operating points in the space of β_1 and β_2 and drawing all feasibility boundaries, we can graphically assess the actual operating window of the process (see Figure 2). As can be noticed by plotting the optimized operating window sizes for the base case and scenario 2 (black dashed line), the rectangle is not able to sufficiently approximate the actual operating window size. However, the rectangle size gradient allows to push the boundaries of the operating window. In case of the methanol process, the productivity and the split fraction boundary are moved, resulting in an increase of the actual size of the operating window. This is due to the fact that productivity and split

Table 1: Design optimization results

Results	Unit	Base case	Scenario 1	Scenario 2
Design variables				
Reactor length	m	8	7	7
Tube diameter	m	0.058	0.065	0.065
Operational variables				
Inlet temperature	K	498	498	498.33
Thermal fluid temperature	K	523	523	530.99
Flexibility dictating parameter				
$\dot{n}_{H_2}(\xi^{\max})$	kmol h ⁻¹	318.39	339.76	360.01
$\dot{n}_{H_2}(\xi^{\min})$	kmol h ⁻¹	96.22	94.76	95.95
$\dot{n}_{CO_2}(\xi^{\max})$	kmol h ⁻¹	106.19	136.29	132.01
$\dot{n}_{CO_2}(\xi^{\min})$	kmol h ⁻¹	30.44	30.48	29.68
$\xi_{\text{ow,MeOH}}$		16.83	25.92	27.02
Objective function improvement	%		54.03	60.56

fraction are highly dependent on temperatures, concentrations and pressures in the recycle stream. A shorter reactor length, larger tube diameter and higher coolant temperature have a beneficial impact on productivity of the reactor and equilibrium of the reactions.

In a last step, we tested dynamic feasibility of the system for all scenarios, assuming dynamic transition between the farthest operating points as worst-case test. For the methanol synthesis process none of the relevant boundaries are violated. The temperature in the reactor reacts sluggish, never reaching critical temperatures for the catalyst. It should be noted that dynamics of the process are highly dependent on reaction kinetics and modelling approaches. Depending on the assumptions made, such large steps between operating points might lead to critical conditions in the reactor. At this point, the design approach proposed here can incorporate advanced control strategies such as adapting the coolant temperature according to the operating point at which operation takes place to prevent operational failure.

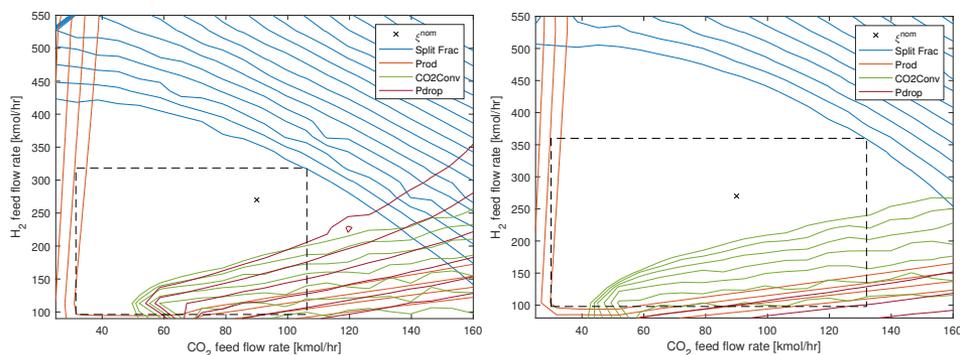

Figure 2: Operating window (white space) and size of the rectangle for the base case (left) and scenario 2 (right).

Finally, it is worth comparing the results achieved by the proposed approach with the outcome of typical mathematical tools from the literature such as the flexibility index, since the objective is rather similar. Comparing the two, we can observe a different design outcome with the proposed

approach. This is due to the fact that the flexibility index is measured by a hyperrectangle which is centered at the nominal operating conditions. By adapting design and operational decision variables, the flexibility index can be influenced, which means changing the size of the hyperrectangle. However, since the length of the sides of the hyperrectangle are bound by the closest process boundary, an increase in the size of the hyperrectangle would not directly lead to an increase in the size of the operating window. We can observe this when considering the examined methanol synthesis process. At the nominal operating condition ξ^{nom} with a H_2 feed flow rate of 270 kmol h^{-1} and a CO_2 feed flow rate of 90 kmol h^{-1} , changing the considered design and operational variables pushes the split fraction boundary, however, shifts the CO_2 conversion boundary towards the nominal operating condition. While the operating window increases, the flexibility index would not adequately represent this aspect, as it would only indicate the maximum deviation to the closest process boundary, which then could be the CO_2 conversion.

6. Conclusions

In this work, we present a design approach to optimize the multidimensional operating window of processes and its equipment in the space of intended fluctuating parameters. We use a dynamic optimization framework to incorporate the operating window size into the design decision and test the approach on the process of green methanol synthesis. The aim is to design a methanol reactor that is highly flexible towards the feed flow rate of H_2 and CO_2 . We track the movement of the operating window size and its boundaries by the size of a multidimensional rectangle spanned from the farthest operating points. Results show that the rectangle is not able to approximate the actual operating window size sufficiently. However, the rectangle size gradient considered in combination with graphical assessment leads to an increase of the actual operating window size of the methanol synthesis process. While the proposed approach does not give a direct sizing of the operating window, it enables to determine parameters that push the process boundaries in order to increase the size of the operating window with relatively low computational effort. Future work should incorporate the actual size of the operating window in order to prevent false movement in the shape of the operating window.

Design and Optimization of Membrane System for Gas Separation

Shivom Sharma* and François Maréchal

École Polytechnique Fédérale de Lausanne, IPESÉ, Sion, 1950, Switzerland
*shivom.sharma@epfl.ch

Abstract

Membrane separation may substitute conventional energy intensive technologies, and it could have cost benefits and lower environmental footprints. Several membrane processes have been developed to achieve higher purity and recovery of products. This study uses a generic membrane superstructure (or system) that facilitates all possible inter- and intra-connections among different membrane stages (or units) which are arranged in series-parallel configurations. The developed mathematical model for the membrane system is a mixed integer non-linear programming (MINLP) problem. The mathematical model is implemented in AMPL, and BARON solver is used to solve it. The MINLP model of the membrane system can choose membrane from a Membrane Database, which has a number of polymeric and inorganic (graphene, carbon molecular sieve, zeolite and metal-organic frameworks) membranes. In this work, two industrial case studies of gas separation are considered: post-combustion CO₂ capture and biogas upgradation by CO₂ removal. The selection of CO₂ removal technology depends on plant location, production capacity and product quality specifications. The chosen applications have challenges in terms of energy consumptions, economics and environmental burden. The separation performance of the membrane system is evaluated and compared for same membrane in all membrane stages. Two optimization problems were solved for each membrane: minimization of total area of membranes and minimization of total mechanical power. For both applications, best performing membranes were identified to target the minimum separation cost.

Keywords: Membrane System, Post-combustion CO₂ Capture, Biogas Upgradation.

1. Introduction

Membrane separation is one of the emerging technologies that has the potential to replace traditional energy intensive separation technologies. In process industry, solvent absorption (amine absorption), solid adsorption (pressure swing adsorption) and cryogenic distillations are used to separate gas mixtures (Tock, 2013; Leung et al., 2014). Recently, gas separation using membranes has received considerable attention for industrial applications, namely air separation, syngas ratio adjustment, hydrogen recovery in refinery, post-combustion CO₂ capture and biogas upgradation by CO₂ removal (Ismail, 2015). Membrane separation has several advantages over conventional gas separation technologies, e.g., no use of chemicals, mild operating conditions, simple installation and easier operation, and flexibility to integrate with other separation technologies.

Several studies have explored post-combustion CO₂ capture from coal and natural gas power plants, using membranes (Kárászov et al., 2020). Zhang et al. (2014) studied post

combustion carbon capture, and amine-based capture system had higher energy consumptions and environmental impact compared to the membrane process. Arias et al. (2016) optimized performance of multi-stage membrane superstructure for capturing CO₂ from flue gases. Lee et al. (2018) optimized membrane superstructure for CO₂ capture from coal power plants, and showed the benefits of using different membranes in different membrane stages. Scholz et al. (2013) performed detailed analysis of biogas upgradation into biomethane using several types of membranes. Finally, Sun et al. (2015) reviewed several biogas upgrading technologies, including cryogenic separation, physical and chemical absorptions, pressure swing adsorption, membrane separation, hydrate formation and biological methods.

Post-combustion CO₂ capture and biogas upgradation have several challenges such as energy consumptions, capital and operating costs. The selection of CO₂ removal technologies depends on plant location, production capacity, product quality specifications, availability of financial resources, environmental regulations and energy integration with CO₂ emitting plant or industrial site. In order to achieve the required purity and capture rate, membranes are arranged in complex series-parallel configurations. This arrangement gives numerous degrees of freedom for membrane system design. In this study, a generic superstructure of membrane modules/units, with all possible inter- and intra-connections, is used (see Figure 1). A mixed integer non-linear programming problem of membrane superstructure has been developed in AMPL (A Mathematical Programming Language). A database of several membranes has been used, and optimization method can choose any membrane from the database.

Two important industrial case studies of gas separation are considered: post-combustion CO₂ capture and biogas upgradation by removing CO₂. There are eight (M1-M8) and seven (m1-m7) membranes respectively in the membrane databases for post-combustion CO₂ capture and biogas upgradation. The separation performance of the membrane system was evaluated and compared for all membranes. For each membrane, two optimization problems were solved: minimization of total area of membrane (TAM), and minimization of mechanical power (TP). The optimization results allow to identify best performing membranes for both applications. In the mathematical model of the membrane system, different membranes can also be used in different membrane stages to improve the separation performance. For both applications, the final solution always contains same membranes in both membrane stages, as Membrane Database has limited number of membranes. In case of large number of membranes in the Membrane Database, the proposed approach can identify best performing membrane clusters, based on the membrane permeability and selectivity. These findings could be useful to the membrane researchers for further improving the performances of their membranes.

2. Membrane Superstructure Model

Figure 1 presents generic membrane superstructure or system. Fresh feed is compressed [$C(F)$] and cooled-down [$HE(F)$] before it enters the membrane system. The fresh feed can go to any membrane stage or unit in the membrane system. Figure 1 shows i^{th} membrane stage of the membrane system, inside the dotted line. Each membrane stage has a membrane module [$MEM(i)$], a mixer [$M(f,i)$], two splitters [$S(r,i)$, $S(p,i)$] on retentate and permeate sides, a compressor [$C(i)$] and cooler [$HE(i)$] for permeate stream. The membrane stage mixer [$M(f,i)$] is used to mix the fresh feed and retentate and/or permeate recycled from the same or different membrane stages.

Finally, there are two mixers $[M(r), M(p)]$ for both product streams. A turbine $[T(P)]$ and a heater $[HE(P)]$ are used to recover the mechanical power, from the retentate side product.

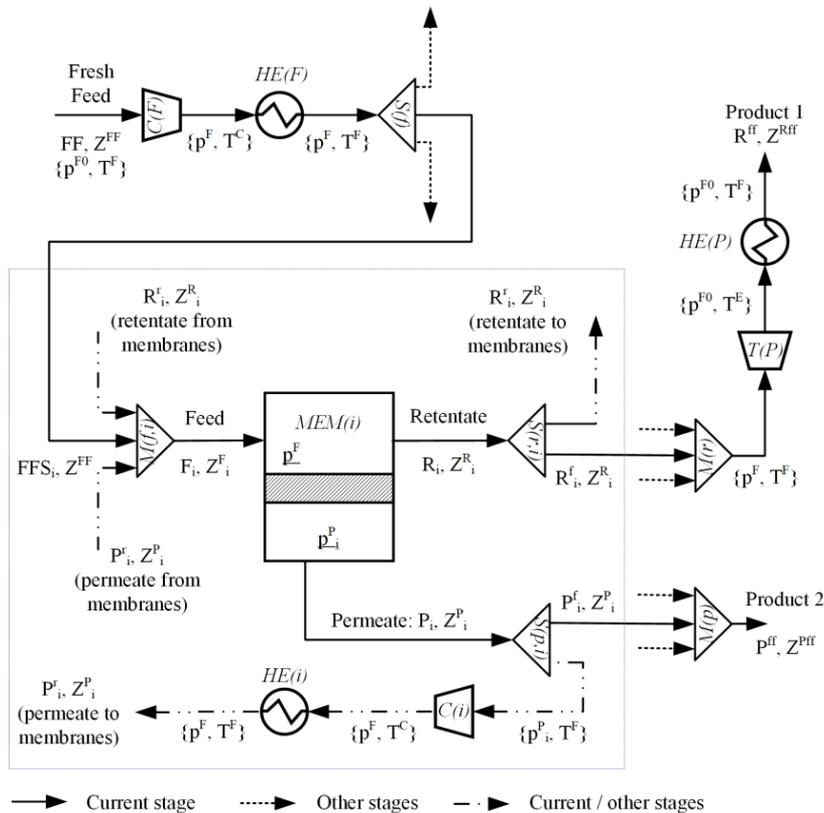

Figure 1: Membrane superstructure for gas separation

The mathematical model for the membrane superstructure is a mixed integer non-linear programming (MINLP) problem. Table 1 summarizes balances and equations for different units in membrane system.

Table 1: Summary of MINLP model for membrane system

Units	Balances or Equations
Membrane system	Mass and component balances
Splitters $[S(F), S(r,i), S(p,i)]$	Mass balance
Mixers $[M(f,i), M(p), M(r)]$	Mass and component balances
Membranes $[MEM(i)]$	Mass and component balances, membrane transport
Compressors, turbines $[C(F), C(i), T(P)]$	Equations for calculating outlet temperatures and powers ($\eta_C = 0.8, \eta_T = 0.85$)
Heaters, coolers $[HE(F), HE(i), HE(P)]$	Heat balance equation for calculating heat duties
Constraints	Limits on the product purities

3. Post-combustion CO₂ Capture

The flue gases contain mainly N₂, O₂, CO₂ and H₂O. This work considers separation of water prior to the use of membrane separation for CO₂ capture. It is assumed that the feed contains 14% CO₂ and remaining 86% N₂. The CO₂ and N₂ mixture have a flow rate of 10 mol/s at 1 bar pressure and 40 °C temperature. The membrane database has eight membranes (M1-M8), and Figure 2(c) shows CO₂ permeance and CO₂/N₂ selectivity for different membranes. M1-M3 are polymeric membranes whereas M4-M8 are inorganic (graphene, carbon molecular sieve, zeolite, metal-organic frameworks) membranes. The feed side pressure for membrane units can vary between 5 and 13 bar (Minh et al., 2008). The CO₂ and N₂ streams from the membrane system have 95% purities.

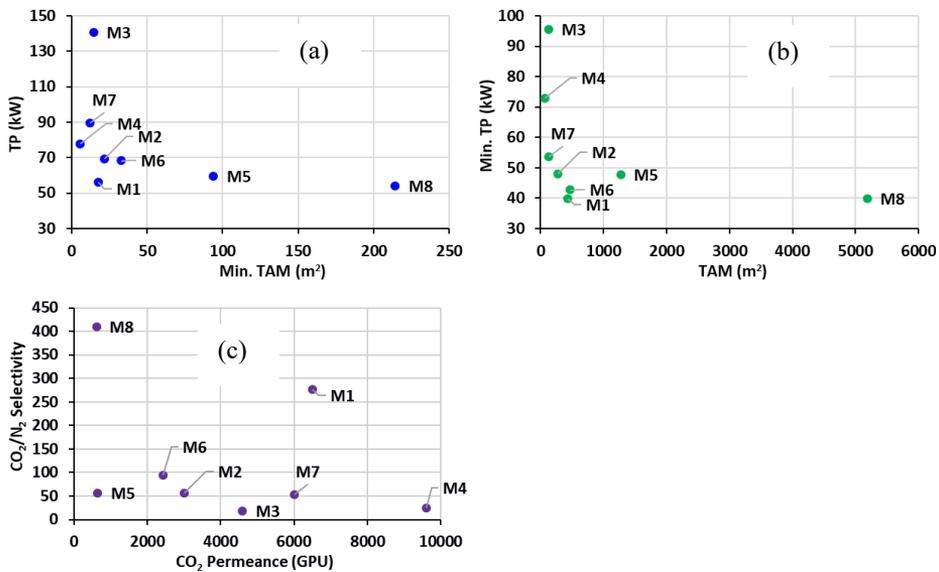

Figure 2: Post-combustion CO₂ capture using different membranes: (a) minimization of total area of membranes, (b) minimization of total mechanical power, (c) CO₂ permeance versus CO₂/N₂ selectivity for all membranes.

For this study, the membrane system has two membrane stages. For each membrane in the membrane database, two optimization problems were solved: minimization of total area of membranes, and minimization of total mechanical power (feed compression + stage compression – product expansion). The optimization problems have 252 variables and 266 constraints, and they were solved using BARON (v21.1.13) solver in AMPL (v20210220), with a maximum solution time of 30 minutes. Figure 2(a) presents optimization results for minimum total area of membranes. This figure also presents related values of total mechanical power obtained for different solutions. Similarly, Figure 2(b) presents results for minimum total mechanical power (2nd optimization problem) for all membranes. To minimize the total cost of separation, both total area of membranes and total mechanical power are equally important. It can be seen from Figures 2(a) and 2(b) that membrane M1 has the best performance for separating a mixture of CO₂ and N₂. Further, membrane M1 has best compromise between permeance and selectivity. Membrane M4 has very high permeance but low selectivity, whereas membrane M8 has very high selectivity but low permeance.

4. Biogas Upgradation by CO₂ Removal

The biogas contains 38% CO₂ and remaining 62% CH₄. The biogas has a flow rate of 10 mol/s at 1 bar pressure and 40 °C temperature. The membrane database for biogas upgradation has seven membranes (m1-m7), and Figure 3(c) shows CO₂ permeance and CO₂/CH₄ selectivity for different membranes. m1-m3 are polymeric membranes whereas m4-m7 are inorganic (graphene, carbon molecular sieve, zeolite, metal-organic frameworks) membranes. Two membrane stages were considered for separating CO₂ and CH₄ mixture. The feed side pressure for membrane units can vary between 5 and 13 bar. The CO₂ and CH₄ streams from the membrane system have 95% purities.

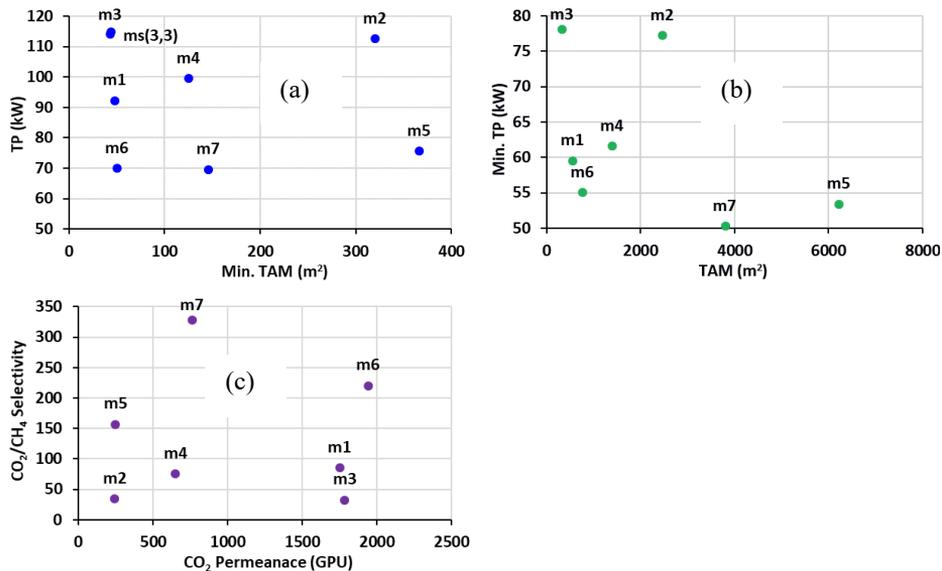

Figure 3: Biogas upgradation by CO₂ removal using different membranes: (a) minimization of total area of membranes, (b) minimization of total mechanical power, (c) CO₂ permeance versus CO₂/CH₄ selectivity for all membranes.

Similar to previous case study, two optimization problems were solved for all the membranes: minimization of total area of membranes, and minimization of total mechanical power. Both optimization problems have 252 variables and 266 constraints, and they were solved using BARON solver in AMPL, with a maximum solution time of 30 minutes. Figure 3(a) presents optimization results for minimum total area of membranes. This figure also present values of total mechanical power obtained for different solutions. Figure 3(b) presents results for minimum total mechanical power for all membranes, along with related total area of membranes. For minimum total cost of separation, solutions obtained for membrane m6 are better than other membranes, as these solutions are nearer to the corner. Membrane m6 has best compromise between permeance and selectivity, as shown in Figure 3(c).

The mathematical model of membrane system can use different membranes in different stages to improve the separation performance. For biogas upgradation, we minimized total area of membranes, and this optimization problem has 250 variables and 268 constraints. The optimal solution uses membrane 3 in both stages (see solution ms(3,3) in Figure 3(a)). Figure 4 provides detail of solution ms(3,3). If we have many membranes

in the Membrane Database, it is possible to identify best performing membrane clusters, for separating a gas mixture.

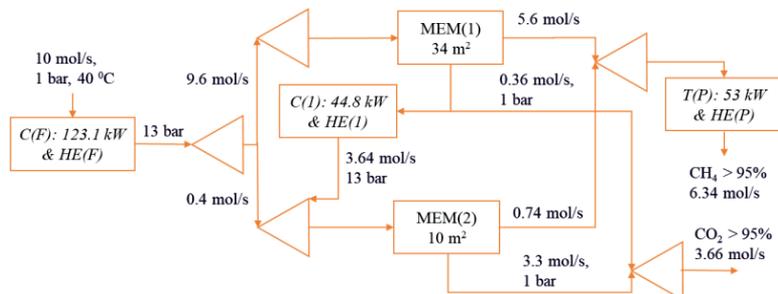

Figure 4: Details of solution ms(3,3); membrane 3 was used in both membrane stages

5. Conclusions

This study develops a mathematical model for multi-stage membrane superstructure. The model is a mixed integer non-linear programming problem that has been implemented in AMPL, and solved using BARON solver. Two case studies, namely post-combustion carbon capture and biogas upgradation were solved using the developed mathematical optimization problem. The optimization results present optimal flows and pressure levels inside the membrane system, and also allow to identify best performing membranes. The proposed approach can identify best performing membrane clusters, based on the membrane permeability and selectivity. This knowledge could be useful to the membrane developers for further improving the performances (selectivity versus permeance) of membranes. The future studies will focus on separating a gas mixture with three components, using different number of membrane stages.

Abstract

Municipal solid waste is a mixture of urban and industrial waste, consisting of biodegradable fractions, such as food waste, waste wood or paper, but also fossil-based fractions, among which plastics, textiles, metals, glass and aluminum. Depending on the type of waste and recovery technique, biogas, biofuels, heat, electricity and metals, are possible value-added products. As both biogenic and fossil carbon are present among waste fractions, the reduction and capture of carbon is crucial in the deployment of sound waste management technologies. There are several physicochemical CO₂ capture technologies, and they have their own benefits, challenges and limitations. Some techniques are in the development phase, and they need to be evaluated for their possible integration within waste-to-energy system. We have developed a waste-to-energy superstructure, including digestion, gasification and incineration as the main waste treatment technologies. The latter is the main contributor of CO₂ emissions. The developed superstructure includes three options for CO₂ capture from flue-gases: amine absorption, temperature swing adsorption and membranes. Amine absorption and membranes are considered for biogas upgradation, whereas pressure swing adsorption and membranes are evaluated for syngas upgradation. This study systematically generates and compares a number of decarbonization options for waste-to-energy system. The formulated optimization problem is a mixed integer linear programming problem, and total annual cost is considered as the performance criterion for generating decarbonizing options. For carbon capture from flue-gases, amine absorption and temperature swing adsorption found to be better options compared to membrane separation

Keywords: Waste-to-Energy; Anaerobic digestion; Gasification; Incineration; CO₂ Capture.

1. Introduction

Waste generation has increased significantly in the past few years. Close to 2 billion tons of municipal solid waste (MSW) are annually produced (worldbank.org). Despite a hierarchy framework to process and treat waste (reduce, reuse, recycle, dispose), about one third is still mismanaged. In that regard, several technologies have been recently developed and are available with different costs and environmental impacts (Brunner and Rechberger, 2015; Lombardi et al., 2015). For instance, frequently overlooked steps, such as waste collection and sorting are now subject of research and optimization, with advanced collection and separation systems established in numerous countries.

Figure 1 shows a simplified flowchart for different waste management pathways, focusing on three major waste categories: MSW, biomass and plastics. MSW has some unsorted biomass and plastics. The biomass contains 12% whey, 55.1% green waste, 18.4% food waste and 14.5% others. Plastics have 74% PET and 26% others (LDPE and HDPE). Anaerobic digestion is used to convert biomass into biogas; the organic material is broken down by bacteria into a methane rich gas in the absence of oxygen. Syngas is produced by gasification of plastics in the presence of air or steam at high temperature, while incineration is a thermal recovery process. If required, both the biomass and plastic fractions of MSW can be thermally valorized. Note that plastics are a major contributor in lower heating value of MSW.

In order to reduce the environmental impact of the waste management, CO₂ can be captured, sequestered and mineralized. Process integration and optimization techniques are useful in identifying sustainable and cost-effective strategies for waste management (Rizwan et al., 2020). Münster and Meibom (2011) have explored the integration of waste into energy system. Puchongkawarin and Mattaraj (2020) developed a decision-making tool for the design of the optimal MSW facilities. Recently, Castro-Amoedo et al. (2021) have studied biowaste valorization along with CO₂ removal from biogas. There are several physicochemical CO₂ capture technologies, such as physical adsorption (pressure swing adsorption, temperature swing adsorption), chemical absorption (amine absorption, ammonia scrubbing, selexol process), membrane separation and cryogenic technology (Tock, 2013). Each technology has its own benefits, challenges and limitations. Some of these technologies (e.g., temperature swing adsorption, membranes) are in the development phase, and they need to be evaluated for their possible integration with waste-to-energy system (Sharma and Maréchal, 2019). Each technology has some key requirements, namely materials, heat and electricity. Further, CO₂ source (biogas, syngas, flue-gases) has specific characteristics, such as composition, temperature, pressure and impurities. Hence, there is a strong need to evaluate and compare the integration of different CO₂ capture technologies within waste-to-energy system.

In this study, we have developed a waste-to-energy superstructure, where digestion (AD), gasification (GAS) and incineration (INC) are the main waste treatment options (i.e. conversion units). The superstructure includes several options for CO₂ capture: amine absorption, temperature swing adsorption and membranes for flue-gases; amine absorption and membranes for biogas upgradation; pressure swing adsorption and membranes for syngas. A mixed integer linear programming (MILP) formulation was implemented in AMPL/GLPK. Eight decarbonizing options/scenarios were systematically generated and compared, using total annual cost as objective function.

2. Waste-to-Energy Superstructure

2.1 Description

Municipal waste generated can be divided into three broad categories: biomass, plastics and MSW. The biomass can be converted into biogas and compost, using an anaerobic digester. The plastics can be recycled as monomers or can be used to produce syngas and char inside a gasifier. Finally, MSW can be combusted inside an incinerator to produce heat (or high-pressure steam). The biogas can be used in a furnace and/or upgraded to natural gas using amine absorption (MEA) and membranes (MEM). Syngas can be upgraded to natural gas using pressure swing adsorption (PSA) and membranes, whereas char can be burned in a furnace for heat recovery. The high-pressure steam from the incinerator is used to generate electricity *via* steam cycle. Amine absorption, temperature

swing adsorption (TSA) and membranes are used for CO₂ capture from flue-gases. With proper infrastructure, heat from waste-to-energy system can be supplied to the district heating networks. The captured CO₂ can be converted into methane using surplus electricity or cheap electricity from the grid. Anaerobic digester is present in Cluster 1 (C1), whereas gasifier and incinerator are considered in Cluster 2 (C2). There is no exchange of mass between clusters, but resources (such as electricity, natural gas and water) can be inter-changed between clusters.

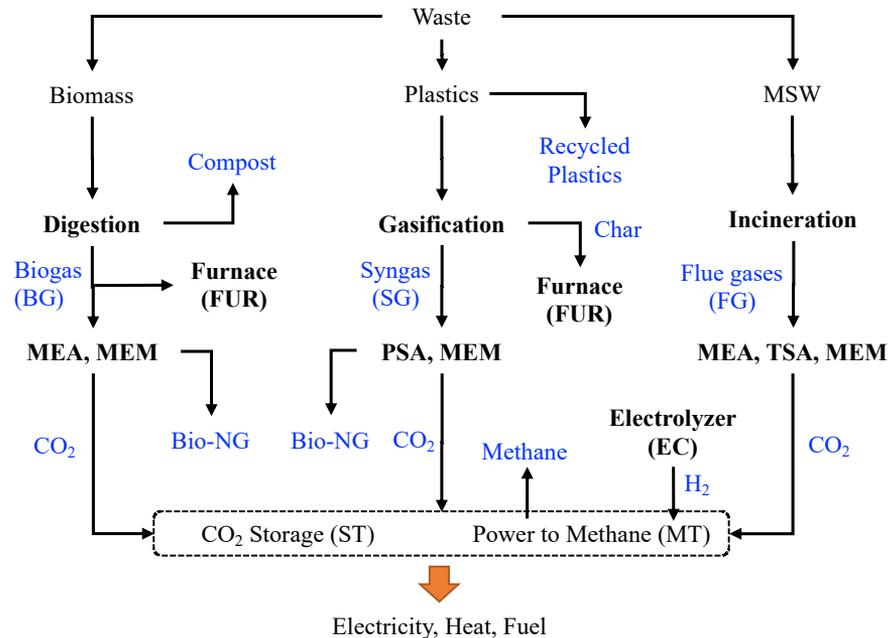

Figure 1: Waste-to-energy superstructure, with carbon capture, utilization and storage.

2.2 Mathematical Formulation

For each technology in the superstructure, linear models were developed that include mass flows, temperature-enthalpy profiles, as well as the use or generation of electricity. Each technology/model also include fixed and variable capital (c_i^{inv1}, c_i^{inv2}) and operating ($c_{i,t}^{op1}, c_{i,t}^{op2}$) costs. Both binary ($\Psi_{i,t}, \Psi_i$) and continuous ($f_{i,t}, f_i$) variables are used. The former accounts for the existence of a unit and the latter for its size. Based on a given objective function, the optimizer defines connections among technologies, levels of use of technologies (material flows) and heat flows. Interested readers are referred to Castro-Amoedo et al. (2021) for more details on the problem formulation.

The optimization problem can be solved for capital cost, operating cost or total annual cost (TAC) (see Eq. 1), in which the first element on the right-hand side concerns operating costs, while the second element pertains to annualized capital expenditures, with i interest rate (0.08) and n assumed lifetime (20 years). Constraints were added to ensure: (i) minimum (f_i^{min}) and maximum (f_i^{max}) units capacities (Eq. 2); (ii) resource consumption (Eq. 3 and 4), with $\dot{m}_{r,i,t}^+$ the reference quantity of resource $\forall r \in R$ needed in each unit; (iii) mass balances (Eq. 5) for each unit; (iv) heat cascade formulation (Eq. 6 and 7) based on Maréchal and Kalitventzeff (1998), where residual heat ($\dot{R}_{t,k}$) is

transferred, according to the 2nd law of thermodynamics, from higher ($k + 1$) to lower temperature level (k). The mathematical formulation is written in AMPL (v20210220) and solved by CPLEX (v12.7.0.0), on a Microsoft Windows v10.0.18363 machine equipped with a 2.4 GHz Intel(R) Xeon (R) 8 core processor and 16 GB RAM.

$$\min TAC (\$/y) = \sum_{t \in T} \sum_{i \in L} (c_{i,t}^{op1} \cdot \psi_{i,t} + c_{i,t}^{op2} \cdot f_{i,t}) \cdot t_t^{op} + \frac{i(1+i)^n}{(1+i)^n - 1} \cdot \sum_{i \in Lu} (c_i^{inv1} \cdot \psi_i + c_i^{inv2} \cdot f_i) \quad \text{Eq. 1}$$

$$f_i^{min} \cdot \psi_{i,t} \leq f_{i,t} \leq f_i^{max} \cdot \psi_{i,t}, \quad \forall i \in L, \quad \forall t \in T \quad \text{Eq. 2}$$

$$\dot{M}_{r,i,t}^+ = f_{i,t} \cdot \dot{m}_{r,i,t}^+, \quad \forall r \in R, \quad \forall i \in L, \quad \forall t \in T \quad \text{Eq. 3}$$

$$\dot{M}_{r,i,t}^- = f_{i,t} \cdot \dot{m}_{r,i,t}^-, \quad \forall r \in R, \quad \forall i \in L, \quad \forall t \in T \quad \text{Eq. 4}$$

$$\sum_{i \in L} \dot{M}_{r,i,t}^- = \sum_{i \in L} \dot{M}_{r,i,t}^+, \quad \forall r \in R, \quad \forall t \in T \quad \text{Eq. 5}$$

$$\sum_{i \in L} \dot{Q}_{i,t,k} \cdot f_{i,t} + \dot{R}_{t,k+1} - \dot{R}_{t,k} = 0, \quad \forall t \in T, \quad \forall k \in K, \text{ with } T_{k+1} \geq T_k, \quad \text{Eq. 6}$$

$$\dot{R}_{t,k} \geq 0, \quad \dot{R}_{t,k_{max}+1} = \dot{R}_{t,1} = 0, \quad \forall t \in T \quad \text{Eq. 7}$$

3. Waste-to-Energy: A Case Study

For this case study, the availabilities of waste are: biomass (BM) = 1.89 t/h, plastics (PL) = 0.25 t/h and MSW = 15 t/h. Maximum heat demands of districts heating networks (DHN) are 500 kW and 15,000 kW respectively for clusters C1 and C2. For DHN, water supply and return temperatures are 60 and 55 °C, respectively. The selling price of biogas/syngas is 15.5 \$/MWh, and selling price of bio-SNG is 30.9 \$/MWh. There is a carbon tax (99 \$/t-CO₂) on CO₂ release into environment. If captured CO₂ is converted into methane, there is carbon credit of 99 \$/t-CO₂. The storage of CO₂ costs 20.6 \$/t-CO₂, without any carbon tax or credit. We have generated several scenarios as shown in Table 1, to analyze different decarbonizing strategies. Scenarios S1, S3, S5 and S7 consider CO₂ storage, whereas scenarios S2, S4, S6 and S8 convert captured CO₂ into methane.

Table 1: Decarbonizing options/scenarios for waste-to-energy system

	Biogas CO ₂ capture	Syngas CO ₂ capture	Flue-gases CO ₂ capture			CO ₂ Storage	CO ₂ to Methane
			MEA	MEM	TSA		
S1	√	√				√	
S2	√	√					√
S3	√	√	√			√	
S4	√	√	√				√
S5	√	√		√		√	
S6	√	√		√			√
S7	√	√			√	√	
S8	√	√			√		√

Table 2 presents results for all decarbonizing scenarios. The capital cost (ACC) is calculated yearly, whereas operating cost (MOC) is evaluated on monthly basis. These results can virtually be divided into several parts (*via* horizontal lines): economics and

waste flows, heat and electricity generation, anaerobic digestion and biogas upgradation, plastics gasification and syngas upgradation, CO₂ capture from flue-gases using amine, membrane and TSA processes, and methanation (CO₂ to methane). The flue-gases from incinerator contain 9,461 kg/h CO₂. The amounts of captured CO₂ by MEA (8,431 kg/h) and TSA (8,516 kg/h) processes are comparable, whereas only 6,445 kg/h CO₂ is captured by MEM process.

Table 2: Optimization results for different scenarios (SN: steam network, PV: photovoltaics, Env: environment, ELE: electricity)

	S1	S2	S3	S4	S5	S6	S7	S8

C2 TSA-CO ₂ -ST, kg/h							8516	
C2 TSA-CO ₂ -MT, kg/h								8516
C1,2 Total CO ₂ -MT, kg/h		888		9319		7333		9404
C1,2 MT-CH ₄ , kW		4482		47065		37034		47495
C1,2 EC-H ₂ , kg/h		161		1695		1333		1710
C1,2 EC-O ₂ , kg/h		645		6777		5333		6839
C1,2 ELE-EC, kW		6722		70581		55537		71225
C1,2 ELE-Market, kW	14860	8348	14828	-52891	12634	-40734	14363	-54208

For scenarios S4, S6 and S8, the electricity produced by the waste-to-energy system is not enough for the methanation, due to large quantity of captured CO₂. Hence, electricity is imported from the grid, and these scenarios are not profitable (negative MOC means profit). The flue-gases from incinerator are the main contributor of CO₂ emissions. We did not compare the decarbonizing options based on capital cost due to large variabilities in the cost estimation. MEA and TSA are heat driven processes, whereas MEM process requires electricity for compression. Further, MEA and TSA processes have comparable CO₂ product quality, which is better than MEM process. Scenarios S3 (MEA, AOC = -984,000 \$/m) and S7 (TSA, AOC = -932,000 \$/m) are more profitable than scenario S5 (MEM, AOC = -614,000 \$/m). More CO₂ has been captured in scenarios S3 and S7, compared to scenario S5. Further, scenario S5 (12,634 kW) exports less electricity to the grid compared to scenarios S3 (14,828 kW) and S7 (14,363 kW). Hence, MEA and TSA are better choices for decarbonizing the waste-to-energy sector.

4. Conclusions

This study presents a waste-to-energy superstructure, comprising digestion, gasification and incineration as the main treatment options. Amine absorption, membrane separation and pressure and temperature swing adsorptions were considered for carbon capture along with methanation for converting captured CO₂ into methane. A mixed integer linear programming problem was formulated for waste-to-energy system. In total, eight decarbonizing options/scenarios were compared, and appropriate cost, credit and tax were used for CO₂ storage, CO₂ conversion to CH₄, and CO₂ emissions to the environment, respectively. For carbon capture from flue-gases, amine absorption and temperature swing adsorption outperformed membrane process, based on the operating cost, amount of captured CO₂ and quality of the CO₂ product.

Process Integration and Techno-Economic Assessment of a Green Biorefinery Demonstration Scale Platform for Leaf Protein Production

Thalles A. Andrade, Morten Ambye-Jensen

Aarhus University, Department of Biological and Chemical Engineering, 8200 Aarhus N, Denmark

Abstract

Green biorefinery corresponds to sustainable processing of green biomass, such as grasses and legumes with a high content of leaf protein and soluble sugars to produce multiple products. The extraction of proteins from leaves represents an attractive alternative solution to the high European dependency on soy imports. A demonstration facility for R&D in Aarhus University Foulum, Denmark, optimizes the separation of protein-rich concentrates from green biomass. Besides the leaf protein concentrate, the facility also produces a fibrous pulp that can be used for ruminant feed, biomaterials, or bioenergy, and a nutrient-rich residual juice, that can be used for biogas production and fertilizer.

The green biorefinery was simulated using Aspen Plus V12 for the processing of grass-clover. The process included the maceration of the harvested biomass; mechanical fractionation into a fiber-rich press cake and a green juice; heat treatment of the green juice for precipitation of soluble leaf proteins; centrifugation and drying of the precipitated protein; and anaerobic digestion of the residual brown juice for biogas production. The simulation was validated based on data obtained from the demonstration plant, resulting in an overall yield of 40 % crude protein in the protein concentrate. The feasibility of the implementation of the biorefinery on a commercial scale was calculated using Aspen Process Economic Analyzer.

Keywords: green biorefinery; leaf protein concentrate; process modeling; techno-economic assessment.

1. Introduction

The increasing world population and increased prosperity lead to increased demands for nutritious food. Simultaneously, the climate changes caused by greenhouse gas emissions and the ecological problems of nutrient leaching, pesticide use, and soil carbon depletion caused by intensive agricultural practices call for the development of alternative and more sustainable ways to produce food, feed, biobased materials, fuels, and energy. This can be done through integrated biorefineries. Perennial green biomass also referred to as forage crops, stands out as a promising feedstock with low environmental impact and is suitable for producing both protein-rich food and feed, biochemicals, and bioenergy (Manevski et al., 2018, Njakou Djomo et al., 2020).

Green biorefining stimulates and increases the synergy of the local agricultural sector (Corona et al., 2018a). Else, the production of leaf protein from forages decreases the dependency on protein-rich feed imports, especially soy, used for monogastric animals. According to FAO, soybean meal imports in Europe increased from 19.1 million tonnes in 1990 to around 26.2 million tonnes in 2019. The majority of the imported protein feeds

are used in pig and poultry meat production. Denmark is the fourth biggest pig producer in the EU, after Spain, Germany, and France, and imports around one million tonnes of protein for feed per year (EUROSTAT, 2021). This makes the biorefining of green forages an attractive local protein production in Denmark.

Besides being rich in protein, forage crops (that includes grass, clover, and lucerne) are a source of fibers, soluble sugars, amino acids, lactic acid, biogas, among other products. This multiple-product green biorefinery system allows developing greener alternatives to conventional products, employing different routes, and integrating different technologies chosen according to the target products. In this scenario, the green biorefinery is presented in a simple form producing a feed protein concentrate, a fibrous pulp, and biogas from the residual liquid. The process was simulated in Aspen Plus V12, based on the results obtained in the green biorefinery demonstration platform located at the Aarhus University Foulum research center, Denmark (Corona et al., 2018; Feng et al., 2021). The anaerobic digester was simulated based on studies previously developed by Rajendran et al. (2014) and Llano et al. (2021). Techno-economic assessment of the biorefinery was carried out at Aspen Process Economic Analyzer V12.

2. Materials and Methods

2.1. Process description

Grass-clover was chosen as the feedstock used in the green biorefinery. The crop is named ForageMax 45 and is a mixture of tall fescue, ryegrass, and red- and white clovers. The grass-clover mixture was harvested and processed at AU Foulum research center. The biomass is harvested whole and directly collected using a GrassTech GT140 harvester and processing generally starts within one hour after the forage is harvested. At the demonstration plant, the grass-clover is first shredded in a stationary cutter to a theoretical length of 4-5 cm. Then, crushed leaves are sent to a CirTech P25 Twin screw press where the solid and liquid streams are mechanically separated. The pressed fiber pulp was set to be sold as ruminants feeding. The pressed green juice is filtered in a 50 μm -filter bowl screen and pumped through a two-step heat exchanger, where the first step recovers heat from the residual liquid (brown juice) and heats the green juice to around 65°C and the second adds additional heat to reach 85 °C. The protein precipitates by heat and solids are separated in a decanter centrifuge producing a protein paste and the residual brown juice. The protein paste, that contains approximately 47 % of dry matter content, is sent to a vacuum drier to reach a dry matter content greater than 95 %. Dried LPC was set to be commercialized as monogastric feeding. Meanwhile, the brown juice was established to be fermented by anaerobic digestion in a biogas plant, due to its high content of easily digested organic compounds. The biogas and liquid digestate can increase the process's profitability. Table 1 presents the composition of the fractions that were used in the simulation.

2.2. Process modeling and simulation

The integrated process was simulated in Aspen Plus V12. The thermodynamic model NRTL was chosen because it correlates and calculates the mole fractions and activity coefficients of different compounds and facilitates the liquid and the gas phase in the biogas production (Rajendran et al., 2014). The feed flow rate was 40 tonnes per hour. Due to its complexity and variable composition, the biomass was defined as a nonconventional solid. In this case, the density and enthalpy of the grass-clover were estimated based on the proximate, ultimate, and sulfate analysis. Gates–Gaudin–Schuhman model was used for the particle size distribution, assuming a max grass length of 30 cm. The maximum particle length was reduced to 5 cm in the cutter. The screw

press was modeled using two stages: an RYield reactor to convert the shredded nonconventional biomass into the biomass composition shown in Table 1, and a separator to split the fiber and green juice streams.

Table 1. Chemical composition (%DM) of the fractions in the grass-clover biorefinery.

Component	Biomass	Fiber	GJ	BJ	LPC
Protein	21.6	17.8	29.2	6.6	47.0
Carbohydrates	15.0	6.7	31.7	50.6	16.9
Hemicellulose	16.7	21.2	7.6	8.9	6.7
Cellulose	19.6	28.7	1.3	0.1	2.2
Lignin	9.0	13.3	0.3	0.3	0.4
Ash	13.1	8.2	23.0	31.3	16.4
Others	5.0	4.1	6.8	2.2	10.4
DM content (%)	18.0	32.8	9.4	4.7	>95.0

The kinetic model in the anaerobic digester was evaluated at thermophilic conditions at 55 °C since the operation in the range of 50 to 65 °C is the best regime for maximizing biogas production (Llano et al., 2021). The anaerobic digester was divided into two steps in the simulation. First, a stoichiometric reactor was used to simulate the hydrolysis reactions based on the extent of the reaction. Hydrolysis of cellulose, hemicellulose, sugars, and lipids are modeled in this reactor. Then, a CSTR was used where the amino acids degradation and the acidogenic, acetogenic, and methanogenic reactions were modeled on a kinetic basis. A residence time of 15 days was defined. The chemical reactions, as well as the fractional conversions and kinetic constants, were found in the literature (Llano et al., 2021; Rajendran et al., 2014). The stream from the digester was cooled down in a flash column to remove water, improving the biogas composition.

2.3. Techno-economic assessment

The techno-economic evaluation was performed in Aspen Process Economic Analyzer V12 based on the process simulated in Aspen Plus. Capital expenses (CAPEX) are determined as a factor of the total purchase of equipment. It includes direct (equipment, installation, instrumentation) and indirect (engineering, construction, contingency) costs, and working capital. Equipment costs were either estimated from the designed process equipment or obtained from the market quotation. Fresh grass-clover is seasonal and only available to harvest between May and October in Denmark. Therefore, the biorefinery should operate during these months, in a total of 4200 hours per year of operation. All operating expenses (OPEX) are based on Danish prices. This includes the raw materials, utilities, and labor costs, as well as the taxes rate and product sales. Electricity, cooling water, and steam are the process utilities required. The LPC selling price was based on the price of soybean meal. Three different prices were compared: conventional (330 USD/tonne), non-GMO (535 USD/tonne), and organic (840 USD/tonne).

3. Results and Discussion

The integrated green biorefinery flowsheet simulated in Aspen Plus is shown in Figure 1. Table 2 presents an overview of the main streams and compares the simulated and expected production. The simulated production per tonne of biomass is validated by the mass streams from Corona et al. (2018b). The volume of biogas estimated in the simulation is higher than the volume estimated by the expected results. This is because the latter estimates the volume of the upgraded biogas, that is the methane potential

produced. Conversely, the simulated results only consider the biogas production before the upgrade, i.e., the biogas stream contains other components, essentially carbon dioxide.

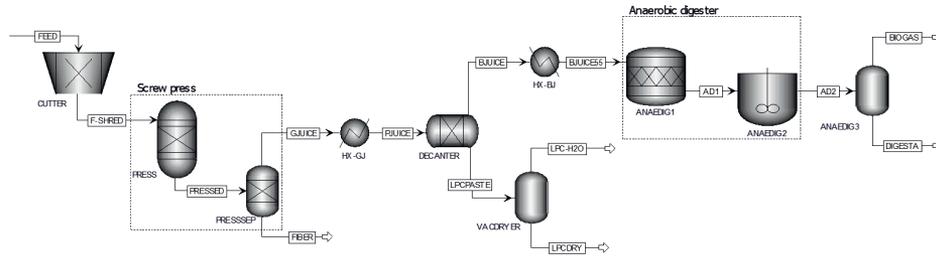

Figure 1: Integrated green biorefinery process diagram to produce feed protein and biogas.

The composition profile of the brown juice, biogas, and liquid digestate fractions, in mole fraction and excluding the water content is shown in Table 3. The macromolecules content was consumed during the anaerobic digestion, leading to the production of components such as ammonia, CO₂, and methane. Methane and CO₂ contents obtained in the biogas phase agree with the results expected in the literature (Penteado et al., 2019).

Table 2. Overview of the main process streams in the integrated green biorefinery.

	Biomass	Fiber	GJ	BJ	LPC	Biogas
Flow rate (tonne/h)	40.0	14.7	25.3	22.5	1.4	0.29
DM content (%)	18.0	32.8	9.4	4.7	98.1	0.0
Simulated input and product (in kg) per tonne (DM) of biomass	1000	668.1	331.9	145.9	184.6	38.43*
Expected input and product (in kg) per tonne (DM) of biomass	1000	668.0	332.0	146.0	186.0	9.15*

*Unit: m³

Table 3. Mole fractions of brown juice, biogas, and digestate excluding the water content.

Component	BJ	Biogas	Digestate
Carbohydrates, lipids	0.798	0.000	0.024
Cellulose, hemicellulose, lignin	0.202	0.000	0.023
Ammonia	0.000	0.001	0.048
Carbon dioxide	0.000	0.405	0.461
Methane	0.000	0.593	0.159
Others	0.000	0.001	0.285

The capital and operating expenses summary, as well as the total product sales when LPC is commercialized using the conventional soybean meal price, are reported in Table 4. The cost of the raw material corresponded to around three-quarters of the total operating cost. In this scenario, the total product sales are smaller than the total operating cost, which means that the expenses are greater than selling profits. Therefore, under those conditions, the implementation of the green biorefinery is unprofitable.

Sensitivity analysis investigated the feasibility of implementing the integrated grass-clover biorefinery to produce LPC, biogas, and fiber. Besides the selling price of the protein, the analysis evaluated the rate of return in case the biomass was estimated cheaper, the CAPEX was reduced and the biorefinery operated the whole year. Figures 2 and 3 presents the variation of the profitability index as a function of the LPC price and

fluctuation on the CAPEX. Figure 3 reports the index when the biomass cost was estimated 20 % cheaper than the cost reported.

Table 4. Techno-economic assessment of the integrated green biorefinery.

CAPEX	Mio. USD	OPEX	Mio. USD/year
Total purchase of equipment	1.96	Raw material	4.72
Direct costs	4.15	Utilities	0.11
Indirect costs	3.09	Labor and maintenance	0.45
Fixed capital investment	7.24	Total operating cost	6.05
Total project capital cost	9.33	Total product sales	5.25

The profitability index shows the relative profitability of the project, showing the present value of the benefits relative to the costs. An index greater than one suggests that the project is profitable. Index lower than one was observed in all the cases when LPC was sold using the conventional price. In the case of selling the LPC at non-GMO prices, the process would be profitable only if the biorefinery operates throughout the whole year, with a biomass price at least 20 % cheaper than the estimated (Figure 3b). Conversely, selling the LPC at the organic price for soybean meals resulted in a profitability index greater than one in different scenarios (Figures 2b, 3a, and 3b).

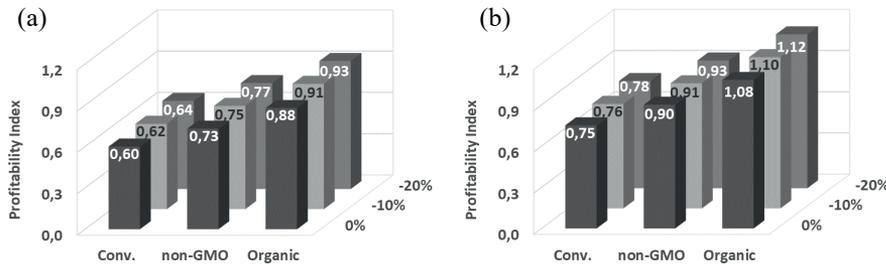

Figure 2: Profitability index of the biorefinery operating during (a) 6 and (b) 12 months per year.

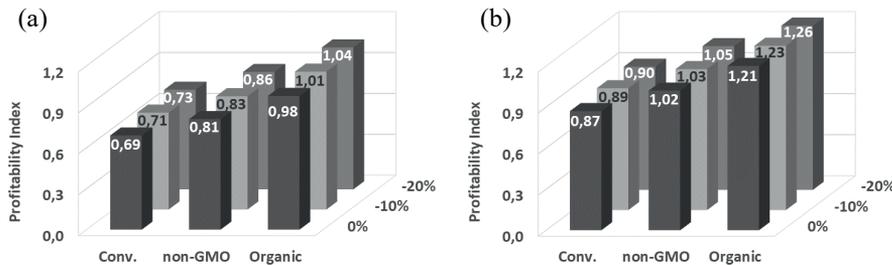

Figure 3: Profitability index of the biorefinery operating during (a) 6 and (b) 12 months per year, at a 20 % cheaper biomass cost.

In the case of annual production, the biorefinery payout return varied between 5 and 6 years, while this return could be reduced to around 4 years if the biomass was cheaper than the estimated value. However, those scenarios are not viable in a Danish environment, where the annual operation is not realistic. To obtain yearly production, the biorefinery needs to integrate the processing of biomasses that are available during winter. This could be grass clover silage, but then the LPC product would be replaced by amino acids, as the soluble protein degrades during ensiling, and the processing should be

adapted to recover amino acids, using membrane filtration instead of precipitation and centrifugation. This scenario was not carried out within this study. Integration of other routes in the biorefinery to obtain higher-value products is also strongly recommended. Upgraded biogas, for example, could increase the total product sales, since biomethane is more expensive than non-upgraded biogas. The same could be obtained separating the white protein, used for human consumption, from the green LPC. The use of fiber and brown juice in other applications also needs further investigation. A complete techno-economic assessment could indicate the best scenario to be implemented.

4. Conclusions

An integrated biorefinery was simulated using data from a demonstration-scale platform. The techno-economic assessment suggested that the process could be profitable for 11 out of 36 scenarios evaluated. Payout return of around 10 years is expected for an organic LPC. Moreover, the cost of biomass has a major effect on profitability. Whole year production would be a good way of increasing the profit, reducing the return time to 5-6 years. However, the process needs to be adapted to other feedstock with different product opportunities. It could also be placed in countries where a continuous annual operation on grasses is viable. The integration of different routes is further recommended.

Abstract

Calcium-looping (CaL) is a promising post-combustion CO₂ capturing technology, showing high compatibility with the cement industry. Nevertheless, this technology is still under development, and its implementation still leads to higher operating costs. Aiming cost reduction, the influence of using alternative fuels, commonly used in the kiln of cement plants, in the CaL calciner was studied in terms of key performance indicators, such as the amount of fuel needed, the carbonator's heat duty, the air separation unit (ASU) energy consumptions, and the amount of CO₂ captured in the process. Thus, a CaL process was modeled using Aspen Plus, incorporating a carbonator model developed using Python. Different random compositions of petroleum coke, tire chip, waste-derived fuels, olive pomace, dangerous liquid residues, and cork residues were studied. It was concluded that the use of petroleum coke leads to lower fuel consumption and ASU consumption due to its higher heating value. However, the alternative fuels studied have advantages in terms of CO₂ capture efficiencies and energy produced in the carbonator due to lower sulfur contents. Therefore, the sorbent flowrates would have to increase to obtain the same capture efficiency using petroleum coke, which would result in a higher process cost. Alternative fuels are promising in CaL and should be a topic for further studies.

Keywords: Calcium-looping, cement, CO₂ capture, alternative fuels, process modeling

1. Introduction

The cement industry is one of the primary industrial sources of CO₂ emissions, responsible for 7 % of the anthropogenic emissions (IEA, 2018). Carbon capture utilization and storage (CCUS) technologies emerge as a strategy to achieve carbon neutrality by 2050, according to the objectives defined in the 13th United Nations Sustainable Goals. A promising CCUS technology is the calcium-looping (CaL) process. This process presents a high synergy with the cement industry since a Ca-based sorbent, limestone, is also a raw material for cement production. This process comprehends two circulating fluidized bed (CFB) reactors, a calciner, and a carbonator. The kiln flue gas is fed to the carbonator, in which the CO₂ is captured, reacting with CaO to form CaCO₃. The carbonation reaction is exothermic and the heat released is used to produce electrical energy through a steam cycle. The CaCO₃ formed in the carbonator enters the calciner to be regenerated to CaO. As the calcination is endothermic, energy must be supplied to the calciner through oxyfuel combustion. The most common fuel used in CaL pilot-plants is still coal (Hornberger et al., 2017; Arias et al., 2018). However, there is an effort to replace it with greener fuels, such as biomass (Alonso et al., 2014). The use of alternative fuels (AFs) leads to the maintenance of fossil fuel reserves and is also reported to enable cost

reduction in cement plants (Chatziaras et al., 2014). Thus, they are partially replacing fossil fuels to fulfill the kiln's energy requirements. The calcium looping process must follow as the cement industry evolves towards using higher percentages of alternative fuels. This work aims to assess the influence of these fuels on CaL performance and evaluate them as an alternative to fossil fuels. The alternative fuels studied were the ones usually consumed in Portuguese cement plants.

2. Model development

2.1. The experimental procedure

An experimental laboratory-scale fluidized bed reactor (FBR) system with an electric oven was used to obtain the multicyclic sorbent deactivation curve of a CaO-based sorbent. The sorbent used was a Portuguese limestone provided by an industrial partner with particle sizes of 250-355 μm . The carbonation and calcination were conducted at atmospheric pressure and 700 °C and 970 °C, respectively. The FBR is fed with synthetic mixtures (at 20 °C, 1 bar, 5 mL/min) of 25 mol% CO₂ and 75 mol% air during carbonation and 80 mol% CO₂ and 20 mol% air during calcination. A limestone sample with approximately 5 g was loaded into the reactor for each experiment. Four deactivation curves were obtained, and the average sorbent conversion was considered.

2.2. The process model

The CaL process model was developed using the commercial software Aspen Plus. A diagram of the process is presented in Figure 1. The calciner ($T = 970$ °C, $p = 1$ atm) was modeled by minimizing the free energy of Gibbs. 100 combinations of 6 different fuels (petroleum coke, waste-derived fuels, tire chip, olive pomace, dangerous liquid residues (DLR), and cork residues) with different random compositions were provided to the calciner to fulfill its energy requirements. The proximate and ultimate analysis of each of these fuels is shown in Table 1. These analyses were provided by an industrial partner and are presented on a dry basis. The sulfur present in all the fuel samples was considered organic. The fuels were burnt in oxyfuel conditions, and the amount of fuel needed was estimated to maintain the calciner's temperature at 970 °C. A 4 mol% O₂ excess was considered in the calciner. A fresh sorbent stream was added to the calciner, and a sorbent purge was withdrawn to reach a steady-state with an average sorbent conversion. High-efficiency cyclones were placed at the exit of both the calciner and the carbonator to separate the CO₂ concentrated stream and the CO₂ free flue gas from the sorbent stream, respectively. They had a separation efficiency higher than 99 wt% and a pressure drop of approximately 0.01 atm. The composition of the flue gas being treated in the carbonator was based on the annual emissions of a Portuguese cement plant (Cimpor, 2019). Currently, the model is customized to describe a pilot-plant unit; therefore, the process was designed to treat a hundredth part of the actual emissions. A heat exchanger between the CO₂ concentrated stream leaving the calciner and the sorbent stream leaving the carbonator was considered in the model, as suggested by Martínez et al. (2013). This heat integration leads to a reduction in the calciner's energy requirements, decreasing fuel consumption. The CO₂ concentrated stream was compressed with moisture removal.

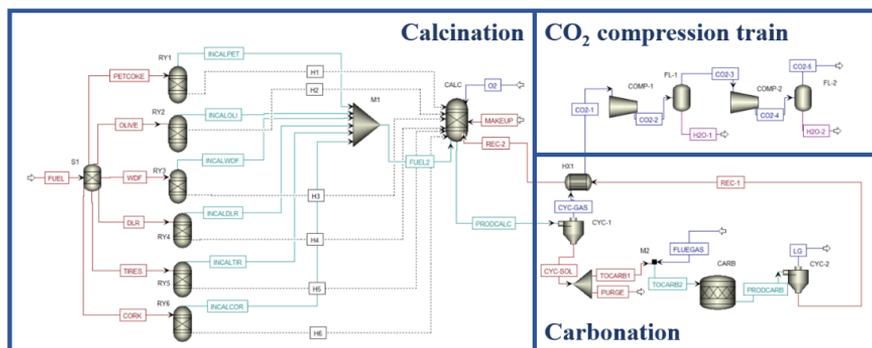

Figure 1. Diagram of the CaL process model developed using Aspen Plus. Solid streams are presented in red, gas streams in blue, liquid ones in pink and gas-solid streams in green.

Table 1. Proximate and ultimate analysis of fuel samples.

Fuel analyses		Petroleum coke	Waste derived fuels	Tire chip	Olive pomace	Dangerous liquid residues	Cork residues
Proximate	Moisture	9.0	26.9	1.4	12.1	22.0	12.1
	Fixed Carbon	87.2	66.2	21.3	90.9	100.0	94.0
	Volatiles	12.0	0.0	63.1	0.0	0.0	0.0
	Ash	0.8	33.8	15.6	9.1	0.0	6.0
Ultimate	Ash	0.80	33.80	15.58	9.10	0.0	6.00
	C	85.80	46.90	71.41	49.80	63.20	51.40
	H	3.92	5.56	4.55	5.83	9.47	5.91
	N	0.00	0.85	0.58	1.59	2.35	0.00
	O	0.00	0.54	0.01	0.00	0.00	0.00
	S	6.16	0.58	1.59	0.16	0.57	0.00
O	3.34	11.77	6.28	33.52	24.41	36.69	

2.3. The carbonator model

The carbonator model followed the work developed by Romano (2012). The model was implemented in Python and returned the CO₂ capture efficiency. This value was inserted on the process model, yielding ash and sulfur flowrates, which entered the carbonator model as an input. This process was repeated until convergence was reached. The deactivation over multiple carbonation/calcination cycles was considered based on the semi-empirical law proposed by Grasa and Abanades (2006). Based on the empirical curves, the deactivation constant, k , and residual sorbent conversion, X_r , were estimated at 0.086 and 4.78, respectively. The experimental fitting of the deactivation is represented in Figure 2. Since there is no combustion occurring in the laboratory calciner, the experiments were performed in the absence of SO₂. The deactivation caused by the presence of sulfur was assumed to follow the correlation proposed by Romano (2012). In the carbonator, the sorbent recycling flowrate to CO₂ flue gas flowrate ratio and the fresh sorbent flowrate to CO₂ flue gas flowrate ratio were set to 6 and 0.5, respectively. The CFB hydrodynamics was considered by applying the model by Kunii and Levenspiel (2000), as proposed by Romano (2012). A reactor height of 40 m and a mean superficial velocity of 5 m/s were considered.

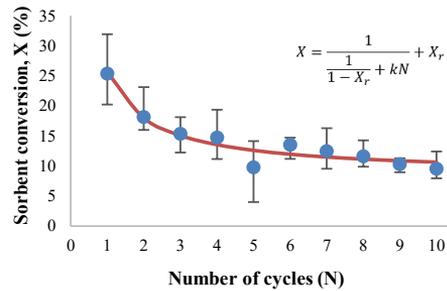

Figure 2. Comparison between model and experimental multicyclic sorbent deactivation. The model deactivation constant, k , and residual sorbent conversion, X_r , were estimated at 0.086 and 4.78, respectively. The experimental data was obtained for a Portuguese limestone (250-355 μm).

3. Results

3.1. Amount of fuel needed

The influence of the fuel mixture composition on the amount of fuel needed in the calciner is presented in Figure 3. The increase of the petroleum coke fraction in the fuel mix corresponds to a decrease in the amount of fuel needed in the calciner. On the other hand, an increase in the waste-derived fuel (WDF) and olive pomace contents results, in general, in an increase in the fuel requirements in the calciner. This increase is explained by the carbon content of the fuels. A higher carbon content results in a higher calorific value, thus in a lower amount of fuel needed in the calciner. Petroleum coke is the fuel with higher C content, and both WDF and olive pomace have low carbon contents.

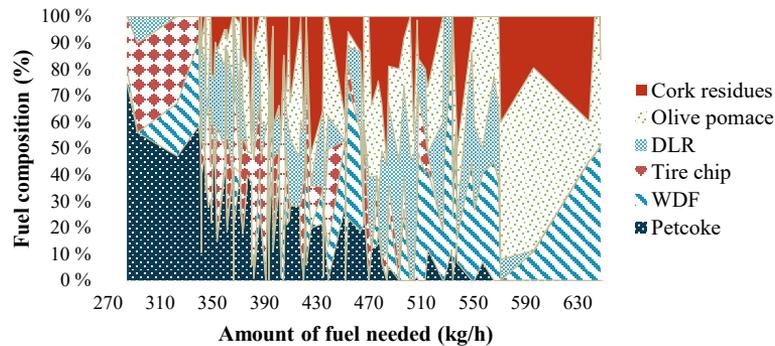

Figure 3. Variation in the mass flowrate of total fuel needed in the calciner as a function of fuel composition variations.

3.2. Air separation unit energy consumptions

The oxygen needs in the calciner and thus the air separation unit electric consumptions decrease with the increased use of petroleum coke, as represented in Figure 4. This decrease was expected, since a higher content of petroleum coke results in lower fuel consumption, thus a lower amount of oxygen required for the combustion reactions. It is possible to see the reverse trend when using higher amounts of olive pomace.

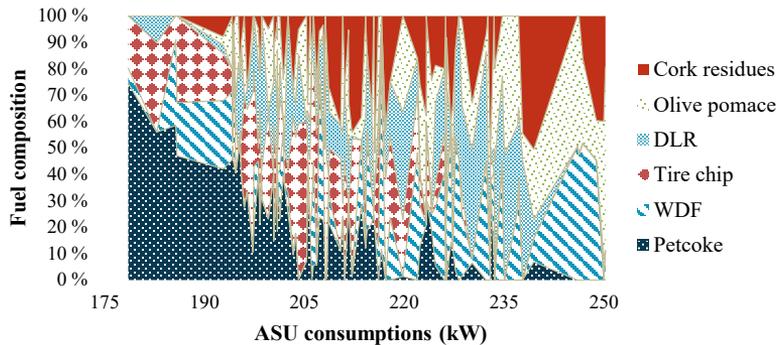

Figure 4. Variation of the air separation unit (ASU) consumptions as a function of fuel composition variations.

3.3. CO₂ capture in the carbonator

As depicted in Figure 5, the increase of the petroleum coke content results in a reduction of the CO₂ capture efficiency. This reduction is related to the high sulfur content of this fuel, as can be seen in Figure 2. Therefore, for presenting the same capture efficiency as the one obtained using the AFs studied, the recycling sorbent stream flowrate would have to increase, thus increasing process costs.

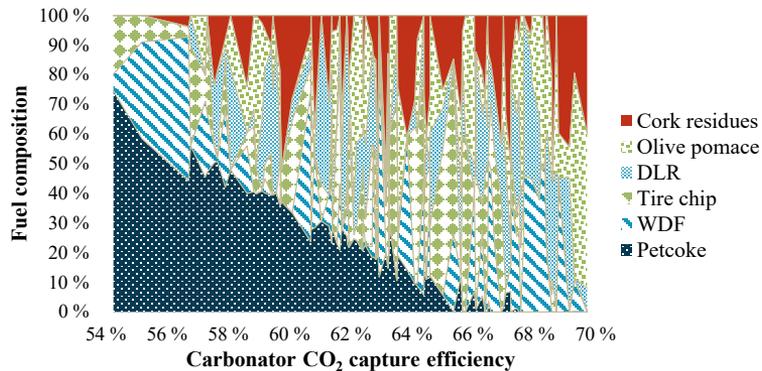

Figure 5. Variation of the carbonator CO₂ capture efficiency as a function of fuel composition variations.

3.4. Carbonator's heat duty

The carbonation reaction is exothermic, thus releasing energy. The influence of each of the fuels in the energy released in the carbonator is presented in Figure 6. It is possible to conclude that the petroleum coke content also significantly impacts the energy released in the carbonator. With the increase of this content, the energy released decreases because of the lower CO₂ capture efficiencies obtained using this fuel. The lower captures mean the extent of the reaction is lower, thus producing less energy.

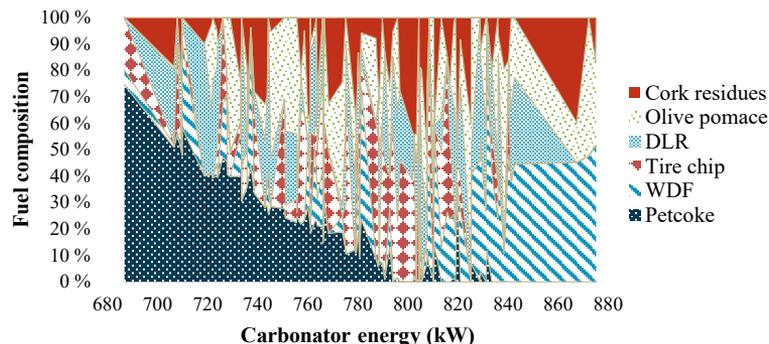

Figure 6. Variation of the energy released in the carbonator as a function of fuel composition variations.

4. Conclusions

The use of fuels commonly consumed in the cement plant, including AFs, was evaluated in terms of total fuel required, ASU electric consumptions, CO₂ capture in the carbonator, and heat released during carbonation. It was concluded that petroleum coke had the highest heating value, thus requiring lower flowrates to fulfill the calciner's energy requirements. Despite the higher AFs' flowrates required, they may reduce fuel costs since their market values are lower than fossil fuels. However, the higher amounts of fuel also lead to higher O₂ usage and, therefore, ASU's electric energy consumption, which corresponds to higher process costs. On the other hand, petroleum coke has a high sulfur content, resulting in lower carbonator CO₂ capture for equal sorbent flowrates; therefore, higher sorbent flowrate and, thus, higher costs are required to keep CO₂ capture efficiency. Consequently, it can be concluded that these AFs are a promising alternative for the CaL process and should be a topic for further studies, including a global comparative economic analysis, where the carbon tax savings due to the negative CO₂ emissions of AFs is considered.

Abstract

The paper presents a systems integration approach for the computational strain design workflow for the identification of reaction eliminations that reshape network connectivity in a way that both biomass production and revenue are simultaneously maximized by utilizing a bilevel optimization framework. The research expands the outer problem of the bilevel approach that is established in the literature with the use of a superstructure scheme that addresses several design options simultaneously with the several options to select the pathways. The superstructure scheme is laid out to reduce model and optimization complexities. We assess the effect of the new optimization goal, for varying number of metabolic interventions to the downstream separation network and the bioprocess revenue. We then compare the enriched model to the previous analysis, which only aims to maximize the production of a target metabolite. To showcase the functionality and effectiveness of the developed model we applied the workflow to a muconic acid producing strain of *S. cerevisiae* (iMM904 GEM) that includes the necessary heterologous pathways. Overall, this computational framework could be an important step to bridge the gap between strain design and process engineering.

Keywords: Systems metabolic engineering, superstructure optimization, bilevel programming, OptKnock, DBTL

1. Background and Motivation

Metabolic engineering has played a central role in the production of chemicals and materials but it can be time consuming and costly to produce strains suitable for industrial production (Choi et al., 2019). Still, recent advances in metabolic pathway reconstruction and in silico modelling have enabled the development of microbial strains suitable for efficient cell-factories. Directed evolution, for instance, has assisted in the expansion of the possible spectrum of products that can be derived from host strains. It involves a cyclic process that aims to reveal functional gene variants through an alternation between gene diversification and screening (Arnold, 2018). It has also made the manufacturing of enzymes and biofuels more environmentally friendly, by shifting the input from petroleum-based to renewable sources such as lignocellulosic.

Emerging infrastructures of Design-Build-Test-Learn (DBTL) paradigms hold a tremendous promise to innovate with new products and novel integrated processes that can be intensified for the highest efficiency. DBTL is a cycle that starts with the Design of the strains based on the industrial specifications through a computational workflow. The next steps are Build, where the strains are manufactured with protein engineering techniques, and then Test with omics analysis and high throughput measurements.

Finally, the Learn step derives insightful solutions, by using data management and life cycle analysis, that are fed back into the first step.

The current DBTL cycle approach in biofoundries and biorefineries, however, remains a disconnected sequence of tasks with an undisclosed potential to integrate. Specifically, the genetic modifications of strains are usually driven by the overproduction of target metabolites without considering downstream processing which can account for up to 80% of the overall bio-production cost (Kiss et al., 2015). The explosion of data masks poor interactions between upstream science and engineering. The Design step typically produces hundreds, thousands, or even millions of candidates, but Build stages proceed with a few choices, often made by heuristics and intuition. The selected choices hold no guarantees for quality and all inheritance and knowledge generated by the in-silico work is lost and unexplored. For instance, by utilizing convex analysis models on Genome Scale Models (GSM) the behavior of cells can be explained and predicted. But, still these models fail to incorporate the downstream processing steps that are ahead. Additionally, the connection between the Design and Learn accounts for the weakest of all interactions in the DBTL cycle. Generally, the Design deploys over-simplified formulations for mass and balances and neglects important aspects of process engineering. Lastly, yields in pilot or industrial scale installations dramatically inferior to initial promises. As such, there is an instrumental potential for the synthesis of in-silico methods meant to optimize the metabolism of organisms and the design of downstream processes.

2. Methodology

To address the issues raised we propose to expand the mathematical formulation of a metabolic reconstruction tool (OptKnock) by including the downstream processing step in the form of a superstructure. In this part, we will present the extension of the model, then explain the mathematical formulation utilized and present the enlisted superstructure.

2.1. Model Extension

The problem faced in this work is the following. Given the target product, the microorganism with constrained based model available and reconstruction options to select, as well as the sequences of process engineering trains with options, optimize the process efficiency, select the metabolic reconstruction and select the process engineering options most suitable to the problem.

The objective function is the maximization of the profit, which is calculated by the final product flow and value, as well as the downstream costs. The problem is constrained by the outer problem, which is the process performance, and the inner problem, which is the cell performance, and together they form a bilevel optimization problem. To simplify the final optimization problem, it was decided to solve it using linear programming, which led to the utilization of simplified engineering models for unit operations and shortcut cost models. Additionally, the engineering processes focused only on the extracellular products as a part of this study.

2.2. Mathematical Formulation

Optknock is a bilevel programming framework for identifying gene knockout strategies for microbial strain optimization (Burgard et al., 2003). The initial OptKnock optimization problem consists of an inner problem and an outer problem. The inner problem aims to maximize the biomass and the outer problem aims to maximize the target product. These two targets are competing for the carbon intake and are referred as a bilevel optimization problem.

The novel approach in this research is that the outer problem is expanded to include new process engineering objectives and the maximization goal is shifted from product maximization to profit optimization. Since profit is derived directly from the desired final product flow, the product is still maximized, but now process engineering is also accounted for. Specifically, the downstream processing is translated in the form of a superstructure. Each processing stage (S) includes the selected possible separation processes (T). Separation steps include pretreatment, cell removal, product isolation, concentration, purification and refinement. The existence of each process is denoted by binary variables. The superstructure's input stream is a variable determined by the optimization problem and is separated into five components: product, liquid by-product, water, cells, and solid by-product. Each process redistributes the stream's components through linearized model equations. The problem can be constrained based on the specific bio-process characteristics and objectives.

Our method entails the identification and the categorization of these technologies as well as the insertion of the model equations and their economic parameters into the optimization problem. The model has been developed in GAMS environment and solved using the BARON global optimization solver. On the tables below, the mathematical formulation is presented.

Table 1 (left): The mathematical representation of the model with the new maximization goal

Table 2 (right): Representation of the additional sets of constraints

maximize Profit	Target Maximization	Outer Problem	Input Data	$F(i) = P(i) + Lbp(i) + W(i)$

				$Lbp_{t2B} \leq Lbp_f$
			Mass Balance Equations	$\forall Z, \sum_{i \in I} X_i \cdot Z = \sum_{i \in I+1} Z$

2.3. Enlisted Downstream Processing

The downstream processing of each bioproduction might be different but the general steps for the treatment of the fermentation broth are similar. The difference lies on the specific process that is chosen. For our case, we selected a broad spectrum of separation processes for each step but these can be adjusted to each specific case. In the case that a step should be omitted we added the option BYPASS where the process flows remain the same for the following step. Below we present the superstructure illustration.

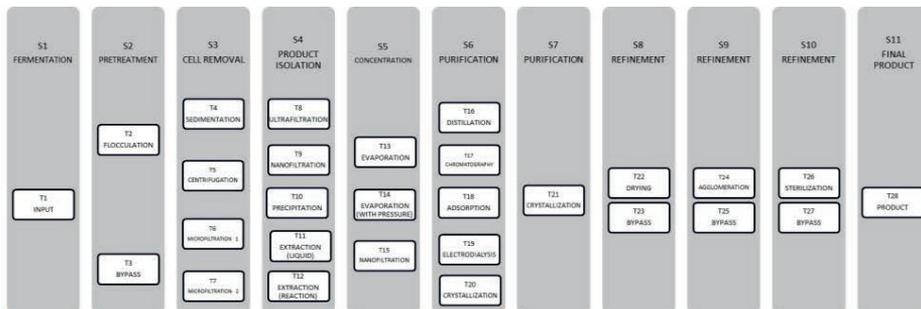

Figure 1: Representation of the enlisted downstream processing superstructure

3. Illustration Cases

Here we will showcase the optimization problem and present a case study for the utilization of the proposed methodology and tool. The case is the production of muconic acid from the strain of *S. cerevisiae* (iMM904 GEM) that includes the necessary heterologous pathways.

3.1. Optimization Problem

The degrees of freedom of the problem include the biological system, meaning the reactions that could be knocked out and the processes engineering objectives that are the separation trains and equipment for a 5 year operation. Firstly, a parametric analysis will be conducted by using only the metabolic reconstruction tool where glucose intake (substrate) and minimum allowed biomass will be set to derive the deleted reactions and output distributions. It is assumed that up to 2 reactions can be knocked out, the separation task can be repeated but with a single and different piece of equipment, no separation stages are repeated in a sequence and the separation mixtures are ideal (e.g. no azeotropes and recycles are allowed). Then, after calculating the initial product flows, they will be inserted to the disconnected superstructure for the downstream processing and the results will be compared to the proposed approach, which is solving the two problems simultaneously. It is expected that designing the biological system and the separation together will yield a more profitable production.

3.2. Case Study

Muconic acid is considered a “bio-privileged molecule” as it enables the production of a variety of useful products such as bio-plastics and energy (Bentell et al., 2001). It can be produced by renewable resources such as lignocellulosic biomass through bio-production (Wu & Maravelias, 2019). Therefore it crucial to build strains, by introducing heterologous enzymes and genes, which can produce muconic acid economically. *S. cerevisiae* is a microorganism that has been used for the production of muconic acid and has been chosen for this study (Wang et al., 2020).

3.2.1. Parametric Analysis (Cases A, B, C)

As it was discussed in this part we conducted a parametric analysis on the biological system. Specifically, we assessed the effect of substrate intake (glucose) and minimum biomass on the final concentration of the product, the liquid by-product and the water. It was revealed that increasing the minimum biomass, with the same glucose intake, led to significantly increased product formation, with a slight decline in the liquid-by product and the same water content. By returning the glucose intake to its initial value and decreasing the minimum biomass it, the results showcased that the product was again

higher than the initial value, but the liquid by-product and the water contents got reduced. The results can be seen on the Table 3.

3.2.2. Conventional Approach (Case C)

Here we set the glucose intake to 0.5 mmol/(dDW·h) and the minimum biomass to 0.01 h⁻¹ and solved the biological system to find the metabolites distribution which were then used to feed the downstream processing superstructure. By solving the problem we found the deleted reactions, the chosen processes, as well as the total profit, which was 1,7 mil. \$. Again, the overall results can be seen on the Table 3.

3.2.3. Simultaneous Approach (Cases D, E, F, G)

By solving the optimization problem simultaneously we were able to reveal different metabolic reconstruction options (deleted reactions), which led to a different selected downstream processing scheme and a more profitable production that reached 16.1 mil. \$ (Case D). This significant increase in profits could not be revealed from the disconnected approach. For Case E, the problem is further constrained by demanding the minimum product flow at the final stage to be 40 kg/h. This forces the algorithm to comply with this restriction and thereby choosing the suitable parameters that decrease the overall profits to 14.9 mil. \$. Similarly, in the following run (Case F) the restriction of maximum water content at the final stage decreases the overall profit to 13.9 mil. \$. Finally, in Case G the two previous restrictions are relaxed and the effect of increased glucose intake is examined. Specifically, at 0.1 mmol/(dDW·h) substrate intake the profits increase to 37.9 mil. \$, a significant increase from Case D, where glucose intake was just the half amount.

3.3. Summary of Results

On the following table, a summary of the results is presented.

Table 3: Summary of all the cases inputs and outputs

Scenario	Conventional			Simultaneous			
	A	B	C	D	E	F	G
Input							
Glucose Intake [mmol/dDW·h]	1	1	0.5	0.5	0.5	0.5	1
Minimum Biomass [h ⁻¹]	0.01	0.05	0.01	0.01	0.01	0.01	0.01
Min Product Flow [kg/h]				0	40		
Maximum Water Flow [kg/h]				0		0.02	
Output							
Deleted Reaction 1	r_3529	r_0892	r_0253	r_0073	r_4025	r_2220	r_3028
Deleted Reaction 2	r_3530	r_1836	r_1994	r_0806	r_4608	r_4608	r_3908
Product [mmol/dDW·h]	0.16	0.47	0.31	0.41	0.41	0.41	0.85
Liquid By-product [mmol/dDW·h]	3.02	2.79	0.71	0.54	0.54	0.54	0.91
Water [mmol/dDW·h]	4.35	4.36	1.82	1.77	1.77	1.77	3.45
Product S11 [Kg/h]				36.6	40.1		
Water S11 [kg/h]				0.027		0.005	
Superstructure							
S1			T1	T1	T1	T1	T1
S2			T3	T3	T3	T3	T3
S3			T6	T6	T6	T6	T6
S4			T12	T10	T8	T8	T12
S5			T13	T13	T13	T13	T13
S6			T18	T17	T20	T20	T20
S7			T21	T21	T21	T21	T21
S8			T23	T23	T23	T23	T23
S9			T25	T25	T25	T25	T25
S10			T27	T27	T27	T27	T27
S11			T28	T28	T28	T28	T28
Profit [mil. \$]			1.7	16.1	14.9	16.9	37.9

From the results above it is evident that there are significant deviations between the simultaneous and the staged approach, including differences in the knockout reactions. At the same time different types of separation trains for each case are observed, where the number and the types of DSP both change as different engineering constraints are used. Even in the simultaneous approach, each case has resulted into different sets of knockouts. Engineering constraints hold a lesser impact on profitability, holding a similar order of magnitude, so the approach can be good for targeting provided that the design stage retains DOF for reaction knockouts and that the optimization is allowed to switch different types of separation

4. Future Work

The present work contributes to the connection between the Design and Learn steps of the DBTL cycle, but still follows a simplified approach on the superstructure construction. Therefore, the development of a complete superstructure with all the possible downstream processes and their respective more realistic equations that describe them, could yield more accurate results. Moreover, this work does not contribute to the Design to Build steps, which consists of the scaling-up, that is affected by kinetic parameters and dynamics. An approach that simultaneously solves the GSMs and kinetics is still needed. Additionally, systematic methods that connect GSMs with the real world are important and therefore complete superstructures have to ‘wait’ before this part of systematization is addressed. The proposed methodology described in the paper has value mostly as a targeting and scoping tool and not as an all-encompassing solution.

Abstract

This paper aims to present an optimization approach for the design and planning of a hydrogen supply chain in Corsica Island. The formulation developed is based on a multi-period approach using a Mixed Integer Linear Programming (MILP) methodology. Three configuration scenarios of the Hydrogen Supply Chain (HSC) considering three single objective case studies are investigated related to the minimization of the total daily cost, of greenhouse gas emissions and of a risk-based index, respectively. The production of hydrogen is expected to cover the future demand of the fuel cell electrical vehicles (FCEVs) fleet planned for the 2030 period. The key innovation proposed here is to reconcile design and strategic planning over a short period using monthly fluctuations of hydrogen demand according to the predicted fuel consumption of the territory. The single objective optimizations for the case study show a decentralized distribution of production, storage and distribution units across the territory, with a lowest hydrogen cost of 8 €/kg during the period of high demand. This approach can be used to explore appropriate incentive mechanisms to boost the hydrogen economy in an isolated territory.

Keywords: Hydrogen, optimization, low-carbon fuel, Mixed-Integer Linear Programming, isolated area.

1. Introduction

The urgency to fight climate change has stimulated more and more interest in shifting investments from fossil-based energy to renewable sources. In that context, islands could play a key role in global development by becoming perfect places for demonstration of new clean technologies and pathways for sustainable development (Krajačić et al., 2008). In these isolated territories, the impact of the fossil fuel price is even higher due to its transport and their grid network is less stable. These reasons make the grid management more difficult and increase the cost of electricity production (Lamas, 2016). The massive integration of renewable energies (RE) on the small island grids could further increase the disturbances between production and demand because of their intermittency. In that context, hydrogen can be viewed as an “energy vector” and play a major role in decarbonization if generated by electrolysis using renewable energy surplus (Krajačić et al., 2008). Due to actual hydrogen demand scale, today investments remain yet too risky for wide-scale green hydrogen production that could compress costs, creating the so-called chicken-and-egg problem.

According to several studies, the economic viability of a hydrogen production system associated with renewable energy sources depends strongly on the identification of an

optimal configuration of the hydrogen supply chain (HSC) (Seo et al., 2020; Won et al., 2017). The HSC design has been mostly studied at the strategic/tactical level compared to the operational levels. The inputs of such models are constituted by a set of options for the production, storage and transportation, while the outputs are relative to the type, number, location and capacity of the production, storage and transportation units. Most works devoted to hydrogen supply chain modelling are based on mathematical programming approaches, mainly Mixed Integer Linear Programming (MILP) and generally limited to single objective (cost minimization) (Won et al., 2017) or bi-criteria assessment, i.e., cost-environment or cost-risk (Kim and Moon, 2008). These contributions generally involve a rolling horizon approach in which the overall horizon is divided into strategic periods during which capital investments are made at the very beginning and which can last up to 10 years. The decision variables made at a given period are then coupled over the large time-span, since the optimization strategy is viewed globally. As reported in (Agnolucci et al., 2013) only a few infrastructure optimization studies explored the spatial and temporal dynamics of demand which was identified as a key sensitive parameter with sources of uncertainty that can be addressed by a stochastic approach (Kim et al., 2008).

The objective of this work is to demonstrate deployment of hydrogen technologies in an integrated manner in a remote territory, here Corsica Island. The formulation is based on the previously developed long-term MILP approach for HSC infrastructure design (De Leon Almaraz, 2014). The key innovation we propose here is to extend this framework to the combined design and planning over a shorter period using monthly fluctuations of hydrogen demand according to the fuel consumption of the territory.

2. Presentation of the methodological framework

2.1. Principles

The methodological framework for the design and operation of a future HSC is treated regarding a geographical and multi-period approach in order to supply hydrogen demand profile of a given geographic area. The optimization problem was formulated as a Mixed Integer Linear Programming (MILP) model using GAMS[®] modeling system with CPLEX 12 solver (De Leon Almaraz, 2014). Three optimization objectives are considered in this study: an economic criterion that consists of the minimization of the total network cost, both in terms of capital and operating expenditures, an environmental criterion related to the global Greenhouse Gas (GHG) emissions of the supply chain and a risk index (Kim and Moon, 2008) subject to: supply, demand, mass conservation and technical performance. A set of techno-economic parameters is considered: production, storage, and transport options, possible locations, available energy sources, capital and operation cost, technical features (efficiency, capacity, lifetime, load factors, storage capacities) and GHG emissions of the various technologies. Several constraints are involved considering continuous, integer and binary variables. The integer decision variables represent the location of facilities, sizing decisions and the selection of suitable production technologies and of transportation modes between facilities. The binary (respectively continuous) variables indicate the hydrogen transport direction (respectively flows). The model then provides as outputs the HSC optimal configuration.

2.2. Model assumptions

The assumptions of the model can be summarized by:

- The territory is divided into grids;
- Production units can only be installed on specified grids;
- Only photovoltaic (PV) and wind power are considered for energy sources;

- Hydrogen is produced only by electrolyzers and supplied in gaseous form;
- Only transport by tanker-trucks may exist between grids;
- Produced hydrogen is dedicated to transport application and distributed via refueling stations.

2.3. Mathematical formulation

The novelty of this work is based on the use of finer grains for time interval definition (i.e. monthly intervals) that require the definition of additional parameters such as the number of operating hours and the power of the electrolyzers.

2.3.1 Constraints

The total availability of primary energy sources in a grid g during time period t ($Atot_{gt}$) is given as a sum of three terms, that correspond to the initial average availability of renewable energy sources ($A0_{egt}$), the import of primary energy sources from the grid network ($IPES_{egt}$) and the rate of consumption of the primary energy sources (ESU_{gt}):

$$Atot_{gt} = \sum_e (A0_{egt} + IPES_{egt}) - ESU_{gt} \quad \forall e, t, g; g \neq g'$$

ESU_{gt} is equal to the product of gamma (γ_{pj}) the rate of utilization of primary energy source by the daily hydrogen production rate for each production plant type p and size j (PR_{pjigt}).
 $ESU_{gt} = \sum_{pji} (\gamma_{pj} \times PR_{pjigt}) \quad \forall g, t; g \neq g'$

The Energy Availability EA_{gte} is the product of the energy power source capacity in each grid during period t and for each energy source (ESP_{gte}) multiplied by the number of hours per month (Mh_t) and the capacity factor for each energy source (CF_{et}) divided by the total number of days per month (dM_t).

$$EA_{gte} = \frac{\sum (ESP_{gte} \times Mh_t \times CF_{et})}{dM_t} \quad \forall e, g, t; g \neq g'$$

The installation of production (IP_{pjigt}), storage (IS_{sjigt}), and distribution (IFS_{fsjigt}) units only occurs at the first period t .

$$IP_{pjigt} = 0, \forall t \neq 1; \quad IS_{sjigt} = 0, \forall t \neq 1; \quad IFS_{fsjigt} = 0, \forall t \neq 1;$$

The minimum and maximum daily production capacity ($PCAP^{min}_{p,i,j}$) and ($PCAP^{max}_{p,i,j}$) is respectively calculated by considering the lower and upper daily capacity factor of electrolyzer type p and size j given in hours per month (respectively $ELCF^{min}_{p,j,i}$ and $ELCF^{max}_{p,j,i}$) and the assigned power of each given electrolyser in kW ($PElec_{p,i,j}$). Nd is the number of days per month and gamma (γ_{pj}) is the rate of utilization of primary energy source (in kWh/kg).

$$PCap_{pij}^{min} = \frac{\left(\frac{ELCF_{pij}^{min}}{Nd}\right) \times PElec_{pij}}{\gamma_{pj}}; \quad PCap_{pij}^{max} = \frac{\left(\frac{ELCF_{pij}^{max}}{Nd}\right) \times PElec_{pij}}{\gamma_{pj}}; \quad \forall p, i, j$$

2.3.2 Objective functions

The monthly average cost of hydrogen ($Mcost_t$) is determined by summing the capital costs of all units over the lifetime of the units (lf) with the maintenance and operating costs ($Opex_t$) of the units over the sum of the total demand for each grid g of product type i in time period t (DT_{igt}) multiplied by the number of days per month (dM_t).

$$Mcost_t = ((Capex_t \div lf) + Opex_t) / \sum_{ig} (dM_t \times DT_{igt}); \quad \forall e, g, t; g \neq g'$$

The total global warming potential is determined from the total daily greenhouse gas (GHG) emissions of the production, storage and transport units. Similarly, the relative

risk of hydrogen activities is determined by risk ratings calculated based on a risk index method including the risk of production, storage and transport (Kim and Moon, 2008).

2.4. Study case

2.4.1 Demand evaluation

Corsica is a French region that is greatly impacted by tourist activities. According to the annual evolution of the fuel consumption in the island, 2.5% of the equivalent energy could be substituted by hydrogen fuel in 2030 (“Le Schéma Régional Climat, Air, Energie (SRCAE) de Corse,” n.d.). This corresponds to a daily hydrogen demand ranging from 4.3 t/day in January to 8.1 t/day in August. The fluctuating hydrogen demand expressed in energetic values is presented in figure 1.

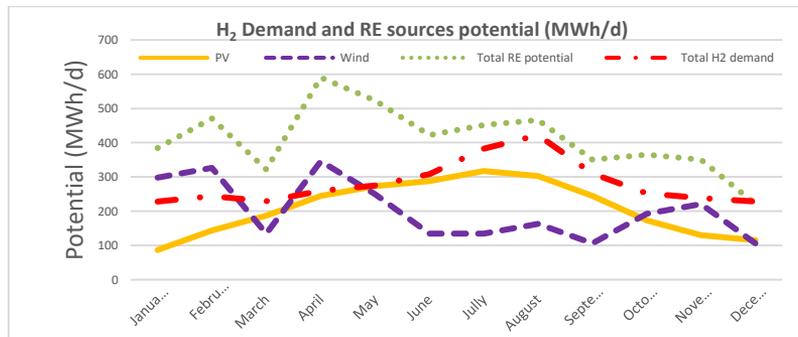

Figure 1: H₂ Demand and RE source potential

2.4.2 Techno-economic parameters

Table 1 presents the minimum and maximum values of the most significant parameters for production, storage, transport and distribution units.

Min-Max	Production unit	Compressor unit	Storage unit	Transport unit	Distri. unit
Capacity	300-5000 (kW)	126 (kg/h)	50-30000 (kg)	670 (kg)	20-1300(kg/d)
CAPEX	1038-3500 (€/kW)	635 (€/kW)	500 (€/kg)	746 (€/kg)	410-1480 (k€)
O&M	0,11-0,20 (€/kg)	0,007 (€/kg)	0,006-0,02 (€/kg)	trip dependent	0,15-0,39 (€/kg)
Efficiency	37,80-52 (kWh/kg)	2,66 (kWh/kg)	-	-	-

Tableau 1: Techno economic data of the production, storage, transport and distribution units

Two types of electrolysis technologies are used, i.e., Alkaline (AE) and Proton Exchange Membrane (PEM) electrolyzers, seen as the most suitable ones for the supply chain in Corsica as they are mature technologies and do not require large heat sources to operate.

2.4.3 Energy sources (cost and potential)

The cost projections used in this work assume that renewable energies will cover 87% of the French electricity demand in 2050 and that 70% of the French nuclear park will be kept. This hypothesis projects the cost of electricity produced by PV and wind power at respectively 16 €/MWh and 35 €/MWh in 2030.

The power generation capacity of the renewable energy sources (PV and wind respectively 60 MW and 40 MW) allocated to the production of hydrogen has been determined according to the available resources on the island and the capacity factor of each technology. Figure 1 shows the forecasted production of these sources for year 2030.

3. Results and discussions

The territory is divided into 9 grids for this study. The results of the simulations show that the model has treated a total of 134308 single equations, 53861 single variables and 24192 discrete variables. The single optimization run led to a maximum CPU time 22s for an instance with CPLEX solver provided with Gams 28.2 (using 7 threads of an Intel Core i5 computer). Figure 2 shows the distribution of the different types of electrolyzers selected and the value of each objective function for each optimization case. The number, size and technology chosen for each configuration is different depending on the objective function used. Large production, storage and distribution units are the most used to reduce the operating cost by mutualizing the maintenance and operation costs. The average production cost obtained is the lowest 12.19 €/kg against 28.03 €/kg and 26 €/kg for the GHG and risk criteria respectively (i.e. expressed as a monthly average cost of production that differs from the levelized cost of hydrogen (LCOH) which takes into account the life cycle of the plant and the discount rate). This cost evolves according to the monthly production rate of hydrogen and the availability of energy sources, reaching its lowest value in August, i.e. 8 €/kg.

A total of 6 transport units are found with cost optimization and one less for the other criteria. The transport from zone 7 to 1 has been replaced by a production unit directly located in zone 1.

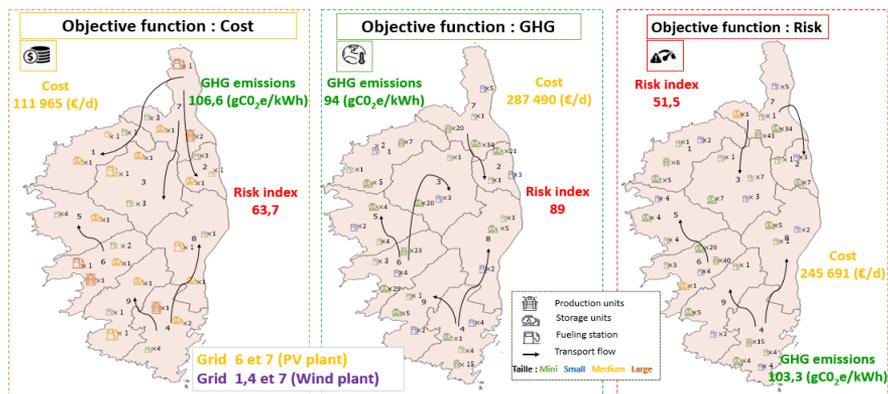

Figure 2: Hydrogen supply chain configuration

The objective based on minimizing GHG emissions leads to a more decentralized configuration with much smaller equipment and more efficient alkaline-type electrolyzers. The amount of GHG emissions is 94 gCO₂e/kWh and although logically most favorable compared to the other criteria, the gap is not significantly high compared to the result obtained with the cost criterion since the technologies considered for hydrogen production involve a green energy mix. Finally, when the optimization criterion chosen is to reduce the total risk index, almost all the equipment chosen are of minimal size because they present less risk. The risk index at this level is 51.5 against 67.3 and 89 for the cost and GHG emission criteria respectively.

According to the season, the distribution of hydrogen can vary. In winter, the distribution rate is at a minimum (670 kg/truck) while in summer it reaches almost 1t/day with no additional transport units. Although the demand in zone 7 is the highest, it provides 56% of the hydrogen supply due to its high production potential. Figure 3 shows the distribution rate for the cost criteria in January and August.

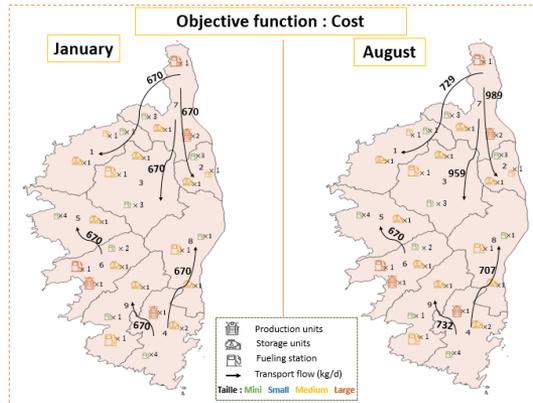

Figure 3: hydrogen distribution during winter and summer

Since photovoltaic energy is the cheapest, it is used up to 74% for the production of hydrogen in order to obtain the most affordable costs. However, the use of photovoltaic energy is still higher than wind energy even for the two other criteria (56% and 65% for the GHG and risk criteria respectively) since the availability of solar energy is higher during periods of high consumption. Photovoltaic power plants are only available in grids 6 and 7 and wind power plants only in grids 1, 4 and 7.

4. Conclusion and perspectives

This paper presented a methodological framework for the design and operation of HSC in Corsica island considering monthly variations in demand. The single objective optimizations for the case study show a decentralized distribution of production, storage and distribution units across the territory. The production cost is still quite high compared to large-scale production chain, but this approach can be used as a framework to support authorities to invest in this field in isolated areas. The next step of this work is to look for the optimal configuration for the three optimization criteria taken simultaneously (multi-objective optimization). This approach can be used to explore appropriate incentive mechanisms to kick-start the hydrogen economy in an isolated territory since the hydrogen cost still remains high even when cost minimization is considered. This optimization approach can also be extended by integrating the geographical and topographical constraints of Corsica.

Abstract

Before the pandemics, society was facing challenges regarding the climate change problem as well as the decline in oil well's production. Now, the economic recovery, which also must be sustainable, represents a bigger challenge. In this context, the development of sustainable biofuels is a key area to accelerate economic recovery. In particular, biodiesel is one of the most produced biofuels worldwide. Nonetheless, all the existent plants are based on vegetable or animal oils (edible, non-edible, and waste); however, these bioenergy sources have limited availability, especially considering that oils derived from cultivated crops compete with lands with other edible crops, affecting food safety. Therefore, the current efforts are focused on the search for other oil sources. Particularly, biodiesel production using oil derived from black soldier fly larvae has been proposed (Jung et al., 2022), since the cultivation of this insect requires reduced spaces of non-fertile lands, and its life cycle is 24 days; thus, this oil has advantages as bioenergy source. Additionally, these insects can be fed with waste (as animal manure, food and agricultural waste, among others); these residues are transformed into biomass with high (35-40%) content of lipids (Feng et al., 2018). Therefore, in this work the optimal configuration for a biodiesel production network is proposed, considering as raw material the oil derived from black soldier fly larvae. Hence, a mathematical model was proposed where all the involved unit operations required for the biodiesel production supply chain were included; for this, a B10 mixture was considered to satisfy the Mexican's demand. As objective functions were considered the CO₂ minimization, and the profit maximization. Results show that is possible to satisfy the current total diesel demand in Mexico using a B10 mixture, generating a national benefit of 3.529E9 USD/y, which represent 0.27% of increase of national Growth Domestic Product; in addition, 90% fewer emissions are released, in comparison with those derived from conventional diesel use.

Keywords: Biofuels, optimization, supply chain, waste management, circular economy.

1. Introduction

Globally energy security and climate change mitigation are the two main drivers of the transformation of the current energy system; a transition from an economy based on fossil fuels to one based on renewable sources, which allows to sustain current economic activities and reduced net carbon emissions. Particularly, transport sector consumes 30% of the total primary energy, being 98% of this consumption obtained from fossil fuels, which is traduced into 8.5 Gt of CO₂ emissions. According to Net Zero by 2050 report

(EIA, 2021), to achieve a de-carbonization in the transport sector is possible, if new policies focused in promote modal shifts and energetic efficiency operations are implemented; in addition to an energy source transition, including electric vehicles and biofuels implementation. Thus, the substitution of fossil fuels, in transport sector, by alternative sources such as solar, wind, biomass has received the greatest attention, given the growing demand and the problems associated with this need (Im-orb et al., 2021).

Particularly, biodiesel is a biofuel alternative to conventional diesel consumption; this is obtained from renewable sources, such as vegetable oils and animal fats through a transesterification reaction with methanol in presence of an acid or basic catalyst. However, nowadays the biodiesel production is mainly obtained from first and second-generation biomass, which results in disadvantages in economic, competitiveness, and use land terms. Specifically, in first-generation biodiesel production, approximately 70% of the total cost is generated by raw materials production, given low profitability. Therefore, new raw materials to reduce costs and avoid competition with food supply are needed; some authors have proposed the use of oils obtained from insects, particularly the one extracted from the black soldier fly larvae (*Hermetia illucens*). In this way, Leong et al. (2015) and Nguyen et al. (2018) proposed that there are many advantages linked to the use of black soldier fly larval oil (BSFO), due to its high-fat content, high reproductive speed, and short life cycles; coupled with the ability to consume organic waste or residues without any application of recovery, being this the main sustainable advantage over other raw materials.

Hence, in this work the supply chain optimization of biodiesel production using BSFO as raw material is proposed, through a mathematical model approach. Current conventional diesel demand in Mexico was used as a case study. In addition, organic residues generated in each State in Mexico are considered as food sources for the black soldier fly larvae production; in addition, this biological treatment contributes to a sustainable management residues strategy.

2. Problem statement

According to the National Biomass Atlas (ANBIO, 2020), Mexico generates 278 million tonnes of organic waste per year, with an estimated energy potential of 2,980 PJ. These kind of residues in developing countries are burned, or dumped into a final disposal site, contributing with negative environmental consequences (Pradhan et al., 2019). On the other hand, the Secretariat of Energy (SENER, 2018) expected a diesel national demand of 405 Mbd in 2021, with annual growth of 1.57%; 30% of the total diesel demand is produced in Mexico, while the 70% is imported. In this way, Mexico is the 13th emitting country of CO_{2e}, with almost 737 million tonnes; 64% of these emissions are given by the energy sector, while 18.5% is released by transport sector, 7% generated by the residues management and 3.9% by the final disposition sites (INECC, 2019). Consequently, in the recent COP26, Mexico committed to reduce 25% of its greenhouse gas emissions, in addition to decrease its emissions from the industry sector through the generation of 35% of clean energy by 2024 and 43% by 2030; these actions enrolled to achieve the objective of keeping the temperature increase below 1.5 °C. Thus, the use of new renewable energy sources that do not compromise food security, ensure economic development, and help achieve the commitments agreed is required; thus, the use of oil from this insect is a promissory raw material for biodiesel production.

3. Methodology

The biodiesel production network in Mexico described in Figure 1 is proposed. As first step, the places (being the 32 states of Mexico) where organic wastes are collected (harvested) are considered. Particularly, only the food loss waste (approximately 1,840,853 tonne/y) are taken into consideration; therefore, if the residues flux is representative in one site, then a black soldier fly biotransformation plant (BP) is installed; this plant will serve as waste management biological center. Then, in each installed BP all the oil from the cultivated larvae is extracted; with the collected oil in each site is produced pure biodiesel through the transesterification process. The final consumer of biodiesel is the Mexican transport sector; in order to supply this biofuel, a B10 mixture is considered to avoid additional costs for engine modifications. In Figure 1, sub-indexes i , k , j , and l have the possibility to take values from 1-32, while s only can take values from 1-6 (considering current conventional refineries).

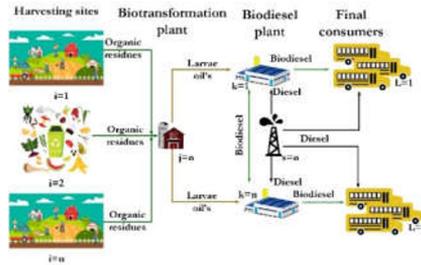

Figure 1. Biodiesel supply chain

3.1 Mathematical model

The proposed approach considers the current situation of organic residues in Mexico and its diesel demand. The organic residues flux in each site ($FR_{i,t}^O$) has the possibility to be dumped in a final disposal site ($RF_{i,j,t}^{s-dump}$) or to be used as feed in the black soldier fly larvae production plants ($RFS_{i,j,t}^{s-oil}$); the sum of both fluxes are equal to the total flux of organic waste produced in each site (i) per week (t), as equation 1 describes. In equation 2, the flux of oil ($OF_{j,t}^{Ext}$), extracted from each tonne of larvae produced (β^{oil}), using the organic residues received as feed ($RFR_{j,t}^O$) in each installed black soldier fly production plant, is calculated.

$$FR_{i,t}^O = \sum_j RFS_{i,j,t}^{s-oil} + \sum_j RF_{i,j,t}^{s-dump}, \forall i \in I, t \in T \quad \text{Eq. 1}$$

$$OF_{j,t}^{Ext} = RFR_{j,t}^O \cdot \beta^{oil}, \forall j \in J, t \in T \quad \text{Eq. 2}$$

Afterward, the collected flux of larvae oil is sent ($OF_{j,k,t}^{sent}$) to the transesterification plant (k) as equation 3 shown; while in equation 4, the biodiesel flux produced per week ($FP_{k,t}^{Bio}$) in each transesterification plant is calculated through the multiplication of the received larvae oil flux ($LO_{k,t}^{rece}$) per a respective conversion factor (μ), tonne of pure biodiesel produced per tonne of larvae oil.

$$LO_{k,t}^{rece} = \sum_j OF_{j,k,t}^{sent}, \forall k \in K, t \in T \quad \text{Eq. 3}$$

$$FP_{k,t}^{Bio} = LO_{k,t}^{rece} \cdot \mu, \forall k \in K, t \in T \quad \text{Eq. 4}$$

Thus, with the pure biodiesel produced in each plant is possible to obtain the B10 mixture (10% of pure biodiesel [$FP_{k,t}^{Bio}$] and 90% of conventional diesel [$FD_{k,t}^{Conv}$]). The expected flux of B10 ($Bio_{k,t}^{Mix}$), in tonnes in each installed plant, is calculated with Equation 5. Then, the B10 flux transported ($Bio_{k,l,t}^{Mix-sent}$) to the consumption sites (l) is computed with Equation 6. Current fuel demand in each site ($FD_{l,t}^{Fuel}$) is lower to sum of available B10 flux ($Bio_{l,t}^{Mix-avai}$) plus conventional diesel flux ($CD_{l,t}^{use}$), as equation 7 describes. Conventional diesel consumption is considered when is not possible to satisfy the fuel demand with B10.

$$Bio_{k,t}^{Mix} = FP_{k,t}^{Bio} + FD_{k,t}^{Conv}, \forall k \in K, t \in T \quad \text{Eq. 5}$$

$$Bio_{l,t}^{Mix-avai} = \sum_k Bio_{k,l,t}^{Mix-sent}, \forall l \in L, t \in T \quad \text{Eq. 6}$$

$$FD_{l,t}^{Fuel} \leq Bio_{l,t}^{Mix-avai} + CD_{l,t}^{use} \quad \text{Eq. 7}$$

Total cost (TC) is calculated through equation 8, in which are summed all the generated transportation cost (C^{Tra}), the cost by the conventional diesel consumption (C^{usoDC}), the cost by the waste management (C^{wm}), and the production of B10 (C^{PB10}). Waste management and B10 production cost include fixed and variables cost for each installed plant. Similarly, the CO₂ emissions (TE) include those due to transportation (E^{Tra}), the use of conventional diesel (E^{usoDC}), the use of B10 (E^{UsoB10}), B10 production (E^{PB10}), and those released by the waste management strategies (E^{wm}).

$$TC = C^{Tra} + C^{usoDC} + C^{wm} + C^{PB10} \quad \text{Eq. 8}$$

$$TE = E^{Tra} + E^{usoDC} + E^{UsoB10} + E^{wm} + E^{PB10} \quad \text{Eq. 9}$$

Equation 10 shows the profit balance (*Profit*), where total costs is subtracted to generated sales by B10 (*Sales*), plus the economic gain by food losses waste management ($Pric^{wast}$). This last earning is considered if the residues are sent to biotransformation plant; hence, the current cost of the final disposal site is removed. Lastly, a multiobjective function was included (*O.F.*) for the profit maximization (*Max profit*) and emissions minimization (*Min CO₂*), Equation 11.

$$Profit = Sales + Pric^{wast} - TC \quad \text{Eq. 10}$$

$$O.F. = Max\ profit; Min\ CO_2 \quad \text{Eq. 11}$$

4. Results

The mathematical optimization model was codified in GAMS® platform, and it includes 47,558 constrains, 273,734 single, and 192 discrete variables. This model was solved as a Mixed Integer Linear Programming problem using the CPLEX solver. The test was carried out in an Intel® Core-i7, with a CPU 3.60 GHz and 8 GB RAM, with an execution time of 1.093 s/assay. The results show that is possible to produce 561,976 tonnes of pure biodiesel per year, this production represents 5.2% of the total diesel demand in Mexico; however, nowadays is impossible the use of pure biodiesel in the current engines available in Mexican transport sector. Thus, 6,811,732 tonne/y of B10 can be produced and used directly in the transport sector without modify the vehicle's engines. Thus, approximately 58% of current diesel demand in Mexico is satisfied with B10, and the rest with conventional diesel. To achieve this amount of B10 production is required the installation of biotransformation plants and biodiesel plants in each State of Mexico as Figure 2 shows. Note that biotransformation plants in white color represent those that received organic wastes from CDMX; this means the plants of 24 States, from 32, receive residues from CDMX, the biggest waste generator. Particularly, CDMX contributes with almost 70% of the food loss waste produced in Mexico, where 6% of the Mexican population

lives. On the other hand, biodiesel plants in yellow color (located in 11 States) are those with the capacity to share B10 with CDMX, which is the city with the bigger flux of B10, due its bigger population. Additionally, arrows in red and black color indicate the fluxes of residues and B10 transported, respectively.

Figure 2. Mexican biodiesel supply chain distribution.

According to the CO₂ emissions quantification performed in GREET software (2021), the raw material generation used in biodiesel production, crops production and residual materials are 39% and 8% (respectively) of the total CO₂ emissions generated by each tonne biodiesel produced. In this way, each tonne of food loss transformed by BSF releases 0.88 kg CO₂ (Pang et al., 2020); therefore, as is shown in Table 1 each tonne of BSFO produce approximately 12 kg of CO₂. This value is 98.8% lower that the emissions generated by the crops production, and 83.3% lower in comparison with other residual products. On the other hand, if all the Mexican food losses waste are sent to a final disposal site are generated approximately 11,497,200 tonne of CO₂, based on the values of emissions indicated by Scukling et al. (2021). However, if these residues are bio-transformed into biodiesel using the BSF, then emissions are reduced in 86%. Table 1 also shows the CO₂ emissions generated by each tonne of biodiesel produced; particularly, the production of 1 tonne of biodiesel from BSFO is 41% and 78% lower in terms of emissions respect to the use of waste cooking oil and soybean oil, respectively.

Table 1. CO₂ emissions comparison

		Raw material production	Total emissions
	Type of raw material	(CO ₂ kg/raw material tonne)	(CO ₂ kg/tonne biodiesel)
Residual	Lard+chicken fat	72	956 ⁰
	Waste cooking oil	72	956 ⁰
	Tallow	72	956 ⁰
Annual	Castor bean	1,031	2,654 ⁰
Annual Mechanized	Soybean	1,031	2,654 ⁰
Perennials	Palm	1,031	2,654 ⁰
Black soldier fly (BSF)	BSFO	12	562 ^c

Note: ⁰ Value reported by Costa et al., 2013; ^ε calculated value using GREET.

5. Conclusion

Food losses waste can be transformed to biodiesel through its processing with the cultivation of black soldier fly, oil extraction from larvae, and its transesterification. This approach promotes a circular economy based on residues management. Moreover, it is possible to satisfy 58% of the national demand using B10 mixtures; at the same time, the food loss waste is processed, reducing the environmental impact, and new green business can be created. To achieve a total de-carbonization of the transport sector new policies, alternative energy sources, as well as higher investment are required.

Abstract

The detrimental environmental impacts of climate change that are a result of high atmospheric CO₂ concentrations have prompted global efforts to limit the continuous increase in greenhouse gas (GHG) emissions. Many are now relying on the deployment of various carbon capture, utilization and storage (CCUS) methods which have been found reliable for reducing CO₂ levels in the atmosphere. Various industries are shifting towards the decarbonisation of their operations through the use of a combination of various CCUS activities. This could involve the conversion of CO₂ into value-added chemicals, the utilization of CO₂ for enhanced oil recovery (EOR), the injection of CO₂ into geological formations and/or oceans, the biological fixation of CO₂, and other similar activities. Such operations are often referred to as CO₂ “sinks”. It is often crucial for industries to identify which CCUS operations to deploy, especially when faced with many choices, since factors such as the cost of implementation and the sink efficiency play a significant role in the sink selection process. In this work, a mathematical model that helps identify optimal CO₂ sink locations within industrial clusters is developed and utilized. Identifying optimal sink locations is an important factor that needs to be considered as part of a CCUS network planning problem. The proposed mathematical model was found to be very useful for identifying optimal CCUS sink selections, and their respective locations. A total of 22.7% of savings in transportation costs have been realized within the network, when compared to the case of having sink locations prescribed upfront.

Keywords: CCUS, Climate Change, Integration, Optimization, Spatial

1. Introduction

Carbon Capture, Utilization, and Storage (CCUS) technologies aim to remove CO₂ from the atmosphere in a safe and effective manner. When talking about the exact terminology used for each, (1) capture refers to the process of capturing CO₂ from exhaust and/or reformed gases at stationary sources, via standardized technologies that are applied pre- or post- combustion, (2) utilization refers to the use of captured CO₂ for the production of value-added chemicals and other useful industrial products, (3) storage (also known as sequestration) refers to the process of transferring captured CO₂ into geological formations and/or oceans, in which it is stored permanently. The investigation efficient CCUS schemes has been the subject of many research papers.

Liang et al. (2009) studied the economic value, as well as the investment characteristics of carbon capture and reuse (CCR) plants in China. Li et al. (2012) developed a qualitative assessment that investigates early opportunities CO₂ capture in advanced gasification plants. Yousefi-Sahzabi et al. (2011) presented a review on the applicability of geo-information technology for the screening and analysis of CO₂ emission sources, transportation and storage possibilities. Wilberforce et al. (2021) presented a thorough investigation of the various technologies that can be harnessed to capture carbon dioxide. Hasan (2015) developed a hierarchical and multi-scale framework for the design CCUS networks at minimum investment, operating and material costs. Al-Mohannadi and Linke (2016a) presented a mathematical model to systematically design low cost carbon integration networks for industrial parks through an integrated analysis of sources, utilization and storage options, while accounting for capture, separation, compression and transmission. Following this, Al-Mohannadi and Linke (2016b) presented an extension to the MINLP that is capable of CO₂ planning network transitions over a time horizon. Zhang et al. (Zhang et al., 2020) developed a superstructure optimization-based framework in the form of a multi-objective mixed integer linear programming (MILP) program, for the deployment of CCUS supply chains. Al-Mohannadi and Linke (2020a) presented a Mixed Integer Nonlinear (MINLP) optimization approach which simultaneously considers natural gas distribution combined with (CCUS), and energy integration. Al-Mohannadi et al. (2020b) then introduced a two-step optimization approach that is capable of evaluating CO₂ reduction policies using a Mixed Integer Linear program (MILP) using a 2-step process. Hetti et al. (Hetti et al., 2020) presented a systematic literature review to critically analyze the feasibility of community level carbon capturing, and explored the prospects of CCSU integration towards transitioning into zero-emission community energy systems. D'Amore et al. (2021) presents a supply chain Mixed Integer Linear Programming method for the optimization of a Europe-wide carbon capture and storage supply chain. Mualim et al. (2021) proposed an improved pinch-analysis based method for carbon capture and storage target and network design, which mainly involves targeting the maximum carbon exchange in the carbon capture and storage system, followed by designing a CCUS network.

Even though much of the previous work has looked into the design of efficient carbon integration and CCUS systems, there exist no models that account for the possibility of having CO₂ utilization sink (or sequestration site) location selections, simultaneously. In other words, the possibility of locating more than one type of sink in the same location, and choosing the best sink out of all that would need to be incorporated in that location (or site) is an important problem, especially if there exists a number of location choices that could potentially be assigned from a selection of different CCUS operations. The proposed extension allows this aspect to be incorporated into the main CCUS model.

2. Methodology

It is often common to use the term “source” to refer to the capture stage of CO₂, while both utilization and storage are often referred to as CO₂ “sinks”. Hence, multiple aspects need to be combined for the successful removal and capture of CO₂, followed by an appropriate selection of utilization and storage options. Moreover, before utilization and storage, captured CO₂ would need to be appropriately conditioned to meet the CO₂ sink requirements. This is often achieved through a combination of treatment, compression,

and pumping operations. Upon this, CO₂ can then be dispatched and transported from the source location at the capture site, to appropriate sink locations. This work introduces the respective sink locations as additional variables that need to be mathematically represented and identified within the model. Each CO₂ sink be assigned one optimal location, which is to be chosen from a set of available locations that are appropriately identified. Figure 1 below represent the sink location problem within the context of source-to-sink CO₂ mapping.

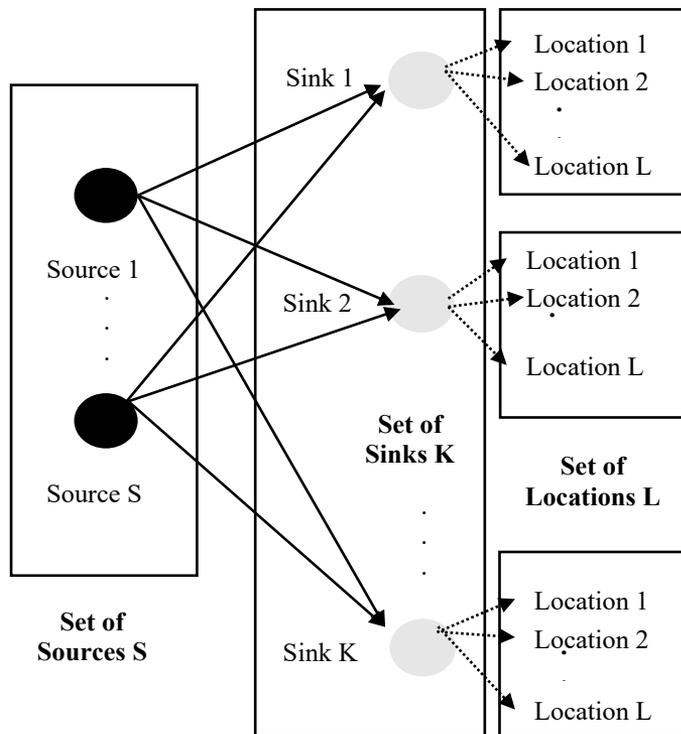

Figure 1. CO₂ Source-Sink mapping with Sink locations

Pipelines are widely used for CO₂ transportation between stationary sources and sinks. However, other modes of transportation may be utilized, depending on the sink type, such as trucks, ships etc. In this work, pipelines were utilized as the primary transportation model. Ultimately, viable CCUS structures must prove to be effective in terms of their ability to reduce atmospheric CO₂ while maintaining its ability to sustain long-term operation. Moreover, identifying effective CCUS schemes based on sink locations must provide economic, as well as environmentally-sustainable solutions. Hence, the cost associated with having a pipeline constructed at each sink location site must be accounted for. Moreover, it is imperative that only one sink site is chosen per source-to-sink allocation, and each sink location in set L must be chosen only once for each sink identified within the CCUS network.

3. Mathematical Formulation

A Mixed Integer Non-Linear Problem (MINLP) has been adopted from Al-Mohannadi and Linke (Al-Mohannadi & Linke, 2016), with the following additional equations that

account for the sink location selection. Even though the overall model is nonlinear, the equations that are needed to account for sink location selections within the problem were all identified to linear, as described below. Superscripts s , k , and l represent the carbon source, carbon sink, and sink locations respectively. S , K and L represent the set of CO₂ sources, CO₂ sinks and sink locations, respectively. T and U represent treated and untreated CO₂ flows, X is a binary variable which takes a value of 1 when source s has a connection with sink k ; and 0 otherwise. Similarly, W is a binary variable which takes the value of 1 when sink k is located at location l , and 0 otherwise:

$$\sum_l W_{kl} = 1 \forall k \in K \quad (1)$$

$$\sum_k W_{kl} = 1 \forall l \in L \quad (2)$$

$$L_{sk} X_{sk} \leq T_{sk} + U_{sk} \forall s \in S, k \in K \quad (3)$$

$$T_{sk} + U_{sk} \leq M_{sk} X_{sk} \forall s \in S, k \in K$$

$$X_{sk}, W_{kl} \in \{0,1\} \forall s \in S, k \in K, l \in L \quad (4)$$

The objective function of this study is set to minimize the total cost of the carbon integration network. The overall cost of the network entails the cost of carbon treatment, compression, transportation and sink processing costs. All carbon-related costs are adapted from Al-Mohannadi and Linke (Al-Mohannadi & Linke, 2016). Moreover, the carbon compression and pumping costs consist of operating and capital costs functions. The central decision variables mainly consist of the carbon source-to-sink flows (treated and untreated) and the respective sink locations. The total cost is obtained by subtracting any obtained revenue, as a result of selling any captured carbon dioxide, from all the previously mentioned costs. Moreover, the model constraints consist of total and component mass balance equations of the different material present throughout the system. Since there are different qualities of sources, an overall mass balance is used to compute actual stream compositions, before they are sent to the sinks. Production and performance constraints were also used, to ensure certain requirements on the amount of material flows, mainly CO₂ capacity constraints, which refer to setting a minimum on the amount of material to be allocated (carbon and ash) or a maximum amount of material that can be accommodated by the available sinks, and composition constraints, which place a restriction on the amount of specific component (carbon) in the flowrate allocated to a specific sink. Moreover, since only one sink site must be chosen per source-to-sink allocation, and no single sink location can be chosen more than once for different sinks. The MINLP combines equations (1-4) above, together with the objective function and mass balance constraints from Al-Mohannadi and Linke (Al-Mohannadi & Linke, 2016). The problem was implemented using What'sBest via MS Excel, and the LINGO solver was used on a laptop with an Intel core i5 processor, 8 GB RAM and a 64-bit Operating System.

4. Case Study

This case study involves the possibility of allocating 4 different types of CO₂ sources, with differing qualities into six different sink possibilities. Table 1 below summarizes the respective flowrate and composition data for each. For each sink, six different location options have been allowed, and the distance data associated with each of those locations are shown in Table 2.

Table 1: Available source and sink data (Al-Mohannadi & Linke, 2016)

Source	Flow MTPD	CO ₂ Composition (%)	Sink	Max.Capacity MTPD	Min.CO ₂ Composition (%)
Ammonia Removal	977	1	Algae	4716.7	6
Steel-Iron	3451	44	Greenhouse	1095.7	94
Power	9385	7	Storage	8847.9	94
Refinery	1092	27	Methanol Sol.	1711.7	99.9
			Urea	1127.1	99.9
			EOR	2913.8	94

Table 2: Sink location data (km)

Source	Location 1	Location 2	Location 3	Location 4	Location 5	Location 6
Ammonia Removal	1.0664	1.7356	0.862	0.9362	0.961	0.9672
Steel-Iron	1.2834	1.9526	1.0432	1.1532	1.178	1.1842
Power	1.7174	1.9446	1.261	1.829	0.5642	0.3162
Refinery	1.5686	1.7958	1.802	1.6802	0.4092	0.5084

In order to demonstrate the proposed approach, a net capture target of 15% (corresponding to a total of 3076 MTPD of captured CO₂) has been imposed on the system. In doing so, only 2 sinks were activated within the network (Methanol and EOR), and the values corresponding to the optimal allocations attained have been provided in Table 3.

Table 3: Summary of optimal source-to-sink allocations and the respective sink locations

	Algae	Greenhouse	Storage	Methanol	Urea	EOR
Ammonia Removal	0	0	0	0	0	977
Steel-Iron	0	0	0	279.1	0	1170.7
Power	0	0	0	0	0	591.3
Refinery	0	0	0	265.4	0	0
Location	-	-	-	Location 5	-	Location 6

While the EOR sink was completely filled to its maximum capacity, the Methanol sink was filled to about 31.8% of its maximum capacity. Moreover, the optimal locations for

each of those 2 sinks has been identified by the solver. Location 5 was assigned for Sink 4 while Location 6 was assigned for Sink 6. The optimal cost of the network was found to be 5,959,719 USD as opposed to a total of 6,013,437 USD when no location optimization is enabled, and each sink is prescribed a location beforehand. Hence, upon enabling the sink location optimization feature, a total of 22.7% of savings in the total transportation costs have been realized within the network, when compared to the case of having the sink locations prescribed upfront. This aspect highlights the importance of sink locations in CCUS networks on the overall transportation costs, and allows for appropriate sink location planning activities, especially within multi-period problems, are studied, and expansion activities are crucial in the system.

5. Conclusions

In this study, a mathematical model that assesses sink location optimization features within carbon integration networks has been introduced. In order to ensure the successful development and implementation of a CCUS network, appropriate planning and location identification of CO₂ sinks is necessary, since significant economic savings in terms of transportation costs can be realised.

Abstract

Bioenergy with carbon capture and storage (BECCS) can produce carbon-negative biofuels from dedicated cellulosic biomass to mitigate global warming; however, the economic and environmental performance of a BECCS system is highly sensitive to carbon incentives and the supply chain (SC) network. Because dedicated bioenergy crops have yet to be planted, there is an opportunity to simultaneously design the SC and choose crop locations that balance the tradeoffs among transportation costs, emissions, biomass yields, and soil carbon sequestration. At the biorefinery, alternative pretreatment and conversion methods lead to different ethanol yields and relative carbon flows among point sources of CO₂ emissions. We present an integrated mixed-integer optimization model for the biofuel SC with a detailed biorefinery model considering CCS that can be used to study the economic and environmental tradeoffs between (i) high resolution SC design and operation, (ii) upstream spatially explicit carbon sequestration in soils by dedicated bioenergy crops, (iii) biorefinery design and operation, and (iv) downstream CCS technology selection and operation. We present a case study with, critically, realistic crop, economic, and environmental data in the US Midwest to explore the effects of key system parameters on the cost and GHG balance of the entire system, and the associated changes in SC and biorefinery design and operation.

Keywords: Sustainability, Supply Chain, Carbon Capture

1. Introduction

An efficiently designed and operated supply chain (SC) from field to product will be required to make cellulosic biofuels competitive with current grain-based fuels and fossil fuels. While a large amount of highly distributed land will need to be converted to biomass to produce an adequate amount of fuel, carefully choosing the location of crop establishment and levels of management (e.g. fertilization) can have a significant impact on crop yields and the greenhouse gas (GHG) balance of the supply system; however, landscape design decisions are typically studied separately from SC and biorefinery design (Field et al., 2018). Crop yields and soil carbon sequestration potentials are field specific and involve complex tradeoffs with downstream SC decisions related to facility location, transportation planning, and inventory management. Optimization modeling at a high spatial resolution can be used to study the above tradeoffs simultaneously to

minimize both the SC costs and GHG emissions. However, the soil carbon sequestration is not the only source of negative emissions. Carbon capture and storage (CCS) technologies installed at the biorefinery have the potential to improve the GHG balance of the system but require additional capital and operational investment.

At the biorefinery, CO₂ is emitted from three different point sources: nearly pure CO₂ from fermentation, ~73 wt.% CO₂ in biogas from anaerobic digestion of wastewater, and ~20 wt.% CO₂ in flue gas from solid residue (primarily lignin) combustion (Humbird et al., 2011). The relative amounts of CO₂ emitted from these point sources varies depending on what pretreatment technology is used. While dilute acid (DA) pretreatment is the most mature, other pretreatments based on ammonia fiber expansion (AFEX) or copper-catalyzed alkaline hydrogen peroxide (AHP) have been developed. In addition to affecting the relative CO₂ emissions from each point source, these pretreatment technologies have different ethanol yields, energy demands, and operating and capital costs. Therefore, a biorefinery model needs to consider different pretreatment technologies and allow for capture from specific point sources independently, which has only recently been considered by Geissler and Maravelias (2021).

Several studies have simultaneously considered SC and CCS optimization for other bioenergy systems (Lainez-Aguirre et al., 2017); however, relaxing assumptions about the availability and location of biomass and modeling a spatially-explicit supply chain is important especially given the opportunity to design the landscape while considering the effect of soil carbon sequestration on the GHG balance. Importantly, modeling the SC and landscape at a high spatial resolution and allowing flexible capture from different point sources of CO₂ at the biorefinery can identify tradeoffs between upstream and downstream designs, operation, costs, and emissions to inform policy decisions. We combine SC and biorefinery design into a flexible integrated model to study the relative economic and environmental impacts under a range of carbon incentives applied to different areas of the system.

In section 2, we present a model for simultaneous optimization of landscape, SC, and biorefinery design. In section 3 we report and discuss the results for a case study in the state of Michigan, USA. Finally, in section 4 we present conclusions and discuss further applications of our research.

2. Supply chain and biorefinery model

The integrated optimization model introduced in this paper consists of three components: a landscape design model, a multi-period logistics network model, and a biorefinery superstructure model. We employ a flexible data workflow to generate realistic high-resolution data for switchgrass grown on marginal lands. First, a geographic raster of marginal land is identified based on a chosen definition (Lark et al., 2020). Next, crop growth is simulated using the SALUS biogeochemical crop model for the chosen lands according to weather, soil, and land use data (Basso and Ritchie, 2015). The resulting biomass yields, soil carbon sequestration potentials, and land areas are processed into a set of fields $f \in \mathbf{F}$ and a set of harvesting sites $j \in \mathbf{J}$ for use in the optimization model. Other model parameters are based on literature values. The model is solved for a representative year broken into time periods $t \in \mathbf{T}$. We use italicized uppercase Latin letters for variables, lower and uppercase Greek letters for parameters, lowercase Latin letters for indices, and uppercase bold Latin letters for sets. The landscape model makes decisions regarding the location of crop establishment, the level of fertilization to apply at each location, and harvest decisions. The associated costs, C^{LAND} , and emissions, GHG^{LAND} , from the landscape model are presented in equations (1) and (2). Emissions

are considered from all on field activities including the annualized impact from crop establishment and soil carbon sequestration.

$$C^{LAND} = \sum_{i,j,t} \lambda_i H_{i,j,t} + \sum_f \rho N_f + \sum_{i,j} \phi_i A_{i,f} \quad (1)$$

$$GHG^{LAND} = \sum_{i,j,t} \Gamma_i^{MG} H_{i,j,t} + \sum_f \Gamma^N F_f + \sum_{i,j} \Gamma_i^{HA} A_{i,f} - \sum_{i,f} GHG_{i,f}^{SOC} \quad (2)$$

Parameter λ_i is the per-Mg cost of harvesting and handling ($H_{i,j,t}$) crop $i \in \mathbf{I}^F$ at harvesting site j . Variable N_f is the amount (kg) of fertilizer applied to field f , and ρ is the cost per-kg of fertilizer. ϕ_i is the annualized per-ha cost of crop establishment and $A_{i,f}$ is the area of field f established with crop i . Emissions are determined similarly with Γ_i^{MG} , Γ^N , and Γ_i^{HA} being the per-Mg crop, per-kg nitrogen fertilizer, and per-ha emissions respectively. Finally, $GHG_{i,f}^{SOC}$ is a decision variable that represents the amount of soil carbon sequestered at field f and is constrained by decision variables related to crop establishment and fertilization. If $GHG_{i,f}^{SOC}$ is positive, the soil at field f sequesters carbon. The logistics model extends work by Ng et al. (2018) to include a more detailed representation of the biorefinery, including CCS (details shown in equations (3)-(6)). The biorefinery superstructure model makes decisions related to the technology selection and interconnection within the facility, the production planning decisions for a representative year, and the capacity of each technology block. A diagram of the biorefinery and the potential interconnections is shown in Figure 1. The SCND model makes decisions for a representative year that include preprocessing depot location, technology, and capacity, biorefinery location, transportation planning, transportation mode, and inventory planning. In the interest of brevity, detailed equations for the SCND model are omitted as a similar logistics model has previously been published (Ng et al., 2018).

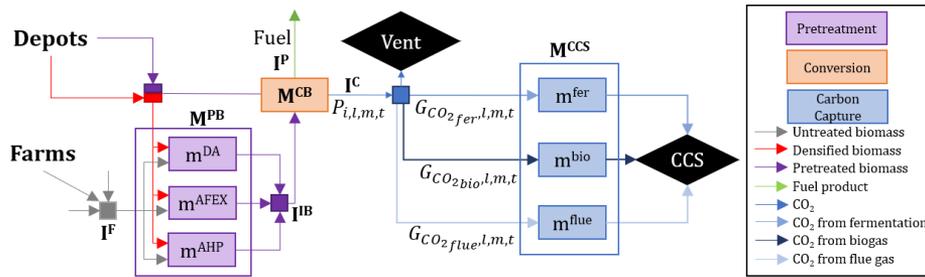

Figure 1. Biorefinery configuration, potential technologies, and potential interconnections.

The pretreatment block is a set of alternatives $\mathbf{M}^{PB} = \{DA, AFEX, AHP\}$. The CCS block $\mathbf{M}^{CCS} = \{FER, FLU, BIO\}$ includes technologies for capturing carbon from each point source (fermentation, flue gas, and biogas respectively). The binary variable $U_{l,m}$ indicates if technology m is installed at biorefinery $l \in \mathbf{L}$, and the capacity $Q_{l,m}$ of each technology is constrained in equation (3) by lower and upper bounds $\epsilon_m^L / \epsilon_m^U$. The variable $P_{i,l,m,t}$ represents the amount of CO_2 , $i \in \mathbf{I}^C$, produced during biomass conversion as different point sources that are available to be consumed by installed CCS technologies. Equations (4)-(6) govern the flow of CO_2 through the biorefinery where $G_{i,l,m,t}^{CCS}$ is the amount of carbon source $i \in \mathbf{I}^C$ consumed by CCS technology $m \in \mathbf{M}^{CCS}$. We introduce two-dimensional set $\mathbf{V} \subset \mathbf{I}^C \times \mathbf{M}^{CCS}$ as the set of valid CCS combinations, so that if element $(i, m) \in \mathbf{V}$, carbon point source i can be captured by CCS technology m .

$$\epsilon_m^L U_{l,m} \leq Q_{l,m} \leq \epsilon_m^U U_{l,m} \quad (3)$$

$$G_{i,l,m,t}^{CCS} \leq \sum_{m' \in \mathbf{M}^{CB}} P_{i,l,m',t} \quad \forall (i, m) \in \mathbf{V}, l, t \quad (4)$$

$$G_{i,l,m,t}^{CCS} \leq Q_{l,m} \quad \forall (i, m) \in \mathbf{V}, l, t \quad (5)$$

$$L_{i',t} = \sum_{l,m \in \mathbf{M}^{PB} \cup \mathbf{M}^{CB}} P_{i',l,m,t}^{IPB-CB} + \sum_{k,m \in \mathbf{M}^{PD}} P_{i',k,m,t}^{ID-PD} + \sum_{l,i \in \mathbf{I}^C, m \in \mathbf{M}^{CCS}} \eta_{i,i',m} G_{i,l,m,t}^{CCS} \quad \forall i' \in \mathbf{I}^B, t \quad (6)$$

The amount of carbon consumed by a CCS technology is bounded by both the amount that is produced in the conversion block (the balance is assumed to be vented if $G_{i,l,m,t}^{CCS} < P_{i,l,m',t}$) and by the installed capacity of appropriate CCS technologies. Finally, $L_{i',t}$, the sale/sequestration of electricity/ CO_2 , $i \in \mathbf{I}^B = \{CSEQ, ELEC\}$, is controlled by equation (6) where $P_{i',l,m,t}^{IPB-CB}$ represents the production of $i' \in \mathbf{I}^B$ from the conversion and pretreatment blocks $m \in \mathbf{M}^{PB} \cup \mathbf{M}^{CB}$, $P_{i',l,m,t}^{ID-PD}$ is the electricity consumption of preprocessing depot technology $m \in \mathbf{M}^{PD}$ at depot $k \in \mathbf{K}$ ($P_{i',l,m,t}^{IPB-CB} = P_{i',l,m,t}^{ID-PD} = 0$ for $i' = CSEQ$) and $\eta_{i,i',m}$ is the conversion coefficient for product i to i' using technology m . We take the convention of variables being ≤ 0 for the consumption of electricity and ≥ 0 for the production. The objective value is given by equation (7) which considers, on an annualized basis, the capital cost, landscape cost, production cost, transportation cost, inventory cost, revenue from byproducts (electricity), and GHG costs respectively.

$$TAC = C^{CAP} + C^{LAND} + C^{PROD} + C^{TRA} + C^{INV} - C^{BY} + C^{GHG} \quad (7)$$

$$C^{GHG} = \sum_t \pi^{SCC} GHG_t^{SC} - \sum_t \pi^{SEQ} L_{CSEQ,t} \quad (8)$$

Equation (8) represents the GHG emissions on a cost basis rather than using an explicit multi-objective approach in order to better compare captured carbon and GHG emissions from the SC (You et al., 2012). To compare the environmental impact of the SC with the impact of CCS at the biorefinery, we introduce two parameters that value CO_2 equivalents (CO_2e) in the objective. The first is the sequestration credit, π^{SEQ} , which applies only to tangible CO_2 sequestered by CCS technologies at the biorefinery. The sequestration credit represents a measurable policy-based tax/credit that can incentivize CCS. The second parameter, π^{SCC} , is the ‘social cost of carbon’ (SCC) which represents the cost impact of all the additional sources of CO_2e (GHG_t^{SC}) that are present from annualized landscape and SC activities, and the impact from replacing grid electricity with excess electricity produced at the biorefinery. Importantly, the SCC also applies to the less readily measurable source of negative emissions, the soil carbon sequestration. By adjusting the two carbon value parameters separately, the integrated model can be used to study the environmental and economic tradeoffs between the landscape, the SC, and the biorefinery. Furthermore, this framework could be easily extended to use multi-objective optimization for further insights into the tradeoff between cost and GHG emissions.

3. Results

We apply the model discussed in section 2 to a case study of Michigan, USA. We use a harvesting site resolution of 8×8 km with 15 potential biorefinery locations, 300 potential depots, and 41,000 potential fields for establishment identified as marginal lands (Lark et al., 2020). The model is implemented in GAMS 36.1 and solved with Gurobi 9.1.2 to a 1% optimality gap on 2.6 GHz Linux cluster machines in under 24h for all instances. The results for a range of values for sequestration credit and SCC are shown in Figure 2. The SC and biorefinery decisions for representative solutions are shown in Figure 3.

and compression, so less electricity is sold when carbon is captured, and therefore a lower total credit is obtained for selling grid electricity. This causes the sequestration credit required to incentivize CCS from a given point source to increase proportionally to the SCC considered. The rate of this increase is determined by the electricity-equivalent energy requirement for capture from that source. It is important to note that the GHG credit for selling grid electricity depends on the electricity production mix, which varies significantly by location and over time. Overall, CCS at the biorefinery has a much greater effect of the GHG balance than SC operation by nearly an order of magnitude.

Applying sequestration credits less than \$25/Mg CO₂ does not incentivize any carbon capture at the biorefinery and therefore has no effect on the total cost. At this level of biofuel production, the SC results in net GHG emissions, so increasing the SCC increases the cost of ethanol production. As the SCC increases, fields with higher soil carbon are chosen, and the rate of increasing total cost diminishes as the SCC increases.

4. Conclusions

We present a model to simultaneously consider high resolution SC design with detailed biorefinery design that includes carbon capture and sequestration. In the case study, we find that CCS at the biorefinery has a much greater impact on the total GHG mitigation of ethanol production than the SC operation. Correspondingly, a sequestration credit has a greater effect on the total cost of ethanol production than a social cost of carbon applied to all other GHG emissions/sequestration. Still, the social cost of carbon impacts what sequestration credit is needed to incentive carbon capture from specific point sources and also effects the optimal SC and landscape configuration. The magnitude of this effect is determined by the energy requirement of capture from that source, and the emissions from local grid electricity, the latter of which varies by location and both of which will change in the future. The proposed model allows for the study of economic and environmental tradeoffs among different stages in the production of biofuels. Its integration of spatially-explicit real-world data makes it a critical tool for future analyses of BECCS systems.

Abstract

Supply chain problems for the production of green electricity and green hydrogen-based fuel for use in utilities and transportation markets are typically represented by large-scale multi-period planning and scheduling models. The solution of such models often presents computational challenges even with state-of-the-art commercial solvers. In this work, we present an effective decomposition based strategy to overcome this challenge featuring a two-stage matheuristic that is embedded in a mixed-integer programming (MIP) solver. The matheuristic first determines a locally optimal solution for the infrastructure planning decisions based on a relaxed solution to the overall problem, and then identifies a locally optimal solution for the operation scheduling decisions. For large-scale supply chain problems, the computational results indicate that the proposed strategy is quite effective.

Keywords: Supply Chain Optimization, Mathematical Programming, Large-Scale Problems

1. Introduction

Due to globalization, liberalization of emerging markets, and population growth, the demands for raw materials and manufactured products are rapidly increasing (Allen et al., 2019). Consequently, supply chains are expanding with alacrity at the global scale and becoming more and more synergistic at the regional scale. At the same time, there has been a societal push towards carbon neutral energy systems that meet their energy requirements via power generated from solar arrays and wind turbines (Shell, 2020; Li et al., 2021).

Unfortunately, the dispatchability of these two types of energy generators are plagued with fluctuations and stochastic intermittencies. To combat these complications, various technologies for storing energy have been put forth, namely, lithium-ion batteries, pumped storage hydro-power, and hydrogen-based dense energy carriers (H-DECs); however, each of these energy storage technologies have their own strengths and weaknesses (Palys et al., 2021). Therefore, there is a need for quantitative frameworks to ensure that the energy systems within supply chains are optimally developed and can operate over a wide range of conditions (Demirhan et al., 2020; He et al., 2021).

In this work, we generalize our previously developed optimization framework for the simultaneous design and operation of energy systems from a single period framework to a multi-period frame-

work (Allen et al., 2021). To address the computational issues that arise in solving multi-period planning and scheduling problems, we have developed a matheuristic that can be integrated into a MIP solver to compute upper bounds at nodes in the branch-and-bound tree – for a detailed review on matheuristics, please see (Archetti and Speranza, 2014). The proposed strategy is agnostic towards the exact MIP formulation of the problem and only assumes: (i) the planning constraints and scheduling constraints can be separated from each other; and (ii) the scheduling constraints can be further divided by their corresponding planning period and representative scenario.

We demonstrate the effectiveness of the framework through the use of a case study wherein we examine the development of a green hydrogen-based supply chain that spans multiple locations over the course of multiple planning periods. We find that the proposed strategy significantly reduces the overall computational time when compared to a state-of-the-art MIP solver.

The outline of this article is as follows: in Section 2 we present the problem statement; in Section 3 we present a MIP formulation for solving multi-period planning and scheduling problems and describe how it can be further decomposed, show the two-stage matheuristic, and outline how the matheuristic can be conjoined with a MIP solver; in Section 4 we present and describe the results to the problem under consideration; and in Section 5 we state some closing remarks.

2. Problem Statement

Consider a central planner who is developing a green hydrogen-based supply chain along the Gulf Coast of Texas and in Southern California over the next thirty years. The central planner would like to produce hydrogen and ammonia via electrolysis and the Haber-Bosch process, respectively, in Houston, Texas and Corpus Christi, Texas. To power these processes the central planner would like to utilize solar and wind farms. To combat the issues in the dispatchability of these generators, the central planner would like to have the ability to store electricity in lithium-ion batteries.

Once the fuels are produced in Texas, they are either transported directly to Long Beach, California or stored to be transported to Long Beach at a later time. After the fuels reach Long Beach, they are: (i) utilized to meet the regions fuel and energy demands as given in Table 1; and/or (ii) stored to be utilized at a later time. It should be noted that electricity can be generated locally via solar farms and/or stored locally in lithium-ion batteries in Long Beach.

Table 1: Energy and fuel demands in Long Beach, California

Material	Planning Period					
	2025	2030	2035	2040	2045	2050
Ammonia [ton/day]	300	350	400	450	500	550
Electricity [GW]	1.0	1.2	1.4	1.6	1.8	2.0
Hydrogen [ton/day]	50	600	900	1100	1300	1500

The cost functions and conversion factors of the processes, storage units, and transportation mechanisms in the problem are taken from a case study in the literature (Allen et al., 2021; Demirhan et al., 2020). The hourly capacity factors for the solar and wind farms are taken from the SIND Toolkit (Hummon et al., 2012) and WIND toolkit (Draxl et al., 2015), respectively.

3. Solution Framework

In this section, we present a generic and compact MIP formulation for solving multi-period planning and scheduling problems. We then describe how the multi-period planning and scheduling problem can be decomposed into a single planning problem and a set of independent scheduling

problems. Finally, we present a two-stage matheuristic that utilizes the decomposed form of the problem to first find a locally optimal integer feasible solution to the planning problem, and then find a locally optimal integer feasible solution to the set of scheduling problems.

3.1. Mathematical Program

The generic and compact MIP formulation of the multi-period planning and scheduling problem is given by Eq. (1). In this formulation there are no underlying assumptions about the structure of planning and scheduling problems except that their corresponding constraint matrices are decomposable. Specifically, it is assumed that planning constraints can be separated from the scheduling constraints and that the scheduling constraints can be further decomposed by their corresponding planning period, $p \in P$, and representative scenario, $s \in S$, where P is the set of planning periods where infrastructure decisions can be made and S is the set of representative scenarios.

$$\min_{x \in X, y \in Y} \{c(x) + d(y) : f(x) = 0; g(x, y) = 0\} \quad (1)$$

The vector, $x \in X$, represents the binary and continuous variables required to describe the planning decisions. The vector, $y \in Y$, represents the binary and continuous variables required to describe the scheduling decisions. The objective functions, $c(\cdot)$ and $d(\cdot)$, capture the capital and operational costs, respectively. The constraints, $f(\cdot) = 0$ and $g(\cdot, \cdot) = 0$, govern the behavior of the planning decisions and scheduling decisions, respectively. It is assumed that a new component of a technology, $t \in T$, can be constructed in each planning period, $p \in P$, at each location, $l \in L$, in the supply chain.

3.2. Decomposition Framework

Figure 1 is an illustration of the block-diagonal decomposable structure of the multi-period planning and scheduling problem. In this illustration, it is assumed that there are three planning periods in which infrastructure decisions can be made – each set of corresponding scheduling problems are represented by a large diagonal block. It is further assumed, that each scheduling problem has been restructured such that it is now composed of three representative scenarios – each of the representative scenarios are illustrated by a small blue diagonal block. From inspection of Figure 1 it is evident that if the planning decisions have been fixed, the problem reduces to nine independent scheduling problems, as given by Eq. (2).

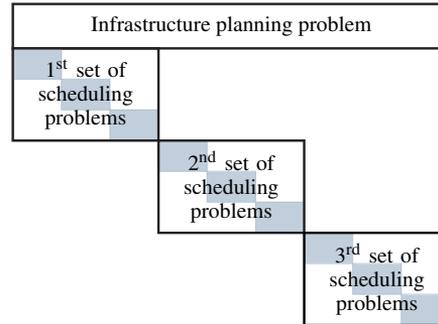

Figure 1: Decomposed formulation of the multi-period planning and scheduling problem

Each of the independent scheduling problems are parameterized by the vector, \bar{x} , which stores a feasible solution for the infrastructure planning decisions. The goal of each scheduling problem is to minimize the operational cost of the system, $d_{p,s}(\cdot)$, during the respective planning period, $p \in P$, and representative scenario, $s \in S$, while simultaneously ensuring that the scheduling constraints, $g_{p,s}(\cdot, \cdot) = 0$, are not violated, where the vector, $y_{s,p} \in Y_{s,p}$, represents the binary and continuous variables required to describe the scheduling decisions as well as any additional slack variables.

$$y_{p,s}^*(\bar{x}) = \arg \min_{y_{p,s} \in Y_{p,s}} \{d_{p,s}(y_{p,s}) : g_{p,s}(\bar{x}, y_{p,s}) = 0\} \quad (2)$$

It should be noted that the size of each scheduling problem is on the order of $|P| \cdot |S|$ times smaller than the original multi-period planning and scheduling problem.

3.3. Two-Stage Matheuristic

In this subsection, we present a two-stage matheuristic, which is given by Algorithm 3.1, for constructing locally optimal integer feasible solutions to multiple-period planning and scheduling problems. In the first stage of the matheuristic, a solution to the infrastructure planning decisions is found by solving a set of independent set covering problems. These set covering problems are parameterized by a relaxed solution to the operational scheduling decisions. In the second stage of the matheuristic, a solution to the operational scheduling decisions is found by solving a set independent scheduling problems. These independent scheduling problems are parameterized by locally optimal solution to the infrastructure planning decisions constructed in the first stage of the matheuristic.

Algorithm 3.1: Two-Stage Matheuristic

input : y – relaxed solution to the operational scheduling decisions
output: locally optimal solution to the planning and scheduling decisions

Function Matheuristic(y):

```

 $\bar{x} \leftarrow \emptyset$ 
foreach  $(t, l) \in T \times L$  do
  |  $\bar{x} \leftarrow \bar{x} \cup x_{t,l}^*(y_{t,l})$ 
end
 $\bar{y} \leftarrow \emptyset$ 
foreach  $(p, s) \in P \times S$  do
  |  $\bar{y} \leftarrow \bar{y} \cup y_{p,s}^*(\bar{x})$ 
end
return  $\bar{x} \cup \bar{y}$ 

```

End Function

The first stage of the matheuristic constructs an integer feasible solution to the infrastructure planning decisions, $\cup_{t \in T} \cup_{l \in L} x_{t,l}^*(\hat{y}_{t,l})$. The parameter, $\hat{y}_{t,l}$, that is passed to the optimization problem, $x_{t,l}^*(\cdot)$, stores a relaxed solution to the scheduling decisions for components of technology, $t \in T$, that are located in location, $l \in L$. In Eq. (3), the goal is to minimize the capital cost, $c_{t,l}(\cdot)$, of constructing the components of a given technology, $t \in T$, over the course of the planning horizon, P , at a specific location, $l \in L$, where the vector, $x_{t,l} \in X_{t,l}$, represents the binary and continuous variables required to describe the infrastructure planning decisions for a specific technology, $t \in T$, at a location, $l \in L$.

$$x_{t,l}^*(\hat{y}_{t,l}) = \arg \min_{x_{t,l} \in X_{t,l}} \{c_{t,l}(x_{t,l}) : f_{t,l}(x_{t,l}) = 0; h_{t,l,p,s}(x_{t,l}, \hat{y}_{t,l}) \geq 0 \forall p \in P, s \in S\} \quad (3)$$

Simultaneously the set covering constraint, $h_{t,l,p,s}(\cdot, \cdot) \geq 0$, ensures that the combined capacities of the components of a given technology are larger than their maximum combined production set points in a relaxed scheduling solution, $\hat{y}_{t,l}$, for each planning period, $p \in P$, and each representative scheduling scenario, $s \in S$. Practically speaking, this constraint ensures that there is always enough production capacity that can operate in parallel for a given technology to cover the production set points given in a relaxed solution to the scheduling problems.

In the second stage of the matheuristic, the locally optimal infrastructure planning decisions, $\bar{x} = \cup_{t \in T} \cup_{l \in L} x_{t,l}^*(\hat{y}_{t,l})$, found in the first stage of the matheuristic are utilized as parameters to generate a locally optimal solution, $\cup_{p \in P} \cup_{s \in S} y_{p,s}^*(\bar{x})$, for the operational scheduling decisions.

3.4. Unification of the Two-Stage Matheuristic and a MIP solver

The matheuristic is integrated into a MIP solver and is called whenever the MIP solver generates a new node in the branch-and-bound tree. Once it is called, a three-stage procedure begins to transpire. In the first stage of the procedure, a relaxed solution to planning and scheduling decisions is accessed from the MIP solver. In the second stage, the solution to these relaxed decisions is passed to the two-stage matheuristic and a locally optimal integer feasible solution is generated. In the final stage, the solution found in the two-stage matheuristic is passed back to the MIP solver as a new upper bound. It should be noted that set covering problems in the first stage of the matheuristic and the scheduling problems in second stage of the matheuristic can be solved in serial or parallel via a MIP solver or a heuristic.

4. Results and Discussion

In this Section, the proposed framework is utilized to solve the aforementioned problem that the central planner is facing. Specifically, the proposed framework is pitted against Gurobi 9.5 utilizing its default parameters through the use of a set of computational experiments that examines how the number of representative scenarios effects the problem’s overall run time (Gurobi Optimization, LLC, 2021). The experiments were performed on a machine with a Intel Xeon W-10885M Processor and 64 GB of RAM.

The MIP formulation of the problem was posed as a mixed-integer quadratic programming (MIQP) problem, please see (Allen et al., 2022) for the constraints and objective function utilized in the model. It should be noted that in the MIQP formulation the bilinear terms arise from the multiplication of the continuous and binary variables in the constraints. Furthermore, we did not linearize these constraints because it was found that Gurobi’s internal linearization toolbox provided a tighter initial linear programming relaxation albeit with a slight increase in the overall computational time.

Table 2 describes the summary statistics for the MIQP formulation for the problem that the central planner is facing. Figure 2 and Figure 3 illustrate the MIP gap of the problem as a function of computational time and the number of representative days for Gurobi when employing its default parameters and for the proposed solution strategy respectively. In both of these bar plot figures, the color of the bar represents the MIP gap at a specific time. It should be highlighted that: (i) when the color of the bar is “black” Gurobi has yet to compute the initial lower bound to the problem; (ii) the y-axis and the color bar scale in both of the figures utilize a \log_{10} scale; and (iii) the problems have been solved a MIP gap of less than 1%.

From inspection of Figure 2 and Figure 3 it is clear that the proposed solution strategy significantly reduces the amount of time that it takes the problem to converge to the desired MIP gap of 1%. Specifically, we find that when the two-stage matheuristic is conjoined with Gurobi, thereby acting as its primal heuristic, the amount of time required to solve the prob-

Table 2: Size of the MIQP formulation for the problem that the central planner is facing

Rep. Days	Binary Variables	Continuous Variables	Constraints
1	97,962	37,482	87,564
2	195,738	74,778	174,756

7	684,618	261,258	610,716
8	782,394	298,554	697,908
9	880,170	335,850	785,100
10	977,946	373,146	872,292

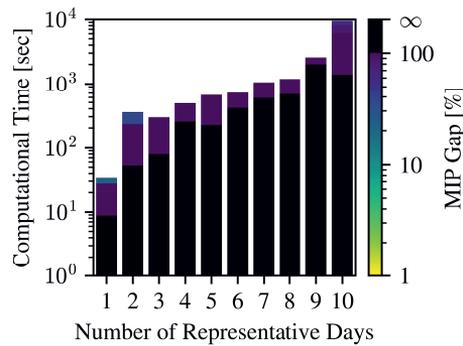

Figure 2: Computational time required to solve the problem utilizing Gurobi employing its default parameters

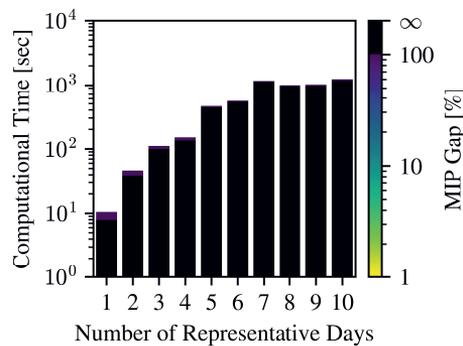

Figure 3: Computational time required to solve the problem utilizing the two-stage matheuristic when it is integrated in Gurobi

lem, once the initial linear programming relaxation was found, was reduced by an average of 93%. This feat is primarily attributed to the strength of the initial linear programming relaxation in which the two-stage matheuristic is utilized to construct a locally optimal solution to the infrastructure planning decisions. This tight relaxation in turn allowed the proposed solution strategy to converge to the desired MIP gap in one iteration for each of the test instances.

5. Conclusion

We have presented a solution strategy for solving large-scale multi-period planning and scheduling problems. We first illustrated that multi-period planning and scheduling problems can be decomposed into a single infrastructure planning and a set of scheduling problems. We then introduced a two-stage matheuristic that allows the problem to be further decomposed into a set of infrastructure planning problems and a set of scheduling problems. We demonstrated the effectiveness of the solution strategy through the use of a case study that examined the development of a national supply chain that produces green electricity and green hydrogen-based fuels for use in utilities and transportation markets. The results show that the proposed strategy significantly reduces the amount of time it takes the problem to converge to the desired MIP gap when compared to Gurobi's default solver. From inspection of the converge plots, Figure 2 and Figure 3, we believe that the framework can be further improved by reducing the amount of time spent computing the initial linear programming relaxation of the problem. This can be accomplished by utilizing a lagrangian decomposition method or by applying a Dantzig-Wolfe reformulation and utilizing a column generation procedure.

Abstract

Pharmaceutical companies are responsible for the consistent delivery of life-saving medicines to patients. Production must be planned to ensure supply-demand balancing and time-dependent capacity constraints must be handled through capacity planning. This work describes an aggregated 4-step framework for mid-term decision support on integrated production and capacity planning including the relevant MILP mathematical models. The framework has been developed by combining theory with observed requirements in industry and it is applied to a case study abstracted from industrial API manufacturing to provide an example of its industrial relevance.

Keywords: MILP, Planning & Scheduling, Pharmaceutical Manufacturing, Capacity Planning

1. Introduction

Pharmaceutical companies must coordinate all parts of their complex supply chain (SC) to deliver life-saving medicines to patients consistently at low cost (Marques et al., 2020). Manufacturing of active pharmaceutical ingredient (API) is a crucial step that is constrained by low manufacturing flexibility, high capital investment and long building & approval timelines. Multi-product manufacturing lines are introduced to increase flexibility but the added system complexity makes it necessary to plan production on the mid-term time horizon spanning months to a few years. On this time horizon, short-term operational effects and long-term capacity changes can be overlooked. Typically, manufacturing at minimum cost is desired which results in a capacity constrained planning problem and the highly regulated pharmaceutical environment means that only certain limited capacity adjustments can be made. Researchers in process systems engineering (PSE) and operations research (OR) have developed models for production planning (Maravelias and Sung, 2009; Hu and Hu, 2016) and capacity planning (Smirnov et al., 2021) but the combined problem of planning production and capacity on the mid-term horizon has received limited attention despite its industrial importance. In this work, we aim to bridge the gap by developing a framework for evaluating capacity in a multi-product, multi-stage, multi-line campaign production environment, which is typical in pharmaceutical manufacturing. The development is based on the planning literature within PSE and OR combined with insights from a pharmaceutical company, and the framework integrates mathematical optimization models for campaign scheduling. The news value consists of creating production plans while accounting for capacity projects

to both provide production plans, expected inventories of all materials and effects of capacity changes as a function of both capacity level and implementation timing.

2. Problem Statement

The capacity and production planning problem can be stated as follows: Given a multi-product, multi-stage, multi-line API manufacturing system, demand profiles for all products and initial inventories of all products and intermediates. Determine optimal system-wide mid-term production plans and any required capacity changes, their amount and timing. This is subject to maintaining all products above their safety levels and specific features of API manufacturing such as changeover and release times.

3. Methodology

In this section, a 4-step framework for combined, model-based production and capacity planning in the pharmaceutical industry is presented. Such an approach is necessary to evaluate mid-term capacity requirements that are variable in both amount and timing along with regular production planning across a complex system. Next, the model is described followed by the framework for evaluating production plans and capacity.

3.1. Campaign scheduling model

The basis of the framework is a campaign scheduling model that is used to assess production capability across the system and estimate mid-term inventory levels for products and intermediates through campaign plan generation. The model is formulated as a discrete time, multi-period, multi-product, multi-stage, multi-line mixed integer linear programming (MILP) model based on the state-task network (STN) (Kondili et al., 1993). It includes new release time parameters Rel_{is} , continuous slack variables for representation of demand backlogging and/or safety inventory violations Δ_{st} , inclusion of time dependency in parameters for both capacity and safety storage level V_{ijt}^{max} , $C_{s,t}^{min}$, respectively, and a new continuous variable that allows the activation and selection of required capacity changes ∇_{ijt} . Overall, the model must be able to determine material balances through the allocation of production to lines while respecting capacity and storage limitations and time requirements for cleaning and quality control of products. Equation 1 determines the continuous material balance variable S_{st} , of product s at time t as a function of continuous variables for production and consumption B_{ijt} , and parameters for task stoichiometry ρ'_{is} and ρ_{is} , and demand D_{st} . Equation 2 enforces a safety inventory. Equation 3 uses binary allocation variables W_{ijt} , to describe allocation of manufacturing to lines through full backwards aggregation and states that only one product can be produced at a time. Equation 4 sets the production amount which is (de)activated by the allocation variable and constrained by the upper system capacity which has a fixed and variable component. Equations 5 is used to enforce sequence-dependent changeover times such that a new task can only start when enough time has passed after the previous task has finished. Equation 6 states that all slack variables must be below a maximum value and Equation 7 enforces all capacity increase variables below their corresponding allocation variable which maintains the link between production and allocation. Equation 8 constrains all capacity variables below a maximum value.

$$S_{st} = S_{s,t-1} + \sum_{i \in T_s} \rho'_{is} \sum_{j \in K_i} B_{i,j,t-P_{is}-Rel_{is}} - \sum_{i \in T_s} \rho_{is} \sum_{j \in K_i} B_{ijt} - D_{st} + \Delta_{st} - \Delta_{st-1}, \forall s, t \quad (1)$$

$$C_{s,t}^{min} \leq S_{s,t}, \quad \forall s, t \quad (2)$$

$$\sum_{i \in I_j} \sum_{t'=t}^{t-p_i+1} W_{ijt'} \leq 1, \quad \forall j, t \tag{3}$$

$$B_{ijt} \leq (W_{ijt} + \nabla_{ijt})V_{ijt}^{max}, \quad \forall i, t, j \in K_i \tag{4}$$

$$\sum_{i \in I_j^{(k)}} W_{ijt} + \sum_{i \in I_j^{(k)}} W_{ij,t-p_i-\theta} \leq 1, \quad \forall t, j, \theta = 0 \dots \tau_{jkk'} - 1 \tag{5}$$

$$\Delta_{st} \leq \Delta^{max}, \quad \forall s \in \text{Products}, t \tag{6}$$

$$\nabla_{ijt} \leq W_{ijt}, \quad \forall i, t, j \in K_i \tag{7}$$

$$\nabla_{ijt} \leq \nabla^{max}, \quad \forall i, t, j \in K_i \tag{8}$$

Different objective functions may be used depending on the questions or problems that are addressed. Objective O1 states that product inventories are maximized on a set of time points. Objective functions O2 and O3 are used in reformulations of the original problem to obtain minimum safety stock violation/backlogging or minimum capacity increase.

$$\text{maximize } \sum_t S_{st}, \forall s \in \text{Products}, t \in \text{Time Points} \tag{O1}$$

$$\text{minimize } \Delta^{max} \tag{O2}$$

$$\text{minimize } \nabla^{max} \tag{O3}$$

3.2. Framework for capacity and production planning

The framework is applicable to production planning problems within pharmaceutical manufacturing. The overall objective of the problem will determine the specific objective function and relevant scenarios to be investigated. It consists of four main steps: (1) system categorization and data collection, (2) baseline supply capability, (3) capacity analysis and (4) supply decision analysis. Baseline performance is tracked through steps 1 & 2, step 3 is added to escalate from a production planning to a capacity planning problem which is demanded by practitioners and step 4 shows the effects of changing the system capacity, operation, etc. Each of the steps will now be described in further detail.

3.2.1. System characterization and data collection

The characterization step is used to establish system boundaries and describe manufacturing of each product and intermediate. System boundaries must be established based on the problem definition to ensure that conclusions are valid and to limit complexity and required assumptions. The system characterization results in the overview in Figure 1 showing production pathways, lines that are set up for specific production and where these lines exist. The data collection step defines model parameters based on internal company systems and people. The data could come from finance systems or it could be extracted from data historians and aggregated into main operations to avoid describing individual pieces of equipment. Future capacities from projects that have already been approved can be added along with any planned downtime. The projects are an outcome of step 3 in the framework and the planned downtime comes out of steps 3 or 4 depending on whether it results in changed capacity or not.

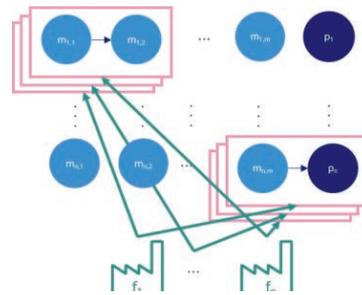

Figure 1: System characterization describing products (dark blue), intermediates (light blue), production lines (pink) and facilities (green).

3.2.2. Baseline supply capability

In step 2, the campaign scheduling model is set up with an objective function(s) that depends on the decision maker (DM) and the type of analysis/type of questions asked.

Next, the model is solved, and the results are reported in terms of key performance indicators (KPIs), for example, minimum inventories, cost or number of changeovers, and illustrations of the plans and inventories. It is our experience that DMs often want to see real plans and inventories rather than just KPIs since these are more relatable and provide a better understanding. If all KPIs are within specifications, step 3 is skipped, otherwise the capacity analysis is carried out.

3.2.3. Capacity analysis

In step 3, the future capacity of the system is explored either through a direct or an indirect approach. In the direct approach, one or more capacity changes are considered and introduced either as scenarios or directly into the model. These changes could originate from modelling activities on the system that result in physical changes or changed operating parameters. In the indirect approach, optimal capacity changes are investigated solely based on the campaign scheduling model to suggest required capacity increases that are given as input to other modelling activities.

3.2.4. Supply decision analysis

In step 4, the effects of any changes to the system (capacity, shutdown, product priority etc.) are determined. The results include scenario-dependent production plans, expected inventories, effects of (capacity) changes and suggested capacity implementation timings and final levels. Relevant KPIs are used to compare baseline supply with the different scenarios to provide the DM with the needed information to decide.

4. Case Study

The case study is abstracted from an industrial manufacturing network that converts raw materials to API on multiple multi-product lines. Plans up to a certain time are fixed due to constraints on manning, material supply, fixed deliveries etc. and used to project initial inventories for all materials along with the state of each equipment (producing, idle, changeover in progress). Demand increases in the pharmaceutical industry typically lead to a situation where capacity becomes constrained. Therefore, in this case study inventories maximization was selected throughout the horizon for all final products. The next sections will describe the solution of the case study through the 4-step framework.

4.1. System characterization and data collection

The baseline system consists of four products (referred to as A-D) and seven production lines in three separate stages (A, B and C) with intermediate storage as shown in Figure 2 (dark blue). Upstream production (USP) lines (A) produce the precursor which is purified in two downstream production (DSP) stages, DSP1 (B) and DSP2 (C), to the final API. The product-line allocations (Table 1) show that not all products visit all stages and final products are therefore defined by the last stage a product visits. As shown in Figure 2 the system used in the current case study (dark blue) was reduced from a larger system by assuming sufficient supply of material from Line A3 to Line B3. Demand data was given by the company as an average over two years with weekly deliveries and all final products have a six-month safety storage level and require four weeks release time for quality control after production. The results based on constant demands are applicable since the demand volatility is less than the final product safety storage levels and no stockouts will thus occur when implementing the generated plans. Table 1 gives yearly

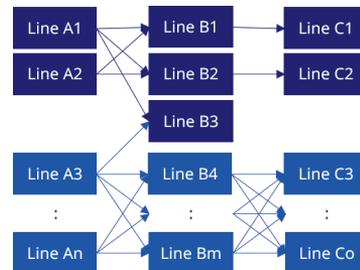

Figure 2: System reduction in a 3-stage environment with USP (A), DSP1 (B) and DSP2 (C)

(46 week) capacities in final product equivalents (scaled by yearly demand) and yields for all product-line combinations that exist. Raw material is unconstrained and therefore the yield in USP is set to 100%. Production is shut down 6 weeks per year (weeks 7, 29-31, 42, 52) and after each shutdown, the first week is spent on ramping-up. Table 1 provides ramp-up coefficients for each line as a fraction of full capacity. Initial levels in final product yearly demand equivalents are: 9 months for final products and 1 month for intermediates. Changeover times are sequence-independent and last 3 weeks in USP and 1 week in DSP.

Table 1: Capacity and yield overview in the format ‘Capacity (Yield)’ and ramp-up coefficients as a fraction of total capacity in the first week after a shutdown. Capacities are reported in units of yearly final product demand equivalent.

	USP		DSP1			DSP2	
	Line A1	Line A2	Line B1	Line B2	Line B3	Line C1	Line C2
Product A	1.5 (1.0)		1.5 (0.5)	1.5 (0.5)	1.5 (0.5)		
Product B	1.5 (1.0)	1.5 (1.0)	1.5 (0.5)			1.5 (0.9)	
Product C		1.5 (1.0)		1.5 (0.5)			1.5 (0.5)
Product D					1.5 (0.5)		
Ramp-up coefficient	0.5	0.5	0.5	0.5	0.5	0.5	0.5

4.2. Baseline supply capability

The campaign scheduling model was set up in Pyomo and solved with CPLEX on a 2-year horizon with a weekly discretization and objective function O1 maximizing final product inventories every half year which weights all products equally and highlights the need for high inventory levels throughout the horizon rather than solely at the end. All slack variables and capacity increase variables were constrained to 0. The results are given in Table 2 (Scenario I) which shows that all KPIs are acceptable, and the company therefore considers manufacturing intermediate for a development product on Line A1. The estimated duration of the production is 12 full-capacity weeks with standard changeover time, release time & ramp-up and delivery in week 84 on the horizon. The problem was solved including the development product which returned an infeasible solution showing that not all product inventories can be kept above their safety levels when the clinical production is introduced. Before continuing to step 3 in the framework, it is relevant to know how far from feasibility the solution is since small deviations from safety stock might be accepted by the DM. Therefore, the model was reformulated with an objective of minimizing the maximum slack value (objective function O2). The reformulated mathematical program (Scenario II) was solved giving an objective value of 0.06 which shows that the lowest expected inventory level is 0.44. If this number is not accepted by the DM, step 3 in the framework can be explored. As can be seen, this example shows that capacity planning is relevant to both account for changing demands for current products but also to handle new product introductions (NPIs).

4.3. Capacity analysis

In step 3, an example of the indirect approach to capacity changes is presented and applied to all legacy products on Line A1. The goal is to determine the minimum amount of capacity required to avoid safety violations since these could result in patients not getting access to life-saving medicines. The reformulation from step 2 was modified by replacing objective function O2 with O3, capacity variables were fixed at 0 for all product-line combinations except for the legacy products (A, B) on line A1, slack variables were fixed at 0 and the program (Scenario III) was solved giving an objective value of 0.16 which shows that a 16% capacity increase on Line A1 is required for both products A and B.

4.4. Supply decision analysis

In step 4 the result from step 3 is used to solve the original problem from step 2 with a 16% increased capacity on Line A1 for legacy products at the beginning of the horizon (Scenario IV). The results (Table 2) show that no safety stock violations occur and the remaining KPIs are close to the baseline (Scenario I). Based on the results, it is recommended to investigate how to achieve the capacity increase and accept the clinical production contingent on finding a solution. If the increase cannot be achieved, the DM will decide if additional information is needed before the clinical production is accepted.

Table 2: Data and results (KPIs) for the 4 scenarios

	Line A1 Capacity	Clinical Demand	KPIs		
			Changeovers	Lowest inventory	Final inventories
Scenario I	Baseline	No	20	0.5	2.64
Scenario II	Baseline	Yes	N/A	0.44	N/A
Scenario III	+16%	Yes	N/A	N/A	N/A
Scenario IV	+16%	Yes	22	0.5	2.72

5. Conclusions & Perspectives

A framework is described for handling mid-term capacity and production planning applied to the pharmaceutical industry. It allows the DM to evaluate current supply capabilities, identify capacity requirements and analyze the effect of specific changes to the system. This knowledge can be used to handle capacity proactively and increase collaboration across the supply chain from development through manufacturing and distribution. The framework was applied to a case study abstracted from industrial API production to give an example of its use. Future research will focus on expanding the framework with specific methods for each step and to add uncertainty to both framework and models. Plan robustness will be added to ensure feasibility subject to certain levels of uncertainty which will reduce volatility and firefighting in the planning processes as requested by industrial practitioners. Additionally, methods for multi-objective optimization will be added and model application will be explored including triggers/frequencies for updating data and applying the framework.

Abstract

Recent clinical outcomes of Advanced Therapy Medicinal Products (ATMPs) highlight promising opportunities in the prevention and cure of life threatening diseases. ATMP manufacturers are asked to tackle engineering product and process-related challenges, whilst scaling up production under demand uncertainty; this highlights the need for tools supporting supply chain planning under uncertainty. This study presents a computer-aided modelling and optimisation framework for viral vector supply chains. A methodology for the characterisation of process-related uncertainties is presented; the impact of input demand and process bottlenecks on optimal supply chain configurations and capacity allocations is assessed. A trade-off between cost and scalability emerges, larger costs incurring at higher input demands, whilst ensuring improved flexibility under demand uncertainty. Furthermore, bottlenecks uncertainty drives the optimisation to alternative strategic decisions, highlighting the need for a systematic integration within the framework.

Keywords: mathematical programming, supply chain optimisation, advanced therapeutics, pharmaceutical manufacturing

1. Introduction

Advanced Therapy Medicinal products (ATMPs) form a novel class of therapeutics with promising outcomes in the prevention and treatment of life-threatening diseases. ATMPs mostly rely on the delivery of genetic components to the target patient; this is achieved either via insertion of a vector carrying the genetic payload (*in vivo*) or by transplanting cells that been engineered to produce therapeutic proteins or factors (*ex vivo*). The gene therapy field is rapidly growing, with the U.S. Food & Drug Administration (FDA) forecasting 10-20 gene therapies approvals per year by 2025 (FDA, 2019). Viral vectors are currently at the forefront of next-generation vaccines and therapeutics. Adenoviral vectors have demonstrated their suitability and flexibility as vaccine carriers, with the commercial approval of Vaxzevria (AstraZeneca), the Janssen and the Sputnik COVID-19 vaccines (EMA, 2021). On the other hand, adeno-associated viruses have shown to be suitable for *in vivo* gene therapy with approvals of Luxturna and Zolgensma, lentiviruses (LV) find broad application in *ex vivo* gene therapy and utilised in the manufacturing of cell-based gene therapy products, such as autologous CAR-T cell therapy (Papathanasiou et al., 2020). As more advanced therapeutics and vaccine platforms reach clinical trials and commercialisation, the field is experiencing a need for innovative solutions for process development, manufacturing and infrastructure to ensure clinical availability and patient accessibility. Similar to product development and manufacturing, ATMPs distribution faces challenges that are often present across pharmaceutical supply chains (SC) (Fig.1). These include capacity planning under uncertainty of demands, clinical trial

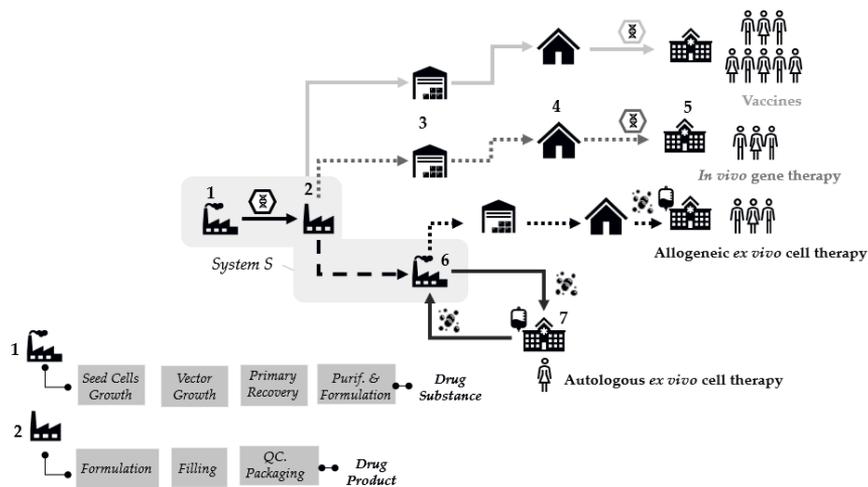

Figure 1: Generalised SCs for viral vectors: (1) primary and (2) secondary manufacturing, (3-4) regional-district storage, (5) hospitals/administration points and (7) leukapheresis sites, (6) cell therapy manufacturing facilities.

outcomes, process capabilities and dosage requirements (i.e. *in-risk* manufacturing and distribution). This highlights the need for informed decision-support tools for ATMPs SCs to improve strategic and operational planning (Sarkis et al., 2021). Several optimisation-based frameworks for scheduling of pharmaceutical plants and SCs under uncertainty have been proposed in recent works (Sousa et al., 2011; Siganporia et al., 2014; Vieria et al., 2019). This study presents (i) a novel methodology for the identification of underlying manufacturing uncertainties in emerging biopharmaceutical industries, focusing on LV vectors SCs (system *S*, Fig. 1) and (ii) an assessment of how these may impact optimal SCs configurations from clinical to commercial scale.

2. Materials & Methods

2.1. Techno-economic modelling

A primary and a secondary manufacturing platform for LV vectors was modelled using SuperPro Designer (Intelligen) to (i) allow for techno-economic assessment of the overall manufacturing process and (ii) evaluate how underlying uncertainties may propagate to key performance indicators of interest of the SC. SuperPro relies on built-in sets of algebraic and differential equations to calculate material and energy balances, sizes equipment, schedules operations and computes CapEx and OpEx. Information regarding production processes, resources costs was obtained from literature (Comisel et al., 2021; Perry and Rayat, 2021) and input ranges were recorded (Table 1). Additional inputs were sourced from SuperPro's industrial-based databases and were assumed to vary within a range of $\pm 50\%$ of their nominal value, preserving order of magnitude and allowing assessment of input significance. The uncertainty analysis was conducted using a SobolGSA-MatLab-Component Object Model (COM)-SuperPro interface, with the primary manufacturing model simulated for 1023 quasi-random combinations of inputs within the pre-defined range.

2.2. Optimisation framework

A mixed-integer linear programming (MILP) problem was developed (Table 2); given a range of production scales, manufacturing and logistics costs, the optimisation identifies (i) candidate

Table 1: Key input ranges for uncertainty analysis

Input	Nominal	LB	UB	Units	Section	Step
Target viral titre (main product)	1×10^7	1×10^6	1×10^8	TU mL ⁻¹	USP	Vector growth
Raw material (medium) cost	33.1	16.6	49.6	\$ kg ⁻¹	USP	Seed cells; vector growth
Reaction task lengths	11.0	8.0	14.0	days	USP	Seed cells; vector growth
Buffer utilisation	150.5	75.3	225.8	kg batch ⁻¹	DSP	Purification
Recovery (%)	90.0	70.0	99.0	-	DSP	Purification (dead-end filtration)
DNA removal task length	60	30	90	min	DSP	Purification (nuclease)
Filtration task length	240	120	360	min	DSP	Purification (dead-end filtration)
Chromatography task length	75	37.5	112.5	min	DSP	Purification (chromatography)
Elution yield (%)	41.0	29.0	90.0	-	DSP	Purification (chromatography)
Raw material (buffer) cost	43.5	21.8	65.2	\$ kg ⁻¹	DSP	Purification (nuclease)
Concentration factor	3	1.5	4.5	-	DSP	Purification (dead-end filtration)
Volume of Eluant	2	1	3	BV	DSP	Purification (chromatography)
Recovery (%)	99.0	70.0	99.0	-	DSP	Purification (ultra-filtration)
Rejection coefficient (%)	1.0	1.0	2.0	-	DSP	Purification (sterile filtration)

SC structures and allocated capacities, (ii) operational plans and (iii) transportation flows. The aim of the optimisation problem is to maximise the total network cost (Eq.1), comprising CapEx, OpEx and transportation costs (Eq 2-6). For manufacturing nodes j and f , the operational cost is subdivided into a labour-dependent component, a variable (batch-size dependent) a facility-dependent cost, accounting for equipment depreciation and maintenance (Eq. 4). A set of logic constraints ensure that feasible connections are established only if nodes are built (Eq. 7-14), whilst imposing 1 size s is selected for every node. Additionally product allocations occur only in installed equipment (Eq. 15-16). Material balances at each node ensure balanced flow between nodes, only if a match is established (Eq. 17, 22-26). In nodes j and f , batches are manufactured in campaigns, with the first batch being collected after α days and subsequent ones every r days (i.e. cycle time) (Eq. 18-21); this holds for USP, DSP and secondary manufacturing process sections.

2.3. Case study: viral vectors

The LV vector SC considered in this study comprises 3 candidate locations for primary and secondary manufacturing respectively, 3 storage nodes and 5 demand zones (i.e. cell therapy facilities). The impact of input demand on optimal SC configuration is assessed via 3 demand scenarios, which capture (i) a Phase I-II clinical demand (1,000 doses y⁻¹ on aggregate), (ii) Phase III-commercial demand (Comisel et al., 2021) and a (iii) commercial demand (Papathanasiou et al., 2020), with a commercial CAR-T cell therapy facility in $L5$. The impact of cycle time r^u and USP processing time α^u uncertainty on SC structures and capacity allocations is also assessed (Table 3). Finally, the resilience of the network is tested by fixing strategic decisions (i.e. scale and number of parallel lines), whilst allowing operational decisions to adjust accordingly, thereby identifying a SC *breakpoint*.

3. Results & Discussion

3.1. Techno-economic modelling and uncertainty analysis

The results of the proposed uncertainty analysis can be decoupled into throughput-related outputs (Fig. 2a-e) and cost-related (Fig. 2f-k) outputs. Process tasks length uncertainty is expected to impact upstream and downstream process (USP, DSP) times, with USP processing time remaining within 40-58 days, as opposed to 1-2 days for the DSP. With cycle times between 12-15 days, USP remains a bottleneck in the process, due to time-intensive batch cell cultures. Overall process capability is impacted (Fig. 2e), as an integer number of batches must be completed within

Table 2: Mathematical formulation of the supply chain optimisation problem

Formulation	Equations	Index

Capital Costs	$TC_j^{CAP} = \sum_{jst} C_s^{CAPjl} Z_{jst}; \quad TC_k^{CAP} = \sum_{ks} C_s^{CAPsl} Y_{ks}$	2-3
Operational Costs	$TC_j^{OP} = \sum_{jstl} C_{LABjl} B_{jstl} + C_s^{VARjli} P_{jstl} + C_s^{LABjl} Z_{jst}; \quad TC_k^{OP} = \sum_{ki} C^{OPki} Q_{kli}$	4-5
	$TC^T = t_c \sum_{ijf} D_{jf} Q_{ijf} + t_c \sum_{ifk} D_{fk} Q_{ifk} + t_c \sum_{ikl} D_{kl} Q_{ikl}$	6
Logic Constraints	$X_{jf} \leq \sum_s Y_{js} \quad \forall j, f; \quad X_{fk} \leq \sum_s Y_{fs} \quad \forall f, k; \quad X_{kl} \leq \sum_s Y_{ks} \quad \forall k, l$	7-9
	$\sum_j X_{jf} \geq \sum_s Y_{fs} \quad \forall f; \quad \sum_f X_{fk} \geq \sum_s Y_{ks} \quad \forall k; \quad \sum_k X_{kl} \geq 1 \quad \forall l$	10-12
	$Z_{jst} \leq Y_{js} \quad \forall j, s, l; \quad Z_{fsl} \leq Y_{fs} \quad \forall f, s, l$	13-14
	$W_{jstl} \leq Z_{jst} \quad \forall j, s, l, i; \quad W_{fsl} \leq Z_{fsl} \quad \forall f, s, l, i$	15-16
Sample Flow Constraints	$Q_{min} X_{jf} \leq \sum_l Q_{ijf} \leq Q_{max} X_{jf} \quad \forall j, f$	17
Manufacturing Constraints	$T_{min} W_{jstl} \leq T_{jstl} \leq T_{max} W_{jstl} \quad \forall j, s, l, i; \quad U_{jst} = \sum_i T_{jstl} \quad \forall j, s, l;$	18-19
Sample Node Balances	$B_{jstl} = W_{jstl} + 1/r(T_{jstl} - \alpha W_{jstl}) \quad \forall j, s, l, i; \quad P_{jstl} = x_{st} B_{jstl} \quad \forall j, s, l, i$	20-21
Network Balances	$\sum_l P_{jstl} = \sum_f Q_{ijf} \quad \forall i, j; \quad \sum_j Q_{ijf} = \sum_l P_{fjstl} \quad \forall i, f; \quad \sum_l P_{fjstl} = \sum_k Q_{ifk} \quad \forall i, f$	22-24
	$\sum_f Q_{ifk} = \sum_k Q_{ikl} \quad \forall i, k; \quad \sum_k Q_{ikl} \geq D_{il} \quad \forall i, l$	25-26

Table 3: Summary of scenarios considered

Scenario	Location-specific product demand (doses y^{-1})					Capability (d b^{-1})	
	L1	L2	L3	L4	L5	α^u	r^u
A	200	200	200	200	200	40	12
B	1,000	1,000	1,000	1,000	10,000	40	12
C	1,000	1,000	1,000	1,000	40,000	40	12
D	200	200	200	200	200	58	15
E	1,000	1,000	1,000	1,000	10,000	58	15
F	1,000	1,000	1,000	1,000	40,000	58	15

the annual operating days (335 days y^{-1}). Uncertainty in USP titers, DSP recovery and material consumption per unit product determines a range of batch sizes (Fig. 2d). Consequently, a varying number and size of output batches impact labour-related OpEx and variable OpEx respectively (Fig. 2h-k). CapEx output ranges instead depend on variability in stream volumetric flows, resulting from uncertainty in medium/buffer consumption rates per unit product produced.

3.2. Supply chain optimisation

The major contributor to SC cost is primary manufacturing accounting for 69-89% of costs across all scenarios considered (Fig. 3b-d). In scenario A, a clinical demand (1000 doses y^{-1}) is fulfilled by a single primary manufacturing site at 500 L, comprising a single USP and DSP line (Table 4). As the demand increases in L5 to commercial-scale (B-C), the framework selects to build the facility at 2000 L, with the addition of 1-3 parallel USP lines. Economies of scale are expected to be a key driver in lowering the unit production cost. At the same time, the installation of a parallel USP line increases the throughput of the facility and the utilisation of the DSP line in J1. Similar trends are seen in scenarios D-F, which consider longer cycle and processing times. Whereas D and E yield the same optimal capacity allocations, in scenario F the different process capability drives the optimisation to install an additional facility in J3, with an extra USP and DSP line respectively compared to C. As shown in Fig. 3a-c, the demand-optimised scenarios B and E

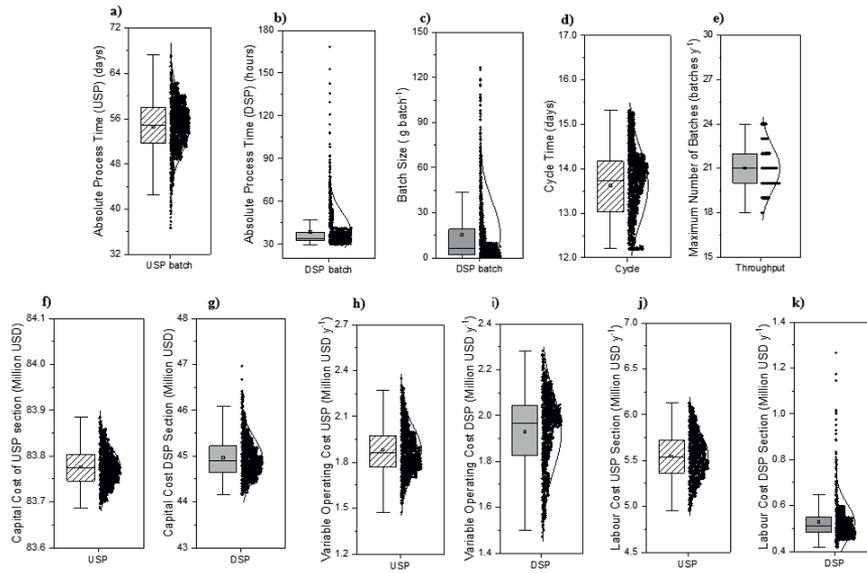

Figure 2: Results of uncertainty analysis for (a-e) throughput-related quantities and (f-k) cost-related quantities for 2000 L scale primary manufacturing process.

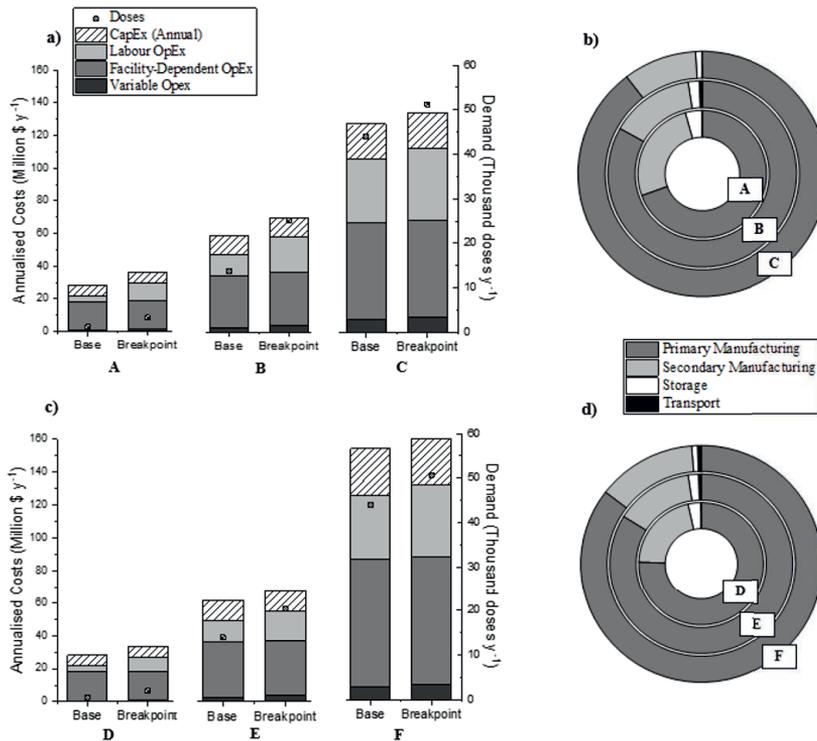

Figure 3: Cost-scalability analysis and SC costs for (a-b) $r^H = 12 \text{ d b}^{-1}$ and for (c-d) $r^H = 15 \text{ b}^{-1}$

Table 4: Summary of capacity allocations by scenario

	Scenario					
	A	B	C	D	E	F
Scale (L)	500	2000	2000	500	2000	2000
Primary Manuf.	$J1$	$J1$	$J1$	$J1$	$J1$	$J1+J3$
USP lines	1	2	4	1	2	2+3
DSP lines	1	1	1	1	1	2
Secondary Manuf.	$F1$	$F1$	$F1$	$F1$	$F1$	$F1+F3$
Scale (vials min^{-1})	50	50	50	50	50	50
F&F lines	1	1	1	1	1	1+1

require the same expenditure to fulfill the input demand, as cost is computed as a function of scale, number of batches and batch size. When assessing scalability, scenario B allows for a scale-up up to 25,000 doses y^{-1} , thanks to the shorter cycle times, whereas the SC network in scenario E saturates at 20,000 doses y^{-1} . Similarly, for scenarios C and F, the two SC networks can scale-up to 50,000 doses y^{-1} , albeit with 20 million USD y^{-1} gap in estimated costs and alternative capacity allocations and transportation links. This could result from a minimisation of transportation cost, which favours in this case a decentralised network as opposed to centralised manufacturing. This highlights the need to (i) carry out strategic decisions whilst considering bottlenecks that can emerge at operational level and therefore (ii) integrate an evaluation of the input uncertainty space as part of the optimisation. The latter is translated into considering uncertainty ranges for all throughput-related and cost-related inputs.

4. Conclusions

This study presents a computer-aided modelling and optimisation framework for vector-based ATMPs manufacturing and distribution networks. The developed tool identifies cost-effective SC structures and capacity allocations for a range of clinical to commercial demand scenarios and quantifies SC scalability under demand uncertainty. A methodology to characterise key process-related uncertainties is proposed; hence, the impact of cycle time uncertainty on SC network performance is demonstrated. The need for augmenting such tool to systematically enumerate the input uncertainty space as part of the optimisation has been highlighted. The identification of a unified resilient solution to realisations of uncertainty outcomes is expected to bring benefits to the emerging ATMPs industry, as it transitions from clinical to commercial operations.

Abstract

In an effort to decarbonize and electrify the chemical industry, the incorporation of renewable energy sources in the energy input portfolio of chemical processes is a key step. To this end, we present a study of the effects of connecting a wind farm to a small-scale chemical process network comprising a shale gas processing plant and steam cracker. The steam cracker is assumed to be able to utilize a hybrid energy stream to support the endothermic cracking reactions, whereby conventional (fossil fuel) heat generation can be replaced with electricity whenever the latter is readily available from the wind farm. We probe the impact of employing this energy blend, as well as the network economics and CO₂ emissions, showcasing the potential benefits of incorporating renewable energy sources in lieu of/in addition to conventional ones to support chemical manufacturing.

Keywords: Decarbonization, Network Modeling, Electrification, Wind Power, Chemical Manufacturing

1. Introduction

The energy use of the industrial sector accounted for 33% of the total U.S. energy consumption in 2020, with almost 60% of this amount being related to chemicals and petroleum and coal products (U.S. Energy Information Administration, 2021c). While the majority of this energy need is met by fossil fuels, wind power contributed up to 8.4% of total U.S. utility-scale electricity generation (U.S. Energy Information Administration, 2021d). However, cases of under-utilization of available wind power are common, with the main issues being the transmission capacity of the wind generation facilities to the main electricity load centers and the inherent variability in generation rates. Infrastructure additions that would only be operational at full capacity when wind power is at its peak are uneconomical. More effective use of wind power could entail expanded local use of electricity at times of peak wind power generation, or finding ways to store energy at times of peak wind power production. In the case of chemical production (which is a form of expanded use of electricity and energy storage), the main advantage would be to (locally) produce chemicals that would be readily compatible with existing fuel transport systems. In this work we investigate modalities for utilizing (peaks in) wind power generation to support the decarbonization and electrification of chemical processing. We utilize a small-scale process network model that represents

a shale gas processing plant, an ethane cracking facility and a wind farm. We consider the limiting case where the endothermic cracker can utilize a hybrid energy stream, comprising an infinitely variable supply of conventional (fossil) fuels and electricity. Depending on the electricity production level, production of the ethane cracker may be fully electrified or fully conventional, or anywhere in between. We choose to maximize overall network profitability, which enables us to study the energy supply with the most cost-efficient use of available wind power. Furthermore, CO₂ emissions are calculated and presented.

2. Background

In recent years, there has been significant research interest in electrification and decarbonization in the chemicals and energy sectors. For example, Chen et al. (2019) evaluated the effect of direct and indirect electrification on the chemical industry by using a methanol process as a case study. Electrification is achieved by changing the energy mix required by the process (direct electrification) or by utilizing alternative feedstocks (indirect electrification). van Rooij et al. (2017) studied CO₂ reduction in the chemical industry by designing a plasma process that would transform CO₂ to CO. In this case, decarbonization is achieved by converting CO₂ into a different and useful molecule. Such approaches are further discussed by Schiffer and Manthiram (2017), who study the electrification and decarbonization of the chemical industry via electrochemistry, focusing on the largest production volume and energy consumption chemicals. Papadis and Tsatsaronis (2020) focus on the energy sector and discuss the challenges and steps that need to be considered on environmental, economic, technical, social and political levels in order to limit the adverse effects on the environment. Even though these researchers, and the many others working in this field, focus on different aspects of electrification and decarbonization, there is a consensus that the integration and efficient use of renewable resources are necessary and will be the main drivers of these efforts.

3. Problem Definition

In order to study the impact of electrifying chemical processing, we consider a canonical process network comprising a natural gas processing plant and ethane cracker, supported by a wind farm whose generation capacity varies throughout the day. The choice of gas processing plant/cracker is motivated by the need to process distributed fossil fuel sources, such as natural gas liquids (NGLs) obtained from shale gas fields. Such distributed processing lends itself naturally to electrification via locally generated renewable energy. In the scenario considered, the gas processing plant utilizes shale gas feedstock and produces natural gas that is ready for use, and NGLs (ethane, propane, butanes, and smaller amounts of heavier hydrocarbons), with the latter used to produce ethylene via steam cracking. In order to obtain a realistic representation of the process economics, we utilize data (process stoichiometries, production costs, material costs, selling prices) from the IHS Markit (2012) Process Economic Yearbook. Data on electricity prices throughout the day are obtained from the Electric Reliability Council of Texas (2021). The capacity of the gas processing plant is 150 million ft³, which is the average capacity for gas processing plants, according to the U.S. Energy Information Administration (2019), and the assumed wind farm capacity is 250 MW.

We represent the network as a directed graph, and describe here a network model in general terms. The set of network nodes is denoted as N , which is comprised of sets of supply nodes (denoted by S), sink nodes (K), conventional unit manufacturing nodes (U), electrified unit manufacturing nodes (Z) and a wind farm node (E). Therefore, $N = S \cup K \cup U \cup Z \cup E$. The set of all the materials and utilities (e.g., natural gas, steam, electricity) in the model is denoted by I and the set of all the technologies used in the manufacturing nodes are denoted as J . A set of inputs $I_{in,m}$ is associated with each node $m \in U \cup K \cup Z$ and a set of outputs $I_{out,n}$ is associated with each node $n \in U \cup S \cup Z \cup E$. Potential flows from node $n \in N$ to node $m \in N$ are represented with a directed edge (n,m) in the graph. The set of all edges representing potential flows of $i \in I$ is then given

by $G_i = \{(n, m) \mid i \in I_{out,n} \cap I_{in,m}\}$. Chemical manufacturing nodes (sets U and Z) are assumed to operate continuously, while the wind farm (set E) may operate intermittently.

The model serves as the basis for formulating a multiperiod linear program (LP). For the case study presented here, the objective function is maximization of the daily total profit:

$$\max P = \sum_{n \in N} \sum_t (R_{n,t} - C_{n,t}) - W \quad (1)$$

where P is the total daily profit from the network, $R_{n,t}$ is the revenue from node n during time period t , $C_{n,t}$ is the cost incurred at node n during time period t , and W is a daily fixed cost (i.e. not dependent on production rate) associated with the wind farm (which incurs fixed costs even when not producing power). Time periods in the model are one hour in length. The revenue term is given by:

$$R_{n,t} = b_{n,t} P_{n,t} \quad (2)$$

where $b_{n,t}$ is the unit selling price of n at time period t and $P_{n,t}$ is the amount of n produced during time period t . The cost term is given by:

$$C_{n,t} = a_{n,t} P_{n,t} \quad (3)$$

where $a_{n,t}$ is the unit cost of producing n at time period t . The fixed charge W for wind farm capital costs, operation and maintenance was estimated as \$118,500/day based on published data (U.S. Energy Information Administration, 2021a; Reuters Events, 2017). Note that wind farm costs may be overestimated because there are financial incentives for the installation of wind farms and renewable energy production that are not accounted for here.

An important aspect of this case study is that the steam cracker can operate on a (hypothetical) hybrid energy source: conventional fossil-based energy, electricity or some combination of the two. In the model the cracker is represented as two different nodes, one in set U and one in set Z ; however, there would physically be only a single hybrid cracker unit. The fraction of energy obtained from electricity is η_e , and from conventional sources $1 - \eta_e$. Here η_e is a continuous variable and $\eta_e \in [0, 1]$.

The constraints in the optimization problem are as follows:

1. There are material and utility balances governing flows in the network. These are formulated in terms of the network flow variables as shown by Giannikopoulos et al. (2021).
2. There may be supply constraints on the raw materials entering the network and demand constraints on the products exiting the network.
3. There may be limits on the flow of electricity to and from the grid, due to transmission constraints.
4. There are constraints on the availability of wind power, based on the variability of wind. This is quantified using the nominal capacity of the wind farm (specified as 250 MW) and multiplying it by a wind capacity factor (WCF) which is a function of time. The wind capacity factor is a representation of the wind energy performance which is assumed proportional to wind speed. For a given time period the wind speed is determined by random sampling from a Weibull probability distribution:

$$f_v = \frac{k}{c} \left(\frac{v}{c}\right)^{k-1} \exp\left[-\left(\frac{v}{c}\right)^k\right] \quad (4)$$

where v is the wind speed (m/s), k is the Weibull shape factor, and c is the Weibull scale parameter (m/s), which is a measure of the characteristic wind speed of the distribution. The WCF is then set

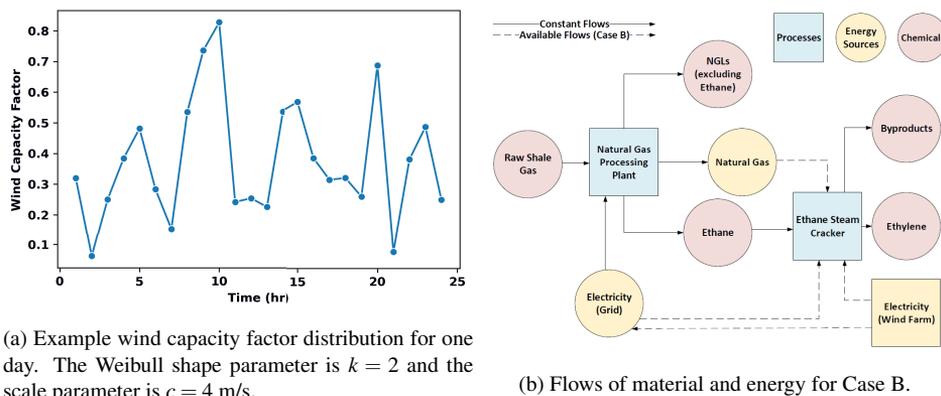

Figure 1: Wind capacity factor distribution and flow diagram for Case B.

to $WCF = \min\{0.1v, 1\}$, with the proportionality factor of 0.1 chosen to obtain an average WCF of about 0.35 (corresponding to the U.S. average). An example plot of the WCF for a 24-hour period is shown in Figure 1a.

Finally, the model accounts for CO_2 emissions from the production of the utilities used (steam, natural gas, electricity), as well as the emissions from the combustion of natural gas. Information about the CO_2 equivalent emissions from production of the utilities is based on data from GREET Argonne National Lab (2021), and information about the emissions from natural gas combustion are based on data from the U.S. Energy Information Administration (2021b). Based on these data, we are able to estimate the CO_2 equivalent emissions from the cracking process, and how these change as the mix of hybrid energy varies between electricity and fossil fuel. Note that these emissions data are not currently included in the objective function for the optimization model; however, this can be easily done (alternatively emissions could be treated as a separate objective in a multiobjective optimization analysis).

4. Case Studies and Results

We are interested in probing the effect of a renewable energy source, in this case the wind farm, in contributing energy to a small-scale process network involving a hypothetical steam cracker that can operate on a hybrid energy source (conventional fossil fuels and/or electricity). As two simple initial case studies, we will first solve the optimization-based model described above for a scenario with no wind farm (Case A), and then solve it for a case in which the wind farm energy is available (Case B). A simplified representation of the network flows for Case B is presented in Figure 1b. In each case, we will be interested in determining the total profit of the network, the total CO_2 emissions and the fraction η_e of electricity-powered operation in each time period. In both cases, there are no raw material supply constraints, so the production levels in the gas plant and ethane cracker are always at full capacity. In Case B, the wind farm can sell electricity to the grid at the prevailing price, but there are restrictions on transmission capacity that limit sales to 12 MWh daily, divided equally over the 24 one-hour time periods. This restriction is an upper limit; thus, the wind farm does not have to sell this amount to the grid, unless it is more profitable for the overall network system. For Case B, the model is run for 5 days, each with a different WCF distribution, in order to better account for the variability of the wind-generated electricity.

In Case B, the production levels due to electrified (production fraction η_e) and conventional operation (production fraction $1 - \eta_e$), are shown in Figure 2. This shows an average day of production,

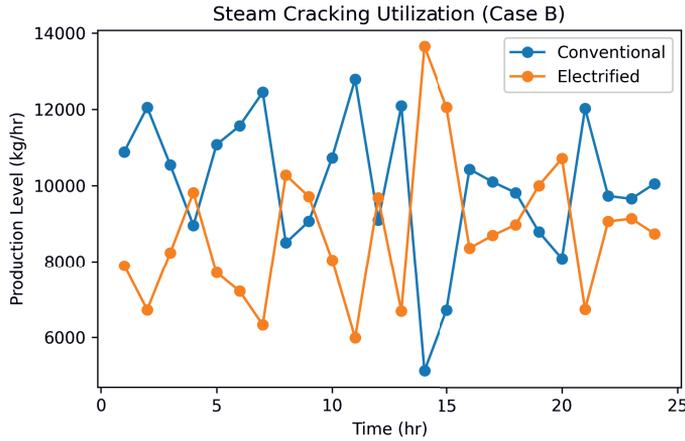

Figure 2: Steam cracking production level for each type of energy used (average at each hour over the five-day period studied).

determined by taking the average at each hour over the five-day period studied. The wind farm sells power to the grid at the maximum allowable rate, with all the remaining power used for the steam cracker. Thus, the degree of electrification depends strongly on the WCF, and tracks the amount of available electrical power closely. For the situation in this case study, both electrical and conventional fossil energy are used continuously throughout the average day. Of course, usage of electricity may be higher or lower depending on the nominal capacity assumed for the wind farm and on values specified for the wind distribution parameters c and k . It is important to note that, for this simple case study, we have assumed that an instantaneous and continuous change can be made between electrical- and fossil-powered operation of the steam cracker, which may not represent the true dynamics of the hybrid-powered operation. But, by considering this limiting case, we can still help evaluate the potential benefits of adopting such a hybrid technology, especially when paired with a renewable energy source.

The objective function in the model is the maximization of the overall network profit. The total network production levels are constant and the same in both cases; therefore, the difference in the total profit between Case A and Case B will stem only from the partial electrification of the cracker and sale of electricity to the grid in Case B, as well as the investment and other fixed costs associated with the wind farm in Case B. A summary of the maximized profit values for Case A and Case B is given in Table 1. We are also interested in the CO₂ equivalent emissions in both cases, as decarbonization is a key goal. Values for the CO₂ equivalent emissions are also shown in Table 1. Comparing Cases A and B, these values indicate a modest decrease in profit but a very substantial decrease in CO₂ emissions due to the addition of the wind farm and hybrid-power operation of the steam cracker in Case B.

Table 1: Network profit and CO₂e emissions for both case studies, with change relative to Case A.

	Case A	Case B–Day 1	Case B–Day 2	Case B–Day 3	Case B–Day 4	Case B–Day 5
Profit (1000 \$/day)	1,009	920 (−8.9%)	913 (−9.5%)	915 (−9.3%)	919 (−8.9%)	917 (−9.1%)
CO ₂ e Emissions (t/day)	812	385 (−52.6%)	482 (−40.6%)	459 (−43.5%)	395 (−51.4%)	436 (−46.3%)

5. Conclusion

In this work, we used a small-scale chemical process network comprising a shale gas processing plant and an ethane steam cracker, with connection to a wind farm, to study the potential use of a hybrid energy system to support the cracker. This hybrid system would allow conventional (fossil fuel) heat generation to be replaced with electricity whenever the latter is readily available from the wind farm. An optimization-based network model was used to develop simple case studies comparing a purely fossil-fueled case with the hybrid case, indicating, for the specific cases considered, that a large reduction in CO₂ emissions could be achieved with only a modest loss of profit. However, given the current incentives for adoption and utilization of renewable energy sources, the profit reduction could be even smaller. This suggests there is long-term benefit in adopting renewable energy resources and pairing them with chemical manufacturing, contributing to emissions reductions through electrification and decarbonization.

Abstract

The shale gas boom in the U.S. has had a strong effect on the U.S. petrochemicals industry. The availability of feedstocks, particularly natural gas liquids (NGLs), has significantly increased, prompting new investments and increased production, as well as research on new technologies and routes to products. Optimization-based industry network superstructure models can be used, with a cost minimization objective, to evaluate the potential of such new technologies and routes. A key aspect of such models is the approach used for propagating material prices and costs as new technology is adopted. This is needed because the extent to which a new technology is used may affect the raw material costs of processes elsewhere in the network, leading to a nonlinear model. In previous work, we proposed a cost propagation method for this situation, leading to solution of the nonlinear problem as a sequence of linear ones. Here we explore an alternative solution strategy based on use of a mixed-integer nonlinear programming (MINLP) model formulation, and compare to the previous approach.

Keywords: Optimization, Network modeling, MINLP, Chemical manufacturing, Supply chain

1. Introduction

Recent technological advancements in hydraulic fracturing and horizontal drilling have led to rapid increases in crude oil and natural gas production in the United States (U.S. Energy Information Administration, 2021). A result of this growth is the significant increase in the production of natural gas liquids (NGLs), which are often abundant in shale gas. NGLs consist mainly of ethane, propane, butanes and (in smaller amounts) C5+ compounds, molecules that constitute some of the most important building blocks of the chemical manufacturing industry. Therefore, the increase in the availability of shale gas and associated NGLs has provided a unique opportunity to expand the U.S. chemical manufacturing industry (Siirola, 2014; Yang and You, 2017).

Given the scale of capital investment involved in industry expansions, judicious decisions must be made regarding the choice of products, technologies and capacities. Network models are often at the core of such decision processes, due to their ability to capture existing and potential pathways and interconnections between different manufacturing processes (Derosa and Allen, 2015).

In recent work (Skouteris et al., 2021), we developed and used a network superstructure model involving several hundred of the highest-volume chemicals and hundreds of potential processing technologies, and considered the industry at the level of the entire United States. The model served as the basis for formulating an optimization-based industry configuration framework, seeking to minimize overall cost. A key innovation consisted of the fact that—in contrast to previous work (e.g., DeRosa and Allen, 2016)—process costs and material prices were allowed to change and respond to external perturbations in the network structure (e.g., adding a new process). To solve the resulting nonlinear problem, we used (Skouteris et al., 2021) a successive linear programming (SLP) approach that alternates between solving a constant-cost linear program (LP) and a special cost-propagation algorithm that updates process costs and material prices based on the LP results. In this paper, we explore another option for solving this nonlinear problem, based on formulating it as a mixed-integer nonlinear program (MINLP). Developing this alternative will enable comparisons to the SLP approach in terms of accuracy and computational efficiency, and is part of our strategy for evaluating the overall efficacy of the SLP scheme. The initial work reported here is focused on a simple network example, which we use for testing prior to scaling up to the larger U.S. industry model.

2. Background

Optimization-based, chemical industry network models originated with the work of Stadtherr and Rudd (1976), who initially focused on minimization of resource usage and subsequently on minimization of industry cost (Fathi-Afshar et al., 1981). Many variations and extensions of this initial work, with different applications, have appeared since, as reviewed by Skouteris et al. (2021) and Derosa and Allen (2015). Network models represent the industry as a directed graph, with nodes corresponding to manufacturing processes and edges corresponding to material and utility flows between the nodes. Each process node j is characterized by a process stoichiometry and a net production cost C_j (including raw material and utility costs plus annualized fixed capital cost and other operating costs) and each edge by a flow rate. The industry network model is then typically formulated as an LP, provided that process and materials costs are assumed to be constant and not dependent on the industry configuration (Derosa and Allen, 2015). The LP is comprised of material balance constraints for each material, as well as supply and demand constraints for primary raw materials and final end products, respectively. The objective is often chosen to be minimization of total industry cost, but many other driving forces have been explored (e.g., environmental considerations). For example, we recently developed (Giannikopoulos et al., 2022) a multi-objective industry network model that, in addition to a minimum total cost objective, also considers minimization of carbon loss (e.g., as CO₂ emissions) in the network, accounting for both feedstock carbon and fuel carbon used to provide process energy.

As established in our previous work (Skouteris et al., 2021), assuming process costs to be constant and independent of the process utilization levels is not always realistic and can lead to the model being unresponsive towards external perturbations to the network, such as introducing a new process. This was addressed by making the process costs dependent on the production levels, thereby rendering the network-level optimization problem nonlinear. To address this, we developed an SLP approach that alternates between the solution of a constant-cost LP and the use of an iterative cost-propagation procedure that updates material prices and thus process costs based on the results of the previous LP. The updated costs are then treated as constants in the next LP and the solution process continues until there are no cost changes. The price update mechanism used was based on the dominant-producer price leadership model (Scherer and Ross, 1990), in which the largest producer of a material determines its price. Complete details of the LP formulation, as well as the cost-propagation procedure used in the SLP approach, are given by Skouteris et al. (2021) and will not be repeated here.

3. MINLP Problem Formulation

As an alternative to the SLP approach, we consider here an explicit MINLP formulation of the problem, which allows for validating the proposed cost propagation/SLP framework. The MINLP formulation and solution procedure will be described here. As a preliminary step, a baseline LP minimizing total industry cost (Skouteris et al., 2021) using constant baseline process costs $C_{j,0}$ is solved, with the solution representing the state of the system prior to any external perturbations (e.g., addition of a new process):

$$\min_{X_j} C_{\text{tot}} = \sum_{j \in J} C_{j,0} X_j \quad (1)$$

$$\text{s.t. } \sum_j a_{i,j} X_j \geq D_i - S_i, \quad \forall i \in I. \quad (2)$$

Here, I and J are the sets of all materials and processes, respectively, in the model, $a_{i,j}$ is the input-output coefficient for material i in process j (negative if material i is consumed in process j , positive if i is produced; unity if i is the main product), X_j is the nonnegative production level of process j (in terms of flow rate of main product), and S_i and D_i are specified exogenous raw material supply and final product demand rates, respectively. Eq. (2) is a combination of material balance, supply and demand constraints and is expressed in terms of annual mass flow rates. From the solution of this baseline LP, the largest producer of each material i occurring as a main product is determined, and the initial price $B_{i,0}$ of i is then set equal to its production cost in this dominant process (currently no profit margin is added). Now a new process is added to the model to study its impact, and the industry network is reoptimized as an MINLP.

As in the SLP approach, the largest producer for each material i occurring as a main product has to be determined, since its cost will be used as the price for i in other processes, and, if i is a main product that is not produced at all in the optimal industry structure, then its price should remain at the initial price $B_{i,0}$. For the MINLP case, these considerations are captured via additional constraints in the optimization problem rather than as a separate calculation task. To avoid using the non-differentiable *max* function, we propose the following constraints:

$$P_i \geq X_j, \quad \forall i \in I_{\text{mp}}, \quad \forall j \in J_i \quad (3)$$

$$P_i \leq X_j + M(1 - d_{i,j}), \quad \forall i \in I_{\text{mp}}, \quad \forall j \in J_i \quad (4)$$

$$\sum_{j \in J_i} d_{i,j} = e_i, \quad \forall i \in I_{\text{mp}} \quad (5)$$

$$P_i \geq e_i \quad (6)$$

Here I_{mp} is the set of all materials produced as main products and J_i is the set of all processes yielding i as a main product. Two binary variables are used: $d_{i,j} = 1$ if process j is the largest producer of i as a main product and zero otherwise, and $e_i = 1$ if i is produced as a main product and zero if it is a main product not produced. M is a constant with a value that must be large enough to be an upper bound for all production rates X_j . When $e_i = 1$, P_i is the largest production rate of i , which occurs in the process j for which $d_{i,j} = 1$. When $e_i = 0$, $d_{i,j} = 0$ and $X_j = 0$, $\forall j \in J_i$. This means that Eqs. (3) and (4) can be satisfied for any $P_i \in [0, M]$. However, this is problematic if $P_i = 0$ since now Eq. (4) can be satisfied for either $d_{i,j} = 0$ and $e_i = 0$ or $d_{i,j} = 1$ and $e_i = 1$. To force $e_i = 0$ and thus all $d_{i,j} = 0$ in this case, we add constraint (6), which ensures that $e_i = 0$ when $P_i = 0$.

The prices B_i (in cents/lb) for each material $i \in I_{\text{mp}}$ and the net unit production costs C_j for each process $j \in J$ are given by

$$B_i = \sum_{j \in J_i} d_{i,j} C_j + B_{i,0}(1 - e_i), \quad \forall i \in I_{\text{mp}} \quad (7)$$

$$C_j = C_{j,0} + \sum_{i \in J} -a_{i,j}(B_i - B_{i,0}), \quad \forall j \in J \quad (8)$$

If there is no production of material i , then $d_{i,j} = 0, \forall j \in J_i$, and $e_i = 0$; thus, the first term in Eq. (7) becomes zero and the second term becomes $B_{i,0}$, the baseline price. Otherwise, if i is produced, then $e_i = 1$; thus, the second term in Eq. (7) becomes zero and the first term becomes the C_j for the largest producer of i ($d_{i,j} = 1$). As in the baseline case, no profit margin has been added. In Eq. (8), the notation $i \cap j$ indicates that the summation is over all materials i participating in process j . The summation represents the change in the materials cost for process j due to price changes.

Finally, since the constraints, Eqs. (3)–(6) will not force $e_i = 1$ when i is produced as a main product, the objective function used in the LP is modified for the MINLP by adding a penalty term:

$$\min_{X_j, P_i, d_{i,j}, e_i, B_i, C_j} \bar{C}_{\text{tot}} = \sum_{j \in J} C_j X_j - \sum_{i \in I_{\text{mp}}} e_i \quad (9)$$

Here the summation over e_i acts to set all e_i not already forced to zero by the constraints to have a value of one.

The MINLP defined by Eqs. (2)–(9) was implemented and solved in GAMS (GAMS, 2021) using the DICOPT solver (Duran and Grossmann, 1986), with the MILP master problems solved by using CPLEX and the NLP subproblems were solved using IPOPT.

4. Discussion

The MINLP formulation was validated on several small-scale networks (not representing physical processes used in practice) prior to use on the much larger full U.S. industry model. The results for the network depicted in Fig. 1 will be described here. In this network, before any external perturbations, there are three supply nodes (P3001, P3002, P3003) providing primary raw materials A, B and C to processes P1, P2 and P4, which in turn produce the intermediates D, E and F. Processes P3 and P5 then can produce the end product G. Overall, there are two competing pathways to produce G, one consisting of P2 and P3, and one consisting of P4 and P5 (each also requiring use of D from P1). The process costs have been set in such way that the P2-P3 pathway is much cheaper than the P4-P5 pathway, resulting in the former being selected in the baseline state.

A new process, P2005, is then introduced in existing network. P2005 produces the intermediate F and can therefore potentially replace P4. If the process costs are assumed to be constant, then any reduction in the cost of F due to use of the new technology P2005 will have no effect on the cost of operating P5, thus hampering the adoption of P2005. However, if the process costs are allowed to vary, as considered here, and P2005 can produce F more cheaply, then the lower price of F will be reflected in the cost of operating P5, thus favoring the adoption of P2005 in the network.

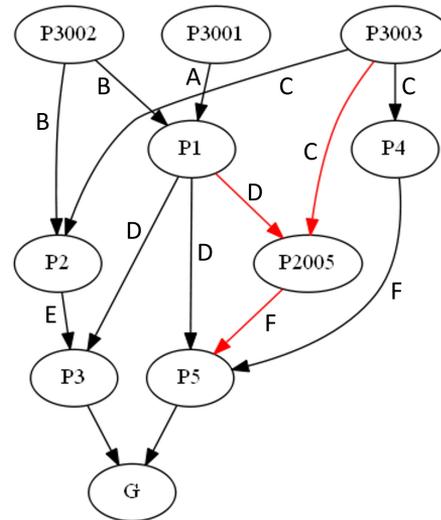

Figure 1: Graph representation of small industry network example problem. Node P2005 and the red edges represent the addition of a new process to the existing network.

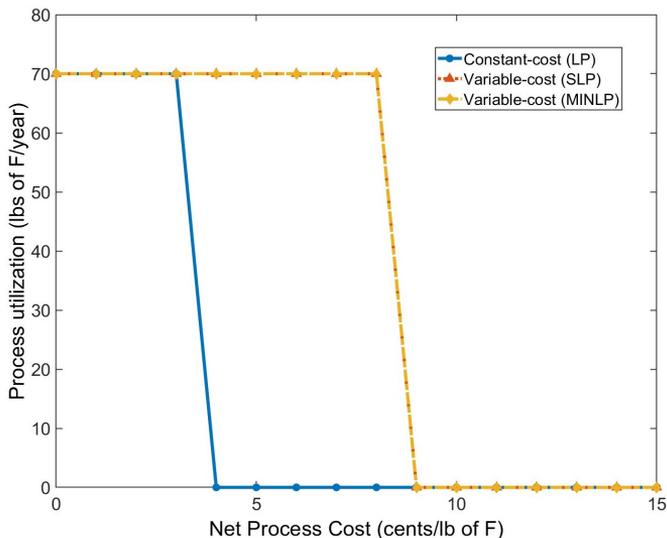

Figure 2: Process utilization for new technology P2005 as a function of its net process cost. Results for the SLP and MINLP methods are the same and overlap.

This can be seen in Fig. 2, which shows the level of adoption of P2005 (in terms of production rate) as a function of its net production cost. These results were obtained by solving the constant cost LP model, the SLP model, and the MINLP model with successively larger values of the P2005 net production cost, incremented by one cent/lb.

In the case of constant costs, where no price and costs changes are propagated throughout the network, the maximum adoption cost for the new process is just 3 cents/lb of F. For higher cost points, the new process is dropped from the optimal network configuration. This is the cost level for which the P2005-P5 pathway becomes cheaper than the P2-P3 one, even if the effect of cheaper F production is not propagated to P5. However, when this effect is propagated, the maximum adoption cost increases to 8 cents/lb of F. This is attributed to a price reduction in F, which is in turn propagated to the operating cost of P5. For example, at the insertion cost point of 5 cents/lb of F, the price of F decreases from 14 to 5 cents/lb, which leads to the cost of P5 decreasing from 13 to 6.7 cents/lb of G. This also leads to the price of G being reduced from 10 cents/lb to 6.7 cents/lb, since its largest producer switches from P3, which has a cost of 10 cents/lb of G, to P5. There is only one production level throughout the cost range where the new process is adopted and this is the same for all cases and is equal to 70 lbs of F/year. This is the amount needed to produce 100 lbs of G/year in P5 based on its specified stoichiometry, which is the value specified for the exogenous demand for G.

Comparing the results of the SLP and MINLP approaches for solving the nonlinear variable-cost problem, it is clear that both approaches yield the same solutions, in terms of adoption rates for the new process (shown in Fig. 2), the production rates of other processes, and the cost and price values (not shown). This, and experience on other small networks, indicates that the original SLP scheme employed in our previous work (Skouteris et al., 2021) was successful in accurately solving the variable-cost problem. In terms of efficiency, the SLP approach is fast and scales up well to the full industry network. The MINLP can be solved in about the same time for this small-scale network, but may not scale as well to the full network. This is a concern that will be further investigated.

5. Conclusions

The increased production of shale gas and, consequently, NGLs has led to a unique opportunity to expand the U.S. petrochemicals industry. Thus, to optimize the benefits of this expansion, it is important to have modeling and computational tools to aid the decision making that is driving this expansion. Network modeling is one such approach for assessing the impact of new technologies. In previous work using network models (Skouteris et al., 2021), we highlighted the importance of considering process costs to be variable, allowing them to respond to the addition of new processes into the industry network, and developed a new framework based on successive linear programming (SLP) to deal with this nonlinear problem. In this work, as an alternative to the SLP approach, we considered a new explicit MINLP formulation of the problem, and used it on a small-scale network example to validate the earlier SLP framework. Both approaches gave the same optimal solutions over a range of net process costs for an added process, indicating no loss of accuracy by using the SLP approach. Both approaches were very efficient computationally on the small-scale example problem, but whether the MINLP approach scales well to much larger problems is a concern. In future work, we will test the MINLP approach described here on the full-scale U.S. chemical industry network.

Abstract

In this work, we propose a novel optimization model based on mixed integer linear programming (MILP) whose goal is to optimize the size and allocation of vehicle fleets under uncertain demand patterns. In contrast to previous contributions, the probability of meeting demand is a model decision and the approach is able to handle any probability distribution to characterize the number of trips required in the network. Furthermore, fleet procurement and contracting decisions for alternative types of vehicles are integrated into the model. The formulation allows to considerably reduce costs by avoiding oversizing and can be adapted to diverse demand characterizations and contracting terms from different industries. The proposed approach is able to tackle problems of real dimensions in very low computational times in comparison to previous works. A real-world case study involving maintenance operations in geographically spread assets is addressed to highlight the model capabilities and draw conclusions.

Keywords: fleet sizing, allocation, planning, optimization, uncertainty.

1. Introduction

Fleet management is a complex logistic process that involves the simultaneous planning of tactical and operational decisions. The sizing of vehicle fleets, their procurement policies and allocation to services are key decisions for modern industries that need to meet the demand of geographically distributed operations. Efficient fleet planning is an indispensable prerequisite to guarantee the supply of services, resources and equipment to keep operations running. Planning maintenance operations in offshore wind farms (Gundegjerde, 2015), sizing and allocating aircraft fleets to airline routes (Repko, 2017), organizing shipments in freight forwarding companies (Zak, 2008) or, in more general terms, optimizing transportation services through a network of origin and destination nodes using a fleet of vehicles (List, 2003) are challenging problems proposed in the literature. Fleet planning integrates short-term and long-term decisions aimed at fulfilling transportation demands that are often subject to uncertainty, usually leading planners to overestimate the number of required resources. An efficient vehicle procurement and utilization plan relies on solving critical tradeoffs between fleet acquisition and contracting costs, asset performance decay and penalties for unmet demand, among others, under a wide range of possible scenarios.

Many contributions have been made to solve this problem. Turnquist and Jordan (1986) propose a mathematical programming model to optimize the fleet size of reusable containers to match production and shipping schedules under deterministic and stochastic travel times. They conclude on the need of further treating demand uncertainty in mesh-like networks. Later on, List et al. (2003) propose a two-stage stochastic formulation for fleet sizing (first stage decision) and allocation to trips

(scenario dependent decision), accounting for uncertainty in the forecasted demand and fleet productivity. The authors highlight the tradeoff between fleet investment costs and the risk of unmet demand, which is solved through a computationally challenging approach. In turn, Wu et al. (2005) propose a linear programming model to address the rental car fleet sizing problem, deciding on the acquisition and sale of vehicles and the assignment and movement of vehicles to different locations to meet seasonal demands, at minimum total cost. Sha and Srinivasan (2016) make use of agent-based simulation to address the tank car fleet sizing problem in the chemical industry under deterministic demand. In 2020, Vanga and Venkateswaran develop an analytical model for sizing fleets of vehicles that carry generalized reusable articles. They consider cases of lost-sales and backorders, and assess the service level for different policies at a later stage. Nevertheless, resource allocation decisions are not considered. Most of the above-mentioned contributions are based on discrete probabilistic scenarios and stochastic modeling frameworks whose complexity grows rapidly with the number of possible outcomes. In most cases, service levels are evaluated after optimization and specific probability functions are used to characterize demand (Papier and Thonemann, 2008). In short, previous authors propose either analytical methods based on limiting assumptions or two-stage stochastic programming models that become intractable for rather small instances.

In contrast to previous approaches, we propose a novel MILP formulation aiming to optimize the size and allocation of vehicle fleets under uncertain demand patterns where the probability of meeting demand is a model decision. Moreover, the model is able to handle any probability distribution to characterize the number of trips required in the network. The optimal number of units to contract from different suppliers should be established according to the most convenient service level, seeking to minimize penalties for unmet demand and costs of contract agreements. The results show that an effective allocation of the contracted fleet to routes can significantly reduce the number of vehicles required for sufficiently high levels of service.

2. Problem Statement

The problem addressed in this work can be stated as follows. Given: (i) a set of nodes, (ii) random variables accounting for the total number of trips to be made between the nodes during the time horizon, (iii) the type of vehicle required in each trip, (iv) alternative contracts with vehicle suppliers, (v) unit costs for vehicle acquisition, rental, hiring/firing, and (vi) penalty costs for unsatisfied demand; we seek to optimally determine: (a) the fleet size for each type of vehicle; (b) the allocation of vehicles to trips over the network; (c) the service level to be provided, usually represented by the probability to meet demand; and (d) the plan of contracts (vehicles hiring/firing) along the time horizon, in order to minimize the total costs.

Figure 1 illustrates the main elements of the model, namely the nodes, the travel times between locations, and random variables accounting for demands, given in number of trips. For simplicity, a Gaussian distribution rectified at zero (Socci et al., 1998) is assumed in the illustrative example, although any probability distribution is eligible for parameterization. Although travel times are symmetrical in this figure, the model is able to consider different travel times according to origin-destination nodes and vehicle types. It is important to highlight that the duration of the trips is one of the critical drivers for the assignment of vehicles to routes. A good allocation will be one that takes maximum advantage of supplier time availability, reduces the number of vehicles in non-critical connections, and reinforces the level of service in the most critical paths.

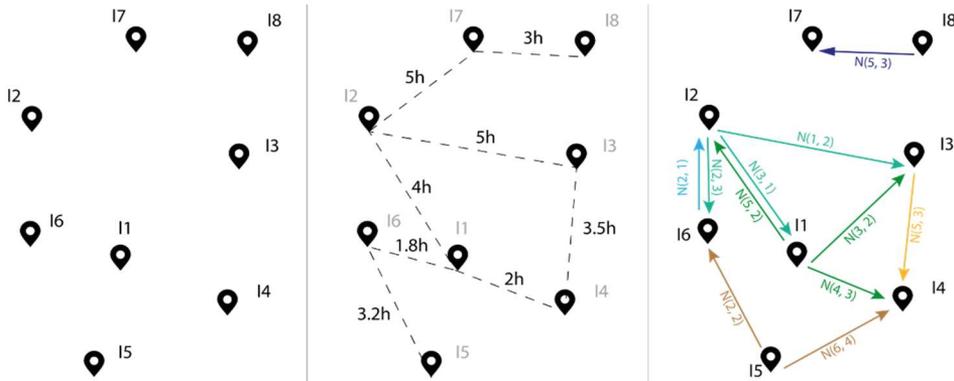

Figure 1 – Left: geographical distribution of the nodes. Middle: travel times between nodes (any direction). Right: random variables accounting for the demand of trips between nodes.

3. Mathematical Formulation

Let $i \in I$ stand for the nodes, $v \in V$ for the vehicle types and $p \in P$ for providers. Moreover, $\tau \in T$ and $k \in K$ represent daily and monthly periods, respectively. Finally, $s \in SL$ are discrete service levels. Two general contracting modes are proposed in the formulation and validated with our industry partner. The first is established on an annual basis, where the supplier makes a certain number of vehicles available for every day of the next year. On the other hand, monthly additions to the fleet are possible through flexible contracts. The objective function is given in Eq. (1), where $QF_{v,p}$ is the number of vehicles to be contracted on an annual basis, and $QV_{v,p,k}$ the number of available vehicles through flexible contracts. Unit costs $cc_{v,p}$, $ccv_{v,p}$ and $ccvt_{v,p}$ are monthly rates for vehicles of type v from supplier p accounting for fixed annual contracting, flexible contracting and flexible contract termination charges, respectively. Lastly, $CDI_{i,j,t}$ stands for the total expected cost due to daily unmet demand, under the selected contracting scheme and fleet allocation.

$$\text{Min } z = \sum_{v \in V} \sum_{p \in P} [QF_{v,p} cc_{v,p} + \sum_{k \in K} (QV_{v,p,k} ccv_{v,p} + QVT_{v,p,k} ccvt_{v,p}) \sum_{i \in I} \sum_{j \in J} \sum_{\tau \in T(k)} CDI_{i,j,\tau}] \quad (1)$$

Each supplier provides vehicles serving during a specific number of hours per day ($hdisp_{v,p}$). The number of vehicles to be procured through different contracts will define the overall number of hours available to meet demands (see RHS of Eq. 2). In turn, the service hours required to meet a given service level may be covered by allocating vehicles to trips over the network. Travel time requirements are defined by assigning vehicles to trips, as in the RHS of Eq. (2). $X_{v,i,j,k}$ is the number of trips from i to j assigned to vehicles of type v during the time period k while parameter $d_{i,j}$ is the travel time between nodes i and j . Then, Eq. (3) accounts for vehicle flow balances.

$$\sum_{i \in I} \sum_{j \in I} (d_{i,j} X_{v,i,j,k}) \leq \sum_{p \in P} (hdisp_{v,p} (QF_{v,p} + QV_{v,p,k})) \quad \forall v, k \quad (2)$$

$$\sum_{\substack{i \in I \\ i \neq j}} X_{v,i,j,k} = \sum_{\substack{i \in I \\ i \neq j}} X_{v,j,i,k} \quad \forall v, j, k \quad (3)$$

The proposed MILP is capable of handling uncertainty in travel demands between nodes for each type of vehicle. We recognize two sources of uncertainty: (a) the intrinsic variability of operations due to external phenomena (e.g. weather conditions),

roadblocks, unforeseen operating inconveniences, among others, which result in the random behavior of the demands around the expected value for each month; and (b) the prediction error, typical in all forecasting tools. Both values are usually synthesized in a dispersion parameter that is transferred as input data to the optimization model. It is important to highlight that the demand uncertainty can be modeled with any probability distribution. Figure 2 illustrates the demand profile in a given network of locations, for a given month and vehicle category. The characterization of the travel demands between nodes is shown for different pairs. The example is based on rectified normal distributions. Each directed arc has an associated mean and a standard deviation, which represent the expected number of trips required from the origin to the destination, and its variability. These parameters are used to build a probability distribution to estimate the cost of unmet demand for each possible service level, as shown in the following equations. Notice that the variability may significantly differ depending on the type of operations to develop in each node.

To compute the cost of the expected unmet demand for a given contracting plan, we illustratively show the calculations based on a normal distribution rectified at zero. Extensions are straightforward. Let $\bar{t}d_{i,j,v,k}$ and $tsd_{i,j,v,k}$ be the mean and standard deviation of the demand of trips of vehicle v between i and j , while cut_v represents the cost of missing one trip of vehicle v . Hence, the cost of expected unmet demand during period k if a service level sl is adopted, can be stated as follows:

$$cutd_{i,j,v,k,sl} = \int_{t=nt_{v,i,j,k,sl}}^{\infty} \frac{1}{tsd_{i,j,v,k}\sqrt{2\pi}} e^{-\frac{(t-\bar{t}d_{i,j,v,k})^2}{2tsd_{i,j,v,k}^2}} cut_v(t - nt_{v,i,j,k,sl}) dt \quad \forall i, j, v, k \quad (4)$$

In Eq. (4) $nt_{v,i,j,k,sl}$ accounts for the number of trips required to reach the service level sl , according to the number of standard deviations over the mean (see Eq. 5). Notice that Eq. (4) can be conservatively approximated by a finite summation as in Eq. (6), which is favored by the integer nature of variable t (i.e., number of trips). $MAXT_{v,i,j,k}$ is the maximum number of trips to achieve full coverage ($sl \sim 100\%$).

$$nt_{v,i,j,k,sl} = \bar{t}d_{i,j,v,k} + \gamma_{sl} tsd_{i,j,v,k} \quad \forall i, j, v, k, sl \quad (5)$$

$$cutd_{i,j,v,k,sl} = \sum_{t'=nt_{v,i,j,k,sl}}^{MAXT_{v,i,j,k}} \frac{1}{tsd_{i,j,v,k}\sqrt{2\pi}} e^{-\frac{(t'-\bar{t}d_{i,j,v,k})^2}{2tsd_{i,j,v,k}^2}} cut_v(t' - nt_{v,i,j,k,sl}) \quad \forall i, j, v, k \quad (6)$$

The optimization of the service level implies solving the tradeoff between the costs of contracting more vehicles to be ready for operation, and the expected costs due to unmet demand. The latter are defined by constraint (7), which imposes a minimum charge depending on the service level selected for every link $i-j$ and vehicle v during month k . That decision is made through the 0-1 variable $Y_{v,i,j,sl,k}$. In turn, Eq. (8) imposes a lower bound to the number of trips $X_{v,i,j,k}$ that are required to reach a service level of kv_{sl} standard deviations over the mean. Note that $KS_{v,i,j,k}$ is a decision variable that equals kv_{sl} if the service level sl is adopted for the link $i-j$ and vehicle v over month k (Eq. 9).

$$CDI_{v,i,j,\tau} \geq \sum_{sl \in SL} cutd_{v,i,j,sl,k} Y_{v,i,j,sl,k} \quad \forall v, i, j, k, \tau \in T(k) \quad (7)$$

$$X_{v,i,j,k} \geq \bar{t}d_{v,k,i,j} + KS_{v,i,j,k} tsd_{v,k,i,j} \quad \forall v, i, j, k \quad (8)$$

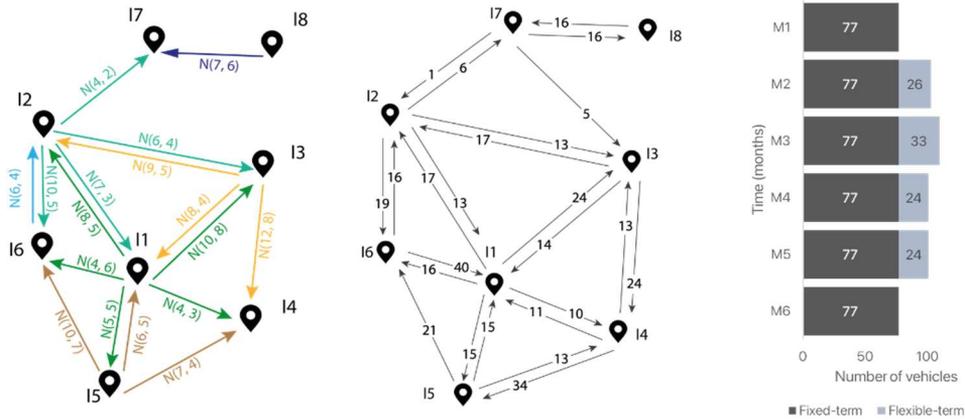

Figure 2 – Optimal solution for one of the vehicle types in the proposed case study.

$$KS_{v,i,j,k} = \sum_{sl \in SL} kv_{sl} Y_{v,i,j,sl,k} ; \sum_{sl \in SL} Y_{v,i,j,sl,k} = 1 \quad \forall v, i, j, k \quad (9)$$

4. Results and Discussion

An illustrative case is proposed in this section to show the potential of the tool. We consider two types of vehicles with weekly travel demands for each pair of nodes that are forecasted for the next 6 months. Each demand is characterized by a rectified normal distribution that captures the possible outcomes of the number of trips required for every week of that month. Figure 2 (left) shows the demand characterization for month 2, whereas the duration of the trips for both vehicles between the nodes is presented in Figure 1 (center). Decision variables to be optimized are the number of vehicles to be contracted on a fixed basis (for the 6 months), the number of vehicles to be hired on a flexible monthly basis, and the service level to be provided by assigning vehicles to every path in the network. The monthly contracting cost is set at US\$ 10,000 and US\$ 14,000 per vehicle, for fixed and flexible contracts, respectively. A penalty cost of US\$ 5,000 is considered for every unsatisfied trip. For this example with 8 nodes the MILP (after preprocessing) comprises 1619 0-1 variables, 329 continuous variables and 331 constraints. The formulation is coded in GAMS and solved using CPLEX 31.5 in a CPU time of 40 s. Figure 2 also illustrates the optimal solution obtained. At the right of Figure 2 we show the optimal contracting scheme for each month.

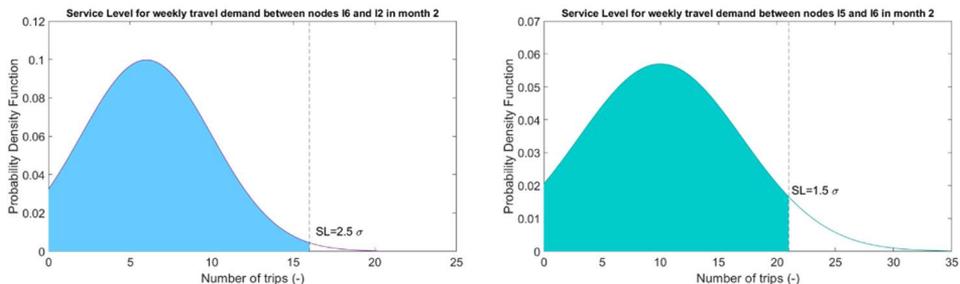

Figure 3 – Optimal service level for some of the links in the illustrative case (month 2).

A total of 77 vehicles are engaged on a fixed basis, and some additional units are hired on a variable basis during months 2, 3 and 4 in order to satisfy demands with the optimal service level. Similarly, Figure 3 illustrates the optimal service level obtained for the routes connecting nodes I6-I2 and I5-I6 during month 2, respectively. It is interesting to note that some routes may reach very high service levels due to the need to pass through those links to fulfill other services. On the other hand, the model has the capability of incorporating different suppliers for the same type of vehicle, accounting for their quality/reliability indicators, and integrating other benefits such as joint contracting (several types of vehicles from the same supplier) and quantity discounts.

5. Conclusions

We have developed a novel MILP mathematical programming model to optimize the size of vehicle fleets and their allocation to trips in a network of nodes asking for transportation services. The model accounts for demand uncertainty with no need to generate scenarios and solve large stochastic formulations. Moreover, the service levels are optimally selected to meet the demand of trips along each pair of nodes. In contrast to previous contributions, the formulation proves to be computationally efficient, flexible and capable of handling demand characterizations under any probability distribution. The model overcomes current industry practices that arbitrarily oversize fleets to avoid non-compliance with critical services. Significant reductions in logistic costs and emissions are observed, yielding a certainly better performance of the supply chain. This is achieved by optimally setting flows, minimizing idle times and avoiding unjustified trips. Since fleet sizing and allocation decisions are made in a single stage, we are currently performing further experiments to assess the quality of our solutions in comparison to two-stage stochastic models where vehicle allocations are recourse (wait-and-see) actions. Future research aims to add routing and inventory decisions to gain greater detail in the solutions and validate the model accuracy with real data.

Abstract

Chimeric Antigen Receptor (CAR) T cell therapy is a type of patient-specific cell immunotherapy demonstrating promising results in the treatment of aggressive haematological malignancies. Autologous CAR T cell therapies are based on bespoke manufacturing lines and distribution nodes that are exclusive to the production and delivery of a single therapy. Given their patient-specific nature, they follow a 1:1 business model that challenges volumetric scale up, leading to increased manufacturing and distribution costs. Manufacturers aim to guarantee the in-time delivery and identify ways to reduce the production cost with the ultimate objective of releasing these innovative therapies to a bigger portion of the population. In this work, we investigate upstream storage to the supply chain network as means to introduce greater flexibility in the modus operandi. We formulate and assess different supply chain networks via a Mixed Integer Linear Programming model.

Keywords: CAR T cell therapy; supply chain optimisation; MILP; personalised medicine; cryopreservation

1. Introduction

Chimeric Antigen Receptor (CAR) T cell therapy is an emerging type of ex vivo autologous cell therapy, where the patient's T cells are collected and are genetically modified to express the CAR (Vormittag *et al.*, 2018). This enables them to better identify and kill cancer cells. The therapy is then administered to the patient. The unprecedented success in early clinical trials involving patients with acute lymphoblastic leukaemia (ALL) and B cell lymphomas have led to historic regulatory approvals from the U.S. Food and Drug Administration (FDA) in 2017 and the European Medicines Agency (EMA) in 2018. Five autologous CAR T cell therapies have been granted approval so far and their demand is expected to rapidly grow in the following decade (UPMC, 2021). They are currently offered at a relatively high price, potentially attributed to the 1:1 business model describing their lifecycle, that varies between \$300,000 and \$475,000 (Spink *et al.*, 2018). Presently, cell therapies are administered to approximately 5,000 patients worldwide. However, projections show that up to 50,000 patients per year will be receiving cell and gene therapies with up to 60 products in 2030 (Quinn *et al.*, 2019).

A unique feature of CAR-T therapies is that the patient's cells are used as raw material and therefore the therapy manufacturing and distribution does not allow volumetric scale-up, posing challenges towards commercialisation (Papathanasiou *et al.*, 2020).

Furthermore, the short shelf life of the therapy introduces tight time constraints challenging distribution and handling, especially under high-demand scenarios. The turnaround time of the therapies from leukapheresis to treatment administration can vary between 15 and 24 days for the commercially available treatments (Nucleus Biologics, 2021). Timely therapy delivery is of utmost importance for the patients as it can significantly impact therapy efficiency (Han *et al.*, 2021). To overcome these limitations, digital tools that utilise the principles of mathematical modelling and optimisation are used to assist decision-making by coordinating the different tasks and identifying the optimal supply chain network structures (Sarkis *et al.*, 2021a). The complexity of the CAR T cell supply chain is reflected by the product's lifecycle (Sarkis *et al.*, 2021b). The main steps of the CAR T cell therapy chain are: (a) leukapheresis, (b) manufacturing, (c) Quality Control, (d) therapy administration under hospital admission.

Given the autologous and sensitive nature of CAR-T therapies, novel, decentralised manufacturing models are considered promising alternatives to a traditional centralised approach, since small scale local manufacturing facilities offer greater flexibility and can significantly reduce transportation costs (Harrison *et al.*, 2018). On the other hand, intermediate storage of the therapies may offer greater flexibility in the operation of the overall distribution network. As far as transportation and storage are concerned, the samples can either be transported fresh (-80 °C) or cryopreserved (-180 °C). In general, cryopreservation is more expensive but allows to extend the shelf life up to 14 days, and therefore is the preferred option when more flexibility is desirable. Cryopreservation currently is conducted at the leukapheresis clinical centres with hospitals not providing this service. The cryopreserved therapy needs to be thawed before it reaches the manufacturing site, something that adds extra complexity to the logistics of the process (Avramescu *et al.*, 2021).

In this work, we present a Mixed Integer Linear Programming (MILP) model for the CAR-T cell therapy supply chain optimisation considering different randomised demand scenarios of up to 2,000 therapies per year. The main objective is to assess the impact of cryopreservation on the supply chain performance in terms of flexibility and risk of loss of the therapy due to short shelf life of non-cryopreserved products. The supply chain networks designed here are assessed with respect to two key performance indicators: (a) average production cost, and (b) average response treatment time.

2. Materials and methods

The mathematical model used in this work is a MILP model that describes the CAR T cell therapy supply chain (Bernardi *et al.*, 2022). The model assists the identification of the optimal supply chain network structure, mode of transport, assignment and sequence of the therapies to the manufacturing facilities, ensuring in-time delivery and minimum therapy cost (Table 1). The supply chain network includes 5 nodes: namely, leukapheresis site, storage, manufacturing site, quality control (QC), and hospital. The therapy lifecycle starts with the patient being assigned to a leukapheresis site, where T cells are separated from the bloodstream. Next, the leukapheresis sample is shipped fresh (-80°C) or frozen (-180 °C, cryopreserved) to the manufacturing site for manufacturing, followed by QC. Finally, the CAR T cell therapy is transported fresh to the hospital for administration to the patient.

In this study, we investigate two cases: fresh or frozen handling of the therapy upstream of the network (Figure 1). In the frozen case, the therapy is cryopreserved, and optional storage is available for up to 8 days. The upper bound of 8 days was chosen as a suitable

window not compromising patient experience. Storing therapies before manufacturing may offer greater flexibility and improved scheduling of a manufacturing facility with given capacity. Bernardi *et al.* proved essential to optimally coordinate manufacturing and distribution tasks. On the other hand, when the therapy is transported fresh (-80 °C) storage is bypassed because of the limited shelf life. The supply chain model aims at simultaneous planning and scheduling with its objective being to minimise the total cost over a long-term planning horizon (annually), while operating the supply chain in the short-term (daily). In addition, the minimisation of the turnaround time appears as a constraint in the model.

Table 1: Overview of the model formulation.

Index	Mathematical Formulation	Description
Objective function		
(1)	$\min C_{total\ cost} = C_{manufacturing} + C_{transport} + C_{storage} + C_{quality\ control}$	Total cost of therapies
Constraints		
(2)	$TRT_p = t_{delivery} - t_{start} \leq U^t$	Return time of therapy
(3)	$CAP_{m,t} = FCAP_m - \sum_p INM_{p,m,t}$	Capacity constraint
(4)	$X1_{c,m} \leq E1_m, \forall c, m, \quad X2_{m,h} \leq E1_m, \forall c, h, \quad \sum_m E1_m \leq U^M$	Network constraints

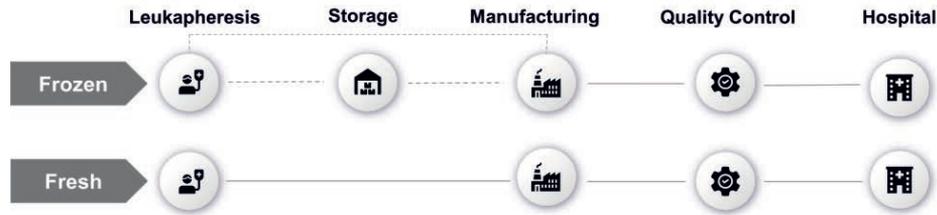

Figure 1. CAR T cell supply chain network with 5 or 4 nodes for the frozen and fresh cases respectively.

The supply chain is tested for different demand scenarios of up to 2,000 patients per year generated by an in-house bi-level decomposition algorithm. The model parameters, such as product demand scales, cost coefficients and current and planned manufacturing facilities sizes are assumed to be deterministic and were obtained through expert discussions with TrakCel Ltd, something that enables the development of industrially accurate cases. This work considers 4 leukapheresis sites and 4 hospitals in the UK and 6 manufacturing sites found in the UK, Europe and US. Following standard European and UK procedures of public or semi-public healthcare systems, it is assumed that the choice of collaborating hospitals and leukapheresis centres is not entirely under the manufacturer’s control. Hence, the two corresponding nodes are provided as model inputs and not as decision variables. For the leukapheresis sites, a capacity of 8 patients daily is assumed, considering that the leukapheresis procedure lasts 2-3 hours per patient. For the hospital site, the capacity is not a bottleneck for the administration of the therapy and therefore no upper limit is provided. The manufacturing sites have a capacity of up to 4, 10, or 31 parallel lines, and a forward-looking scenario of 7 days of manufacturing

duration is assumed. Quality control takes place in the manufacturing site and the hospital and leukapheresis centres are different facilities located in the same area. Transportation can happen either within 24 or 48 hours in case of fresh therapy and 24, 48 or 72 hours in case of frozen therapy, regardless of the transport mode (i.e. truck, rail etc). This is to align with standard practice in the cell therapy market where courier contracts are cost based on the estimated delivery time. The fresh transportation costs are 50% less than the frozen ones.

The model is implemented in Python 3.7.1 and Pyomo 6.1.2 and solved with CPLEX 12.9. All computational experiments were performed in a 24-core Xeon E5-2697 machine with 196GB. Here we present the results for the two cases (fresh and frozen) for demand profiles of increasing size. All scenarios are solved using a bi-level decomposition algorithm that is capable of reducing the computational complexity of the model and providing optimal solutions at reduced CPU times (Erdirik-Dogan and Grossmann, 2008; Terazzas-Moreno and Grossmann, 2011). The CPU time ranged between 12 s and 950 s.

3. Results and discussion

The proposed model is used for the design and assessment of the optimal supply chain network for four different demand scales (200, 500, 1,000 and 2,000 patients annually). The demand scenarios considered are assumed to be homogeneous and repeated every trimester. The model is allowed to invest in the establishment of up to two manufacturing facilities for the optimal network structure.

Figure 2 depicts the results for the four scenarios in terms of average production cost and return time per therapy. The average cost per therapy is broken down into transport cost, manufacturing cost and Quality Control cost. The storage cost is negligible and thus not presented in the graph. Figure 3 illustrates the utilisation of the manufacturing facilities for the scenario of 500 therapies per year.

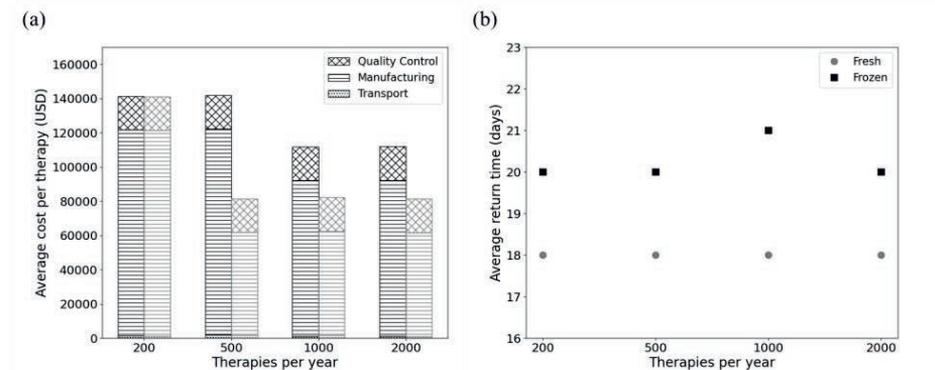

Figure 2. Comparison of fresh (black) and frozen (grey) transportation of the CAR T cell therapies based on (a) average cost per therapy (USD), where the cost is broken down in transport cost, manufacturing cost and Quality Control cost and (b) average return time per therapy.

In Figure 2a, we can observe that for the scenario of 200 patients per year the average cost per therapy is identical for fresh and frozen transportation, whereas in all the other cases the frozen transportation leads to a significantly reduced cost per therapy. This can be attributed to the incorporation of storage in the model, as it allows for improved manufacturing planning. The manufacturing cost is the biggest contributor to the total cost, with QC cost being fixed in every scenario and transportation costs being negligible.

The average return time for fresh transportation is 18 days for all demand scenarios, and 20 days for the majority of frozen transportation scenarios (Figure 2b). This is expected as in the frozen case the model can choose to store samples for up to 8 days and choose between 3 modes of transport (24, 48 or 72 hours). The cost vs return time trade-off can be observed in Figure 2; when the total return time of therapy decreases, the cost increases.

The steepest decrease of 43% of the average therapy cost takes place in the 500 therapies per year scenario. The model proposes the establishment of two manufacturing facilities (m3 and m6) in the case of fresh therapy with a total of 20 parallel lines (Figure 3a), while in the case of frozen therapy it chooses to build only facility m3 with a total of 10 parallel lines (Figure 3b). From Figure 3a we can observe that the facility m6 in the fresh case is substantially underutilised, resulting in an increased manufacturing cost per therapy. In the frozen transportation case, m3 is roughly always operating at maximum capacity leading to decreased manufacturing costs. Therefore, the reduction in the average therapy cost is attributed to the supply chain network structure and utilisation of the manufacturing facilities.

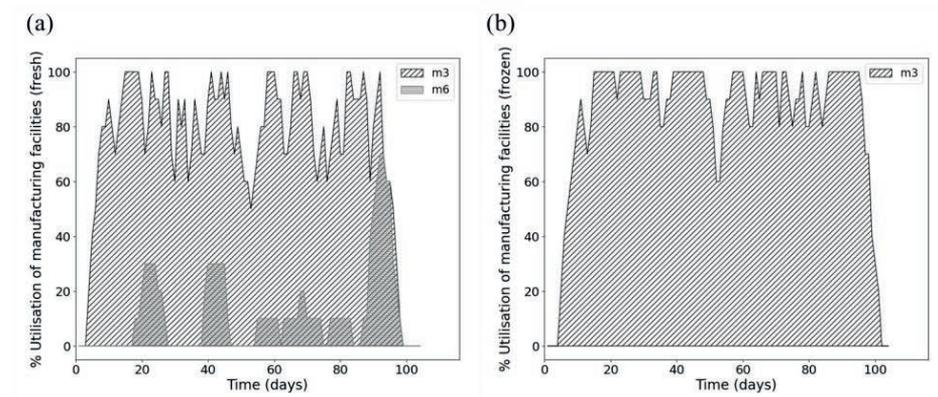

Figure 3. Utilisation of manufacturing facilities to be built for (a) fresh transportation and (b) frozen transportation in the 500 therapies per year scenario.

4. Conclusions

In this work, the impact of cryopreservation was assessed compared to fresh therapy transportation by the utilisation of a digital tool based on mathematical modelling and optimisation. The MILP model provided useful insights for the design and optimal supply chain networks in personalised therapies. Cryopreservation increases the shelf life of the samples, allowing to utilise an intermediate storage between the leukapheresis centre and the manufacturing facility. The results indicate that the extra flexibility granted by cryopreservation almost always leads to a decrease in the average therapy cost under the investigated demand scenarios, but the average vein-to-vein time slightly increases. Overall, the model identifies a trade-off between cost and average return time. The cost reduction achieved in the frozen case is linked to an improved manufacturing planning, which can potentially debottleneck the complex supply chain and logistics, and ultimately decrease the risk of loss of the therapies- especially for high-demand scenarios. Future work will aim to assess the effect of variable manufacturing time and failure rates of fresh versus frozen manufacturing on the supply chain robustness and on the average therapy cost.

5. Acknowledgements

Funding from the UK Engineering & Physical Sciences Research Council (EPSRC) for the Future Targeted Healthcare Manufacturing Hub hosted at University College London with UK university partners is gratefully acknowledged (Grant Reference: EP/P006485/1). Financial and in-kind support from the consortium of industrial users and sector organisations is also acknowledged.

Abstract

A novel hybrid algorithm integrating advantages of genetic algorithm (GA) on computational efficiency and sequence-based mixed-integer linear programming (MILP) model on solution optimality is proposed for industrial-scale scheduling problems of multipurpose batch plants. The computational results show that the hybrid algorithm has strong convergence and is efficient to generate the same or better schedules with less computational efforts compared to the existing methods.

Keywords: Scheduling; Multipurpose batch plants; Hybrid algorithm; Genetic algorithm

1. Introduction

Scheduling multipurpose batch plants is challenging due to the process flexibility and layout complexity. Specifically, products are produced using product-specific processing steps with batch splitting, mixing, and recycling allowed. A variety of mixed-integer linear programming (MILP) models have been proposed, including sequence-based and time-grid-based models (Harjunkoski et al., 2014). Discrete-time models confirm its capability on processes with time-varying availability but fail to guarantee data accuracy due to discretization errors. Unit-specific event-based models are prominent on solution optimality. However, they are hard to solve industrial-scale problems as the appropriate number of event points is unknown a priori. Although several decomposition methods (Nishi et al., 2010) have been attempted, generation of optimal or near-optimal solutions with low computational costs for large-scale scheduling is still an unresolved issue.

Hybrid algorithm is promising to address large-scale problems as integrating advantages of multiple approaches. Recently, a discrete-continuous algorithm (Lee and Maravelias, 2018) was developed to generate approximate solutions quickly in first stage and then refine the solution to optimality. Metaheuristics are superior in high solution quality and computational efficiency. He and Hui (2010) and Woolway and Majozi (2018) demonstrated the GAs are efficient to schedule multipurpose batch plants in short time frames due to their inherent parallelism and strong global search capability. Therefore, in this work, we take advantages of GA on low computational costs and integrate it with a sequence-based MILP model to generate near-optimal or optimal solutions for scheduling of industrial multipurpose batch plants. The computational results show that the designed algorithm can generate the same or better solutions and reduce the computational time, over one order of magnitude in some instances, compared to existing methods.

2. Genetic algorithm

A novel GA is designed to generate suboptimal or optimal solutions using short computing time. In GA, an encoding set Pop_c of individual chromosome c is defined to represent solutions for a given problem. One chromosome $c = \{c^1, c^2, c^3\}$ comprises of

three parts representing production sequence, unit assignment and task repetition, respectively. In the first part, a variable $c_n^1 = p \in \mathbf{S}^P$ represents product p going to be manufactured at n -th production step in the production. In each production step, one batch of the selected product p is produced, and one product may be produced for multiple batches to satisfy order demands. In the second part, $c_{mi}^2 = j \in \mathbf{J}_i$ is the assigned unit j for batch m of task i that have multiple feasible units. In the third part, c_o^3 is a binary variable. When $c_o^3 = 1$, the o -th performed task would be repeated. c^3 is designed to influence the sequence of tasks performed to produce different batches of products.

A decoding algorithm is designed to synthesize solutions based on above solution representation. It steps iteratively through c^1 to produce products until demand requirements are met. In each production step, the producing task $i \in \mathbf{I}_{S^P}^P$ for the product p must be performed and other tasks providing intermediate states would be performed when the state is insufficient. Unit assignments are determined by c^2 , and whether to repeat the performed task is decided by c^3 . For minimization of makespan, a heuristic rule ‘earliest starting strategy’ is adopted to start every batch of tasks as early as possible.

$$f_c = (1/MS_c)^{20} \quad (1)$$

Fitness value of individual c is calculated using Eq.(1), where MS is makespan. The roulette wheel method is adopted to select parents who would be subjected to two-point crossover and two-point mutation. A knowledge-guided search (Zheng and Wang, 2018) is incorporated to adjust production sequence and unit assignment of child chromosome based on experiential possibility. Pr_{np}^g denotes the experiential possibility of product p is produced at n -th production step (i.e. $c_n^1 = p$) at g -th generation. At each generation, the experiential possibility is updated based on memory and experiences from NF elitists in current generation, as indicated in Eq.(2), where $I_{np}^{sc} = 1$ if $c_n^1 = p$ for the sc -th selected elitist. Evolution of the GA terminates until maximum generation is reached.

$$Pr_{np}^g = (1 - a) \cdot Pr_{np}^{g-1} + a \cdot \frac{\sum_{sc=1}^{NF} I_{np}^{sc}}{NF} \quad (2)$$

3. Sequence-based MILP formulation

Sequence-based MILP formulation is developed where two binary variables $X_{imi'm'}$ and $X_{S_{imi'm's}}$ are defined to denote the sequential relations between batch m of task i and batch m' of task i' on unit $j \in (\mathbf{J}_i \cap \mathbf{J}_{i'})$ and storage $s \in (\mathbf{S}_i \cap \mathbf{S}_{i'})$, respectively. A binary variable z_{im} is defined to denote if batch m of task i is performed. A task that is allowed to be processed in multiple processing units is divided into different tasks. All batches of a task should be processed in sequence, as constrained in Eq.(3).

$$z_{im} \leq z_{i(m-1)} \quad \forall i, m > 1 \quad (3)$$

Sequence constraints are formulated as Eq.(4-6). If the batch m of task i precedes one batch m' of the task i' on a unit j , it must also precede the batch $(m' + 1)$ of task i' , as indicated in Eq.(4). Similarly, the batch m' of task i' succeeds batch $(m - 1)$ of task i if it is processed after the batch m of task i , as Eq.(5). Eq.(6) expresses the sequential relation between two batches of different tasks i and i' performed in one same unit.

$$X_{imi'(m'+1)} \geq X_{imi'm'} \quad \forall j, i \in \mathbf{I}_j, i' \in \mathbf{I}_j, i \neq i', m, m' < M \quad (4)$$

$$X_{i(m-1)i'm'} \geq X_{imi'm'} \quad \forall j, i \in \mathbf{I}_j, i' \in \mathbf{I}_j, i \neq i', m > 1, m' \quad (5)$$

$$X_{imi'm'} + X_{i'm'im} \geq z_{im} + z_{i'm} - 1 \quad \forall j, i \in \mathbf{I}_j, i' \in \mathbf{I}_j, i < i', m, m' \quad (6)$$

Batch size b_{im} is bounded by the maximum B_i^{max} and minimum B_i^{min} capacity.

$$B_i^{min} \cdot z_{im} \leq b_{im} \leq B_i^{max} \cdot z_{im} \quad \forall i, m \quad (7)$$

Eq.(8) indicates the duration constraint, where a_i and β_i are fixed and variable terms of processing time, respectively. If a state s is subject to zero-wait ($s \in \mathbf{S}^{ZW}$), the duration of its producing task ($i \in \mathbf{I}_s^P$) is exactly equal to the processing time in Eq.(9). Sequencing constraints for the same task and different tasks in a unit are given in Eq.(10) and Eq.(11).

$$T_{im}^f \geq T_{im}^b + a_i \cdot z_{im} + \beta_i \cdot b_{im} \quad \forall s \in \mathbf{S}, s \notin \mathbf{S}^{ZW}, i \in \mathbf{I}_s^P, m \quad (8)$$

$$T_{im}^f = T_{im}^b + a_i \cdot z_{im} + \beta_i \cdot b_{im} \quad \forall s \in \mathbf{S}^{ZW}, i \in \mathbf{I}_s^P, m \quad (9)$$

$$T_{i(m+1)}^b \geq T_{im}^f \quad \forall i, m < M \quad (10)$$

$$T_{i'm'}^b \geq T_{im}^f - H \cdot (1 - X_{imi'm'}) \quad \forall j, i \in \mathbf{I}_j, i' \in \mathbf{I}_j, i \neq i', m, m' \quad (11)$$

Variable T_{ims}^S denotes the transfer time of batch m of task $i \in \mathbf{I}_s$ into or out from the dedicated storage of state s . Eq.(12) enforces for batch m of task $i \in \mathbf{I}_s^P$ producing s , the transfer time T_{ims}^S equals to its finish time T_{im}^f . The start time (T_{im}^b) of batch m of task $i \in \mathbf{I}_s^C$ consuming s equals to its transfer time out from the storage in Eq.(13). Sequences on storage for batches of the same tasks and different tasks are given by Eqs.(14-15).

$$T_{ims}^S = T_{im}^f \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s^P, m \quad (12)$$

$$T_{ims}^S = T_{im}^b \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s^C, m \quad (13)$$

$$T_{i(m+1)s}^S \geq T_{ims}^S \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, m < M \quad (14)$$

$$T_{i'm's}^S \geq T_{ims}^S - H \cdot (1 - XS_{imi'm's}) \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, i' \in \mathbf{I}_s, m, m', i \neq i' \quad (15)$$

Eqs.(16-18) are formulated to enforce precedence of batches on storage, which are similar to Eqs.(4-6). When task i and i' can be processed in the same unit and related to one state, sequence relations for their batches keep consistent on the unit and storage, as Eq.(19).

$$XS_{imi'(m'+1)s} \geq XS_{imi'm's} \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, i' \in \mathbf{I}_s, i \neq i', m, m' < M \quad (16)$$

$$XS_{i(m-1)i'm's} \geq XS_{imi'm's} \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, i' \in \mathbf{I}_s, i \neq i', m > 1, m' \quad (17)$$

$$XS_{imi'm's} + XS_{i'm'ims} \geq z_{im} + z_{i'm'} - 1 \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, i' \in \mathbf{I}_s, m, m', i < i' \quad (18)$$

$$XS_{imi'm's} = X_{imi'm'} \quad \forall j, s \in \mathbf{S}^{IN}, i, i' \in \mathbf{I}_s \cap \mathbf{I}_j, m, m', i \neq i' \quad (19)$$

$CB_{imi'm's}$ is defined to monitor batches m' of task i' transferred before batch m of task i ($i \neq i'$) in Eqs.(20-22) or task ($i = i'$) by Eq.(23). It equals to $b_{i'm'}$ if batch m' of task i' is transferred before or at the same time as batch m of task i . Otherwise, it equals to 0.

$$CB_{imi'm's} \leq B_{i'}^{max} \cdot XS_{i'm'ims} \quad \forall s \in \mathbf{S}^{IN}, i, i' \in \mathbf{I}_s, m, m', i \neq i' \quad (20)$$

$$CB_{imi'm's} \geq b_{i'm'} - B_{i'}^{max} \cdot (1 - XS_{i'm'ims}) \quad \forall s \in \mathbf{S}^{IN}, i, i' \in \mathbf{I}_s, m, m', i \neq i' \quad (21)$$

$$CB_{imi'm's} \leq b_{i'm'} \quad \forall s \in \mathbf{S}^{IN}, i, i' \in \mathbf{I}_s, m, m', i \neq i' \quad (22)$$

$$CB_{imim's} = b_{im'} \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, m, m' < m \quad (23)$$

The inventory level of state s after transfer of batch m of task i is calculated by Eq.(24), being positive and less than the maximum storage capacity ST_s^{max} . Eq.(25) enforces total amount transferred must satisfy storage limitation, where In_0_s is the initial inventory.

$$0 \leq \sum_{i' \in I_s} \sum_{m': (i=i' \cap m > m') \cup (i \neq i')} \rho_{i's} C B_{imi'm's} + \rho_{i,s} b_{im} + In0_s \leq ST_s^{max} \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, m \quad (24a,b)$$

$$0 \leq \sum_{i \in I_s} \sum_m \rho_{is} \cdot b_{im} + In0_s \leq ST_s^{max} \quad \forall s \in \mathbf{S}^{IN} \quad (25a,b)$$

For the objective of minimizing makespan, demand constraints are given in Eq.(26). Makespan must exceed the finish and transfer time of all batches.

$$\sum_{i \in I_s^p} \rho_{is} \cdot \sum_m b_{im} \geq D_s \quad \forall s \in \mathbf{S}^p \quad (26)$$

$$MS \geq T_{im}^f \quad \forall i, m \quad (27)$$

$$MS \geq T_{ims}^s \quad \forall s \in \mathbf{S}^{IN}, i \in \mathbf{I}_s, m \quad (28)$$

4. Hybrid framework

A hybrid algorithm is proposed to harness GA and sequence-based MILP, as illustrated in Figure 1. There are three stages in the hybrid framework: GA is first used to generate good-quality solutions; determinations on the batch numbers of tasks and sequencing relations are extracted; the majority of the binary variables in the sequence-based MILP model are fixed based on the extracted information and the MILP model is finally solved to optimality. Multiple feasible solutions ($P_{size} \cdot 0.01$) generated by GA are optimized using the third-stage MILP model, where P_{size} is the population size of GA.

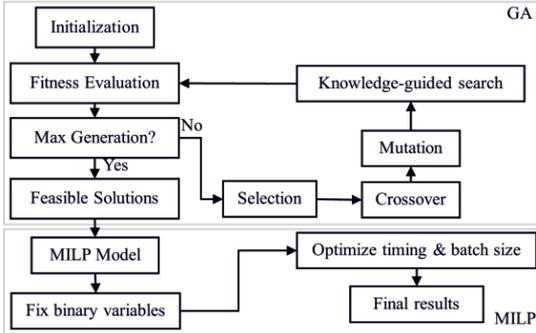

Fig.1 Illustration of hybrid algorithm

Batch size and timings would be optimized in the sequence-based MILP model. Therefore, in GA, batch sizes of tasks are assumed to be maximum and processing times are assumed to be fixed as maximum value (i.e. $\tau_i^G = \alpha_i + \beta_i \cdot B_i^{max}$). The strategies for fixing binary variables in the MILP model are described as follows. Two tasks $i \in \mathbf{I}_i^g$ and $i' \in \mathbf{I}_i^g$ in the MILP model denote one task performing on two different units. If there is no task i' belonging to \mathbf{I}_i^g , all performed batches $m \in \mathbf{M}_i^G$ of task i in the solution from GA must be processed in the MILP model. That is $z_{im} = 1 \forall i: \exists i' \in \mathbf{I}_i^g, m \in \mathbf{M}_i^G$. One batch m of a task $i \in \mathbf{I}_i^g$ starts at time TB_{im}^G . If there are consecutively idle times from any time $t \in [TB_{im}^G, TB_{im}^G + \tau_i^G/2)$ to time $t' > t + \tau_i^G/2$ on unit $j' \in \mathbf{J}_i'$, the batch m is assumed to be potential to divide into two batches, including batch m on unit j (i.e. $z_{im} = 1$) and batch $m' = \mathbf{M}_i^G + 1$ of task i' on unit j' in the MILP model; otherwise, $z_{im} = 1$ and $z_{i'm'} = 0$. The sequencing relations between batches of tasks on the same unit in the solution from GA are used to fix $X_{imi'm's}$. $XS_{imi'm's}$ is partially fixed by enforcing batch m' of task $i' \in \mathbf{I}_s^C$ to start after batch m of task $i \in \mathbf{I}_s^P$ that provides required state for batch

m' (i.e., $XS_{im'i'm's} = 1$). Also, batch m' of task $i' \in \mathbf{I}_s^C$ starts before the finish of batch m of task $i \in \mathbf{I}_s^P$ whose s is consumed by the batch m' to ensure inventory level of the state lower than the maximum storage capacity (i.e., $XS_{i'm'ims} = 1$).

5. Case studies

Five examples are solved to evaluate the performance of the proposed hybrid algorithm. Examples 1-2 are from He and Hui (2010), where instances I1 and I4 are small instances whilst the instances I2, I3 and I5 are large ones. Example 3 are the Kallrath example from Velez et al. (2015), which is an industrial-scale example. Finite intermediate storage and zero-wait policy are involved in Examples 1 to 3. Examples 4 and 5 are the Example 1 and PP solved by Lee and Maravelias (2018). GA is implemented in MATLAB 2020 and the sequence-based MILP formulation is solved using CPLEX 12.10/GAMS 33.2 on a desktop computer with AMD Ryzen™ 9 3900X 3.8 GHz and 48 GB RAM running Windows 10. We also solve these examples using the MILP models from Vooradi and Shaik (2012) and Velez et al. (2015) denoted as VS2012 and VM2015, respectively, as well as a hybrid algorithm from Lee and Maravelias (2018) denoted as LM2018.

Table 1. Computational results for examples 1 to 3

VS2012		VM2015				Hybrid algorithm

I7	12	40	-	1856.3	60	39	103.9	39	18.7
I8	23	58	17.3	>3600	60	52	93.9	52	58.2

The computational results for Example 1 to 3 are presented in Table 1. Results show that our hybrid algorithm can yield global optimality for all solved instances. Comparing to VS2012, the computational times are dramatically decreased in all instances. Also, better solutions are found for most cases (e.g. I3, I6, I7 and I8) using our algorithm. Although the proposed hybrid algorithm obtains the same optimal solution as VM2015, our algorithm requires significantly less computational efforts (< 5 minute) for the large-scale problems. For example, our algorithm leads to a reduction in computational efforts by about one order of magnitude while solving I3 of Example 1 and I7 of Example 3.

We also address the benchmark examples with complex features on processing times. The computational results are provided in Table 2. The results show the effectiveness of the proposed framework on generating optimal or near-optimal solutions within short time frames (1 minute) even for the examples with large demands (Example 4) or complex process structures (Example 5). In the proposed framework, the first-stage GA is critical

to reduce computational effort. For instance, a good solution (44) for I11 is found in 5 seconds by GA but more than 1 hour using the discrete-time model in LM2018. The high quality of the final solutions can be contributed to the integration of the MILP model.

Table 2. Computational results for examples 4 to 5

	Demand				LM2018			Hybrid algorithm			
	P1	P2	P3	P4	H	Dis. MS	MS	CPU Time (s)	GA. MS	MS	CPU Time (s)
Example 4											
I9	100	200	-	-	40	15.5	14.25	0.8	15.5	14.25	2.5
I10	300	300	-	-	60	27	25.37	2.5	27	25.37	4.2
I11	500	400	-	-	80	44	41.38	>3600	44	41.38	6.2
Example 5											
I12	23	25	24	23	120	68	63.56	13.1	68	63.85	7.9
I13	26	50	48	46	200	120	115.9	47.9	120	115.3	62.2

6. Conclusions

In this work, a hybrid algorithm is proposed for scheduling multipurpose batch plants with a wide range of processing features, such as variable conversion fraction, processing time and multiple storage policies. The computational results demonstrate the effectiveness of the proposed algorithm to solve large-size problems to optimality. More importantly, the computational times are significantly reduced to reach optima within 5 mins, leading this hybrid strategy potentially to use as an industrial operational optimisation tool.

Abstract

The use of discrete-event simulation has been gathering relevance to explore dynamic solution generation approaches in the design and planning of biomass supply chains. In this work, the combination of simulation with an optimization module in a hierarchical sequence is proposed, in order to compute the decision variables of interest to validate the economic viability of the supply chain network. The results highlight the advantage to assess strategic/tactical solutions with a more precise liability of overall uncertainty factors, such as the availability of biomass sources and demand variability.

Keywords: Design and planning, biomass supply chain, discrete-event simulation.

1. Introduction

The dynamic structure of current supply chains poses significant challenges to the implementation of effective decision support systems. This complexity often entails the simultaneous assessment of different business criteria for most strategic and operational decisions, in an interdependent structure of stakeholders facing with operational uncertainty. With the advent of digitalization, the development of decision support systems is demanding an enterprise integration with faster decisions (Vieira et al., 2021). It represents a contend for the traditional modeling techniques to encompass the tradeoffs of different dimensions, with particular importance to the growing sustainability implications of economic, environmental, and social levels.

Within the modeling research of complex systems, the development of Digital Models, Twins or Shadows have been addressed in the fields of planning and control improvement. The scope often aims at high-resolution views of physical systems or focus on specified traces when fast reaction is crucial (Liebenberg et al., 2020). Due to this multi-level decision-support, discrete-event simulation (DES) can generate a digital representation with useful data information and performance indicators (e.g. lead time, makespan, resources setting, capacity utilization), allowing to model uncertainty and evaluate how the system reacts in different scenarios as a sequence of events in time.

It is recognized the growing importance in replacing fossil resources consumption by biomass to produce bioenergy and biomaterials at integrated biorefineries (Paulo et al., 2015). However, beyond its environmental contributions, attracting investment requires additional efforts to increase its competitiveness with an efficient supply chain network, gauging the diverse biomass sources to the demand of each region. The overall challenges

concerning its design and planning can include the (1) selection of biomass sources, type, and quantities; (2) storage locations/capacities and preprocessing technologies; (3) processing facilities with technology definition, capacity, and location; (4) type of products/byproducts and respective amounts; (5) demand centers, location and quantity to satisfy; or (6) logistic operations at the supply chain nodes. Moreover, these strategic decisions are greatly influenced by the uncertainty on biomass availability and quality, products demand, or the non-mature biorefineries technologies for pre/processing operations.

The biomass supply chain design under uncertainty has been an active area within the research community in recent years. Despite largely supported by analytical optimization modeling studies, DES approaches have been gaining relevance to address the behavior and performance under different conditions to describe uncertain scenarios. For example, simulation can be used to validate the long-term economic viability of a biorefining supply chain, as presented by Sukumara et al. (2015). To examine the economic performance of the supply chain over time, including supply and demand variability, a simulation model is created to determine the optimum feedstock requirement, capital investment, and operating costs of the process. Another recent contribution, Pinho et al. (2016) modeled the biomass supply chain using DES to estimate the system behavior regarding stochastic drive and chipping times to improve management and scheduling tasks. And Eriksson et al. (2017) develop a model for weather-driven analysis of forest fuel systems, with a DES approach analyzing the supply chains that account for active and passive machine activities, such as quality changes during storage. The results illustrate significant improvements concerning machine capacity requirements.

Following the recognized advantage of DES to model uncertainty, the application to decision support in the design and planning of biomass supply chains remains fairly unexplored. The aim of this work is to explore a hybrid simulation-optimization approach, with focus on the representation of the dynamics and uncertainty interactions of the real supply chain system by means of an event-based model. This preliminary study outlines the combination of an optimization-based solution to be evaluated in a virtual model that accurately simulates the characteristics of the biomass/bioproduct flows and the network performance under alternative scenarios to generate a solution. As follows, we present an overview of methodology and discuss the results in a case study example for a biomass supply chain problem.

2. Methodology

Due to the stochastic and complex nature of biomass supply chains, an adequate choice for an effective solution generation approach resumes the research for hybridization of techniques to overcome the computational burden. As noted by Figueira and Almada-Lobo (2014), the potential hybridization of simulation with optimization approaches combines the advantages of the system detail representation with the ability to optimize solutions, leaving the hard-to-model constraints to the former. Despite this hierarchical combination can be defined in one-way or iterative, here we focus on the case where analytical models can be formulated and their solutions simulated (optimization-based simulation), in order to compute some variables part of the solution generation. The analytical model generates a solution under ideal conditions, while the simulation considers the inherent variability and provides the expected realistic outcomes.

For the proposed case of a biomass supply chain, the economic viability of a solution for the strategic/tactical decisions comprises the definition of which biomass sources supply raw-material for the integrated biorefineries to satisfy demand centers within a

transportation network. However, matching the uncertain biomass seasonality throughout the given time horizon to each center demand can generate a reduced income output. Therefore, we devise the methodology composed by an optimization module to generate an initial deterministic solution, completed at the simulation module which evaluates the dynamic representation of process interconnections.

2.1. Optimization module

Based on the work of Paulo et al. (2015), this module is composed by a MILP model using GAMS/CPLEX which is stated as follows: given (a) a superstructure defining all possible locations of biomass sources (with the corresponding availability per type), biorefineries and demand centers, considering the distances between all points; (b) transportation modes and their costs, biomass acquisition costs, biorefinery installation, fixed/variable operating costs (for a set of discrete capacities); and (c) the conversion factors of the different biomass types into products and corresponding demand; determine the optimal supply chain network structure with the (d) number, location, technology and capacity of biorefineries to install, with the corresponding amounts produced and demand centers to serve; and (e) amount of each biomass type collected at each source and transportation flows between each pair of facilities; so as to (f) minimize the supply chain total cost (Eq.1).

$$\begin{aligned} \text{Total Cost} = & \sum (\text{Biomass Cost} + \text{Fixed/Variable Operating Cost at Biorefineries} \\ & + \text{Transportation Costs} + \text{Annualized Investment Cost}) \end{aligned} \quad (1)$$

2.2. Simulation module

The embedded biomass supply chain structure of operations is evaluated with a DES model implemented in SIMIO, which computes the output scenario statistics involving the occurrence of events at discrete time point using probability distributions of parameters. The main components and library of objects available at the SIMIO software are used to achieve the most accurate representation of the network nodes, which requires advanced programming of the system properties. As a general concept of the model principles, an 'entity' (e.g. demand order) will arrive, is processed by a sequence of 'servers' (e.g. biorefinery), and then departs from the system. The level of detail, uncertainty factors and problem assumptions should be considered as suitable to case objectives. Due to the scope limitations of the present work, the focus relies in the time horizon variability of biomass availability at each selected source, the technology conversion performance at the biorefineries and bioproducts prices. For simplification, it was considered the software's default number of replications to guarantee statistical significance.

The interaction of the two modules aims to generate a supply chain configuration accounting with the precise simulated biomass/bioproducts flows in order to compute a techno-economic investment viability. Adequate parameter availability, unfulfilled demand penalty and prices forecast was considered to examine the economic performance cashflows over time. To account for the time value of money, the simulation model tracks the net present value (*NPV*) of the biomass supply chains operations (Eq.2), for n time periods, CF_k as annualized value of cashflow at year k and i discount rate.

$$NPV = \sum_{k=0}^n \frac{CF_k}{(1+i)^k} \quad (2)$$

3. Case Study

The described methodology has been applied to an illustrative case study of bioethanol and biodiesel production in Portugal. The supply chain structure integrates the process of harvesting and biomass collection, biorefineries, demand centers and all the logistic activities for biomass and bioproducts transportation. Considering the 278 portuguese municipalities, 150 are considered as biomass supply sources (i) (the remaining municipalities were excluded due to low biomass availability), and 28 locations are candidate to biorefineries installation (k), to satisfy the 18 portuguese districts in biodiesel and bioethanol demands (v). Two types of biomass types are considered: Sugar/starch biomass (b1) and seeds/animal fats (b2), processed by fermentation (m1) and transesterification (m2) technologies at the biorefineries to bioethanol and biodiesel, respectively. All models run in an Intel(R) Xenon(R) CPU ES-2660v3@2.60GHz with 64GB RAM, with GAMS (25.1.1 ver.), using CPLEX (12.8.0.0 ver.) solver, and SIMIO (9.5 ver.).

3.1. Results discussion

Setting the problem input data for a 12-months' time horizon, the optimization module generates an optimal cost solution with the supply chain characteristics presented in Table 1, with the number of biomass collection sources and total biomass amounts to be transported to the installed biorefineries. The biorefineries properties, as well as the total amount of production to entirely fulfil the demand centers by each of the biorefineries, are also displayed. While the optimal solution yields a network with assumed conditions, variability in biomass availability has influence on supply chain performance over time and directly linked to demand variability. At the simulation module, these biorefineries activities that account for biomass sources transportation, conversion to final bioproducts, product distribution and sale prices, are assessed.

Table 1. Optimal supply chain characteristics

Biomass type	Biomass collection sources	Total biomass (ton)	Biorefinery	Total product. (ton)	Demand centers
b1	i5, i8, i9, i14, i16, i26, i29, i34, i35, i38, i43, i53, i69, i74, i75, i78, i87, i89, i90, i94, i100, i112, i114, i115, i123, i126, i135, i143	700 575	Location: k13 Tech: Fermentation Cap: 250 000 ton Product: Bioethanol	241 435	v2, v7, v8, v11, v14, v15
b1	i1, i2, i4, i6, i7, i18, i21, i22, i27, i39, i41, i49, i51, i52, i58, i62, i63, i67, i72, i76, i88, i96, i97, i98, i103, i108, i109, i112, i122, i127, i129, i131, i132, i134, i137, i146	598 416	Location: k16 Tech: Fermentation Cap: 250 000 ton Product: Bioethanol	206 229	v1, v5, v6, v9, v10, v12, v13, v18
b1	i11, i20, i23, i42, i46, i50, i77, i83, i86, i117, i118, i119, i138, i142, i145	217 627	Location: k26 Tech: Fermentation Cap: 75 000 ton Product: Bioethanol	75 000	v1, v3, v6, v7, v10, v11, v13, v14, v15, v16, v17, v18
b2	i1, i6, i7, i9, i14, i16, i26, i29, i34, i35, i38, i39, i43, i49, i53, i67, i72, i74, i90, i94, i98, i108, i112, i114, i115, i131, i134, i135, i143	14 383	Location: k20 Tech: Transesterification Cap: 250 000 ton Product: Biodiesel	4 770	v3, v4, v13, v16, v17

The optimal solution of this supply chain is then modeled in SIMIO to simulate its feasibility, considering the defined parameters distributions (from historical public data of energy regulatory agency) and the year seasonality of biomass availability and bioproducts demand applied to each corresponding location (Table 2). By recording the monthly flows between nodes, the DES model is run for a period of 15 years to compute the variability and cashflows of this initial scenario, considering a discount factor of 3%.

Table 2. Seasonality discretization of biomass availability and bioproducts demand

Seasons/Months		Annual biomass availability	Biodiesel annual demand	Bioethanol annual demand
Winter	(Dec. – Feb.)	10%	21%	25%
Spring	(Mar. – May)	40%	20%	23%
Summer	(Jun. – Aug)	30%	31%	26%
Fall	(Sep. – Nov.)	20%	28%	26%

The simulation results displayed in Figure 1, related to the first year of the investment period, allows to verify the virtual utilization of the optimal theoretical capacity installed and the corresponding costs breakdown, enabling a more accurate assessment of the design decisions. Likewise, in Figure 2 is possible to identify that the availability of biomass less concentrated in Fall and Winter seasons does not allow to fulfil all corresponding districts’ demand of bioproducts. Therefore, an additional scenario can be simulated to include the additional installation of a dry-storage warehouse for biomass buffer at each biorefinery that does not satisfy associated seasonal demand, k13, k16 and k20. This scenario enables to satisfy the entire country’s demand and increases the project investment NPV from –95,2 M€ to 26,3 M€.

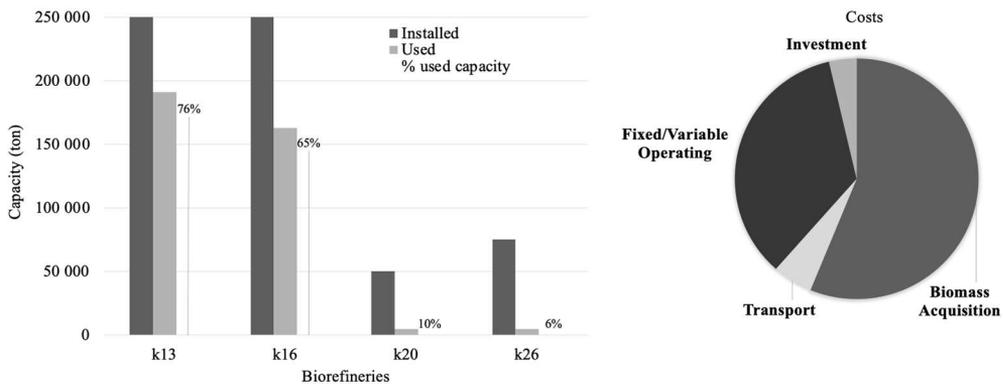

Figure 1. Results of simulated capacity utilization of each biorefinery and costs breakdown for the first year of investment project

4. Conclusions

The present work proposes the integration of a hybrid simulation-optimization approach for the design and planning of biomass supply chains, in which the role of the DES is to mimic the real-world environment to evaluate an optimized solution under dynamic and uncertain interdependent conditions. The results demonstrate that this combination offers

a method with potential to deal with such strategic/tactical decision liabilities, such as the importance of storage warehouse or pre-processing facilities to generate an efficient supply chain solution. Future work will explore the DES capabilities to assess a more robust definition of the nodes, configuration, and capacities of the supply chain by increasing the detail of the uncertainty effects in the overall operations.

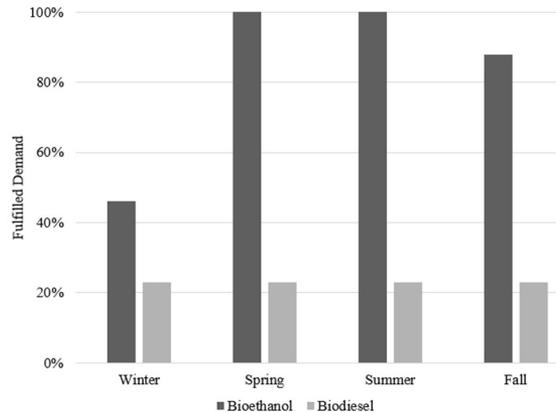

Figure 2. Percentage of total fulfilled demand of each bioproduct per season

Abstract

Nowadays there is a growing concern regarding greenhouse gas emissions and their consideration in the supply chain design. In this work we present a robust stochastic model for the design of a supply chain under uncertainty of CO₂-allowance prices and market demand. The three-echelon petrochemical supply chain superstructure consists of four production plants in Europe, storage associated with these plants and four possible markets. At each plant different products can be produced according to the available technologies. The goal is to maximize the expected net present value (ENPV), while reducing the amount of CO₂ equivalent emissions. We implemented the carbon cap and trade model from the European Union emissions Trading System, whose goal is to reduce the emission cap over time in order to achieve a climate-neutral EU by 2050. We combine the environmental LCIA data, required to determine the global warming potential, with the forecast of CO₂ allowance prices. The problem involves a multi period mixed-integer linear program (MILP) formulation, which was implemented in Python using Pyomo and solved using IBM's CPLEX algorithm. To deal with uncertainty in market demand and CO₂-allowance prices, we implemented an ARIMA model and generated multiple scenarios. Since a full discretization of the resulting probability space leads to a number of scenarios that exceeds capacities of state-of-the-art computers with ease, decomposition techniques are applied. The obtained results show an improvement of the economic performance when compared to the results from the deterministic approach that is being widely used in literature.

Keywords: CO₂ price uncertainty, stochastic model, optimum supply chain management, Augmented Lagrangian Relaxation

1. Introduction

In a globalized world the efficiency of supply chains is gaining more importance. Supply chains integrate different activities, resources and institutions to ensure effective production, storage and distribution of products. Real world uncertainties can have a large impact on the design and efficiency of a supply chain. In this paper, we not only focus on uncertainties in the market demand (which have been studied extensively in the literature), but also on uncertainties in the CO₂ prices. In this work we will consider the European Union Emissions trading system, whose goal is to achieve a climate neutral EU by reduction of the maximum amount of allowed emissions over time, c.f. European Union (2016). The study of combined uncertainty in CO₂ prices and demand require the use of a huge number of scenarios for fully discretizing the underlying probability space. Since this exceeds capacities of modern day computer with ease, we combined various techniques to being able to obtain a supply chain design that takes these combined uncertainties into account.

We first generated a large number of scenarios and clustered them according to their economic and environmental performance. In order to solve the resulting stochastic mixed-integer linear program, we applied an Augmented Lagrangian Relaxation (ALR) scheme together with an alternating direction of multipliers to ensure separability of the problem into subproblems. The resulting subproblems could then be solved in parallel to reduce computational time. For more information regarding ALR see Boyd S., Parikh N., Chu E., Peleato B., Eckstein J. (2011); Conejo A. J., Castillo E., Mínguez R., García-Bertrand R. (2006).

To the best of our knowledge, a combination of the before mentioned methods for the study of combined uncertainty in a European three-echelon petrochemical supply chain has never been used before.

2. Methodology

In this section, we briefly introduce the problem under study. Also, we review the different techniques that were combined in order to compute a stochastic supply chain model that adapts to the scenarios under study.

2.1. Problem statement

The studied three-echelon petrochemical supply chain superstructure consists of 4 production plants in Europe: Kazincbarcika (Hungary), Leuna (Germany), Mantova (Italy) and Wloclaweck (Poland). Each plant has an expansion limit between 10 and 400 kt/year and an initial capacity of 20 kt/year, c.f. Guillén-Gosálbez, G., Grossmann, I.E. (2009). All plants can produce acetaldehyde, acetone, acrylonitrile, cumene, isopropanol and phenol using one of 6 available technologies involving up to 18 different chemicals. There is a warehouse associated to each plant having the same expansion limits and initial capacities. Initially, the inventory is empty. The material flow between plant and warehouses, as well as warehouses and markets, is limited to 500 kt/year. A minimum demand satisfaction of 30% is specified. The initial maximal amount of CO₂ emissions is $2 \cdot 10^8$ kg CO₂ equivalent, with a 2.2% yearly reduction rate.

2.2. Supply chain model

The model under study is composed of environmental impact, economical assessment, capacity constraints and mass balance equation blocks. The objective is to maximize the expected net present value, while satisfying all of these equation blocks. The cap-and-trade system provides a link between economic and environmental performance. Since a full description of the model would turn out to be quite long and considering the page limit, we refer the reader to Ruiz-Femenia et al. (2013) for more details on the model. The most important equations read

$$\text{GWP}(t, s) \leq \text{MAX}_{\text{CO}_2}(t) + \text{BUY}_{\text{CO}_2}(t, s) - \text{SALES}_{\text{CO}_2}(t, s), \quad \forall t, s \quad (1)$$

$$\begin{aligned} \text{NET}_{\text{CO}_2}(t, s) &= \text{PRICE}_{\text{CO}_2}(t, s) \cdot \text{SALES}_{\text{CO}_2}(t, s) \\ &\quad - \text{COST}_{\text{CO}_2}(t, s) \cdot \text{BUY}_{\text{CO}_2}(t, s), \quad \forall t, s \end{aligned} \quad (2)$$

$$\begin{aligned} \text{NETE}(t, s) &= (1 - \text{TAX}) \left[\text{EARNINGS}(t, s) - \text{EXPENSES}(t, s) + \text{NET}_{\text{CO}_2}(t, s) \right] \\ &\quad + \text{TAX} \cdot \text{DEP}(t), \quad \forall t, s \end{aligned} \quad (3)$$

Equation (1) describes the available emissions for the supply chain at each time-step t and scenario s , and consists of the maximum amount of emissions allowed by the system in each year, as well as the amount of bought as well as sold emissions. In equation (2), the economic impact of the emissions trading on the supply chain is calculated. We call this quantity NET_{CO_2} . This term is then taken into account when calculating the net earnings for a specific time and scenario, as described in equation (3).

2.3. Uncertainty in CO₂ allowance prices and market demand

In order to make decisions on a supply chain design, oftentimes a deterministic approach is chosen in literature. Since uncertainties are not taken into account, and computations are done for a fixed deterministic setting, this can be considered a risky approach. In the design of a supply chain, there are many possible sources of uncertainty, such as CO₂ allowance prices, changes in raw material prices, energy prices, demand, etc. If these uncertainties are not taken into account, the resulting design may perform poor in unexpected future situations. In this paper, we consider uncertainties of demand and CO₂ allowance prices through combined scenarios. Each scenario represents a possible time-dependent evolution of both parameters. By taking the uncertainties into account when computing an optimal supply chain design, the result will be more robust to future changes in both parameters than the classical deterministic approach. The scenarios for the CO₂ allowance prices were generated using an autoregressive integrated moving average (ARIMA) model. ARIMA models are defined by three parameters. The first parameter determines the non-seasonal polynomial degree. The second one is the order of differentiation used to remove seasonal trends. The third parameter is the number of moving average terms, which is related to the accuracy of approximations produced by an update of the parameters from fitting the model to the historical data. In Shumway and Stoffer (2000), details can be found.

Appropriate values of the parameters were identified by fitting the historical data from 2009 to 2021 and using the Akaike and Bayesian information criteria. In our case, the best-fitting model is ARIMA (7, 1, 8).

Random time series data for the demand of each chemical at each market were generated using a normally distributed random growth with a standard deviation of 7% to a given start value at time $t = 0$. We compared the environmental and economic performance of 1000 combined scenarios, and grouped them into 20 clusters using the K-means algorithm (see fig. 1). The centroids of each cluster were then used as scenarios for the stochastic program. For an overview of clustering methods see Omran et al. (2007).

2.4. Augmented Lagrangian Relaxation

The aim of decomposition methods is to solve many easy-to-solve subproblems instead of one hard-to-solve full problem. We split the full problem into subproblems containing information only on one scenario. The main difficulty then lies in the linking of the non-scenario dependent variables from each subproblem, since these should coincide. To do so, we included as many non-anticipative constraints to the model as there are non-scenario dependent variables. These non-anticipative constraints represent the complicating constraints of the model, which have to be relaxed by introducing them as penalty terms into the objective function, together with new multipliers. Since our objective is a linear function, we added additional quadratic penalty terms to ensure convergence of the method, resulting in the so called Augmented Lagrangian Relaxation of the problem. Because of the appearing products of variables from different scenarios in the quadratic penalty terms, the resulting objective is not decomposable into subproblems for each scenario anymore. To overcome this problem, the alternating direction method of multipliers is used. This method linearizes the product of variables from different scenarios using values of previous iterations for one of the appearing variables. The result is a relaxed problem that is fully decomposable into subproblems only involving one scenario each.

A tolerance of 5% was set as stopping criteria for the ALR-loop. After each iteration, if the stopping criteria was not fulfilled, the multipliers will be updated according to the subgradient method and a new iteration is started, and we refer to Conejo A. J., Castillo E., Mínguez R., García-Bertrand R. (2006) for details. The overall procedure is explained in fig. 2

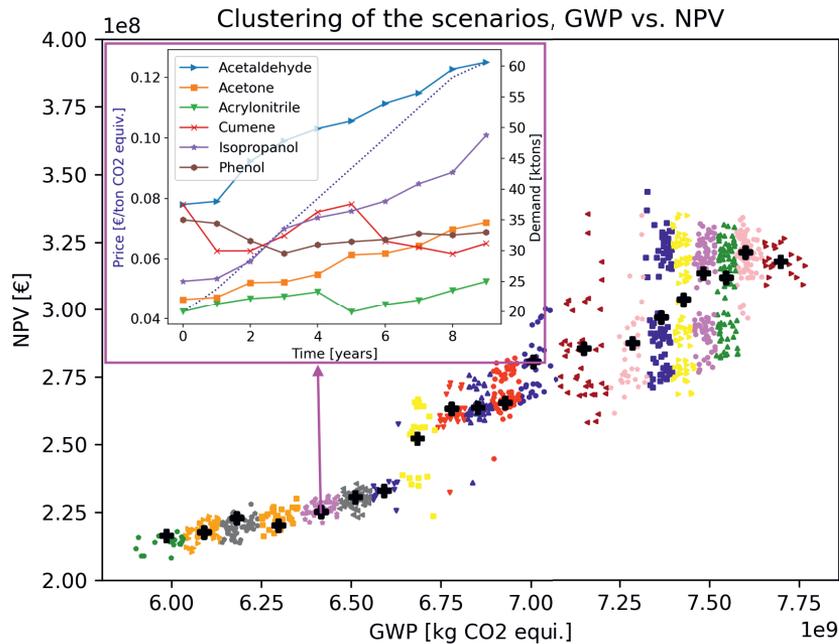

Figure 1: Economic and environmental performance of 1000 deterministic scenarios. The scenarios are clustered in different colors and the centroids are marked with a +. For the exemplary cluster centroid 5, the values of the CO₂ allowance prices (dotted blue line) and demand in the market Leuna for the 6 products over time are shown.

3. Results

Numerical experiments were conducted on a MacBook Pro model 2020 with 16 GB Ram and macOS 11.2.1. The model has been implemented in Python using Pyomo and solved using IBMs CPLEX algorithm.

Thanks to the method of alternating direction of multipliers, each subproblem can be solved independently of the others. This allows for a massive speedup through parallelization, since in the best case one processor only solves one or a few subproblems per iteration. According to the previous runtime of each subproblem, a redistribution of subproblems among the processors will be carried out between iterations. The goal is to reduce the total runtime per iteration by balancing the expected runtime of each processor. In our case (on 6 processors), we could speed up the solution process by about 80% compared to sequential solving. The problem was moreover reformulated and the number of variables per subproblem could be reduced from about 27000 to 24000, further simplifying the solution process.

We validated our method by comparing the obtained stochastic supply chain design against its deterministic counterpart from a scenario with an average investment cost, which is typically the one chosen by companies. In average, the stochastic model leads to an increase of the net present value by approx. 927600 € while reducing the global warming potential by around 225000 tons of CO₂-equivalent.

The resulting stochastic supply chain design has a net present value (NPV) of 254603229 € and

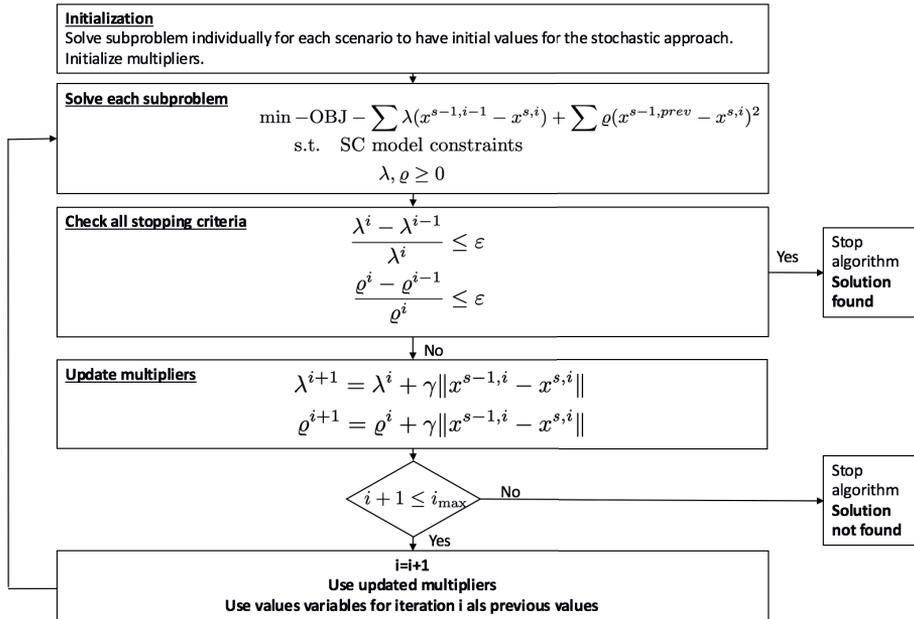

Figure 2: Schematic representation of the iterative solution algorithm. The problem has been separated into subproblems with additional coupling constraints, that appear as penalty terms in the corresponding objective function. The multiplier update uses a subgradient method.

a global warming potential (GWP) of 7624500 tons CO₂ equivalent. In average, 580 tons of CO₂ equivalent will be bought each year. In fig. 3, the capacities of the different technologies of each plant, as well as the total quantities transported between warehouses and markets in the last time-step are presented.

The major expansions have taken place at the Wloclaweck and Kzinbcarcika plants, which have the lowest production costs. At all plants, the capacity for technology 5 “Reaction of benzene and propylene” was expanded most, since cumene is not only one of the products demanded at all four markets, but also the raw material for the production of phenol and acetone (technology 6). Sines and Tarragona markets are mainly supplied by the Mantova plant, which is the closest one. These decisions reduce not only transportation costs, but also emissions.

4. Outlook and further work

We are currently working on a supply chain design, which is able to represent the penalties associated with a non-satisfaction of the demand. In this work, we studied the impact of uncertainty in market demand and CO₂ prices on the supply chain design. Nevertheless, a study for uncertainties in different parameters should be carried out, in order to recognize which parameters possibly have a higher impact on the performance. We are also working on increasing the feasible number of scenarios and assess the information loss caused by the clusterization. Considering the ALR loop, there are still many open questions regarding a robust choice and update of the multipliers for each iteration, which tend to have an enormous impact on the solvability of the stochastic model.

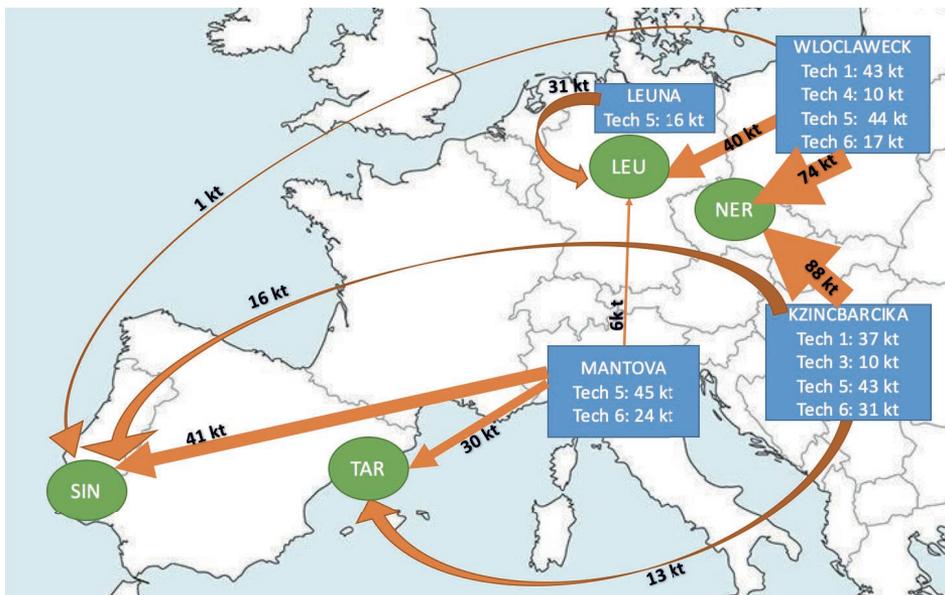

Figure 3: Stochastic supply chain design for the last time-step. The blue boxes represent the four plants and their respective warehouses. Capacity expansion information for each technology is included in the corresponding box. The four markets, Sines (SIN), Tarragona (TAR), Leuna (LEU) and Neratovice (NER) are represented with green circles. The orange arrows represent quantities transported (in kt) between each plant/warehouse and each market.

Abstract

Despite the increasing development of optimisation-based approaches over the last decades, simulation methods are still widely employed for problems that could instead be optimised. Simulation relies on achieving feasibility through a trial-and-error procedure and provides meaningful and useful resources to find quick or rigorous solutions. On the other hand, optimisation provides proper capabilities for automatic and systematic searching over the solution space. Although more computationally expensive, optimisation has been increasingly used due to the recent technological improvements and research developments in the wake of the Industry 4.0. However, industrial decision-making is still often carried out manually, which indicates an urgent need for addressing the difficulties, complexities, and issues in the implementation of automated tools. This work aims to provide guidance for industrial operations towards selecting proper decision-making capabilities. An industrial perspective on simulation and optimisation decision-making is provided, whereby highlighting the issues and challenges faced by industrial peers, and the current gaps between academic research and industrial implementation. This includes the interplay between simulation and optimisation tools, academic research, and industrial implementation. From an industrial perspective, we provide guidance for incorporating academic knowledge by the industry, exposing what are the industrial requirements to be further addressed, and assisting industrial peers towards achieving further breakthroughs.

Keywords: Optimisation, simulation, planning, scheduling, decision-making.

1. Introduction

Recent Industry 4.0 (I4) developments comprising digital transformation, big data, machinery automation, advanced analytics, and decision-making frameworks, offer opportunities for improvement in multiple applications of diverse fields. I4 technologies provide further automation of decisions with faster and more efficient operations, reduced costs, and higher product quality. There has been an urgent need for replacing outdated processes and tools more efficient and automated systems. This is fundamental towards achieving safer, more profitable, and more efficient industrial operations. In this work, we discuss simulation versus optimisation capabilities for industrial processes with particular emphasis from an industrial perspective.

Simulation methods have been historically used for decision-making. They rely on achieving feasibility through a trial-and-error procedure and provide meaningful and

useful resources to quickly find solutions for real-world problems. Simulation refers either to manual decisions (e.g., to be determined by the operations team) or to automatic computer-based algorithms (e.g., rigorous simulation) based on ranges and probabilities. Over the last decades, simulation-based software has been extensively developed for industrial applications (Yang et al., 2020).

Optimisation tools have arisen as improved alternatives for automated decisions. They provide proper capabilities to systematically find optimal (and better) solutions. Their searching algorithms are based on mathematically proven concepts in order to guarantee optimality. However, due to the increasing complexity that scales with the type and size of the formulation, there are limitations in the application of optimisation depending on the problem to be solved and the availability of computational resources. Despite such complexity issues, recent advances on decision-making algorithms and computer-aided resources have increasingly provided enhanced capabilities for properly addressing and solving industrial applications (Franzoi et al., 2018; Brunaud et al., 2020).

Such simulation versus optimisation ideology is widely known and discussed in academia. Both approaches have their advantages with highly important and meaningful applications. Nevertheless, there is a huge gap between the methodologies and strategies presented by the state-of-the-art literature and the capabilities currently used by the industry. Many industrial decision-making methods and tools are still obsolete. Common reasons include lack of knowledge, training, and qualification to employ better decision-making. This is often a result of the resistance to change from both the people and organisations. Consequently, further breakthroughs and enhancements towards improved operations are compromised or not properly exploited. Given the current economic scenario with increasing competitiveness, most companies either struggle to survive or miss significant opportunities to achieve economic and operational improvements.

In this work, we stimulate a discussion on simulation and optimisation capabilities and emphasise the importance of employing appropriate tools according to the industrial needs, limitations, and requirements for each process or application. Particular emphasis is given to the petroleum refinery industrial sector, where the decision-making process often relies on trial-and-error, manual, and simulation-based strategies and tools despite the emerging applicability of their optimisation counterparts.

2. Simulation-based versus optimisation-based industrial capabilities

Despite the increasing development and implementation of optimisation methodologies, algorithms, and tools over the last decades, the industry still heavily relies on simulation-based methods and software. In many cases, simulation is indeed more suitable or advisable. However, many organisations are still outdated in terms of software and technological capabilities, whereby not realising or exploiting opportunities to achieve increased operational efficiency and economic value. In fact, many problems and applications that could be optimised are instead handled by less efficient simulation tools. Some key differences and applications of simulation and optimisation methods are illustrated in Figure 1. Such concepts are fundamental to understand how to best employ the current industrial capabilities in a proper and efficient fashion.

A typical example of highly complex processing industry that still requires computational-based improvements, especially in terms of software and methodologies employed for the decision-making process, are petroleum refineries. In the following, we address the topic of simulation-based versus optimisation-based capabilities for

petroleum refinery operations, although such discussion and concepts are generally valid for other industries and applications as well.

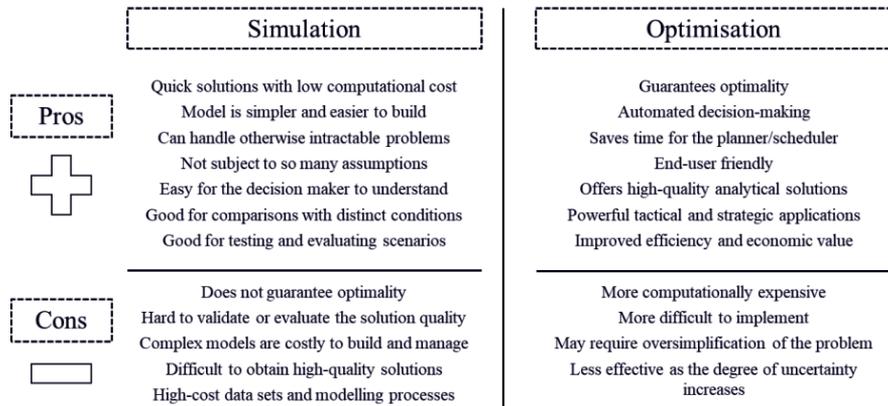

Figure 1: Simulation versus optimisation decision-making.

3. An industrial perspective on petroleum refinery decision-making

Petroleum refinery operations require determination of variables over a complex processing network, in which planning and scheduling decision-making are often performed aided by computer-based software and resources. The scheduling decision-making comprises the crude oil scheduling (feedstock edge), processing scheduling (unit-operations and streams throughout the process), and blend scheduling (product edge blending). Despite a vast amount of research and tools on scheduling optimisation, refineries worldwide still employ scheduling simulation software. That leads to feasible or suboptimal solutions, and it is typically performed based on manual or automatic trial-and-error methods (Li et al., 2020). For planning decision-making, refinery planning software are employed to determine the production throughout the plant over weeks or months. Similar to the scheduling decisions, simulation tools are still often employed to assist in the identification of financial losses or profit opportunities in the refinery through evaluation based on trial-and-error (and therefore, limited) scenarios.

There are important aspects on planning/scheduling decision-making from an industrial perspective, which comprise the interplay between simulation tools, optimisation tools, academic research, and industrial implementation, as shown in Figure 2.

Simulation versus optimisation: Simulation is still employed for problems and applications that could be better solved or handled by optimisation methods. The main reasons include insufficient knowledge to implement or develop better approaches, lack of trained or qualified personnel, fear of change, lack of investments, etc. In addition, many companies still have highly experienced planners/schedulers that manage the entire operational decision-making process, in which outdated tools are often used, and which compromises further breakthroughs and enhancements towards improved operations.

Industrial implementation of simulation tools: Trial-and-error or try-and-test simulation methodologies, either commercial or home-grown planning/scheduling, rely on simulating events to test feasibility, where the user is often responsible for manually testing different scenarios and keeping track of convoluted decision-trees that do not work

or prove feasible (Menezes et al., 2015). The simulation software is often time-consuming due to the need of continuously check and update the processing data to achieve good or proper solutions. Such procedure is not reliable, may take hours or days, and does not guarantee even feasible solutions. Furthermore, in the best-case scenario, the simulation software provides a limited number of solutions to be chosen by the planner/scheduler. This leads to exhausting efforts to model, save, and manage the numerous scenarios and to update the modelling premises and situations that constantly change. A typical outcome is that planners/schedulers abandon the solutions given by the software and return to their simpler manual spreadsheets. Hence, this translates into even less efficient decisions to be incorporated in the plant, which results in reduced operating capacity, increased process variability and uncertainty, not efficient nor reliable solutions, etc.

Industrial implementation of optimisation tools: Optimisation software can overcome some of the simulation issues often faced by planners and schedulers. However, such commercial tools are often expensive, require previous knowledge or proper training, and may be subject to resistance from the users or organisation that heavily rely on the currently used methodologies/tools and that are against or afraid of changes.

Industrial implementation of academic research: A proper discussion is required on the applicability of the methods developed in academic research into industrial processes. Planners and schedulers argue that academic research is not fully adaptable or suitable in the industrial environment, especially because of the simplifications proposed to solve complex-scope and large-sized problems. Such simplifications are often not realistic and do not provide proper capabilities for industrial implementation. Moreover, academic research that is applicable and coherent with industrial applications is often not investigated and employed by potentially interested companies.

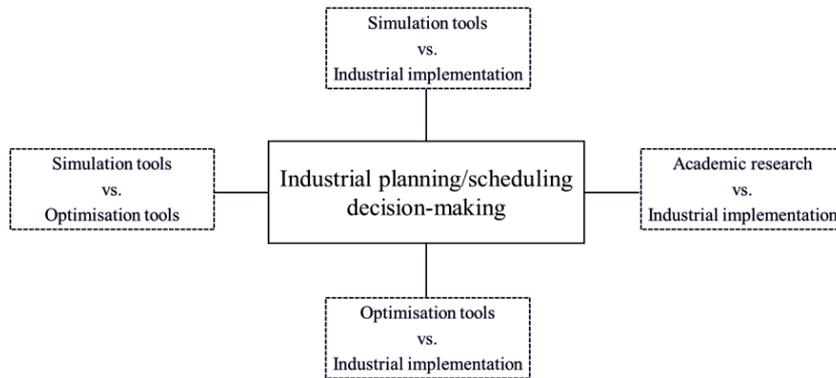

Figure 2: Interplay between simulation tools, optimisation tools, academic research, and industrial implementation.

4. Guidelines for enhanced industrial capabilities

A fundamental concept regarding the application of computational-based tools for industrial processes is that both simulation and optimisation are relevant and important, but for distinct purposes and applications. Simulation can be used to evaluate multiple distinct scenarios in order to provide information on how a given system is expected to work, i.e., system response under different conditions. There have been long joint developments in simulation tools for the industry, including strong collaboration in tailoring opportunities and solutions according to the industrial needs, graphical user

interfaces for operator interactions, and rigorous simulation software, which are widely used for controlling process conditions according to operational limitations, constraints, or requirements. Conversely, optimisation provides enhanced decision-making capabilities for identifying better solutions under specific scenarios or operating conditions. This includes finding better process conditions that lead to the optimal solution of a given problem or application.

The decision on whether to use simulation or optimisation strongly depends on the problem, application, complexity, and solution requirements. Simulation is preferred for applications in which optimisation may fail (e.g., highly degenerate, nonconvex, or complex problems) and when the operational and economic benefits of optimal solutions do not worth the requirements of resources (e.g., time, effort) for the development and implementation of optimisation methods. Simulation is indeed quite important for diverse industrial problems, but it is fundamental to highlight the importance of employing optimisation methods for applications that are optimisable, i.e., suitable to be solved by optimisation-based algorithms and tools rather than simulation-based or trial-and-error procedures. In fact, many works from the literature (Khor and Varvarezos, 2017; Franzoi et al., 2021) emphasise the importance of investigating such applications for replacing simulation by optimisation whenever the latter is suitable and applicable aiming to achieve better process efficiency and improved operations.

A key topic to be further addressed by the industry is the importance and necessity to seek better and more efficient decision-making capabilities. This involves technological and research advancements in software, tools, resources, and methodologies that provide a positive impact on the operational decision-making with increased economic value. Organisations must overcome the traditional resistance and limitations imposed by outdated tools and methods. Towards an enhanced decision-making reality within the Industry 4.0, it is fundamental to learn with the state-of-the-art technological development and to adhere to novel and improved capabilities currently available for industrial applications. Within this context, it is highly advisable to gather academic knowledge on planning and scheduling applications. This can be achieved by research and development teams, and through academic-industry collaborations. Such concepts may provide high-quality implementable research with mutual overall benefits. An illustrative example is provided as follows to exemplify industrial operations driven by simulation tools that could be better managed by their optimisation counterparts.

5. Illustrative example

The scheduling operations to be determined in a crude oil refinery are assisted by a scheduling simulation software that provides potentially feasible solutions. The software requires manual inputs and checking of information in multiple distinct simulations, which typically takes hours for an experienced scheduler to determine the solution to be implemented in the plant. Replacing it by an optimisation decision-making tool requires investments in research and software and may take months for proper development and testing. Such an optimisation capability is anticipated to provide:

- Easier and quicker rescheduling of the problem whenever needed.
- A pool of multiple optimal solutions that can be chosen by the user depending on any processing limitation or requirement.
- Possibility of continuously optimising the problem and integrating the updated solutions with the scheduling operations in an automatic and systematic fashion.

- Significant economic savings in the operations.

In addition, the solution can be checked manually to ensure high quality and consistency, and the simulation tool can be used as an alternative if the optimisation fails.

6. Conclusions

An industrial perspective on simulation and optimisation decision-making capabilities is provided herein, whereby highlighting some key gaps and challenges. Such aspects include the interplay between simulation tools, optimisation tools, academic works, and industrial implementation. Simulation is still widely employed for problems that could be rather optimised; simulation tools are often not easily or properly applicable; optimisation tools are often not available or require additional resources; and despite huge academic breakthroughs, most methodologies are not suitable for industrial implementation.

Simulation tools have been historically employed for industrial applications. Recently, optimisation decision-making has been increasingly used given the enhanced industrial capabilities (e.g., technological improvements, higher computer power) and research developments (e.g., improved algorithms and methodologies). This provides significant advancements with more efficient processes and operations. The main benefits include more flexible, adaptable, and reliable processes with higher economic value. In this work, we emphasise the importance of optimisation replacing simulation for problems and applications that are optimisable. Such concepts are widely known in the academic literature, but further improvements are still required in the industry.

The industrial decision-making is often carried out manually. Therefore, there is an urgent need to address the main difficulties, complexities, and issues on replacing simulation by optimisation from an industrial perspective. This work aims to stimulate the discussion on such meaningful topics from an industrial perspective and to provide guidance for incorporating academic knowledge by the industry, exposing the industrial requirements still unaddressed or that need further development or improvements, and assisting industrial peers on how to properly achieve such breakthroughs.

Abstract

Two-stage stochastic scheduling problems (TSSP) are computationally demanding and challenging to solve in a monolithic fashion, as they often involve numerous discrete and continuous variables. One option is to apply decomposition methods (e.g. Benders, Progressive Hedging, etc.) with the idea of splitting the original problem into smaller ones that progressively approach the solution of the monolithic formulation. Here, we propose an alternative decomposition method based on the so-called Similarity Index (*SI*). The *SI* measures the similarity of schedules along a discretized time horizon. The non-anticipativity constraints of the TSSP are removed from the model and an *SI* is incorporated instead in the objective function to be maximized. Then, the original problem can be divided into subproblems on a scenario basis. An iterative procedure is set up so that the subproblems solutions progressively increase the global *SI*. The algorithm stops when the *SI* has reached a value of 1, i.e, the first-stage decisions are identical for all subproblems. The *SI* decomposition was successfully applied to an industrial-like TSSP of an evaporation network, using different MILP solvers: CPLEX and Gurobi. Two instances of different size and scenarios were considered. For the small one, significant improvements over the monolithic approach were not observed. However, for the large instance, our decomposition method was considerably faster.

Keywords: Online Scheduling, Decomposition Methods, Uncertainty, MILP

1. Introduction

Two-stage stochastic formulations are a popular way to take uncertainty into account in scheduling formulations. In two-stage scheduling problems (TSSP), the decision variables are split into two categories: here and now decisions (first-stage variables) which have to be taken now with the available information and cannot be changed later; and wait and see decisions (recourse variables) which are adjusted according to the realization of the uncertain parameters. This results in large-scale problems that involve both continuous and discrete variables which are computationally demanding to solve. Hence, uncertainty is often ignored in online or closed-loop scheduling, as such applications require providing solutions in real-time. One possibility to overcome this obstacle is to use decomposition methods. Unfortunately, not many ideas have arisen different to the classic approaches: the Benders Decomposition (Benders, 1962) and the Progressive Hedging (PH) algorithm (Rockafellar and Wets, 1991).

The Benders method, and its variations, is widely employed but has a high computational burden too, as each iteration generates either an optimality or a feasibility cut to reduce the feasible region of the master problem (Rahmaniani et al., 2017). The PH algorithm decomposes over scenarios by computing suitably penalties with average values of the decision variables in each iteration (Peng et al., 2019). However, the discrete nature of some first-stage decisions may provoke that the solutions obtained by the independent scenarios lead to opposite values in each iteration, so convergence of PH to a feasible solution is not guaranteed.

Here we propose a novel decomposition method based on the idea of measuring how *similar* the first-stage decisions are among the different scenarios. Such single measure is provided by the so-called similarity index. All subproblems are solved simultaneously in an iterative way, updating a weight for maximizing the similarity index. The proposal is tested in an industrial-like case study.

The concept of similarity index and the algorithm of the decomposition method are described in Section 2. Section 3 presents the case study that is used for testing our proposal. The results are presented in Section 4. Lastly, the paper closes with Section 5 where the conclusions are presented.

2. Similarity Index

The Similarity Index (SI) in a TSSP, first proposed by Palacín et al. (2018), is an aggregated measure of how similar the recourse variables are among the scenarios, i.e., an indication of the solution robustness. It is calculated by fuzzifying the discrete decisions over a specified time horizon, so that a decision taken at instant t is weighted by 1 (100%), but it also influences the nearby time instants t_n with a decreasing value that is proportional to the time difference $|t - t_n|$. See Figure 1 for a graphical representation. The SI is then computed as the total intersection area among the scenarios schedules, normalized by the maximum possible area (where all the solutions would coincide). Consequently, an SI equal to 1 means that the schedules for all the scenarios are identical.

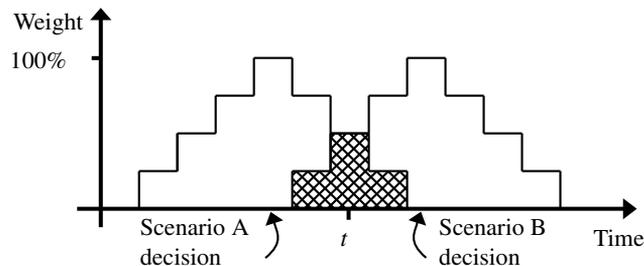

Figure 1: Example of fuzzifying the same discrete decision along seven time periods in two scenarios. The SI is computed from the intersection between both scenarios A and B and the total fuzzified area.

There is no reason to restrict the SI to the recourse variables. In a TSSP, by definition, the non-anticipation criterion enforces the first-stage variables to be identical. Therefore, if the SI were applied to them, it would necessarily take the value of 1. However, if the non-anticipativity constraints are removed from the formulation, the global model would be block-separable on a scenario basis, i.e., each scenario could be solved as an independent scheduling problem. Those solutions would not coincide in the first-stage and the SI would be lower than 1. However, an iterative procedure could be set up so that the subproblems (scenarios) are solved iteratively while pushing the SI up to the point where the solutions coincide in the first stage.

From now on, just fuzzification along the two neighboring time periods is considered to enhance the understanding of the decomposition method. The formula for computing the similarity index

for first-stage variables in this case is shown in (1).

$$SI := \sum_{t=1}^{t_R} \frac{\min_{e \in \mathcal{E}} \{y_{te} + 0.5y_{(t-1)e}|_{t>1} + 0.5y_{(t+1)e}|_{t<t_R}\}}{2t_R - 1} \quad (1)$$

Where t_R is the end of the robust horizon, \mathcal{E} is the set of uncertainty realization scenarios, and $y_{te} \in \{0, 1\}$ are the binary variables of the scheduling problem. Decision variables outside the robust horizon do not contribute towards the SI calculation.

Note that the $\min\{\cdot\}$ operation is nonlinear, so (1) cannot be used in linear scheduling formulations. Nonetheless, a lower bound for the SI can be computed using slack variables s_t and inequalities as in (2) and (3). The slack variables need to be maximized in the objective function of the optimization problem so that the lower bound on the SI is tight. Consequently, the right-hand side of (2) is incorporated in the objective function.

$$SI \geq \sum_{t=1}^{t_R} \frac{s_t}{2t_R - 1} \quad (2)$$

$$s_t \leq y_{te} + 0.5y_{(t-1)e}|_{t>1} + 0.5y_{(t+1)e}|_{t<t_R} \quad \forall e \in \mathcal{E}; t : 1, \dots, t_R \quad (3)$$

2.1. Decomposition Algorithm

Two similarity indexes need to be computed. The *Local Similarity Index* (SI_e) is computed as part of the optimization subproblems. The SI_e are maximized individually in each subproblem so that the similarity of the local solution with respect to the other scenarios is as high as possible. Hence, the computation of the local SI_e requires information from the other scenarios. For the subproblems to be separable, a previous solution from the other subproblems needs to be used. Such *reference* solution is the one corresponding to the scenario that yielded the worst local SI_e in the previous iteration. Using all the scenarios solutions can lead to competitive behavior among subproblems, so the global problem may get stuck in an infeasible solution and convergence is never reached. A *Global Similarity Index* (SI) is computed using the solutions collected from the subproblems. It is used to update a parameter that progressively increases the importance of maximizing the local SI_e . The subproblems read as in (4).

$$\begin{aligned} & \underset{y_{te}, s_t}{\text{minimize}} && J_e - \lambda \sum_{t=1}^{t_R} \frac{s_t}{2t_R - 1} \\ & \text{subject to} && \text{Local model constraints} \\ & && s_t \leq \bar{y}_t + 0.5\bar{y}_{t-1}|_{t>1} + 0.5\bar{y}_{t+1}|_{t<t_R} \quad t : 1, \dots, t_R \\ & && s_t \leq y_{te} + 0.5y_{(t-1)e}|_{t>1} + 0.5y_{(t+1)e}|_{t<t_R} \quad t : 1, \dots, t_R \end{aligned} \quad (4)$$

Where J_e is the original objective function and λ is a Lagrange-like multiplier that is updated in each iteration using a formula inspired by the sub-gradient method (Shor, 1985) as in (5). The variables \bar{y}_t contain the solution of the scenario that yielded the worst SI_e in the previous iteration.

$$\lambda_{k+1} = \lambda_k - \alpha_{k+1} (SI - 1) \quad (5)$$

In (5), α is the step size, decreased in each iteration. For instance, $\alpha_{k+1} = 0.9\alpha_k$.

The proposed algorithm starts by initializing the multiplier parameter λ and the discrete decision variables in the previous iteration \bar{y}_t to zero, which implies that the local SI_e is set to zero in the first iteration. The next steps of the algorithm comprise the calculations that are repeated until the stop criteria are met. The subproblems are solved in parallel and both their solutions and their local SI_e are collected. The global SI is calculated using (1). The solution of the scenario that yielded

the worst local SI_e is assigned to the variables \bar{y}_t that will be used in the subsequent iteration to re-compute the local SI_e . The multiplier parameter λ is updated using (5) and the termination criteria is checked. If neither the global SI has reached 1 nor the maximum iterations have been reached, the process is repeated. The solution of the subproblems y_{te}^* is reported after the algorithm has converged. Algorithm 1 summarizes these steps.

Algorithm 1 Similarity Index Decomposition

Require: $\alpha_0, \text{tol}, k_{\max}$

- 1: $k \leftarrow 0, \lambda_0 \leftarrow 0, \bar{y}_t \leftarrow 0$ ▷ Initialization
- 2: **repeat**
- 3: **for** e in \mathcal{E} **do**
- 4: $y_{te}^*, s_t^* \leftarrow \arg \min_{y_{te}, s_t} J_e - \lambda_k SI_e$ ▷ Solve (4)
- 5: $SI_e^* \leftarrow SI_e(s_t^*)$
- 6: **end for**
- 7: $SI \leftarrow \text{Eq. (1) with } y_{te}^*$ ▷ Global SI computation

3. Case study

The similarity index decomposition was tested in an industrial-like case study of an evaporation network. Each evaporation plant is made up of two evaporation chambers with several heat exchangers in between. The objective is to concentrate an inlet stream of a certain product so that it is recycled to the main process of the factory. The plants need to be cleaned regularly as fouling increases steam consumption and production costs. The scheduler must assign products and loads to plants and decide when to stop the plants for cleaning.

The allowed transitions between stages are clearly defined: A plant that is under operation can go to standby or remain in operation. A plant in standby can go to a cleaning stage or remain on standby. A plant that is in a cleaning stage can go directly to operation or go to standby. And finally, a clean plant on standby can remain in such a state or start operating. Additionally, the model shall account for: a plant can only process a product at a time; only one cleaning stage can occur per day; if a product has been assigned to a plant, it cannot be changed unless the plant is cleaned; a terminal cost is established for plants that end up in an advanced fouling state at the end of the scheduling horizon, etc.

Palacín et al. (2018) formulated a two-stage scheduling problem for this case study using the pre-defined precedence approach. Here, we recall their example and apply our decomposition method to two different instances of the problem. The model equations are not displayed for brevity. Using the notation in such paper, Equation (1) for computing the global SI becomes:

$$SI = \sum_{v \in \mathcal{V}} \sum_{s \in \mathcal{S}} \sum_{t \in \mathcal{M}_R} \frac{\min_{e \in \mathcal{E}} \{E_{vtse} + 0.5E_{v(t-1)se} |_{t>1} + 0.5E_{v(t-1)se} |_{t < t_R}\}}{n_v (2t_R - 1)} \quad (6)$$

Where \mathcal{V} is the set of evaporation plants, \mathcal{S} is the set of possible stages, \mathcal{M} is the set of days in the discretized scheduling horizon, \mathcal{P} is the set of products, and \mathcal{E} is the set of uncertainty realization scenarios. The binary variables E_{vtse} specify if a plant v at day t is at stage s in the scenario e . The total number of evaporation plants is denoted by n_v .

The local similarity index is computed using (2) and (3), updated to the case study notation as shown in (7) and (8) respectively.

$$SI_e = \sum_{v \in \mathcal{V}} \sum_{s \in \mathcal{S}} \sum_{t \in \mathcal{M}_R} \frac{s_{vts}}{n_v(2t_R - 1)} \tag{7}$$

$$\begin{aligned} s_{vts} &\leq \bar{E}_{vts} + 0.5\bar{E}_{v(t-1)s|t>1} + 0.5\bar{E}_{v(t+1)s|t<t_R} \\ s_{vts} &\leq E_{vts} + 0.5E_{v(t-1)se|t>1} + 0.5E_{v(t+1)se|t<t_R} \quad \forall v \in \mathcal{V}, s \in \mathcal{S}, t \in \mathcal{M}_R \end{aligned} \tag{8}$$

Where \bar{E}_{vts} are the binary variables of the subproblem that yielded the worst SI in the previous iteration. Consequently, \bar{E}_{vts} are not decision variables of the optimization problems. Each subproblem is then formulated using the model equations in Palacín et al. (2018), except for the non-anticipativity constraints, plus inequalities (8).

4. Results

Two problem instances of the case study were analyzed, denoted by A and B. In instance A, the scheduling problem was solved for three plants, two products, and four scenarios for the products demands. The resulting problem had 18000 variables, 17280 of which were binary. The subproblems had 4320 binary variables each. Instance B consisted of a larger problem with nine plants, three products, and sixteen scenarios for the products demands. The resulting model had 196000 variables, 90% of which were binary. The sub-problems had 11025 binary variables each.

Both instances were solved in GAMS 36.2.0 using IBM ILOG CPLEX 20.1 and Gurobi 9.1. The maximum execution time was set to one hour and the relative gap tolerance to zero. The default values were used for the rest of the solvers options. The monolithic problems of both instances were solved using concurrent optimization on 32 CPU threads. The subproblems of the decomposed approach were solved using 8 threads in instance A, and 2 in instance B.

The execution time and the final relative gap for each solver are reported in Tables 1 and 2 for instances A and B respectively.

Table 1: Instance A: Three plants, two products and four scenarios.

Approach	CPLEX		Gurobi	
	Gap	Time	Gap	Time
Monolithic	0.00%	30.84s	0.00%	7.46s
Decomposed	0.00%	26.88s	0.00%	20.91s

For instance A, both solvers could reach the optimal solution in less than a minute with the monolithic approach. Our decomposition method outperformed the monolithic approach only when using CPLEX. Using Gurobi, it was around three times slower. However, this problem instance is relatively small and the advantages of using the decomposition method are only fully realized in large settings as instance B. The algorithm converged in five iterations.

Table 2: Instance B: Nine plants, three products and 16 scenarios.

Approach	CPLEX		Gurobi	
	Gap	Time	Gap	Time
Monolithic	0.76%	3600s*	0.00%	2590.12s
Decomposed	0.00%	40.58s	0.00%	42.89s

For instance B and using CPLEX, the monolithic approach only managed to get a 0.76% gap solution within the specified time limit. The decomposed approach greatly outperformed it by arriving to the optimal solution in only 40.58 sec. Furthermore, when the time limit was increased to one day, CPLEX could only get a 0.44% gap solution. It is clear that the solver struggles to improve the optimality gap after finding a feasible solution. Unlike CPLEX, Gurobi managed to get an optimal solution within the time limit with the monolithic approach, specifically 2590.12 seconds. However, our decomposition algorithm was around sixty times faster, arriving to the optimum in just 42.89 seconds. The decomposed approach only needed two iterations to converge.

5. Conclusions

This work proposed a novel decomposition method that uses a single indicator to measure the similarity between discrete-time schedules. The non-anticipativity constraints are removed from the formulation, which enables a scenario-based decomposition. Each scenario is solved as an independent problem that includes the maximization of the similarity among the other scenarios. An iterative procedure is repeated until the first-stage variables of all the subproblems coincide. This setting enables parallelization beyond the native capabilities of the optimization solvers.

Note that the algorithm only has two tuning parameters: the step-size decrease rate α and the length of the time horizon along the discrete decisions are fuzzified for computing the similarity index. The proposed method was tested in two problem instances of different sizes. In the smaller one, significant improvements were not observed when using the decomposition approach. However, in the larger instance, the computation time required for achieving optimal solutions was significantly reduced with the decomposition method. When using CPLEX, the monolithic approach could not arrive to an optimal solution in one hour. In contrast, our decomposition method managed to arrive to an optimal solution in less than a minute. When using Gurobi, the optimal solution was obtained around sixty times faster. In conclusion, the potential of our proposal is fully realized as the number of scenarios increases.

The convergence properties of the similarity index decomposition have not been studied yet and future work will focus on it. We also aim to extend the method to non-linear mixed-integer (MINLP) scheduling problems and continuous-time scheduling formulations.

Abstract

Scheduling of crude oil operations is one of the most critical and challenging problems in petroleum refineries. Crude oil operations have more impact on the profitability of the whole refinery as these operations are the first steps of refinery operations. Crude oil operations scheduling is a complex problem as many complicated relationships and many conditions must be considered. In a refinery, a planner tries to schedule all crude oil operations by using a wide variety of complex and very dense data sets. Daily planning is mainly based on manual scheduling by trial and error method and operational experiences. Therefore, as a planner, it is almost impossible to reach the optimal solution or even a satisfactory feasible solution by handling all the data sets in a short period. Unfortunately, there is no efficient and adaptive tool or software that can be used for different refinery scheduling cases. In this study, an efficient scheduling and allocation model for an oil refinery located in İzmir is developed for unloading crudes into multiple storage tanks from the vessels arriving at various times, blending crudes, and feeding the crude distillation units from these tanks at various rates over time. To tackle the scheduling problem effectively, a Mixed Integer Linear Program (MILP) is formulated. The model is solved for the refinery, and satisfactory solutions are gathered.

Keywords: crude oil operations, short-term scheduling, MILP, optimization.

1. Introduction

Scheduling of crude oil operations is one of the most critical and challenging problems in oil refineries. Crude oil operations have a high impact on the continuity and profitability of the refinery, as it is the first step of the all refinery operation process. Besides, crude oil operations scheduling is very complex due to continuous, discrete, and binary variable optimization, and it is known as NP-hard (Li-ping & Nai-qi, 2011).

Scheduling tool provides some utilities such as (1) crude storage optimization, (2) the best evaluation of the monthly plan implementation, (3) guiding the operations, (4) optimal sustainable operations even with unexpected changes, and (5) comparison actual operating results with planning objectives. It also enables to use of superior capacity, increases plant efficiency and improves visibility and control throughout the supply chain. Therefore, the necessity of computer aided methods to optimize refinery operations should be considered in quick response to problems and opportunities and making a decision (Reddy et al., 2004a). The optimization of production plans is a hot topic for both industry and academia due to its advantages.

Several mathematical methods such as linear programming (LP), mixed-integer linear programming (MILP), and mixed-integer nonlinear programming (MINLP) are used to solve scheduling problems. Also, numerous modeling approaches were suggested to handle various scheduling problems related to different production environments, process constraints, and features. Especially, time representation is one of the most important features of modeling approaches taken in models, as it determines many aspects consisting of modeling flexibility, size, and constraints types (Lee et al., 2019). All present formulations of timing can be categorized into two main types, namely discrete and continuous-time formulations. The first attempts in scheduling problems are based on the discrete-time approach in which the time horizon is split into a count of time slots of uniform durations and events (Shah, 1996; Reddy et al., 2004b and Saharidis et al., 2009). Unlike the discrete-time approach, the time slots are not uniform in the continuous-time approach so that events can start and end at any point in the continuous-time domain (Yadav et al., 2012; Chen et al., 2012 and Karuppiyah et al., 2008).

In this paper, a new MILP model is formulated for the refinery scheduling problem involving crude oil unloading from vessels, transferring crude between tanks, and charging the crude distillation units (CDUs). The long-term scheduling problem of an oil refinery located in İzmir is addressed to find the optimum schedule. Compared to other refinery structures in the literature, the tanks are not categorized as charging and storage tanks in this refinery. The tanks here are used for both charging and storage. Also, around 50 types of crude oil can mix in the tanks. Several specific operational features make refinery management as a complex problem. There is no effective computer tool or study in the literature for such a complex oil refinery to our best knowledge. The motivation in the study is that the model formulation reflects real characteristics of the refinery structure and operations, so it is valuable for the theory to take shape in an industrial applications. The discrete-time model is preferred in this study as it allows handling the constraints more easily than continuous models.

2. Materials and Methods

In this section, the process to be analyzed is described, and then the MILP formulation to optimize the process is presented.

2.1. Process Description

In this paper, the scheduling of crude oil operations is conducted for an oil refinery located in İzmir, Turkey. Since, the planning department makes decisions for very complex crude oil operations manually, it is impossible to reach the optimal solution or even a feasible solution by handling all the data sets in a short period. Thus, it is crucial to develop an optimization tool for an effective management of crude oil operations.

Crude oil operations of the refinery are difficult to determine manually with the ever-increasing constraints. Operations in the İzmir Refinery consist of 1 docking station, 12 crude oil tanks, and 2 CDUs. An overview of crude oil operations is shown in Figure 1. Various crude oil types are shipped to the refinery and processed according to their yield. There are about 50 different types of crude oil that have been received and processed by the refinery up to now, and more different types of crude oil may also be shipped. It is very hard to process varying types of crude oil because of immiscibility and precipitation problems. Since it is hard to manage to have one storage tank for each 50 or many crude oil types; crude oil storage, blending and charging operations are handled in the same tank. Also, blending may occur in the pipelines if multiple tanks are opened. Besides, some of the crude oil types have unique properties and must be stored in particular tanks.

Therefore, tanks are labeled as national and non-national, and also with a pump and without a pump. Domestic crude oils should be stored at specific tanks because of government regulations. Also, specific types of crude oils are stored in tanks that have pumping infrastructure installed to feed continuously for economic reasons. However, this brings out other constraints related to pumps. Furthermore, operations on tanks are complex because of the piping system and measuring tank content. As unloading from vessels to tanks and transfers between tanks are using the same piping system, these operations cannot be done simultaneously. Also, only unloading or charging operations for one tank are allowed to measure tank content correctly. Operability to complex tank processes is the main concern in the refinery, and thus, there are too many constraints related to tank operations. Having too many crude oil types causes operational burdens in CDUs. Each crude oil has widely varying properties, processability and product yields, so they have minimum and maximum rates to be processed in each CDUs. Most of these constraints are unique to the İzmir Refinery, and there is limited information in the literature.

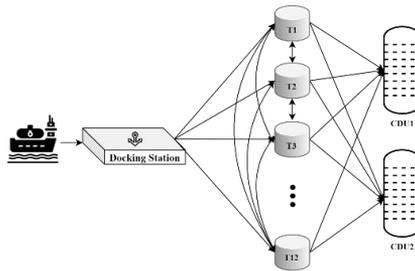

Figure 1. An overview of crude oil operations

2.2. Proposed MILP

In this section, the proposed MILP model is presented that corresponds to the scheduling problem described above. The model uses a discrete-time formulation that includes 24-hour intervals over a scheduling horizon of 60 days. The following assumptions for the model are considered: (1) Perfect mixing occurs at each tank. (2) Remaining crude oil in the pipeline during the unloading is neglected. (3) Resting times in tanks are ignored.

The modeled system has $t \in T$ days, $i \in I$ crude oil tanks, $j \in J$ CDUs, $h \in H$ crude oil types, and there are four operations $o \in O$ which are unloading, transfer-sending, transfer-receiving, and charging. Crude oils have $p \in P$ set of distinguishing properties such as American Petroleum Institute (API) gravity and sulfur. Tanks, pumps, and CDUs have $m \in M$ set of minimum and maximum limits in terms of these features and volume limits. Lastly, $k \in K$ vessels arrive at the system over the planning horizon.

The parameters of the model are set as follows: the initial volumes of tanks, $VI_{h,i}$ (m^3); API-sulphur contents and blending properties of crude oil types, $PR_{h,p}$ and $TB_{h,hh}$, respectively; minimum and maximum capacity of tanks, LC_i and UC_i ; whether the tank has a pumping system, E_i ; unloading limits to each tank, UL_i ; tolerance limit to obtain whether a crude oil type is going to be considered for blending, To_i ; maximum transfer capacity between tanks, $FL_{i,ii}$. Vessels have three descriptive parameters which are arriving times $KT_{k,t}$, volume and crude oil type of each vessel, KV_k , and $KH_{k,h}$ respectively. Also, the parameters for the CDU characteristics are total processing volume, $TD_{i,j}$; maximum charging capacity from each tank to each CDU, $DL_{i,j}$; min-max limits of processing each crude oil in each CDU, $MR_{i,h,j,m}$; API and Sulphur content limits of each CDU, LA_j , UA_j and US_j , respectively. Finally, $card^I$ shows the count of the total number of elements within the set I .

While scheduling, unloading, transfer, and charging amounts and the volume of tanks in terms of crude oil types for each time period are determined, so the variables for them are defined as $u_{t,i,k}$, $tr_{t,ii,h}$, $c_{t,i,j,h}$, and $v_{i,t,h}$ respectively. The API ($a_{i,j}$) and Sulphur ($s_{i,j}$) values of CDUs are needed to be known for each CDU. To ensure operating conditions, some binary variables are defined. Let $ub_{t,k}$ and $cb_{t,i,j}$, show whether there is any unloading and charging operations, respectively. $tk_{i,t,o}$ shows whether a tank is assigned to an operation. Lastly, $y_{i,i,h}$ represents whether the crude oil types exist in the tanks.

The planning process is required to be managed with minimum transfer operation as it restricts the other crucial operations. Thus, the objective function is the minimization of total transfer operations, Eq. (1). The first set of constraints include material balance, pump, and operational limitations. Material balances are given in Eq. (2). Eq (3) states that the volume $v_{i,t,h}$ must be within the capacity limits of tanks. Eqs. (4-6) ensures that the amount of flow in unloading, transfer, and charging (if there is any) operations should not exceed the pump limits. There are 2 CDUs, so there can be two charging operations for each tank per time period, Eq. (7). The operational limits in charging for pumping tanks are given Eqs. (8a-8c). Only one transfer or unloading operation is allowed at the same time due to the line structure of the system, given in Eqs. (9a-10). There cannot be simultaneous inflow and outflow to the tank. However, there can be two outflows, Eq. (11). As a result of this condition, simultaneous unloading and transfer operations are not allowed for a tank, Eq. (12).

$$\min Z = \sum_t \sum_i \sum_{ii} \sum_h (tr_{t,ii,h}) \quad (1)$$

$$v_{i,t,h} = v_{i,t-1,h} + \sum_k (u_{t,i,k} * KH_{k,h}) + \sum_{ii} (tr_{t,ii,i,h}) - \sum_{ii} (tr_{t,ii,i,h}) - \sum_j (c_{t,i,j,h}) \forall i, h, t \quad (2)$$

$$LC_i \leq \sum_h (v_{i,t,h}) \leq UC_i \forall i, t \quad (3)$$

$$\sum_k (u_{t,i,k}) \leq tk_{i,t,1} * UL_i \forall i, t \quad (4)$$

$$\sum_{ii} \sum_h (tr_{t,ii,i,h}) \leq tk_{i,t,2} * FL_{i,ii} \forall i, t \quad (5a,5b) \quad \sum_{ii} \sum_h (tr_{t,ii,i,h}) \leq tk_{i,t,3} * FL_{i,ii} \forall i, t$$

$$\sum_h (c_{t,i,j,h}) \leq cb_{t,i,j} * DL_{i,j} \forall t, i, j \quad (6)$$

$$\sum_j (cb_{t,i,j}) \leq tk_{i,t,4} * 2 \forall i, t \quad (7)$$

$$\sum_i (cb_{t,i,j} * E_i) \leq 2 \forall t, j \quad \sum_i \sum_j (cb_{t,i,j} * E_i) \leq 3 \forall t \quad \sum_i \sum_j (cb_{t,i,j} * (1 - E_i)) \leq 2 \forall t \quad (8a,8b,8c)$$

$$\sum_i (tk_{i,t,2}) \leq 1 \forall t \quad \sum_i (tk_{i,t,3}) \leq 1 \forall t \quad (9a,9b)$$

$$\sum_k (ub_{t,k}) \leq 1 \forall t \quad (10)$$

$$tk_{i,t,1} + (0.5 * tk_{i,t,2}) + tk_{i,t,3} + (0.5 * tk_{i,t,4}) \leq 1 \forall t, i \quad (11)$$

$$card^i * (1 - \sum_k (ub_{t,k})) \geq \sum_i (tk_{i,t,2}) \forall t \quad (12)$$

Constraints related to unloading operations are as follows: Eq. (13) ensures that all the volume of that vessel should be unloaded. However, the whole volume of vessel may not be unloaded in just one time period. Thus, the sum of volume unloaded from one vessel in each time period must be equal to the total volume of that vessel, Eq. (14). Vessels should be unloaded sequentially, Eq. (15).

$$\sum_t \sum_i (u_{t,i,k}) = KV_k \forall k \quad (13)$$

$$ub_{t,k} * KV_k \geq \sum_i (u_{t,i,k}) \forall t, k \tag{14}$$

$$ub_{t,k} + ub_{t,t,k-1} \leq 1 \forall k, t < tt \tag{15}$$

The total charging amount may change on daily basis. Eq. (16) states that the total charging amount must be equal to the input value. Same conditions are also applied to the ratio of crude oil types that are going to be charged into CDUs, Eq. (17).

$$\sum_i \sum_h (c_{t,i,j,h}) = TD_{t,j} * 24 \forall t, j \mid TD(t, j) \neq 0 \tag{16}$$

$$\sum_i (c_{t,i,j,h}) \leq TD_{t,j} * 24 * 0.01 * MR_{t,h,j,max} \forall t, h, j \mid MR_{t,h,j,max} \neq 0 \wedge MR_{t,h,j,max} \neq 100 \tag{17}$$

The calculation of API and Sulphur values belonging to the CDUs are stated in Eqs. (18-19). The API and Sulphur contents must then be within given bounds, Eqs. (20-21)

$$a_{t,j} = \left(\sum_i \sum_h (PR_{h,API} * c_{t,i,j,h}) \right) / (TD_{t,j} * 24) \forall t, j \tag{18}$$

$$s_{t,j} = \left(\sum_i \sum_h (PR_{h,SULPHUR} * c_{t,i,j,h}) \right) / (TD_{t,j} * 24) \forall t, j \tag{19}$$

$$LA_j \leq a_{t,j} \leq UA_j \forall t, j \tag{20}$$

$$s_{t,j} \leq US_j \forall t, j \tag{21}$$

Finally, blending constraint is handled in Eq. (22). Eq. (23) states that if the volume of *h* crude oil type is above the tolerance limit, then the binary variable takes the value 1 as it should be considered in the blending constraint.

$$y_{t,i,h} + y_{t,i,h,h} \leq 1 \forall i, t \geq 2, h > hh \mid TB_{h,h,h} = 0 \tag{22}$$

$$v_{i,t,h} - TO_i \leq y_{t,i,h} * UC_i \forall t, i, h \tag{23}$$

3. Results and Discussions

In line with the needs of the planning department, the time horizon is chosen as 60 days. The time interval of 24 hours is used. The selected industrial case study contains 20 vessels shipped 9 different types of crude oil, 2 CDUs, 12 tanks (2 tanks are in maintenance), including 13 crude oil types. The volume of vessels varies between 40,000 and 175,000 m³ and total volume of 20 vessels is about 1.9 million m³. The final model includes 93,398 variables, of which are 10,524 binary, and 28,829 constraints. The scheduling problem is solved by CPLEX in GAMS 28.2.0 using an Intel Xeon Gold 6252 CPU @2.10 GHz with 12.0 GB of RAM. The optimum solution is obtained within 1191.09 seconds of CPU time. The MILP model results are shown in Figure 2 for the first 10 days of the planning period.

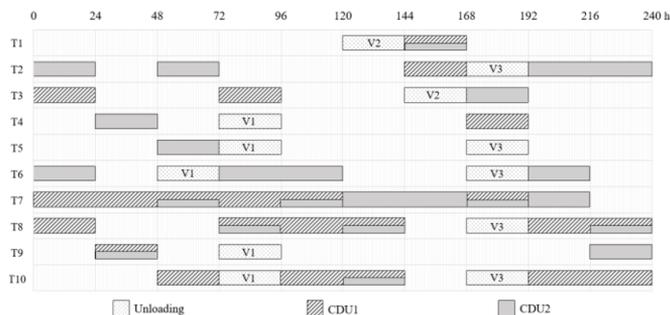

Figure 2. Gantt chart of optimal solution for first 10 days -of planning period

The results of MILP is compared with the planning department's schedule in Table 1. According to the results, there are no transfer operations in MILP results, because the objective function of the MILP is the minimization of total transfer operations. It is also observed that the computation time of the MILP model is shorter than the working hours of the experienced planner and selected tanks, charge compositions based on actual results are compatible with the MILP model results. On the other hand, more tanks are used to unload each vessel's operations, and the total number of switching tanks for charging to CDU is more in MILP result than the planning department's schedule. Therefore, we may conclude that the results of MILP are promising and satisfactory for the given case. However, there is still room for improvement.

Table 1. Comparison of MILP and planning department's schedule

	MILP Model	Planning Department
Computation time	1191.09 sec. (0.33 h)	7200 sec. (2 h)
Total number of transfer operations / Duration	0	3 / 20 h
Penalty time of vessels	24 h for 3 rd vessel (V3)	-
Total duration of unloading operations	120 h	58 h
Total number of used tanks for unloading operations	12	7
Total number of switching tanks for charging to CDU	54	26

4. Conclusions

The industrial applications of optimization-based scheduling methods are highly challenging tasks. The proposed discrete MILP model supports optimal decision making in operational planning processes of the refinery and reflects real-life scheduling problems. The model is promising in terms of support in decision making of production planning. As a further research, a multiple objective programming can be developed for taking account the other criteria given in Table 1. Furthermore, continuous-time modeling can be considered as a better optional technique to identify the planning conditions, and the model can be extended to the other refinery cases.

Abstract

Colombia is formulating policies to accelerate the energy transition, decarbonize its industries and decrease its dependency on fossil fuels. In this work we present a novel optimization framework for the carbon capture, utilization, and storage (CCUS) design applied to the Colombian case. The model maximizes the net present value considering technologies for carbon capture, multimodal transportation, CO₂ utilization for enhanced oil recovery (CO₂-EOR) and geological storage to meet a given target on greenhouse gases (GHG). The novelty of this work is the integration of the CCUS design with the oil field development for CO₂-EOR. Thus, the optimal petroleum production campaign (i.e., production wells for CO₂ injection) is computed based on the oil production profiles, petrophysical properties and economic data. Moreover, this approach provides insights regarding investments on carbon capture technologies such as timing, sizing, location, and type of technology. The model also determines the optimal transportation mode considering on-shore (pipelines, railcars, and trucks) and off-shore (pipelines and ships). We tested our approach on a nationwide long-term planning horizon (20 years), considering 30 CO₂ emissions sources distributed across 12 regions in the country, 16 carbon capture technologies, 3 different plant sizes (small, medium, and large), 6 potential oil fields for CO₂-EOR, 2 sinks for geological storage, and 4 multimodal transportation modes. Results shown a carbon capture cost of 99.8 USD/t, with a cost breakdown of 45%, 30% and 25% allocated into the carbon capture processes, CO₂ transportation and CO₂-EOR utilization, respectively.

Keywords: supply chain design, carbon capture, utilization, and storage, CCUS, enhanced oil recovery, CO₂-EOR

1. Introduction

Global CO₂ emissions declined to 31.5 Gt CO₂ in 2020 in comparison to 33.4 Gt CO₂ in 2019, this partial recovery is entirely related to restrictions on transport activity in 2021 due to the Covid-19 pandemic. However, the emissions projected future growth to 33 Gt CO₂ in 2021 (IEA, 2021). Even with an increase in CO₂ emissions from oil of over 650 Mt CO₂ in 2021, these should remain 500 Mt CO₂ below 2019 levels. This reduction in emissions is achieved due to the global concern in mitigating fossil fuels use and the strategies of CCUS. In Colombia, the target is to reduce greenhouse gas emissions by 50% in 2030 and is much more closely aligned with the country's objective of achieving carbon neutrality by 2050 (UPME, 2019). To achieve these goals, is necessary to consider key aspects like increase the use of new renewable energy sources, efficient use of energy, and analysis of CCUS supply chain.

Herein, we present an optimization framework for the CCUS supply chain design. Our approach can be distinguished from previous studies in the following aspects: firstly, a complete CO₂-EOR model that involves evaluating the real considerations in the field such as petrophysical properties, dynamic oil and CO₂ production profiles and some operative's conditions are integrated into the CCUS model. Secondly, a transport patterns considered by Zhang et al., (2020) with free movements between sources and reservoirs are incorporated. And thirdly, surrogate models to evaluate the capital expenditure (CAPEX) and operational expenses (OPEX) proposed by Hasan et al., (2015) are incorporated into the CCUS model.

2. Model formulation

The main components of a CCUS supply chain include: i) stationary CO₂ sources, ii) carbon capture facilities, iii) transport network and, iv) geological storage and CO₂-EOR as utilization. The proposed mathematical model is based on the multiperiod model for CCUS published by Han et al., (2012). In this model, a superstructure composed of regions (g) enclosing different types and sizes of capture, sequestration and utilization facilities is formulated as a large-scale mixed-integer linear programming (MILP). The CO₂ captured from an emission source in a region g , according to an established target, can be sent to sequestration or utilization facilities within the same region g or to another region g' depending on its capacity and availability. Regions are connected to each other by different potential transportation modes (pipeline, truck, railcar, and ship) and different types and sizes of intermediate storage are also considered in the regions to adequately supply the non-pipeline transportation modes.

Han et al., (2012) considered utilization facilities to produce biobutanol and green polymers in South Korea. For the Colombian case, we have assumed EOR-CO₂ as the potentially most important use of CO₂. The EOR-CO₂ has been modeled considering the typical petrophysical properties of oil reservoirs and the dynamic oil and CO₂ production profiles. The oil and CO₂ production rates depend on the CO₂ injection rate, where the CO₂ injection and production rates are normalized by hydrocarbon pore volume ($HCPV_m$, [m³]) of each reservoir m . According to Eq. 1, $HCPV_m$ is a function of reservoir properties as area (A_m , [m²]), net pay thickness (h_m , [m]), average porosity (ϕ_m , [-]), and the initial water saturation ($S_{wi,m}$, [-]).

$$HCPV_m = A_m h_m \phi_m (1 - S_{wi,m}) \quad \forall m \quad (1)$$

The oil production is normalized by the original oil in place ($OOIP_m$, [m³]) which is defined following the Eq. 2.

$$OOIP_m = \frac{HCPV_m}{\beta_{oi,m}} \quad \forall m \quad (2)$$

Where $\beta_{oi,m}$ represent the initial oil formation volume factor. Each reservoir is characterized by a unique $HCPV_m$, and it determines the oil and CO₂ production rates of the field. The oil and CO₂ production profiles, considering high, medium, and low oil production, are calculated using a piecewise linearization strategy of the dimensionless curve representing the incremental recovery factor for oil and the cumulative CO₂ production (both as a function of cumulative CO₂ injection as shown in Figure 1).

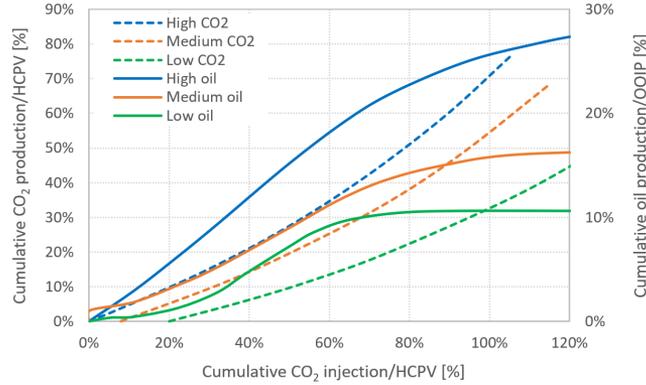

Figure 1. Cumulative production of oil (solid) and CO₂ (dash) for high, medium, and low oil recovery and CO₂ production (Adapted from Kolster et al., 2017)

The rate of CO₂ injected each period of time t per field ($CO2INJ_{m,t}$, [Mt/y]) is limited by both the maximum CO₂ injection rate per well ($qCO2_m^{max}$, [Mt/(y·well)]) and the number of injection wells available in the field ($WI_{m,t}$, [well]). According to Eqs. 3 and 4, $qCO2_m^{max}$ is assumed equal as the historical water injection rate in the field and $WI_{m,t}$ is limited to the oil fields drilling campaign ($wt_{m,t}^{max}$, [well]).

$$CO2INJ_{m,t} \leq \sum_{td \leq t} qCO2_m^{max} * WI_{m,td} \quad \forall m, t \quad (3)$$

$$\sum_{td \leq t} WI_{m,td} \leq wt_{m,t}^{max} \quad \forall m, t \quad (4)$$

The $CO2INJ_{m,t}$ is normalized with the $HCPV_m$ to calculate the cumulative CO₂ injection ($CO2INJCUMH_{m,t,h}$, [-]), as seen in Eq. 5; where ΔT is the time between two consecutive time periods.

$$\sum_h CO2INJCUMH_{m,t,h} = \Delta T * \sum_{td \leq t} \left(\frac{CO2INJ_{m,td}}{HCPV_m} \right) \quad \forall m, t \quad (5)$$

Each linear segment of the production curves h is limited by lower ($loinj_{m,h}$, [-]) and upper ($upinj_{m,h}$, [-]) limits (see Eq. 6) and each linear segment is selected introducing a binary variable ($BinH_{m,t,h}$) that can active only one of the linear segments as shown in Eq. 7.

$$loinj_{m,h} * BinH_{m,t,h} \leq CO2INJCUMH_{m,t,h} \leq upinj_{m,h} * BinH_{m,t,h} \quad \forall m, t, h \quad (6)$$

$$\sum_h BinH_{m,t,h} \leq 1 \quad \forall m, t \quad (7)$$

The cumulative oil and CO₂ produced ($CO2PRODCUM_{m,t}$, [-], and $OILPRODCUM_{m,t}$, [-], respectively) are calculated with the Eqs. 8 and 9. Where $aco2_{m,h}$ and $\beta co2_{m,h}$ represent the slope and the intercept of the linear segment h of the CO₂ breakthrough curve, respectively; $aoil_{m,s}$ and $\beta oil_{m,s}$ represent the slope and the intercept for each segment s of the oil performance curve.

$$CO2PRODCUM_{m,t} = \sum_h (\alpha_{co2,m,h} * CO2INJCUMH_{m,t,h} + \beta_{co2,m,h} * BinH_{m,t,h}) \quad \forall m, t \quad (8)$$

$$OILPRODCUM_{m,t} = \sum_s (\alpha_{oil,m,s} * CO2INJUMS_{m,t,s} + \beta_{oil,m,s} * BinS_{m,t,s}) \quad \forall m, t \quad (9)$$

Eq. 10 represents a CO₂ mass balance at the inlet of the injection well in function of the fresh CO₂ for EOR ($CO2PURC_{m,t}$, [Mt/y]), the recycled CO₂ ($CO2RECY_{m,t}$, [Mt/y]) and the injected CO₂. In our model, the fresh CO₂ rate is used to integrate the EOR-CO₂ module with the CCUS model proposed by Han et al. (2012).

$$CO2PURC_{m,t} + CO2RECY_{m,t} = CO2INJ_{m,t} \quad \forall m, t \quad (10)$$

The economic model in this framework is adapted from the one proposed by Calderón & Pekney, (2020). In our model we maximize the net present value (NPV , [MUSD]), which is function of the global CCUS supply chain profit after taxes and penalties ($CASHFLOW_t$, [MUSD]), the global capital costs of the supply chain ($CPXCCUS_t$, [MUSD]) and the interest rate (ir , [-]), as shown in Eq. 11.

$$NPV = \frac{CASHFLOW_t - CPXCCUS_t}{(1 + ir)^{t-1}} \quad (11)$$

3. Results

The mathematical model was formulated as a MILP that maximizes the net present value of the CCUS supply chain. The optimization problem was implemented in GAMS 33.2.0 and was solved using CPLEX v12.10.

Table 1. Selected capture technology for the CCUS model

Source	Capture technology	Size	Facilities No.
ET={2,...,7}		small	6
R1-H2-2	Compressor	small	1
F-4-NatCO ₂		small	1
F-5-NatCO ₂		small	1
PG-G = {1,7,8}	Abs-MEA	small	4
R1-FCC={1,2}		small	2
R1-CHP-1, R1-HDT-2	PSA-MVY*	small	5
R2-FCC-1, R2-CHP-6		small	2
R1-HDT-2		medium	1
Cem={1,3,7}	PSA-WEI*	small	5

*Zeolite-based physical adsorption of CO₂ for Pressure Swing Adsorption (PSA) technologies. MVY (Mobil composition of matter-seVentY) and WEI (Weinebeneite) are zeolites considered by Han et al., (2015).

The main considerations about the components of the CCUS supply chain analyzed in this study are the following: **(a)** the data for CO₂ sources and sinks was taken from Yáñez et al., (2020), as seen Figure 3. Comprising emissions from natural sources (F-4-NatCO₂ and F-5-NatCO₂), oil (R1 and R2, aggregated into 14 emission sources), cement (Cem-1, ..., Cem-7), power generation (PG-G-1, ..., PG-G-7), and bioethanol (ET2, ..., ET7) industries. Nodes A, B, H, K, M, and N are candidate oil fields for CO₂-EOR process, and nodes C1 and C2 are candidates for geological storage. **(b)** surrogate models for investment and operating costs developed by Hasan et al., (2015) were considered for modelling CO₂ capture technologies. **(c)** finally, three transport patterns (source-sink, source-source and sink- sink matching) with free movements between sources and sink,

as summarized by Zhang et al., (2020), were assumed for the multimodal-network transportation. The other parameters for transport and intermediate storage were taken from Han et al., (2012).

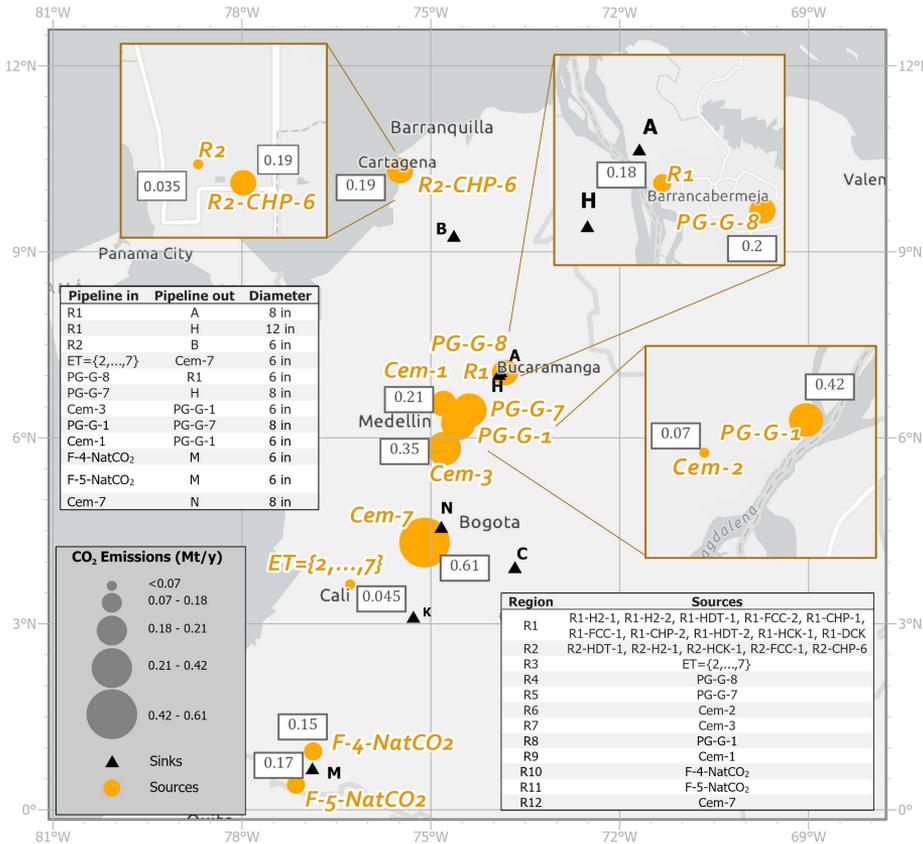

Figure 3. CO₂ sources, storage, and utilization projects in Colombia.

Absorption based on monoethanolamine (Abs-MEA) is selected for sources with a CO₂ concentration as low as 4% (PG-G-1, PG-G-7 and PG-G-8), since Abs-MEA is the only one that works in this concentration range. On the contrary, compression is selected for sources with high CO₂ concentration (ET={2,...,7}, R1-H2-2, F-4-NatCO₂ and F-5-NatCO₂). For refineries, with concentrations of 7%, the technology with the lowest investment and operational costs is PSA-MVY. Finally, when the concentration is as high as 47% as in the case of the sources: Cem-1, Cem-3 and Cem-7, the model uses the PSA-WEI capture technology, which is the one with the lowest costs for this CO₂ concentration (see Table 1). Even though the model considers 2 sinks for geological storage, the optimal solution chooses EOR as the main use for CO₂ because it represents economic benefits as opposed to the geological storage. Results of transport infrastructure are consistent, since it minimizes the costs of the network by choosing pipelines with the smallest possible diameters (6 and 8 in) to connect most of the sources with the sinks. Although it also selects 12 in pipelines to connect sources with high capture capacity, such as the R1 source. Results shown a carbon capture cost of 99.8 USD/t, with a cost breakdown of

45%, 30% and 25% allocated into the carbon capture processes, CO₂ transportation and CO₂-EOR utilization, respectively.

4. Conclusions

The motivation for this study is to present an optimization framework to support decision making for a CCUS supply chain. For this purpose, we formulated a mathematical model that considers: **(1)** the integration between EOR and CCUS in a supply chain configuration that includes petrophysical properties, dynamic oil and CO₂ production profiles and operating conditions, **(2)** transport patterns with free movements between sources and sinks, and **(3)** a surrogate model which calculates the investment and operating cost for carbon capture technologies taking into account different plant sizes and CO₂ concentrations. The model was tested with representative information from the Colombian context for the capture and use of CO₂ for EOR. The optimal solution is coherent and presents the number and size of capture technologies necessary for each source and the configuration of the transport network based on pipelines. Future research may focus on considering a more detailed model representation for designing the CO₂ pipeline transportation network.

Abstract

Decision-making capabilities and solution approaches for industrial scheduling operations are often inefficient. Both the academic literature and industry require further investigation of scheduling strategies and methodologies to achieve further breakthroughs, in which a proper selection of modelling and optimisation parameters is imperative. This work investigates the impact of time-step size and time-horizon length on multiple scheduling applications. Small time-steps provide better management of feedstocks, more efficient production, and higher profit, whereas long time-horizon can leverage spot market opportunities and achieve a more comprehensive formulation. Moreover, such parameters are especially meaningful in combination with continuous rescheduling strategies. A blend scheduling case study is employed in this work, whereby the operational scheduling and economic value of the process are investigated over distinct conditions in three examples. The interplay between rescheduling optimisation and the aforementioned scheduling parameters is highlighted. The insights drawn are useful for diverse problems and scenarios, and can significantly provide further operational and economic enhancements for industrial applications.

Keywords: Scheduling, optimisation, mathematical programming, rescheduling, industrial processes, decision-making capabilities.

1. Introduction

Computer-aided tools have been increasingly employed for scheduling operations, in which recent advances on decision-making modelling and optimisation, solving algorithms, and computer-aided resources (Franzoi et al., 2018) have provided enhanced capabilities for properly addressing and solving large-scale scheduling applications. Such mathematical representations require the pre-determination of scheduling parameters such as time-step size and time-horizon length, whose importance and impact are often neglected in the literature on the topic. This work addresses the topic of scheduling optimisation based on discrete-time formulation, whereby providing a relevant discussion on scheduling parameters used in the modelling and optimisation. These parameters are determined according to the type of problem to be solved or to the required solution in terms of accuracy or timeliness. Common choices for industrial applications are in the order of seconds or minutes (e.g., real time optimisation and control), hours or days (e.g., scheduling), months or years (e.g., procurement planning and process design).

The time-horizon length should be chosen according to the desired application and the computational resources available. Large time-horizon lengths incorporate future information into the formulation/optimisation decision-making, which is helpful for

adjusting the scheduling operations according to the known or expected scenario in the plant. In addition, the time-horizon plays a key role on the interplay between the scheduling solution to be implemented in the process and the market/sales decision-making through spot market opportunities.

Large time discretisation may cause lack of accuracy and may not fully exploit scheduling opportunities in terms of better economic value and operations (Lee and Maravelias, 2018). Small time-steps overcome such issues but lead to large formulations with potentially intractable models. However, this has been recently overcome by the recent technological advances, which provide proper capabilities for breakthrough research on large-scale optimisation. Small time-steps are closely related to online scheduling (also referred to as rescheduling) applications. Online scheduling concepts are especially important because a continuous cycle of improvement is required to reduce the deviation between the model predictions and the actual values in the plant. Operational data used in the scheduling are typically out of date or not integrated with the production, which leads to inconsistencies in the prediction throughout the process. According to Gupta et al. (2016a), rescheduling facilitates the adaptation of the schedule under uncertainties and unforeseen events, in addition to considering new information as soon as possible, which aims to increase the economic value of the process. In previous work, Franzoi et al. (2021) discuss and illustrate the importance of rescheduling for handling data uncertainty and disturbances, maintaining feasibility, restoring optimality, and providing more reliable and effective capabilities for industrial applications. Importantly, such benefits can only be achieved through a continuous cycle of updates and re-optimisations.

Although the literature on the topic indicates the importance of addressing small time-steps and large time-horizon for improved scheduling operations, to the best of our knowledge there are no works that provide comprehensive quantitative analyses and results on the impact of these features on the scheduling economics and operations. In this work, we investigate the influence of the time-step and time-horizon lengths in the scheduling solutions aiming to achieve a better understanding on the role and importance of these elements for scheduling solutions. Such discussion can be especially important to establish guidelines for future research on the topic aiming to develop more efficient methodologies and to achieve enhanced industrial operations.

2. Scheduling parameters: time-step and time-horizon

There is not standard practices or common understanding about how to properly define time-steps, time-horizon, and time-periods within scheduling formulations. On one hand, the academic literature lacks more comprehensive and conclusive studies and analyses on the impact of such parameters towards improved scheduling optimisation. On the other hand, industrial organisations worldwide do not have a standardised or optimum approach to address that question. The scheduling operations are often not properly optimised, in which outdated manual/simulation capabilities are still employed; or the optimisation tools are not sufficiently accurate or applicable. Even under the utilisation of proper and effective optimisation, the approaches, strategies, and methodologies used within the decision-making capabilities are often not appropriate. That requires an accurate representation of the problem with an integrated mathematical modelling environment (e.g., detailed operations, inclusion of operational constraints, limitations, and requirements), consideration of external factors (e.g., noises, disturbances, and uncertainties), determination of scheduling parameters, proper computational balance and tractability, etc. An important factor within this context concerns the proper selection of

scheduling parameters to be used in the mathematical formulation and optimisation. Previous literature on scheduling optimisation indicates the lack of standards to address such a question. For example, Panda and Ramteke (2019) uses time-steps of 8-hours and time-horizon of 14 days; Hou et al. (2015) considers 10-days time-horizon and 1-day time-step; Dai et al. (2021) employs 7-days time-horizon and 1-day time-step of; and Kelly et al. (2017) proposes time-horizon of 7-days and time-step of 2-hours. Ideally, the time-horizon should be as large as possible and the time-step should be as small as possible, but proper balance is fundamental to overcome computational limitations.

A previous study (Franzoi et al., 2021) addressed the importance of a continuous cycle of scheduling updating for industrial operations. In this work, we investigate how scheduling parameters, namely, time-step size and time-horizon length, affect the scheduling optimisation and its solution, whereas aiming to achieve proper balance between model complexity and computational effort. To the best of our knowledge, such analyses are missing in the state-of-the-art literature and may provide meaningful insights for improved scheduling optimisation capabilities in future works on the topic. Small time-steps enlarge the search space in the optimisation, which provides additional degrees of freedom and potentially better solutions. Large time-horizon provides further information that may significantly improve the scheduling decision-making towards better solutions. Assuming the formulation is suitable to be solved in acceptable computational time, both these concepts are meaningful and present potential for enhanced scheduling capabilities. Importantly, they need to be carefully analysed for each application to achieve proper balance between computational tractability and solution quality.

3. Problem statement

To investigate how the time-step and time-horizon sizes affect the scheduling optimisation and its solution, a blend scheduling optimisation problem for the production of diesel is addressed. Figure 1 illustrates the proposed network. There are two incoming diesel streams D1 and D2 with distinct qualities in terms of specific gravity and sulphur content. They are connected to four intermediate storage tanks S1 to S4 to be further blender in the BLENDER unit. The outgoing mixture is sent to final storage tanks F1 to F6 to be further distributed according to the demand of product P1. The data are presented in Table 1, including the properties of intermediate and final streams (i.e., specific gravity and sulphur content), their estimated market value (negative for costs of feedstocks and positive for selling prices of products), and the maximum incoming/outgoing flowrates.

Table 1: Data for the blend scheduling optimisation problem.

Unit	D1	D2	P1
Specific gravity (g/mL)	0.80	0.95	0.88
Sulphur content specification (g/g)	0.90	1.20	1.00
Maximum incoming/outgoing flowrate	100	100	500

The demands of product P1 over the time-horizon is randomly generated between 40 and 100 bbl/day, which are represented as hard bound constraints (e.g., contractual demands) and must be met. It is assumed that each daily demand needs to be supplied by a single tank F. The scheduling optimisation aims to continuously supply the demand of P1 meeting the product specifications to maximise the refinery profit.

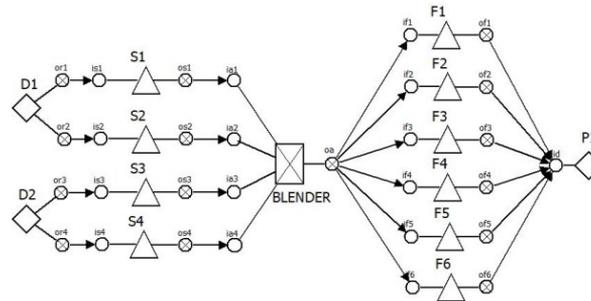

Figure 1: Blend scheduling problem flowsheet.

4. Examples and results

Three examples are proposed to evaluate how scheduling parameters affect the computational effort and solution quality (operations and economic value). They respectively address the impact of the time-step size, time-horizon length, and rescheduling combined with enhanced scheduling parameters. The examples are built as mixed-integer nonlinear programming (MINLP) problems and solved by a two-stage optimisation approach. The mathematical model and the optimisation framework are omitted for the sake of simplicity; for further details, see Franzoi et al. (2021).

4.1. Example 1: Analysis on the time-step size

Example 1 investigates the impact of the time-step size on the scheduling. This is especially important to manage operations with tanks and flows throughout the process. Small time-steps are helpful to exploit additional degrees of freedom whereby achieving more efficient operations. For example, formulations involving tanks typically consider that simultaneous incoming and outgoing flows are prohibited in the same tank. Thus, large time-steps may impose difficulties either to obtain a good schedule or to implement the solution in the plant. Two scenarios are considered:

- Scenario 1a optimises the future 20-days scheduling considering time-steps of 2-days each in a single optimisation with 10 time-periods.
- Scenario 1b optimises the future 20-days scheduling considering time-steps of 1-day each in a single optimisation with 20 time-periods.

Table 2 provides information on the scheduling solution for each scenario, which illustrates the importance of small time-step sizes. Smaller time-steps provide 6% profit increase associated with better feedstock management and less product giveaway.

Table 2: Scheduling solution for Example 1.

	Scenario 1a	Scenario 1b	Difference
Contractual demand met (%)	100	100	-
Refinery profit (k\$)	66	70	4
Computational time per optimisation (s)	1	2	1

4.2. Example 2: Analysis on the time-horizon length

Example 2 explores the impact of the time-horizon length on the scheduling. Since the beginning of the event horizon (Day1), there is a known spot market demand of 500 bbl of product P1 available at Day20, with market price 10% above the average and that can be either partially or fully met. Two scenarios are proposed:

- Scenario 2a optimises the future 20-days scheduling considering time-steps of 1-day each in a single optimisation with 20 time-periods.
- Scenario 2b performs sequential 10-days optimisations within a moving horizon rescheduling strategy (see Franzoi et al. (2021) for further information) with 1-day time-steps. There are 10 optimisations, from Day1 to Day10 until Day11 to Day20.

Table 3 presents important aspects of the scheduling solution for each scenario, which illustrates the importance of employing a sufficiently large time-horizon length.

Table 3: Scheduling solution for Example 2.

	Scenario 2a	Scenario 2b	Difference
Contractual demand met (%)	100	100	-
Spot market demand met (%)	45	100	55
Refinery profit (k\$)	121	105	16
Computational time per optimisation (s)	10	2	8

Due to the larger time-horizon in Scenario 2a, the spot market opportunity is considered in the formulation/optimisation since Day1, which provides flexibility for the plant to adjust its production accordingly. In addition, the optimisation capabilities are especially useful to ensure whether the scheduling is able to comply with the demand requirements in terms of amount and qualities. Conversely, although such spot market information is known since Day1, Scenario 2b includes it in the formulation/optimisation only at Day11, so that the scheduling does not have enough time/resources to adjust the production and misses the opportunity of selling additional product at a higher price.

4.3. Example 3: Analysis on the role of continuous rescheduling

Example 3 investigates the importance of large time-horizon length within continuous rescheduling optimisation. A spot market opportunity becomes available for Day20, in which there is an additional demand of 500 bbl of P1 with market price 10% above average and that can be either partially or fully met. However, such information is only known since Day5. Three scenarios are proposed. Information on the scheduling solution is shown in Table 4.

- Scenario 3a optimises the future 40-days scheduling considering time-steps of 1-day each in a single optimisation with 20 time-periods. The spot market opportunity is considered in the formulation.
- Scenario 3b optimises the future 15-days scheduling considering time-steps of 1-day each in two optimisations with 15 time-periods each (Day1 to Day15 followed by Day16 to Day30). The spot market opportunity is considered only in the second scheduling formulation, from Day16.
- Scenario 3c optimises the future 15-days within a moving horizon rescheduling strategy with 1-day time-steps in a total of 15 optimisations. The spot market opportunity is considered in the formulation since Day15.

Table 4: Scheduling solution for Example 3.

	Scenario 3a	Scenario 3b	Scenario 3c
Contractual demand met (%)	100	100	100
Spot market demand met (%)	0	32	100
Refinery profit (k\$)	146	155	175
Computational time per optimisation (s)	30	5	5

The large time-horizon in Scenario 3a does not capture the spot market information. There is no safety stock available and the production could not exploit such additional opportunity because. Scenario 3b considers the spot market demand only in the second optimisation run, which does not provide enough time/resources to properly adjust the production. On the other hand, higher flexibility is provided in Scenario 3c due to the continuous rescheduling operations, which allow to include the updated information into the model as soon as it becomes available. This illustrates the importance of such interplay of scheduling parameters with rescheduling strategies towards improved scheduling operations. It is worth noting that although such example emphasises spot market opportunities which are common in petroleum refineries, other fields or industries have similar cases involving peaks of demand (e.g., seasonal markets, peak of sales, etc.).

5. Final remarks and future guidelines

There is an important interconnection between rescheduling strategies and the selection of scheduling parameters. Despite highly relevant for industrial applications, such topic has been rarely discussed in the literature. In this work, we address scheduling parameters such as time-step size and time-horizon length and highlight their particular importance in combination with rescheduling strategies. The results indicate that a) proper choice of time-step size provides better selection and management of feedstocks, more efficient production, less giveaways, and higher profit; b) spot market opportunities can be better exploited by large time-horizon lengths, which is especially useful to account for future information that might be available; c) rescheduling strategies are fundamental for enhanced scheduling operations, especially when combined with proper selection of the aforementioned parameters.

Seeking enhanced industrial capabilities, it is fundamental to investigate scheduling parameters through extensive testing to identify better strategies and achieve improved solutions. The analyses carried out in this work are useful for diverse problems, applications, and conditions, and can significantly provide further operational and economic enhancements. The examples focus on the petroleum refinery industry, but the ideas and discussion provided are valid for other industrial applications as well.

Abstract

Pharmaceutical supply chains tend to be complex, and its management encounters several challenges. In this work, a decision-support tool based on a multi-objective mixed integer linear programming model is proposed, aiming to integrate several strategical-tactical decisions while considering the three pillars of sustainability, which are addressed as objective functions. The economic assessment is performed through the Net Present Value (NPV). The environmental impact assessment follows the Life Cycle Analysis (LCA) methodology. Accessibility of pharmaceutical products is the major focus for the social assessment, aiming to provide an equal distribution based on the burden of diseases which is made through a DALY-based metric (Disability-Adjusted Life Year). The model is applied to a representative case study aiming to discuss different optimization scenarios and allowing to understand the effect of decisions on each performance indicator. Important results were obtained that show that sustainability issues influence the supply chain design and planning.

Keywords: Pharmaceutical Industry, Sustainable supply chains, Equity, MILP

1. Introduction

The 2030 Agenda of Sustainable Development comprises several goals intended to drive global and national policies in the direction of a sustainable development of our societies. Within these goals, one seeks to support well-being at all ages and guaranteeing healthy lives, while another fosters inclusive and sustainable economic growth, employment, and proper work for all (Johnston, 2016).

Pharmaceutical companies represent a group of healthcare companies that have been facing strengthened regulations concerning economic, environmental, and social issues, driving them towards more sustainable supply chains. Moreover, pharmaceutical companies dealing with vaccines need to cope with particularities regarding the product itself, such as storage temperature and shelf-life time, influencing the resources needed to be allocated to each facility (Lemmens *et al.*, 2016). This sector plays a critical role in the healthcare structure of each country by providing medicines and vaccines with direct impact on population's quality of life. Undoubtedly, medicines are responsible for preventing and treating diseases, enhancing, or preserving health, and to avoid exacerbation of existing illnesses (Pfizer, 2019). Accordingly, along with the direct benefits for population, medicines and vaccines also contribute towards a significant cost reduction in the total healthcare costs of each country by decreasing the need for long-term care services and/or costly surgeries. Hence, addressing equity in access when designing and planning pharmaceutical supply chains has proven to be essential and helps driving this sector in the direction of a more socially sustainable industry.

Bearing in mind the described scenario for pharmaceutical supply chains, particularly when dealing with vaccines, the present work aims to study how to make strategic and tactical decisions to help attaining sustainability objectives, where the integration of social concerns is the main focus.

2. Problem Definition and mathematical formulation

The proposed model follows the work developed by Mota *et al.* (2018), where a decision-support tool for the design and planning of sustainable supply chains focusing on strategic-tactical challenges is suggested. Adaptations were made to better shape demanding characteristics of the pharmaceutical industry, such as storage technologies needed at warehouses. The generic supply chain representation considers a four-echelon structure (see Figure 1), where the raw materials flow from suppliers to factories to be transformed into final products. At factories, production technology selection is possible. Once the final products are obtained, they can either flow to warehouses or directly to markets to be sold. At warehouses, storage technology selection is possible. Moreover, transshipment between warehouses is allowed and transportation between different entities may be done by either unimodal or intermodal transportation, by road, air and sea.

Figure 1. Modelled supply chain structure

The three pillars of sustainability are introduced as objective functions. The economic objective function is obtained from the maximization of the Net Present Value (NPV) by calculating the sum of the discounted cash flows of each time-period, at an interest rate. These cash flows are obtained through the net earnings (NEt), which are given by the difference between incomes and overall costs, where the former corresponds to the amount of products sold at a certain price, and the latter by the following costs:

- raw material costs (first term)- number of products purchased from suppliers times the unit raw material cost (rmc_{mi});
- production operating costs (second term) - amount of final products produced (P_{mgit}) times the unitary operating costs of each production technology (opc_g);
- storage costs (third term)- amount of final products stored with technology g (S_{mgit}) times the unitary operating cost of storage technology (opc_g);
- transportation costs (fourth term)- flow of products transported through transportation mode a ($X_{mai jt}$) times the transportation cost per kg.km (tc_a), weight of each unit of product transported (pw_m) and distance traveled (d_{ij});
- hub handling costs (fifth term)- flow of products through the hub terminals at the airports or seaports times the unit handling costs at these terminals (hhc_j);
- airline/freighter contracted costs - contracted costs (cfp_i) for the allocated transportation capacity and/or for hub terminal use per time period (sixth term);
- inventory costs (seventh term)- amount of products in stock (S_{mgit}) times the unitary stock cost, (sc_m);

- labor costs at entities (eight and night terms) and labor costs for technologies' use (tenth term), which vary with the fixed (w_i), the variable ($wpsq$) number of workers at each entity and the number of workers needed for each technology (w_g), respectively. The labor cost at each location (lc_i), the weekly working hours (wwh) and the number of weeks per time period (wpt) are also considered, The last term describes the depreciation of the capital invested (Dpt) with tr being the tax rate.

$$\begin{aligned}
 NE_t = (1 - tr) & \left[\sum_{\substack{(m,i,j) \in F_{INCFP} \\ (a,m,i,j) \in NetP}} psu_m X_{mai jt} \right. \\
 & - \left(\sum_{\substack{(m,i,j) \in F_{OUTSUPRM} \\ (a,m,i,j) \in NetP}} rmc_{mi} X_{mai jt} + \sum_{\substack{(m,g) \in H_{prod} \\ i \in I_f}} opc_g P_{mgit} \right. \\
 & + \sum_{\substack{(m,g) \in H_{stor} \\ i \in (I_f \cup I_w)}} opc_g S_{mgit} + \sum_{\substack{(a,m,i,j) \in NetP \\ a \in (A_{plane} \cup A_{boat} \cup A_{trucks})}} tc_a \cdot pw_m \cdot d_{ij} \cdot X_{mai jt} \\
 & + \sum_{\substack{(a,m,i,j) \in NetP \\ (j \in I_{plane} \wedge i \notin I_{plane}) \cup (j \in I_{boat} \wedge i \notin I_{boat})}} hhc_j \cdot X_{mai jt} + \sum_{i \in (I_{plane} \cup I_{boat})} cfp_i \cdot Y_i \\
 & + \sum_{\substack{(m,g) \in H_{stor} \\ (m,i) \in V}} sc_m S_{mgit} + \sum_{i \in (I_f \cup I_w)} w_i \cdot lc_i \cdot wwh \cdot wpt \cdot Y_i \\
 & + \sum_{i \in (I_f \cup I_w)} wpsq \cdot lc_i \cdot wwh \cdot wpt \cdot YC_i + \sum_{\substack{(m,g) \in H \\ i \in I_f}} w_g \cdot lc_i \cdot wwh \cdot wpt \cdot Z_{gmi} \left. \right) \\
 & + tr \cdot DP_t \left. \right] \quad (1)
 \end{aligned}$$

The environmental objective function is obtained through the minimization of the environmental impact, where the environmental impact of production, storage, transportation, and entity installation is calculated for each midpoint category c , summed and normalized as represented in equation (2).

$$\begin{aligned}
 \min EnvImpact = \sum_c \eta_c & \left(\sum_{\substack{t \in T \\ (m,g) \in H}} ei_{mgc} pw_m P_{mgit} + \sum_{\substack{t \in T \\ (m,g) \in H}} ei_{mgc} vpu_m S_{mgit} \right. \\
 & + \sum_{\substack{t \in T \\ (a,m,i,j) \in H}} ei_{ac} pw_m d_{ij} X_{mai jt} + \sum_{\substack{t \in T \\ (a,m,i,j) \in H}} ei_{ic} YC_i \left. \right) \quad (2)
 \end{aligned}$$

Availability and affordability are considered by the Access to Medicine Index (AtMI), as crucial when addressing equity in access to medicines, and within these two concepts, AtMI considers that countries with highest disease burden and less ability to pay for medicines need to be prioritized. The burden of disease of a country can be measured through the metric DALYs (Disability-Adjusted Life Years), which reflects the sum of mortality and morbidity, providing a more encompassing view on health status of a population. Henceforth, the above-mentioned metric (DALY as a rate per 100,000 population) is incorporated into an objective function allowing the maximization of pharmaceutical accessibility, as represented in equation (3). In this equation, the higher the disease burden, the higher will be the value of the social factor of location i (e_i^{DALY}), thus prioritizing the location of entity i (through the decision variable Y_i) in countries with higher disease burden, as well as countries with lower levels of health expenditure.

$$\max \text{PharmaAccess} = \left(\sum_{i \in (I_f \cup I_w)} e_i^{DALY} \cdot Y_i \right) \quad (3)$$

The model additionally considers constraints that account for material balances, supply capacity, flows of products at entities, inventory levels, production, and storage technology capacities, as well as transportation capacity constraints.

3. Case-Study

The developed model is applied to a real based case-study of a supply chain of meningococcal meningitis' vaccine. Input data include the **markets which demand has to be satisfied** (U.S, Europe, Latin America, Eurasia, Asia, Africa, Middle East, Canada and Australia), **suppliers and manufacturing sites**, which include the ones already established in U.S. (Pennsylvania), Canada (Toronto), Europe (France), and Asia (India), and a fifth possible location for a factory in Africa (Kenya) is proposed so as to cover the "African meningitis belt". Moreover, **warehouses**' locations include U.S. (Pennsylvania), Canada (Toronto), Europe (France), Asia (India) and Latin America (Brazil). Possible new warehouse locations are included in the case-study: two in Africa, one in Kenya and one in Nigeria, one in Middle East (Israel), Eurasia (Russia) and Australia. The **product** considered in the study needs to be refrigerated (stored at 2° to 8°C) and each product stock keeping unit (SKU) contains 5 single-doses of meningitis vaccines.

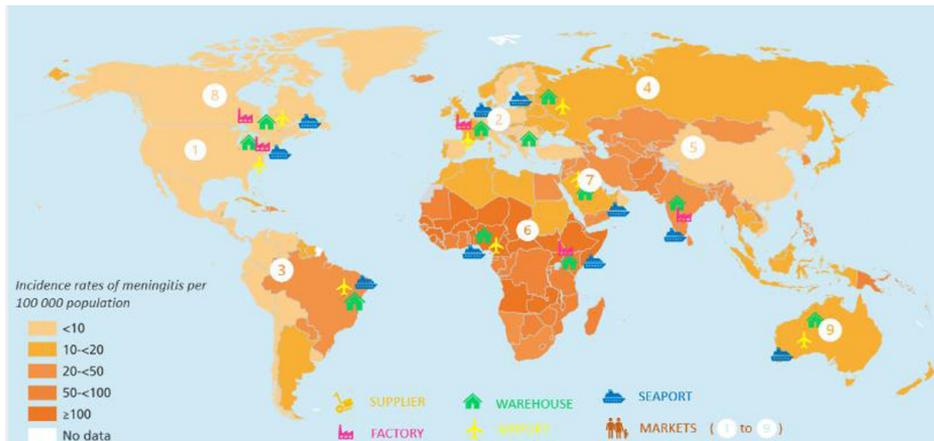

Figure 2. Superstructure considered for the case-study

Decisions were made on facility location (suppliers, factories, warehouses, hub terminals, and markets), production and storage levels as well as transportation network established.

4. Results and Discussion

Different cases are studied using a lexicographic optimization so as to obtain non-dominated solutions (see Table 1):

Case A: optimum economic performance.

Case B: optimum social performance.

Case C: optimum environmental performance.

Table 1. Summary of results considering the different cases being studied

Decisions	Cases		
	A	B	C
Entity locations	Suppliers and factories: Asia and Africa Warehouses: India and Kenya	Suppliers and factories: Asia, Europe, Canada, US, Africa Warehouses: Europe, US, Asia, Canada, Africa	Suppliers and factories: Asia, Europe, Canada, US, Africa Warehouses: Europe, US, Asia, Canada, Africa
Production levels	Most production in Asia (94%)	Most production is in Asia (38%) and Europe (32%)	Most production is in Europe (33%), Canada (26%) and Africa (20%)
Storage technology	Refrigeration	Refrigeration	None
Transportation network	Trucks of big capacity Intercontinental transportation by plane and boat	Trucks of big capacity Intercontinental transportation by boat	Trucks of big capacity Transportation by plane and boat were highly required

The most profitable solution is obtained in case A, which is not the scenario with the worst social and environmental performances. In case B, the best social performance is obtained, however this is also the case where environmental indicator perform its worst, at a cost of a 3% increase, approximately, on the environmental impact when compared with optimal performance obtained in case C. As of case C, the minimum environmental impact is achieved at a cost of approximately 1% reduction in the NPV over the same period of 10 years and social performance achieves its worst value when achieving the greenest solution, with a 67% decrease in equal access of medicines comparing with the best solution obtained in case B. Thus, the greener solution has both the worst economic and social performances.

In case A, factory in Asia is the one with higher production levels. Regarding case B, the major production of vaccines is done in Asia and Europe and in case C the installed capacity is more uniformly distributed between the five factories installed. Regarding warehouses' installed capacity, one can note that, while in case A only two warehouses are considered, located in India and Kenya, in case B seven warehouses are included in the supply chain. This can be explained by the more socially beneficial case being analyzed in situation B and being the maximization of economic objective function the second indicator considered, thus allowing for less profitable structures when comparing with case A (which corresponds to the maximization of NPV as the first indicator being maximized). Finally, in case C, no warehouses are installed, which can be due to the more evenly distribution of production across the installed factories, leading to the less need of keeping inventory in warehouses. Moreover, installation of warehouses has an impact to the environment associated, which is aimed to be minimized, as well as further costs.

The smaller variation in economic performance among the three cases can be justified by the significant contribution of production to the total costs. Moreover, by assuring a total

demand satisfaction, the cost of production can only be minimized up to a certain point, for instance, by locating a factory in a country with lower construction and labor costs. The small variation in the environmental impact across the different cases can also be justified by the major contribution of production technology to the total environmental impact. Hence, it would be important to address different options of greener production so as to minimize the impact for the environment. Recovery and remanufacturing of pharmaceutical products are extremely challenging, not only due to their limited shelf-life, but also because of their hazardousness for the environment, humans, and animals. According to some researchers on this topic, such as Amaro and Barbosa-Póvoa (2008), outdated vaccines should be properly collected to recycle, remanufacture or to be destroyed at incineration centers. These activities can potentially reduce negative environmental impacts caused by production activities of the pharmaceutical industry.

5. Conclusions and future work

The presented work proposes a decision-support tool for the design and planning of a pharmaceutical sustainable supply chain, allowing to study and comprehend the effect of each decision on the performance indicators. The application of the developed model allows for the comprehension of connections among different supply chain activities, providing an opportunity to better understand the performance of different sustainability indicators across the supply chain.

Future work is foreseen regarding recovery of pharmaceutical products, use of alternative technologies and other transportation modes (such as rail transportation). Moreover, the developed model will still be improved so as to explore different social indicators, as well as to consider uncertainty, such as uncertainty in supply, demand, production times, and also regarding the transportation modes used.

Abstract

Jatropha curcas and castor oils are non-edible materials that can be used to produce biodiesel. When designing a biodiesel production process, an important aspect is that each raw material has a different lipid profile and different free fatty acids content. This may affect the performance of the production process. Nevertheless, with a proper design-control strategy, a given process can handle the variations on the composition of the raw material, maintaining the quality of the product. In this work, a strategy for the design and control of a process to produce biodiesel from *Jatropha curcas* oil with variations in triglycerides' composition of the raw material. The process is first designed in Aspen Plus V. 8.8. Then, control loops are established in Aspen Dynamics, applying disturbances of $\pm 10\%$ to the feed flowrate to test the proposed loops and the parameters of the controllers. The compositions on the feed streams are varied, maintaining the same structural design for the equipment on the process. The effect of these variations on the process operation is assessed, and the capability of the proposed control structure to stabilize the process while maintaining the product quality is verified. In general terms, the proposed control structure allows keeping the product with the desired quality, stabilizing the process after variations in the composition of the *Jatropha curcas* oil.

Keywords: biodiesel, controllability, feed composition disturbance.

1. Introduction

The use of low-quality vegetable oils helps reducing the production costs of biodiesel associated with the raw material. *Jatropha* oil is an example of this type of raw material, having a high content of free fatty acids and water. Biodiesel is mainly produced through the process of transesterification of triglycerides, with alcohol and alkaline catalysts. One of the main difficulties when working with this type of raw material is that, when synthesizing biodiesel through transesterification, alkaline catalysts could easily cause a saponification reaction that leads to the formation of soaps, which makes difficult biodiesel's downstream purification. It has been determined that to obtain good yields in the transesterification reaction, the raw material must have a percentage of free fatty acids lower than 1% (Rani et al., 2013). Berchmans and Hirata (2008) proposed producing biodiesel using *Jatropha* oil through 2 routes: using 1 reactive stage or with 2 reactive stages. For the one-stage approach, it has been observed that yields of up to 80% are

obtained using excess methanol in the reaction; this is due to the high amount of free fatty acids present in the *Jatropha* oil. On the other hand, an acid-catalyzed oil pretreatment stage allows reducing the concentration of the free fatty acids, and the presence of secondary reactions such as saponification is avoided. With this two-stages strategy, there are higher yields in the production of biodiesel, amounting to 90% under optimal conditions. Likewise, the use of different alcohols applied in the transesterification of triglycerides to produce biodiesel has been reported, where methanol and ethanol are the most used, although isopropanol cannot be ignored. It has been verified that by means of the synthesis of biodiesel using methanol and ethanol, a biofuel with characteristics that comply with the quality standards of the American standard ASTM D6571 and the European standard EN 14214 is obtained (Castillo Ospina et al., 2011; Degfie et al., 2019). Castillo Ospina et al. (2011) proposed a design for biodiesel production process with ethanol, using *Jatropha* oil with oleic acid and linoleic acid content. The process has an acid pretreatment stage followed by the alkaline transesterification of triglycerides, resulting in a high performance in the process, with a final product complying with the American standard.

The plantwide control strategy is highly recommended for its application in processes that have recycle streams, heat integration, and the interconnection of several unit operations, which is the case for a biodiesel production process through homogeneous catalysis. da Silva et al. (2019) conducted a study using the Aspen Dynamics software where different control structures were evaluated for the plantwide control strategy used in a biodiesel production process. Other works have developed decentralized control structures for biodiesel production processes with disturbances in the production (Sheng et al., 2011) or the feed flowrate (Cheng et al., 2014) In the last decade, the plantwide control strategy has been increasingly implemented in biofuel production and studied in complex processes. The processes that are fed with vegetable oils considered of low quality, such as *Jatropha* oil, have not been the exception. In order to have the capacity to satisfy a specific biofuel demand, applications of plantwide control strategies have been reported in which annual biodiesel production is maintained while respecting the quality of the biofuel produced. The plantwide control strategy is used for tuning the control loops following the corresponding heuristics proposed by different authors, and the methodologies proposed for the analysis of the perturbations applied to the system (da Silva et al., 2019; Luyben, 2013). In this study, a plantwide control strategy is proposed and assessed for a biodiesel production process, using *Jatropha* oil as raw material. The effect of composition variations in raw material on dynamic performance is analyzed, and the potential of the control structure to reject such perturbations is assessed.

2. Case study

The biodiesel production process presented in this work operates with *Jatropha* oil feed. *Jatropha* plant has a high potential for cultivation in Mexico. Table 1 reports the lipid composition of the oil used as a basis for the design of the process. This oil, composed of 4.5% free fatty acids, was characterized in Sinaloa, Mexico (Araiza Lizarde et al., 2015). In Mexico, the production of *Jatropha curcas* is favored by the different climatic and ground conditions throughout the country. According to a study carried out by INIFAP (2012), in Mexico there are at least 3,000,000 hectares with optimal conditions for the harvest of *Jatropha*. In addition, it is reported that up to 1,000,000 plants can be harvested per hectare, and a *Jatropha* plant provides approximately 3 seeds, and each of these produces 6.25×10^{-5} liters of oil (Hooda and Rawat, 2006). Based on the aforementioned

information, a process feeding of 3,500 kg/h of vegetable oil was proposed, since Mexico could produce this amount annually.

Table 1. Lipid composition of *Jatropha* oil.

Fatty acids (4.5% wt)	Triglycerides (95.5% wt)
Palmitic acid (4.1% wt)	Trypalmitin (4.1% wt)
Oleic acid (46.87% wt)	Triolein (46.87% wt)
Linoleic acid (45.18% wt)	Trilinolein (45.18% wt)
Linolenic acid (3.85% wt)	Trilinolenin (3.85% wt)

Figure 1 shows the process proposed to produce biodiesel. The *Jatropha* oil pretreatment stage is implemented; this step is catalyzed by an acid. The second reactive stage is where the transesterification of triglycerides to ethyl esters takes place. Likewise, downstream of the esterification and transesterification reactors, there is a neutralization reactor, where the catalysts are neutralized, and the resulting salts are separated to improve the efficiency of the process. Furthermore, with the help of a decanter, the biodiesel phase and the ethanol-glycerol-water phase are separated; the oily phase goes to a series of equipment where the biodiesel is washed and separated from the impurities to finally obtain the refined biofuel. On the other hand, the aqueous phase is directed to two distillation columns where most of the ethanol and glycerol present in the stream are recovered. Sensitivity analysis has been applied to the process equipment with available degrees of freedom, mainly the reactors and distillation columns, to obtain the best operating variables, aiming to keep costs down and maintain product quality. The NRTL thermodynamic model was used in the proposed process; however, in the phase separation stages with the presence of ethyl esters with glycerol, such as the decanter and the biodiesel washing column, the UNIFAC-LL model is used (Berchmans and Hirata, 2008).

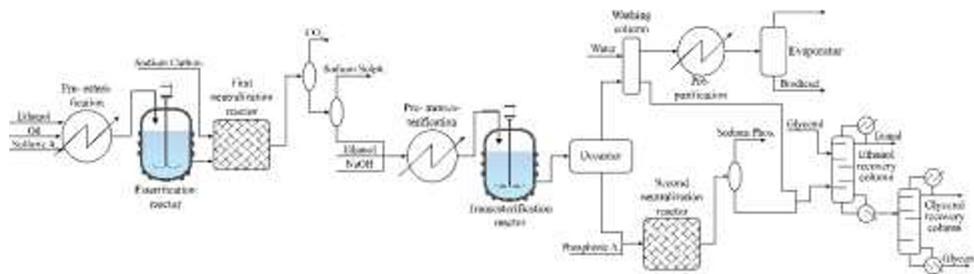

Figure 1. Process flowsheet.

3. Control strategy

The plantwide control methodology allows covering the studied system, given by a chemical process with different stages and many variables. This can be done by decentralizing the process. For processes with no recycling of matter and energy integration, it is possible to perform a decomposition based on process units to be addressed in individual problems (Luyben 2013). Control objectives have been defined in each of the process units used to produce biodiesel. These control objectives are mainly the operating variables that have the greatest influence on the operation of the equipment; this is easily detectable with the knowledge of the operation of the process. In addition, an open-loop analysis of the process has been carried out, where perturbations of $\pm 10\%$ have been applied in the oil feed flow.

Taking into consideration the proposed control objectives, the control ties proposed in the control strategy are established and shown in Table 2. To determine the location of the temperature controllers in the distillation columns, an analysis was carried out to observe the variations that the temperature presented between one stage to another, selecting the stage with the greatest variation in temperature. The controllers used are of the proportional-integral (PI) type; these are enough to control pressure and level due to the zero complexity in these control loops. In addition, to control the temperature in non-extreme systems, the PI controller is a good option (Luyben, 2013). The level and pressure controllers were tuned following the heuristics reported in Luyben (2013); however, to tune the temperature controllers, the Ziegler and Nichols method was used, supported by the tuning tool included in the Aspen Dynamics software.

Table 2. Proposed control loops.

Equipment	Controlled variable	Manipulated variable
Pre-esterification	Inlet stream temperature	Heat duty
Esterification reactor	Temperature	Heat duty
	Level	Output stream flow
Pre-transesterification	Output stream temperature	Heat duty
Transesterification reactor	Temperature	Heat duty
	Level	Output stream flow
Decanter	Liquid 1 level	Output liquid 1 flow
	Liquid 2 level	Output liquid 2 flow
Ethanol recovery columna	Pressure	Condenser heat duty
	Reflux tank level	Distilled flow
	Reboiler tank level	Condensate flow
	Stage 15 temperature	Reboiler heat duty
Glycerol recovery column	Pressure	Condenser heat duty
	Reflux tank level	Distilled flow
	Reboiler tank level	Condensate flow
	Stage 3 temperature	Reboiler heat duty

4. Results

The operation of the process has been considered for 8,160 hours of annual production (340 days), based on that, the process has the capacity to produce 30,000 tons of biodiesel per year. The steady-state process reduces the amount of free fatty acids present in the oil, with the pretreatment stage operating at 70°C. This temperature is important since having higher temperatures would decrease the performance of the reactor and elevation in costs. Likewise, in the transesterification reactor, high yields are obtained due to the lower presence of free fatty acids, in addition, with the conditions proposed such as operating at 70°C, a global conversion of triglycerides to ethyl esters above 99% was obtained. The characteristics of the obtained biodiesel have been compared with those presented in the EN 14214 standard, being satisfactory in all areas. In addition, the distillation columns allow the recovery of a good amount of ethanol and glycerol, which could be reused through the implementation of recycling.

The control strategy is evaluated in different ways. First, perturbations of $\pm 10\%$ were applied to the mass flowrate of the oil fed to the process, analyzing the behavior of the controlled variables throughout the process. In both cases, the behavior in the esterification reactor and the transesterification reactor stabilizes relatively easily. The

controllers in the distillation columns stabilize after a couple of hours, and the greatest variations are observed in the temperature controller. The purity of ethanol and glycerol remains above 99.5% in both cases, and the foregoing is shown in Figure 2. In addition, the biodiesel obtained, although in greater quantity, resembles its characteristics to those recommended by the European standard.

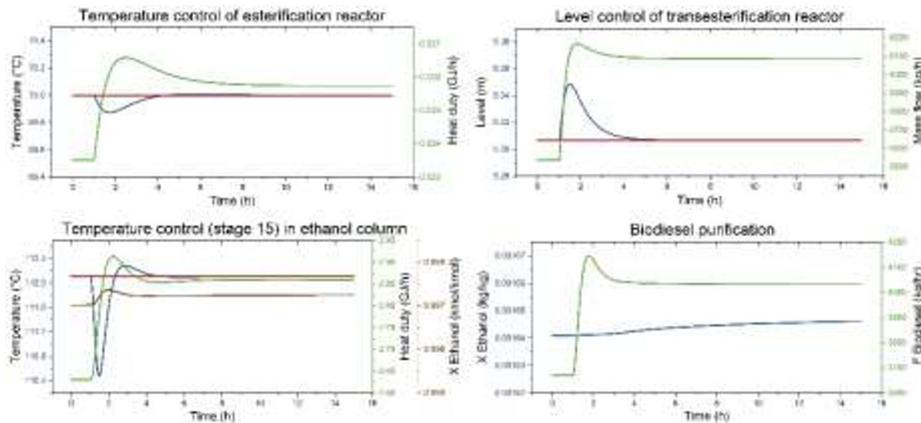

Figure 2. + 10% variation in oil feed mass flowrate.

Because of the composition of *Jatropha curcas* varies depending on its harvest origin, the capacity of the process was evaluated in the face of variations in the composition of the oil fed to the process, based on typical compositions previously reported (Araiza Lizarde et al., 2015; Guevara-Fefer et al., 2016). In these cases, the tank levels of the important equipment in the process are affected by the variation in the molar composition of the oil, however, these are less than the variation in the mass flowrate. In the distillation columns, the temperature controllers are the ones that present the greatest variations, this mainly due to the significant changes that the molar composition of the same type of oil can present due to being harvested under different conditions.

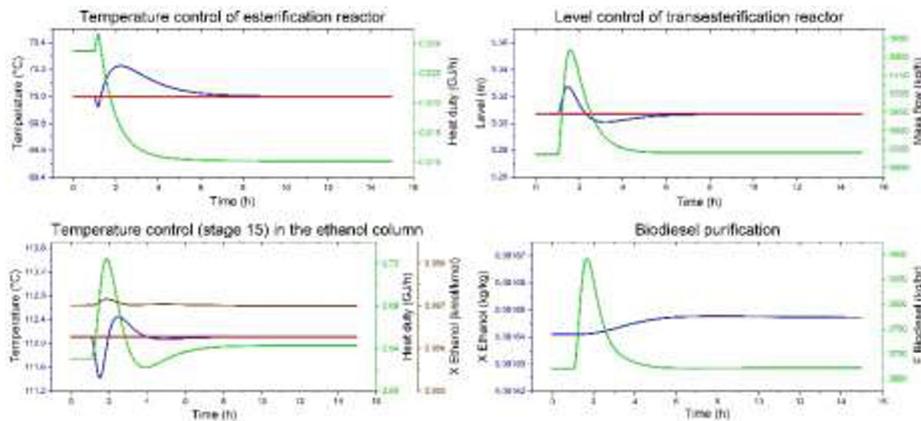

Figure 3. Composition variation in *Jatropha* oil fed.

In these cases, the purity of the ethanol and glycerol undergo small changes, while the purity and quality of the biodiesel obtained are satisfactorily maintained, as can be seen in Figure 3.

5. Conclusions

The design for a biodiesel production process has been carried out in a simulation environment, allowing the analysis for the complete process to be carried out. The operating conditions of the most influential stages in the process were analyzed through sensitivity analysis corresponding to each equipment, which proved to be enough to obtain a product capable of complying with the international regulations to which biofuels are subjected.

The proposed control strategy proved to be appropriated for the requirements sought in the work, which are the production of biodiesel from *Jatropha* oil, considering the variability of its composition or its availability. However, there are still areas of opportunity, among which it can be mentioned that the method used to tune the drivers was the Ziegler-Nichols method, which tunes the driver empirically. This can be improved by implementing a methodology to optimize these parameters, or else complement the closed-loop strategy with optimization. On the other hand, in the control loops proposed in the project, although the application with the cases presented was correct, a methodology was applied to close these loops sequentially and without considering the dead time in the controllers. This was mainly done because the proposed biodiesel production process does not contain material recycles or energy integration.

Abstract

Cascade control is a multi-loop control structure often used in industrial applications, which offers a possibility for applying advanced controllers. This paper compares cascade control with type-1 fuzzy controllers, type-2 fuzzy controllers, and PID controllers on the case study of a tubular chemical reactor. The primary controllers are type-1 fuzzy PID and PD controllers, type-2 fuzzy PID and PD controllers, or conventional PID controllers. The secondary controllers are type-1 fuzzy P, type-2 fuzzy P or conventional P controllers. Simulation results demonstrate that cascade control with both types of fuzzy controllers can assure better values of followed performance indices and higher energy savings measured by the coolant consumption during control of the tubular chemical reactor.

Keywords: cascade control, type-1 fuzzy control, type-2 fuzzy control, PID control, tubular chemical reactor.

1. Introduction

Between advanced control strategies, fuzzy logic control is often found in applications where conventional closed loop control does not assure satisfactory results because of non-linearity, asymmetric dynamics, or uncertainties in the controlled processes. Fuzzy logic control is based on the theory of fuzzy sets pioneered by Zadeh (1965). Zadeh (1975) also introduced the concept of the type-2 fuzzy logic. History, application, and possible future of fuzzy control are summarized in Guerra et al. (2015). Mendel (2018) introduced rule-based systems from type-1, interval type-2 and general type-2 fuzzy systems. Mittal et al. (2020) offered overview of past, present, and future trends of type-2 fuzzy logic applications including theoretical and practical implications.

Cascade control is a multiloop control strategy that enables using of advanced controllers. Meng and Hou (2011) designed cascade control with main fuzzy PID controller and auxiliary PID controller for hydro-viscous drive speed regulating start. Kumbasar and Hagra (2013) proposed a cascade control architecture, which includes the inner and outer control loops for the path tracking control of mobile robots in presence of uncertainty. García et al. (2007) designed fuzzy logic controller with intermediate variable as an alternative for cascade control with fuzzy controllers and compared both strategies. Xie and Liu (2017) formed fuzzy cascade control based on known control history for superheated temperature.

Despite intensive research and promising applications in various fields, there is a lack of studies devoted to implementation of type-1 fuzzy logic controllers (T1FLCs) and type-2 fuzzy logic controllers (T2FLCs) to tubular chemical reactors and T2FLCs in cascade control. The main goal of this paper is to show that cascade control (CC) with T2FLCs can guarantee energy savings and better performance compared to CC with conventional

PID controllers and is alternative to CC with T1FLCs when controlling systems with uncertainties, asymmetric dynamics or nonlinear systems, as tubular chemical reactors.

2. Cascade fuzzy control

2.1. Cascade control

Cascade control (CC) (Figure 1) is a multi-loop control structure used in process industry to improve control under immeasurable disturbances (Bequette, 2003). In Figure 1, C_1 is the primary (main) controller, C_2 is the secondary (auxiliary) controller, P_1 is the primary controlled system, and P_2 is the secondary controlled system. Signals r_1 and r_2 represent reference values, y_1 and y_2 are controlled outputs, e_1 and e_2 are errors, u_2 is the manipulated variable that results from the control input calculated by C_2 influenced by the disturbance d_2 . The disturbance d_1 influences the primary controlled output y_1 . Both controllers in the CC can be fuzzy controllers.

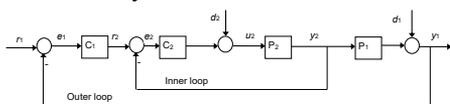

Figure 1: Scheme of a cascade control system

2.2. Type-1 fuzzy control and interval type-2 fuzzy control

The structure of T1FLC is represented in Figure 2. The crisp inputs to the dynamic controller can be errors, derivatives of errors, integrals of errors or previous values of measurements backward in time. Fuzzifier converts input data to degrees of membership by a lookup in one or several membership functions. Rule base includes various empirical rules. Defuzzifier converts the resulting fuzzy set to numbers that enter the process as control inputs.

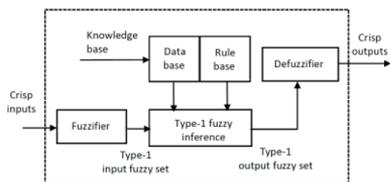

Figure 2: Type-1 fuzzy controller

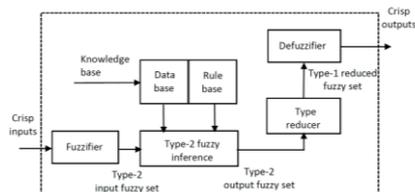

Figure 3: Interval type-2 fuzzy controller

Figure 3 represents structure of T2FLC. The rule base for T2FLC remains the same as for T1FLC, but its membership functions are type-2 interval fuzzy sets, and a reducer must be used prior defuzzification (Kumbasar, 2014). The advantage of using type-2 fuzzy logic (FL) compared to type-1 FL is that type-2 FL can handle uncertainty in control, which may be due to noise, dynamic changes in the environment, or imprecision in the models (Mittal et al., 2020).

3. Case study

The case study from chemical engineering domain is devoted to a tubular chemical reactor (TCR) with exothermic consecutive reactions $A \xrightarrow{k_1} B \xrightarrow{k_2} C$ in the liquid phase and with the co-current cooling (Dostal et al., 2015). Vasičkaninová et al. (2019) did steady-state analysis and step-response based identification of the TCR and based on presented results, TCR is the nonlinear system with asymmetric dynamics and can be treated as a system with uncertainty. As B is the main product and C is the side product, it is necessary to

keep the concentration c_B at the reference value. In CC of TCR, the concentration c_B is the primary controlled output and the temperature of reaction mixture T is the secondary controlled output. The manipulated variable is the flow rate of coolant q .

3.1. *Cascade control of the tubular chemical reactor using conventional PID controllers*
 The transfer function of the PID controller has the form (Mikleš and Fikar, 2007)

$$C = k_p \left(1 + \frac{1}{t_i s} + t_d s \right) \tag{1}$$

where k_p is the proportional gain, t_i is the integral time, t_d is the derivative time. The secondary controller was tuned experimentally as a P controller. The primary PID controller was tuned using the Rivera-Morari method (PID-RM) and the primary PI controller was tuned using the Cohen-Coon method (PI-CC) (Bequette, 2003). Two primary controllers assuring best simulation results were chosen from several designed controllers and no fine-tuning was done. Table 1 presents the controller parameters.

Table 1: PID controller parameters

Controller parameters	Primary controllers		Secondary controller
	PID-RM	PI-CC	P
k_p	1.95	2.18	-0.4
t_i	14.30	3.86	
t_d	0.67		

3.2. *Cascade control of the tubular chemical reactor using fuzzy controllers*

3.2.1. *Secondary type-1 fuzzy P controller and secondary type-2 fuzzy P controller*

Both, the secondary type-1 fuzzy P controller (P-T1FLC) and the secondary type-2 fuzzy P controller (P-T2FLC) were designed as Sugeno-type fuzzy inference systems (FISs), each with 2 rules

$$\text{If } e \text{ is } A_i \text{ Then } f_i = p_i e + q_i \tag{2}$$

where e is the error, p_i, q_i are the consequent parameters presented in Table 2 together with the antecedent parameters A_i and the parameters of the symmetric Gaussian membership function σ_i, c_i (Zhao and Bose, 2002) used for fuzzification of inputs.

Table 2: Parameters of symmetric Gaussian functions, antecedent and consequent parameters

Rule	σ_i	c_i	A_i	p_i	q_i
1	5.93	-14.79	A_1	-0.029	0.23
2	5.93	-0.81	A_2	-0.031	0.24

3.2.2. *Primary type-1 fuzzy PD controller and primary type-2 fuzzy PD controller*

Both, the primary type-1 fuzzy PD controller (PD-T1FLC) and the primary type-2 fuzzy PD controller (PD-T2FLC) were designed as the Sugeno-type FISs with 6 rules:

$$\text{If } e \text{ is } A_i \text{ and } \frac{de}{dt} \text{ is } B_i \text{ Then } f_i = p_i e + q_i \frac{de}{dt} + r_i \tag{3}$$

where e is the error, de/dt is the derivative of error, A_i, B_i are the antecedent parameters and p_i, q_i, r_i are the consequent parameters, which are presented in Table 3.

Sugeno-type FISs were generated using the subtractive clustering method. Triangular membership functions (Zhao and Bose, 2002) were used for fuzzification of inputs and Table 4 presents parameters of used triangular membership functions.

Table 3: Antecedent parameters and consequent parameters

Rule	A_i	B_i	p_i	q_i	r_i
1	A_1	B_1	121.29	-16.33	316.04
2	A_1	B_2	-22.92	-68.84	329.37
3	A_2	B_1	87.13	-192.30	201.02
4	A_2	B_2	30.52	128.56	370.74
5	A_3	B_1	103.65	-28.07	142.95
6	A_1	B_3	84.70	-4.02	178.70

Table 4: Parameters of triangular membership functions

e			de/dt		
a_i	b_i	c_i	a_i	b_i	c_i
-0.96	-0.05	0.86	-0.59	-0.28	0.006
-0.01	0.86	1.78	-0.28	0.02	0.32
0.87	1.78	2.70			

3.2.3. Primary type-1 fuzzy PID controller and primary type-2 fuzzy PID controller

Both, the primary type-1 fuzzy PID controller (PID-T1FLC) and the primary type-2 fuzzy PID controller (PID-T2FLC) were designed as the Sugeno-type FISs with 8 rules:

$$\text{If } e \text{ is } A_i \text{ and } \frac{de}{dt} \text{ is } B_i \text{ and } \int e dt \text{ is } C_i \text{ Then } f_i = p_i e + q_i \frac{de}{dt} + r_i \int e dt + s_i \quad (4)$$

where e is the error, de/dt is the derivative of error, $\int e dt$ is the integral of error, p_i, q_i, r_i, s_i are the consequent parameters. Table 5 presents the antecedent and consequent parameters. Table 6 shows the parameters of the symmetric Gaussian membership functions (Zhao and Bose, 2002) used for the fuzzification of inputs.

Table 5: Antecedent and consequent parameters

Rule	A_i	B_i	C_i	p_i	q_i	r_i	s_i
1	A_1	B_1	C_1	52.44	-0.41	132.53	45.48
2	A_1	B_1	C_2	25.95	11.54	31.96	52.56
3	A_1	B_2	C_1	27.66	-0.40	0.18	330.32
4	A_1	B_2	C_2	-2.44	0.07	0.15	330.53
5	A_2	B_1	C_1	129.66	91.08	21.09	111.06
6	A_2	B_1	C_2	141.61	-18.23	6.13	66.79
7	A_2	B_2	C_1	144.14	-2.60	11.26	85.82
8	A_2	B_2	C_2	13.47	-2.26	50.51	16.70

Table 6: Parameters of symmetric Gaussian membership functions

e		de/dt		$\int e dt$	
σ_i	c_i	σ_i	c_i	σ_i	c_i
0.82	-0.04	0.06	-0.26	3.12	0.17
0.59	1.83	0.05	0.07	3.07	7.29

4. Simulation results

The MATLAB/Simulink R2021b programming environment was exploited for simulations using CPU i7-11700 2.50 GHz, 32 GB RAM. The simulation results for six scenarios in reference tracking and disturbance rejection are presented in Figures 4 and 5.

The primary reference value was the desired value of the product concentration $c_B = 2.15 \text{ kmol m}^{-3}$. The disturbances were represented by increasing the flow rate of the reaction mixture from 0.2 to $0.36 \text{ m}^3\text{s}^{-1}$ at time 100 s and then by decreasing to $0.1 \text{ m}^3\text{s}^{-1}$ at time 200 s . The results were compared numerically assessing the total consumption of cooling water V during control, the integral performance index IAE (integrated absolute error), and ISE (integrated squared error) defined e. g. in Mikleš and Fikar (2007). Table 7 summarizes these numerical results.

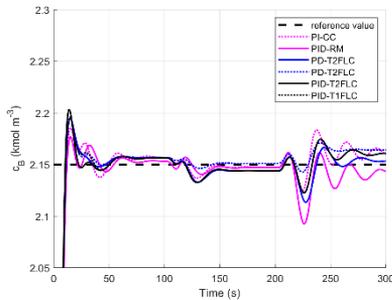

Figure 4: Control responses of the product concentration c_B in six scenarios

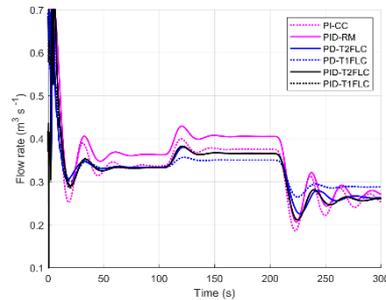

Figure 5: Trajectories of the manipulated variable in six scenarios

Table 7: Values of V , IAE, and ISE

Scenario	Primary controller	Secondary controller	V (m^3)	IAE ($\text{kmol m}^{-3} \text{ s}$)	ISE ($\text{kmol}^2 \text{ m}^{-6} \text{ s}$)
1	PI-CC	P	100.4396	9.9652	8.4881
2	PID-RM	P	108.3361	9.7175	8.5058
3	PD-T1FLC	P-T1FLC	99.7704	9.5105	8.4505
4	PD-T2FLC	P-T2FLC	99.2400	9.6808	8.4572
5	PID-T1FLC	P-T1FLC	98.5960	9.9505	8.4576
6	PID-T2FLC	P-T2FLC	98.5958	9.7361	8.3604

CC with PID-T2FLC and P-T2FLC guaranteed the lowest coolant consumption and the coolant consumption using CC with PID-T1FLC and P-T1FLC was almost the same. The coolant consumption increased by 0.65 % if CC with PD-T2FLC and PD-T2FLC was used and by 1.19 % for CC with PD-T1FLC and P-T1FLC. CC with conventional PID-RM and P assured the highest coolant consumption. CC with PD-T1FLC and P-T1FLC reached the lowest value of IAE and the second best according to IAE was CC with PD-T2FLC and P-T2FLC. The worst cascade control according to IAE achieved conventional CC with PI-CC and P controllers. The IAE increased in this CC by 4.78 %. The best value of ISE assured CC with PID-T2FLC and P-T2FLC. The second best was the CC with PD-T1FLC and P-T1FLC with the ISE value greater by 1.08%. CC with PID-RM and P controller was the worst with the ISE value higher by 1.74% compared to the best CC with PID-T2FLC and P-T2FLC. Comparing the coolant consumption, the ISE and IAE values, the CC with the primary PID-T2FLC and the secondary P-T2FLC was the best CC scenario.

5. Conclusions

CC with conventional controllers, type-1 fuzzy controllers, and type-2 fuzzy controllers was studied on TCR. CC with the primary PID-T2FLC and the secondary P-T2FLC

assured the most efficient operation of TCR. This scenario assured the lowest coolant consumption and the lowest value of the ISE performance index. According to the IAE performance index, CC with the primary PD-T1FLC and the secondary P-T1FLC was the best. The second best was CC with the primary PD-T2FLC and the secondary P-T2FLC. Based on the comparison of all results, it can be stated that both types of FLCs can be used successfully in cascade control for reaching the goals of control. Application of more complicated fuzzy type-2 controllers helped to improve the energetic efficiency of the studied TCR measured by coolant consumption. Further intensive research in this field will continue in the future.

Design and Implementation of an Optimal Control Framework for Post-combustion CO₂ Capture Process

Gaurav Mirlekar, Lars O. Nord

Department of Energy and Process Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

Abstract

The high penetration of renewable sources into fossil fuel-based thermal power plants demand for operational flexibility with Carbon Capture and Storage (CCS) technologies. Post-combustion CO₂ Capture (PCC) processes using chemical absorption of CO₂ in flue gas need to cope with flexible operation and the CO₂ capture rate must be controlled under fluctuating flue gas conditions. To fill this gap, in this work, an optimal control framework is proposed and implemented on PCC with monoethanolamine (MEA)-based CO₂ capture process simulation. A two-input-two-output control structure is selected from PCC that consist of flue gas flow rate and lean MEA flow rate as the input/manipulated variables while CO₂ capture rate and reboiler duty are considered as the output/controlled variables. Open-loop simulations are performed in which simulated step tests are designed by individually moving the input variables as steps and collecting the resulting data for the output variables. The classical autoregressive model with exogenous inputs (ARX) method is used for deriving the data-driven simplified dynamic model that can be embedded inside the Biologically Inspired Optimal Control Strategy (BIO-CS) casted as Model Predictive Control (MPC) to compute control moves for simultaneous control of both output variables in the dynamic simulation. The results are compared to the standalone Proportional-Integral-Derivative (PID) controller existed in the simulation in terms of the time required to reach new steady state and output tracking error. The proposed approach improves the overall performance of the process resulting in faster and flexible setpoint tracking during ramp decrease in the flue gas flow rate case study and thus providing a promising alternative.

Keywords: Carbon Capture and Storage (CCS), Process Control, Dynamic Simulation.

1. Introduction

The global Greenhouse Gas (GHG) emissions need to peak now and be reduced to net-zero by 2050 to fulfil the Paris agreement (Figueres et al. 2017). Fossil fuel-based thermal power plants accounts for the majority of the GHG, such as CO₂ release. Therefore, these energy processes can be integrated with Carbon Capture and Storage (CCS) technologies to mitigate CO₂ emissions and produce cleaner electricity (Dutta et al. 2017a). In addition, hydrogen can, as an energy carrier, enable decarbonization and increased deployment of renewable energy through sector coupling of transport, industry, buildings, as well as the power sector. Norway has the potential to produce hydrogen from the abundant natural gas resources with CCS and provide Europe with blue hydrogen required for the long-term plans (Skar et al. 2018). For such clean energy, post-combustion CO₂ capture (PCC) processes using chemical absorption of CO₂ in flue gas from power plants are the most near-term carbon capture technologies (Dutta et al.

2017a). However, the regeneration of chemical solvents is a highly energy intensive process that require particular attention. The excess heat requirement at the reboiler in the stripper lead to an increase in the overall energy requirements (Dutta et al. 2017b). Additionally, the CO₂ capture rate needs to be maintained at a desired level during power plant load variations that changes flue gas flow rates. In the past, PCC plant behavior has been analyzed by variations in steam extraction from the power plant and plantwide control methods have been studied for suitable control structures using dynamic simulations (Dutta et al. 2017a). Few studies have been performed to examine the effect of controlling the CO₂ capture rate when the PCC plants operate under fluctuating flue gas conditions. In industry, decentralized control structures and open-loop responses for load changes have been experimentally studied for flexible operations (R. Montanes et al. 2018). Additionally, the applications of nonlinear Model Predictive Control (MPC) have been demonstrated on PCC pilot plants considering CO₂ capture ratio as a controlled variable and reboiler duty as a constraint (Hauger et al. 2019). However, the simultaneous control of CO₂ capture rate and reboiler duty has not been analyzed yet. Therefore, a control strategy capable of mitigating the effects of fluctuations and improve overall performance of the system during simultaneous control with minimal human interference must be implemented.

In recent years, a Biologically Inspired Optimal Control Strategy (BIO-CS) is developed and implemented on different processes. The applications of BIO-CS include (i) a nonlinear first principle-based fermentation process model; and (ii) a simulation of a subsystem from the Integrated Gasification Combined Cycle (IGCC) that involves absorption column associated with the Acid Gas Removal (AGR) using physical solvent selexol (Mirlekar et al. 2018a, 2018b). The results of the implementation show that the BIO-CS can tackle various challenges such as, nonlinearities in the process models, multivariable control structures, performance improvement in terms of setpoint tracking error and response time when compared with classical Proportional-Integral-Derivative (PID) controller. Specifically, BIO-CS casted as MPC has displayed faster computational time advantage over standalone BIO-CS. Hence, to address challenges in CCS technologies combined with power plants, in this work, a design of an optimal control framework is presented and its implementation on PCC with monoethanolamine (MEA)-based CO₂ capture dynamic process model simulation is illustrated. The BIO-CS as MPC approach is at the core of this optimal control framework with inclusion of steps that needs to be considered during the implantation of the framework on PCC simulation. The application of the developed framework addresses problems related to control stricture with multiple variables, connection between two software platforms, maintaining required CO₂ capture rate during variations in the flue gas flow rate and increasing energy efficiency.

The paper is organized as follows: section 2 describes the PCC process; section 3 discusses the design of an optimal control framework with details on implementation steps; section 4 consists of framework implementation case study and closed-loop simulation results; section 5 concludes the paper.

2. Post-combustion CO₂ Capture (PCC) Process

The post-combustion CO₂ capture process considered for application in this paper is a dynamic simulation of an amine-based chemical absorption process in Aspen HYSYS[®] V10 (Aspen HYSYS[®] software). As depicted in Figure 1, this process consists of two cylindrical columns representing absorber and regenerator/stripper respectively. The flue gas stream containing nitrogen, water and CO₂ enters the absorber column from

the bottom. The lean solvent stream consisting of a mixture of fresh MEA, CO₂ and water is connected at the top of the absorber. In the flowsheet, the flow rate of the lean MEA is regulated via PID controller for desired CO₂ capture rate. The absorber and stripper are represented by equilibrium-based stage models and random packing material. After the absorption process, the treated gas stream at the top obtained after desired CO₂ capture with trace amount of CO₂ is released into the atmosphere.

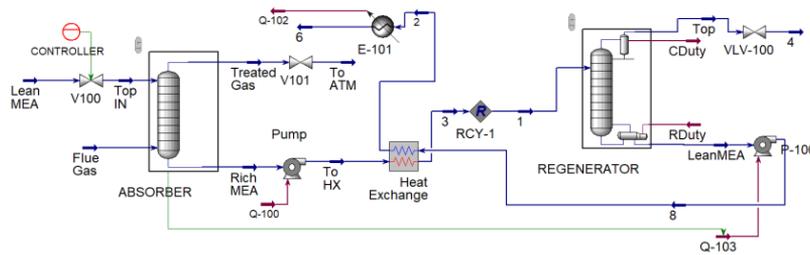

Figure 1: Schematic of the dynamic simulation of the PCC process in Aspen HYSYS[®]. The rich solvent stream coming from the bottom of the absorber is pumped through a heat-exchanger and sent at the top of the regenerator. The heat exchanger employed for heat transfer between rich and lean solvents is modeled using plate-fin configuration and the thermal properties are estimated from the steady-state conditions. CO₂ is separated from the rich solvent in the regenerator with condenser and reboiler modeled as volumes with suitable heat duty. The separated CO₂ stream at the condenser is sent for storage or compression while the lean solvent stream at the bottom of the regenerator is pumped backed into the heat-exchanger. Pumps are modeled by specifying their efficiencies and duty. Few assumptions are also made in this dynamic simulation, for example, the piping is ignored, and the corresponding pressure drop is included in the neighboring equipment. The dynamic simulation model of PCC process is validated using data from the pilot plant available in the literature (Dutta et al. 2017a). The fluctuations in the flue gas flow rate caused by ramp down or ramp up activities performed during load variations affect CO₂ capture rate and energy requirements when such PCC model is connected to a power plant. This issue in a dynamic operation of the system is addressed using the optimal control framework in this work and discussed in the next section.

3. Optimal Control Framework

- The design of an optimal control framework consists of three steps.
- i. Data-driven PCC model development for controller design
 - ii. Formulation of BIO-CS casted as MPC
 - iii. Implementation of control laws on the simulation plant

These steps are summarized in a block diagram depicted in Figure 2. The data-driven dynamic process model of PCC system is developed as a first step in the design of an optimal control framework. Initially, input/manipulated and output/controlled variables are selected based on the previous knowledge of the PCC process. For the implementation case study considered in this paper, flue gas flow rate and the valve opening that regulates lean MEA flow rate are chosen as the input variables while CO₂ capture rate and reboiler duty are considered as the output/controlled variables. Next, the open-loop simulation is performed by moving each input variable as a step change to the process. The obtained data, plotted in Figure 3, is used in the classical autoregressive model with exogenous inputs (ARX) method for deriving the simplified dynamic model. After the data processing, the dynamic characteristics of the PCC system are represented in a typical continuous-time state-space model format to be employed in the control strategy. The

second crucial step in this framework is the design of a controller based on previously developed BIO-CS that mimics ant's rule of pursuit phenomenon. In this case, BIO-CS casted as MPC configuration is used for implementation purposes due to its computation time advantage (Mirlekar et al. 2018b).

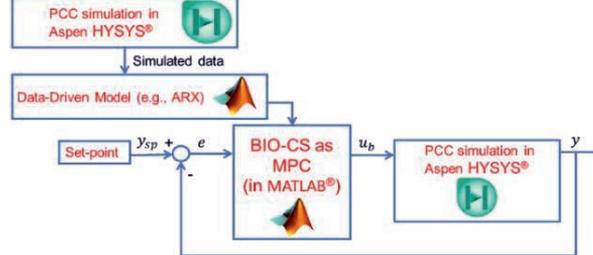

Figure 2: Schematic representation of the optimal control framework

In BIO-CS as MPC formulation, the optimal control problem associated with each agent is solved considering a fixed setpoint trajectory of an output variable for error minimization. *dynopt* (a freely available optimal control toolbox) is employed to solve the optimal control problems associated with BIO-CS as MPC and the optimal input trajectories are computed (MATLAB[®] software, *dynopt* library). Specifically, *dynopt* is a gradient-based solver that utilizes the orthogonal collocation on finite elements method in conjunction with the constrained nonlinear minimization function *fmincon* to determine optimal control trajectories.

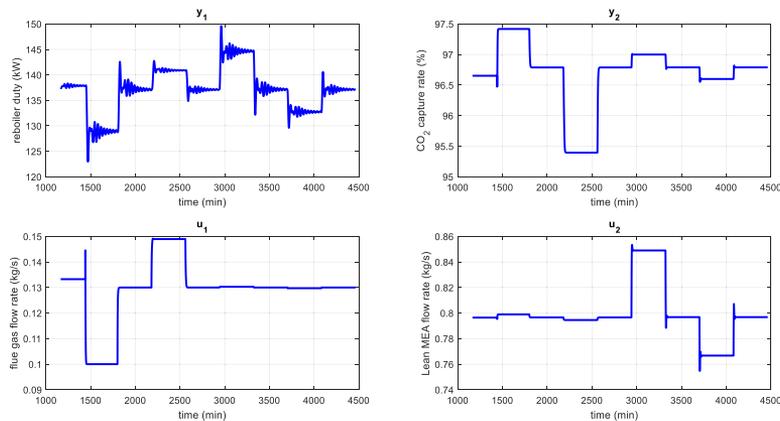

Figure 3: Open-loop simulation data used in the model development

The third important step deals with the implementation of control moves on the PCC simulation plant in an online manner. For this purpose, a freely available MATLAB[®] - Aspen HYSYS[®] link is employed for communicating the controller and the simulation plant model. As shown in Figure 2, the BIO-CS as MPC developed as a script can compute control trajectory (u_b) over a sample time horizon and call simulation for implementation using link. The script/function is paused until the implementation is being performed via simulation/integration for a specified time/horizon. Once this specified time is reached at a feedback sample time, the values of output variables (y) are sent back from simulation to controller and the loop is closed where controller subroutine is called for calculation of control trajectory (u_b) for the consecutive time horizon. The computational time for control moves calculation is about 2 seconds. In the next section, the analysis of the implementation results is presented.

4. Implementation Results

The PCC system model and the optimal control framework described in previous sections are employed for implementation purposes. Figure 4 shows the closed-loop simulation results of optimal control framework in comparison with standalone PID controller implementation for setpoint tracking case study. These results are assessed in terms of time to reach steady-state and the output setpoint tracking error. The case study mimics a real-world scenario in which variations in flue gas flow rate are introduced based on the ramp down operations of a power plant.

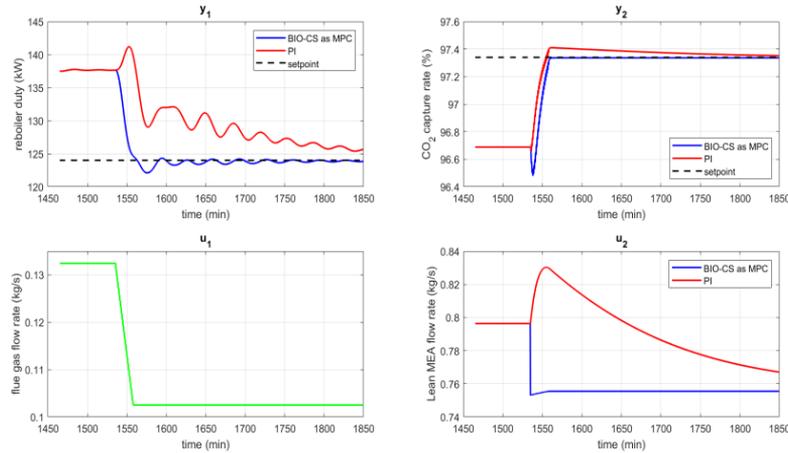

Figure 4: Closed-loop simulation results: setpoint tracking case study

For such simulation, a transient trajectory replicating a 10% ramp decrease in flue gas flow rate is applied over a period of 24 minutes followed by a constant flue gas flow rate profile for next five hours as an input to the process and represented by green solid line. Such dynamic operation is controlled by manipulating the valve opening that regulates the lean MEA flow rate for setpoint tracking scenario. For PI controller application, a fixed setpoint value of 97.34% is given for CO₂ capture rate with controller gains as $k_c = 0.1$ and $\tau_c = 0.25$. Note that the reboiler duty cannot be controlled by PI controller. The standard Aspen HYSYS[®] algorithm type is chosen for PI and tuning parameters are selected from the literature (Dutta et al. 2017b) and extensive simulation runs. In the case of BIO-CS as MPC implementation, prediction horizon/pursuit time (Δ) of 5 minutes and the feedback sample time of 1 minute is selected. A constant setpoint trajectory of 97.34% and 124kW shown by black dashed line is supplied for CO₂ capture rate and reboiler duty, respectively. PID controller is disabled, and the valve opening calculated by BIO-CS as MPC with the objective of minimizing the difference between the setpoints and the output variables is supplied to the system. The formulation of BIO-CS as MPC allows simultaneous control of both the outputs giving major advantage over standalone PI controller. As depicted in Figure 4, the corresponding output data associated with CO₂ capture rate and reboiler duty as well as the computed input trajectory of lean MEA flow rate is recorded during both control strategy implementation. During the implementation of the developed approach, the reboiler duty and CO₂ capture rate reach the desired setpoint in approximately 60 and 25 minutes from the time of introduction of flue gas flow rate ramp down profile, respectively. The settling time and the output tracking error with respect to the setpoint for both the outputs for PI execution are relatively large when compared with the BIO-CS as MPC performance. This translates into reasonably high

reboiler duty and higher energy demand to achieve required CO₂ capture during PI implementation. Thus, these results illustrate the benefits of employing the optimal control framework.

5. Conclusions

In this article, the implementation of an optimal control framework on PCC process simulation was demonstrated successfully. The goal of the control strategy design was to track the setpoints of the desired variables, in this case CO₂ capture rate and reboiler duty, during ramp decrease in the flue gas flow rate. Following objectives were accomplished in this paper: (i) A systematic design of the proposed methodology with BIO-CS as MPC at the core and steps that need to be followed during its implementation; (ii) address challenges associated with the interaction of multiple variables representing PCC control structure; (iii) communicate two software platforms and enhancing the capabilities of the process simulator. The results showed that the developed approach improves the time required to reach new setpoints for multiple outputs and the setpoint tracking error when compared with traditional control approaches. Therefore, such advancements increase energy efficiency and reduce GHG emissions in the decarbonized economy where integrations of CCS technologies into the thermal power plants is necessary. The studies associated with disturbance rejection cases and simulation of more challenging scenarios will be the subject of investigation in the future. The developed framework thus provides a promising methodology for advanced control of energy systems with CCS technologies addressing flexible operations.

Data Driven Process Monitoring, from Fault Detection and Diagnosis Points of View, in Industry 4.0 Context

Hamed Ardakani, Hadiseh Hemmati, Manuel Rodriguez Hernandez ^a

^a*Chemical Engineering Department, Universidad Politecnica de Madrid, Madrid 28040, Spain*

Abstract

Non-upgraded process monitoring approaches rationally and methodically cannot cope with the vast, diverse, and heterogeneous so-called "Big Data" produced rapidly due to Industry 4.0 applications. They require radical enhancements in the computational capacity, required CPU time, precision, and flexibility to emulate newly emerged technologies. The Industry 4.0 context, also known as networked information-based technology, is the most current level of industrial innovation that significantly improves the quality of processes and products.

This paper reviews the Fault Detection and Diagnosis (FDD) scheme as a requisite component of the process monitoring systems, considering Industry 4.0 requirements. Furthermore, to represent the adequate Industry 4.0 FDD framework, different applied technologies associated with Industry 4.0 are studied concisely.

Keywords: Industry 4.0, Process Monitoring, Big Data Analytic.

1. Introduction

The Industry 4.0 context outlines an evolution towards innovative products and the digital world. Through it, industrial automation technologies are at the beginning of a new modern period. With the intention of process monitoring, data with distinct and complex characteristics must be analyzed. Internet of Things (IoT) devices and sensors used in Industry 4.0 produce Big Data that may possess various forms of uncertainty (Hariri et al., 2019). Analyzing complex uncertain data in Industry 4.0 is a time-consuming and challenging task that necessitates the use of relevant Big Data Analytics (BDA) platforms to transform Big Data into smart data to derive hidden knowledge (Zhang et al., 2010).

Process monitoring of Industry 4.0 and large-scale systems can be tricky due to the many sensors, the high correlation among the measured variables, and the complex interaction between the faults and symptoms (Lau et al., 2013). Studies prove that applying regular process monitoring systems, such as the SCADA system, begets difficulties manipulating Industry 4.0 challenges (Tan et al., 2018). Typical process monitoring methods would produce tremendous computation pressure when faced with large-scale, complex data. They are ineffective in interpreting high-speed data flowing from various sources because of their congenital deficiencies (Gokalp et al., 2017).

In the era of Industry 4.0 and Big Data, data-driven approaches find a particularly proper context for expanding their application scopes and growing in diversity and importance (Reis and Gins, 2017). Data-driven process monitoring methods do not need the process

model and the associated expert knowledge. They have become increasingly popular in recent years, especially in complex industrial processes (Ge et al., 2013), and represent one of the most reliable areas in research and practice. However, they also have some crucial shortcomings: they depend on unbiased data, and training and testing samples should be drawn from the same distribution of data (Saufi et al., 2019).

The process monitoring challenges presented by Industry 4.0 technologies must be well answered to make them provide acceptable performance. In this paper, process monitoring requirements in the Industry 4.0 context, mainly from the data-driven FDD points of view, are studied. In this regard, fundamental components of the Industry 4.0 context are addressed, too.

2. Industry 4.0 and Associated Technologies

The transition from Industry 3.0 to Industry 4.0 requires inclusive analysis to develop a strategic plan (Zhou et al., 2016). Industry 4.0 adoption demands considerable capital investments; therefore, its characteristics for prospective transformation should be principally comprehended. Industry 4.0 is driven by several emerging concepts and technologies, including Cyber-Physical Systems (CPS), the IoT, data analytics, cloud systems, etc. For any process to be regarded as Industry 4.0, constant connectivity, human assistance, and decentralized decision-making are absolute necessities (Muhuri et al., 2019).

The introduction of CPS is one of the most remarkable changes and the core foundation of Industry 4.0. It is based on the idea of integrating the physical and virtual worlds. It removes the boundaries between these two worlds and promotes the interconnection of physical and cyber elements (Angelopoulos et al., 2020). “Things” in CPS can communicate with each other through an IoT communication platform to detect their environment, interpret available data, and act on the physical world. The IoT offers promising transformational solutions that enable the real-time interconnection of different sensors, actuators, machines, etc., safely (Xu et al., 2018). It is one of the most significant contributions to Industry 4.0 and intelligent manufacturing. The industrial IoT is a subset of the IoT and follows the exact core definition, but the “things” and goals of the industrial IoT are usually different (Thames and Schaefer, 2016).

One of the relevant concepts of Industry 4.0 is Big Data. The main characteristics of Big Data include volume, velocity, variety, veracity, and value (Yan et al., 2017). In general, Big Data refers to datasets that cannot be perceived, acquired, managed, and processed by conventional tools within a tolerable time because of their size, which usually reaches Petabyte (=1024 Terabyte) or Exabyte (=1024 Petabyte) (Nguyen et al., 2020). Since usual computers may not succeed in processing Big Data, performing the respective analysis with the cloud system would be simpler and more efficient. The main objective of cloud computing is to use enormous computing and storage resources under concentrated management to provide Big Data applications with rigorous computing capacity (Chen et al., 2014).

Cloud system developments aim to minimize the cost of capital investments in infrastructure set-up, reduce maintenance efforts, and achieve efficient management. Parallel processing, virtualized resources, and data service integration with scalable storage are all advantages of cloud system technologies. Cloud computing developments offer solutions for the storage and processing of Big Data. The role of cloud systems is crucial for Big Data as they can provide any infrastructure and a variety of tools on-demand. Given that the emergence of Big Data accelerates the growth of cloud computing, the reciprocal association between them is constructive (Nguyen et al., 2020).

3. Process Monitoring within Industry 4.0 Context

In the Industry 4.0 context, thousands of devices and sensors would be installed to collect and analyze data (Henao-Hernández et al., 2019). To extract essential information from Big Data obtained from a variety of sources, it must be synthesized into structured data, which removes constraints imposed by format, dimension, and other factors (Yan et al., 2017).

Applying a well-organized data processing framework to monitoring Big Data has become a considerable challenge. Therefore, new difficulties in understanding and managing Big Data and extracting underlying knowledge have emerged (Zhang et al., 2018). The consequential considerations are to verify that the data is of high quality and that the data sources are trustworthy. The first step to monitoring Big Data is determining where and how to store it. The following step, data processing, requires rapid data loading and querying. Additionally, efficiency and adaptivity in storage space utilization and dynamic workload patterns are expected. The next step is to analyze data that applies algorithms to interpret data and extract unknown valuable patterns, relationships, and information (Zhang et al., 2018).

3.1. Big Data Analytics

BDA refers to collecting, storing, processing, analyzing, and distributing the data and providing an integrated framework that supports decision-making. Time and infrastructure are dominant factors in BDA that would be met through cloud computing systems (Londhe and Prasada Rao, 2018). BDA tools are suitable for Industry 4.0 to ease cleaning, formatting, and transforming industrial data (Santos et al., 2017). However, there are various difficulties in applying BDA in Industry 4.0. The two primary ones would be to choose the most relevant data and to develop a model capable of exploring the underlying dependence structures (Zhu et al., 2018). Moreover, visualization of the results, heterogeneous data generated by different equipment, and incomplete data are problems for real-time BDA (Gokalp et al., 2017).

To monitor Big Data, FDD systems must possess the ability to convert problems to small ones to make better decisions and reduce costs (Hariri et al., 2019). Obviously, some primary strategies have been adopted to achieve this needed attribute. Applying several parallel algorithms, called parallelization, that work simultaneously, either doing the same tasks or different ones, and using incremental (gradual) learning algorithms that learn from data step-by-step are among the most common ones (Zimányi and Kutsche, 2015). Moreover, a hybrid of these two strategies could be a solution, too. Additional regular proposed methods in the literature are divide-and-conquer, instance selection, and granular computing (Hariri et al., 2019). This problem within the Industry 4.0 context is addressed through cloud system technology that significantly assists practical processing.

3.2. Fault Detection and Diagnosis

In general, none of the FDD methods has all the desirable features that a flawless technique must possess (Ardakani et al., 2017). Hybrid frameworks are recommended to cover the weaknesses of individual strategies and propose robust FDD systems. In a hybrid framework, methods are integrated while belonging to any type (Reis and Gins, 2017).

Fault detection and fault diagnosis are both significantly essential, but it should be noted that fault detection compared with fault diagnosis is a well-developed topic. Besides, the required time for fault detection would be trivial compared with the fault diagnosis, which may take days. Therefore, fault diagnosis needs more research concentration, while process monitoring systems commonly employ both simultaneously (Reis and Gins, 2017).

The most popular supervised data-driven FDD approaches are based on classification methods that would be considered a classification problem (Venkatasubramanian et al., 2003). Without requiring explicit mathematical models, classifiers could be trained based on pattern recognition principles on historical data, including information about normal and different faulty situations. By optimizing or adjusting the parameters, the learning process enables these classifiers to extract knowledge from data. Then, the trained classifiers can be used for process supervision to detect and diagnose faults in the process output measurements (Shokry et al., 2017).

The classifiers would be categorized into multiclass classifiers and One-Class Classifiers (OCC). Multiclass classifiers for training need at least two labeled classes of samples, while OCCs need only one class for training (Chiang et al., 2004). Depending on the FDD purposes, any combination of the classifiers may be applied. Multiclass classification of Big Data is a subject of broad interest in machine learning research. It is necessary to extract process conditions between different classes that may also be imbalanced, making it challenging to differentiate faults from normal data (Sleeman and Krawczyk, 2021). Because of the possible time constraints and sample availability, the FDD algorithms would be divided into four general groups: batch learning, incremental learning, online learning, and anytime learning (Zimányi and Kutsche, 2015). For smart FDD, real-time access to Big Data is necessary to identify faults in the shortest possible time. For monitoring Big Data, the speed with which the data is processed must meet the rate at which it is received, and this is one of the critical criteria for selecting the FDD framework (Khan et al., 2017).

3.3. Advanced Techniques

For employing FDD in the Industry 4.0 context, there is a limitation to using traditional data-driven methods, although they would be implemented in some circumstances (Yan et al., 2017). Therefore, several advanced machine learning techniques for monitoring Big Data such as Deep Learning (DL), Active Learning (AL), feature learning, distributed learning, and transfer learning are proposed. Among them, DL and AL have attracted more attention. AL, categorized into semi-supervised approaches, is applicable when data is abundant while related reliable labels are scarce or expensive. Learning in this manner is a time-consuming and not always straightforward task, but AL is designed to select critical samples for labeling to achieve high accuracy. In the literature, three main AL scenarios are proposed: membership query synthesis, stream-based selective sampling, and pool-based sampling (Qiu et al., 2016).

DL is a branch of machine learning that processes data through multiple non-linear processing layers. It is defined as the modeling of neural networks, while “deep” stands for adequate layers of representations (Kotsiopoulos et al., 2021). To construct a DL model, many parameters and hyper-parameters must be determined (Dekhtiar et al., 2018), but they are considered the most promising machine learning technique in many manufacturing fields nonetheless (Dogan and Birant, 2021). In recent years, the most common DL models used extensively in FDD systems include convolutional neural networks, restricted Boltzmann machines, deep belief networks, and deep neural networks (Angelopoulos et al., 2020). The ability to handle high-dimensional and multivariate data and discover formerly unknown knowledge makes DL techniques crucial in Industry 4.0 (Kotsiopoulos et al., 2021). In the Industry 4.0 context, DL models have been extensively implemented in FDD systems, although the high performance of DL comes with challenges and costs (Saufi et al., 2019). Training DL with Big Data is tricky since iterative calculations are often complicated to be parallelized. Therefore,

there is a tremendous surge of interest in applying parallel algorithms for training deep models (Chen and Lin, 2014).

4. Conclusions

Because of the subject's importance, there has been an increasing demand for research to provide insights into the concerns, difficulties, and solutions related to the monitoring, design, implementation, and management of Industry 4.0. Still, many impediments need to be resolved to launch Industry 4.0 applications into various industrial sectors, notwithstanding all the endeavors made up to now.

Industry 4.0 enhances process monitoring performance by quickly providing more information. In addition, process monitoring systems, particularly FDD frameworks, reinforce Industry 4.0 by efficiently extracting the required information from unprocessed data and transforming it into valuable knowledge.

The data processing in the Industry 4.0 FDD framework must be investigated profoundly since the rapidly available Big Data in Industry 4.0 is quite heterogeneous and may include vast amounts of uncertainty. Moreover, because of the volume of Big Data in the Industry 4.0 context, developed FDD models must be in accordance with the cloud system and its associated techniques to prevent computational burden and delay in detecting and diagnosing abnormal situations.

Abstract

Reinforcement Learning (RL) has received interest within the context of decision making under uncertainty in the process industries. The primary benefit of RL arises from the formulation of the control problem as a Markov decision process (MDP), meaning that it inherits the benefits of accounting for uncertainty in a closed loop feedback control framework and models dynamics very generally via conditional probability density functions. This enables RL to handle problems with various types of exogenous and endogenous uncertainties. Despite this there has been little reported uptake of RL in the process industries. This is partly due to the inability to provide optimality guarantees under the model used for learning, but more importantly due to safety concerns. This has led to the development of RL algorithms in the context of ‘Safe RL’. Here, we present an algorithm that leverages the variance prediction of Gaussian process state space models to a) handle operational constraints and b) account for mismatch between the offline process model and the real online process. The algorithm is then benchmarked on an uncertain Lutein photo-production process against nonlinear model predictive control (NMPC) and several state-of-the-art Safe RL algorithms. Through definition of key performance indicators, we demonstrate the efficacy of the method with respect to objective performance and probabilistic constraint satisfaction.

Keywords: Safe Reinforcement Learning; Optimal Control; Dynamic Optimization; Bioprocess Operation; Machine Learning

1. Introduction

The operation of nonlinear, uncertain batch processes is a well established research focus within the academic community. Both modelling and control often poses challenges. Recent focus in the domain of control (and online optimization) has considered how best to integrate data accrued from process operation to inform decision-making and account for model uncertainties. Historically, consideration of model uncertainty in the context of optimization has been handled via stochastic and robust variants of model predictive control (MPC) (Heirung et al. (2018)). However, batch processes are often characterised by multiple, nonlinear dynamical regimes, which makes model construction notoriously difficult. This has somewhat limited the efficacy of general model predictive control in application to these processes, as they are reliant upon accurate finite dimensional (and closed form) descriptions of the true system dynamics, which has led to the rise of statistical process control approaches within industry (see Yoo et al. (2021)).

Recent efforts to remedy the apparent challenges of batch processing have manifested in the development of various scenario (Maiworm et al. (2015)), distributionally robust (Zhong et al. (2021)) and learning-based MPC approaches (Hewing et al. (2020)). Another approach is provided by Reinforcement Learning (RL). Strictly speaking RL does not require a model explicitly, lending to interpretation as model-free decision making algorithms. However, the data intensity and requirement for exploration of different control decisions necessitates offline model simulation to pre-learn a control policy (via RL) before deployment to the real process. As a result of the presence of process model-mismatch between the real process and the model used for simulation, there is a potential for one to observe distributional shift when the policy is deployed to the real process. In such a case, RL would be making extrapolative control decisions via a data-driven model and may drive the process in to operationally undesirable regimes. Further to this, process operational constraints are not explicitly handled within the Markov decision process framework. Hence, for RL to be applied safely to the process industries, development of training approaches and frameworks are required. In this work, we present an algorithm that leverages the posterior predictive distribution of a Gaussian process simulation model to jointly handle process model-mismatch and joint chance constraints. The ideas we present in this work combine the concepts of pessimism and constraint tightening, which are common to the fields of batch (or offline) RL and stochastic MPC, respectively.

2. Methodology

2.1. Problem Statement

In this work we assume that the system concerned is Markovian and expresses uncertain process dynamics, such that discrete time process evolution may be described as follows:

$$\mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{u}_t, \mathbf{s}_t) \quad (1)$$

where $\mathbf{x} \in \mathbb{X} \subseteq \mathbb{R}^{n_x}$ are states; $\mathbf{u} \in \mathbb{U} \subseteq \mathbb{R}^{n_u}$ are control inputs from a given control set; $\mathbf{s} \in \mathbb{S} \subseteq \mathbb{R}^{n_s}$ are realisations of process uncertainty termed generally to describe various sources of uncertainty; and, $t \in \{0, \dots, T\}$ is a discrete time index within a discrete finite time horizon. We would like to solve the following chance constrained problem:

$$\mathcal{P}(\pi_C) := \begin{cases} \max_{\pi} J \\ \text{s.t.} \\ X_0 \sim p(\mathbf{x}_0) \\ \mathbf{x}_{t+1} = f(\mathbf{x}_t, \mathbf{u}_t, \mathbf{s}_t) \\ \mathbf{u}_t \sim \pi(\mathbf{u}_t | \mathbf{x}_t) \\ \mathbf{u}_t \in \mathbb{U}; \mathbf{s}_t \in \mathbb{S} \\ \mathbb{P}(\cap_{i=0}^T \{\mathbf{x}_i \in \mathbb{X}_i\}) \geq 1 - \alpha \\ \forall t \in \{0, \dots, T\} \end{cases} \quad (2)$$

where $\pi_c(\mathbf{u}_t | \mathbf{x}_t)$ defines a conditional probability density function, that provides a distribution over controls given observation of state; $\mathbb{X}_t = \{\mathbf{x}_t \in \mathbb{R}^{n_x} : A_j^T \mathbf{x}_t - b_j \leq 0, \forall j \in \{1, \dots, n_g\}\}$ is the set of states that satisfy an affine ($A_j \in \mathbb{R}^{n_x}$ and $b_j \in \mathbb{R}$) constraint set at a given time index; $\alpha \in (0, 1]$ is the probability allowed for violation of the constraint set for all time indices; $p(\mathbf{x}_0)$ defines the initial state distribution, which is treated a random variable, X_0 ; and, $J = \mathbb{E}_{\pi}[\sum_{t=0}^{T-1} R_{t+1}]$, is the process objective, which is equivalent to the expected sum of rewards, $R_{t+1} \in \mathbb{R}$, over the discrete time horizon. The reward is provided by a function, $R : \mathbb{X} \times \mathbb{U} \times \mathbb{S} \rightarrow \mathbb{R}$, that ranks process evolution with respect to control objectives. Due to the presence of joint chance constraints and uncertain process evolution (neither of which can be expressed via finite dimensional or closed

form expressions), one is typically required to make approximations to Eq. 2 (to obtain finite dimensional and closed form surrogate expressions) (Heirung et al. (2018)). Despite the problem formulated here, RL is generally only able to find a policy which optimizes a given objective, \hat{J} . Specifically, in the paradigm of policy optimization, parameterizations of a policy are learned, such that:

$$\theta^* = \arg \max_{\theta} \hat{J}(\theta, \cdot) \quad (3)$$

where $\theta \in \mathbb{R}^{n_{\theta}}$ define the parameters of the policy. As a result, constraints are handled via a penalty function. When the constraints are subject to realizations of uncertain variables, $\mathbf{s} \in \mathbb{S}$, the specification of the penalty function is more involved. Recently, the concept of constraint tightening has been translated from the domain of stochastic MPC to RL (see. e.g. Petsagkourakis et al. (2020)). In the following we outline an approach that leverages the posterior predictive distribution of Gaussian process (GP) models to jointly identify a constraint tightening mechanism and to handle process model mismatch.

2.2. Gaussian Process State Space Models

GPs operate within a nonparametric, Bayesian inference framework. This allows us to exploit statistical relationships we assume exist within the data to identify a function, $f: \mathbb{R}^{n_z} \rightarrow \mathbb{R}$. One can make predictions, $\mathbf{f} = [f(\mathbf{z}_1), \dots, f(\mathbf{z}_N)]$, where $f(\mathbf{z}_i) \in \mathbb{R}$, by simply querying the function at given model inputs. In order to proceed we assume the availability of a dataset $\mathcal{D} = \{Z, Y\}$, expressive of discrete time process evolution, where $Z = [\mathbf{z}_1, \dots, \mathbf{z}_N]^T$, such that $\mathbf{z}_i = [\mathbf{x}_i^T, \mathbf{u}_i^T]$ and $Y = [\mathbf{y}_1, \dots, \mathbf{y}_N]^T$, $\mathbf{y} \in \mathbb{R}^{n_y}$, represents measurements of the system state. A GP is fully specified by a mean, $\mathbf{m}(\cdot)$, and covariance function, $k(\cdot, \cdot; \lambda)$, which is parameterised by some hyperparameters λ . Selection of the mean, covariance function, and the associated hyperparameters, defines the *prior*. Inference in GPs utilizes a Bayesian framework. Therefore, a variant of Bayes' rule is used to predict the discrete time evolution of a specific component of the system state. Given the training data and modeling assumptions regarding the mean and covariance functions, this allows us to identify a *posterior* predictive distribution, $p(\mathbf{f}|Y^j, Z, \lambda)$, descriptive of discrete time process evolution. Here, $Y^j \in \mathbb{R}^N$, denotes the j^{th} column of Y . Identification of λ is achieved by maximisation of the marginal log-likelihood. If a Gaussian likelihood is chosen, the *posterior* is constructed exactly as a Gaussian distribution. At a new test point \mathbf{z}^* , a posterior predictive distribution over function values, f^* , may be identified as:

$$p(f^*|Y^j, Z, \mathbf{z}^*, \lambda) = \mathcal{N}(\mu(\mathbf{z}^*; Y^j, Z, \lambda), \sigma(\mathbf{z}^*; Y^j, Z, \lambda)) \quad (4)$$

where μ and σ have closed form expression. As GPs are multiple-input, single-output models, if one has an n_x systems states to dynamically model, then n_x separate GP models can be constructed independently and then assembled to form a state space model. It is worth emphasising that this state space model represents a probabilistic forecast of discrete time process evolution i.e. is an approximation of Eq. 1.

2.3. Integration of Gaussian Process State Space Models for Safe Reinforcement Learning

In the following, we show how to use GP state space models to identify closed form expressions for the probabilistic constraints via the concept of constraint tightening. Specifically, we leverage Boole's inequality which enables us to decompose the probability of constraint violation α across the n_g constraints, such that the probability of violating constraint j , may be defined as $\iota_j = \alpha/n_g$.

Having decomposed the joint chance constraints into individual chance constraints, we then deploy the Cantelli-Chebyshev inequality to obtain robust and closed form surrogate expressions for each chance constraint. The idea here is to identify an approximate tightened constraint set $\hat{X}_t = \{\mathbf{x}_t \in$

$\mathbb{R}^{n_x}: A_j^T \bar{\mathbf{x}}_t + \boldsymbol{\varepsilon}_{j,t} - b_j \leq 0, \forall j \in \{1, \dots, n_g\}$, where $\boldsymbol{\varepsilon}_{j,t} = f(\Sigma[\mathbf{x}_t], \iota_j)$ is a constraint and time index specific backoff; $\Sigma[\mathbf{x}_t]$ is the finite variance of the state; and, $\bar{\mathbf{x}}_t$ is the nominal (mean) state - all of which can be estimated by the posterior distribution of the GP state space model. The relevance of the Cantelli-Chebyshev inequality here is that it provides means to identify a backoff in closed form (i.e. $f(\Sigma[\mathbf{x}_t], \iota_j)$). Satisfaction of this tightened constraint set can then be handled by optimization of an l_p norm penalty function, for example see Mowbray et al. (2021). Having identified means to handle the joint chance constraints, we deploy the concept of pessimism as is common to the domain of batch (or offline) RL. Specifically, we wish to reduce exploitation of regions of the GP state space model, where the predicted variance (which expresses both aleatoric and epistemic uncertainties) is high - this is achieved by adding a penalty in the objective function. In doing so, it is expected that the effects of distributional shift when the policy is transferred to the real system will be minimised. In summary, the analysis provided here enables the identification of a closed form function, $\varphi: \mathbb{X} \times \mathbb{U} \times \mathbb{X} \rightarrow \mathbb{R}$, which includes penalty for constraint violation and for high uncertainty regions of the GP state space model. Policy optimization of φ then handles both the joint chance constraints and plant-model mismatch:

$$\theta^* = \operatorname{argmax}_{\theta} \mathbb{E} \left[\sum_{t=0}^{T-1} \varphi(\bar{\mathbf{x}}_{t+1}, \Sigma[\mathbf{x}_{t+1}], \mathbf{u}_t) \right], \quad (5)$$

In practice, the Cantelli-Chebyshev backoff, $\boldsymbol{\varepsilon}_{j,t}$ often proves conservative. To compromise between constraint satisfaction and operative performance, we plan to tune $\boldsymbol{\varepsilon}_t = [\varepsilon_{1,t}, \dots, \varepsilon_{n_g,t}]$, $\forall t$ via a set of multipliers $\boldsymbol{\xi} = [\xi_1, \dots, \xi_{n_g}]$, which are identified by solving an upper-level Bayesian optimization problem. For specific information on the Bayesian optimization scheme used, see Mowbray et al. (2021). A bilevel optimization problem is formed as a result.

3. Case Study

3.1. A Fed-Batch Lutein Photo-production process

The work developed in this paper focuses on online optimization of fed-batch bioprocesses. The performance of the proposed soft-sensors is assessed in case study on a Lutein photo-production process, which was first detailed in del Rio-Chanona et al. (2017). We assume the same model structure (which is nonlinear) and kinetic parameters as detailed in this study. The model itself describes the evolution of biomass, nitrate and lutein concentration, with lutein production strongly controlled by the complexities of cell metabolism, which are dependent on nitrate availability and incident light intensity. We additionally introduce uncertainty in the form of 5% parametric uncertainty. A set of three affine constraints were imposed on the problem, all of which reflect real operational concerns, such as the preservation of biomass productivity and limits on biomass concentration for the purposes of downstream separation. The objective of process operation is to maximise productivity of lutein production, which enables us to define J so as to reward lutein concentration and penalise nitrate concentration at the end of the batch. For full details of the case study please refer to Mowbray et al. (2021).

3.2. Case Study Design and Benchmarks

The study itself is purely computational. Because of this, we leverage the availability of the uncertain, mechanistic model (that is equivalent to Eq. 1) and conceptualise that it represents the real system. The relevant procedures to demonstrate the methodology proposed then follow: a) generate a dataset (that in practice could be available from e.g. design of experiments) by sampling the uncertain mechanistic model with space filling control trajectories; b) deploy the methodology described by building a GP state space model with the dataset and identify a policy through the framework detailed by Figure 1; c) deploy the policy identified to optimize the real uncertain process (model); and, d) benchmark the performance against NMPC, first order constrained

optimisation in policy space (FOCOPS) (Zhang et al. (2020)), the model-based offline policy optimization (MOPO) algorithm (Yu et al. (2020)), and the conservative offline model based policy optimization (COMBO) algorithm (Yu et al. (2021)). The first two benchmarks represent the best case deterministic method, and a state-of-the-art constrained RL method. The latter two are offline (batch) RL methods and designed to account for mismatch. In all RL benchmarks, constraints are handled by incorporating deterministic expressions for the hard constraint sets into a penalty function within the GP state space model. In FOCOPS, the mechanism for pessimism was implemented into the objective function to mitigate process model-mismatch. The evaluation and comparison of the different algorithms' performance was based on metrics that quantify the quality of the policy identified with respect to two main operational objectives: the expected process objective, J and the probability of constraint satisfaction, $F = \mathbb{P}(\bigcap_{t=0}^T \mathbf{x}_t \in \mathbb{X}_t)$. In the algorithm proposed one can choose to set a lower bound on $F \geq 1 - \alpha$. Clearly, closed form expression is unavailable so F is instead approximated via the sample approximate, F_{SA} , and a statistically robust metric, F_{LB} , which accounts for the limitation of finite samples. All RL policies were trained via the GP state space model and then validated on the uncertain process model, via Monte Carlo (MC) simulation.

4. Results and Discussion

All algorithms observed extensive hyperparameter tuning to ensure objective comparison could be made. All tuning was conducted via Bayesian optimization via the same scheme and objective used to tune the multipliers $\xi \in \mathbb{R}^{n_g}$ proposed in Section 2.3; also, the probability of constraint violation was set $\alpha = 0.01$. Table 1 details the result. The results demonstrate the ability of the

Table 1: Results of policy transfer to the real uncertain process (i.e. the mechanistic model). SCCPO indicates the method proposed.

KPI	SCCPO	NMPC	FOCOPS	MOPO	COMBO
J	13.65 +/- 0.082	11.58 +/- 4.07	12.31 +/- 0.092	10.56 +/- 0.065	13.24 +/- 0.082
F_{SA}	1.0	0.12	1.0	1.0	1.0
F_{LB}	1.0	0.148	1.0	1.0	1.0

method proposed to handle both constraints and mismatch. This is especially reinforced by the relative performance to NMPC, where the model is exactly the same as the uncertain real process and the only difference that exists is the presence of parametric uncertainty in the real process. All RL benchmark methods (MOPO, COMBO, FOCOPS) handle constraints with the desired probability. It is thought that this arises due to the implementation of a backoff as introduced through a) the pessimism mechanism present in MOPO and FOCOPS, b) the nature of the conservative mechanisms that underpin COMBO as well as c) the utility of hyperparameter tuning utilised in the experiment. However, it should be noted that the action of these mechanisms is not specific to any given constraint, which may go some way to explaining the conservative control performance. This is reinforced by Fig. 1, which demonstrates the policies learned on the real process over 500 MCs. The figure shows the RL methods are able to well handle the process uncertainty (with all policies showing stable, low variance control profiles). This jointly ensures sufficient nitrate conditions, whilst minimising waste. The NMPC scheme shows high variance in the controls, which arises from an inability to account for mismatch in constraint satisfaction. This leads to high variance in the productivity of the batch. The SCCPO algorithm gains performance benefits because it is able to incorporate uncertainty information into constraint satisfaction, and observes a less conservative policy, e.g. it has the lowest feasible nitrate concentration at batch termination.

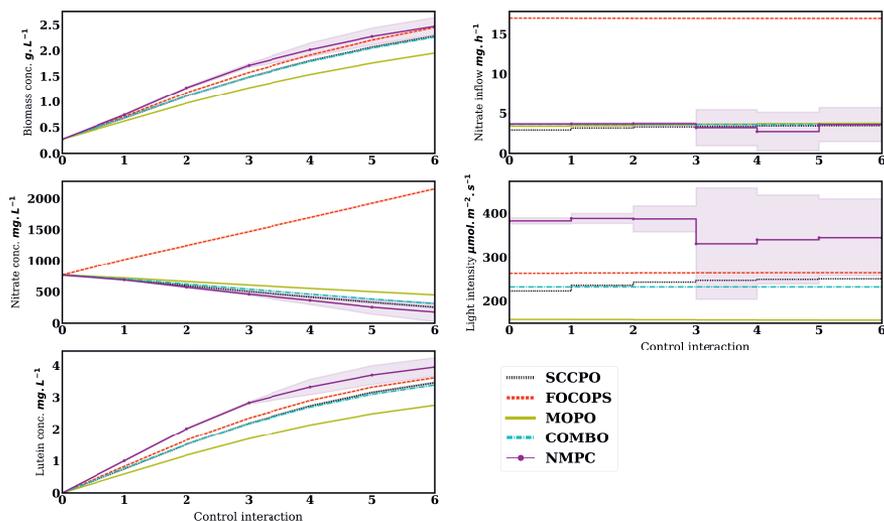

Figure 1: Final learned policies evaluated over 500 MCs on the *real* process. Plots on the left: show the state distributions (± 1 standard deviation) induced by the policies; the right shows the distribution of controls.

5. Conclusions

In this work, we have presented an algorithm that handles both operational constraints and process model-mismatch for the deployment of RL policies for the online optimization of uncertain, nonlinear fed-batch process systems. The algorithm has been benchmarked against best case deterministic method in the form of NMPC (observing a performance benefit of 13%) and state-of-the-art safe and offline RL methods (observing a performance benefit of 4%). The performance of the approach was demonstrated to be advantageous relative to the benchmarks proposed.

Abstract

There is an increasing need to monitor industrial key variables by inferential (soft) sensors. This contribution deals with the challenge of increasing the accuracy of inferential sensors yet maintaining the simple (linear) structure. In order to fulfill these opposing requirements, we design a linear multi-model inferential sensor (MIS) that switches between two models. We enhance the design of a sensor by continuous switching and optimized data labeling. The case study deals with a non-linear model of pressure-compensated temperature often used in distillation columns monitoring and control. The results show a significant accuracy improvement of MIS over a single-model sensor. The studied MIS design approaches present a great potential for practical use.

Keywords: Inferential Sensor, Monitoring, Data-based Design, Multi-model Prediction

1. Introduction

The inferential (soft) sensors (IS) find applications in all industrial and engineering fields. They provide a frequent and accurate estimation of key process variables, and therefore play a significant role in industrial monitoring (Li et al., 2021; Mojto et al., 2021; Qi et al., 2021). The principle of IS is to use the measurements from the easy-to-measure variables (e.g., temperatures, pressures) to estimate hard-to-measure variables (e.g., concentration) (Qin et al., 1997; Zhu et al., 2020).

Industrial processes usually exhibit nonlinear behavior. It significantly reduces the estimation accuracy of the simple (linear) inferential sensors. The nonlinear behavior can be compensated by the design of more complex (nonlinear) inferential sensors. Supposing the linear model structure should be maintained, it is possible to reduce the nonlinear aspect of the industrial processes by designing a so-called multi-model inferential sensor (MIS) (Khatibisepehr et al., 2012).

The standard approach for MIS design does not guarantee the continuity of the model. This can lead to significant stability issues of the (control) system that uses MIS. The further drawback is the a priori labeling of the training set without considering its impact on the MIS accuracy.

This paper investigates improvements of the standard MIS design. We enhance the approach by a continuous switching logic based on the support vector machines (SVM) methodology (Boser et al., 1992). Subsequently, this approach is extended by the optimized data labeling. We compare the effectiveness of these approaches by analyzing the performance of the single-model inferential sensor (SIS) and MIS for the nonlinear model of pressure-compensated temperature *PCT*. This

contribution deals with a special case of the sensor structure with two linear models. A possible extension with multiple models is discussed in Mojto et al. (2022).

2. Problem Statement

We aim to find a multi-model inferential sensor (MIS) with two models of the following form:

$$\hat{y} = \begin{cases} p_1^\top x + b_{p,1}, & \text{if } x \in \mathcal{R}_1, \\ p_2^\top x + b_{p,2}, & \text{if } x \in \mathcal{R}_2, \end{cases} \quad (1)$$

where $\hat{y} \in \mathbb{R}$ stands for the inferred (desired) variable, $x \in \mathbb{R}^{n_p}$ is a vector of the input data, n_p is a number of input variables, $p_i \in \mathbb{R}^{n_p}$ represents a vector of the sensor parameters in region \mathcal{R}_i and $b_{p,i}$ is a constant sensor off-set. Regions of individual model validity denoted as \mathcal{R}_i represent convex polyhedra such that $\mathcal{R}_1 \cap \mathcal{R}_2 = \emptyset$.

2.1. MIS-std: A Standard Approach to the Design of Multi-model Inferential Sensor (MIS)

The standard approach of the MIS design (MIS-std) involves three sequential steps:

1. A priori labeling of the training dataset. We use k -means clustering (Forgy, 1965).
2. Data classification for switching-logic design. The considered approach is support vector machines (SVM) with linear separators (Boser et al., 1992).
3. Individual sensor training. The parameters of the linear models within the MIS structure are fitted by using standard least-squares regression.

The main limitations of MIS-std are: (a) the designed models of MIS are not necessarily continuous, (b) a priori labeling of the training dataset is unaware of its impact on the MIS accuracy.

3. Design of MIS with Advanced Approaches

3.1. MIS-con: An Approach to the Design of MIS with Continuous Switching

To deal with the first limitation of MIS-std, a novel approach (MIS-con) is developed. It combines the SVM-based data classification with the individual sensor training in the optimization problem:

$$\min_{\substack{w, b_w, e \geq 0 \\ p_1, b_{p,1}, p_2, b_{p,2}}} \sum_{i=1}^n z_i (y_i - p_1^\top x_i - b_{p,1})^2 + (1 - z_i) (y_i - p_2^\top x_i - b_{p,2})^2 + \alpha \|w\|_2^2 + \beta \|e\|_1 \quad (2a)$$

$$\text{s.t.} \quad (2z_i - 1)(w^\top x_i + b_w) \geq 1 - e_i, \quad \forall i \in \{1, 2, \dots, n\}, \quad (2b)$$

$$p_1 - p_2 - w = 0, \quad b_{p,1} - b_{p,2} - b_w = 0, \quad (2c)$$

with the number of measurements n , a normal vector and a constant off-set of the separation hyperplane, respectively, w and b_w , a vector of slack variables e , and a vector of binary parameters z that results from the data labeling procedure with $z_i = 1$ if $x_i \in \mathcal{R}_1$ and $z_i = 0$ if $x_i \in \mathcal{R}_2$. The constraints (2c) ensure continuity at the switch between the two models. This is achieved by establishing the intersection of model surfaces to coincide with the determined switching hyperplane.

As the a priori data labeling can be inappropriate for the design of a MIS with continuous switching, we allow small violations of the labeling using the slack variables e in (2b). We also consider that the user can aim at giving up some portion of model (training) accuracy for the better separation by widening the separation band. The latter feature is established by minimizing $\|w\|_2^2$ in (2a). The described features can be enforced/weakened by tuning of the positive weights α and β .

3.2. MIS-con-lab: An Approach to the Design of MIS with Optimized Data Labeling

We propose the approach MIS-con-lab to mitigate the inaccuracies caused by the a priori labeling of the training dataset. This approach searches directly for the optimal data labeling by adding z among the optimized variables in (2a). The underlying optimization problems reads as:

$$\min_{\substack{z \in \{0,1\}^n, w, b_w, e \geq 0 \\ p_1, b_{p,1}, p_2, b_{p,2}}} \sum_{i=1}^n z_i |y_i - p_1^T x_i - b_{p,1}| + (1 - z_i) |y_i - p_2^T x_i - b_{p,2}|, \text{ s.t. Eqs. (2b)–(2c)}. \quad (3)$$

We adopt the sum of absolute errors criterion in (3) to reduce the complexity of the optimization problem as this can now be transformed to mixed-integer linear program (MILP). If the sum of squared errors is used in the objective function, the optimization problem turns into mixed-integer nonlinear program (MINLP) that might be challenging especially when n is high. Moreover, the sum of squared errors criterion tends to reduce significant deviations, whereas the small deviations are neglected. This can reduce the MIS accuracy in the presence of outliers in the dataset.

MIS-con-lab can employ the regularization by penalizing the magnitudes of e and w as in the MIS-con approach to balance between the MIS accuracy and distinction of the individual models.

The problem (3) serves primarily to decide about data labels, i.e., distribution of the training data and, subsequently, of model validity regions. After fixing the values of z , the final training can be performed via solving (2). This two-step approach does not require the a priori labeling of the training set and can provide optimal MIS for the prize of an increased computational burden.

The problem (3) can be transformed to MILP via: (a) the epigraph reformulation (Milano, 2012) of the absolute value, (b) the big-M method (Griva et al., 2008) to linearize the bilinear constraints. As the variables z are binary, the big-M method does not require any new integer variables.

4. Case Study

In this contribution, the design of MIS is tested for the estimation of pressure compensated temperature PCT . This is a phenomenological variable used very often in the petrochemical industry. It is derived by combining the Antoine and Clausius-Clapeyron equations as (King, 2016):

$$\frac{1}{PCT} = \frac{R}{H_v} \ln \left(\frac{P}{P_{\text{ref}}} \right) + \frac{1}{T}, \quad \text{with } x = (T, P), \quad y = PCT, \quad (4)$$

where H_v is the heat of vaporization, R is the universal gas constant, P_{ref} is the reference pressure, P is the absolute pressure, and T is the absolute temperature. The ground-truth parameters of the PCT model are $R = 8.314 \text{ J/mol/K}$, $H_v = 55,940.550 \text{ J/mol}$, $P_{\text{ref}} = 145,325 \text{ Pa}$. The data used in this work is generated within the following intervals:

$$523.2 \text{ K} \leq T \leq 573.2 \text{ K}, \quad 2,000 \text{ Pa} \leq P \leq 20,000 \text{ Pa}, \quad 618.5 \text{ K} \leq PCT \leq 902.7 \text{ K}. \quad (5)$$

Despite the PCT model is usually used within low-pressure devices, the pressure scale used here is even lower. We use this scale in order to provide a more apparent nonlinear behavior of PCT .

We further assume that the training data of PCT is corrupted with some noise. The noise is generated as a random variable from the standard normal distribution. In order to remove the discrepancies in the variables magnitudes (P , T , PCT), we normalize the variables (P_{norm} , T_{norm} , PCT_{norm}) used in the further experiments to lie within the interval $[0, 1]$.

We study two different scenarios (clustered and uniformly distributed dataset) each with 140 synthetic measurements. The weighting parameter α is set to zero and the weighting parameter β is set to 0.01. The calculations are executed in MATLAB using Yalmip (Löfberg, 2004). The MIS approaches use Gurobi (Gurobi Optimization, 2021).

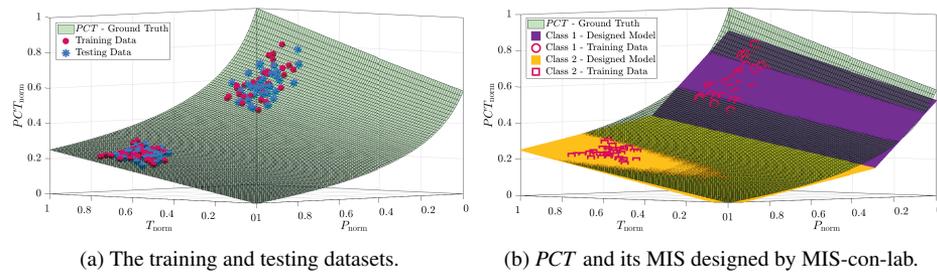

Figure 1: The PCT model on the clustered dataset.

Table 1: The median computational times (CPU time) for 100 simulation runs (clustered datasets).

	SIS	MIS-std	MIS-con	MIS-con-lab
CPU time [s]	< 0.01	0.4	0.4	5.1

4.1. Clustered Dataset

This scenario mimics the situation when the industrial data is well treated from the systematic errors. We can indicate two distinct clusters of measurements in Fig. 1a, where each cluster represents a particular operating point. The measurements are evenly divided into clusters with 50% of the measurements being randomly distributed into the training set (red points) and the rest to the testing set (blue stars). For lucidity of the results, we perform 100 runs with similar datasets.

We first analyze the performance of the trained MISs on one representative run in Fig. 1b. The ground-truth PCT is approximated by two linear models of MIS designed according to the corresponding classes of training datasets (class 1 – circles, purple model surface; class 2 – squares, yellow model surface). The accuracy of the MISs designed using all studied methods is the same. We visualize the results for MIS-con-lab as this approach has optimized the data labels.

The results in Tab. 1 indicate longer computational time of the MIS approaches compared to SIS, as expected. The results also show that MIS-std and MIS-con impose a lower computational burden than MIS-con-lab in this case. The optimized binary variables significantly increase the computational time of the MIS-con-lab approach.

A statistical evaluation of the results from 100 simulation runs is shown in Fig. 4. The accuracy of each method (via RMSE – root mean square error) on the testing set (RMSE-TS) is characterized by the blue box (25th–75th percentile, indicating variance), red line (median), and red crosses (out-

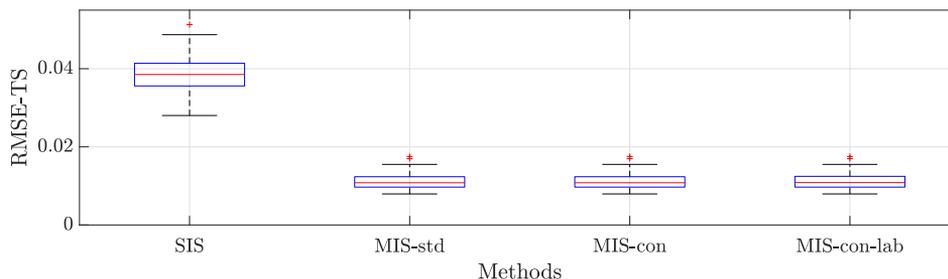

Figure 2: The prediction accuracy statistics on the testing dataset (RMSE-TS) of the designed inferential sensors from 100 simulation runs with different clustered datasets.

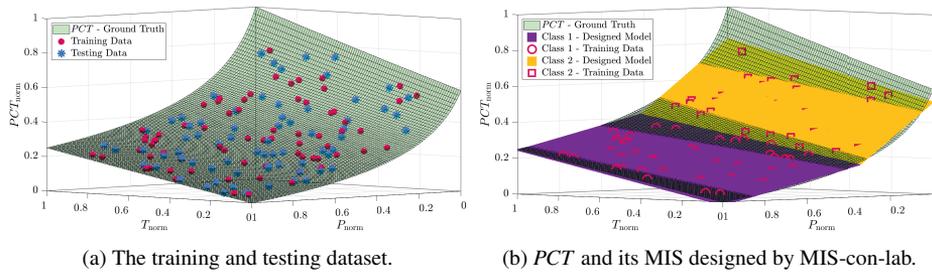

Figure 3: The PCT model on the uniformly distributed dataset.

Table 2: The median prediction accuracy on the training (RMSE-TR) and testing (RMSE-TS) datasets from 100 simulation runs (uniformly distributed datasets).

	SIS	MIS-std	MIS-con	MIS-con-lab
RMSE-TR $\times 10^3$	44.2	18.7	19.2	11.8
RMSE-TS $\times 10^3$	44.9	21.5	19.8	14.0
CPU time [s]	< 0.01	0.3	0.3	20.4

liers). We can conclude that the average/median accuracy and its variance are improved by MISs compared to SIS. The performance of all the designed MIS is the same. The MIS-std and MIS-con approaches can reach comparable accuracy to the MIS-con-lab approach as the (clustered) datasets in this scenario are appropriate for the k -means clustering (a priori labeling). The small accuracy variance confirms the good performance of these approaches.

4.2. Uniformly Distributed Dataset

This scenario involves data uniformly distributed over the whole considered range of the PCT model (see Fig. 3a). Such setting covers the cases of non-ideal industrial datasets, which usually involve this type of data. The available data is randomly and evenly distributed into the training and testing sets. These sets contain the same number of measurements. To provide accurate conclusions, we generate 100 similar datasets and statistically evaluate the results.

The results from one representative simulation run are shown in Fig. 3b. We can see that the MIS is approximated by two models (model 1 – purple surface; model 2 – yellow surface). These models are designed by the MIS-con-lab approach. We visualize the results from this approach because its accuracy is higher compared to other studied approaches.

The results in Tab. 2 prove the highest accuracy of the MIS-con-lab approach on both training and testing datasets. This method outperforms MIS-std by about 35%. Furthermore, we can indicate a slightly lower accuracy of the MIS-con approach compared to MIS-std on the training dataset. This is expected as the MIS-con approach gives up some prediction accuracy for the model-switching continuity. On the other hand, the MIS designed by MIS-con performs better on the testing set. It seems that the enforcement of continuity weakens the effects of the measurement noise in the training dataset and leads to more accurate models. The results from the computation time (CPU time) indicate a higher computational burden of the MIS-con-lab approach compared to the previous scenario (see in Tab. 1). The increased computational burden is caused by the provided dataset nature, which increases the data labeling complexity.

The results in Fig. 4 confirm the superior accuracy of the MIS-con-lab approach over SIS. The accuracy statistics of MIS-std and MIS-con involve several outliers that represent the accuracy comparable to SIS. These outliers can illustrate the low performance of the a priori labeling on

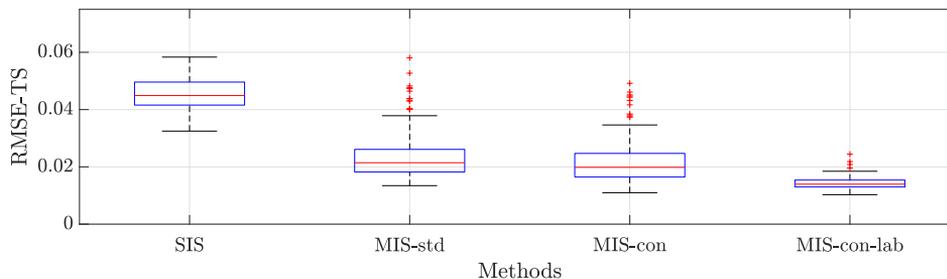

Figure 4: The prediction accuracy statistics on the testing dataset (RMSE-TS) of the designed inferential sensors from 100 simulation runs with different uniformly distributed datasets.

the uniformly distributed training dataset. The variance and number of outliers in Fig. 4 show the superiority of the MIS-con-lab approach in this respect.

5. Conclusions

This contribution is focused on the multi-model inferential sensor design using two sensor models with continuous switching and with optimized data labeling. We presented novel design approaches and compared their effectiveness against the standard design approach and against a single-model inferential sensor. The results suggest a significant accuracy improvement of the multi-model inferential sensor compared to a single-model one. The comparison of the approaches shows a very promising potential of the approach with optimized data labeling as it designs the most accurate inferential sensor and does not suffer from the limitations of the standard approach.

Model predictive control for greenhouse condition adjustment and crop production prediction

Guoqing Hu^a, Fengqi You^a

^a*Cornell University, Ithaca, New York, 14853, USA*
gh429@cornell.edu

Abstract

Greenhouse cultivation targets provide protection to the plantations from severe weather and become a way to achieve controlled agricultural production. The appropriate control of the climate within the greenhouse can lead to the growth of potential yields and the extension of the growing season. However, greenhouses are usually constructed in a way without further consideration to the energy efficiency, leading to the need for an advanced automation control system to save the energy budget. Model predictive control (MPC) has been acknowledged as a suitable control strategy to solve the problem of regulating the climate and growth processes, plus MPC can also guarantee the fulfilment of the constraints specification. To develop the state-space model (SSM) required for the proposed MPC, we start by studying the dynamics of the greenhouse and crop based on the building geometry, weather dynamics, and input control signals. Afterward, we use data-driven techniques and system identification methods to construct the SSM and then incorporate the SSM into the proposed MPC framework. Based on the proposed data-driven dynamic SSM model and the data-driven uncertainty set, we propose a novel data-driven RMPC framework, which is capable of controlling the greenhouse's temperature, humidity, CO₂.

Keywords: Model Predictive Control, Greenhouse Model, Crop Model.

1. Introduction

The greenhouse is gaining popularity in recent years because of its significant contribution to the sustainable intensification of crop production in many countries (Villagran et al., 2020). Greenhouse control can be further developed into a low-cost production system, which is compatible with the shortage of natural resources and the low investment capacity of the growers (Chen and You, 2021). These agronomic and financial benefits give sufficient incentives for developing the control of greenhouse (Bennis et al., 2008). However, the control of the greenhouse is usually deemed as a complex process, regarding its multi-input multi-output (MIMO) and nonlinear characteristics. The greenhouse presents time-varying behavior and is disturbed generally by meteorologic conditions. All these difficulties adversely affect the control performances of classical controllers to the greenhouse (Fourati and Chtourou, 2007). Model predictive control (MPC) has been acknowledged as a suitable control strategy to solve the problem of regulating the climate and growth processes, handling all scheduling decisions effectively (Chu et al., 2015). Besides, MPC can also guarantee the fulfillment of the constraints specification (Camacho and Alba, 2013). MPC is a model-based control strategy that determines the optimal control sequence by solving a sequence of numerical optimization problems with constraints over a specific horizon based on the prediction

model (Agachi et al., 2016). The first input in the optimal sequence is sent into the system, and the entire computation is repetitively performed at subsequent control intervals following a receding horizon approach (Qin and Badgwell, 2003). Several efforts are conducted. In El Ghoumari et al. (2005), the authors have demonstrated the advantageous control of MPC in regulating the temperature of greenhouse compared to the PID control. In Gruber et al. (2011), the nonlinear MPC was proposed and further proved the control performance of MPC in regulating the diurnal temperature in the greenhouse around the desired reference. Despite the progress made over the years, there still exists some knowledge gap: None of the research mentioned above considers the crop model, but they only focused on the control to the greenhouse. The crop model can contribute significantly to greenhouse cultivation while being applied to the optimization work (Lentz, 1998).

In this work, we propose an MPC framework that minimizes the greenhouse's energy and natural resources consumption as well as maximizes crop production. To develop the state-space model (SSM) required for the proposed MPC, we start by studying the dynamics of the greenhouse based on the building geometry and dynamics. To take a further step, we also add the crop model and correlate it to the greenhouse model mentioned before. Afterward, we use data-driven techniques and system identification methods to construct the SSM and then incorporate the SSM into the MPC framework. Weather forecast data and measurement data about ambient temperature, relative humidity, and wind speed are gathered. Based on the proposed dynamic SSM model and forecast values, we can develop the MPC framework which can be adopted for the automation control system. This MPC framework is capable of controlling the greenhouse's temperature, humidity, CO₂, irrigation, and fertilization. The proposed framework not only is computationally efficient but also mitigates the wasted consumption issues that arise from the greenhouse power regulation.

2. State-space model construction

2.1. Greenhouse model

Vanthoor et al. (2011) has designed the greenhouse model which studies the impact of outdoor climate and greenhouse design on the indoor greenhouse climate. Weather information is comprehensively considered in this model, including ambient temperature, ambient relative humidity, global radiation, diffuse radiation, and wind speed. This model is adopted in this research regarding its fulfillment of the following three requirements: 1) this model can adequately predict the temperature, water vapor pressure, CO₂ concentration greenhouse indoor air under different greenhouse designs and regional climate; 2) this model is able to take greenhouse construction parameters and climate adjustment facilities into consideration. 3) This model is also ready to be incorporated with the tomato yield production model (Rezvani et al., 2021).

2.2. Crop model

Although Vanthoor et al. included tomato growth in the model, fertilization and irrigation were not considered. These two factors are crucial to crop production and tightly related to the quality of the crop. Therefore, we apply the VegSyst model designed by Gallardo et al. (2011). In this model, we are able to retrieve the crop growth rate by compiling the weather information data and adjusting the fertigation rate (Shang et al., 2020). Therefore, we can now develop the steady-state matrix required by the MPC framework.

2.3. System identification

Although we have the physics-based model which can describe the correlation between each state, the linear SSM is preferred in MPC computation because of computational efficiency. Therefore, we apply the system identification to the nonlinear model to identify the SSM which combines the greenhouse model and crop model. The SSM is described in the following equation:

$$x_{t+1} = Ax_t + B_u u_t + B_v v_t + B_w w_t \quad (1)$$

Where A is a 9×9 state matrix. In this SSM, 9 states are considered, including cover temperature, internal temperature, mat temperature, tray temperature, floor temperature, soil temperature, water vapor density, CO_2 density, and growth rate. B_u is a 9×7 input matrix, in which 7 control signals are considered: heater, fans, humidifier, dehumidifier, CO_2 enrichment, irrigation, and nitrogen enrichment; B_v is a 9×5 weather disturbance matrix which describes the linear correlated impact from weather data. In this research, we consider 5 weather information, including ambient temperature, ambient relative humidity, global radiation, diffuse radiation, and wind speed. B_w is a 9×3 weather forecast uncertainty matrix. Three major forecast uncertainties are considered including temperature forecast error, humidity forecast error, and wind speed forecast error (Shang et al., 2019). Figure 1 demonstrates the results of system identification. The overall mean absolute percentage error (MAPE) for the linearization is 7.06 %, indicating that this SSM is sufficiently accurate in describing the nonlinear physics correlation between each state.

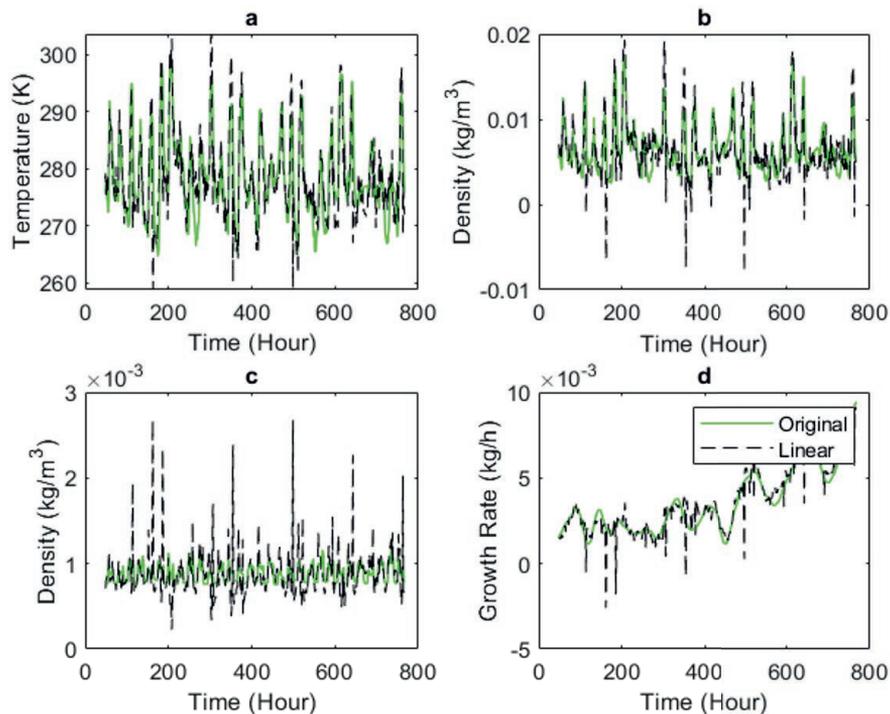

Figure 1. System identification results of: (a) indoor greenhouse temperature (b) water vapor density (c) CO_2 concentration (d) growth rate. The linear results are demonstrated as a dashed black line and original nonlinear model results are represented in a green solid line.

3. Model predictive control framework

After acquiring the SSM for the control framework. The MPC optimization problem can be formulated as below:

$$\begin{aligned} \min \quad & \sum_{i \in B_u} c_i u_i + \lambda_i^T L_i \lambda_i - \alpha \sum_{j \in X_{crop}} x_j \\ \text{s.t.} \quad & F_u u \leq f_u, \\ & F_x [Ax + B_u u + B_v v + B_w w] \leq f_x + \lambda \end{aligned} \quad (2)$$

Where F_x , F_u , f_x , f_u represent the state variable constraints matrix, control input constraints matrix, constraints for state variables, and constraints for the input. L is the weighted cost matrix that penalizes the violation to the constraints (Jia et al., 2021). λ is the slack variable that allows some extent of violation to the hard constraints. In this problem, we introduce the soft constraint to the optimization to ensure the feasibility and help alleviate the over-pessimism or infeasibility of hard constraints (Meseguer et al., 2006). Besides minimizing the cost of energy consumption and violation of the constraints, we also try to maximize crop production. α is the weighted coefficient for crop production. This coefficient is necessary because the growth rate is a much smaller value compared to the energy cost and to the constraint-violation penalty. The absence of this coefficient will lead decision impartial to the growth condition of the crop. x_{crop} is the growth rate states from the state matrix A .

4. Control profile

In this research, we simulate the greenhouse located in Ithaca, the USA from 0:00, March 1st, 2020 to 23:00, March 30th, 2020. The initial conditions are set as (Chen et al., 2021):

- For all temperature values, the starting conditions are 298.15 K
- The initial water vapor density is set as $2.5 \times 10^{-3} \text{ kg/m}^3$
- The initial CO₂ concentration is set as 0.8 kg/m³
- The initial growth rate is set as 0 kg/hr

The constraints are set as follows: For daytime (from 7:00 to 19:00), the upper limit for temperature is 302.5 K and the lower limit is 297 K; the upper limit for relative humidity is 90% and the lower limit is 80%. For nighttime (from 19:00 to next day 7:00), the upper limit for temperature is set as 297.5 K and the lower limit is 288.7 K. The relative humidity range is from 65 % to 75 %.

The control results are demonstrated in Figure 2 and Figure 3. We can observe from plots that temperature has fewer violation cases than for humidity control profile. The reason behind this is that the forecast error of temperature only occupies less than 1 % of the actual measured value (when temperature value is recorded as in kelvin), whereas the forecast error of humidity can be away from the actual measurement value up to 25 %. Therefore, the humidity forecast error can drive the control decision away from the desired constraints.

The crop growth curve is illustrated in Figure 4. We can conclude that the crop is steadily growing.

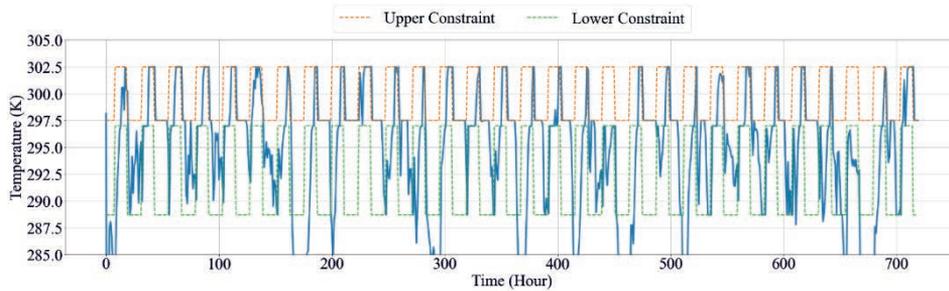

Figure 2. Temperature control profile of greenhouse from March 1st 0:00 to March 30th 0:00 in 2020. The orange dashed line indicates the upper limits for the temperature constraints while the green dash line for the lower limits.

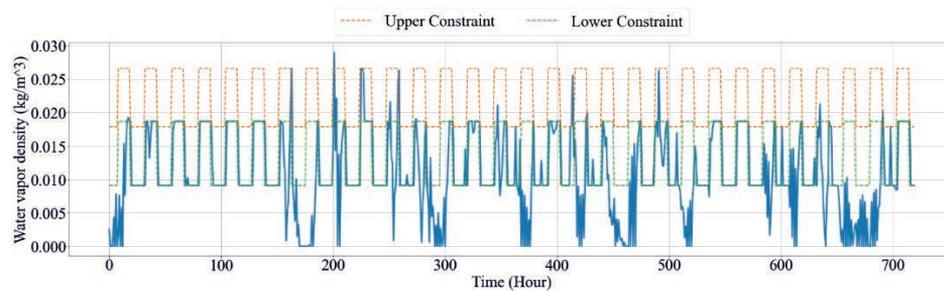

Figure 3. Humidity control profile of greenhouse from March 1st 0:00 to March 30th 0:00 in 2020. The orange dashed line indicates the upper limits for the temperature constraints while the green dash line for the lower limits.

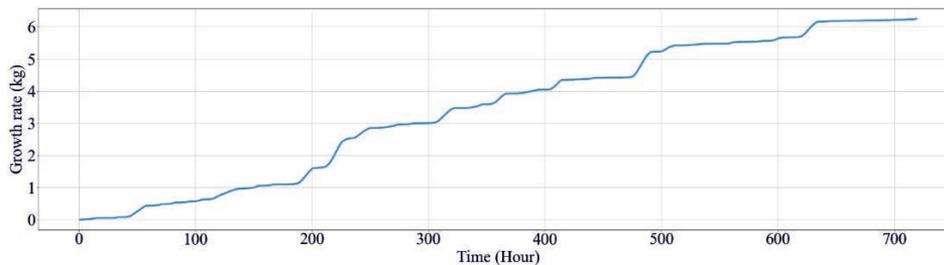

Figure 4. Gross tomato production profile from March 1st 0:00 to March 30th 0:00 in 2020.

5. Discussion

In this research, we focused on developing the MPC framework for the SSM, which combines the greenhouse model and crop model. Thanks to the linearization process, the average CPU time for each case is only 0.044 seconds, which is sufficient to finish the optimization procedure within the sampling interval of 8 hours. Plus, the soft constraint within the optimization also ensures feasibility (Lu et al., 2020). However, the drawback of this MPC framework is also noticeable. The violation of the constraints is not negligible in this control profile, as these violation cases may result in a harsh climate in the greenhouse and become harmful to the tomato growth. Therefore, Robust MPC, which takes forecast errors into consideration in obtaining optimal control inputs, should be used in this case to hedge against the forecast uncertainties.

Abstract

As a large amount of industrial data have been acquired by distributed control system (DCS), data-driven process monitoring methods have attracted a significant research interest. However, various types of noise are also collected with signal together from process instruments and data transformation, which could compromise the information of signal itself and provide a huge challenge for data analysis and modeling. Moreover, noise contents of different measurements, such as temperature measurements, pressure measurements, flow measurements, and etc., may be also varied in industrial process. Therefore, the selection of decomposition scale has a great influence on the denoising effect, while among methods reported in the literature, the decomposition scale is usually constant for all measurements in a process.

In this research, a novel standard to characterize an optimal denoising depth for each measurement is proposed. Wavelet decomposition is first selected to extract the high-frequency features of signals in different measurements for its ability to retain the local characteristics of signals in both time and frequency domains. Then information entropy is applied as a standard to characterize the depth of wavelet decomposition. An optimal decomposition scale is determined by maximizing the retention of raw signal information in each measurement. According to this standard, signal in each measurement can be processed individually according to its optimal decomposition scale. Then the processed data can be further applied to a multivariate statistics method for a more effective process monitoring. In order to verify the effectiveness of this method, the research is implemented on an industrial continuous catalytic reforming process. The results show that abnormal operational conditions can be detected earlier on the basis of the proposed method compared to other methods without considering the denoising of different variables respectively.

Keywords: wavelet denoising, process monitoring, information entropy, continuous catalytic reforming process.

1. Introduction

Production safety in chemical industry is always considered as a prerequisite, whether it is from the perspective of design or production operations. In fact, large-scale chemical production is always accompanied by a great potential safety hazard due to harsh operating conditions and various unexpected disturbances, which will cause huge losses to human lives and national economy. To prevent safety accidents, process monitoring technology has been developed in chemical processes to assist operators to detect

abnormal changes in a process plant timely. Take advantage of the real-time data collection technology provided by distributed control system (DCS), data-driven feature extraction methods have been widely adopted for fault detection. For example, as a conventional multivariate statistical method, principal component analysis (PCA) has been widely used by projecting high dimension data into a feature space and achieved good results on simulation data of Tennessee-Eastman process (MacGregor, et al., 1995). However, the actual measurement value obtained from DCS is inevitably coupled with various types of noise during data transmission. Numerous researches have been conducted to solve this problem. The widely used wavelet transform method has shown a powerful denoising effect in chemical industry by adopting both time and frequency analysis (Bakshi, 1999). Li and Wen developed a wavelet-PCA method for air-handling units monitoring, by which the advantages of wavelet transform method for data preprocessing in process monitoring has been demonstrated (Li, et al., 2014). When applying wavelet denoising, the selection of wavelet basis function and denoising depth shows a great impact on the denoising effect. Among methods reported in the literature, the decomposition scale is usually constant for all measurements in a process. However, noise distribution and contents of different measurements, such as temperature measurements, pressure measurements, flow measurements, and etc., varies in industrial process. Therefore, it is necessary to determine a proper denoising standard to achieve an optimal denoising effect for each measurement.

The aim of this paper is to extract data features for process monitoring under the premise of determining an optimal denoising depth for each type of measurement. When denoising different measurements such as temperature measurements, pressure measurements, flow measurements, and etc., it can be found that the noise contents of them are different in industrial process. On this basis, information entropy maximization, which has been proved to be a useful wavelet parameters selection standard introduced by Altay and Kalenderli (Altay, et al., 2014), is adopted to determine an optimal denoising depth for each measurement. Since signal in each measurement has been processed according to its optimal decomposition scale, the processed data are further applied to a PCA model for a more effective process monitoring. According to the results obtained from an industrial reforming heat exchanger unit, it can be seen that the fault could be earlier detected with a lower false alarm rate by the proposed method compared with other methods with only one denoising policy.

2. Methodology

In this section, the methods applied in this work are introduced.

2.1. Wavelet Threshold Denoising Method

Wavelet threshold denoising method is an effective time-frequency signal processing tool. Signals are decomposed based on a scaled and translated mother wavelet given as

$$\int_{-\infty}^{+\infty} \varphi(t) dt = 0 \quad (1)$$

In continuous wavelet transform (CWT), the decomposed coefficients are given as

$$CWT(u, s) = \int_{-\infty}^{+\infty} x(t) \frac{1}{\sqrt{s}} \varphi^* \left(\frac{t-u}{s} \right) dt \quad (2)$$

where u and s are the scaling and translation parameters. $x(t)$ is the raw signal. The discrete form of CWT is obtained by sampling the time-scale plane. In discrete wavelet transform (DWT), the decomposed coefficients are given as

$$DWT(a,b) = \int_{-\infty}^{+\infty} x(t) \frac{1}{\sqrt{a}} \phi^* \left(\frac{t-b}{a} \right) dt \quad (3)$$

where a and b are the discrete versions of u and s . De-noising of signals in the wavelet domain can be done in decomposition, thresholding and reconstruction three steps.

2.2. Shannon entropy

Shannon entropy is a concept introduced from physical systems by Shannon to estimate the amount of information (Shannon, 1948), its calculation is given as follows,

$$S = \sum_{i=1}^l p_i \log_2 \left(\frac{1}{p_i} \right) \quad (4)$$

where l is the total number and p_i is the probability of the situation i in the system. Maximum information entropy can be applied in the wavelet de-nosing process for parameter selection, the probability can be calculated as follows,

$$p_i = E_j / \sum_{j=1}^M E_j = \left(\sum_{k=1}^{K_j} w_{j,k}^2 \right) / \sum_{j=1}^M \left(\sum_{k=1}^{K_j} w_{j,k}^2 \right) \quad (5)$$

where E_j is the energy in time scale level j and M is the maximum time scale level. K_j is the number of wavelet coefficients in time scale level j . $w_{j,k}$ is the processed wavelet coefficient. Maximum separation between signal and noise can be calculated using the maximization of entropy technique calculated by Equation 6, which gives the optimal value of j and helps to determine an optimal mother wavelet.

$$S = S_{signal} + S_{noise} = \sum_{i=1}^k p_{i,signal} \log_2 \left(\frac{1}{p_{i,signal}} \right) + \sum_{i=1}^k p_{i,noise} \log_2 \left(\frac{1}{p_{i,noise}} \right) \quad (6)$$

2.3. Principal component analysis (PCA)

PCA is a classical feature extraction technique by projecting high dimensional data into a lower feature space, which has been widely used in process monitoring with T^2 and SPE statistic. Given normalized n observations of m measurement variables $X_{n \times m}$, the covariance matrix of X can be calculated as follows,

$$Cov(X) = \frac{X^T X}{n-1} \quad (7)$$

Then singular value decomposition is employed to $Cov(X)$, a score matrix T and a loading matrix P are determined by retaining the first k features that contain the most information. The raw matrix X can be decomposed as follows,

$$X = TP^T + E = t_1 p_1^T + L + t_k p_k^T + E \quad (8)$$

where p , t are the loading vector and score vector, and E is the residual matrix. For online monitoring, T^2 statistic and SPE statistic can be calculated as monitoring statistics to measure the deviation in the principal component space and residual space respectively.

3. Selection of optimal denoising parameters and its application on an industrial continuous catalytic reforming process

In this chapter, the implement procedures of proposed research on the selection of optimal denoising parameters are introduced with the case study of an industrial continuous catalytic reforming process.

3.1. Continuous catalytic reforming process and data description

The proposed Shannon entropy-based denoising strategy is applied to an industrial continuous reforming process, which contains four reactors, four furnaces and a plate heat exchanger. The pressure drop of the plate heat exchanger is of great importance because it will increase with various factors, such as environment temperature and equipment factors. However, the increase in the pressure drop is usually a process of slow change, and is difficult to be detected in time by operators. Therefore, it is necessary to build an effective process monitoring model in this process to detect the faulty deviation at its early stage. The process variables applied in this work are shown in Table 1.

Table 1 Process variables in the industrial continuous catalytic reforming process.

Variable	Description	Variable	Description
T01	Outlet temperature at cold side	PD10	Outlet pressure at cold side
T02	Inlet temperature at hot side	PD11	Pressure drop at hot side
T03	Inlet temperature at cold side	PD12	Pressure drop at cold side
T04	Outlet temperature at hot side	PD13~16	Reactor pressure drop 1
F05	Naphtha feed flow	T17~20	Furnace outlet temperature
F06	Circulating hydrogen flow	T21~24	Reactor outlet temperature
PD07	Inlet filter pressure drop at cold side	T25~28	Furnace temperature drop
PD08	Inlet pressure at cold side	PD29	Reactor inlet pressure
P09	Circulating hydrogen pressure		

3.2. Determination of the optimal denoising parameters

In this section, the selection of denoising parameters in wavelet denoising, containing mother wavelets, decomposition levels, thresholds and thresholding rules are introduced. In most existing denoising methods, all process variables are denoised under a same standard, which is called identical denoising in this work. A widely-used mother wavelet 'db4' is chosen and a decomposition level is selected properly according to the length of data. After decomposition, threshold for each layer is determined with a universal fixed threshold method. As for the thresholding rule, it has been proved that noise can be separated effectively from signal with soft threshold rule. However, considering noise content in different measurements, a novel Shannon entropy-based denoising strategy is applied to the industrial continuous reforming process. With the adjustment of mother wavelets and decomposition levels, the wavelet coefficients at different denoising depths are obtained. Then the fixed threshold and soft threshold rule are chosen for coefficient processing. Based on the processed coefficients, the signal entropy and noise entropy under different denoising parameters can be calculated. On this basis, the optimal mother wavelets and decomposition levels for different measurements can be found according to the criterion of maximum information entropy.

3.3. Process monitoring method based on new Shannon entropy denoising

A Shannon entropy-based denoising method and principal component analysis method are combined for process monitoring on an industrial continuous catalytic reforming process. The detailed flowchart of the monitoring process is shown in Figure 1. Historical data under normal operating conditions is selected for denoising. The optimal wavelet parameters suitable for the data set are determined according to the maximum information entropy criterion. Then the denoised historical data are input into the raw PCA model for

training. For the processing of real-time data, the previous denoising parameters are applied for its denoising. Then the denoised real-time data is input into the trained PCA model for testing. On the basis of this, the final monitoring results are obtained.

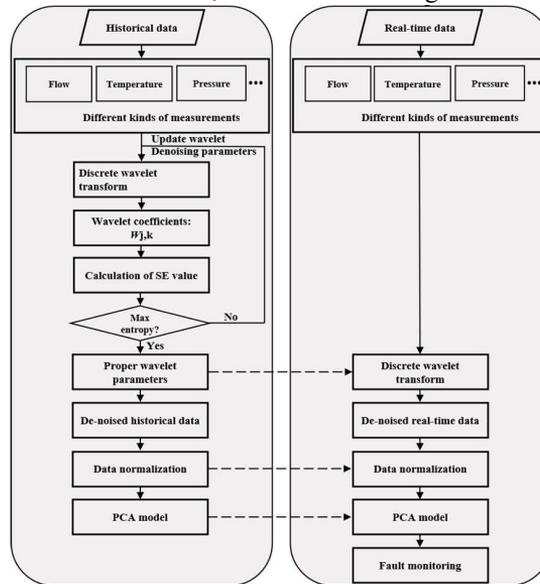

Figure 1 The detailed flowchart of the monitoring process.

4. Results and discussion

On the basis of wavelet threshold method, signals from an industrial continuous catalytic reforming process are denoised. Signal distribution of pressure variable PD07 before and after denoising is shown in Figure 2 and it can be seen that wavelet threshold method is effective for signal denoising. Three different measurements including temperature variable, flow variable and pressure variable are respectively denoised based on the maximum information entropy criterion. After normalization, the noise distribution of the variables in the time domain is shown in Figure 3. It can be seen that the noise extracted from the raw measurements conforms to the zero-mean distribution. More importantly, the result shows a higher degree of noise pollution in the pressure and flow measurement compared with the temperature measurement. Therefore, it's necessary to determine optimal denoising parameters for different measurements.

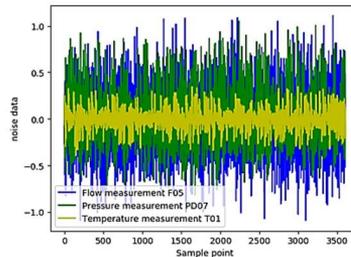

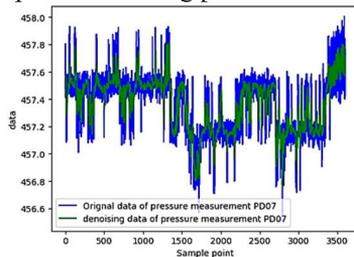

Figure 2 Signals before and after denoising Figure 3 Noise distributions of three measurements

Both historical data and real-time data are input into the PCA model in the form of a 400-length sliding window for process monitoring. The parameters of identical denoising are

introduced in Section 3.2. In separate denoising, mother wavelets and decomposition layers are determined by the maximum information entropy criterion. The parameters for temperature measurements are SYM4, 4 layers while a higher decomposition scale is recommended in pressure and flow measurements for their higher noise contents, which are SYM4, 6 and SYM8, 6. Then monitoring results based on the raw, identical denoised and respective denoised data are compared. Due to page limitations, the monitoring results without denoising have not been displayed. Based on the monitoring model constructed from raw data, the slowly changing fault can be identified at 471th sample. As is shown in Figure 4 and Figure 5, the control limit of the statistics based on the identical denoising method is exceeded at 252nd sample while the respective denoising one exceeded at 236th sample. Compared with the identical denoising method, the slowly changing fault can be detected 16 minutes earlier by the proposed method.

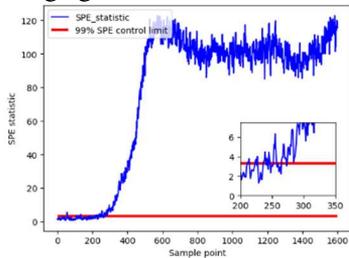

Figure 4 Result for identical denoising

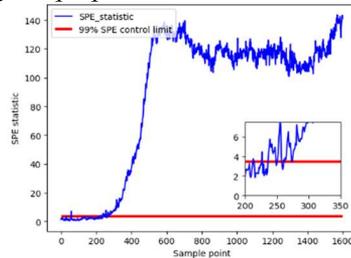

Figure 5 Result for respective denoising

5. Conclusions

In this work, a novel wavelet denoising strategy for industrial process data is proposed and applied to process monitoring with PCA. By considering the difference in noise distribution and contents of various types of variables, signal in each measurement is processed by wavelet transform individually according to its optimal decomposition scale, which is determined by information entropy maximization. Since each type of signal has been denoised to an optimal level, the signal feature could be effectively extracted by PCA, leading to a better process monitoring result. The method is applied to an industrial continuous catalytic reforming process, the slowly changing fault can be earlier detected by the proposed method compared with other methods without considering the denoising of different variables respectively. Compared with other studies with undifferentiated denoising, the determination of optimal denoising parameters on different measurements is discussed in detail in this work, which can provide a novel idea for the selection of denoising parameters in industrial practice.

Abstract

As a representation of the difference between observed and expected behaviors, residual has been widely used in monitoring methods based on the mechanism models, but the accurate mechanism models of certain complex processes are hard to obtain. With the rapid development of artificial intelligence, the accuracy of data-driven prediction models has been significantly improved, which makes it possible to reflect a certain status of the process by data-driven models instead of mechanism models. The residuals between status estimations from data-driven models and observations can be calculated to indicate status changes in the process. Therefore, residual-based multivariate statistical models are established for faults detection. Quite a few data-driven monitoring methods based on predicted residuals have been proposed. However, the influence of different prediction models on prediction residuals and monitoring performance hasn't been fully discussed. Referring to the above issue, various data-driven prediction models including PLS, SVM, and LSTM are applied in the Tennessee Eastman (TE) process and a real industrial case to study the influence of prediction models, evaluation indicators, distribution of prediction residuals on monitoring performance. A statistical analysis on corresponding residuals is also conducted to investigate its impact to monitoring performance.

Keywords: Multivariate linear regression, Time series modelling by LSTM, SVM (Support Vector Machine), Selection strategy of prediction models, Statistical feature of residuals

1. Introduction

Most modern chemical processes are known with large-scale, and highly complex with multiple variables (Nor, Hassan, & Hussain, 2020), which leads to the rapid growing need of process safety and reliability. To fulfill this need, process monitoring gains more and more attention recently. Many process monitoring methods have been proposed, which can be basically classified into mechanism model-based methods and data-driven methods.

An important step of mechanism model-based methods is to generate residual between measurements and estimations, and residuals are further evaluated to detect changes in their behavior caused by faults. However, the performance of mechanism model-based methods is limited by the accuracy of the model especially for certain complex processes whose mechanistic model are hard to obtain. Nowadays, data-driven methods, which solely rely on the data, are developed due to the widespread application of the instruments and distribution control system. Instead of mechanism model-based methods, data-driven

methods are introduced to reflect a certain status of the process for residual generation. Residuals obtained under normal operating conditions can be approximately considered as noise. Furthermore, the monitoring based on residuals variety can avoid the influence of data fluctuation and noise to achieve the early faults detection.

Various data-driven methods are introduced to generate residuals, which are further integrated into the residual-based process monitoring methods for better monitoring performance. Tong et.al proposed a data-driven residual generation method based on PLS for process monitoring(Tong, Lan, Yu, & Peng, 2019) to present more efficient fault detectability. Kazemi et.al used the estimated residual signal to univariate statistical control charts by developing SVM models (Kazemi, Giralt, Bengoa, Steyer, & Technology, 2020). Tao et.al proposed a LSTM-residual model on the MIT-BIH arrhythmia database to detect arrhythmia (Tao, Liu, & Liang, 2021). In the above researches, residuals are generated by linear, nonlinear and dynamic nonlinear models with the consideration of process characteristic.

Inspired by the above researches, the influence of prediction models, evaluation indicators, distribution of prediction residuals on monitoring performance are discussed in this study, where PLS, SVM and LSTM are selected as prediction models, PCA is selected as the monitoring model.

The rest of paper is organized as follows. The related methods are briefly reviewed in section2. Section 3 presents the residual-based monitoring method. The Comparison results of the Tennessee Eastman process and a real case are discussed in section 4. section 5 gives the conclusion.

2. Preliminary

In this section, the methods applied in this work are introduced.

2.1. Partial least squares regression (PLS)

Partial least squares regression (PLS) is a well-known linear prediction method by modeling latent relations between input and output variables. It was introduced by the Swedish statistician Herman O. A. Wold to predict dependent variables form independent variables and to describe the common structure underlying the two variables. As a linear method, PLS is a suitable choice for datasets that do not fit the traditional expectations demanded by ordinary regression(Pirouz, 2006).

2.2. Support vector machine (SVM)

Support vector machine (SVM) is a supervised learning model with associated learning algorithms that analyze data for prediction and classification analysis. It is developed at AT&T Bell laboratories by Vladimir Vapnik with colleagues. It can be used in regression to achieve multivariate pattern regression analysis with excellent generalization capability and high prediction accuracy(Awad & Khanna, 2015).

2.3. Long Short-Term Memory Network (LSTM)

LSTM is a deep neural network to capture the historical information of time series, and it is suitable for the prediction of long-term nonlinear series(Hochreiter & Schmidhuber, 1997). The prediction model established by LSTM can extract the nonlinear and dynamic characteristics of process data to achieve satisfactory prediction performance.

2.4. Principal components analysis (PCA)

PCA is a dimensionality reduction technology widely used in pattern recognition, image processing and feature extraction(Pearson, magazine, & science, 1901). For the purpose of process monitoring, Hotelling T^2 statistics and squared prediction error (SPE)

statistics are introduced to monitor the variation of feature space and residual space respectively.

3. Establishment of residual-based monitoring models

The residual-based monitoring method is employed to get the approximation of the local process state through prediction models, then the multivariate statistical methods are used to monitor the change of the prediction residual to achieve the early detection of faults. The complete procedure of residual-based monitoring method is presented as Figure 1.

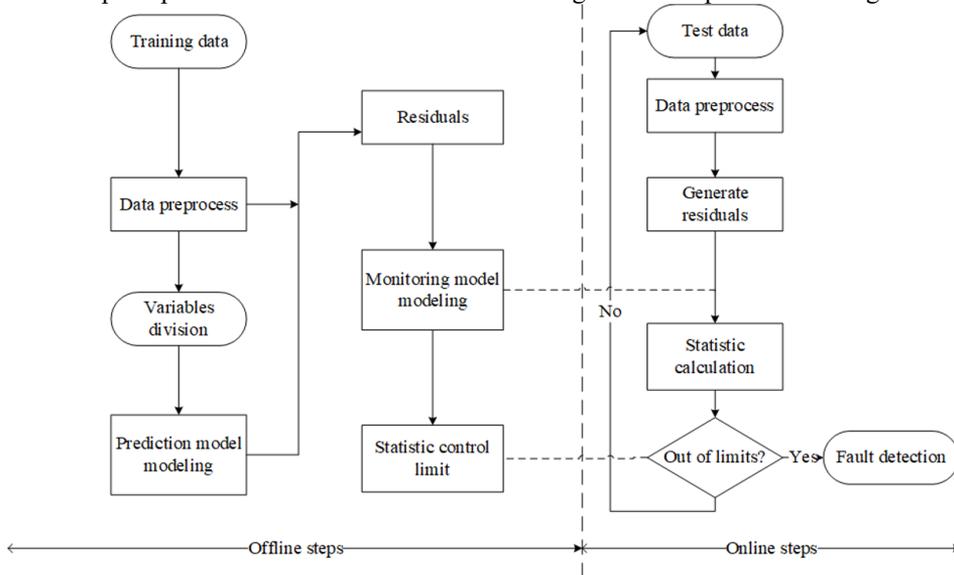

Figure 1. The detailed flowchart of the monitoring process

4. Case study

In this section, three representative prediction models are used for generating residuals, and PCA is used for residual monitoring for a fair comparison of monitoring performance. PLS-PCA, SVM-PCA and LSTM-PCA are applied in TE process and an industrial case to compare the influence of different prediction models on the performance of residual-based process monitoring methods.

4.1. Tennessee Eastman process (TE) process

Tennessee Eastman (TE) process proposed by Eastman Chemical Company is a widely used benchmark test based on a real industrial process for process monitoring. There are 33 measurement variables and 21 faults in TE process. The technological process of the TE simulation process can be briefly introduced as: the reaction raw materials A, C, D, and E are input into the reactor in gaseous form, and the main products G and H of the process are generated under the action of the catalyst. In addition, the process will produce by-products, namely by-product F.

In this case, 960 sample points are selected to establish residual-based model. It is divided into three parts: 500 sample points as training data for prediction model, 100 sample points as verifying data for prediction model and 360 sample points as training data for the monitoring model. Fault 3, fault 5 and fault 15 are hard to detect due to other

researcher's study, so 18 faults are used as testing data for the monitoring model (Chiang, Russell, & Braatz, 2000).

Table 1. Alarm point, FDR (%) and FAR (%) of 19 Faults in the TE process

Fault No.	Alarm point			FDR			FAR		
	PLS-PCA	SVM-PCA	LSTM-PCA	PLS-PCA	SVM-PCA	LSTM-PCA	PLS-PCA	SVM-PCA	LSTM-PCA
1	165	165	170	99.75	99.5	99.13	0.625	0.625	1.25
2	204	191	180	95.13	96.5	98.38	0.00	0.00	5.00
4	161	161	201	100.00	100.00	56.75	0.00	0.63	20.00
5	161	162	176	100.00	99.88	61.13	0.00	0.63	20.00
6	161	161	200	100.00	100.00	99.88	0.00	0.00	23.13
7	161	161	164	100.00	100.00	99.88	0.00	0.00	21.88
8	180	183	180	94.88	96.63	98.25	0.00	0.63	42.50
10	183	185	171	80.88	81.13	76.88	0.00	0.00	15.63
11	169	169	193	64.00	66.25	56.38	0.00	0.00	20.63
12	162	163	190	99.38	99.63	95.75	0.00	0.00	36.88
13	203	201	215	95.13	95.25	97.13	0.00	0.00	5.63
14	162	162	-	99.88	99.88	40.75	0.00	0.00	26.25
16	169	167	175	86.75	86.00	70.63	0.00	0.63	51.88
17	182	182	211	95.88	96.25	61.25	0.63	0.00	62.50
18	244	244	265	89.75	89.75	88.13	0.00	0.63	43.13
19	171	171	327	85.00	84.75	53.63	0.00	0.00	28.13
20	225	225	240	90.63	77.375	85.38	0.00	0.00	28.75
21	618	649	684	44.25	39.13	78.50	0.63	1.25	52.50
Average	-	-	-	90.06	89.33	78.76	0.10	0.28	28.09

As shown in Table 1, it is a comparison of fault alarm points, fault detection rate (FDR) and false alarm rate (FAR) of three residual-based process monitoring methods. It can be seen from Table 1 that for most faults, the monitoring performance of PLS-PCA and SVM-PCA algorithms is better than that of LSTM-PCA. Among them, the PLS-PCA algorithm has the highest average FDR for 18 faults and the lowest false alarm rate.

In residual generation part, the prediction errors of 28 variables can be obtained through their corresponding regression models. The average root-mean-square error (RMSE) of PLS, SVM and LSTM for these 28 variables are 0.465, 0.466 and 0.035, respectively. Among them, the average RMSE of LSTM is the lowest, however, the monitoring performance of residual-based LSTM-PCA model is not the best. This indicates that when the prediction model is only selected by lowest prediction error, the performance of the monitoring model is not necessarily the best.

When the process is under normal conditions, the prediction model residuals should be the noise in data, which should conform to the normal distribution. Quantile-Quantile plot is a method to compare two probability distributions by plotting their quantiles against

each other(Huang, Qiao, Liu, Liu, & Dai, 2019). Through the analysis for residuals of all variables, it shows that the probability of most residuals obtained from PLS and SVM consisting with the normal distribution is higher than the probability of residuals obtained from LSTM. Taking the variable stripper underflow (stream 11) as an example, as shown in Figure 2 (the Q-Q plots), compared to residuals from LSTM, points of residuals obtained from PLS and SVM are closer to the diagonal, which illustrates that the prediction residuals from PLS and SVM is more consistent with normal distribution.

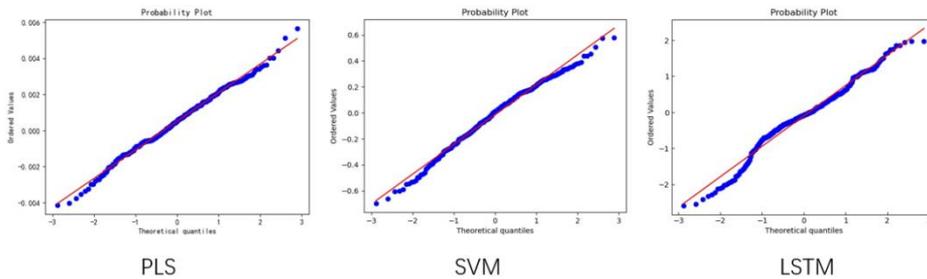

Figure 2. The Quantile-Quantile plots of the regression model in TE process

4.2. Industrial case

Data from continuous catalytic reforming unit are utilized to further illustrate the relationship between prediction model residuals and monitoring performance. In this case, 4000 sample points are selected to establish residual-based model. It is divided into three parts: 2000 sample points as training data for prediction model, 1000 sample points as verifying data for prediction model and 1000 sample points as testing data for prediction model. 2500 fault points, including a reactor temperature abnormal change, are collected as testing data for the comparison of monitoring performance.

Table 2. Alarm point in the industrial case

Methods	PLS	SVM	LSTM
Alarm point	204	191	210

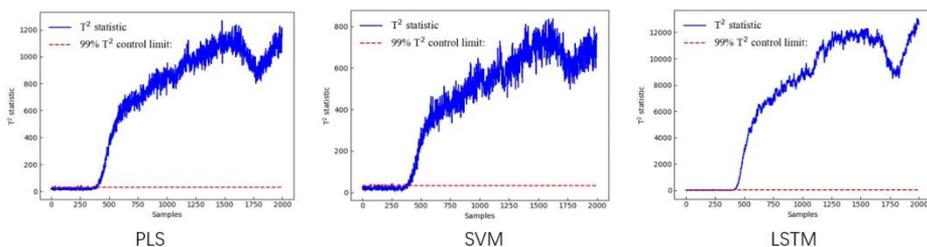

Figure 3. Monitoring results in the industrial case

As shown in Table 2 and Figure 3, it is a comparison of fault alarm points of three residual-based process monitoring methods. It can be found that SVM-PCA detects this fault at 191th sample which has a significantly earlier alarming time compared with PLS-PCA and LSTM-PCA.

Taking the cold-end outlet temperature of heat exchange as an example, as shown in Figure 4, compared to PLS and LSTM, points of residuals obtained from SVM are closer to the diagonal, which illustrates that the prediction residuals from SVM is more consistent with normal distribution.

The analysis results of two cases above states that: (1) The prediction error of the prediction model isn't the dominant factor in determining the monitoring performance, and the prediction model with the lowest prediction errors can't achieve best monitoring performance necessarily; (2) Through the research on the residual distribution of three representative prediction methods, the consistency of the residual distribution and the normal distribution has a certain corresponding relationship with the monitoring performance, which could be a factor to select the prediction model for residual-based monitoring method.

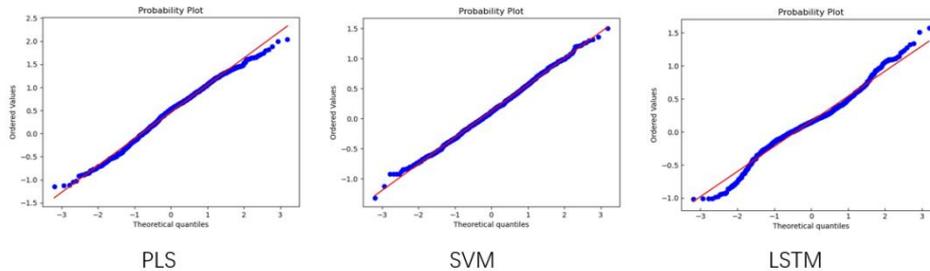

Figure 4. The Quantile-Quantile plots of the regression model in the industrial case

5. Conclusions

The influence of prediction models, evaluation indicators, distribution of prediction residuals on monitoring performance are discussed in this paper. Through the comparison of these three models, it can be seen that in addition to the traditional evaluation indicators, whether the residuals are normally distributed is also important indicators that affect the monitoring performance. The above factor should be considered in the selection and establishment of the prediction model for the residual-based monitoring method.

Abstract

Bioprocess development is commonly characterized by long development times, especially in the early screening phase. After promising candidates have been pre-selected in screening campaigns, an optimal operating strategy has to be found and verified under conditions similar to production. In view of the large number of strains and the process conditions to be tested, high-throughput cultivation systems provide an essential tool to sample the large design space in short time. Furthermore, cultivating cells with pulse-based feeding and thus exposing them to oscillating feast and famine phases has shown to be a powerful approach to study microorganisms closer to industrial bioreactor conditions. We have recently presented a comprehensive platform, consisting of two liquid handling stations coupled with a model-based experimental design and operation framework to increase the efficiency in High Throughput bioprocess development. Using calibrated macro-kinetic growth models, the platform has been successfully used for the development of scale-down fed-batch cultivations in parallel mini-bioreactor systems. However, it has also been shown that parametric uncertainties in the models can significantly affect the prediction accuracy and thus the reliability of optimized cultivation strategies. To tackle this issue, we implemented a multi-stage Model Predictive Control (MPC) strategy to fulfill the experimental objectives under tight constraints despite the uncertainty in the parameters and the measurements. Dealing with uncertainties in the parameters is of major importance, since constraint violation would easily occur otherwise, which in turn could have adverse effects on the quality of the heterologous protein produced. Using the feedback information gained through the evolution along the tree, the control approach is significantly more robust than standard MPC approaches without being overly conservative. We show in this study that the application of multi-stage MPC can increase the number of successful experiments, by applying this methodology to a mini-bioreactor cultivation operated in parallel.

Keywords: high-throughput, model-predictive control, scale-down, multi-stage

1. Introduction

1.1. High-throughput bioprocess development

The development of a process in biotechnology is enormously time-consuming. Not only does it take a long time to find a suitable strain from a huge collection of strains, but the identification of optimal process conditions for this strain also takes a lot of time and resources. Especially due to the increased demand for resource-saving and environmentally friendly bioproducts, the requirements for faster process development are also increasing. Miniaturization and parallelization are two recent technologies that can accelerate throughput in screening processes and process development (Hemmerich et al., 2018). In particular, the use of liquid handling stations and the application of computer-aided and model-based methods could make a decisive contribution to holistic and faster process development (Hans et al., 2020). These methods have already been used for optimal experimental re-design as well as process insights and faster strain phenotyping (Anane et al., 2019).

1.2. Implications of MPC for optimal automated bioprocess development

Fed-batch is still the most widely used process strategy in bioprocessing. Here, the change of the feeding rate plays an important role. Classically, feeding sequences after the batch phase follow an exponential course, based on a previously defined growth rate. However, it can easily happen that the selected growth rate is either too low and thus the process takes a long time to reach a certain cell density or that the feeding rate was selected too high and oxygen limitation can occur. This is a problem for various processes, as it causes unwanted stress reactions and can significantly influence the yield (Baez & Shiloach, 2014). Model predictive control is a method that has been widely used in the chemical industry and has also shown good success in several simulation studies in bioprocess engineering but has had little application in real experiments (Rathore et al., 2021). This is mainly due to the fact that good estimates for the underlying parameters must be available for the model and that the inherent system dynamics in microbial cultivations with e.g. *E. coli* are much different compared to other cultivation systems like mammalian cell cultures. Finding good values for this is often time consuming and the values are subject to large uncertainties. We show here our implementation of a combination of moving horizon estimation for parameter estimation and multi-stage model predictive control. This strategy provides rough estimates for the parameters for new strains where no information is available in a short time, and multi-stage MPC is then used to compute an optimal feeding regime while explicitly taking into account the uncertainty of such parameters. As more information, in the form of measurements, is gathered, the parameter estimation can be improved and the multi-stage MPC can include this information online to improve the performance while ensuring robust process control and avoiding oxygen limitation. Since the dissolved oxygen tension (DOT) is measured with a first order delay, it is not possible to control the process optimally by means of a PID controller, since the violation of the constraint always occurs after a glucose pulse has been added. In this respect, a model-based control with prediction of whether a selected pulse satisfies the constraint is necessary. This is another reason to take the uncertainties of the parameter values into account, as this approach has proven to be significantly more robust than previous approaches (Lucia et al., 2013). By using our fully automated liquid handling station, we can quickly take many measurements to adapt our model well to the new strain and at the same time use the outputs of the MPC to optimally adjust the process online.

The multi-stage approach in particular makes it possible to still ensure robust process control even with inaccurate estimated values for the parameters.

2. Material and Methods

Initial testing experiments for the parameter estimation were conducted on our high-throughput bioprocess development platform, although the actual multi-stage experiments were performed *in silico*. The platform comprises two liquid handling stations (Freedom Evo 200, Tecan, Switzerland; Microlab Star, Hamilton, Switzerland), a mini bioreactor system (48 BioReactor, 2mag AG, Munich, Germany) and a Synergy MX microwell plate reader (BioTek Instruments GmbH, Bad Friedrichshall, Germany). With this setup, the platform is capable to perform up to 48 cultivations in parallel. DOT and pH are measured online, while the concentrations of the other state variables, i.e. glucose, acetate and biomass were measured at-line using enzymatic kits. The reader is referred to (Haby et al., 2019) for a detailed description of the facility and sampling procedure. The multi-rate sampling frequency of the different states poses another challenge for the optimization, as DOT is measured every 60 s, while the other state variables are only measured every 20 min.

The MHE part for parameter and initial state estimation can be generally formulated according to (1), subject to (2).

$$\min_{\theta, x_{0,r}} \frac{1}{2} \|x_{0,r} - x_{0,r,old}\|_{W_x}^2 + \frac{1}{2} \|\theta - \theta_{old}\|_{W_p}^2 + \sum_{k=0}^{N_{MHE}} \frac{1}{2} \|h(x_r(t), u_r(t), \theta) - y_{meas}(t)\|_{W_y}^2 \quad (1)$$

$$\text{s.t.} \\ \dot{x}_r(t) = f(x_r(t), u_r(t), \theta) \\ \theta_{min} \leq \theta \leq \theta_{max} \quad (2)$$

The estimate for the states at the initial point of the window are then denoted by $x_{0,r,old}$, the current parameter vector θ , the parameter vector from the previous horizon θ_{old} . The squared norm is applied to all calculations and the optimizer tries to minimize the deviations over the time window of length N_{MHE} of the measurements y_{meas} and the predicted outputs $h(x_r(t), u_r(t), \theta)$, considering the inputs $u_r(t)$ and current parameter vector. Each norm is further weighted by the factors W_x, W_p, W_y .

The optimization problem that is solved to compute the optimal inputs via MPC is:

$$\min_{u_r} -W_M X_r(t + N_{MPC}\Delta t) - W_L \sum_{k=0}^{N_{MPC}-1} X_r(t + k\Delta t) \quad (3)$$

$$\text{s.t.} \\ \dot{x}_r(t) = f(x_r(t), u_r(t), \hat{\theta}) \\ x_r(t_0) = \hat{x}_{0,r} \quad (4)$$

$$\text{DOT}_r(t) \geq 20\%, \quad u_r(t) \geq 3\mu\text{L}$$

Where W_v and W_L denote the weightings for the terminal- and the stage-cost, respectively. The goal was to maximize the biomass X_r in the shortest time while at the same time avoiding oxygen limitation, i.e. having a level of at least 20% dissolved oxygen in the medium. The macro-kinetic growth model used in this study hence consists of 6 ordinary differential equations (ODEs) including the measured oxygen as well as an

algebraic equation describing the actual oxygen, forming a system of differential-algebraic equations.

The problem was solved using the do-mpc software which utilizes orthogonal collocation on finite elements to discretize the system, which can then be solved using NLP optimizers (Lucia et al., 2017). One main challenge when operating this system is the non-continuous property of the inputs. Since glucose feeding is bolus-like, concentrations and volumes are changed at discrete time points. To deal with this, mass balances must be solved for the respective pulse additions, and it is mathematically more difficult to solve the system. The reader is referred to (Kim et al., 2021) for an in depth description of the underlying model and description of the optimization process. To consider the uncertainties in the parameters, a scenario tree is built. Here, each branch of the tree represents a possible combination of the uncertain parameter combinations. At each node, the optimization problem is solved again considering the current parameter uncertainty and an optimal trajectory is identified. When the parameter uncertainty is large, this approach yields much better constraint satisfaction than nominal MPC approaches. In this contribution, we tested the multi-stage approach to consider the uncertainties for a prediction horizon of 180 min and a robust control horizon of 10 min.

3. Results and discussion

Based on our previous work, where we showed the advantage of using MPC to obtain higher biomass while avoiding oxygen limitation compared to a predefined feeding regime (Krausch et al., 2020), we extended our work to account for the uncertainties in the parameters. Compared to the nominal MPC, multi-stage MPC offers the opportunity to consider the inherent uncertainties of the model parameters to be more robust. This is especially important to ensure that the defined constraints are not violated. Especially for processes with a large uncertainty in the parameters or difficult to predict dynamics, this offers a much better possibility of process control. In this setup, the framework was used to consider the uncertainties of three important model parameters, namely the maximum substrate uptake rate $q_{S,max}$, the yield coefficient of biomass per substrate excluding maintenance $Y_{XS,em}$ and the volumetric oxygen transfer coefficient $k_L a$. All these parameters can affect the oxygen consumption and hence easily lead to constraint violation. Choosing the right parameters in the scenario tree could be supported by using a subset selection method with sensitivity analysis or further data-driven approaches like PCA (Thombre et al., 2019). Many studies have shown the advantage of advanced control methods such as MPC, but have mainly been studying the nominal case for optimization (Chang et al., 2016; Ulonska et al., 2018). As depicted in Figure 1, the multi-stage MPC calculates a lower feeding rate compared to the nominal MPC, since it considers the uncertainties in the parameters. The nominal MPC can actually only ensure that the constraints are not violated if the parameters are well estimated and have very low uncertainty. The multi-stage approach, on the other hand, can identify an optimal feeding regime and account for the strength of uncertainties via a feedback loop. This is particularly advantageous for processes about which little information and measurement data are available like in early screening of new strains and therefore the parameter uncertainties are correspondingly large. Accordingly, taking these uncertainties into account leads to a lower feeding behavior in contrast to the nominal MPC, but to a much more robust process behavior. In particular, the system can react quickly in an unpredictable manner if the constraint is violated, since oxygen limitation also has a

strong influence on the expression of numerous genes and thus could strongly change the dynamics of the system.

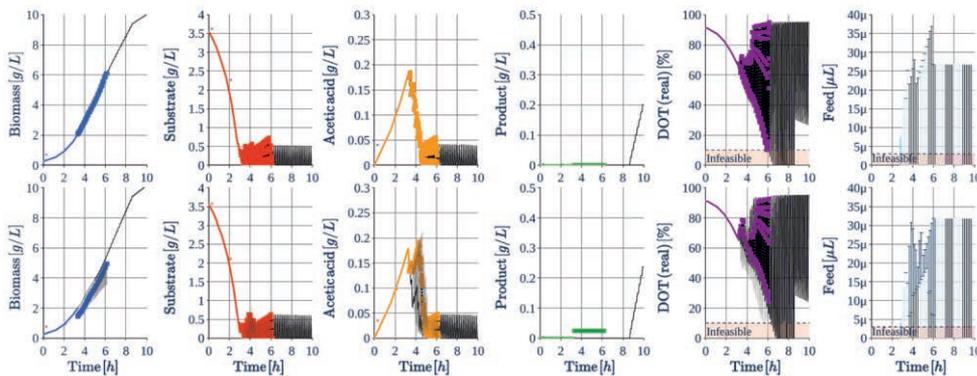

Figure 1: Comparison of nominal (upper) and multi-stage (lower) MPC at 3 h. The multi-stage approach guarantees constraint satisfaction even when the uncertainties are considered. Uncertainties for the DOT and feed are shown as shaded plots and error bars, respectively.

4. Conclusion and outlook

In this study, we have shown that a robust multi-stage MPC approach that takes into account the uncertainties in the parameters is even better than a nominal MPC. Violation of the constraint is a problem for many bioprocesses and there are various approaches to control bioprocesses. With the predictive approach, the constraints can be met well before they are violated, and the process can be guided to its optimum, so constraints are satisfied even in case of high uncertain parameters. However, the computational effort increases significantly with the number of parameters and the underlying uncertainties, so careful consideration must be given to which parameters the uncertainties should be considered for. Future work will need to deal with this problem by being more flexible in terms of what parameter uncertainties are considered and how large the prediction horizon should be, since the problem size is growing exponentially with a larger robust horizon or number of uncertain parameters to account for. Another aspect is to represent the product formation with the help of data-driven models, so that the process can also be optimized in this respect.

Abstract

Dynamic Micro/Ultra-filtration technology has shown to be an intensified process able to provide improved selectivity and/or throughput required in challenging separations. However, there is a trade-off between operating conditions to achieve optimal operation which is time-variant and difficult to estimate. Herein, a platform for online system identification is built for a dynamic ultrafiltration system, where the Forgetting Factor Recursive Least Squared (FFRLS) method is investigated to describe transmembrane evolution at constant flux operation for a real wastewater pilot plant. The model predictions have around 4% average error, predicting relatively fast and slow system dynamics. Therefore, the model has a good permeability estimation useful to determine the membrane fouling rate in real-time.

Keywords: Online system identification, ARX model, Dynamic ultrafiltration, Membrane fouling rate modelling.

1. Introduction

Ultra and Micro-filtration are mature separation technologies widely used in water treatment, food, beverage, pharmaceutical and biotechnological industries. Membrane filtration processes have shown remarkable performance in terms of selectivity, throughput, low footprint and system modularity, operation at mild conditions, low chemical consumption, and relatively simple operation and automation. However, filtration technology is challenged to guarantee optimal stable operation under unmeasured high-variance inlet disturbances, which highly influence the system performance. The reason is two time-variant coupled phenomena referred to as concentration polarization and membrane fouling, which promote decay in the separation performance in terms of selectivity and/or throughput. To recover system performance, physical/chemical cleaning is forced, which substantially affects process operating costs and processing time (Baker, 2012).

To mitigate the adverse effect of concentration polarization and irreversible fouling, the dynamic operation has been proposed instead of conventional crossflow filtration (Prado-Rubio, O.A., 2012). This corresponds to a non-invasive physical technique where a portion of permeate is reversed using a high frequency – short duration backshock. This inverted flux can partially remove membrane fouling and disrupts the boundary layer

adjacent to the membrane surface. The latter avoids a high solute concentration at the membrane surface which reduces membrane rejection (López-Murillo *et al.*, 2021). The intensifying effect of the dynamic membrane operation has been shown in diverse applications, where overall performance can be improved significantly by reverting flux periodically (Prado-Rubio, O.A., 2012; López-Murillo *et al.*, 2021). As a drawback, process intensification can be only accomplished by a specific combination of operating conditions. Those are relatively complex to determine due to the system dynamic and unmeasured disturbances. Thus, to obtain an economically attractive operation scenario, the filtration unit must adapt to the operating conditions relaxing and tightening the driving force along with the operation. As expected, massive experimental work is required to establish a sustainable operation in real industrial conditions and sometimes operating conditions cannot be reliably estimated (Prado-Rubio, O.A., 2012).

Therefore, it is relevant to explore different modelling approaches for dynamic ultrafiltration that allows exploiting PSE tools to improve process design and operation. Recently, we have investigated off-line modelling approaches to describe dynamic membrane filtration, including scheduled linear time-invariant (LTI)-SISO and MISO autoregressive models, neural networks, and hybrid approaches (Prado-Rubio and Huusom, 2015; Prado-Rubio and Von Stosch, 2017; Grisales Díaz *et al.*, 2017). Those approaches have shown to be useful for process design but have limitations for optimal operation/control. Therefore, there is still a need for tools to determine the membrane state during real operation, thus, to have a chance to optimize the relatively high energy demanding system. The purpose of this contribution is to implement and investigate a platform to describe the dynamic filtration system based on online system identification. The platform aims to provide a real-time representation of the dynamic ultrafiltration system, focused on the fouling rate represented by the membrane permeability evolution. For testing, the platform uses a database of experimental data which are provided in real-time, and the Forgetting Factor Recursive Least Squared (FFRLS) method to correlate operating conditions when the system is operated at constant membrane flux. Thus, an estimation of the membrane permeability is performed to indicate the membrane fouling rate. This contribution corresponds to a preliminary effort to investigate the modelling approach for dynamic ultrafiltration which later can be implemented in a pilot plant.

2. Methodology

The platform has been implemented in Matlab® 2019b in three modules. The platform emulates the real system by using a database from experiments of dynamic filtration at field conditions, which have been exported from .txt (raw data from the PLC) to a .mat file. Accounting for the large sequential experiments database, continuous long-term system operation is emulated combining data from different operation scenarios. Within the algorithm, the first step is to pre-process the information for subsequent system identification including a data reconciliation strategy, and emulate real sampling time data access. Finally, the platform uses a custom-made function for Recursive Least Squared parameter estimation with forgetting factor to correlate the membrane flux and the manipulable transmembrane pressure, thus estimating the membrane permeability. Then model quality is determined and subsequently membrane permeability is predicted and analyzed.

2.1. Experimental data – produced water treatment using dynamic ultrafiltration

Produced water is wastewater in the oil and gas industry after most of the crude oil has been separated into an oil field. Produced water is a complex emulsion mainly composed of organic matter, oils, microorganisms, heavy metals, chemicals, salts, dissolved oxygen, among others. Produced water treatment is challenging accounting for the complex mixture and the time-variant nature depending on the oil well maturity and location. Membrane technology has been tested for produced water management since conventional specific gravity-based technologies have difficulties coping with the stricter environmental legislations for water disposal. Dynamic ultrafiltration experiments were performed in a real produced water treatment plant, where effluents from different sections of the processing facility were fed to the membrane system (Prado-Rubio, 2012). The membrane system was operated at constant flux using the step-up/step-down methodology (Beier & Jonsson, 2009). Under this operation strategy, the transmembrane pressure is increased during operation to compensate for the increasing transport resistance due to fouling. The pilot plant records data from flow rates, absolute pressure, and temperature every 3 seconds. Inlet and outlet water quality was characterized offline using spectrophotometry. During the long-term experiments, inlet water varied between $30 < \text{Total Suspended Solids (TSS)} < 100 \text{ mg/l}$ and $3 < \text{Total Hydrocarbons (TH)} < 1200 \text{ mg/l}$. The membrane treatment removed above 96% of TSS and 94% of TH. For this application, a subset of 26 experiments is employed to test the developed tool, those experiments contain approximately 22000 data points for every variable.

2.2. Signal pre-processing

In previous work, a signal processing algorithm has been developed which allows reconstructing frequency and amplitude of the *in-situ* cleaning strategies namely backshock and backflush (Prado-Rubio and Von Stosch, 2017). This was necessary due to the induced signal delays to avoid potential overlapping of both cleaning strategies and fast dynamics of the backshock that cannot be captured by the used sampling time in the PLC. This signal reconstruction algorithm has shown to be useful for off-line system identification and therefore, it is incorporated in the platform. However, the user can define if these reconstructed signals are used for online process identification. Additionally, in this emulated application, the user defines which experiments are used for testing. Taking advantage of the large database, different operation scenarios have been evaluated pilling nonconsecutive experiments to assess the online system identification methodology and predictions. During this investigation, scenarios from single experiments up to 7 pilled experiments were evaluated.

2.3. Online system identification

System identification tools are well-established within process control including offline and online strategies. Forgetting Factor Recursive Least Squared (FFRLS) is the most used method for system parameter identification since it is simple and stable. The forgetting factor adjusts the proportion of old and new data employed so the proportion of old data is reduced when new data is available. This algorithm has a fast convergence to the actual value (Diniz, 2013). FFRLS method is employed to correlate the evolving transmembrane pressure to operate the dynamic filtration unit at constant membrane flux, where the membrane flux is controlled through a PI control. The linear dependency of

both variables is evident in the pore-flow model, where the membrane flux (J) is proportional to the transmembrane pressure (TMP) (Baker, 2012):

$$J = L_p(TMP) \quad (1)$$

The membrane permeability (L_p - L/m² h bar) is expected to decrease during operation due to the increase in transport resistance generated by concentration polarization and fouling. Permeability evolution is a function of the operating conditions such as the inlet concentrations, pH, temperature, ionic strength, membrane, flow rates, pressures, cleaning strategies, among others. Based on the pore-flow model, it is natural to use a simple ARX model to correlate variables. ARX has been applied for offline system identification of this system previously. For preliminary modelling approach assessment, FFRLS has been implemented to estimate the TMP signal as output using the membrane flux as an inlet. In this way, the model can predict the membrane permeability evolution as an indirect indication of the membrane fouling rate.

As inputs, the user defines the model order, and the forgetting factor is a tunable parameter. The implementation was validated using the recent functions included in Matlab® for online system identification. The estimation quality is evaluated against the available experimental data and moving average method.

3. Results

As mentioned previously, different combinations of the experiments were investigated to determine the modelling approach capabilities. As an example, a particular situation is depicted in this contribution: operation under low fouling rate, followed by high fouling rate experiment and returned to low fouling rate operation. This case is particularly interesting since it contains subcritical and supercritical flux operations. Simulations were performed for a sequence of polynomials order (from 1 up to 4) and exploring the influence of the forgetting factor. First, it was evidenced that the online system identification procedure was substantially faster than the sampling time, allowing to have faster sampling time in forthcoming experiments (e.g., every second). Secondly, increasing the order of the polynomials led to a high correlation between parameters without improving the model quality. Therefore, for illustration purposes, first-order models were sufficient to match previously obtained results with higher-order MISO offline system identification (Prado-Rubio and Von Stosch, 2017).

In Figure 2, the quality of the model predictions is depicted. It should be mentioned that the estimation is performed in real-time, thus, the figure is animated. Conventionally, forgetting algorithms have shown to be suitable for tracking slow dynamics while having more difficulties describing fast changes. Interestingly, the online ARX model can reproduce most of the fast behaviour associated with the backshock and backflush, while following the slow dynamics associated with the membrane fouling. This indicates that the identified model has a high degree of experimental data reproduction under different operating strategies. Most of the data have around 4% average prediction error, while there are some points with up to 10%.

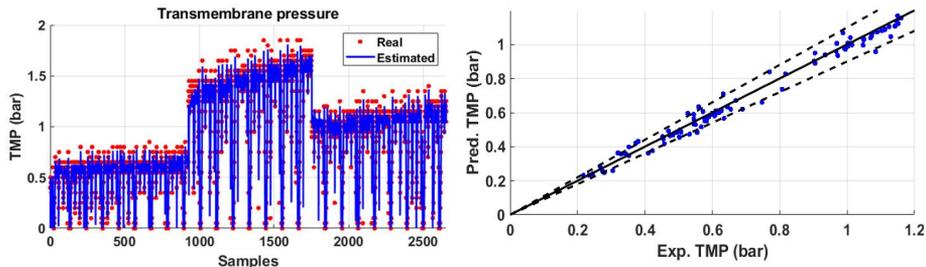

Figure 2. Simulation results of the real experimental data and model predictions. (a) full data set and (b) parity diagram for TMP using moving window average with 20 samples plus $\pm 10\%$ error.

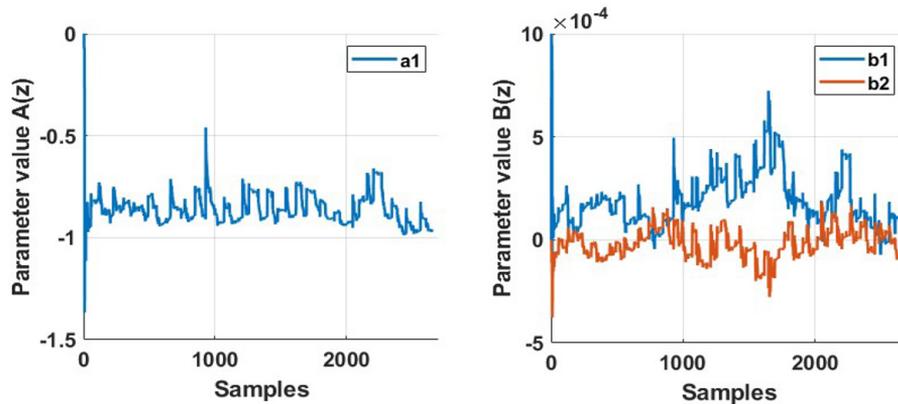

Figure 3. Adaptive parameters evolution to reproduce different fouling rate experiments.

The adaptive evolution of the parameters can be seen in Figure 3, where $A(z)$ and $B(z)$ are the polynomials for the backward shift operator z^{-1} , defining the system transfer function. As expected from the pore-flow model, the changes in the membrane permeability are tracked by B . Despite the lack of interpretability of those parameters, interestingly, $b1$ captures the increase of the fouling rate evidenced in the transmembrane pressure. Besides, the parameter $b2$ might not be entirely necessary, thus it could be omitted, and the system could be represented by even a simpler first-order discrete model.

Finally, Figure 4 depicts the predicted average permeability and the average estimated from the raw data. The online model provides a clearer representation of the membrane permeability, where it is evident the trend which indicates the fouling rate, instead of using the instantaneous estimation based on the raw data. Although *in situ* cleaning was performed, a permeability decrease was observed in all windows studied (at low or high TMP). According to the operation strategy, the controlled operation increases the transmembrane pressure to compensate for the adverse influence of fouling. At low flux operation (subcritical) the TMP increment is tolerable and associated with reversible fouling, increasing the desired flux can generate undesirable irreversible fouling. The threshold between both operation windows is challenging to estimate due to its time-variant nature, but this approach has shown that can estimate the average membrane permeability instead of the instantaneous permeability, which can be used to define an adaptive controller to avoid excessive membrane fouling during operation.

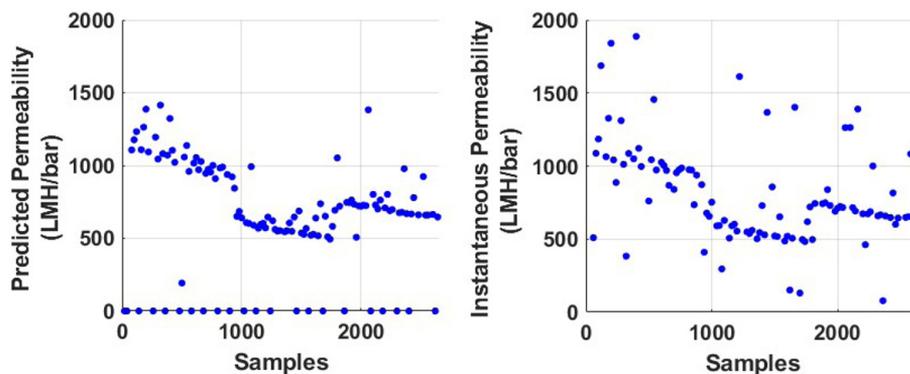

Figure 4. Comparison between predicted average permeability and average instantaneous permeability from raw data

4. Conclusions

Despite the simplicity of dynamic membrane filtration systems, its modelling has shown to be challenging accounting for the time-variant nature of the involved transport phenomena. Herein, a tool for online system identification has been implemented to allow process engineers to investigate dynamic ultrafiltration modelling. This platform is used to predict changes in transmembrane pressure (TMP) with an averaged error lower than 4%. Thus, it provides a better membrane permeability estimation compared to previous efforts with off-line system identification or using raw data to have an instantaneous calculation. This estimation provides an indirect estimate of the membrane fouling rate. These preliminary tests are encouraging to pursue an implementation in a real system to introduce adaptive control actions into the system operation, which will have a significant impact on the operation of membrane-based treatment systems.

Abstract

We report progress of an ongoing work to develop a virtual sensor for flowability, which is a critical tool for enabling real time process monitoring in a granulation line. The sensor is based on camera imaging to measure the size and shape distribution of granules produced by wet granulation. Then, statistical methods were used to correlate them with flowability measurements such as ring shear tests, drained angle of repose, dynamic angle of repose, and tapped density. The virtual sensor addresses the issue with these flowability measurements, which are based on off-line characterization methods that can take hours to perform. With a virtual sensor based on real-time measurement methods, the prediction of granule flowability become faster, allowing for timely decisions regarding process control and the supply chain.

Keywords: virtual sensor, monitoring, flowability, machine learning, size and shape distribution

1. Introduction

The manufacturing of tablets often relies on a granulation step to improve the processability of a pharmaceutical powder blend. By converting them into granules, flowability, tabletability, compressibility, and compactibility can be improved. These properties are considered to be the critical quality attributes (CQA) of the granulation unit; and in a wet granulator, the monitoring of these properties is considered critical. Unfortunately, characterization tests for these CQAs are usually off-line methods that can take hours to measure and require sample reduction procedures that can lead to significant sampling errors. It is thus important to develop faster ways to estimate the CQAs and minimize sampling error.

In a wet granulation platform employing a fluidized bed, it is possible to measure the size and shape distribution of a finished batch of granules as it discharges from the product hopper. If these real-time measurements of size and shape can be used to automatically predict the CQA of the discharging granules, decisions regarding the batch and the process could be made much faster. This time advantage could save future batches from failure, provide valuable information about the raw material, and allow optimization of

the control process parameters of downstream unit operations to match the characteristics of each batch of granules.

Particle size and shape distributions are known to be strong indicators of granule properties, so they have a great potential to be reliable predictors of a granule's CQA's. However, their measurement result in a large number of data points that are difficult to manage and process. In practice, these distributions often get reduced to 1 to 3 D-values (i.e., D10, D50, D90) prior to analysis. There has been demonstrated success in this strategy, but this practice can lead to significant loss of information from the dataset, especially when the distributions have statistical central tendencies that do not fall close to those selected D-values. An ideal solution would be to employ all available information from the size and shape distribution measurements, and then to use an appropriate data reduction technique that maximizes the relevant information from the distribution measurements. By implementing this with an appropriate feature extraction technique, the reduced dataset should maximize correlatability with properties of interest such as flowability.

Aside from the predictor variables (i.e., size and shape distribution), the need for data reduction and feature extraction is also applicable for the predicted variables (i.e., the CQA's), especially for flowability. Since there is no singular measure for it, several methods exist to characterize flowability. Often, the goal in characterization is to select the method with test conditions that can closely match the conditions to which the granules are subjected to during processing. For some applications, a single method might suffice. But if granules will be subjected to tablet pressing, they will be subjected to quasi-static flow conditions in the hopper of the tablet press, as well as dynamic flow conditions inside the feed frame. Hence, several methods are required to ensure that the granules would result in quality tablets. Furthermore, each of these methods produce multiple test result parameters that are highly correlated. This can potentially result into a large dataset that needs to be appropriately reduced to make it more manageable and maximize its predictability with real-time measurements of granule size and shape distributions.

2. Methods

2.1. Data Reduction: Principal Component Analysis (PCA)

PCA is a method that reduces the dimensionality of large datasets while retaining most of its information. This is achieved by taking an orthogonal decomposition of the covariance matrix of process variables along the directions that explain the maximum variation of the data. (Wold *et al.*, 1987) While this method gives the same number of principal components as the original variables in the dataset, it also puts maximum possible variance in the first few principal components, making it possible to drop the rest of the principal components without losing much information. With the appropriate selection of principal components, data analysis and exploration can be performed on lower number of dimensions.

2.2. Latent Variable Regression

2.2.1. Linear Regression: Partial Least Squares (PLS)

With both the predictor and the predicted variables requiring data reduction through PCA, linear regression on their projections to latent spaces can be performed (i.e., projection to their principal components). This process is known as Partial Least Squares, and it is a

widely used technique in areas such as chemometrics bioinformatics, neurosciences, and sensor development, to name a few.(Liu and Chen, 2014)

3. Materials and Equipment

3.1. Granules

The granules used in this study are made with varying compositions of lactose and microcrystalline cellulose as the excipient, acetaminophen (APAP) as the active pharmaceutical ingredient (API), and either hydroxypropyl cellulose (HPC) or polyvinylpyrrolidone as the liquid binder solution. The excipient, API, and binders are prepared in varying compositions and wet granulation process conditions to produce granules with different flowability characteristics. This work studied four types of granules labelled as: HHIU1, HHIU2, HHIU3, and HHIU4.

3.2. Granulation Equipment

The granules are produced by wet granulation using the Xelum platform manufactured by Syntegon. Xelum employs a fluidized bed, where the pharmaceutical powders are automatically dosed and pneumatically charged with the liquid binders that facilitate the formation of granules. Moreover, granulation and drying takes place in the same process chamber, which eliminates the need to transfer wet granulate and improves the system's reliability.

3.3. Size and Shape Distribution Measurement

The size and shape distribution of the granules are measured using Eyecon₂, which is a direct imaging particle analyzer developed by Innopharma Technology. By using a camera to take images of the particles at-line or inline, this tool uses image analysis algorithms to detect particle boundaries and fit an ellipse around them. The ellipse gives a major and a minor diameter, which when averaged gives a third dimension to estimate a 3D volume of the particle using the equation:

$$Volume = \frac{\pi}{6} \times D_{min} \times D_{max} \times D_{ave} \quad \text{Equation 1}$$

Using this volume, an equivalent spherical diameter is computed, and this diameter is the basis for the size distribution reported by Eyecon₂. Size distributions are reported as D-values, which are based on the cumulative size distribution. Reporting distributions in this manner fixes the number of variables for every possible form of size distributions.

The major and minor diameters of each particle are also reflective of its shape, which may be quantified as eccentricity, as shown in the following equation.

$$Eccentricity = \sqrt{1 - \left(\frac{D_{min}}{D_{max}}\right)^2} \quad \text{Equation 2}$$

Eyecon₂ inherently acquires a distribution of eccentricity/shape but reports, by default, the distribution as a mean and relative standard deviation.

3.4. Flowability Measurements

The set of flowability measurements employed in this study covers both quasi-static flow and dynamic flow. Quasi-static flow is characterized by the ring shear tester and partly by tapped density analysis, while dynamic flow is characterized by drained and dynamic angle of repose.

3.4.1. Ring Shear Tester (RST)

The Schulze ring shear tester is an essential tool for hopper design since it is mainly concerned with quasi-static flow. In this technique, powder is loaded normally to a specific bulk density and then sheared until the material begins to flow. Data is collected as yield strength as a function of normal stress. From these measurements, the flow function coefficient can be computed, which may also be referred to as flowability. Additionally, other parameters such as internal friction, wall friction, and bulk density can be determined from the Schulze RST.

3.4.2. Drained Angle of Repose and Jamming Onset

The drained angle of repose is measured using the Flodex™ tool, which essentially measures the ability of a powder to fall freely under gravity through an orifice. Initially, the powder is contained in a hopper with a flow disk at the bottom. The disk has an orifice that can be opened via a discharge valve to start the powder flow. After opening the discharge valve, not all the powder in the hopper would be able to flow out and this residual powder would remain between the edge of the orifice and the hopper walls. The angle between the surface of this residual powder and the orifice disk is called the drained angle of repose and is correlated with the flowability of the powder.

3.4.3. Dynamic Angle of Repose

The dynamic angle of repose is measured using a rotary drum developed by GranuTools called the GranuDrum™. The powder is loaded into a drum that can be rotated at a set rotating speed. As the drum is rotated from rest, the angle of the powder surface increases from horizontal until an avalanche occurs. The angle at which this happens may be referred to as the yield point and is correlated with flowability. Thereafter, the powder surface is maintained at an angle from horizontal, and this is recorded automatically using back-lit cameras as the dynamic angle of repose. As the rotation speed of the drum changes, the dynamic angle of repose also changes, revealing interesting rheological behaviors of powder during flow.

3.4.4. Tapped Density Analyzer

Tapped density analysis is performed by another tool developed by GranuTools called GranuPack™. This tool minimizes operator error during filling and volume measurements using automation and sensor technologies. Powder is loaded onto a cylinder container and its density is monitored as the container is tapped continuously. As the powder is tapped, the density increases until it asymptotically approaches a maximum. The density may be expressed as the Hausner ratio, which is basically the ratio between the tapped density and the poured density. The dynamics of the compaction during tapping is also automatically captured via the parameters characteristic number and tau. The characteristic number is the number of taps at which the density is between between the poured density and the asymptotic density (i.e., density at infinite number of taps), while Tau is another characteristic number extrapolated from an exponential model (Philippe and Bideau 2003) fitted onto the compaction curve.

4. Results and Discussion

4.1. Principal Component Analysis on Size and Shape Distributions

Size and shape distributions measurements can result in at least 24 variables as shown in the x-axis of Figure 1. Applying principal components analysis (PCA) on the dataset reduced the number of variables into just 3 principal components (PC), which can explain up to 97% of the variance in the original dataset.

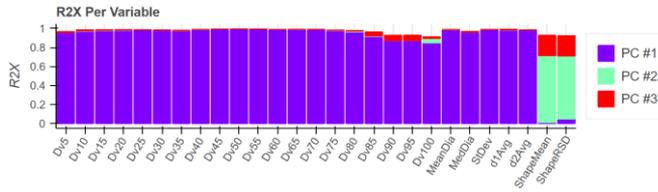

Figure 1. Explained variance per size and shape distribution variable

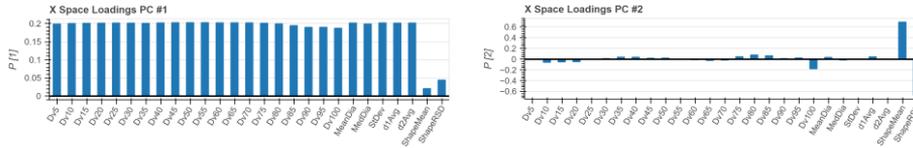

Figure 2. Loadings of size and shape distribution variables on principal component 1 (left figure) and principal component 2 (right figure)

This drastic reduction of variables suggests that many of them are highly correlated, as shown in the loadings plot in Figure 2. This is the case for the size distribution variables, as they dominate influence on the first principal component, which explains 89% of the variation in the original data. On the other hand, shape-related variables (i.e., the shape mean and relative standard deviation) have the strongest influence on the second principal component, supporting the importance of measuring shape distributions, and not just size.

4.2. Predicting Flowability Data

Measurements from the Schulze RST can lead to 9 different parameters (or variables) that are related to flowability. Similar to the Eyecon2 data, most of the variation in these parameters (up to 98%) can be explained by only three principal components. Hence, by applying partial least squares using three principal components onto the Eyecon2 data (as the predictor variables) and the RST data (as the predicted variables), the parity plot of the flow function coefficient (FFC) shown in Figure 3 show good prediction performance. Although not shown, similar performance was also observed for the rest of the variables.

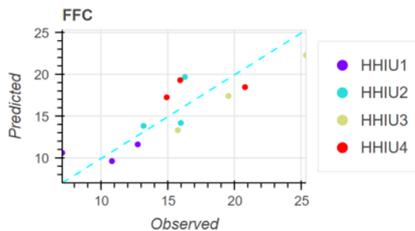

Figure 3. Predicted vs observed flow function coefficients measured from Schulze RST.

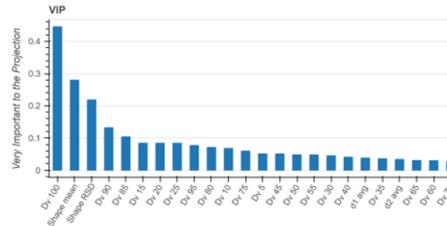

Figure 4. Ranking of variable importance to the PLS projections.

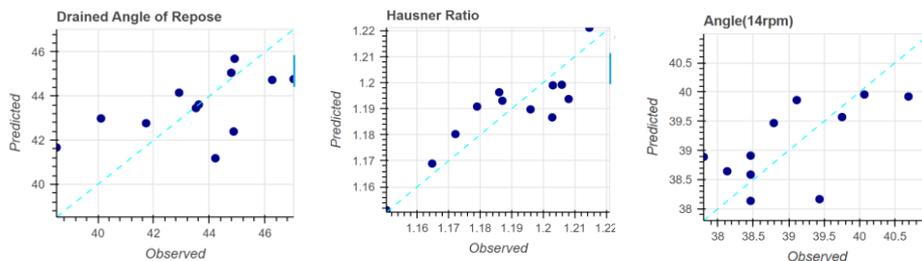

Figure 5. Parity plots for selected dynamic flow test parameters: drained angle of repose (left), Hausner ratio (middle), and dynamic angle of repose (right).

The performance of the PLS model can be attributed to the effectiveness of using all available information instead of selecting some and then ignoring the rest. Figure 4 shows how the larger D-values (e.g., D85, D90, and D100) and the shape parameters contribute the most to the PLS projections and hence its performance. This not only corroborates the importance of measuring shape distributions, but also the folly of selecting certain D-values such as D50, D10, and D90. As shown in Figure 4, those variables are not the most important. Using the aforementioned techniques, similar results were achieved from the dynamic flow tests, as shown in Figure 5 for selected parameters from the Flodex (left figure), GranuDrum (middle figure), and GranuPack (right figure) measurements.

5. Conclusions

Using PLS regression, sensor models were developed to predict flowability measurements based on size and shape distribution of granules, and parity plots show good predictability for all flowability measurements. The importance of shape measurements as well as using the complete size distribution, instead of selecting a few D-values, in the predictive performance was highlighted.

6. Acknowledgements

PCA and PLS computations were performed using the Phi toolbox (github.com/salvadorgarciamunoz/pyphi) for multivariate analysis by Dr. Sal Garcia.

Abstract

Controllers are often tuned during plant commissioning, with a fixed process model. However, over time degradation can occur in the process, the process model and the controller, making it necessary to either re-tune the controller or re-identify the process model. Authors have proposed a variety of approaches to identify plant-model mismatch (PMM) and control performance degradation (CPD). While each approach may have its own advantages and disadvantages, they are generally designed to function on different timescales. The differing timescales result in the need for a multi-level hierarchical approach to monitor, detect, and manage PMM and CPD, as illustrated through a continuous pharmaceutical manufacturing application, i.e., a direct compression tablet manufacturing process. This work also highlights the requirement for index-based metrics, that enable the impact of PMM and CPD to be quantified and assessed from a control performance monitoring perspective, to aid fault diagnosis through root cause analysis to guide maintenance decisions for continuous manufacturing applications.

Keywords: control performance monitoring, plant-model mismatch, nonlinear model predictive control.

1. Introduction

The pharmaceutical manufacturing industry is being pushed to transition from batch to continuous process operation due to potential improvement in process controllability and product quality. Additional factors such as the development cost of new medicines makes it both desirable and feasible to produce smaller annual volumes of targeted dosages for smaller patient populations. Due to stringent regulations placed by regulatory bodies, the development of reliable real-time process monitoring, control and management approaches is of crucial importance, so that deviations in critical material (CMAs) and critical quality attributes (CQAs) can be minimized (Su et al., 2019). These include the need for efficient estimation and control frameworks, and algorithms to monitor these frameworks to identify and quantify plant-model mismatch (PMM) and control performance degradation (CPD). Quantification of PMM and CPD can in turn support higher level fault detection and diagnosis efforts.

Identification and management of PMM and CPD has received significant attention in the control literature. PMM can arise in the continuous manufacture of oral solid dosage for several reasons, e.g., the feeder refill step can introduce disturbances that can affect CMAs such as bulk density (Destro et al., 2021), and this can in turn result in deviations in the CQAs. A minimum variance-based assessment criterion was proposed by (Harris,

1989) to assess the condition of the working control loop but was limited to single-input-single-output (SISO) systems. More recently, partial correlation coefficient (PCC)-based and mutual information (MI)-based approaches were proposed by (Badwe et al., 2009; Chen et al., 2013) to identify PMM: both approaches are well-suited to handle cases where there is high correlation between manipulated variables. Advanced estimation and control strategies such as the moving horizon estimation-based nonlinear model predictive control (MHE-NMPC) framework have also been employed for continuous pharmaceutical manufacturing applications to handle the impact of PMM (Huang et al., 2021). While identification of PMM is important, quantifying the PMM and assessing its impact on control loop behavior will aid higher level decision making related to maintenance and safety. (Wang et al., 2012) proposed a control performance index (CPI) and loop robustness index (LRI), based on the integral absolute error and sensitivity margin to quantify PMM and CPD, respectively. Each of the methods described thus far are computed on different timescales, e.g., LRI requires identification of the transfer functions for the MIMO system and can only be carried out during regularly scheduled maintenance, while MI can be computed more frequently using closed operating data, and the MHE-NMPC framework is designed to operate on a significantly shorter timescale. Therefore, it is important to develop a multi-level hierarchical approach to utilize the quantitative information regarding PMM and CPD from different timescales, that will further support root cause diagnosis efforts and aid higher-level maintenance decisions for continuous pharmaceutical manufacturing applications.

To summarize, since the LRI which is based on the sensitivity margin is limited in applicability to SISO systems, this work seeks to extend its applicability by utilizing the disk margin proposed by (Seiler et al., 2020) for MIMO systems. This work also proposes a multi-level hierarchical framework to handle metrics that quantify PMM and CPD on different timescales to support higher level decision making related to safety and maintenance. Practical applicability will be demonstrated through an illustrative example that focuses on the continuous manufacture of oral solid dosage. The rest of this work is organized as follows. In Section 2, components of the hierarchical framework will be explained. An illustrative example using a rotary tablet press will be presented in Section 3, along with a discussion on the results. Concluding remarks will be presented in Section 4.

2. Methodology

The aim of this work is to propose an approach that enables efficient interpretation and management of quantitative information obtained from different metrics on different timescales to support higher-level fault detection and diagnosis efforts which in turn aid decision making related to maintenance and safety. The Quality-by-Control (QbC) framework proposed by (Su et al., 2019) presents a 3-level hierarchical framework for control that includes equipment-based control at Level 0, process analytical technology (PAT)-based property feedback control at Level 1, and model-based supervisory control at Level 2. This work seeks to demonstrate that the framework can incorporate quantifiable metrics to carry to enable multi-level control performance monitoring. A schematic illustration of the multi-level hierarchical framework is presented in Figure 1. Like the original QbC framework, Level 2 hosts the MHE-NMPC framework where online estimation and control is accomplished. Level 2 operates on the shortest timescale, e.g., in seconds. Metrics such as the integral absolute error (IAE), magnitude-to-product (M2P), and duration-to-reject (D2R) serve as preliminary indicators that monitor the

effectiveness of the framework. This information is utilized to determine if attention need to be paid to the metrics from Level 3. Level 3 operates on a longer timescale, e.g., in minutes or hours depending on process dynamics, where closed loop operating data is utilized to compute the MI and covariance matrix-based indices. The MI index allows the engineer to determine the number of input-output channels affected by PMM and identify these channels. The covariance matrix-based approach proposed by (Yu and Qin, 2008) is utilized to track CPD. If severe deterioration in either metric is identified at Level 3, attention needs to be paid to the metrics from Level 4. LRI for Level 4 can only be computed during scheduled maintenance as it requires the collection of open-loop data to re-identify transfer functions. The CPI for Level 4 also provides information regarding the impact of PMM on control loop behavior and can be used in combination with the LRI to determine the urgency of required maintenance. It should be noted that the proposed hierarchy enables early detection of PMM and CPD through the monitoring of metrics from different levels and time scales. Metrics obtained from all levels can be fed into an analytics platform to aid maintenance decision making and root cause analysis. However, this is out of the scope of the current work as it will require monitoring metrics from other components of the process, e.g., condition of unit operations, to demonstrate the strength of analytics platform, and will be addressed in subsequent work.

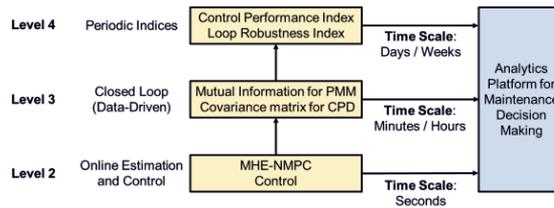

Figure 1. Schematic illustration of multi-level hierarchical framework for control performance monitoring.

3. Case Study

The case study presented in this work utilizes the process model for the rotary tablet press provided by (Huang et al., 2021) as the benchmark. The system consists of five input variables: dosing position (Dose), pre-compression thickness (Ptck), main compression thickness (Mtck), turret speed (Tret), and concentration of glidant (Csil), and four controlled variables: tablet weight (Twei), pre-compression force (Pcom), production rate (Prod), and tensile strength (Tstr). A process schematic listing the unit operations and available PAT measurements is provided in Figure 2. Model parameters for three cases of PMM (no PMM, mild PMM, and high PMM) are provided by (Huang et al., 2021).

3.1. Level 2 Monitoring

Monitoring indices for Level 2 for this case study are available in (Huang et al., 2021), where the ability to distinguish between high PMM and the other two cases was demonstrated. However, due to the effectiveness of the MHE-NMPC framework, the indices were unable to clearly distinguish between the case of no PMM and mild PMM, as PMM was effectively managed when mild. Therefore, attention needs to be paid to the indices from Level 3 to determine if the three cases of PMM can be clearly distinguished.

3.2. Level 3 Monitoring

For Level 3, MI for PMM functions by examining the correlation between the error residuals and the manipulated variables. A pseudo-binary random signal (PRBS) was utilized to provide sufficient excitation to the system to compute the MI metrics. A

summary of the results for all three cases of PMM is provided in Table 1. While the level of PMM cannot be easily visualized using the raw MI values, the percentage difference compared to the base case (no PMM) makes quantification of PMM straightforward. A threshold of 10% was set for this case study. For mild PMM, five input-output channels showed PMM, while seven input-output channels were identified for high PMM. The channels experiencing degradation are highlighted in yellow. The percentage increase is also significantly higher for high PMM. This result highlights the need for Level 3 monitoring indices due to its ability to distinguish between varying degrees of PMM.

Figure 2. Process schematic.

The covariance matrix-based assessment criterion utilized in this work was proposed by (Yu and Qin, 2008), where a generalized eigenvalue analysis is used to assess control performance. Using the case of no PMM for demonstration purposes, this case study examined three different scenarios of controller tuning, where the parameters and their values are provided in Figure 3, with the prediction horizon, control horizon, and past window of measurements in the MHE framework denoted by N_p , N_c , and N_{past} , respectively. An eigenvalue greater than 1 implies degraded performance for a particular control loop, and a value lower than 1 implies improved performance. A summary of the generalized eigenvalues, and their confidence intervals is provided in Table 2.

Table 2. Summary of generalized eigenvalue analysis for controller tuning.

Loop	Adequate Tuning				Poor Tuning			
	1	2	3	4	1	2	3	4
Eigenvalue	1.20	1.02	1.00	0.99	2.38	1.07	1.04	0.94
Lower Limit	1.09	0.93	0.91	0.90	2.17	0.97	0.94	0.85
Upper Limit	1.31	1.11	1.09	1.08	2.59	1.17	1.13	1.02

For cases of adequate and poor tuning the lower limit of the confidence interval for one loop is greater than 1, confirming degraded performance. This result is important to note as the difference between adequate and ideal tuning cannot readily be distinguished visually from the time series plots (see production rate in Figure 3 (a) and (b)).

3.3. Level 4 Monitoring

Level 4 monitoring indices, CPI and LRI, were designed to be utilized together for decision making. CPI is based on the IAE and provides a means to compare the benchmark performance to current operation. While CPI is a useful indicator, the LRI provides additional information regarding the stability and robustness of the system. To enable use of the LRI for MIMO systems, this work utilizes the disk margin proposed by (Seiler et al., 2020) instead of the sensitivity margin obtained from the Nyquist plot, to make it easier to quantify and visualize the robustness of different input-output channels. Computing the LRI is a 3-step process that involves: (1) identification of the open-loop transfer functions of the MIMO system, (2) computation of disk margin for all channels, (3) computation of LRI for all channels. A summary of the CPI and LRI values for the same case study presented by (Huang et al., 2021) is provided in Table 3 and Table 4, respectively. Negative values for both the CPI and LRI indicate degradation in control performance and loop robustness. As the level of PMM increases, the CPI values become increasingly negative, indicating increased degradation in control performance. In this example, the LRI for most channels (with the exception of turret speed-tensile strength channel) are also increasingly negative in the presence PMM, implying that the robustness and stability of those channels are affected as well, requiring maintenance actions. The channels with no values were open loop unstable for both the benchmark and monitored cases. This case study demonstrated how metrics from the different timescales can be evaluated to determine if maintenance actions are required. Indices from the shortest timescale, i.e., Level 2, evaluate the feasibility of continued operation, but the indices from Levels 3 and 4 allow process engineers to periodically evaluate the urgency of required maintenance.

Table 3. Summary of CPI metrics for different cases of PMM.

	Twei	Pcom	Prod	Tstr
No PMM	0.000	0.000	0.000	0.000
Mild PMM	-0.007	-0.072	-0.421	-0.157
High PMM	-0.389	-0.214	-0.657	-0.305

Table 4. Summary of LRI metrics for different cases of PMM.

	(a) Mild PMM				(b) High PMM			
	Twei	Pcom	Prod	Tstr	Twei	Pcom	Prod	Tstr

Csil	-	-	-	-	-	-	-	-

4. Conclusions

This work demonstrated how the QbC framework could be applied to enable multi-level control performance monitoring by incorporating indices from different timescales. Future work includes the development of a data analytics platform to aid decision making for continuous manufacturing industries, and experimental validation on the pilot plant at Purdue University.

Abstract

Crystallization is widely used in the pharmaceutical industry to purify reaction intermediates and final active pharmaceutical ingredients. This work presents a novel implementation of Inverse Reinforcement Learning (IRL) approach where an agent observes the expert's optimal control policies of a crystallization process and attempts to mimic its performance. In essence, an Apprenticeship Learning (AL) setup was developed where the expert demonstrates the control task to the IRL agent to help attain effective control performance when compared to the expert. This is achieved through repeated execution of "exploitation policies" that simply maximizes the rewards over the consecutive IRL training episodes. The cooling crystallization of paracetamol is used as a case study and both proportional integral derivative (PID) and Model Predictive Control (MPC) strategies were considered as expert systems. A model based IRL technique is implemented to achieve effective trajectory tracking which ensures final crystal size, considered as the critical quality attributes, by reducing the deviation from the optimal reference trajectories namely process temperature, supersaturation, and particle size. The performance of the trained IRL agent was validated against the PID and MPC and tested in presence of noisy measurements and model uncertainties.

Keywords: Apprenticeship Learning; Reinforcement Learning; Inverse Reinforcement Learning; Batch Crystallization.

1. Introduction and Background

Crystallization is one of the most widely used techniques in the pharmaceutical industry to purify intermediates and final active pharmaceutical ingredients (API) (Benyahia, 2018). It is significant that effective control strategies are required to regulate the target critical quality attributes such as crystal size, shape distributions, purity, and polymorphism. The downstream processes also depend on the ability of the crystals to flow, dry, and filter. Pharmaceutical industries are subject to stringent regulatory requirements for product quality as a small deviation from the target quality can create significant impacts on quality control, safety, efficacy, and shelf life (Lakerveld et al., 2015). This may even lead to the failure of the clinical trials during the early development stages, post-approval, and drug recalls that leads to severe economic setbacks.

Owing to the recent and significant development in the field of computer science, Artificial Intelligence (AI) has witnessed a resurgence of interest over a broad research and industrial applications. Reinforcement Learning (RL) is one among those techniques

that has been well-investigated and implemented in field of robotics and automation industries (Roveda et al., 2018). Similar investigations and developments have motivated the adoption of RL as a new control strategy for a variety of applications. RL has also been used to control chemical reactions and demonstrated its potential advantages compared to some of state-of-the-art algorithms and control techniques, such as PID (Zhou et al., 2017). The use of RL in presence of various uncertainties and measurement noise in real-world dynamic systems has also gained a lot of interest. For instance, Petsagkourakis et al., 2020 implemented a RL-based control strategy for a batch bioprocess with various uncertainties (measurement and process noises). Benyahia and coworkers, demonstrated the advantages of combining RL with a Kalman Filter (KF) for controlling batch crystallization processes for achieving robust control in presence of measurement noise and plant-model mismatch (Benyahia et al., 2021). With the continuous and successful implementations of RL in various domains, there has been a growing demand for effective training strategies. Transfer Learning (TL) is one among the most effective methods to accelerate the learning process while parallelly achieving better performance. In essence, TL follows a sequential training approach to address the continuously evolving training objectives (Taylor and Stone, 2009).

This paper outlines a novel IRL application for crystallization processes. Previously, Apprenticeship Learning (AL) approaches included the definition of a reward function that mimics the behavior of an expert controller (Mowbray et al., 2021). Such implementations rely on human expertise to capture the underlying theories of the expert controller. This paper, on the contrary, is an effort to train an agent to mimic the expert controller's actions by shadowing them. The IRL agent was associated with a KF for further TL-based trainings to deal with various levels of noise in one of the most critical measurements in crystallization; the number of crystals (number of counts). Towards this end, this paper promotes an initial IRL approach to mimic the behavior of the expert controllers, and later use TL-based training strategies with an intension to exploit and understand the potential of RL for crystallization control.

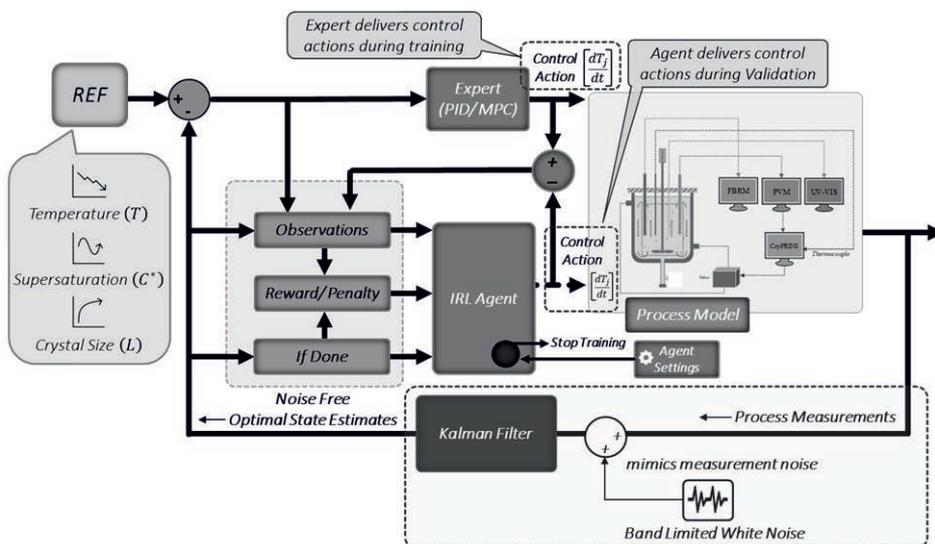

Figure 1: Overview of the IRL training and validation setup

2. Problem Formulation

The central objective of this work is to exploit the existing AI-based techniques to build robust controllers that can effectively compete with the efficiency of the traditional proportional integral derivative (PID) and Model Predictive Control (MPC) strategies. To achieve this objective, this paper presents the use of IRL approach combined with RL, TL and KF techniques to build a very responsive and efficient control strategies for batch crystallization processes that deals with various uncertainties (measurement noise and plant-model mismatch). This work makes use of three reference trajectories for process temperature, supersaturation, and particle size to ensure the product’s critical quality attributes are within safe and acceptable margins. The reference trajectories are computed using model-based open-loop dynamic optimization method illustrated by Nagy et al., 2008, where the focus was on maximising the crystal size. The case study for this work uses the batch crystallization process of Paracetamol in water. The details of the dynamic mathematical model used for this case study can be found in our previous literature (Benyahia et al., 2021). The kinetic parameters of the growth and nucleation were obtained from the literature (Nagy et al., 2008). The agent’s policy and value function definitions are based on the Deep Deterministic Policy Gradient (DDPG) technique. Please refer to our previous literature for the details regarding the agent definitions used in this work (Benyahia et al., 2021).

The setup used for this IRL training strategy is shown in **Figure 1**. During training, the expert controller (PID/ MPC) acts on the jacket temperature (manipulated variable) of the batch crystallization process. The chosen IRL approach will penalise the agent for deviations beyond a critical limit from the expert’s actions. This allows the agent to imitate the expert’s behaviour while reducing the training effort. The training makes use of a reward function that is defined based only on penalties. Therefore, the maximum theoretical reward that can be achieved in this case is zero which means that the agent’s control actions are equivalent to the expert’s (PID/ MPC) actions. In the context of IRL training, the agent will focus on minimizing the total penalties received per training episode. However, to reduce the training time, a reasonable value closer to the maximum theoretical reward was selected to stop the training. After training, the saved agent can be used to validate the performance of the IRL strategy. At the validation stage, the control loop is disconnected from the expert’s control actions and replaced by the RL agent. This ensures that the trained agent is the only control system for the batch crystallizer acting on the jacket temperature, which is used as the manipulated variable.

$$R_{t1} = \left(\underbrace{0((E_a - A_a) \leq 0.1)}_{\substack{\text{Zero penalty if the difference between the agent's and} \\ \text{the expert's control action is within an acceptable range}}} \bigvee -10(E_a - A_a) \right)$$

A proportional penalty if the difference is beyond the acceptable range

$$R_{t2} = \left(\underbrace{0(|T_e| \leq 0.1)}_{\text{Penalty for Temperature Tracking}} \bigvee -(|T_e|) \right) + \left(\underbrace{0(|S_e| \leq 0.1 \times 10^{-3})}_{\text{Penalty for Supersaturation Tracking}} \bigvee -5(|S_e|) \right) + \left(\underbrace{0(|L_e| \leq 1)}_{\text{Penalty for Crystal Size Tracking}} \bigvee -10(|L_e|) \right)$$

Figure 2: Simplified overview of the reward Function

It is important to note that this work includes IRL and RL trainings in two steps. Accordingly, **Figure 2** presents the simplified overview of the separate reward functions used in the first and second stages. The reward function for the first step (R_{I1}) focuses on the IRL approach, where the agent is forced to learn by shadowing the expert controller. The reward definition for the second step (R_{I2}) is focused on exploiting the training results obtained in the first step by combining them with RL, TL, and KF techniques. The goal was to improve the performance of the trained IRL agents with subsequent trainings targeted at more accurate and multiple trajectory tracking. The addition of KF to the trainings can help to address the issues related to various measurement noises and plant-model mismatch.

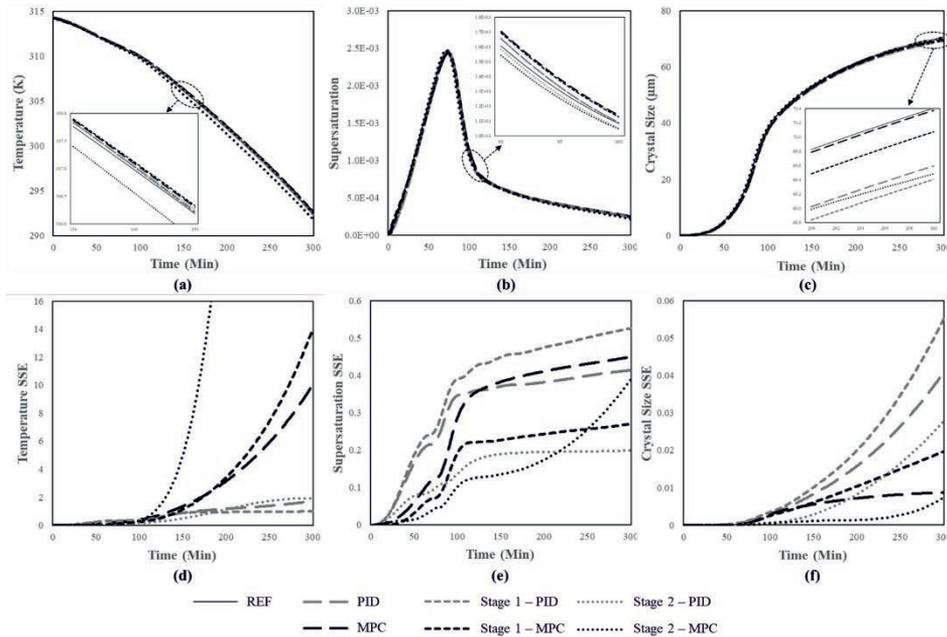

Figure 3: Overview of the validation results after stage 1 and stage 2 training.

3. Result and Discussion

The trained agents were validated in two stages in conjunction with the two-step training strategy suggested in **Figure 2**. **Figure 3** presents the comparison between the validation results captured at the end of each stage of the trainings conducted. The trajectories of the sum of the squared errors (SSE) presented in **Figure 3d, e** and **f** provide further qualitative insights about the difference in accuracy between the two stages of the trainings. The mean crystal size was considered as the target critical quality attribute and higher penalties were defined for control actions resulting with larger deviations from the reference trajectory. For a better insight, **Figure 3f** indicates that the performance of the stage1 trainings are not far off from the target expert controllers (PID/ MPC). However,

with subsequent second stage trainings, the performance of the agents has achieved an even more effective performance compared the target expert controllers (PID/ MPC).

Figure 4 is used to present the benefits of including KF during the second stage of training. The idea is to present the usefulness of KF to deal with various measurement noise and uncertainties related to plant-model mismatch. In other words, the use of KF will help achieve more effective training by providing optimal state estimates which enable more reliable and accurate evaluation of the rewards associated with the agent's control actions. The measurement noise (band-limited white noise) was introduced to the output signal related to the number of particles (μ_n) predicted by the process model. It is one of the most important real-time process measurements commonly obtained by a Focused Beam Reflectance Measurement (FBRM) technique. Similarly, the plant-model mismatch is introduced to the kinetic growth parameter (k_g) of the process model. It is important to note that separate trainings were conducted for cases with measurement noise and plant-model mismatch. The trajectories of the sum of the squared errors (SSE), presented in **Figure 4d, e, and f**, provide further qualitative insights about the difference in accuracy between the two stages of the trainings. Again, to obtain a clear conclusive performance comparison, it is necessary to pay more attention to **Figure 4f**. This is simply because of the highly weighted penalty over crystal size deviations. It is also worth noting that the results shown in **Figure 4** does not include the actual expert controllers (PID/ MPC), instead it is the comparison between the two stages of the IRL agent trainings investigating the usefulness of KF in the context of measurement noise and model uncertainties. The results indicate that the integration of KF at the second stage of the trainings is clearly beneficial, and with further TL-based trainings, the accuracy and performance of the agents can be further improved.

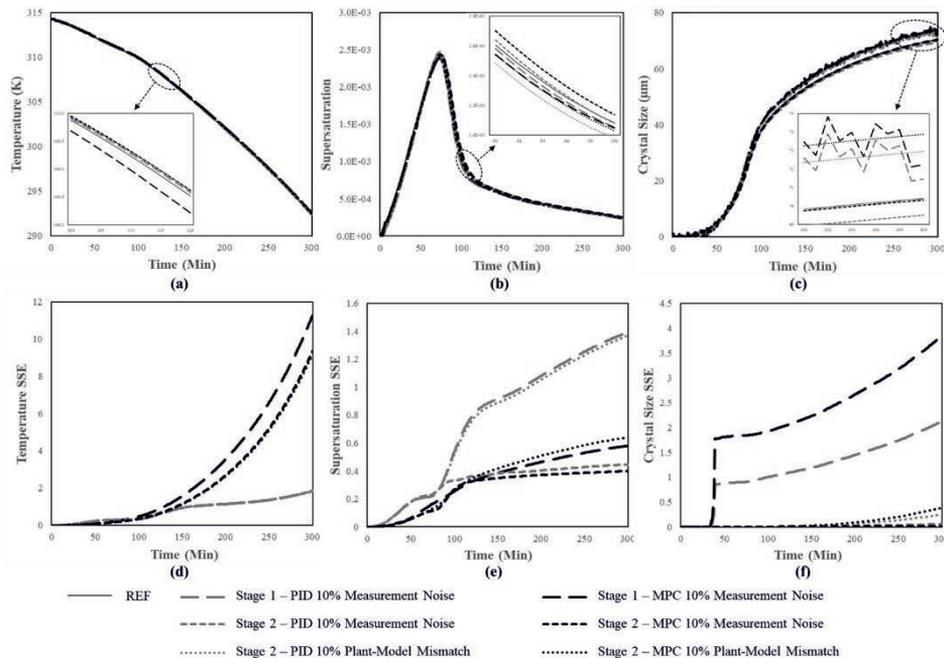

Figure 4: Overview of the results showing the benefits of integrating KF in the stage 2 training.

4. Conclusion

This paper demonstrated the use of model-based RL control policies for the trajectory tracking control of a batch crystallization process. Initially, the agent was trained using an IRL approach to mimic the behavior of the PID and MPC. A range of reward functions defined with penalties-only (no rewards) fashion were used to achieve the highest score in a reasonable amount of time, using the best compromises between exploration and exploitation. The resulting IRL agents were then validated by comparing their control performance against the expert controllers. It was shown that the IRL approach can exhibit a very close performance to the benchmark controllers. Later, the IRL agents' performances were further enhanced by conducting subsequent TL-based RL trainings. The results revealed that the IRL approach combined with TL and KF can demonstrate robust control performance in presence of noisy measurements and model uncertainties.

Dynamic Real-Time Optimization with Closed-Loop Prediction for Nonlinear MPC-Controlled Plants

Daniela Dering^a and Christopher L. E. Swartz^{a*}

^a*Department of Chemical Engineering, McMaster University, 1280 Main Street West, Hamilton L8S 4L8, Canada*
swartzc@mcmaster.ca

Abstract

Current trends toward globalization and electricity market deregulation are requiring increasingly dynamic operation of chemical processes. In this paper, we develop a dynamic real-time optimization (DRTO) formulation for plants controlled by NMPC. It utilizes a prediction of the plant under the action of constrained NMPC. At every prediction time-step, an NMPC problem determines the control inputs that are applied to the dynamic process model. We show that the unconstrained NMPC problem for SISO systems affine in the inputs has a single stationary point that corresponds to the global optimum, and numerical experiments suggest that a similar property holds for the constrained problem. This allows the embedded NMPC subproblems in the DRTO formulation to be replaced by their first-order Karush-Kuhn-Tucker (KKT) conditions, yielding a single-level optimization problem. We show that the DRTO with embedded NMPC subproblems can lead to significant improvement in plant performance, and also compare the performance of NMPC to that of linear MPC.

Keywords: NMPC, DRTO, Karush-Kuhn-Tucker conditions

1. Introduction

Real-Time Optimization (RTO) utilizes a rigorous steady-state plant model to compute the set-point trajectories that optimize an economic process metric. These set-points are then provided as targets to a multivariable controller, generally model predictive control (MPC), that computes the input values applied to the plant. Because RTO utilizes a steady-state plant model, it is not executed during process transitions, but only when the plant has reached an almost steady-state operation (Darby et al., 2011). This particular limitation is averted if a dynamic plant model is used instead. This variation of RTO is commonly referred to as DRTO. In a recent development, Jamaludin and Swartz (2017) proposed to account for the MPC action in the DRTO formulation. This new variation, named CL-DRTO, models the closed-loop response of the plant, and has been shown to improve process economics compared to a DRTO formulation that utilizes an open-loop prediction of the plant dynamics (Jamaludin and Swartz, 2017). An alternative paradigm is economic model predictive control (EMPC) (Ellis et al., 2014) that replaces standard MPC by optimizing the process economics and computing the input values simultaneously. EMPC versions that utilize linear and nonlinear dynamic models have been proposed. It has been argued that the EMPC problem can not be solved as frequently as standard MPC due to the problem complexity, and that the integration of economic optimization and control in one problem lead to conflicting objectives, which may hinder process safety (Würth et al., 2011). The EMPC and DRTO approaches are representative of the so called single and two-layer control architecture, respectively.

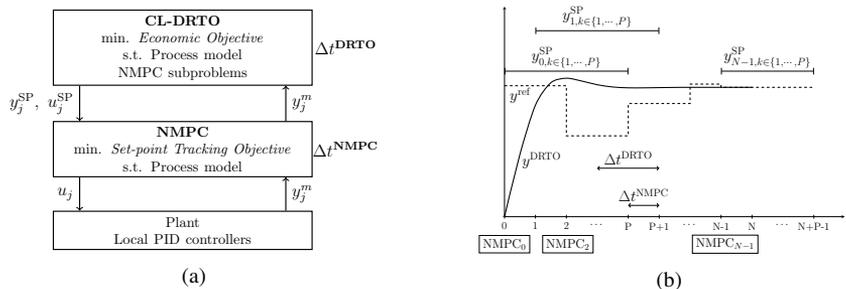

Figure 1: Schematic representation of (a) two-layer approach, and (b) optimal solution of CL-DRTO problem.

While linear MPC is the prevalent control strategy in chemical enterprises (Qin and Badgwell, 2003), it can perform poorly for large transitions and/or in highly nonlinear plants. The reason is that the built-in linear model provides a poor approximation in regions away from the steady-state operation, exacerbated by strong nonlinearity. Moreover, in multiproduct plants, multi-linear models may have to be used in order to appropriately model all the operating regions. Due to these limitations, nonlinear model predictive control (NMPC), that uses a nonlinear process model, is often the preferred choice of control strategy for highly nonlinear processes.

In this study, we propose a DRTO formulation similar to that in Jamaludin and Swartz (2017) but that accounts for the action of a nonlinear model predictive control (NMPC) instead of linear MPC. To avoid a bilevel optimization problem, we use the associated first-order Karush-Kuhn-Tucker (KKT) conditions to account for the NMPC action in the DRTO formulation. We consider in this paper systems that are affine in the control inputs, and derive conditions under which the unconstrained NMPC problem yields a single stationary point, which corresponds to the global optimum. Numerical experiments suggests that a similar property holds for the input constrained problem as well, supporting the reformulation of the embedded NMPC problems using the corresponding KKT conditions. Performance of linear and nonlinear MPC for controlling a SISO nonlinear system in the presence and absence of a DRTO layer is compared.

2. Formulation

Figure 1a provides an schematic representation of the framework for online real-time optimization and control of a chemical process implemented in this study. The CL-DRTO layer computes the reference trajectories y^{ref} and u^{ref} that optimize an economic or target tracking objective function. The set-point trajectories y_j^{SP} and u_j^{SP} are extracted from the reference trajectory and provided to the lower level NMPC that then computes the input values u_j applied to the plant. The lower-level NMPC and upper-level DRTO problems are executed at time periods Δt^{NMPC} and Δt^{DRTO} , respectively, with $\Delta t^{DRTO} / \Delta t^{NMPC} \in \mathbb{Z}^+$.

In order to account for the closed-loop behavior of the process in the CL-DRTO formulation, an NMPC problem is formulated at every time-step j along the DRTO prediction horizon to determine the input values used in the process model. Figure 1b shows a schematic representation of the response of a plant under the combined action of DRTO and NMPC. N and P are, respectively, the CL-DRTO and NMPC prediction horizon, M is the NMPC control horizon and y^{DRTO} is the output trajectory predicted by the DRTO process model. The set-point trajectories used in the NMPC subproblems are extracted from the reference trajectory y^{ref} . Note that the NMPC problem solved after time-step $N - P + 1$ sees beyond the CL-DRTO horizon N , and for that reason the reference trajectory is extended until $N + P - 1$. More detail about the CL-DRTO problem formulation is

provided in the next sections. We highlight that the general formulation and solution approach are similar to that proposed in Jamaludin and Swartz (2017), but with the linear MPC (LMPC) replaced by NMPC. We use the Python backend of CasADi (Andersson et al., 2019) and the interior point solver IPOPT (Wächter and Biegler, 2006) to implement and solve the optimization problems in this study.

2.1. Process Model

The process model includes the mathematical model of the plant, bounds on the optimization variables and process outputs, and constraints linking the process model to the NMPC subproblems. The discrete plant model is assumed to have the following form

$$x_{j+1}^{\text{DRTO}} = f^{\text{DRTO}}(x_j^{\text{DRTO}}, u_j^{\text{DRTO}}) \quad \forall j \in \mathcal{J}_0^{N-1} \quad (1a)$$

$$y_j^{\text{DRTO}} = Cx_j^{\text{DRTO}} \quad \forall j \in \mathcal{J}_1^N \quad (1b)$$

where $x_j^{\text{DRTO}} \in R^{nx}$ and $y_j^{\text{DRTO}} \in R^{ny}$ are column vectors of the predicted state and output values at time-step j , respectively. $u_j^{\text{DRTO}} \in R^{nu}$ is the vector of input values computed via solution of j^{th} NMPC subproblem, that is $u_j^{\text{DRTO}} = u_{j,0}^{\text{NMPC}}$, where $u_{j,k}^{\text{NMPC}} \in R^{nu}$. $C \in R^{ny \times nx}$ is a matrix that relates the states to the outputs, and $\mathcal{J}_a^b = \{j|a \leq j \leq b, j \in Z_0^+\}$ is a set of time-steps. $f^{\text{DRTO}}(\cdot)$ is a nonlinear function obtained via discretization of the dynamic plant model.

The optimization degrees of freedom are the reference trajectories $y^{\text{ref}} = [(y_1^{\text{ref}})^T, \dots, (y_{N+P-1}^{\text{ref}})^T]^T$ and $u^{\text{ref}} = [(u_0^{\text{ref}})^T, \dots, (u_{N+M-2}^{\text{ref}})^T]^T$ where $y_j^{\text{ref}} \in R^{ny}$ and $u_j^{\text{ref}} \in R^{nu}$. For j beyond the CL-DRTO horizon, the reference trajectories are held constant, that is $y_j^{\text{ref}} = y_N^{\text{ref}} \forall j \in \mathcal{J}_{N+1}^{N+P-1}$ and $u_j^{\text{ref}} = u_{N-1}^{\text{ref}} \forall j \in \mathcal{J}_N^{N+M-2}$. Additionally, lower and upper bounds can be imposed on the optimization variables and predicted outputs. Set-point hold constraints to force the reference trajectory to have a constant value for a specified number of time-steps could also be applied.

2.2. NMPC subproblems

The NMPC subproblems are assumed to have an equivalent formulation to the lower-level NMPC in Figure 1a:

$$\min_{u_j^{\text{NMPC}}} \Phi_j^{\text{NMPC}} = \sum_{k=1}^P (y_{j,k}^{\text{NMPC}} - y_{j,k}^{\text{SP}})^T Q (y_{j,k}^{\text{NMPC}} - y_{j,k}^{\text{SP}}) + \sum_{k=0}^{M-1} \left[\Delta u_{j,k}^T R \Delta u_{j,k} + (u_{j,k}^{\text{NMPC}} - u_{j,k}^{\text{SP}})^T S (u_{j,k}^{\text{NMPC}} - u_{j,k}^{\text{SP}}) \right] \quad (2a)$$

$$\text{subject to } x_{j,k+1}^{\text{NMPC}} = x_{j,k}^{\text{NMPC}} + \Delta t^{\text{NMPC}} f(x_{j,k}^{\text{NMPC}}, u_{j,k}^{\text{NMPC}}), \quad \forall k \in \mathcal{J}_0^{P-1} \quad (2b)$$

$$y_{j,k}^{\text{NMPC}} = Cx_{j,k}^{\text{NMPC}}, \quad \forall k \in \mathcal{J}_1^P \quad (2c)$$

$$\Delta u_{j,k} = u_{j,k}^{\text{NMPC}} - u_{j,k-1}^{\text{NMPC}}, \quad \forall k \in \mathcal{J}_0^{M-1} \quad (2d)$$

$$u_{j,k}^{\text{NMPC}} = u_{j,M-1}^{\text{NMPC}}, \quad \forall k \in \mathcal{J}_M^{P-1} \quad (2e)$$

$$u_{\min}^{\text{NMPC}} \leq u_{j,k}^{\text{NMPC}} \leq u_{\max}^{\text{NMPC}}, \quad \forall k \in \mathcal{J}_0^{M-1} \quad (2f)$$

$$u_j^{\text{NMPC}} = \left[\left(u_{j,0}^{\text{NMPC}} \right)^T, \dots, \left(u_{j,M-1}^{\text{NMPC}} \right)^T \right]^T \quad (2g)$$

where $Q \in R^{ny \times ny}$ is a positive definite matrix, and $R \in R^{nu \times nu}$ and $S \in R^{nu \times nu}$ are positive semidefinite matrices. $u_{j,k}^{\text{NMPC}} \in R^{nu}$, $x_{j,k}^{\text{NMPC}} \in R^{nx}$ and $y_{j,k}^{\text{NMPC}} \in R^{ny}$ are, respectively, the input, state and

output values for the j^{th} NMPC subproblem at time-step k . $f(\cdot) : R^{nx+nu} \rightarrow R^{nx}$ is the dynamic model of the process, here assumed to be affine in the inputs and given by

$$\frac{dx}{dt} = f(x, u) = g(x) + B(x)u \quad (3)$$

with $g(x) : R^{nx} \rightarrow R^{nx}$ and $B(x) : R^{nx} \rightarrow R^{nx \times nu}$. We assume that $f(\cdot)$ is smooth, continuous and differentiable in R^{nx+nu} . In linear MPC formulations, $f(\cdot)$ is a linear function and the resulting control problem a convex quadratic programming problem with linear constraints. Due to the convexity property, the first-order Karush-Kuhn-Tucker (KKT) conditions are necessary and sufficient for global optimality (Nocedal and Wright, 2006), and they can be used instead of Equation 2 in the CL-DRTO (Jamaludin and Swartz, 2017) allowing solution as a single-level optimization problem. Because in this study $f(\cdot)$ can be nonlinear, problem 2 is potentially non-convex. Next we show some results that suggest that problem 2 with $f(\cdot)$ defined as in Equation 3 has a unique local optimum for Single-Input Single-Output (SISO) systems, that is when $ny = nu = 1$.

Consider the smaller NMPC problem,

$$\min_v \quad \Phi_R = \sum_{k=1}^P Q(y_k - y_k^{\text{SP}})^2 \quad (4a)$$

$$\text{subject to} \quad x_{k+1} = x_k + \Delta t f(x_k, u_k), \quad \forall k \in \mathcal{J}_0^{P-1} \quad (4b)$$

$$y_k = Cx_k, \quad \forall k \in \mathcal{J}_1^P \quad (4c)$$

$$v = [u_0 \dots, u_{P-1}]^T \quad (4d)$$

which retains all potential sources of nonconvexity in problem 2. For a SISO system, we have $y_k^{\text{SP}}, y_k, u_k \in R$ and $x_k \in R^{nx}$, $Q > 0$ is a scalar and $C \in R^{1 \times nx}$ a row vector. $v \in R^P$ are the optimization variables, $f(\cdot)$ is defined as in Equation 3, and Δt is the sampling time. Φ_R is ultimately a function of only x_0 , v , and $y^{\text{SP}} = [y_1^{\text{SP}}, \dots, y_P^{\text{SP}}]^T$, since the equalities in Equations 4b and 4c can be used to eliminate y_k . The first-order KKT conditions for problem 4 are simply $\nabla_v \Phi_R(v, x_0, y^{\text{SP}}) = 0$, where

$$\nabla_v \Phi_R(v, x_0, y^{\text{SP}}) = 2 \begin{bmatrix} \left((y_1 - y_1^{\text{SP}})QC + \sum_{k=2}^P (y_k - y_k^{\text{SP}})QC \frac{\partial x_k}{\partial x_1} \right) \frac{\partial x_1}{\partial u_0} \\ \left((y_2 - y_2^{\text{SP}})QC + \sum_{k=3}^P (y_k - y_k^{\text{SP}})QC \frac{\partial x_k}{\partial x_2} \right) \frac{\partial x_2}{\partial u_1} \\ \vdots \\ \left((y_{P-1} - y_{P-1}^{\text{SP}})QC + (y_P - y_P^{\text{SP}})QC \frac{\partial x_P}{\partial x_{P-1}} \right) \frac{\partial x_{P-1}}{\partial u_{P-2}} \\ \left((y_P - y_P^{\text{SP}})QC \right) \frac{\partial x_P}{\partial u_{P-1}} \end{bmatrix} \quad (5)$$

We have that for $z \in R^n$ and $w \in R^m$, $\frac{\partial z}{\partial w}$ is a $n \times m$ matrix with $(ij)^{\text{th}}$ element $\frac{\partial z_i}{\partial w_j}$. Substituting $\frac{\partial x_k}{\partial u_{k-1}} = \Delta t B(x_{k-1})$ in Equation 5, and assuming $CB(x) \in R - \{0\}$ for all $x \in R^{nx}$, we obtain that the unique stationary point of $\Phi_R(v, x_0, y^{\text{SP}})$ is given by $y_k - y_k^{\text{SP}} = 0$ for all $k \in \mathcal{J}_1^P$. This expression can be solved explicitly for the optimal value of the optimization variables v . Moreover, note that this solution corresponds to the global optimum of problem 4, since it leads to $\Phi_R(v, x_0, y^{\text{SP}}) = 0$. Therefore, the first-order KKT conditions are necessary and sufficient for problem 4. This result suggests that they may also be necessary and sufficient for problem 2 since the constraints in Equations 2d-2f are linear and the additional terms in the objective function are convex. To substantiate this conjecture, we solved the constrained problem in Equation 2 for distinct SISO systems using both the first-order KKT conditions and an optimization solver, for thousands of different initial guesses for the optimization variables. The first-order KKT conditions yield a system of nonlinear equations with complementary constraints (e.g.

$\mu_k^1(u_{j,k}^{\text{NMPC}} - u_{\min}^{\text{NMPC}}) = 0$, $\mu_k^2(u_{\max}^{\text{NMPC}} - u_{j,k}^{\text{NMPC}}) = 0$, $\forall k \in \mathcal{J}_0^{M-1}$ where $\mu_k^i \in R^+$ are Lagrange multipliers), that are handled using an exact penalty formulation (Ralph and Wright, 2004). For all the test problems, the KKT conditions and optimization solver returned the same optimal solution for all initial guesses.

3. Case Studies

We use the CL-DRTO formulation with embedded NMPC subproblems reformulated via the KKT conditions for optimization and control of an isothermal nonlinear CSTR used to produce five grades A, B, C, D and E via the reaction $3R \xrightarrow{k} P$ (Flores-Tlacuahuac and Grossmann, 2006). The dynamic model is given by

$$\frac{dC_R}{dt} = \frac{F}{V}(C_0 - C_R) - kC_R^3$$

where C_0 and C_R are the composition of the inlet and outlet stream, respectively. F is the inlet and outlet flow rate, V is the volume of liquid in the reactor, and k is the reaction rate constant. For this study, we use $C_0 = 1$ mol/L, $V = 5$ m³, $k = 2$ L²/mol²h (Flores-Tlacuahuac and Grossmann, 2006). Using the previous introduced notation, we have that $x = C_R$, $u = F$, $C = 1$, $g(x) = -2x^3$, $B(x) = 0.2(1 - x)$. We use NMPC and DRTO parameters $Q = 1$, $R = 0.2$, $S = 0$, $M = 3$, $P = 30$, $N = 50$, $\Delta t^{\text{NMPC}} = 0.5$ h, $\Delta t^{\text{DRTO}} = 2$ h and impose the bounds $0 \leq u_{j-1,k}^{\text{NMPC}} \leq 3$, $0 \leq y_j^{\text{DRTO}} \leq 0.6$, $0 \leq y_j^{\text{ref}} \leq 0.8$ for all $k \in \mathcal{J}_0^{M-1}$, $j \in \mathcal{J}_1^N$. The bounds on $u_{j,k}^{\text{NMPC}}$ are sufficient to prevent $CB(x) = 0$ from being a feasible solution, and we do not have to impose constraints on the output values in the NMPC subproblems. The NMPC and DRTO process model is discretized using the forward-Euler method with a step size of 0.1.

We consider an economic (Φ^{ECO}) and set-point tracking (Φ^{SP}) objective function formulation to be minimized:

$$\Phi^{\text{ECO}} = \sum_{j=1}^N \Delta t^{\text{NMPC}} u_{j-1} - 50R_j^1 R_j^2, \quad \Phi^{\text{SP}} = \sum_{j=1}^N (y_j - y_j^{\text{targ}})^2$$

$$R_j^1 = 0.5 \tanh\left(\gamma\left(y_j - y_j^{\text{targ}}(1 - \varepsilon)\right)\right) + 0.5, \quad R_j^2 = 0.5 \tanh\left(\gamma\left(y_j^{\text{targ}}(1 + \varepsilon) - y_j\right)\right) + 0.5$$

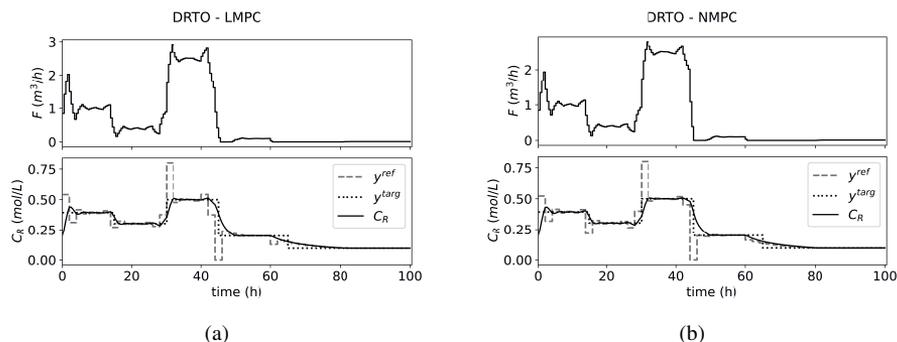

where y_j^{targ} is the specified target output concentration at time-step j , γ defines the steepness of the switching function R_j^i , and ε is the tolerance by which y_j can deviate from y_j^{targ} . We have that $R_j^1 \approx 1$ if $y_j > y_j^{\text{targ}}(1 - \varepsilon)$, and it is zero otherwise. Similarly, $R_j^2 \approx 1$ if $y_j < y_j^{\text{targ}}(1 + \varepsilon)$, and it is zero otherwise.

We compare the performance of NMPC against that of linear MPC for closed-loop control of the nonlinear CSTR, both when the CL-DRTO layer is present (Figure 1a) and when it is not. The target output trajectory y^{targ} is provided as set-points to the control layer in the latter case. The objective values at the end of the simulation horizon for these control implementations are given in Table 1. For both, LMPC and NMPC, the objective values improve considerably when the set-points are computed by the DRTO layer. The NMPC controller tends to lead to an overall better plant performance compared to LMPC. We note that by accounting for the control action, the DRTO becomes aware of the LMPC and NMPC limitations, and can therefore compute reference values that to an extent compensate for that.

The plant input and output trajectories for the case when the set-point tracking objective function is used in the CL-DRTO are shown in Figure 2. The response is quite similar for both controllers despite some small differences in the reference trajectory. We note that the value of F , while small (0.01 m³/L), is not zero after 70 hours (Flores-Tlacuahuac and Grossmann, 2006).

Table 1: Objective values for NMPC and LMPC control implementations.

	LMPC	NMPC	DRTO-LMPC	DRTO-NMPC
Φ^{ECO}	-6543	-6,592	-7,241	-7,292
Φ^{SP}	0.4388	0.4407	0.1479	0.1402

Figure 2: Input and output trajectories for the nonlinear plant under the action of CL-DRTO with embedded (a) LMPC and (b) NMPC subproblems, and Φ^{SP} as the objective function.

4. Conclusion

In this study, we proposed a DRTO formulation for plants controlled by NMPC. We showed that the unconstrained NMPC problem for SISO systems affine in the inputs has only one stationary point that is also the global optimum. Numerical experiments suggest that this property also holds for the constrained NMPC problem, making the first-order KKT conditions necessary and sufficient for global optimality. This allows us to use the associated KKT conditions to account for the NMPC control action in the DRTO formulation. At every time-step the control problem is solved to compute the input value used in the process model. The results indicate a better performance of the NMPC compared to linear MPC, and show that significant improvement in plant performance can be achieved by accounting for the control action in real-time optimization.

Abstract

In this work, an economic Dynamic Real-Time Optimization (DRTO) of the operation of a solar thermal plant is conducted. A planning phase is used to improve the use of storage, and a storage state target is included in the objective function of the DRTO. The weight of this term in the objective function is adjusted. The trajectories for the flow rates obtained with the DRTO algorithm are used in a simulation model undergoing disturbances on the solar irradiation. This methodology is compared with a simulation following the flow rate trajectories obtained during the planning phase. The results show an improvement in the total expenses and the percentage of solar energy used to satisfy the demand, with a reasonable tracking of the storage state target, bringing good perspectives for the implementation of the method in a real environment.

Keywords: Dynamic real-time optimization, solar thermal energy, simulation.

1. Introduction

In order to achieve greenhouse gases emissions reduction, developing solar thermal plants and making the most of them appear crucial. In addition to the design, the operation of the plant can be optimized in order to reduce the operating cost, help to meet the heat demand and cut down the fossil fuel consumption in heat production. Dynamic optimization was used to optimize the operation of a solar thermal plant including a storage tank during 36 hours using weather and load forecasts (Scolan et al., 2020). Trajectories for the flow rates in the different parts of the solar plant were computed. Especially, the use of the storage tank was optimized to extend the time period where solar heat could be supplied to the consumer. More studies focusing on the dynamic optimization of Concentrated Solar Power (CSP) plants can be found in the literature. In these studies, the operation of the plant is optimized in order to maximize the income from electricity selling, with a variable electricity price and a thermal energy storage (Lizarraga-Garcia et al., 2013; Wittmann et al., 2011). Hybridization of the solar plant with a back-up fossil fuel has also been considered, leading to a larger amount of solar energy collected (Ellingwood et al., 2020; Powell et al., 2014). These studies show an improvement in the performance of the solar thermal plants, with more energy collected at a lower cost. However, it is difficult to predict the weather and the heat demand accurately several days ahead of time and dynamic optimization cannot consider disturbances, such as differences in planned weather and heat demand, to adapt the optimal strategy. The lower level in the hierarchical operation of a plant is the control. The controllers in a solar thermal plant are generally basic controllers such as PID (Proportional Integral Derivative) tracking a target value for the outlet temperature of the solar field. More complex controllers, suited for nonlinear systems with various

dynamics, have been studied for CSP plants to improve the disturbance rejection and the uncertainty handling (Camacho et al., 2007). Furthermore, it is possible to integrate an economic objective in the controller (Engell, 2007). In two studies, this approach was used to minimize the back-up fossil fuel consumption in a solar system including storage (Pintaldi et al., 2019; Serale et al., 2018). The authors suggest that a hierarchical structure, with a decoupling between the dynamic optimization and the control tasks might improve the use of storage. A Dynamic Real-Time Optimization (DRTO) could be used to compute reference trajectories for the flow rates that will be tracked by controllers (Kadam, 2002). The DRTO of a solar plant was performed in only one study (Pataro et al., 2020). The flow rate in the concentrating solar field was optimized in real-time using measurements of the ambient conditions and an economic objective function. However, the storage management was not considered. Based on this literature survey, an economic DRTO of a solar thermal plant including storage is carried out in this paper.

2. Solar thermal plant description and modelling

A typical layout for a solar thermal plant was chosen for this study and is presented in Figure 1. The production loop is composed of a solar field with 12 loops of 15 flat plate collectors each, corresponding to a panel surface of 2873 m². A glycol-water (30/70 volume) mixture is heated up in the solar field. It can by-pass the heat exchanger connecting the production circuit to the secondary circuit during the warm-up phase of the solar field, until a target temperature is reached. Once collected in the secondary loop, the solar heat can be stored in the stratified storage tank for later use or directly delivered to the consumer circuit. The storage tank can be discharged to supply heat to the consumer circuit when solar irradiance is too low to meet the demand. These different operational modes make the operation of the solar thermal plant flexible, but nevertheless complex. Variable speed pumps and control valves are used to operate the plant. A back-up gas heater, not modelled and not represented in Figure 1, is associated to the solar thermal plant to meet the load curve.

Details about the nonlinear models used for each element of the solar thermal plant can be found in (Scolan et al., 2020). In this paper, the solar field is modelled as an equivalent surface panel to speed up the calculations.

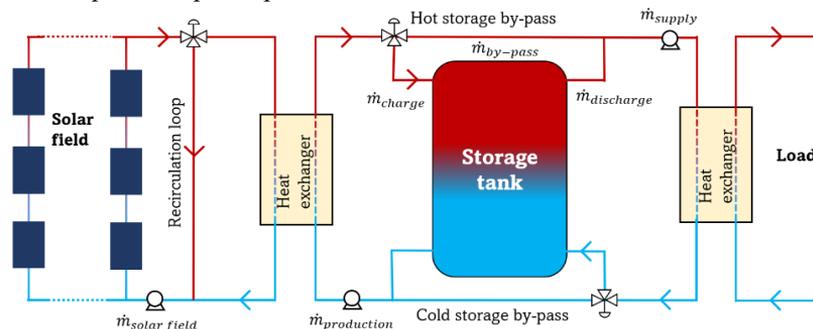

Figure 1: Architecture of the solar thermal plant

3. Dynamic Real-Time Optimization methodology

The structure of the algorithm used to optimize in real-time the solar thermal plant is presented in Figure 2. First, an offline Dynamic Optimization (DO) based on weather and load forecasts is performed for a 2-day period. The objective function for this planning phase is to minimize the costs associated with the electricity used for pumping

(130 €/MWh) and the gas (80 €/MWh) used in the backup heater. A value is given to the stored energy at the end of the time horizon because the stored heat could be valuable beyond the end of this optimization (17.5 €/MWh from (Scolan et al., 2020)). Finally, a penalty term is added to smooth the trajectories computed for the flow rates in the different parts of the plant. The planning phase is used for the storage management. Indeed, storage has slower dynamics than the rest of the plant and needs to be considered on a longer time period.

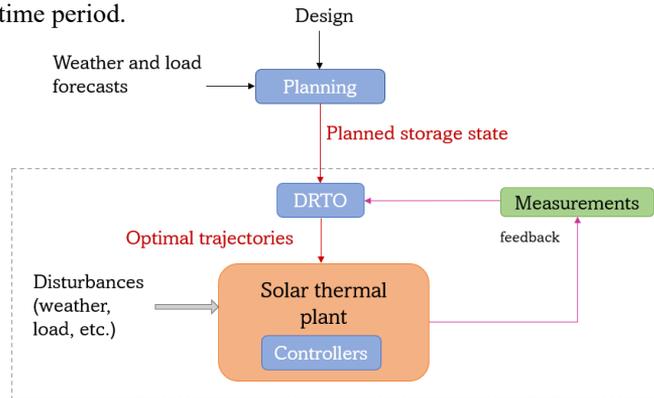

Figure 2: Optimization algorithm

The DRTO methodology is applied during daytime of the first day of the complete time horizon using the two layer approach presented in (Kadam, 2002). It starts when the warm-up phase of the solar field is completed, which corresponds to a temperature at the outlet of the solar field of 70°C. The objective function for the DRTO also minimizes the cost of gas and electricity and smooths the trajectories obtained for the flow rates. In addition, a term that minimizes the difference between the planned stored energy and the actual energy stored at the end of the day is added. A new DRTO is carried out every hour, until the end of the day. Thus, the time horizon shrinks for every DRTO (from about 12h to 1h) and the computational time also reduces from 15 minutes to less than 5 minutes. The models and the resolution method could be modified in future work to speed up the calculations. Measurements of temperatures in the different parts of the solar thermal plant are used to determine the initial state. Disturbances are also measured, and weather forecasts are updated. A simulation model is used to represent the solar thermal plant and provide the feedback measurements. The optimal trajectories are sent to the simulation model of the solar thermal plant. Perfect control is assumed in first approach, so the exact optimal trajectories are followed in spite of disturbances. The optimizations were conducted in the Gams software and the solar thermal plant was simulated in Matlab. The optimizations, solved using the simultaneous approach, are initialized with results from simulations with standard operation strategy. The complete discretized model involves up to 28,000 variables for the first DRTO with a time horizon of about 12 hours.

4. Case study

4.1. Inputs

For the weather forecasts, averaged data over the last 50 years in Pau, France, are used. For this study, two summer days are chosen: a sunny day followed by a cloudy day, as shown in Figure 3 with GHI standing for Global Horizontal Irradiance. This configuration imposes the use of storage to avoid exceeding the heat demand the first day and to supply some solar heat the second day despite the low solar irradiation.

For the real-time data during the first day, an uncertainty of p %, several values of p being tested, is applied to the entire curve of solar irradiance. Other inputs, such as ambient temperature or heat load are considered certain in this work. Weather forecasts are updated before each DRTO, as shown in Figure 4, for the hours 9 and 14 with an uncertainty of - 30 % on the GHI. This procedure is used in this first approach, but real data for weather forecasts and measurements should be used for more realistic results.

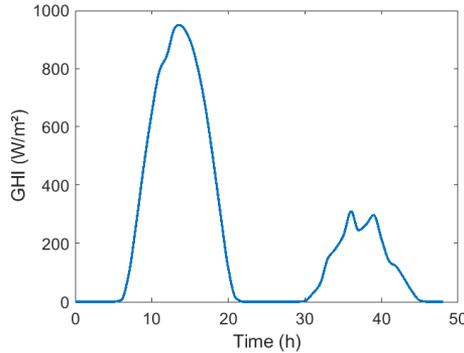

Figure 3: Solar irradiance forecast

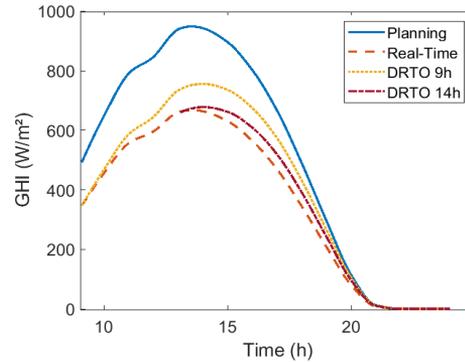

Figure 4: Real-Time solar irradiance and updated forecasts

The load curve is considered constant, with a value of 836 kW. The consumer flow enters the heat exchanger at 55°C. The storage is initially at 60°C, which represents a partially charged storage. The temperatures in the solar thermal plant are equal to the ambient temperature at the beginning of the planning phase. The initial state for the DRTO during daytime is retrieved from the planning when the temperature at the outlet of the solar field reaches 70°C.

4.2. Outputs

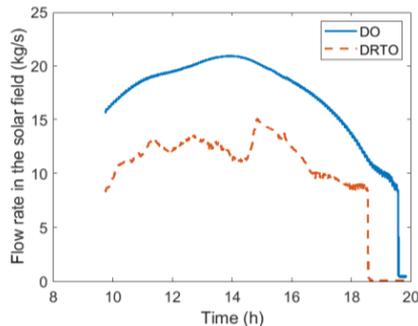

Figure 5: Comparison between DO and DRTO

Figure 5 shows an example of trajectories obtained for the flow rate in the solar field $\dot{m}_{solar\ field}$ from the planning (DO) and the DRTO with an uncertainty of - 50 % on the GHI. It can be observed that $\dot{m}_{solar\ field}$ is lower for the DRTO. In order to achieve a temperature high enough for storage and heat supply, a lower flow rate is used in the solar field associated with lower pumping cost. Similar trends can be seen for the other flow rates in the plant.

4.3. Following of the planned heat storage state

As mentioned in Section 3, the objective function of the DRTO includes a term to minimize the difference between the planned heat storage state at the end of the first day and the actual storage state. The energy difference is multiplied by the gas price (80 €/MWh) in the objective function, since the lack of stored energy will be compensated by gas in the backup heater. The cost associated with the failure to follow the planning is affected by a weight, which needs to be adjusted.

On Figure 6 two performance criteria are plotted for different weights. On the left axis, the difference between the stored energy at the end of the day and the planned target is drawn. On the right axis, the difference between the cost during the day and the lowest

cost achieved for the DRTO without any objective on storage is shown. It can be observed that, with a higher weight, the target on the storage state is better achieved but it is at a higher cost because less heat is delivered to the consumer and thus more gas is used to complete the demand. DRTO without any target on storage (weight of 0) leads to less expenses for this first day but it will cost more money on the second day where little solar heat can be produced. For the remaining part of this paper, a weight of 0.65 is chosen as it represents a good compromise between total cost for the day and tracking of the storage target.

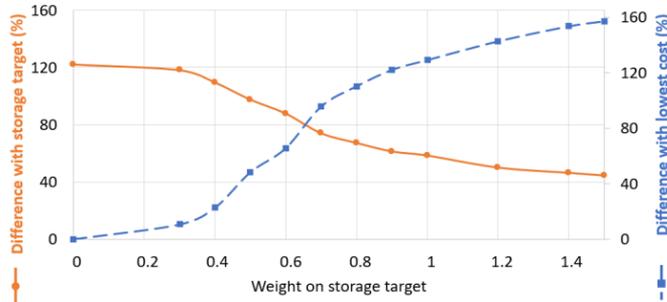

Figure 6: Effect of weight on storage target in the objective function on storage and costs

4.4. Results for different uncertainty levels on the GHI

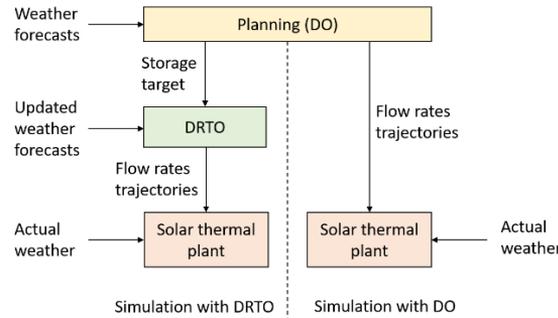

Figure 7: Comparison of simulations based on DO or DRTO

Figure 7 presents the methodology used to assess the improvements in the solar thermal plant operation obtained with DRTO. The DRTO method presented in section 3, and repeated on the left-hand side of the diagram, is compared to a simulation following the flow rates trajectories obtained during the planning phase (DO) but undergoing the disturbance on the solar irradiation.

The results of the comparison of the simulations based on offline and real-time optimizations of the solar thermal plant are presented in Table 1, for different values of disturbances on the GHI. Only negative disturbances are considered to avoid exceeding the heat demand in the simulation based on DO trajectories. Table 1 shows an improvement (bold characters) for DRTO compared to DO in the total cost (between 15 % and 44 %) and the percentage of solar energy directly used to satisfy the demand, for every case tested. However, it is at a price of a decrease in storage state monitoring. A study over a longer time period, a week or even a month, would help to assess the benefits of DRTO since the storage state at the end of the last day would be less important and the cost and solar percentage would be the only performance criteria. In Table 1, it can be noticed that for a higher uncertainty level on the GHI, the overall performance of the solar thermal plant is improved with DRTO, with a high solar energy percentage (+ 52 % compared to DO) and a small difference in storage state tracking (- 20 % compared to DO). The results observed depend on the weight chosen in the previous section. Based on these observations, a variable weight should be considered: for a small uncertainty level, the storage state target should be tracked, and the weight should be adjusted to ensure a good tracking while minimizing the cost. However, for a large

uncertainty level, the storage state target cannot be met, and it seems more suitable to minimize the cost of the day without consideration for the planned stored energy.

Table 1: Solar thermal plant performance in simulations based on DO or DRTO for different disturbances on the GHI

	GHI – 10 %		GHI – 20 %		GHI – 30 %		GHI – 40 %		GHI – 50 %	
	DO	DRTO	DO	DRTO	DO	DRTO	DO	DRTO	DO	DRTO
Difference with storage target (%)	- 17.5	- 48.0	- 35.2	- 65.9	- 54.5	- 79.3	- 75.3	- 101.9	- 97.7	- 117.3
Total expenses (€)	218.6	121.7	291.3	191.3	369.0	291.3	451.9	373.3	540.4	456.6
% Solar heat	69.3	83.0	58.5	72.5	47.0	57.4	34.7	45.3	21.6	32.8

5. Conclusion

The economic DRTO of a solar thermal plant was conducted, with a planning phase to improve storage management. The weight used for the tracking of the storage target was adjusted to make a compromise between the income achieved on the first day and the tracking of the storage target ensuring revenues the second day. Using the chosen weight, DRTO was compared with a simulation based on offline DO for various levels of uncertainty. The results indicate a general improvement in the operation of the solar thermal plant, especially for large uncertainty on the solar irradiation. Future work should focus on the testing of the methodology with real data and over a longer period of time.

Abstract

High-throughput robotic platforms boost gathering informative data sets to support bioprocess development by resorting to on-line redesign of asynchronous parallel experiments. Due to significant uncertainty in both structure and parameters of mathematical models of bioreactors during early developmental stages, a probabilistic Bayesian approach is proposed. A novel algorithm that combines Asynchronous Posterior Sampling (APS) of model parameter distributions with chance-constrained optimization is used to bias data sampling depending on the modeling goal. As new data are available, model parameter distributions are updated using variational Bayesian inference. Myopic posterior sampling is then used online for purposefully changing cultivation conditions in parallel experiments. The proposed approach is based on a probabilistic macroscopic model, whereas the modelling goal is specified by integrating domain expertise and preferences via a reward function. A case study related to *Escherichia coli* expressing a desired product is used to demonstrate that a trade-off between improving parametric precision and biasing data gathering towards bioprocess optimization is achieved. Results obtained are encouraging for autonomous operation of robotic platforms.

Keywords: Bayesian inference, optimization, Experimental design, Probabilistic Models.

1. Introduction

The availability of high-throughput robotic platforms (Cruz Bournazou et al., 2017; Haby et al., 2019) demands a systematic methodology to efficiently explore large experimental search spaces while generating informative data sets to support model-based optimization during bioprocess development in the face of uncertainty. To this aim, online re-design of parallel experiments must explicitly pursue the goal of biasing data gathering to increase parametric precision only for the reduced region of operating conditions of interest. In the field of biopharmaceuticals, with the main goal of improving the understanding of innovative processes and reproducible end-use product quality, statistical analysis of available data highlights the importance of actively striking a balance between exploring for new knowledge and exploiting what is already known to account for scale-up effects on bioprocess development (Hernández Rodríguez, et al., 2019). The use of a Bayesian (probabilistic) approach (Martínez, et al., 2021) is appealing to account for significant prediction errors in macroscopic dynamic models of biological systems which are too shallow to comprehensively describe the full complexity of switching in metabolic pathways when responding to changes in the operating conditions or to the addition of an inducer for protein expression (Kiparissides et al., 2011).

2. Online re-design via posterior sampling

2.1. Bayesian set up

Let Ξ denote a parameter space, \mathcal{U} a decision space, and \mathcal{Y} an observation space. A probabilistic macroscopic model of a bioreactor is defined by a joint probability distribution over the following set of stochastic variables:

- x : y : the $n \times n_t$ hidden states time-series; the $p \times n_t$ observations (sampled data),
- u : the $n_u \times n_t$ redesign actions time-series,
- $\theta; \varphi$: the $n_\theta \times 1$ evolution parameters; the $n_\varphi \times 1$ observation parameters,
- α : the state noise precision (structural errors),
- σ : the measurement noise precision (analytical and sensor calibration errors).

From sample to sample in a dynamic experiment, these variables follow the equations:

$$\begin{aligned} x_t &= f(x_{t-1}, \theta, u_{t-1}) + \eta_t; \quad \eta_t = N(0, \alpha^{-1} \mathbf{I}), & \text{(hidden) state evolution} \\ y_t &= g(x_t, \varphi) + \varepsilon_t; \quad \varepsilon_t = N(0, \sigma^{-1} \mathbf{I}), & \text{observation (samples)} \end{aligned} \quad (1)$$

where f (resp. g) is the first-principles model (observation model), and η_t (observation ε_t) is the state (resp. measurement) modeling errors (noise). A probabilistic model of a bioreactor is then completed by specifying the (initial) Gaussian prior distributions for its parameters θ, φ . Also, Gamma distribution priors are defined for the precision hyperparameters α, σ .

We now consider a Bayesian setting, where at stage t a sample $\xi_t^* \in \Xi$ is drawn from a prior distribution $p_t(\xi)$ of model parameters $\xi = \{x, x_0, \theta, \varphi, \alpha, \sigma\}$. Depending on the modeling goal, a redesign action $u_t^* \in \mathcal{U}$ is chosen as if ξ_t^* were the true vector of parameters in a deterministic model, then the redesign action u_t^* is performed and the resulting (next) outcome y_{t+1} is measured. Using variational Bayesian inference (Daunizeau et al., 2014), the posterior $p(\xi_{t+1}^* | u_t^*, y_{t+1})$ is obtained, and a new stage of experimental redesign begins by using Thompson sampling (Russo et al., 2018). Thus, online re-design proceeds for n stages, resulting in a data sequence $D_n = \{(u_t^*, y_{t+1})\}, t = 1, \dots, n$, which is an ordered set of action-observation pairs in a dynamic experiment.

2.2. Goal-oriented online redesign

Let us assume that the desired redesign goal is specified via a *reward* function $r: \Xi \times \mathcal{D} \rightarrow \mathbb{R}$ that drives online decisions towards gathering informative data at the end of the experiment. Here, \mathcal{D} denotes the set of all possible data sequences that can be generated in a dynamic experiment. It is worth noting that depending on how r is defined, the data sequence D_n may be biased differently. The reward function can be related either to improving model selection, parametric precision, productivity, or a combination thereof. Alternatively, the modeling goal can be related to cumulative rewards gathered at the end of the experiment. In the latter case, online re-design decisions may require propagating beliefs from the current stage t onwards. In this work, a simple and intuitive strategy is used for online re-design aiming to maximize the estimated final reward \hat{r}_n at the end of the experiment based on sampling the posterior $p(\xi_{t+1}^* | u_t^*, y_{t+1})$ of the data D_{t+1} collected so far and exploring the redesign decision space using a deterministic model of the bioreactor dynamics with parameter ξ_t^* , by solving the mathematical program:

$$u_t^* = \operatorname{argmax}_{u \in \mathcal{U}} \hat{r}_n(\hat{y}_n | \xi_t^*, \hat{x}_t, u_t), \quad (2a)$$

$$\text{Subject to Eqs. (1) and } \mathcal{C}(x, u) \geq 0 \quad (2b)$$

where $C(x, u)$ stands for physiological constraints that prevents undesired cultivation conditions. In robotic platforms having n_{MBR} mini bioreactors, the optimization problem in Eq. (2) can be solved for each one of them. The optimal solution found u_t^* is expected to maximize the sampled value \hat{r}_n of the reward function by assuming that the value $\xi_{t,i}^*$ is the true one (unknown) vector of model parameters, \hat{x}_t is the inferred current state and \hat{y}_n is the predicted observation at the end of the experiment for a given action u_t . A schema of the procedure for online re-design using posterior sampling is shown in Fig. 1.

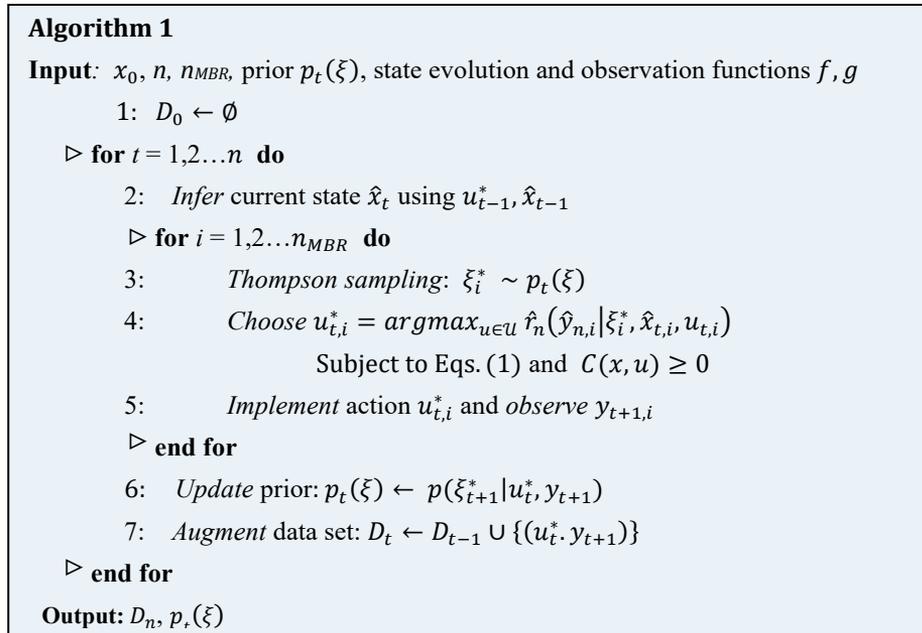

Figure 1. Online re-design strategy using Thompson sampling.

When several asynchronous parallel experiments are made, there are many possibilities for implementing the strategy in Fig. 1 to explore the search space depending on the modeling or optimization goal. The main advantage of the proposed approach is that predictions by different model parameterizations generated by posterior sampling can be experimentally tested in different mini bioreactors (MBRs), which depending on how it is done, gives rise to very different trade-offs between exploration and exploitation.

3. Case study

The proposed method was tested using artificial data generated based on the model proposed in Nickel et al. (2017), consisting of six differential equations and eighteen parameters. Eight MBRs for *Escherichia coli* fed-batch cultivations were run over a six-hour period. Samples are taken every thirty minutes and biomass (X), glucose (Glc) and acetate (Ac) concentrations are measured at-line, whereas the oxygen (O_2) is measured continuously using an online sensor. Based on new data, glucose pulses are computed following the model-based optimized feeding strategies for each MBR, and then the experiment is redesigned online. The aim of the experimental design is to find an optimal feeding profile that maximizes the amount of biomass obtained at the end of the run without allowing the oxygen concentration to drop below 20% in any of the MBRs.

The first-principles model is assumed to have the same structure as the one used to create the artificial data (no structural process-model mismatch) and 5% gaussian noise was added to the simulated values. The priors $p(\xi)$ were chosen to be wide enough to contain the real values of the parameters. The algorithm, the models and all optimization routines were implemented using Matlab 2021a. Model inversion is performed using the VBA toolbox by Daunizeau et al., (2014). Details about the toolbox can be found in the literature. Results obtained for eight MBRs runs are shown in Fig. 2. The biomass and oxygen concentrations are plotted for all bioreactors. For oxygen, only the minimum value for each sampling interval is shown for clarity. As biomass concentration increases, dissolved oxygen tension drops steadily until glucose fully depletes (not shown in Fig. 2). After that, the oxygen concentration increases until a new glucose pulse is added to the mini bioreactor, which gives rise to a drop in the dissolved oxygen tension. Once the new glucose is consumed, oxygen concentration rises again, until another pulse is fed. This pattern is repeated until the end of the experiment for all MBRs. The optimizer chooses the feeding strategy for each MBR based on the model parameterization resulting from Thompson sampling. Even when all MBRs start from the same initial condition, the different strategies give rise to a wide range of process states. However, most of the experimental datapoints are skewed towards the region of high productivity without constraint violation.

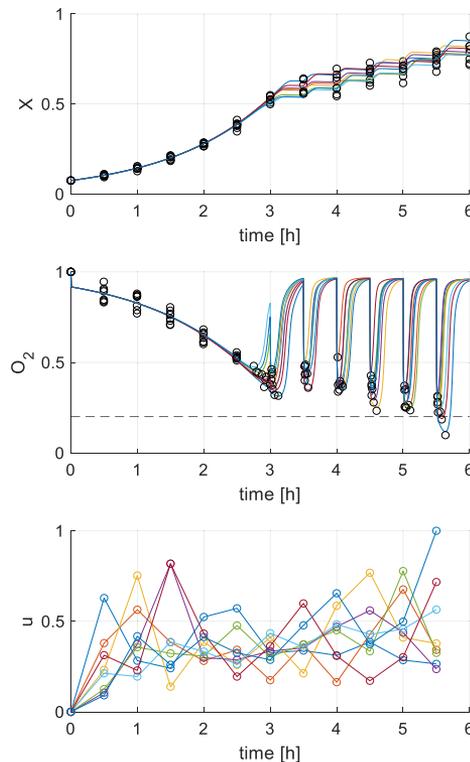

Figure 2. Normalized values for biomass and oxygen concentrations (thick lines: model predictions, circles: experimental datapoints), together with the feeding strategy for each MBR.

After each sampling time, the parameter distributions are updated with new data from all MBRs. The evolutions of some selected model parameters are presented in Fig. 3. As can be seen, the uncertainty of model parameters is significantly reduced in the first iteration and then it slowly decreases, as the mean values converge to some stationary values. This fast convergence is probably because the artificial data generator and the first-principles model have the same structure. If structural mismatch is present, convergence may take more iterations and modeling uncertainty will not be completely reduced.

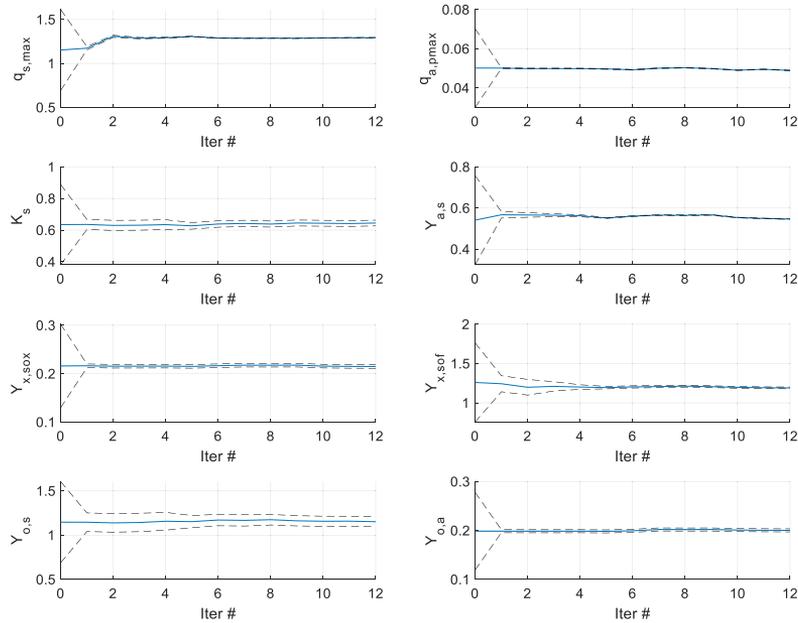

Figure 3. Evolution of selected model parameters during the experiments. Solid lines: mean values of the distributions, dashed lines: 95% confidence intervals.

Once the parallel eight experiments have been completed, the probabilistic model is updated using the complete dataset (model predictions are shown as solid lines in Fig. 2) that is biased towards improved operating conditions, which is the main objective of the proposed approach for parallel experimental redesign. The Bayesian nature of the resulting model allows for a probabilistic formulation of the optimization problem for each MBR (see Luna and Martinez, 2018):

$$u^* = \operatorname{argmax}_{u \in U} E[m_{X,end}] \quad (3.1)$$

$$\text{Subject to } \Pr(O_{2,min} > 20) > 95\% \quad (3.2)$$

where $m_{X,end}$ is the biomass amount obtained at the end of the experiment (in mg) and $O_{2,min}$ is the minimum dissolved oxygen tension (in percentage saturation). The prior and the posterior distributions of the model parameters are used to solve the chance-constrained mathematical program in Eq. (3). The resulting model-based optimized feeding strategy can be tested in a simulated experiment for a standalone bioreactor. The final amount of biomass obtained as well as the minimum dissolved oxygen concentration

during the testing run are presented in Table 1 for both model parameterizations. The uncertainty in model predictions using the prior distributions is significantly higher compared to that of the probabilistic model with the posterior distributions. As a result, the *a priori* optimized feeding profile is more cautious than the one with the probabilistic model parameterized using the updated distributions; for the later a higher amount of biomass is obtained while the dissolved oxygen tension is kept above the threshold value during the whole run. The information content of the generated data in the redesigned parallel experiments is aptly biased for solving the optimization problem in Eq. (3).

Table 1. Performance comparison of model parameterizations

	X_{end} [mg]	$O_{2,min}$ [%]
u_{prior}^*	19.7	57.59
$u_{posterior}^*$	31.6	21.20

4. Concluding remarks

A new approach for on-line redesign of parallel experiments using Thompson sampling was proposed. Results obtained for the case study demonstrate the advantages of enforcing chance-constrained physiological constraints in balancing exploration with exploitation based on sampling model parameter distributions for feed rate optimization.

Abstract

Integrated continuous bioprocessing (ICB) holds great promise towards achieving higher efficiency, a critical target for ensuring the advent of biopharmaceutical manufacturing. Culture productivity must be drastically improved to reduce production cost projections, especially in comparison to traditional fed-batch process platforms (Pollock et al., 2017). The present paper explores the benefits of continuous bioprocessing, employing dynamic optimisation of upstream fermentation for production of monoclonal antibodies (mAb). Industry-standard cultures of hybridoma cells have been used to develop models of mAb bioreactor operation. These models track several state variable trajectories of interest, including profiles for viable cells, substrates, by-products and the target mAbs product. Dynamic optimisation of both operation modes (fed-batch and perfusion bioreactors) has been undertaken, with the objective function of maximizing the final mAb product titers through optimal feeding strategies in two reactor types for improved culture proliferation. The clear differences in terms of reactor space (capital costs) and time (operating costs) are highlighted, and a fair comparison basis is established so as to evaluate performance. For both modes of operation, a technoeconomic analysis illustrates the implications of optimal bioreactor designs, with a view to systematic decision-making in mAb ventures.

Keywords: Biopharmaceutical manufacturing; monoclonal antibodies; dynamic optimisation.

1. Introduction

Monoclonal antibodies (mAbs) are immune proteins which are genetically engineered within laboratories for the treatment of a variety of ailments, including some autoimmune diseases and cancers (Schulze-Koops et al., 2000), (Adams et al., 2005). In terms of commercial expansion, mAbs are currently the fastest growing biopharmaceutical product type in the market, representing the majority (57%) of total European Medicines Agency (EMA) biopharmaceutical approvals between 2015 and 2018 (Grilo et al., 2019).

Traditionally, biopharmaceutical process platforms have consisted of a series of batch mode operating units as seen in Figure 1. Batch operation has been favoured due to its inherently simpler configuration for the manufacture of small-scale speciality products such as (bio)pharmaceuticals (Shirahata et al., 2019). Despite this, the industrial drivers of process economics and rapid quality control generate a strong motivation to pursue semi-continuous or (preferably) continuous industrial scale biomanufacturing. The need to provide accessible therapies in developing countries, and the advent of biosimilars, means that optimising process economics is more imperative than ever in today's market. Steadily improving efficiencies of commercially available bioreactors address this need.

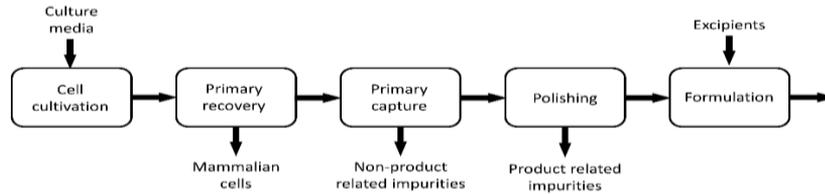

Figure 1: Generalised process platform for the manufacture of biotherapeutic proteins.

The Quality by Design (QbD) framework set out by the U.S. Food & Drug Administration (FDA) highlights the need to explore continuous processing for many therapies, and our recent paper stresses the role of parametric model analyses (Jones and Gerogiorgis, 2021). The present study capitalises on dynamic modelling and optimisation methods towards probing technoeconomic potential for fed-batch and perfusion bioreactors to manufacture mAbs. Dynamic optimisation solutions are first established in order to elucidate feeding and outlet trajectories for maximised mAb production. Following this, both bioreactor designs and cost components are studied within a technoeconomic framework, providing novel insights into operational efficiency and potential for manufacturing cost reductions.

2. Dynamic Modelling and Optimisation for mAb Production

2.1 Dynamic Model of CHO Cell Fermentation

A widely cited model published by De Tremblay et al. (1992) has been selected as a basis for the dynamic study, the state variables of which are presented in Table 1. Growth rates, consumption rates and productivities have been modelled using Monod kinetics, and all relevant kinetic parameters are detailed in the original publication. In this biosystem, hybridoma cells secrete mAbs and growth limiting metabolites (lactate and ammonia). Throughout the time domain, both designs are inoculated with glucose and glutamine substrates, to promote culture growth. In the perfusion bioreactor design, the outlet flow consists of a bleed flow to modulate cell density, and a harvest flow to recover protein.

Table 1: Dynamic model for mAb production (De Tremblay et al., 1992).

$$\frac{dV}{dt} = F_{in} - F_{out} \quad (1) \quad \frac{d[X_V]}{dt} = (\mu - k_d)X_V - \frac{(F_{in} - F_{harvest})}{V}X_V \quad (2)$$

$$\frac{d[GLC]}{dt} = (GLC_{in} - GLC) \frac{F_{in}}{V} - q_{GLC}X_V \quad (3) \quad \frac{d[GLN]}{dt} = (GLN_{in} - GLN) \frac{F_{in}}{V} - q_{GLN}X_V \quad (4)$$

$$\frac{d[LAC]}{dt} = q_{LAC}X_V - \frac{F_{in}}{V}LAC \quad (5) \quad \frac{d[AMM]}{dt} = q_{AMM}X_V - \frac{F_{in}}{V}AMM \quad (6)$$

$$\frac{d[mAb]}{dt} = q_{mAb}X_V - \frac{F_{in}}{V}mAb \quad (7)$$

2.2 Dynamic Optimisation of Fed-Batch and Perfusion Bioreactors for mAb Production

A technoeconomic comparison of both (fed-batch and perfusion) bioreactors hosting the mAb biochemical system of Table 1 should proceed on the basis of dynamic optimisation, to ensure that the two are used in the most productive (albeit diverse) regime of operation. For both cases, a heavily constrained Non-Linear Programming (NLP) problem emerges. Manipulated and state variable profiles of these ODEs have been discretised in time using orthogonal collocation of finite elements, thus facilitating NLP solver use (Biegler, 2007). The fed-batch bioreactor optimisation is solved with APOPT (Hedengren et al., 2014). The perfusion bioreactor optimisation is solved via IPOPT (Wächter and Biegler, 2006).

3. Results and Discussion

3.1 Dynamic Optimisation of a Fed-Batch Bioreactor for mAb Manufacture

Fed-batch dynamic optimisation has been conducted with the initial conditions and state variable constraints exactly as specified by De Tremblay et al. (1992), enabling the validation of our bioreactor design and optimisation results. Key design trajectories are illustrated in Figure 2. The manipulated (inlet flowrate) variable discretisation is varied between 0.05 L day^{-1} and 0.10 L day^{-1} , to analyse its effect on bioreactor performance. The bioreactor time horizon discretisation has been set to 0.5 days for both optimisations.

The trajectories of the state variables for both fed batch designs are very similar across the entire time domain, suggesting the additional flowrate set points provided by the finer (0.05 L day^{-1}) discretisation step provided no tangible benefit to bioreactor performance. Furthermore, we underline that an improved final mAb titer (157 mg L^{-1}) is achieved in comparison to the previous, lower optimised titer (147 mg L^{-1}) (De Tremblay et al., 1992).

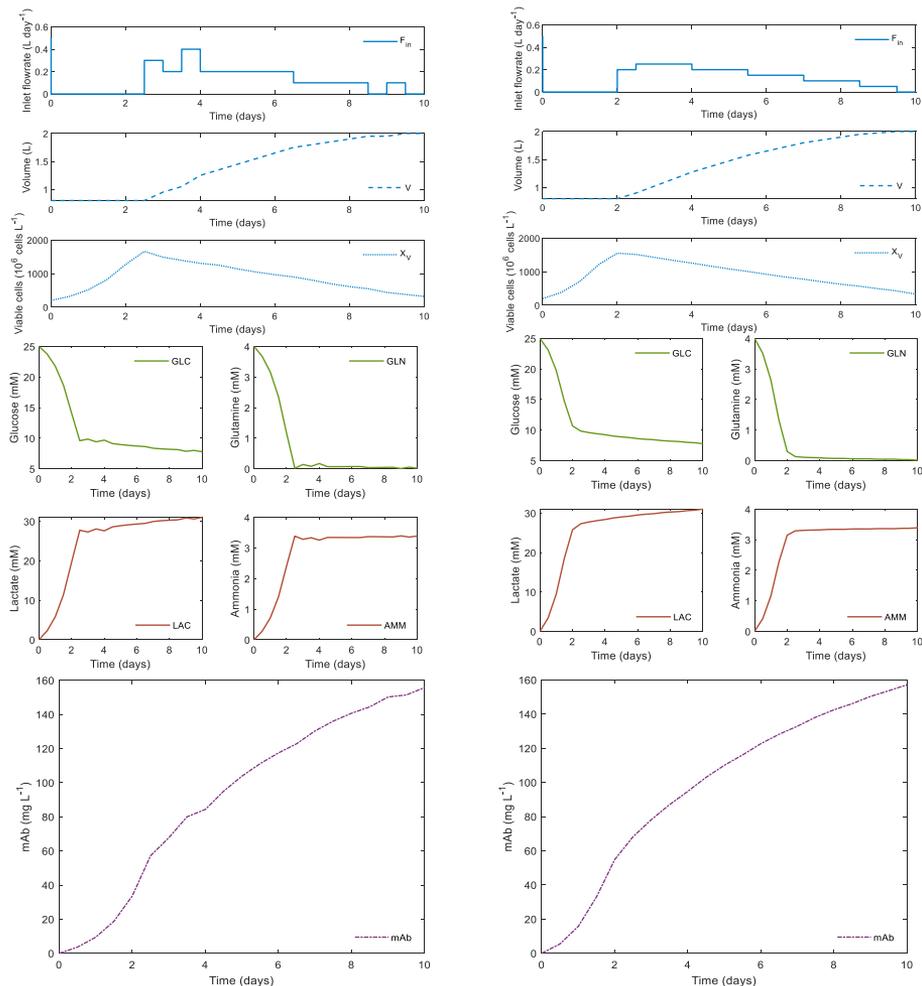

Figure 2: Optimal fed-batch bioreactor trajectories for 0.10 L day^{-1} and 0.05 L day^{-1} (R).

3.2 Dynamic Optimisation of a Perfusion Bioreactor for mAb Manufacture

Identical initial conditions and inlet flowrate constraints have been used for optimising the fed-batch and perfusion bioreactors. Manipulated variables include bleed and harvest flows, and their constraints were set equal to the inlet flowrate constraints. Key variable and mAb titer trajectories for the optimised perfusion reactor are illustrated in Figure 3.

Some fundamental features of the trajectories are summarised to analyse performance. The bleed flowrate remained fixed at zero throughout the time domain so as to retain the maximum number of cells in the reactor during operation, maximizing mAb production. A significantly larger quantity of total feed has to be provided in the optimised perfusion system, in comparison to the optimised fed-batch bioreactor (3.96 L compared to 1.20 L). The ability to harvest growth-limiting by-products of lactate and ammonia in the perfusion system has been shown to be highly beneficial to the bioreactor productivity. The importance of harvesting is evident when comparing final mAb titers for the systems, as perfusion achieves 210 mg L^{-1} , representing a 33.8% increase vs. the fed-batch case.

3.3 Comparative Technoeconomic Analysis of Fed-Batch vs. Perfusion Bioreactors

Extensive technoeconomic analysis of the two optimised bioreactors required a basis of operation and industrial scale unit sizing; reported campaign lengths vary for these, so a typical fed-batch (15 days) and perfusion time (30 days) are explored for both designs. Industrial fed-batch bioreactor sizes reported are much greater than respective perfusion units. This disparity is due to the difference in maturity of the technologies, as less than 10% of commercial biotherapeutics are manufactured via perfusion (Lindskog, 2018). Bioreactor sizes of 2000 L and 12000 L have been previously employed for perfusion and fed-batch operation modes, respectively, in the literature (Farid, 2007; Yang et al., 2019). The nominal mAb basis considered in our analysis is 200 kg annually (Klutzb et al., 2016). Figure 4 shows the annual operating cost breakdown for both bioreactor types, different initial cell densities and campaign times. Despite handling higher cell densities better, increased perfusion bioreactor culture and medium demands induce higher cost for the higher ($40 \cdot 10^6 \text{ cells mL}^{-1}$) density designs. Conversely, the perfusion bioreactor operation shows improved cost viability vs. fed-batch, for the low ($0.2 \cdot 10^6 \text{ cells mL}^{-1}$) density case.

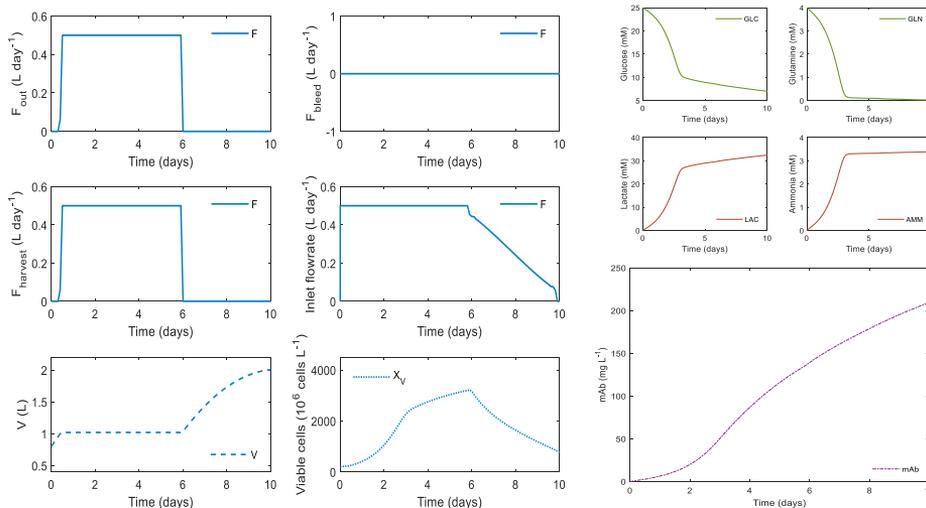

Figure 3: Optimal perfusion bioreactor trajectories of manipulated and state variables

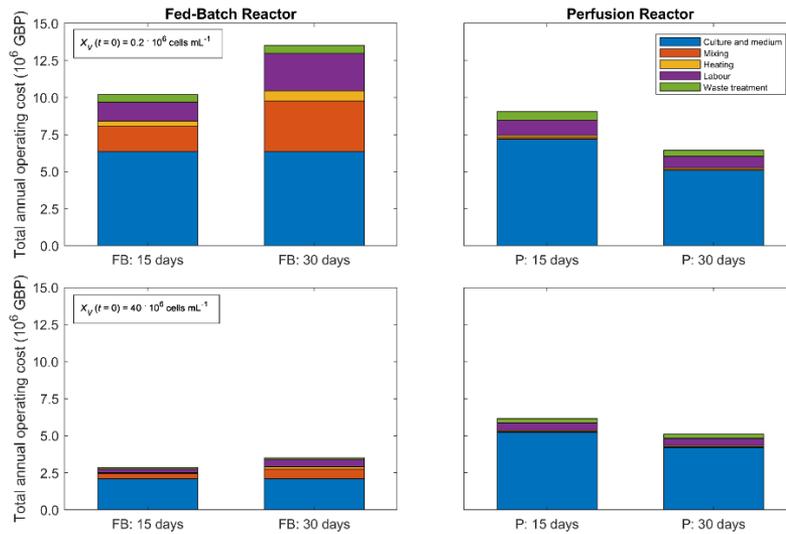

Figure 4: Operating costs of optimised (FB: fed-batch, P: perfusion) industrial designs.

A key difference concerns higher utility (heating and mixing) costs needed for fed-batch reactor vessels, even if fixed (purchase) cost per L is lower. Extended campaigns benefit perfusion bioreactor designs, but adversely affect fed-batch reactor cost-effectiveness. These observations in Fig. 4 plots agree with the established understanding that perfusion bioreactor campaigns should be longer than fed-batch bioreactor ones (Yang et al., 2019).

Finally, it is important to analyse the long-term viability of these designs for industrial implementation. Accordingly, the Cost Of Goods Sold per gram of mAb (COGS) metric is computed for the fed-batch and perfusion designs with lowest operating costs (Eq. 8).

$$\text{COGS} = \frac{\text{NPC} (\pounds)}{\text{Total mAb Production (g)}} \quad (8)$$

The Net Present Cost (NPC) is another key metric, being a function of capital expenditure (CapEx), operational expenditure (OpEx), interest rate (r) and plant lifetime (τ) (Eq. 9).

$$\text{NPC} = \text{CapEx} (\pounds) + \sum_{i=1}^{\tau} \left(\frac{\text{OpEx} (\pounds)}{(1-r)^i} \right) \quad (9)$$

For the technoeconomic analysis performed here, a range of fixed interest rates elucidated the sensitivity of the optimised designs to market pressures. The COGS results for both modes and interest rates between 1-10% (15-year plant lifetime) are shown in Figure 5.

Despite initially being marginally favourable for perfusion design (due to reduced capital expenditure from smaller vessel material), COGS value indicate that perfusion design is eventually outperformed by the fed-batch design soon afterwards (and well ahead of mAb plant lifetime), due to clear Operating Cost (OpEx) differences. At higher interest rates, perfusion mode exhibits a significant COGS value surge towards the end of plant lifetime.

For identical plant lifetime and interest rates, the fed batch design experiences a relatively small change in COGS, reinforcing the conclusion that the more established fed-batch reactor technology is still more cost-effective for mAbs in the biopharmaceutical industry.

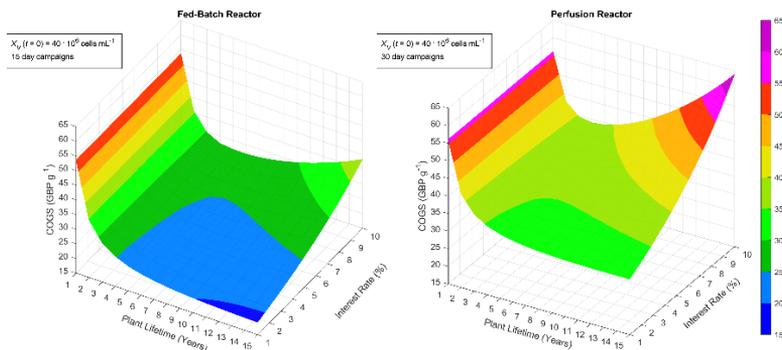

Figure 5: Cost of goods sold per gram analysis for the optimised industrial designs.

4. Conclusions

Technoeconomic analysis via dynamic optimisation of a hybridoma cell line employed for fed-batch as well as perfusion mode mAb production has been addressed in this study. The mAb titer for the optimised fed-batch design is improved compared to the previous literature value reported (De Tremblay et al., 1992). A further enhancement of the mAb titer for bench-scale design has been established for the perfusion bioreactor, highlighting the importance of reactor harvest flowrate in manipulating cell dynamics for proliferation. The economic analysis considers the cost-effectiveness of both (fed-batch and perfusion) bioreactor systems, for two initial viable cell densities and two campaign durations. Larger initial cell densities decrease Operational Cost (OpEx) for both bioreactors, while longer campaign times clearly benefit perfusion vs. fed-batch bioreactor performance. Plant lifetime analysis is conducted via the Cost Of Goods Sold (COGS) per gram metric, showing lower long-term viability of perfusion designs, especially for high interest rates.

Abstract

The present contribution addresses the design of feedback control in a biodiesel washing column with structured packing. The column dynamics is described with a pseudo-homogeneous dispersion model previously developed in gPROMS[®] ModelBuilder and validated against industrial data. The operation of the extraction column was analysed for scenarios where biodiesel composition changes, presence of contamination in biodiesel inlet, and change of glycerol concentration in the washing water inlet. The impact of these disturbances on the column hydrodynamics (e.g., flooding, phase inversion) and product quality was analysed. Finally, the performance in open-loop, closed-loop, and closed-loop with decouplers of the system was carefully compared.

Keywords: Biodiesel, Liquid-liquid extraction, Process Control, Dynamic simulation

1. Introduction

Biodiesel (fatty acids methyl esters or FAME) is a recognised renewable substitute of fossil diesel, and its production in Portugal has been steadily increasing with an average annual growth rate of 4.1 % since 2013 (Knoema, 2021). A recent trend in the European Union is the increasing incorporation of waste cooking oils (WCO) in biodiesel production (Grinsven et al., 2020), due to its lower cost and by new regulations limiting the production of first-generation biodiesel. This trend causes the formulations of raw oil to fluctuate significantly, requiring more process flexibility and adequate control systems to maintain the product within strict quality standards and prevent operational problems.

Existing literature devoted to process control in the biodiesel industry focuses on the transesterification reaction section, while the biodiesel washing step is described with shortcut methods (Brásio et al., 2016). However, the increase of the incorporation of lower-quality feedstocks in biodiesel processing may originate operation problems in the column due to subtle changes in the oil composition, leading to more frequent shutdowns and higher maintenance costs. As such, simplified models are of limited use to mitigate these issues and design effective control systems.

This work aims to implement a robust control system based on a real industrial biodiesel washing column model to prevent operational problems and keep the product within quality standards. The remaining of the paper is structured as follows: the implementation and tuning of the control scheme are demonstrated in Section 2; the results are presented in Section 3, followed by final remarks in Section 4.

2. Development of the control strategy for the extraction column

The dynamic model of the extraction column was developed in gPROMS[®] ModelBuilder following a detailed pseudo-homogeneous approach shown in (Pinho, 2021). The washing column is static, has structured packing and operates isothermally. The general transient mass balance equations for the continuous and dispersed phases, the boundary and initial conditions, and the hydrodynamic behaviour of the column are detailed in Mohanty (2000) and Pinho (2021) based on the most accurate state of the art. The overall model was validated with data retrieved from an industrial unit, Pinho (2021). For simplicity sake, all input/output variables will be presented in this section as deviation variables. This analysis was conducted with WCO-based biodiesel at 45 °C and a solvent-to-feed ratio (S/F) of 13.5 vol%.

Regarding extraction columns, most control systems focus on the interface level between the two phases inside the column and outlet concentrations control. If this level is not adequately stabilised, the dispersed layer can flood, causing the loss of solvent and product (Weinstein et al., 1998). Typically, the manipulated variables (MV) used to control the holdup and product composition are the dispersed-phase flow rate, the continuous-phase feed/effluent flow rate and the rotor speed (in the case of agitated Kühni columns).

2.1. Open-loop testing and system linearisation

The impact of disturbances in input variables related to the biodiesel formulation, such as interfacial tension, density, viscosity, and inlet glycerol composition (that reflects a poor phase separation) on the glycerol composition (wt%) of the biodiesel outlet stream, flooding percentage of both phases, holdup and in the phase inversion parameter (χ) was analysed. The effect of step disturbances in the inlet and outlet biodiesel and water mass flow rates over the outputs mentioned above are also shown.

To proceed with the development of a control system in MATLAB[®], it was necessary to linearise the system, which was achieved with the *System Identification* toolbox. All transfer functions had a fit to the estimation data higher than 94 % and are listed in Tables 1 to 3.

Table 1: Transfer functions for the outlet flow rates and output variables.

Transfer Functions	$Q_{\text{out water}}$ (kg/h)	$Q_{\text{out biodiesel}}$ (kg/h)
Biodiesel Glycerol Composition (wt%)	$\frac{-5.98E(-3)}{s^2+121.6s+644.9}$	$\frac{0.016s+0.135}{s^3+137.3s^2+8362s+4.40E04}$

2.2. Variable pairing

The classical methods of Relative Gain Array (RGA) and Singular Value Analysis (SVA) were used to analyse the multivariable process control problem (Seborg et al., 2011). Since manipulating both inlet and outlet flow rates for biodiesel and water would lead to an over-specified system, only the outlet streams are considered for control purposes. On the other hand, Weinstein et al. (1998) demonstrated that manipulating the outlet instead of the inlet flow rate would lead to smoother system behaviour. Consequently, the mass fraction of glycerol in biodiesel and holdup are the two controlled variables. The recommended pairings from RGA and SVA the pairings: glycerol outlet composition — water outlet flow rate, and holdup — biodiesel outlet flow rate are recommended. These pairings have a λ of 0.83 (compared to 0.82 and 1.40) and a condition

number of 3.78, whilst other pairings have a condition number of ∞ . The other possible pairings presented singular steady-state gain matrices, meaning that they are ill-conditioned. The control scheme implemented is illustrated in Figure 1. The nomenclature used in Figure 1 will refer to the controllers in the following subsection.

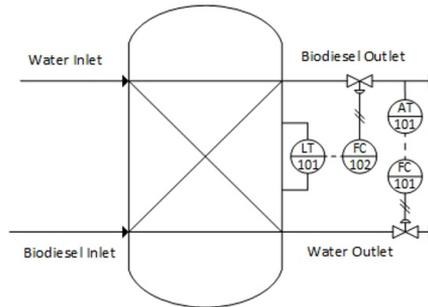

Figure 1: Control scheme for the biodiesel extraction column.

2.3. Controller tuning

Knowing which variables to pair, it is necessary to tune the controllers. The controllers tested were evaluated based on integral error criteria in set-point tracking and disturbance rejection. The three most used integral error criteria are the integral of the squared error (ISE), the integral of the absolute value of the error (IAE), and the integral of the time-weighted absolute error (ITAE). Here, the IAE was the deciding factor to select the controllers. The control system was also analysed in terms of relative stability with the concepts of Gain Margin (GM) and Phase Margin (PM) (Seborg et al., 2011). Saturation was added to the MV, -10% to 10% for biodiesel and -20% to 20% for water mass flow rates. For this process, set-point changes are not expected, so only the results for disturbance rejection are shown.

Starting with the FC101 controller, the Ziegler-Nichols (ZN) and Internal Model Control (IMC) tuning methods were tested. These methods and respective tuning procedures are detailed in Seborg et al. (2011). The controller settings for the different tuning methods are presented in Table 4, with the values of GM and PM. The controller is in parallel, and the derivative mode has a filter N . For the disturbance rejection, a disturbance of -80% in the interfacial tension was applied to the system. The PI controller tuned with IMC has the smallest value of IAE.

Table 4: Controller settings for the controller FC101 according to ZN and IMC tuning methods and Gain and Phase Margins.

Tuning Method		ZN		IMC	
Controller mode		PI	PID	PI	PID
Controller Settings	K_P	-2.05E06	-2.73E06	-2.24E06	-1.07E09
	K_I	-7.21E07	-1.60E08	-6.36E07	-1.41E11
	K_D	-	-1.16E04	-	-8.08E05
	N	-	100	-	100000
Relative Stability	GM	68	1392	67	2
	PM	34	23	37	47

Similarly to FC101, the controller FC102 was tuned with two different methods. Both ZN and IMC tuning approaches were tested; however, the IMC tuning technique (in Mathematica[®]) failed to return a viable controller. Hence, the Cohen-Coon (CC) tuning method was used (Cohen and Coon, 1953). The controller settings and relative stability margins are shown in Table 5. Analysing this table and taking the IAE criterion as the deciding factor, the PI controller tuned with CC rules has a slightly better performance when compared with the other ones.

Table 5: Controller settings for the controller FC102 according to ZN and CC tuning methods and Gain and Phase Margins.

Tuning Method		ZN		CC	
Controller mode		PI	PID	PI	PID
Controller Settings	K_P	3.02E04	4.03E04	5.76E04	5.34E04
	K_I	1.64E06	3.65E06	9.21E06	5.18E06
	K_D	-	111	-	91.7
	N	-	100	-	1000
Relative Stability	GM	∞	∞	∞	∞
	PM (°)	156	∞	125	∞

Two decouplers were added to minimise the interaction between the closed-loops, which is observable by the peaks in Figure 3, for example, in Section 3. However, analysing the transfer function of one of the decouplers, a real right-half plane pole was identified, which makes it unstable. Hence, static decouplers were used instead.

3. Results

After implementing the multiloop with decouplers, the system response was evaluated in open-loop, closed-loop, and closed-loop with static decouplers to disturbances in interfacial tension, biodiesel density and feed glycerol composition are presented in Figures 2 to 4. The response of the MV is not shown here.

It is observed that the addition of decouplers to the control system was beneficial. The control of holdup significantly improved with the reduction of settling-time and lower overshoots; the control of biodiesel glycerol composition was not ideal due to an increase in oscillation; however, the overshoots were minimised. Additionally, the closed-loop interactions were reduced by adding decouplers, which successfully reduced excessive controller action.

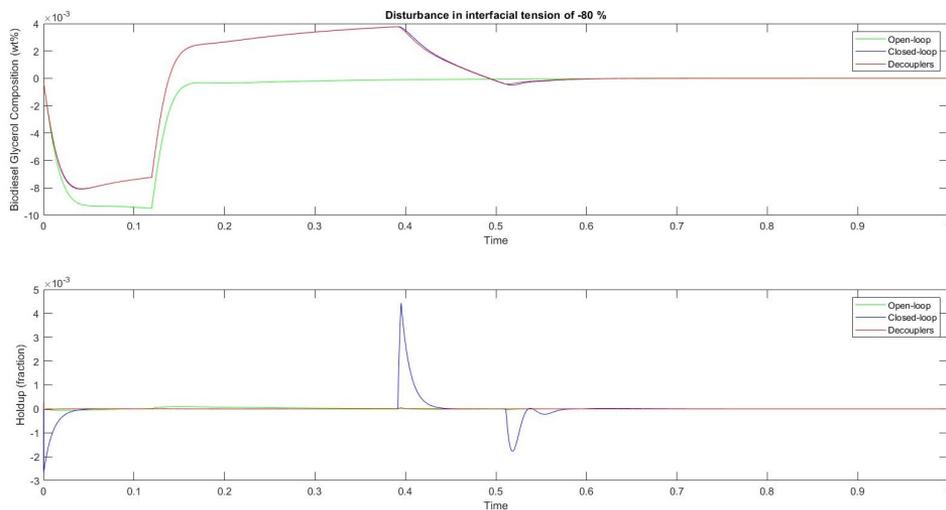

Figure 2: Evolution of the controlled variables: biodiesel glycerol composition (wt%) and holdup fraction to a disturbance in interfacial tension of -80% .

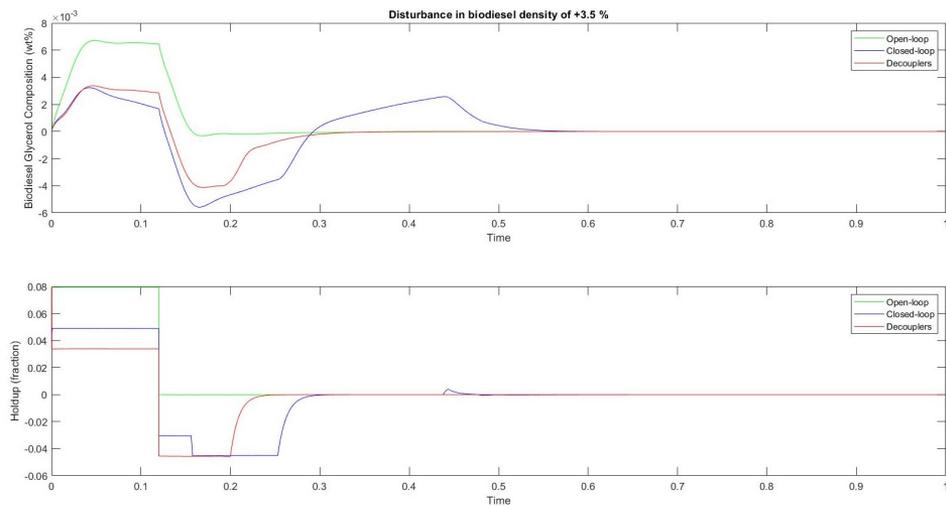

Figure 3: Evolution of the controlled variables: biodiesel glycerol composition (wt%) and holdup fraction to a disturbance in biodiesel density of 3.5% .

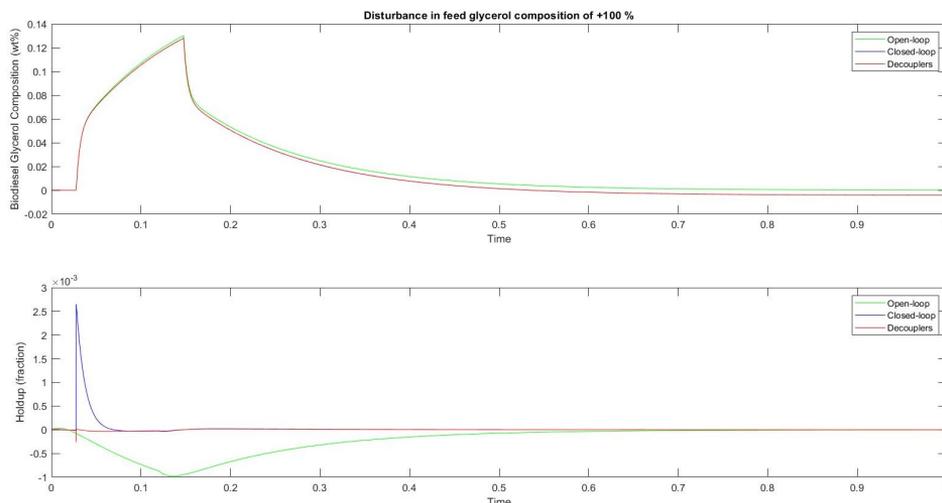

Figure 4: Evolution of the controlled variables: biodiesel glycerol composition (wt%) and holdup fraction to a disturbance in feed glycerol mass composition of 100 %.

4. Conclusion and Future Work

The present work focuses on the implementation of a 2×2 control system on a dynamic model of a biodiesel washing column. The model was developed in gPROMS[®] ModelBuilder using a rate-based approach and describing the dispersed phase as pseudo-homogeneous. In this model, mass transfer phenomena, hydrodynamics and biodiesel properties are estimated. The model was validated with industrial data provided by an industrial partner and successfully predicts the solubility of the solutes in the washed biodiesel.

The system is analysed to implement a control scheme. The best-suggested pairing is Glycerol outlet composition in the biodiesel-water outlet flow rate and holdup-biodiesel outlet flow rate. The controllers are then tuned with the IMC and CC methods, respectively. The addition of static decouplers is successful in minimising strong loop interactions. Overall, the control system has a good performance for set-point tracking and disturbance rejection.

Abstract

As the pharmaceutical industry transitions from batch to continuous manufacturing, real-time monitoring, and mechanistic model-based control are essential to conform to FDA quality standards. Glidants and lubricants are known to affect the Critical Quality Attributes (CQAs) of a tablet such as tensile strength, tablet porosity, and dissolution profile (Razavi et al., 2018; Apeji and Olowosulu, 2020). Quantitative models for predicting these effects are essential for enabling centralized control strategies of lubricant and glidant feeding and blending in direct compression tableting lines. This work presents the development of mechanistic reduced order models to capture the effects of lubricant (magnesium stearate) and glidant (silica) on CQAs and Critical Process Parameters (CPPs). A Latin Hypercube experimental campaign with thirty different mixing conditions of silica with MCC (Avicel PH200) and APAP (Acetaminophen) was carried out using a Natoli NP400 tablet press and a SOTAX AT4 tablet tester. Experiments show that the tensile strength and blend bulk density are significantly affected by the mixing conditions of silica. Similarly, adding magnesium stearate (MgSt) changes the bulk density of the blend, compaction force required to form a tablet, and tensile strength of the tablet, depending on the lubrication conditions (Mehrotra et al., 2007; Razavi et al., 2018).

Keywords: Lubricant effects, glidant effects, continuous pharmaceutical manufacturing

1. Introduction

The production of tablets in the pharmaceutical industry has predominantly been operated in batch mode, where tablets are produced using a specified amount of raw materials within a given time frame. In recent years, with the advent of process analytical technology (PAT) sensors, the transition from batch to continuous manufacturing has been made possible. However, modeling and advanced understanding of the tablet production process is essential to implement continuous manufacturing in the pharmaceutical industry. In particular, active process control using the Quality-by-Control (QbC) approach (Su et al., 2019) requires predictive and fast models of the tablet Critical Quality Attributes (CQAs). Therefore, steady-state mechanistic models which can predict Critical Process Parameters (CPPs) and CQAs of tablets are essential to the implementation of robust control strategies in the direct compression tableting line.

In continuous manufacturing, it is essential that the powder has good flowability. A glidant, such as colloidal silica (Silica), is an excipient added to improve powder flowability. A lubricant, such as magnesium stearate (MgSt), helps reduce internal friction during compaction and tablet-tooling

friction during ejection. Typically formulations use 0.25%-1% w/w of MgSt and 0-0.02% w/w of Silica. Even when added in such small amounts, these excipients significantly affect the bulk properties of the powder, such as bulk density (Mehrotra et al., 2007), and surface properties, such as the strength of solid bridges formed during compaction. This change in the properties of the blend naturally impacts the tableting process and the CQAs of the final tablet (Razavi et al., 2018; Van Veen et al., 2005), including its dissolution profile, and in turn, the bioavailability of the active pharmaceutical product (API).

It is well-known that MgSt increases the bulk density of the powder and reduces the tensile strength of the tablets (Mehrotra et al., 2007). Quantitative models to describe the effects of MgSt on the tensile strength and elastic modulus of tablets were proposed by Razavi et al. (2018). However, little research has been carried out to quantify the effects of Silica. In this paper, mechanistic reduced-order models of the entire tableting process, i.e., algebraic models based on the understanding of the underlying physical mechanisms which describe the effects of Silica and MgSt on tablet CQAs, are proposed and calibrated. These models are a means to implement moving horizon estimation-based non-linear model predictive control (MHE-NMPC) for the tablet press at Purdue's pharmaceutical continuous manufacturing pilot plant (Huang et al., 2021).

The paper is organized as follows. In Section 2, the design of experiments (DoE) to study both MgSt and Silica is described. In Section 3, the quantitative models proposed for CPPs and CQAs of the tableting process are discussed, with a special focus on the differences between MgSt and Silica effects. Section 4 discusses conclusions and directions for future work.

2. Materials and Methods

Two experimental campaigns were carried out, one to study the effects of Silica and the other to study the effects of MgSt. The materials used in this study were microcrystalline cellulose Avicel PH200 (MCC), 10% w/w acetaminophen (APAP), and Silica and MgSt at different concentrations. The DoE to study the effects of Silica was carried out using a mixture of MCC, APAP, and Silica. MCC and APAP were mixed in a Tote blender with 0-0.2% w/w Silica for 10-30 minutes. The in-die thickness was kept constant at 3.1 mm and the dosing position was chosen to be 7-11 mm, to manufacture tablets having a broad range of relative densities, i.e., 0.6-0.9. The tablet press turret speed was varied between 25-35 rpm. A Latin Hypercube sampling (Viana, 2013) of turret speed, dosing position, concentration, and mixing time for 30 experiments was created using the MATLAB function `lhsdesign`. The same procedure was repeated for the second DoE to characterize the effects of MgSt. Blends with 0-2% w/w MgSt, APAP, and MCC were prepared by mixing in a Tote blender for 11-30 minutes. The in-die thickness was also chosen to be 3.1 mm, the dosing position 9-13 mm, and the tablet press turret speed 11-20 rpm. Tablets formed with MgSt blends required higher dwell time as compared to Silica blends and hence lower turret speeds were used in the MgSt DoE. In this case, a Latin hypercube design of 20 experiments was created. Next, tablets were manufactured using a Natoli-NP400 tablet press using D-type tooling with shallow cup depth. For each run in the DoE, a SOTAX AT4 tablet tester was used to measure tablet thickness, diameter, weight, and hardness of 50 tablets under steady-state manufacturing conditions. The tablet press hopper was filled with 0.5 kg of the blend at the start of each experimental run.

3. Reduced Order Models

The bulk density of a powder ρ_b is observed to be affected by shear strain γ imparted to the powder during mixing (Mehrotra et al., 2007). As the total shear increases, the bulk density initially increases and ultimately reaches a plateau, during which no further change in the bulk density is observed. The following asymptotic relationship between the bulk density and total shear is

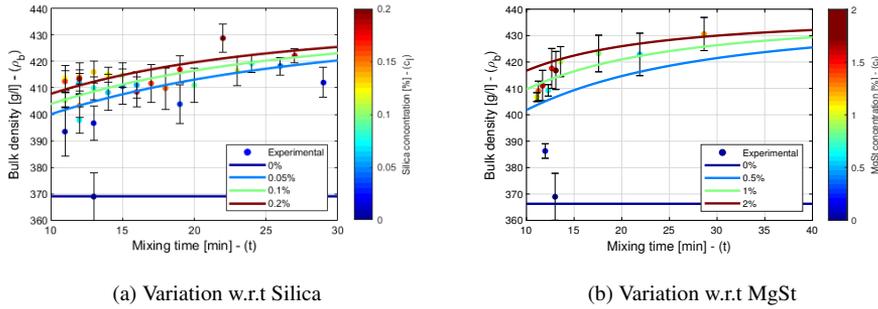

Figure 1: Bulk density increases with increase in concentrations for both Silica and MgSt.

proposed to capture this trend

$$\rho_b = \rho_{b,\infty} - \frac{\rho_{b,\infty} - \rho_{b,0}}{1 + C_\rho} \quad \text{with} \quad C_\rho = \frac{c_l^{r_1} (\gamma + \gamma_0)^{r_2}}{r_3} \quad (1)$$

where $\rho_{b,\infty}$ and $\rho_{b,0}$ represent the bulk densities when the shear imparted is infinite and zero respectively, C_ρ is a lumped parameter which defines the glidant or lubricant mixing conditions, where c_l is glidant or lubricant concentration, γ is the shear imparted to the powder during mixing, γ_0 is the initial shear imparted during pre-blending, and r_1, r_2, r_3 are fitting parameters. The total shear $\gamma + \gamma_0$ is considered proportional to mixing time. Figure 1 shows that increasing the concentration or mixing time of Silica or MgSt results in an increase in bulk density. The bulk density gradually increases and reaches an asymptotic value.

The tablet weight, W , is affected significantly by the process parameters such as the turret speed (n_T), feeder speed (n_F), dosing position (fill depth $-H^{\text{fill}}$) and diameter of the tablet (D). If turret speed is too high, then the die may be filled unevenly, resulting in undesired deviation in tablet weight, ultimately affecting the dosage of the active ingredient. The weight of a doubly-convex tablet formed by Natoli D-type tooling with cup-depth, h , is computed as follows:

$$\frac{W}{\rho_b V^{\text{fill}}} = -\xi_1 \frac{n_F}{n_T} + \xi_2 \frac{H^{\text{fill}}}{D} + \xi_3 \left(\frac{H^{\text{fill}}}{D} \right)^2 \quad (2)$$

with the volume of die-cavity, V^{fill} , given by

$$V^{\text{fill}} = \frac{\pi D^2 H^{\text{fill}}}{4} + \frac{\pi h}{6} \left(\frac{3D^2}{4} + h^2 \right) \quad (3)$$

where ξ_1, ξ_2, ξ_3 are fitting parameters. The same model describes the trends for both MgSt and Silica blends.

The main compaction force F_{punch} for the effect of Silica can be estimated using Kawakita equation (Kawakita and Lüdde, 1971):

$$\sigma_{\text{punch}} = \frac{4F_{\text{punch}}}{\pi D^2} = \frac{\rho^{\text{in-die}} - \rho_b / \rho_t}{[\rho^{\text{in-die}}(a-1) + \rho_b / \rho_t] b} \quad (4)$$

with the in-die relative density, $\rho^{\text{in-die}}$, given by

$$\rho^{\text{in-die}} = \frac{W}{\rho_t V^{\text{in-die}}} \quad (5)$$

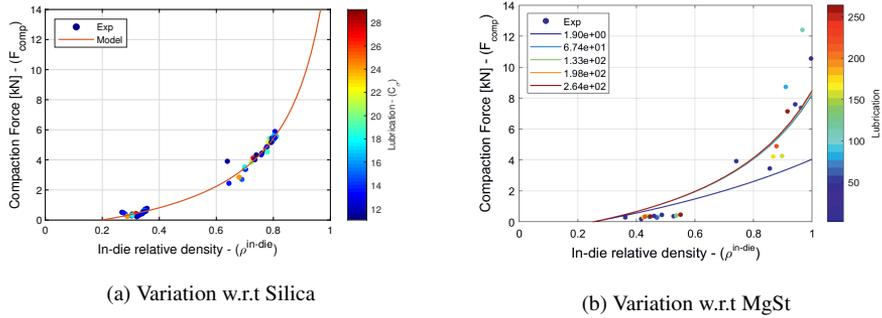

Figure 2: (a) shows that compaction force is independent of mixing conditions of Silica. (b) shows that compaction force decreases with increase in lubrication.

where σ_{punch} is the compaction pressure, ρ_t is the true density of the blend, a and b (MPa) are Kawakita parameters, $V^{\text{in-die}}$ is the volume of die-cavity with main compression thickness $H^{\text{in-die}}$, given by

$$V^{\text{in-die}} = \frac{\pi D^2 H^{\text{in-die}}}{4} + \frac{\pi h}{3} \left(\frac{3D^2}{4} + h^2 \right) \quad (6)$$

The compaction force for MgSt blends depends on lubrication conditions (Figure 2b). This effect is incorporated by modeling the parameter a as

$$a = \frac{a_0 - a_\infty}{1 + C_c} + a_{0,\infty} \quad \text{with} \quad C_c = \frac{c_l^{p_1} (\gamma + \gamma_0)^{p_2}}{p_3} \quad (7)$$

with C_c where $a_0, a_\infty, p_1, p_2, p_3$ are fitting parameters. The compaction force does not depend on the mixing conditions of Silica (Figure 2a), whereas it increases with increasing lubrication 2b.

Elastic recovery, ε_ρ , of a tablet is defined as

$$\rho^{\text{tablet}} = \rho^{\text{in-die}} (1 - \varepsilon_\rho) \quad (8)$$

with the out-of-die tablet relative density, ρ^{tablet} , given by

$$\rho^{\text{tablet}} = \frac{W}{\rho_t V^{\text{tablet}}} \quad (9)$$

and the out-of-die tablet volume after elastic recovery, V^{tablet} , with bellyband, H^{tablet} given by

$$V^{\text{tablet}} = \frac{\pi D^2 H^{\text{tablet}}}{4} + \frac{\pi h}{3} \left(\frac{3D^2}{4} + h^2 \right) \quad (10)$$

Elastic recovery is not sensitive to mixing conditions of Silica (Figure 3a) and is governed by (Gonzalez, 2019)

$$\varepsilon_\rho = \varepsilon_0 \frac{\rho^{\text{in-die}} - \rho_{c,\varepsilon}}{1 - \rho_{c,\varepsilon}} \quad (11)$$

However, with increase in lubrication with MgSt, the elastic recovery increases (Figure 3b). This trend is captured by modifying the ε_0 as follows:

$$\varepsilon_0 = \varepsilon_\infty + \frac{\varepsilon_\phi - \varepsilon_\infty}{1 + C_\varepsilon} \quad \text{with} \quad C_\varepsilon = \frac{c_l^{q_1} (\gamma + \gamma_0)^{q_2}}{q_3} \quad (12)$$

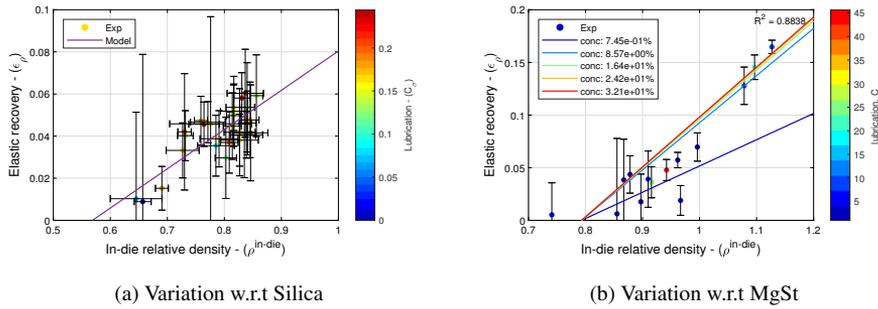

Figure 3: (a) shows that elastic recovery is independent of mixing conditions of Silica, (b) shows that elastic recovery increases with increase in lubrication.

where ϵ_∞ , ϵ_ϕ , q_1 , q_2 , q_3 are fitting parameters.

Tensile strength of a tablet is an important CQA since it is correlated with tablet dissolution. The tensile strength σ_t of a tablet depends on lubricant or glidant concentration and mixing time as follows (Kuentz and Leuenberger, 2000)

$$\sigma_t = \sigma_0 \left[1 - \left(\frac{1 - \rho^{\text{tablet}}}{1 - \rho_{c,\sigma_t}} \right) e^{(\rho^{\text{tablet}} - \rho_{c,\sigma_t})} \right] \quad (13)$$

where, ρ_{c,σ_t} is the critical relative density at which the tablet starts forming and σ_t goes to zero. The tensile strength at zero-porosity, σ_0 , is given by

$$\sigma_0 = \frac{\sigma_{0,\phi}}{1 + C_\sigma} \quad \text{with} \quad C_\sigma = \frac{c_l^{b_1} (\gamma + \gamma_0)^{b_2}}{b_3} \quad (14)$$

and

$$\rho_{c,\sigma_t} = \frac{\rho_{c,\sigma_t,\phi} - \rho_{c,\sigma_t,\infty}}{1 + C_p} + \rho_{c,\sigma_t,\infty} \quad (15)$$

where $\rho_{c,\sigma_t,\phi}$, $\rho_{c,\sigma_t,\infty}$, b_1 , b_2 , b_3 are the fitting parameters (Razavi et al., 2018). $\sigma_{0,\phi}$ and $\rho_{c,\sigma_t,\phi}$ represents the tensile strength and critical relative density corresponding to no lubrication, $C_\sigma = 0$. As the concentration or mixing time of Silica or MgSt increases in the formulation, softer tablets with lower tensile strength are formed (Figure 4). The decrease in tensile strength of lubricated tablets would be due to a combination of changes in physical properties of the blend, as well as the increased elastic recovery of lubricated tablets. Whereas, the tensile strength of tablets formed with Silica blends decreases solely due to changes in physical properties of blended material since elastic recovery is independent of Silica mixing conditions.

4. Conclusion

The results of the experiments demonstrate that the glidant Silica affects the bulk density of the blends, and the tensile strength, and consequently, the dissolution profile, of tablets. In particular, bulk density increases with an increase in glidant concentration or mixing time, whereas tensile strength decreases. However, interestingly, compaction force and elastic recovery show no dependency on the mixing conditions of Silica. In contrast, the lubricant MgSt affects all the CQAs of a tablet. Specifically, bulk density increases with an increase in lubrication, and tensile strength decreases. The elastic recovery and compaction force increase with the increase in lubrication.

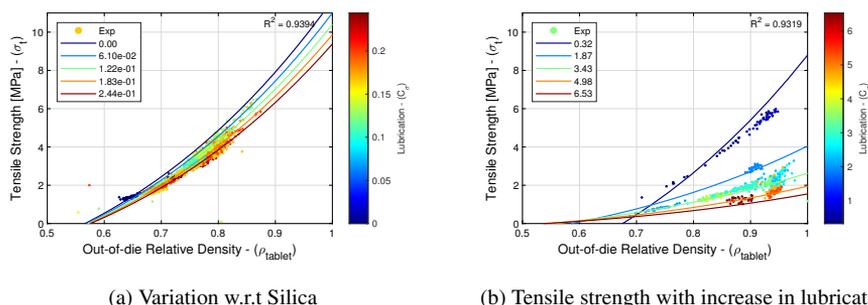

Figure 4: Tensile strength decreases with increase in concentration or mixing time, for both Silica and MgSt.

The effects of Silica and MgSt differ for compaction force and elastic recovery. The practical application of mechanistic models is to use them as steady-state models in MHE-NMPC control of rotary tablet press (Huang et al., 2021). Future work includes integrating the lubricant and glidant feeder with the tablet press to control tablet properties. Additionally, Residence time distribution models (RTDs) will be added to the MHE-NMPC framework to enhance real-time process control.

Health-aware control using hybrid models applied to a gas-lifted oil well network

José Matias^{a*}, Salmon Y. Ghebredngl^a and Johannes Jäschke^a

^a*Chemical Engineering Department, Norwegian University of Science and Technology, Sem Sælandsvei 4, Kjemiblokk 5, Trondheim, 7491, Norway*

Abstract

A health-aware controller (HAC) aims at finding the optimal trade-off between system reliability and productivity. By considering the system health, the controller can avoid unexpected equipment breakdown while improving the system economic performance. In subsea oil extraction industry, new and more stringent environmental, safety, and regulatory requirements are imposed every year. Thus, this industry can benefit from the implementation of this type of controllers for tasks such as equipment monitoring, or flow assurance. One challenge when implementing a health-aware controller is to derive models that represent the failure mechanism of subsea equipment using physics-based relationships. An alternative is to use data-based models. Instead of relying on physical knowledge, this type of models determine the input-output relationships using only data observed experimentally. In this paper, we propose the use of a hybrid HAC, where first-principles relations describe the mass and energy balances, while the system degradation evolution is represented by a data-driven model. We test two different structures, a linear regression and a neural network model. We investigate their performance in open-loop, carrying out an uncertainty analysis on the predicted degradation variability, as well as in closed-loop. The simulation results show that HAC's performance is dependent on the type of data-driven model used for predicting degradation, and the more complex model does not necessarily give a better overall result.

Keywords: Model predictive control, Hybrid Modeling, Diagnostics and prognostics

1. Introduction

In subsea oil and gas extraction systems, unexpected breakdowns and maintenance interventions are very costly. In such systems, choke valves are critical for the process safety because they are responsible for regulating the system pressure, and controlling the oil and gas flows from the reservoir to the system. The useful life of the choke valves is severely affected by sand particles, which are extracted from the reservoir together with the products of interest. The sand managing strategy is outlined early in the field development to ensure appropriate selection of equipment as well as instrumentation for monitoring, controlling and handling sand production. However, even with all these precautions, a very conservative operational strategy is often adopted. Typically, the production strategy is defined based on worst-case valve degradation scenarios, leading to sub-optimal operation and potential profit loss (Verheyleweghen and Jäschke, 2018).

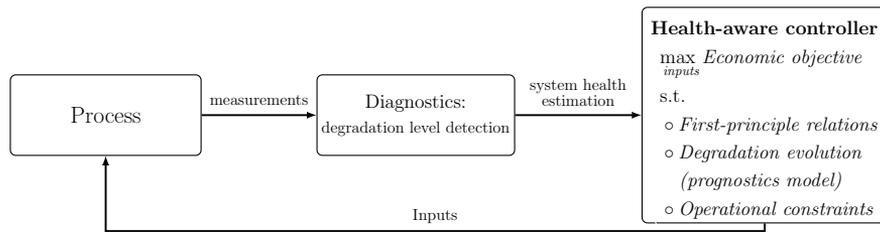

Figure 1: Health-aware controller block diagram, adapted from Matias et al. (2020)

Hence, there is a trade-off between maximizing production and minimizing equipment degradation in subsea production systems that needs to be addressed for optimal operation. Our paper uses a health-aware controller (HAC) (Escobet et al., 2012) strategy to deal with this problem. In HAC, equipment health monitoring tools are integrated to the control structure as illustrated in Fig. 1. The goal is to avoid conservative operation by actively steering plant degradation and preventing unexpected breakdowns.

A HAC was already implemented in a simulated subsea oil well network in Matias et al. (2020). The authors used the phenomenological model of DNV (2015) for erosive wear as the “real” degradation mechanism. They assumed perfect knowledge of the choke valve degradation evolution as well as of the current degradation state, which is unrealistic. In turn, we propose the use a data-driven models of the system, which were obtained by Jahren (2021), for inferring the current valve degradation (*diagnostics*) based on pressure, flow, and temperature measurements along the wells. Then, we use the same model inside the health-aware controller to predict the degradation evolution (*prognostics*).

2. Case Study: Gas-lifted oil well network

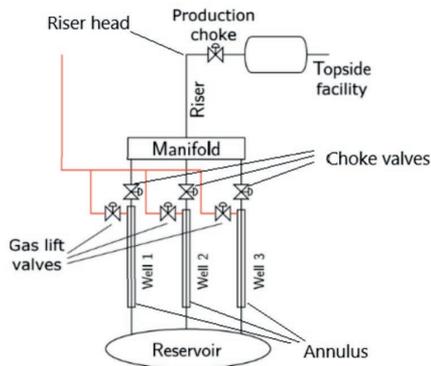

Figure 2: Gas lifted oil production system (Verheyleweghen and Jäschke, 2018)

In subsea systems, wells connect the oil and gas reservoirs to manifolds on the seabed. Then, long pipelines called risers direct the fluids to the topside facilities. The main driving force of this process is the reservoir natural pressure. However, in some cases, this pressure is not high enough to lift the fluids. One alternative to solve this problem is to use gas lift.

In gas lifted wells, gas is injected through an annulus, which is a void between the well and its external casing. By injecting gas, the fluid mixture density decreases. Consequently, the hydrostatic pressure on the reservoir outlet also decreases leading to larger oil outflows. However, if too much gas is injected, the pressure loss due

to friction overcomes the effects of the hydrostatic pressure difference, decreasing the well oil production.

Therefore, for optimizing the production, we want to find the gas lift injection flowrate that maximizes the oil flowrates. On the other hand, larger oil flowrates imply in a larger sand outflow from the reservoir, which decreases the remaining useful life of the choke valves. The degradation indicator here is the length of crack on the internal parts of the valve caused by erosive wear of the sand particles. Hence, by applying a health-aware controller to this system, we want to find the gas lift injection that optimizes this trade-off between optimizing production and extending the valve's remaining useful life.

3. Health-critical constraints and objective function

A challenge in the implementation of the health-aware controller is how to represent the trade-off between production and degradation, as well as defining health-critical constraints. In Matias et al. (2020), the authors represented the degradation threshold as a soft constraint, and then added slack terms in the objective function to penalize violations. This alternative presents two shortcomings. First, the performance of the controller is highly dependent on the weights of the economic and slack terms of the objective function, and tuning them is challenging. Second, from an operational point of view, it is difficult to define a representative degradation threshold for the equipment health.

For handling these issues, we use an exponential utility objective function Φ instead. It represents the trade-off between the risk of the choke valves breaking down and the economic gains. In the subsea oil well network of Fig. 2, the economic objective is to maximize the oil production of the three wells (i.e. $\phi = \sum_{i=1}^3 Q_{o,i}$). Assuming that we know an acceptable range for the degradation of the choke valves d , represented by $[d_L, d_U]$, the resulting exponential utility objective function at time k can then be written as:

$$\Phi(k) = \sum_{i=1}^3 \frac{(1 - e^{-\delta_i(k)Q_{o,i}(k)})}{(\delta_i(k) + \varepsilon)}, \quad \text{where} \quad \delta_i(k) = \frac{d_i(k) - d_L}{d_U - d_L} \quad (1)$$

where, ε is a small value added to avoid division by zero. The intuition behind this choice is the following: let us assume that the gas lift injection in well i , $Q_{gl,i}$, is chosen such that the oil production $Q_{o,i}$ in the well increases. However, the contribution of this gain to Φ depends on the normalized degradation δ_i , as illustrated by Fig. 3. Larger degradation levels lead to a risk-averse operation, in which the controller would accept lower levels of production rather than possibly breaking down the system. On the other hand, for degradation levels equal or lower than d_L , the controller would have a risk-taking approach and always seek the largest production level as possible.

4. Choosing the data-driven model

Next, we explore the combination of two of the data-driven modeling strategies presented in Jahren (2021) (linear regression (LR) and neural network regression (NNR)) with the

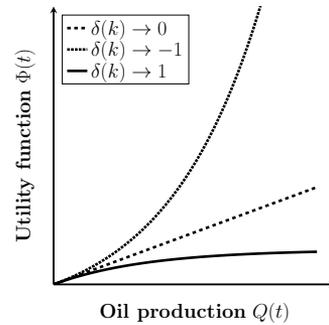

Figure 3: Exponential utility objective function.

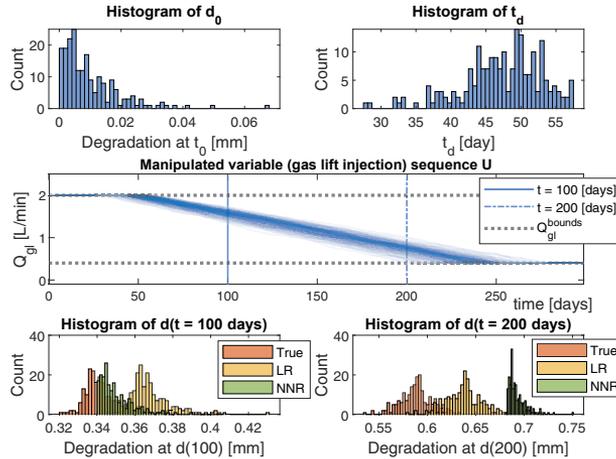

Figure 4: Open-loop Analysis. The bottom plot shows the variability of the predicted system degradation at $k = 100$ and $k = 200$ days.

health-aware controller. For training the models, the authors performed synthetic experiments using the valve degradation model of DNV (2015) as the real system. Both LR and NNR yielded very accurate predictions of the erosion rates on normalised unseen test data. For defining which one should be combined with the controller, we propose two different analysis, one in open-loop and another in closed-loop. In both cases, we also consider the valve degradation model of DNV (2015) as the real system. The structure of the LN and NNR and details about their training and validation can be found in Jahren (2021). The codes of all the simulations are available at <https://github.com/Process-Optimization-and-Control/Health-Aware-Controller>.

4.1. Open-loop analysis: uncertainty propagation through the models

In the open-loop tests, we run an uncertainty analysis that aims at quantifying how the variability of the model inputs affect the outputs of the data-driven models. The model output of interest is the system degradation at time k , $d(k)$, whereas the two model inputs subject to uncertainty are the choke valve degradation at the beginning of a given interval d_0 and the manipulated variable sequence \underline{U} :

$$d(k) = f(d_0, \underline{U}), \quad \text{where} \quad \underline{U} = [u_0, u_1, \dots, u_k] \quad (2)$$

Ideally, we would use historical data from operation under the influence of a health-aware controller to determine the input uncertainty. Since these data may not be available before implementing the controller, we use different probability density functions for representing our *a priori* knowledge/intuition about the operation. According to the results of Matias et al. (2020), we assume that, at the beginning of the simulation, the manipulated variables will be at the upper bound (i.e. trying to produce as much as possible). At time t_d , the controller infers that the degradation will be out of the acceptable degradation range if the production level does not decrease. Then, it starts changing u accordingly.

The described situation can be represented by:

$$\underline{\mathbf{U}} = [u_0, u_1, \dots, u_{t_d}, u_{t_d} - \Delta u_1, \dots, u_{t_d} - \sum_{t=1}^{k-t_d} \Delta u_t], \quad \text{with} \quad u_0 = u_1 = \dots = u_{t_d} = u_{\max} \quad (3)$$

In addition, we assume that the initial degradation d_0 can be higher than zero. For representing the described uncertainty, we use the following probability distributions:

$$d_0 \sim 0.01\text{Exp}(1), \quad \Delta u_t \sim \Delta u_{\max}\text{Beta}(1, 5), \quad t_d \sim 50\text{Weibull}(1, 10) \quad (4)$$

The histograms of d_0 and t_d , as well as the resulting input trajectories $\underline{\mathbf{U}}$ can be seen in Fig. 4. For the open-loop analysis, we generate 200 samples of the distributions, feed them to the model in Eq. 2, and integrate the system forward in time. The output uncertainty is analyzed at arbitrary time instants $k = 100$ and $k = 200$ days (bottom plots). For comparison, we also plot the “real” degradation uncertainty obtained with the model of DNV (2015). Although both data-driven models represented the test data set accurately in Jahren (2021), they were trained and validated in synthetic data generated randomly, which did not correspond to the operation of a health-aware controller. When using data that mimic the operation of a HAC, the neural network represents the output mean better at the beginning; however, the prediction drifts with time. Regarding variability, the linear regression shows a better approximation of the standard deviation at both time instants. Since HAC is implemented in a receding horizon fashion, one may choose to combine the neural network model to the HAC due to the smallest deviation of the mean degradation estimation in the short term. Moreover, due to the fact that its standard deviation is smaller than the true process, the worst-case open-loop predictions of the neural network is likely to be more conservative than the real one, which may be preferable.

4.2. Health-aware controller: Closed-loop results

Next, we run the hybrid health-aware controller in closed loop. The HAC has to manipulate the gas injection of three wells in order to maximize oil production, while prolonging the remaining useful life of the valves as much as possible. The simulation setup is similar to Matias et al. (2020). However, instead of defining a threshold for the degradation, we define an acceptable range, with $d_L = 0$ and $d_U = 0.6$ mm. We also impose bounds on the gas injection $[0.5, 2]$ kg/s. We use a prediction horizon of 50 days and a control horizon of 20 days. We consider that the wells have a constant sand production. However, well 1 produces less sand than the other wells, and wells 2 and 3 have exactly the same sand production. We also assume that well 2 has a larger reservoir outflow. Therefore, the choke valve in well 2 should have the smallest useful life. We also train the data-based models in data only from well 1, leading to plant-model mismatch in wells 2 and 3.

The results are shown in Fig. 5. We assume that the valves break after the crack length reaches the 0.65 mm threshold (which is unknown to the controller). Regarding the system diagnostics (top plot in Fig. 5), the strategies show a significant underestimation of the current valve degradation. We only show the value of well 2, which is the health-critical well. By analyzing the manipulated variables (middle plots in Fig. 5), we see that the NNR-based controller is not able to detect that the system will break until around 130 days. In turn, the LR-based starts to react around 80 days. We hypothesize that this unexpected behavior comes from the fact that the NNR-based controller prediction is worse

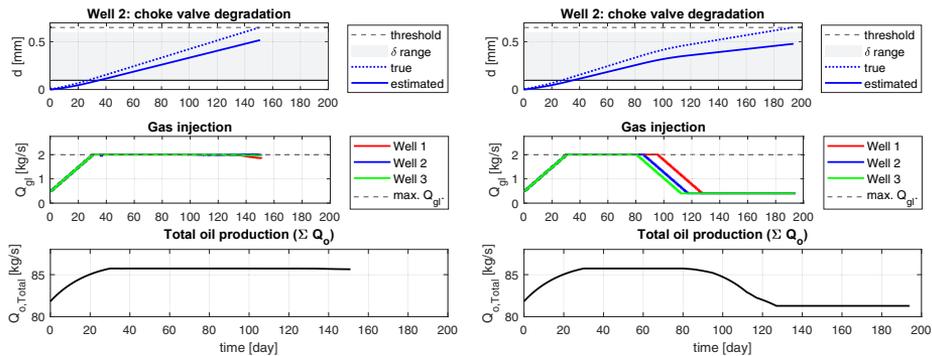

Figure 5: Closed-loop analysis. Plots on the left are related to the NNR-based HAC and plots on the right to LR-based HAC. The LR-based hybrid controller has a total production 25 % higher than the NNR-based. The breakdown time is 194 days for the LR-based versus 151 for the NNR-based.

when the degradation levels are higher, as indicated in the open-loop analysis. The solver then cannot properly extrapolate the system future behavior and fails to decrease the gas injection. However, a rigorous analysis of the neural network prediction behavior is much more challenging than the linear regression due to its black box nature.

5. Conclusion

The hybrid health-aware controller is applied to a synthetic case study of an oil and gas well network with artificial gas-lifting. We test two different data-driven model structures, a simple linear regression and a neural network regression model. The proposed controller is a possible alternative to find the optimal trade-off between increasing production and prolonging equipment useful life. However, plant-model mismatch due to the data-driven models for the diagnostics and prognostics steps had a detrimental effect on HAC's performance. The main conclusion is that HAC's performance is dependent on the type of data-driven model and the quality of its extrapolations capacity. Moreover, control strategies that rely on data-driven models should be tested in both *open* and *closed* loop simulations before implementation. Finally, we showed that using an exponential utility objective function in the health aware controller yields a good representation of the trade-off between system reliability and productivity.

Abstract

A promising approach to reduce the time to market of chemical products is the application of modular plants, which are composed of standardized, previously developed Process Equipment Assemblies (PEAs). As this approach goes along with process intensification as well as continuous and highly autonomous operation, human operator performance might benefit from a more structured guidance to fully understand the system and interact with it whenever it is necessary. With the major goal of reducing human error, Vicente and Rasmussen (1990) introduced the Ecological Interface Design (EID), suggesting that an interface should provide a virtual ecology, connecting the work domain to the human operator. EID is based on Work Domain Analysis (WDA), which is a 2-dimensional Abstraction-Decomposition Space. The decomposition hierarchy in the horizontal direction gives information about the superficial structure of the plant; while, the abstraction hierarchy in vertical direction provides multi-level knowledge representation of how each component in the process is working.

In this study, the effects of applying EID for modular plants is investigated. To this end, a pilot modular plant, namely Safety-Demonstrator (Pelzer *et al.*, 2021), has been considered as the use case. It consists of a total of two PEAs: one for feeding the reactants and the other one for the reaction. At first, WDA has been done for this modular plant, and afterwards an EID has been developed. This approach not only helps operator understanding the system and making better decisions in challenging situations, but also shows potential to facilitate exploiting the changeability feature of MPs and selecting the best PEAs for a specific function of the process.

Keywords: Modular Plants; Ecological Interface Design; Safety-Demonstrator Case Study

1. Introduction

The availability of many different alternative products in food, pharmaceutical, and chemical industries shortens the products' lifecycles and results in volatile global market (Lier and Grünewald, 2011). To stay competitive in such a global market, companies should not only be able to produce the new demanded products in a shorter time, but also manage to change their production capacity based on the market. Moreover, to address the different global demands for a product, it is essential to develop mobile production technologies, allowing for the transport of a chemical plant from one location to another.

Designing Modular Plants (MPs) is a promising approach to fulfil these requirements (Holm *et al.*, 2015).

To facilitate flexible production, MPs are designed in a hierarchical structure. The lowest level of the hierarchy denotes to components, which are the non-separable, smallest units of a plant. A combination of components providing a specific process engineering function (e.g. heating) is called Functional Equipment Assemblies (FEA). Then one or more FEAs together build a Process Equipment Assembly (PEA) providing a procedural step (e.g. distillation). Each PEA has its own process automation allowing for decentralized operation. Exchanging information from one PEA to another and to the higher level control layer necessitates a standard data exchange format describing the PEAs. This standardized descriptive document is called Module Type Package (MTP).

MPs are at the top layer of the hierarchy, including at least one PEA. To control the connections between PEAs, a superior automation layer, called Process Orchestration Layer (POL), is also considered.

Considering the abovementioned features of MPs, they offer lots of important benefits. Apart from reducing the plant engineering time by a factor of 50% (Holm, 2016), they also increase the flexibility of production. In fact, not only the PEA change (inter-modular level) results in a new process, but also by changing FEAs (intra-modular level) the operating range can be modified (in the allowable range considered by the PEA manufacturer) (VDI 2776-1, 2020). Nevertheless, to help operators to deal with this complex system and exploit its outstanding features, the right information, with the best format should be provided to them.

In the quest to develop better human-machine interactions, the concept of Ecological Interface Design (EID) was introduced by Vicente and Rasmussen in 1990 (Vicente and Rasmussen, 1990). EID is based on Work Domain Analysis (WDA), which is a two dimensional hierarchical space (abstraction hierarchy (AH) in vertical direction and decomposition hierarchy in horizontal direction), aiming at providing a formalism to represent the work domain. The categorized information in WDA is then visualized in an operator understandable way. This information flow from the work domain to the operator and vice versa is called EID.

WDA and EID as a strong cognitive tool for visualization, has been used in many different fields, such as air traffic control (Ahlstrom, 2005), computer network management (Burns, Kuo and Ng, 2003), road transport structure (Salmon *et al.*, 2019), and medicine (Hajdukiewicz *et al.*, 2001). As a proof of concept, Jamieson and Vicente (Jamieson and Vicente, 2001) applied the EID to petrochemical process engineering. They applied the EID for the process of fluid catalytic cracking. Their results indicated that their developed EID can lead to higher operator adaptation, facilitate continuous learning, and assist distributed, collaborative work.

Considering the complexity of MPs; and at the same time, the promising results from previous applications of EID for chemical processes has motivated us to investigate the application of EID for MPs. To this end, safety demonstrator (Pelzer *et al.*, 2021), an experimental MP in Process to Order (P2O) lab in TU-Dresden has been considered as a use case. This MP consists of two PEAs for feeding and reaction, and each of them includes several FEAs. In the following subsections, at first, a WDA for this use case will be developed, and then, an interface will be suggested.

2. Development of Work Domain Analysis

Figure 1 illustrates the developed WDA for the safety demonstrator. As can be seen, the horizontal direction shows the part-whole relation (decomposition hierarchy) and for the

case of a MP, it can be considered as: $MP \rightarrow PEA \rightarrow FEA \rightarrow \text{Components}$. While this hierarchy deals with the superficial feature of the MP, the AH in the vertical line has a more in-depth viewpoint and focuses on how the plant works. Indeed, as we go down the AH, we are actually answering the question how the goals of previous layer are achievable. As a result, each cell of this two dimensional space provides a model with different amounts of details and yet complete for this work domain. It should be mentioned that describing the WD in the upper layers of the AH is more useful in the top layers of the part-whole hierarchy, and as we go down the AH, lower levels of part-whole decomposition hierarchy tend to be more informative (Son *et al.*, 2019). Each layer of the AH is described in the following:

Goal (also known as functional purpose): this layer illustrates the purpose of the process in the most abstract and therefore less technical way. As can be seen in Figure 1, in this study, three major goals, i.e. 1) production of a chemical, 2) safety, and 3) flexibility of MPs have been considered.

Function (also known as abstract function): this layer answers the question what are the functions that we need to reach the goals of the previous layer. As Figure 1 reflects, this layer of the AH involves the PEA, FEA, and components sections of the decomposition hierarchy. In this study, the control function has been also considered and their relationship between different sections of the process is identified. It should be mentioned that the heat transferred between the process and the ambient has been ignored. As can be seen, this layer does not contain any explanation of the technical terms or phenomena taking place in each equipment. It is noteworthy to mention that in Figure 1 only PEA2 is shown.

Behavior (also known as generalized function): with the help of a causal graph, this layer describes the phenomena taking place in the process. As can be seen in Figure 1, the control functions of previous layer are shown as conditional statements and their influence on each phenomena is clarified. To avoid a too complex graph, Figure 1 only shows the causal graph of PEA 2.

Structure (also known as physical function): the phenomena considered in previous layer are realized in this layer. Indeed, this layer relates the phenomena to the symbols of the equipment in Process and Instrumentation Diagrams (P&IDs). This layer is not drawn in Figure 1.

Physical form: this layer is the closest to the reality and it can be a photo or a video of the real plant, helping the operator making sure about the status of an equipment (e.g. looking at the color of the flames of a flare). In this study, this layer has not been considered.

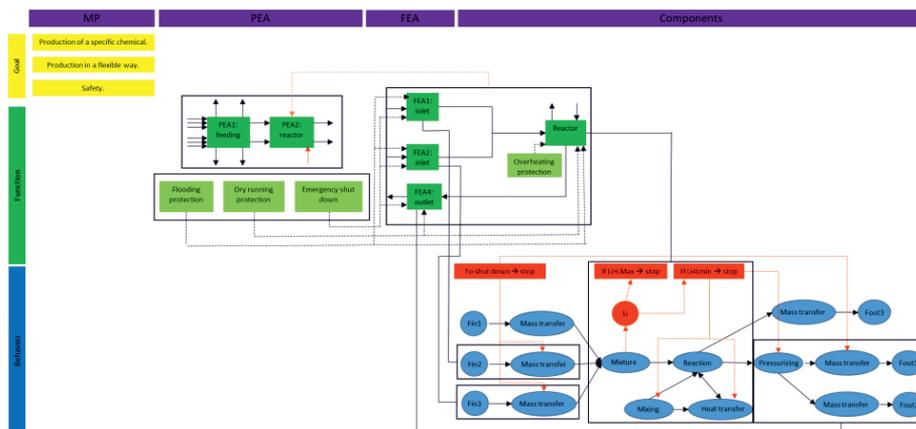

Figure 1: WDA for the safety demonstrator. (The lines between layers shows how to relationship. Function layer: dark green boxes show the PEAs and FEAs, light green boxes are the control functions of the process, solid arrows are mass (black) and energy (red) input and outputs, black dashed arrows show the composed of relation, and orange dashed arrows show aggregation relation. Behavior layer: arrows have causal meaning (black: process related, red: control function related)

3. Mock-up Interface Description

Based on the previously mentioned WDA and to illustrate its specific features, a Human Machine Interface (HMI) has been designed. It is noteworthy to mention that *Axure RP 10* has been used to develop this mock-up interface. In the following subsections the specific features of the EID will be discussed.

3.1. Different Views with Different Amounts of Details

One of the most obvious and yet important characteristics of WDA is its ability to provide different layers of details. Figure 2 (A) demonstrates a general view of the safety demonstrator. In the case of this figure, the green checkmark at the corner of PEA 1 indicates that it is working well; however, the red cross mark in the corner of PEA 2 suggests that something is wrong or maybe some action is necessary in this PEA. Therefore, the operator can further investigate the issue by looking at more details of PEA 2 (Figure 2 (B)). Moreover, different FEAs in a specific PEA are visualized in a categorized way (Figure 2 (B and C)). By using the home and upwards arrow buttons in the bottom of the page, one can respectively go to the overall view and one-layer upper view of the MP. These different views of the process help the operator to find the root cause of an alarm much easier.

3.2. Explanation of the automatic control system

While there has been a great improvement in automatic processes and cyber-physical production systems, it is impossible to omit the operator. In fact, the control systems are getting more and more complex and so does the interaction with them. Hence, if the control system is able to explain how it works and why it is active, it would be a significant help for the operator to integrate with the system (Gil *et al.*, 2019). In the case of this study, the consideration of the control functions (e.g. flooding protection) in the WDA offers an ability of the interface to explain the activated control function. For example, if the flooding protection control function of PEA 2 starts working, the interface should show a message that the liquid level in the reactor is higher than normal and therefore the valves in FEA1 and FEA2 are blocked (see Figure 2 (B)).

3.3. Phenomena representation of the process

Another very interesting feature of WDA is the behavior layer, in which the phenomena taking place in the process is explained in a machine-readable format (in this study with the aim of a causal graph (Figure 2 (D))). This representation of the process results in an ability of the interface to explain the effect of operator decisions on the performance of the process. For instance, there are three major phenomena occurring in the reactor of PEA 2: mixing, heat transfer, and reaction (see the row of behavior in Figure 1). If the operator decides to increase the mixing speed, the interface should be able to popup a message and tell him this action would result in more reaction and heat transfer. From a psychological viewpoint, these types of analysis involve the knowledge based behavior of the human operator (Vicente and Rasmussen, 1992; Jamieson and Vicente, 2001).

In this study, we have only focused on the phenomena of one equipment. However, there is a possibility to use this approach and estimate the effect of changing one parameter on

the next steps of the process. This has a specific importance for MPs, as they are highly changeable and it would be very beneficial if the system is able to qualitatively comment on the influence of changing a FEA on the sequential steps of the process. It is noteworthy to mention that the MPs vendors do not produce a module (PEA, or FEA) only for one exclusive chemical media, but the aim is to build the modules for as many chemical systems as possible. Thus, it would be really beneficial to add the phenomena hierarchical structure (which is not specific to a chemical system) to the MTP of PEAs.

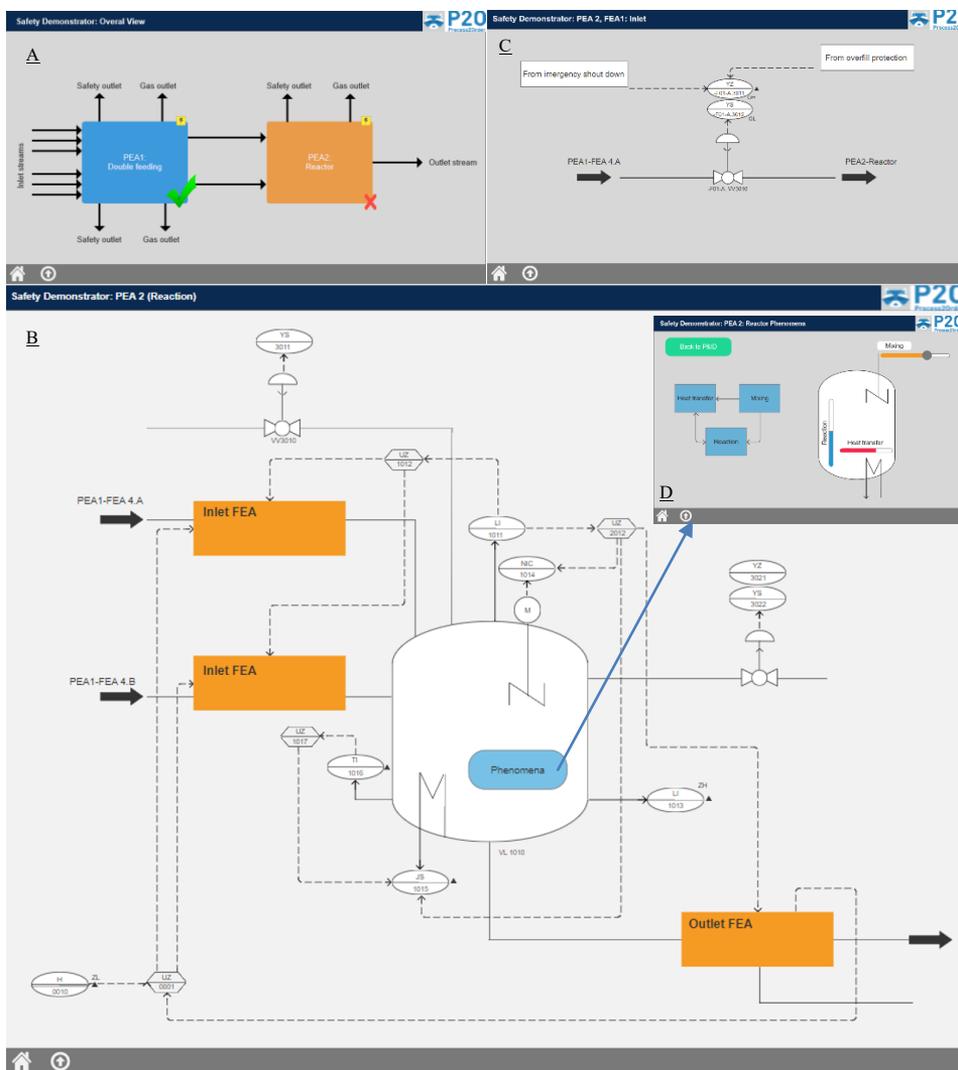

Figure 2: EID for safety-demonstrator, A) overall view to the process, B) view of the PEA2 (reaction), C) PEA2, FE1, D) Phenomena representation of the CSTR in PEA2

4. Conclusion

In this study, the concept of EID has been investigated for MPs. For this purpose, safety demonstrator, an experimental MP built in P2O lab, has been considered as the use case.

At first, WDA for the use case has been done to represent not only the superficial features of the plant (decomposition hierarchy), but also its more in-depth features of how it works (abstraction hierarchy). Based on the developed WDA, an EID has been suggested for the use case. Notable among important characteristics of this interface are its ability to show different views of the process (with different amounts of details), explanation of the control system, and representation of the phenomena taking place in the process. A crucial future step would be to evaluate the effectiveness of the developed interface by interviewing some experts. This study also shows some promising start point for using phenomena representation in the MTP of MPs to distinguish the effect of changing one FEA on the subsequent process steps.

Path-following for parametric MPCC: a flash tank case study

Caroline S. M. Nakama^a, Peter Maxwell^a and Johannes Jäschke^a

^a*Department of Chemical Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway*

Abstract

Mathematical programs with complementarity constraints (MPCC) can arise in process models that contain discrete decisions such as switches, phase changes, and flow reversal. Path-following methods are an important part of advanced-step nonlinear model predictive control (NMPC) due to the ability to deal with changes in the active-set of constraints. In this work, we introduce a path-following algorithm for parametric MPCC demonstrated on a flash tank case study. We show that this algorithm can successfully track the solution without the need for fine discretization or identifying the exact points where active-set changes occur, which are important properties for NMPC implementation.

Keywords: Mathematical programming with complementarity constraints, parametric sensitivity, path-following

1. Introduction

Nonlinear model predictive control (NMPC) is a process control method that formulates and repeatedly solves an optimization problem using a nonlinear dynamic model representation of the process as constraints. When configuring an NMPC problem, it is important to have a model that can describe the process as accurately as possible within a defined range of the process variables, and that calculations can be performed during the time between two measurements, i.e., the optimization problem needs to be rapidly solved. Systems with switches, phase changes, or flow reversal, for example, result in models with nonsmooth decisions, which make optimization problems with dynamic models challenging to solve, especially with a limited time frame. For representing such processes, complementarity constraints can be used: they specify the relationship between two variables, enforcing that at least one of them must be at its bound. Optimization models with this type of constraint are called mathematical programs with complementarity constraints (MPCC). These models are inherently non-convex and fail to satisfy the Mangasarian–Fromovitz constraint qualification due to the complementarities, requiring reformulation strategies to handle these constraints with standard NLP solvers (Baumrucker et al., 2008).

Advanced-step NMPC (asNMPC) is a real-time control technique that uses a prediction of the next state variables based on the current control action as the initial values (here they can be seen as parameters) to solve the optimal control problem in advance between the sampling times. When the new sample is available, the solution is updated based on the sensitivity at the optimal solution with respect to the initial state (Diehl et al., 2005; Zavala and Biegler, 2009). Hence, computational delay between sampling and implementing the control action is reduced. A limitation of the original asNMPC is the assumption that the active-set of constraints does not change from the

optimal to the updated solutions. Path-following algorithms can be employed to handle this issue, since change in the active-set can be detected by discretizing the difference between the predicted and sampled states or by using an active-set identification method (Kungurtsev and Jaschke, 2017; Jäschke et al., 2014).

Literature on path-following of parametric MPCC (PMPCC) is scarce; to the best of the authors' knowledge, the only investigation on the topic was conducted by Kungurtsev and Jäschke (2019). They propose two algorithms: one is based on a penalty-term reformulation for MPCC (Baumrucker et al., 2008), while the other traces active-set bifurcations that stem from bi-active complementarity constraints, assuming that a reliable active-set method is available.

In general, PMPCCs pose a number of formidable challenges for numerical solution, arising from the inherent combinatorial nature of the problem and the interaction with the parameter dependence. Herein, we vastly simplify the problem by means of two key assumptions:

- i due to the nature of NMPC, the exact locations of active-set changes are not required but only determination of the solution at successively given values of a scalar parameter; and,
- ii that we are considering MPCC such that each complementarity constraint can only be non-simple (bi-active) at a small number of discrete points.

These two assumptions permit a much more straightforward handling of the problem yet still apply to a selection of practical problems. For example, the second assumption will be valid for most physical systems, whereby active-set changes occur only at a few discrete points (e.g. when phase transitions occur). We focus on the demonstration of this method with a flash tank case study, in which we obtain solutions for relevant points along the optimal path.

2. Background

In this section we present relevant definitions and concepts necessary for the algorithm described in the next section. We begin with the definition of complementarity constraint, roughly following the exposition in (Scheel and Scholtes, 2000). Consider a matrix-valued function $F : \mathbb{R}^n \rightarrow \mathbb{R}^{l \times q}$,

$$F(w) := \begin{bmatrix} F_{11}(w) & \dots & F_{1q}(w) \\ \vdots & \ddots & \vdots \\ F_{l1}(w) & \dots & F_{lq}(w) \end{bmatrix} \quad (1)$$

with $w \in \mathbb{R}^n$. A general complementarity constraint can be expressed as

$$F_{1k} \perp F_{2k} \perp \dots \perp F_{lk}, \quad F_{ik} \geq 0, \quad \text{for } i = 1, \dots, l \quad \text{and } k = 1, \dots, q \quad (2)$$

i.e., at least one entry of each column in F is zero with the remaining assuming nonnegative values. In practice, l is often equal to 2 and F_{ik} mostly represent variable bounds.

A parametric MPCC (PMPCC) is an extension of traditional parametric NLP optimization models in the sense that it contains at least one complementarity constraint and can be solved as a function of one or multiple parameters. For a parameter vector $p : \mathbb{R} \rightarrow \mathbb{R}^r$, we can define PMPCC($p(t)$) as

$$\min_{w(p(t))} \quad \varphi(w(p(t)), p(t)) \quad (3a)$$

$$\text{s.t. } h(w(p(t)), p(t)) = 0 \quad (3b)$$

$$g(w(p(t)), p(t)) \geq 0 \quad (3c)$$

$$F_{1k}(w(p(t)), p(t)) \perp \dots \perp F_{lk}(w(p(t)), p(t)) \quad \text{for } k = 1, \dots, q \quad (3d)$$

$$F_{ik} \geq 0, \quad \text{for } i = 1, \dots, l \quad \text{and } k = 1, \dots, q \quad (3e)$$

where $\varphi : \mathbb{R}^n \times \mathbb{R}^r \rightarrow \mathbb{R}$, $h : \mathbb{R}^n \times \mathbb{R}^r \rightarrow \mathbb{R}^s$, $g : \mathbb{R}^n \times \mathbb{R}^r \rightarrow \mathbb{R}^q$, and $F : \mathbb{R}^n \times \mathbb{R}^r \rightarrow \mathbb{R}^{l \times q}$ are smooth functions. Dropping explicit notation for dependence on t , the Lagrangian for Eqs. (3) is

$$\mathcal{L}(w(p), p, \lambda) := \varphi(w(p), p) - \mu(p)^T h(w(p), p) - \nu(p)^T g(w(p), p) - \Gamma(p)F(w(p), p) \quad (4)$$

where $\lambda = (\mu, \nu, \Gamma)$ is arranged in the natural manner by reshaping the matrix Γ columnwise into a vector. $\Gamma(p)^T F(w(p), p)$ is the inner product of the corresponding Γ with the F matrix.

The reason we define parametric optimization models is that we wish to map some interval $I_t = [t_a, t_b]$ to the solution curve $(w^*(p(t)), \lambda^*(p(t)))$, $t \in I_t$ of PMPCC($p(t)$) by calculating a piecewise homotopy along t . Locally, this requires calculating the sensitivity of w^* along t .

For the inequality and complementarity constraints, we define the corresponding g and F active-sets at some point $w(p)$ as $A_g(w(p)) := \{i : g_i(w(p)) = 0\}$ and $A_F(w(p)) := \{(i, j) : F_{ij} = 0\}$.

Mirroring terminology used in eigenvalue analysis, a complementarity constraint $F_{.j}$ is considered *simple* at point w if only one constraint in that column $F_{.j}$ is active. It is *nonsimple* if more than one constraint in $F_{.j}$ is active. This latter situation is often termed ‘bi-active’ in the case of two active constraints.

A point $w(p)$ feasible to PMPCC($p(t)$) is termed *weakly stationary* if there exists multipliers λ such that, where \circ is the Hadamard (elementwise) product,

$$\nabla_w \mathcal{L}(w(p), p, \lambda) = 0 \quad (5a)$$

$$\nu(p) \geq 0 \quad (5b)$$

$$\nu(p)^T g(w(p), p) = 0 \quad (5c)$$

$$\Gamma(p) \circ F(w(p), p) = 0. \quad (5d)$$

A point $w(p)$ which satisfies Eqs. (5) and further satisfies that $\Gamma_{ik} \geq 0$ if there exists some $j \neq i$ such that $F_{ik}(w(p), p) = F_{jk}(w(p), p) = 0$ is termed *strongly stationary*. In plain language, this condition is stipulating that if $F_{.k}$ is simple then there is no restriction on the associated Lagrange multiplier whereas if it is nonsimple then the associated Lagrange multipliers must be nonnegative. Thus, we see that for strongly stationary points, a simple complementarity constraint behaves akin to an equality constraint. The strongly active-set for g is defined as $A_g^+(w(p)) := \{i \in A_g(w(p)) : \exists \nu_i > 0 \text{ satisfying Eqs. (5)}\}$.

We now describe how we obtain the sensitivity of PMPCC($p(t)$) with respect to t by reduction locally to a parametric nonlinear program (PNLP). For $t \in I_t$, we assume that the F constraints are nonsimple or strong complementarity of the inequality constraints fails only at a (small) finite number of discrete points so that $I_t = \{t_a\} \cup I_1 \cup I_2 \cup \dots \cup \{t_b\}$, say, where each $I_i \subset I_t$ is an open interval. Within each I_i , the complementarity constraints can then be considered as equality constraints and strong complementarity of g holds, so the PMPCC reduces to a PNL, which is more amenable to known solution methods. Therefore, within each I_i , $A_F^+(w(p)) = A_F(w(p))$ and $A_g^+(w(p(t)))$ is invariant. For PNL($p(t)$), $t \in I_i$, assume that $\varphi(\cdot, \cdot)$, $h(\cdot, \cdot)$, $g(\cdot, \cdot)$, and $F(\cdot, \cdot)$ are twice continuously differentiable in a neighborhood of $w^*(p(t))$ satisfying the first-order optimality conditions, and that the linear independence constraint qualification (LICQ) and strong second order sufficient condition (SSOSC) hold. For PNL($p(t)$) $|_{t=t_0}$, LICQ implies that the dual space is a singleton (Kyparisis, 1985), i.e., the multipliers are unique. By taking the total derivative with respect to t of the stationarity conditions and active constraints of PNL, we obtain the following linear system

$$\underbrace{\begin{bmatrix} \nabla_{ww}^2 \mathcal{L} & \nabla_w h & \nabla_w gA & \nabla_w F_A \\ (\nabla_w h)^T & 0 & 0 & 0 \\ (\nabla_w gA)^T & 0 & 0 & 0 \\ (\nabla_w F_A)^T & 0 & 0 & 0 \end{bmatrix}}_{M(w(p(t)), p(t))} \underbrace{\begin{bmatrix} \dot{w} \\ \dot{\lambda} \end{bmatrix}}_{\dot{v}(p(t))} = - \underbrace{\begin{bmatrix} (\nabla_{wp}^2 \mathcal{L}) \dot{p} \\ (\nabla_p h) \dot{p} \\ (\nabla_p gA) \dot{p} \\ (\nabla_p F_A) \dot{p} \end{bmatrix}}_{b(w(p(t)), p(t))} \quad (6)$$

where $\dot{p} = \frac{dp}{dt}$, $\dot{w} = (\nabla_p w)\dot{p}$, $\dot{\lambda} = (\nabla_p \lambda)\dot{p}$, g_A includes only strongly active inequalities, F_a includes only (simple) active F constraints, and parameter dependence has been omitted for brevity.

3. Methodology

For the algorithm, we require access to a robust active-set identification method; we used an adaptation of a method in (Oberlin and Wright, 2006) along with some custom heuristics. The essential feature of the algorithm is to calculate a piecewise approximant $v(p(t)) = [w(p(t)) \lambda(p(t))]^T$ to the solution $v^*(p(t))$ by numerically integrating along the solution curve between active-set changes. In the canonical formulation of a first-order initial value problem, this can be expressed as $\dot{v}(p(t)) = f(t, v(p(t)))$ for $v(p(t_0)) = v_0$ where v_0 is a known initial point. From Eq. (6) and $M(p(t))$ invertible, $f(t, v(p(t))) = \dot{v}(p(t)) = M(w(p(t)), p(t))^{-1} b(w(p(t)), p(t))$; in practice, a linear solver is used to calculate $f(t, \cdot)$. In our implementation, we used an adaptive stepsize Runge–Kutta integrator, which maintains the truncation error within a predetermined bound by adjusting the stepsize. Event detection is used periodically to check whether an active-set change has occurred within the last integration step; this should not happen too often since the active-set identification is a comparatively expensive calculation. If an active-set change has occurred then, for the current $t_{(k)}$ held fixed, equality-constrained Newton iterations are performed with the new active-set until the error in the approximant $v(p(t))$ is sufficiently small; the number of elements in λ , and hence v , may also change if the cardinality of the active-set changes. The integration step can loosely be considered a ‘predictor’ step whereas the Newton iterations are a ‘corrector’ step. However, the error is nominally controlled by the adaptive stepsize numerical integration. Note that if the active-set identification encounters a nonsimple complementarity constraint, by assumption we can perturb $t_{(k)}$ by some small $\varepsilon > 0$ to again obtain simple complementarity constraints. This ensures the algorithm can always calculate the sensitivity.

Algorithm 1 Path-following for PMPCC(t) for $t \in I_t = [t_a, t_b]$

τ is set to maximum active-set recalculation interval
 $t_{(0)} \leftarrow t_a$, $\tilde{v}_{(0)} = [\tilde{w}_{(0)} \tilde{\lambda}_{(0)}]^T \leftarrow v_a$ where v_a is in a neighbourhood of the initial solution
 Calculate $A_{g,(0)}^+ = A_g^+(\tilde{w}_{(0)})$ and $A_{F,(0)}^+ = A_F^+(\tilde{w}_{(0)})$
 $v_{(0)} \leftarrow \text{Newton}(\tilde{v}_{(0)}, A_{g,(0)}^+, A_{F,(0)}^+)$
 $k \leftarrow 0$, $t_{AS} \leftarrow t_{(0)}$
repeat
 $k \leftarrow k + 1$
 Perform predictor integration step to obtain approximate $(t_{(k)}, \tilde{v}_{(k)})$
 if $t_{(k)} > (t_{AS} + \tau)$ **then**
 repeat
 Calculate $A_{g,(k)}^+$ and $A_{F,(k)}^+$
 if $A_{F,(k)}^+$ nonsimple **then**
 $t_{(k)} \leftarrow t_{(k)} + \varepsilon_t$
 end if
 until $A_{F,(k)}^+$ is simple
 $v_{(k)} \leftarrow \text{Newton}(\tilde{v}_{(k)}, A_{g,(k)}^+, A_{F,(k)}^+)$, $t_{AS} \leftarrow t_{(k)}$
 else
 $v_{(k)} \leftarrow \tilde{v}_{(k)}$
 end if
until $t \geq t_b$

It is immediately apparent that the relationship between integration stepsize $t_{(k)} - t_{(k-1)}$ and the active-set identification interval τ is important because it determines whether there will be any

transient ‘overshoot’ of an incorrect solution.

4. Case Study

We use the same case study presented in Kungurtsev and Jäschke (2019), in which a flash tank with a 3-component feed flow $Q \in \mathbb{R}$ and composition $z \in \mathbb{R}^3$ is simulated. We seek to analyze how the split between vapor $V \in \mathbb{R}$ and liquid $L \in \mathbb{R}$ products with composition $y \in \mathbb{R}^3$ and $x \in \mathbb{R}^3$ respectively vary with temperature $T \in \mathbb{R}$ for a fixed pressure $P \in \mathbb{R}$. For that, we set up the following optimization model

$$\min \frac{1}{2}(aQ - V)^2 dt \quad (7a)$$

$$\text{s.t.} \quad \sum_{i \in \mathcal{C}} \frac{z_i(K_i - 1)}{1 + a_i(K_i - 1)} = 0 \quad (7b)$$

$$K_i = \frac{P_i^{\text{sat}}}{P} = \frac{y_i}{x_i} \quad \text{for } i \in \mathcal{C} \quad (7c)$$

$$\log_{10}(p_i^{\text{sat}}) = A_i - \frac{B_i}{T + C_i} \quad \text{for } i \in \mathcal{C} \quad (7d)$$

$$L + V = Q \quad (7e)$$

$$Lx_i + Vy_i = Qz_i \quad \text{for } i \in \mathcal{C} \quad (7f)$$

$$a - s_V + s_L - a_t = 0 \quad (7g)$$

$$0 \leq s_V \perp V \geq 0 \quad (7h)$$

$$0 \leq s_L \perp L \geq 0 \quad (7i)$$

$$0 \leq a, x, y \leq 1 \quad (7j)$$

$$K, p^{\text{sat}} \geq 0. \quad (7k)$$

Constraint (7b) is the Rachford–Rice equation, which calculates the fraction of the feed that goes to the vapor phase, V/Q , represented by $a_t \in \mathbb{R}$. $K \in \mathbb{R}^3$ is determined by Raoult’s law, given by constraint (7c). $P_i^{\text{sat}}(T) \in \mathbb{R}$ is the vapor pressure of the pure component $i \in \mathcal{C} = \{1, 2, 3\}$ at temperature T calculated using Antoine’s equation (7d), where $A_i \in \mathbb{R}$, $B_i \in \mathbb{R}$ and $C_i \in \mathbb{R}$ are constants for each compound i . Constraints (7e) and (7f) correspond to the total and component-wise mass balances respectively. Constraints (7g)–(7j) are necessary to ensure that $V/Q \in [0, 1]$. The Rachford–Rice equation results in negative values and values greater than one for a_t if T is lower than the mixture’s bubble point or larger than its dew point respectively, which would be physically impossible. Therefore, complementarity constraints (7h) and (7i) are considered; in the form of Eq. (2), $F_{11} = s_V$, $F_{21} = V$, $F_{12} = s_L$ and $F_{22} = L$. $s_L \in \mathbb{R}$ and $s_V \in \mathbb{R}$ are slack variables that represent how much a_t is lower than 0 and larger than 1 respectively. Variable $a \in \mathbb{R}$ represents the actual ratio V/Q , which is enforced by constraints (7g) and (7j). Note that $a = V/Q$ is not enforced as a hard constraint and, instead, is used as the objective function to be minimized. In this problem, temperature is the only parameter; we use $T(t_a) = 380$ and $T(t_b) = 400$.

5. Results

For the results presented here, the following values were used: $Q = 1$ kmol/s, $z = [0.5, 0.3, 0.2]^T$, $P = 5$ bar, $A = [3.98; 4.00; 3.93]^T$, $B = [1065; 1171; 1183]^T$, and $C = [-41.14; -48.83; -52.53]^T$. In Fig. 1a, the solution paths of primal variables L and V are shown. The maximum integration stepsize and τ in this run was set small, at 0.1, so the active-set changes are detected almost immediately after they happen. The corresponding complementarity slack variables s_l and s_v are shown in Fig. 1b. For a larger maximum stepsize of 5.0, there is less certainty where the actual active-set change happened and a jump is clearly visible, see Fig. 1d.

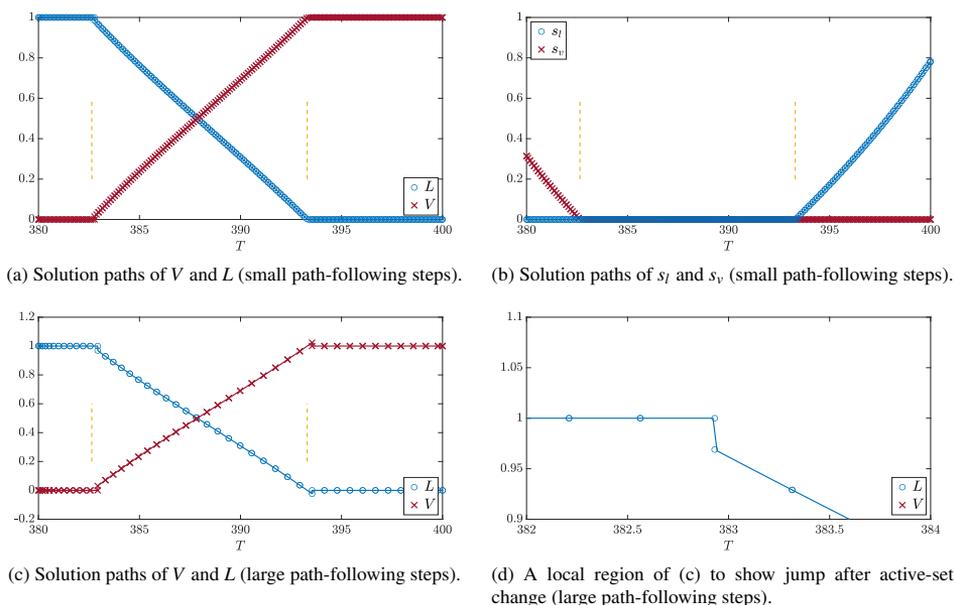

Figure 1: Top row, stepsize of 0.1: (left) L (circle) and V (cross) solution paths; (right) s_L and s_V paths. Bottom, stepsize of 5.0: (left) as above; (right) zoomed-in to region showing jump. Active-set changes indicated in vertical dashed lines (yellow).

6. Conclusion

We have demonstrated on the flash tank case study that the presented algorithm is a suitable method for path-following PMPCC. Since it does not require the identification of the exact location of active-set changes and that relatively coarse discretization can be used, this algorithm is a promising candidate for use in advanced-step NMPC of models with complementarity.

resmis@iitg.ac.in*

Abstract

Process industries frequently encounter oscillations in control loops. Oscillations present in control loops could be an indication of one or more faults in the process such as valve stiction and controller tuning issues. These faults would negatively impact the performance of any process by degrading the quality of the product/output, reducing average throughput, increasing energy consumption etc. In this article, we propose a neural-network-based approach for oscillation detection. Various feature engineering strategies based on domain knowledge are adopted to improve the accuracy, precision and recall of oscillation detection while reducing the computational efforts. Fast Fourier Transform (FFT) and FFT of ACF (Autocorrelation function) of the dynamic process data are used as input features to the neural network. Feature selection based on peaks in the frequency domain data (for both FFT and FFT of ACF) is used for reducing the number of features. A sensitivity study on the variation of accuracy, precision and recall on the number of input features is also part of this work. An 80% reduction in number of input features is obtained compared to methods available in literature without compromising performance, and thus can be easily embedded in chips for online implementation. An accuracy of 96% and a recall of 0.95 for oscillatory data are obtained for the proposed algorithm.

Keywords: Oscillation detection, Feature selection, Feature engineering, Machine learning, Neural network, ACF, FFT

1. Introduction

The presence of oscillations in process data is a very common problem in industries. Oscillations are one of the major causes that deteriorate the performance of any control loop in process industries Srinivasan et al. (2011); Jiang et al. (2007). The presence of oscillations in process variables would result in poor product quality and production losses, and are not desirable. Oscillations can be due to various reasons like stiction in valves, controller tuning issues or due to some external disturbances. Early knowledge of oscillations present in the data and possible cause for the oscillations can help in mitigating its effect on the plant performance.

Although various techniques have been proposed in literature for oscillation detection (Thornhill et al., 2003; Jelali and Huang, 2010; Dambros et al., 2019b; Venkatasubramanian et al., 2003), their performance is poor for actual plant data. With the advent of machine learning, a few machine learning (ML)-based techniques have also been proposed recently for oscillation detection and diagnosis Dambros et al. (2019c,a). Although these techniques show high accuracy in detecting oscillations, they rely on a large number of input features in the frequency domain (obtained from FFT or Fast Fourier Transform of the time-domain signals). Dependency on a large number of

input features may result in erroneous detection of oscillations especially in presence of noise and may limit its industrial application. Moreover, the period and amplitude identification is poor.

This article proposes feature engineering and feature selection strategies based on domain knowledge for improving neural network-based oscillation detection. The proposed approach helps to reduce the number of features required for accurate detection of oscillations in process data.

2. Dataset available

The proposed approach was trained and validated using the synthetic dataset provided by Dambros et al. (2019c). The dataset contains dynamic process data for 110,000 process variables that contain non-oscillatory (43705 process variables), oscillatory (33174 process variables), and irregular oscillatory variables (33121 process variables). Class 0 refers to non-oscillatory, class 1 refers to oscillatory and class 2 refers to irregular oscillatory variables. Since this is a synthetic data, we have the information on which variables are non-oscillatory/ oscillatory/ irregular oscillatory. This is a multi-class classification problem. To avoid bias in oscillation detection due to varying magnitudes, the data is normalized before sending them for oscillation detection.

3. FFT-based Neural Network Approach for Oscillation Detection

Dambros et al. (2019c) presented a deep feedforward neural network (NN) for automatic oscillation detection using frequency domain data as input features. As different variables would be sampled at different rates, the dynamic data would be of different lengths and cannot be used as input features for NN directly. Hence, the dynamic process data was transformed to frequency domain through Fourier transform such that each variable had a length of 4097 samples. Dambros et al. (2019c) created a large synthetic dataset and the algorithm (after training) when tested on a subset of this synthetic data (test set) showed a high accuracy of 97% in detecting oscillations. However, the NN model uses 4097 input features and thus have a very large set of weights making it a computationally expensive method. The need to process large number of features makes it difficult to embed the algorithm in chip for online implementation. The proposed oscillation detection algorithm in chips and Optimization of hyperparameters is also difficult due to large size of the neural network. In this section, we discuss a Neural network model for oscillation detection that uses a subset of frequency domain features selected based on the peaks in FFT spectrum.

Similar to Dambros et al. (2019c), the time-domain data is first converted to frequency domain and the amplitudes corresponding to non-negative frequencies is chosen as FFT is symmetric. This results in 4097 amplitude values corresponding to 4097 frequencies for each variable. However, instead of using the entire frequency domain data for NN model, we select a few significant features based on domain knowledge. A peak in the FFT spectrum indicates presence of oscillations in the data. Practically, we can only find the maximum value of the FFT spectrum. To see whether the identified maxima is a peak, one has to rely on some heuristics based on adjacent amplitude values and thus, are not very accurate. This is why we needed an alternate data-based method for oscillation detection. Here, we use this idea that the maximum amplitude in FFT of the data and its adjacent amplitude values (corresponding to adjacent frequencies) are the most significant features in determining whether that variable data is oscillatory or not. A subset of significant features is chosen by identifying the maximum amplitude and a small neighborhood around it. Considering m amplitude values on both sides of the maximum value, the total number of input features will be $2m + 1$ including the maximum FFT value. We can alter the complexity of the network by varying the value of m . Sensitivity analysis was performed to find the optimal value of m . Various values of m are chosen and a neural network model (of same structure) is built for each m . This method would be referred as Method 1 hereafter. The structure of the neural network model used and the results obtained are described next.

Table 1: Oscillation detection results and sensitivity studies when a subset of FFT of data is used as input features

No. of Features ($2m + 1$)	Confusion Matrix	Accuracy	Precision			Recall			Computational time
			Class 0	Class 1	Class 2	Class 0	Class 1	Class 2	
11 ($m = 5$)	$\begin{bmatrix} 3450 & 100 & 435 \\ 1158 & 1828 & 41 \\ 2035 & 58 & 895 \end{bmatrix}$	61.73%	0.519	0.92	0.653	0.866	0.604	0.299	14.1s
21 ($m = 10$)	$\begin{bmatrix} 3653 & 40 & 292 \\ 965 & 1992 & 70 \\ 1840 & 29 & 1119 \end{bmatrix}$	67.64%	0.566	0.966	0.755	0.917	0.658	0.374	14.5s
31 ($m = 15$)	$\begin{bmatrix} 3710 & 38 & 237 \\ 905 & 2086 & 36 \\ 1788 & 40 & 1160 \end{bmatrix}$	69.56%	0.579	0.964	0.810	0.931	0.689	0.388	15.8s
101 ($m = 50$)	$\begin{bmatrix} 3782 & 5 & 198 \\ 644 & 2314 & 69 \\ 1107 & 30 & 1851 \end{bmatrix}$	79.47%	0.684	0.985	0.874	0.949	0.764	0.620	17.1s
201 ($m = 100$)	$\begin{bmatrix} 3856 & 3 & 126 \\ 345 & 2616 & 66 \\ 596 & 51 & 2341 \end{bmatrix}$	88.13%	0.804	0.980	0.924	0.968	0.864	0.783	18.9s

4097	$\begin{bmatrix} 3968 & 2 & 15 \\ 152 & 2810 & 65 \\ 201 & 52 & 2735 \end{bmatrix}$	95.13%	0.918	0.981	0.972	0.996	0.928	0.915	64.7s

3.1. Neural-network classifier

A three layer feed forward neural-network with neurons 400, 100 and 20 respectively in each layer is used for detecting oscillations in data. This neural-network was implemented in Python software by setting the hyperparameters 'batch size' as 10000, 'activation function' as 'Hard Sigmoid', and 'Optimization algorithm' as 'adamax'. The network is trained using a training dataset of 100,000 variables' data. The remaining 10,000 variables' data have been used for testing which contains 3985 non-oscillatory variables, 3027 oscillatory and 2988 irregularly oscillatory variables.

The results of oscillation detection for the test set using the trained model for various number of input features are provided in Table 1. The confusion matrix provided is such that the rows represent the true classes and the columns represent the predicted classes. The variation of accuracy, precision and recall with number of features is depicted in Figure 1. As the number of features increase from 11 ($m = 5$) to 4097 (full data), accuracy monotonically increases from 61.73% to 95.13% on the test set. Note that there isn't any significant improvement in accuracy by increasing the number of features from 401 to 4097. At the same time, the model precision for classes 1 and 2, and recall for class 1 have reduced when number of features were increased from 401 to 4097. Further, model training time for 401 features was around 21sec whereas it took more than a minute for training the model with 4097 features was around 65 sec for the training set. Note that these computational times are reported without including the time required for hyper-parameter optimization. This is because we have not performed hyper-parameter optimization since we are using the same network structure for all m values. Hyper-parameter optimization would improve the performance of each model.

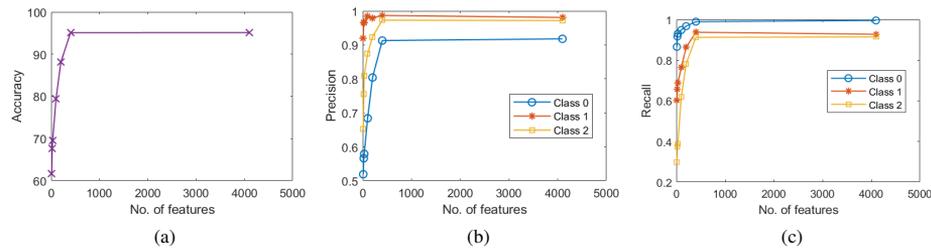

Figure 1: Variation of accuracy, precision and recall for the neural network classifier based on FFT features

4. FFT of ACF as input features

Although we were able to obtain almost similar accuracy of the full model using reduced number of features, another feature engineering strategy was attempted in search of an approach which can provide better performance with reduced number of features.

Autocorrelation Function (ACF) provides the correlation of a signal to itself at different time lags. It helps in finding repeating patterns in a signal. An important property of ACF is that it is oscillatory for an oscillatory signal with the same period of oscillation as the signal. This domain knowledge is used to extract useful features from process data. If the original variable data is oscillatory, ACF of the data will also be oscillatory. Hence, the presence of peaks in FFT of ACF of the data is an indication of oscillations in the original data. ACF shows noise free oscillations even if the original data is noisy and thus can be used as a better tool to identify oscillations.

As a first attempt, instead of using FFT of data as features, FFT of ACF of the data was used as input features for the neural network. The same approach as described in Section 3 is used to select a subset of features from FFT of ACF. Maxima of FFT of ACF is identified for each variable and $2m + 1$ amplitude values in the neighborhood of maxima are used as features. For each m , the same neural network structure as described in Section 3.1 is used. The network needs to be trained for each value of m as the input features are different. The method of using a subset of features from FFT of ACF of data is referred to as Method 2 hereafter. Depending on the value of m chosen, we obtain different performance in detecting oscillations as shown in Table 2. Although we obtained an accuracy greater than 90% for 401 features, we see that the performance is poorer than the earlier case with FFT of data as input features (Method 1). However, the predictions showed that we were able to correctly predict the class for some of the cases where Method 1 failed. Hence, the algorithm was further improved by incorporating features from both FFT of data and FFT of ACF of data.

The final method (Method 3) adopted for oscillation detection is a neural network that uses combination of subsets of FFT of data and FFT of ACF of data as input features. Again, maxima of FFT of data was identified and $2m + 1$ features in the neighborhood were picked. Similarly, $2m + 1$ features in the neighborhood of maxima of FFT of ACF of data were picked resulting in a total of $4m + 2$ input features. The results obtained for various values of m are provided in Table 3. Note that the accuracy has been improved to 95.96% for 802 features which is better than the accuracy obtained for Method 1 using 4097 features. Thus, a better accuracy is obtained with 80% reduction in the number of features. Computational time has also reduced. As the workstation used is of high configuration, the reduction in computational time is not much. However, for a normal desktop, computational time would be improved considerably with 80% reduction in number of input features. Moreover, since the purpose of the algorithm is to detect oscillations, recall of

Table 2: Oscillation detection results and sensitivity studies when a subset of FFT of ACF of data is used as input features

No. of Features ($2m + 1$)	Confusion Matrix	Accuracy	Precision			Recall			Computational time
			Class 0	Class 1	Class 2	Class 0	Class 1	Class 2	
11 ($m = 5$)	$\begin{bmatrix} 3046 & 481 & 458 \\ 699 & 2224 & 104 \\ 1492 & 271 & 1225 \end{bmatrix}$	64.95%	0.582	0.747	0.686	0.764	0.735	0.410	14.8s
21 ($m = 10$)	$\begin{bmatrix} 3582 & 194 & 209 \\ 800 & 2164 & 63 \\ 1687 & 124 & 1177 \end{bmatrix}$	69.23%	0.590	0.872	0.812	0.899	0.715	0.394	14.8s
31 ($m = 15$)	$\begin{bmatrix} 3781 & 67 & 137 \\ 818 & 2121 & 88 \\ 1708 & 63 & 1217 \end{bmatrix}$	71.19%	0.599	0.942	0.844	0.949	0.701	0.407	15.1s
101 ($m = 50$)	$\begin{bmatrix} 3842 & 4 & 139 \\ 332 & 2275 & 420 \\ 583 & 67 & 2338 \end{bmatrix}$	84.55%	0.808	0.970	0.807	0.964	0.752	0.782	17s
201 ($m = 100$)	$\begin{bmatrix} 3897 & 10 & 78 \\ 181 & 2575 & 271 \\ 397 & 117 & 2474 \end{bmatrix}$	89.46%	0.871	0.953	0.876	0.978	0.851	0.828	19.6s
401 ($m = 200$)	$\begin{bmatrix} 3899 & 12 & 74 \\ 121 & 2800 & 106 \\ 340 & 118 & 2530 \end{bmatrix}$	92.29%	0.894	0.956	0.934	0.978	0.925	0.847	21.2s
4097	$\begin{bmatrix} 3933 & 5 & 47 \\ 81 & 2737 & 209 \\ 194 & 90 & 2704 \end{bmatrix}$	93.74%	0.935	0.966	0.914	0.987	0.904	0.905	65.2s

classes 1 and 2 are more significant. Using methods 1 and 2, maximum recall obtained was 0.938 for class 1 and 0.913 for class 2. Using this approach, we are able to increase the recall to 0.95 for class 1 and 0.94 for class 2 using just 802 features. Also, with 8194 features, we are able to achieve 96.61% accuracy. Note that these results are obtained using a neural network for which hyper-parameter optimization have not been performed. Performance of the algorithm is expected to increase with optimized hyper-parameters. On the other hand, with respect to Dambros et al. (2019c), the work had been carried out using 4097 features of the FFT of the signal alone as the input and had achieved an accuracy of 97% in their work. The proposed method, albeit having 80% less number of features, provides an accuracy of 96%.

Hence, from various feature engineering and selection strategies, it was found that a neural network that uses 802 input features combined from FFT of data and FFT of ACF of data is the best choice in terms of accuracy as well as computational time. It was also found that there is a trade-off between accuracy and computational time. Based on application, if a lower computational time is required, a lower number of features can be used at the cost of lesser accuracy.

5. Conclusions

Neural network-based algorithms for accurate and fast detection of oscillations in process data are discussed in this article. Various feature engineering strategies based on domain knowledge have been implemented to improve the accuracy and computational effort of the method. FFT of data and FFT of ACF of data have been used as input features. To reduce computational complexity, significant features are selected based on the peaks or maximas in FFT and FFT of ACF. It was observed that neural network classifier performed better when a combination of FFT and FFT of

202 ($m=50$)	$\begin{bmatrix} 3765 & 15 & 205 \\ 447 & 2347 & 233 \\ 650 & 53 & 2285 \end{bmatrix}$	83.97%	0.774	0.972	0.840	0.945	0.775	0.765	44.2s
402 ($m=100$)	$\begin{bmatrix} 3845 & 18 & 122 \\ 201 & 2709 & 117 \\ 329 & 111 & 2548 \end{bmatrix}$	91.02%	0.879	0.954	0.914	0.965	0.895	0.853	41.1s
802 ($m=200$)	$\begin{bmatrix} 3914 & 14 & 57 \\ 75 & 2876 & 76 \\ 115 & 67 & 2806 \end{bmatrix}$	95.96%	0.954	0.973	0.955	0.982	0.950	0.940	47.2s
8194	$\begin{bmatrix} 3961 & 5 & 19 \\ 82 & 2887 & 58 \\ 128 & 47 & 2813 \end{bmatrix}$	96.61%	0.950	0.982	0.973	0.994	0.954	0.941	174.7s

ACF features were used as input features rather than using FFT features alone or FFT of ACF features alone as the input to the neural network. The performance saturates while computational time increases with increasing number of features. The neural network classifier based on 802 input features (401 FFT and 401 FFT of ACF) was found to be a best compromise in terms of accuracy/precision/recall and computational time. Efficacy of the proposed method on real plant data needs to be tested. Prediction of amplitude and period of oscillation using the proposed feature set would be attempted in future.

Abstract

In this paper we develop an advanced multi-parametric model predictive control approach for the control of an evaporation process in the pharmaceutical industry. The proposed strategies set the foundation for the development of controllers that aim to work with different molecules and different thermodynamic scenarios without repeating the process design and process control design steps. First, a comprehensive mathematical model of the process for one molecule type is developed and implemented within gPROMS. The model, along with its experimental set-up validation, is then used for the development of the advanced control strategies. Finally, the performances of the control strategies are validated against the original high-fidelity model, thus closing the loop. The simulations show good performances and satisfactory behavior.

Keywords: multi-parametric/explicit model predictive control, pharmaceutical processes, evaporation process.

1. Introduction

Due to their complex nature, pharmaceutical plants are required to operate near operational constraints with very strict product quality specifications and deal with complex and highly integrated processes, varying production targets, raw material variability and process/model uncertainty (Ierapetritou et al. 2016, Su et al. 2019, Seborg et al. 2017, Rantanen and Khinast 2015). Using model based control approaches greatly affects the time and resource utilization for the development process; certain pharmaceutical process design problems, under assumptions, can be transformed into process control problems (Nascu et al. 2016, Politis et al. 2017, Wang et al. 2017). If we consider a pre-existing pharmaceutical process in which a new molecule comes in, i.e. in the form of a newly developed active pharmaceutical ingredient (API), the standard approach requires a series of Design of Experiments (DoE) to be performed for the new process to be designed. However, only information regarding the material properties of the new molecule are required. A model based, material properties aware controller can make the necessary adjustment to adapt to the new molecule thus alleviating the need of computationally expensive and time consuming DoE's.

In this work we set the foundation for advanced multi-parametric model predictive control (mp-MPC) systems for a continuous evaporation process that are designed to work with different molecules without repeating the process design and process control design steps. The first step is to design a model of the process for one molecule type. This model will be then used to design advanced mp-MPCs for different molecules. Explicit/multi-parametric model predictive control (mp-MPC), solves offline the optimization problem using multi-parametric programming and derives the control inputs as a set of explicit linear functions of the system states, disturbances, set-points, etc (Pistikopoulos et al. 2002, Diangelakis et al. 2017). The performances and limits of the designed control schemes are tested on the model developed within the gPROMS platform for varying operating targets and process disturbances. The designed methodologies show good performances: fast settling time and no significant overshoot or undershoot. Moreover, this work represents the first step towards the development of advanced MPCs that are designed to work with different molecules and different thermodynamics scenarios without redoing the process design and process control steps.

2. Theoretical background

2.1. Process Description

Evaporation is a unit operation that separates liquids from solids by means of heat transfer via vaporization or boiling. The purpose of evaporation is to concentrate a solution containing a non-volatile solute (e.g., solids) and a solvent (e.g., liquid). Evaporating a portion of the solvent concentrates the solute into a more viscous liquid product. (Bryan W. Hackett 2018, Govatsmark and Skogestad 2001, Bloore and O-Callaghan 2009). Evaporation may be carried out as a batch or continuous process. This work focuses on evaporation as a semi continuous process as presented in Figure 1, in which the feed streams are continuous and the product is pushed out every 10 minutes.

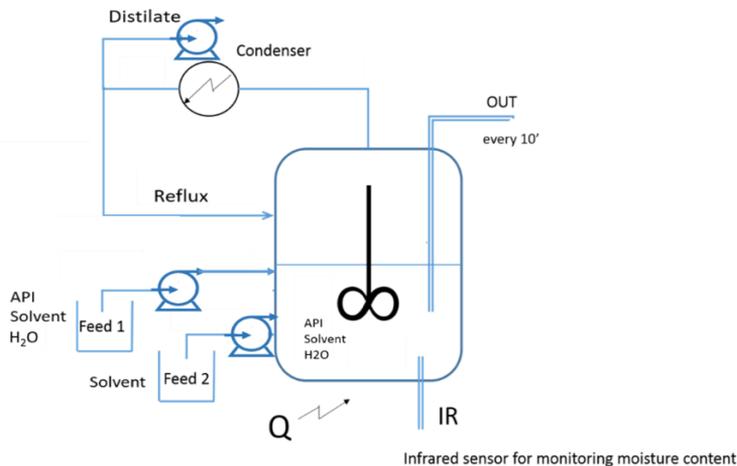

Figure 1 Evaporator scheme

The crude solutions (Feed 1 and Feed 2) are continuously pumped into the evaporator. A calculated mass flow rate for Feed 1 solution is set to achieve a target mass feed rate of API. A calculated mass flow rate of solvent is also continuously pumped into the evaporator (Feed 2). The vapour phase inside the evaporator consists of water and solvent only. The vapour condenses in the condenser and the excess distillate continuously flows

back into the evaporator as reflux. The calculated mass flow rate of solvent, and the calculated distillate mass flow rate, are set to achieve a given target composition of API and water in the solution flowing from the evaporator into the crystallization process. The solution from the evaporator is transferred intermittently about once every 10 minutes. The two feed streams into the evaporator and the distillate exiting the evaporator have mass flow control with a Coriolis mass flow meter in the loop. The mass flow rate of concentrated API solution flowing out of the evaporator is indirectly controlled because it is a consequence of the three mass flow inputs. Heat input to the evaporator is set at a constant amount which is higher than needed for the distillate mass flow. A Fourier Transform Infrared Spectrometer (FTIR) is installed into the bottom of the evaporator, measuring in real time the water and API content in the evaporator.

2.2. Process Model

The process model for the Evaporation process, presented in Figure 1 was adapted from the out-of-the-box evaporation model of gPROMS for the needs of this work. The model uses gSAFT thermodynamic package to model the thermodynamic properties. This model will be further used for the design of the control strategies as well as to test the performances of the designed controllers. It can operate regardless the choice of API and solvents (given thermophysical properties libraries). Moreover, the user can change the parameters of the two feeds, the rate of heat flow to the evaporator (Q - the amount of heat energy transferred to the evaporator per unit of time), the reflux constant as well as the configurations and initial conditions for the drum. The reflux constant is a value between 0 and 1 specifying the ratio in which reflux goes back in the evaporator.

The inputs of the model are Feed 1 flow rate (API, Solvent, H₂O), Feed 2 flow rate (Solvent), the reflux flow rate (Solvent, H₂O) as well as the heat flow rate to the evaporator, (Q). The controlled variables are the concentrations of API and H₂O. The measured variables for this process are the feed rates from Feed 1, Feed 2, reflux, temperature and the concentration of API, Solvent and H₂O inside the evaporator.

The model was tested for different APIs and different Solvents where open loop simulations were run for different initial conditions. The initial conditions are the same as the ones used in the real experiment. The flowrates variable are measured in [kg/sec], the concentrations for the feeds, the concentrations in the evaporator as well as the concentrations at the output of the evaporator are given in wt% and the input energy is given in [J/sec].

2.3. Multi-parametric Model Predictive Control

The following mp-QP optimization problem is solved to obtain the control laws using the POP toolbox (Oberdieck et al. 2016, Pistikopoulos et al. 2015, Pistikopoulos et al. 2007a, Pistikopoulos et al. 1999) and determine the controller:

$$\begin{aligned}
 \min_u J &= \hat{x}'_N P \hat{x}_N + \sum_{k=1}^{N-1} x'_k Q_k x_k + \sum_{k=1}^{N-1} (y_k - y_k^R)' Q R_k (y_k - y_k^R) + \\
 &\quad + \sum_{k=0}^{N_u-1} (u_k - u^R)' R_k (u_k - u^R) + \sum_{k=0}^{N_u-1} \Delta u'_k R 1_k \Delta u_k \\
 \text{s.t.} \quad &x_{t+1} = A x_t + B u_t + G w_t \\
 &y_t = C x_t + v_t \\
 &y_{\min} \leq y \leq y_{\max} \\
 &u_{\min} \leq u \leq u_{\max} \\
 &x_t \in X \subseteq \mathfrak{R}^p, u_t \in U \subseteq \mathfrak{R}^s
 \end{aligned} \tag{1}$$

where \hat{x} are the estimated states given by the state estimator, y outputs and u controls, w are the process disturbances and v the measurement noise, all (discrete) time dependent vectors. The subsets of output variables that get tracked have time-dependent set points y^R . Finally, Δu are changes in control variables, $\Delta u(k) = u(k) - u(k-1)$. The prediction horizon is denoted by N and control horizon by N_u . X , U are the sets of the state and input constraints that contain the origin in their interior. Both $Q > 0$, the objective coefficient for the states and $P > 0$, the terminal weight matrix for the states, are symmetric semi-positive definite matrices. The quadratic matrix for manipulated variables $R > 0$ is a symmetric positive matrix, QR is the quadratic matrix for tracked outputs and RI is a weight matrix for the control action changes (Δu).

3. Results

For the design of the mp-MPC controller the methodology presented in the previous section is used. The following tuning parameters are used: the objective coefficients for states (x), $Q=0$ when we have no state estimation and $Q=1$ in the case with state estimation, the control horizon $N_u=1$ and the prediction horizon $N=20$. The control actions for this process are in different ranges, for the first control action, Q , the nominal value is 45 while for the second control action the nominal value is $8.95e-6$. Moreover, it can be observed from Figure 2 that the control action on Feed 2 is penalized more than the control action on Q , H_2O concentration changes will be slower and API concentration changes will be faster. The higher the value of the weight factor, the more the command will be penalized.

First the optimization problem (1) is solved offline using the POP toolbox which will result in a map of all possible solutions. Once the look-up table is obtained, the controller will only have to perform simple function evaluations to derive the optimal control action that will be given to the process to take it to the desired setpoint value.

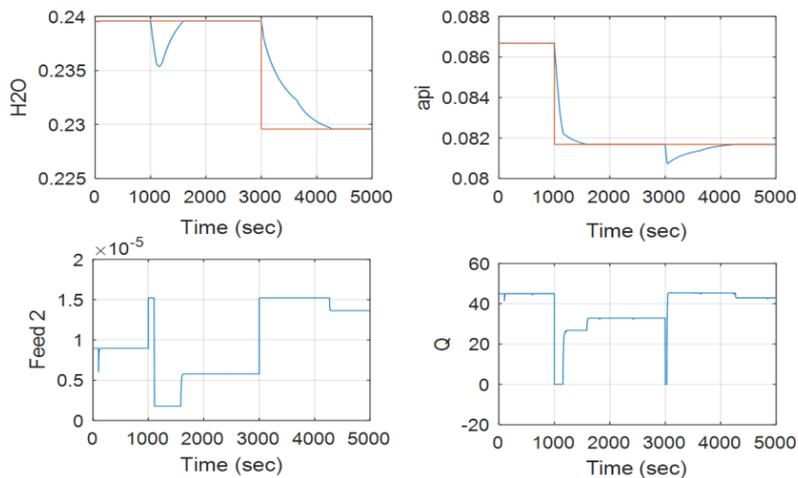

Figure 2. Closed loop response (mp-MPC). Step change on API and H_2O concentration. -4.16% step change on H_2O concentration and -5.7% API concentration. The H_2O and API concentration is given in wt%, U control action Feed 2 is the flowrate in [kg/sec] and U control action Q is in [J/sec].

A step change of -5.7% is given to the API concentration set point and a step of -4.16% is given to the H_2O concentration set point and the results are presented in Figure 2. The

designed controller due to its tuning parameters has a less aggressive behaviour, a fast enough settling time, and does not result in any undershoot/overshoot.

It can be observed that the step on the API reference will also affect the H₂O concentration and the H₂O reference will affect the API concentration but the controller is able to deal with the step changes and bring both concentrations back to the setpoint values.

To further test the performances of the designed controllers, a more realistic disturbance signal is designed as presented in Figure 3. The three different disturbance pattern signals are applied to the three concentrations of Feed 1: H₂O, Solvent and API once the process reaches steady state.

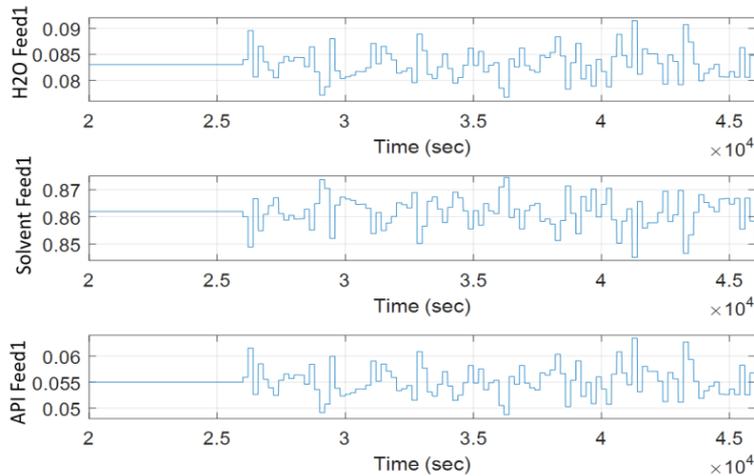

Figure 3. Realistic disturbance signal. The concentrations of API, Solvent and H₂O are represented in wt%

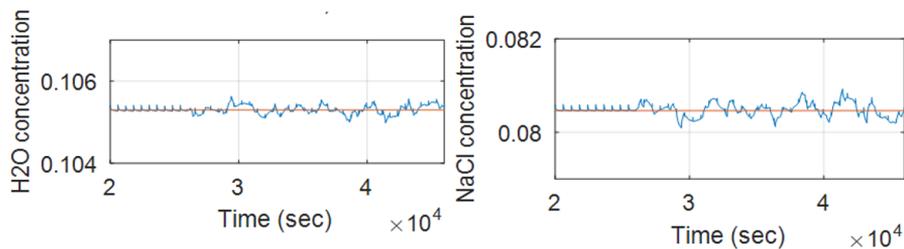

Figure 4. Closed loop response using a realistic disturbance signal

From Figure 4 it can be observed that the mpMPC controller is able to compensate for the disturbances introduced by Feed 1 (H₂O, Solvent, API). Since the mpMPC is multivariable, each control action will be responsible for both outputs.

4. Conclusions

In this paper we develop a multi-parametric model predictive control strategy for the control of the concentration inside of a continuous evaporation process. We start by developing a comprehensive mathematical model of the process for one molecule type

and implement it within the gPROMS platform. To analyze the performances the designed controllers are tested on the developed gPROMS model for: reference tracking, step changes in references as well as disturbances on the input concentration. The developed strategies show good performances without having significant overshoot or undershoot as well as a fast settling time. Moreover, the controllers are capable of maintaining the desired setpoint values while rejecting disturbances.

Abstract

This paper investigates the flexible operation of a Continuous Oscillatory Baffled Reactor for the hydrothermal synthesis of zeolites to find the economically optimal operating trajectory in the presence of varying electric energy prices. The process and the rigorous dynamic model are introduced. The performance of the dynamic optimization scheme is evaluated in simulation studies. A clear benefit of the dynamic adaptation to the variations of the energy price is demonstrated.

Keywords: dynamic optimization, Continuous Oscillatory Baffled Reactor, energy price based operation, demand side management

1. Introduction

The electric energy supply is in a transition towards renewable power sources. Due to their high volatility, the inclusion of electric energy renewable sources is a major challenge for the process industry. The fluctuating power supply and the largely steady demand of continuous processes create a supply-demand mismatch. This leads to high variations in the electric energy prices, which are expected to be amplified in the future as demonstrated by Göransson et al. (2019).

The ability to react to energy price variations, therefore, has two benefits, first an economic benefit of using electric energy at low-price levels and second to increase the stability of the energy grid by adapting the demand. The approach presented here dynamically adapts the throughput and the heating duties to optimize the productivity of the process, while ensuring a mean production rate and the specified product quality.

Similar approaches have already been reported in the literature for scheduling problems under the headline of demand-side management (DSM) as presented by e.g. Leo et al. (2021) or Brée et al. (2018). In these, the plant dynamics are neglected and steady-state models used instead. However, with fast-changing prices of electric energy, the steady-state assumptions do not hold. In those cases, calculated schedules using steady-state models can lead to suboptimal performance or constraint violation as shown by Caspari et al. (2019). Therefore, the non-linear dynamic plant model is used to calculate an optimal dynamic schedule.

The approach of an optimized time-varying continuous operation is investigated in this paper for a hydrothermal production of zeolites in a continuous plant as presented in Ramirez Mendoza et al. (2020). The production of zeolites is an energy-intensive process which is typically performed in batch reactors. The shift to continuous operation has several advantages such as heat integration and lower variations of product quality. The sedimentation problem of the suspended solid is solved by using the Continuous Oscillatory Baffled Reactor (COBR) concept. However, the adaptive flexible operation of the distributed continuous plant is a main challenge, which motivates this paper.

2. Process overview

A schematic representation of the process is shown in Figure 1. The reactants are previously mixed and fed as a suspension of amorphous solids. The feed is preheated with an integrated heat exchanger. The suspension is fed into the Continuous Oscillatory Baffled Reactor, which is equipped with three direct electrical heaters. The three heaters have different lengths as shown in the schematic. The heating duties of the three heaters can be set individually. Within the COBR reactor, the hydrothermal formation of zeolites is performed at elevated temperatures, the residence time is approximately 80 min. The suspension of crystalline zeolites leaves the reactor and is used to heat the feed stream. The operational limits of the reactor are a minimal flow rate of 60 L/h and a maximum temperature of 413.15 K of the reaction medium and of the reactor wall. The product requirements are a minimum crystallinity of 98% and a fixed average throughput.

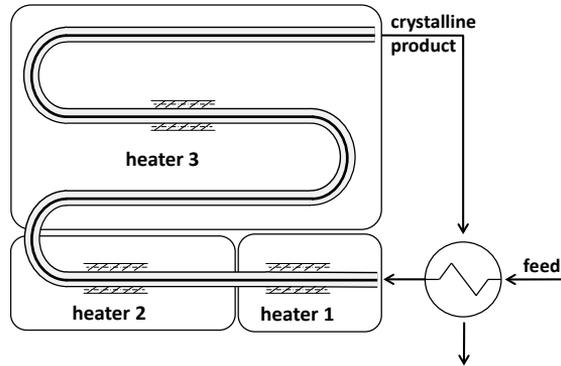

Figure 1: Schematic of the process

The suspension of crystalline zeolites leaves the reactor and is used to heat the feed stream. The operational limits of the reactor are a minimal flow rate of 60 L/h and a maximum temperature of 413.15 K of the reaction medium and of the reactor wall. The product requirements are a minimum crystallinity of 98% and a fixed average throughput.

2.1. Model

The reactor dynamics are described with the partial differential equations (1).

$$\rho c_p \partial_t T_w = \dot{Q}_E + \dot{Q}_H - \dot{Q}_{Rw} \quad (1a)$$

$$\rho c_p \partial_t T = -u \rho c_p \partial_z T + \rho c_p \partial_z [\lambda \partial_z T] + \dot{Q}_{Rw} / \rho c_p \quad (1b)$$

$$\partial_t c_i = -u \partial_z c_i + \partial_z [D \partial_z c_i] + r_i \quad (1c)$$

$$\partial_t n = -u \partial_z n + \partial_z [D \partial_z n] + G \partial_L n + B \quad (1d)$$

$$B = k_n(T)(c_I - c_{I,eq})c_{am} \quad (1e)$$

$$G = k_g(T)(c_I - c_{I,eq}) \quad (1f)$$

The energy balance of the wall temperature is shown in (1a) in which the effects of the heat transfer to the reaction medium, the loss to the environment and heat input of the direct electrical heaters are incorporated. The axial dispersion model for the energy and concentration balances of the reaction suspension is shown in (1b),(1c). The reaction term r_i describes the conversion from the amorphous state via dissolved ions in the liquid phase to the crystalline product. The population balance (1d) describes the particle density distribution (n) in size (L) with a heterogeneous nucleation term (1e) and the size-independent growth model (1f). It is solved using the method of moments. The spatial discretization is approximated using the finite differencing method on 30 grid points. The resulting non-linear ordinary differential equation model has 240 dynamic states.

2.2. Process economics

The profit of the process includes the influence of the product revenue, the reactant and energy costs and the fixed costs as shown in (2).

$$\text{Profit} = \underbrace{P_p \cdot \dot{m}}_{\text{product revenue}} - \underbrace{P_{Rs} \cdot \dot{m}}_{\text{reactant cost}} - \underbrace{P_E \cdot \dot{Q}_H}_{\text{energy cost}} - \underbrace{C_{Fix}}_{\text{fixed cost}} \quad (2)$$

The fixed costs can be neglected when optimizing the operating conditions since the additive term in the objective does not influence the solution of an optimization problem. The other terms are scaled with a reference operating point and divided by the (negative) net revenue. The scaled operational cost is shown in equation (3), in which the parameter γ described the scaled price of electric energy.

$$\Phi(u, \gamma) = -\dot{m}/\dot{m}_{ref} + \gamma \dot{Q}_H/\dot{Q}_{H,ref} \quad (3)$$

3. Optimization problem

3.1. Dynamic optimization problem

The formulation of the dynamic optimization problem of the flexible operation is shown in equation (4). The operation over one and a half day is minimized assuming perfect knowledge of the future price of electric power.

$$\min_{u,x} \int_0^{t_f} \Phi(u, \gamma(t)) dt \quad (4a)$$

$$\text{s.t.: } \dot{x} = f(x, u), \quad (4b)$$

$$0 \geq g(x, u), \quad (4c)$$

$$\bar{X}_j \geq 0.98 \quad \forall j \in [1, K] \quad (4d)$$

$$\bar{V}_j = \dot{V}_{fix} \quad \forall j \in [1, K] \quad (4e)$$

$$\int_0^L T(t_f, \cdot) dz = \int_0^L T(0, \cdot) dz \quad (4f)$$

$$\int_0^L m_3(t_f, \cdot) dz = \int_0^L m_3(0, \cdot) dz \quad (4g)$$

The objective (4a) is the scaled cost defined in (3). The dynamic process model is represented by (4b). The process bounds defined in section 2 are represented by (4c). The restrictions on the mean throughput and the mean product quality are included as averaging constraints (4d)-(4e) in the dynamic optimization problem. These constraints must be met on three ($K = 3$) subsequent averaging horizons which have the length of 12 h each. The specified crystallinity and the specified throughput should be reached on average over 12, 24 and over 36 hours. This reduces the needed storage capacity without losses of productivity. The optimization will be repeated after 24 h and therefore the solution for the horizon between 24 h and 36 h will not be applied but in combination with the endpoint hold-up constraints (4f),(4g), terminal sell-off effects can be reduced in this manner which is further discussed in 4.1.

The resulting non-linear optimization problem was implemented using the software CasADi by Andersson et al. (2018) and solved with the IPOPT solver. The ode model (4b) is solved using orthogonal collocation on two finite elements using second order Radau polynomials. The optimization problem has 103.968 variables and is solved within 3-4 h.

3.2. Static optimization problem

Additionally, a static optimization problem is defined in (5) which represents a scenario in which the plant dynamics is infinitely fast. The objective function and process bounds are the same as in (4). Constraint (5b) enforces a steady-state operation, while the mean crystallinity and throughput are enforced by (5d) and (5e).

$$\min_{u_i, x_i} \sum_{i=0}^N \Phi(u_i, \gamma) \quad (5a)$$

$$\text{s.t.: } 0 = f(x_i, u_i), \quad (5b)$$

$$0 \geq g(x_i, u_i), \quad (5c)$$

$$\bar{X}_i \geq 0.98 \quad \forall i \in [0, N] \quad (5d)$$

$$\bar{V}_i = \dot{V}_{fix} \quad \forall i \in [0, N] \quad (5e)$$

4. Results

4.1. Terminal sell-off

The terminal sell-off commonly observed in economic MPC literature e.g. by Ellis et al. (2014), is caused by the approximation of the infinite horizon optimization problem by a finite horizon optimization problem which results in suboptimal performance for a continuous operation. The results of the optimization problem (4) with a constant price of energy are shown in Figure 2. In the second and third plot, the results with the end-point constraints (4f),(4g) are shown, while in the first plot the results without end-point constraints are displayed. In the first and the second plot, one averaging horizon was used ($K = 1$), whereas in the third plot, two averaging horizons were used ($K = 2$). The black dotted line represents the steady-state optimum. The

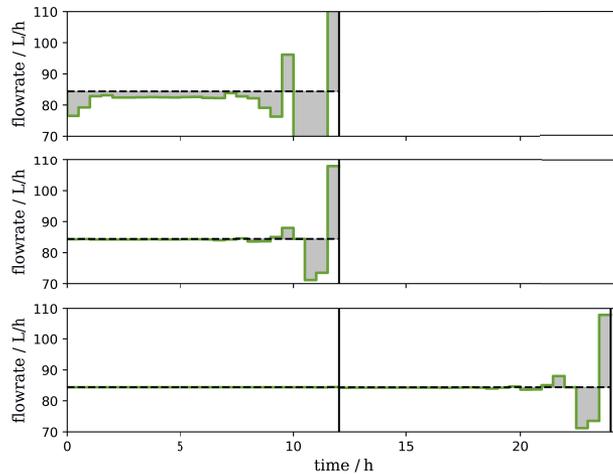

Figure 2: Optimal calculated flowrates for different number of averaging horizons and different end-point constraints

influence of the final horizon can clearly be observed by the deviation of the dynamic optimization results from the steady-state result. However, the effect is far more prominent in the first case without terminal constraints. The terminal sell-off leads to a deviation even at the beginning of the optimization horizon. Using the end-point constraints (4f),(4g) this effect is reduced. However, it still leads to a deviation close to the end of the horizon. Using the end-point constraints and an additional averaging horizon the deviation from the steady-state optimum is shifted to the end of the second averaging horizon, whereas no deviation in the first horizon is observed. The solution proposed in this work is similar to the approach in MPC, i.e. discarding the results for the final horizon and re-solving the optimization problem with a shifted time frame.

4.2. Dynamic optimization

The results of the solution of the dynamic optimization problem (4) with a time-varying energy price are shown in Figure 3. The variation of the energy price is assumed to be a square wave with a relative amplitude of 0.56 and a frequency of 0.167 1/h which is displayed in the bottom plot. The initial state $x(t = 0)$ is the optimal steady-state for the specified production rate. The temperature and the crystallinity at the reactor outlet are displayed in the upper two plots. The corresponding inputs, the flow rate and the heating powers are shown below. The green solid line in the plots represents the calculated optimal trajectory. In the fourth plot, the three areas represent

the heating powers of the first, the second and the third heater. The coloured dotted line shows the solution of the static optimization problem (5) for the given price variation while the black dotted line is the optimal steady-state for the average production rate. The average values of the flow rate and of the crystallinity are constrained. The deviation to these average values is shown with the grey shaded areas. The vertical black lines show the end of the averaging horizons after 12 h, 24 h and 36 h.

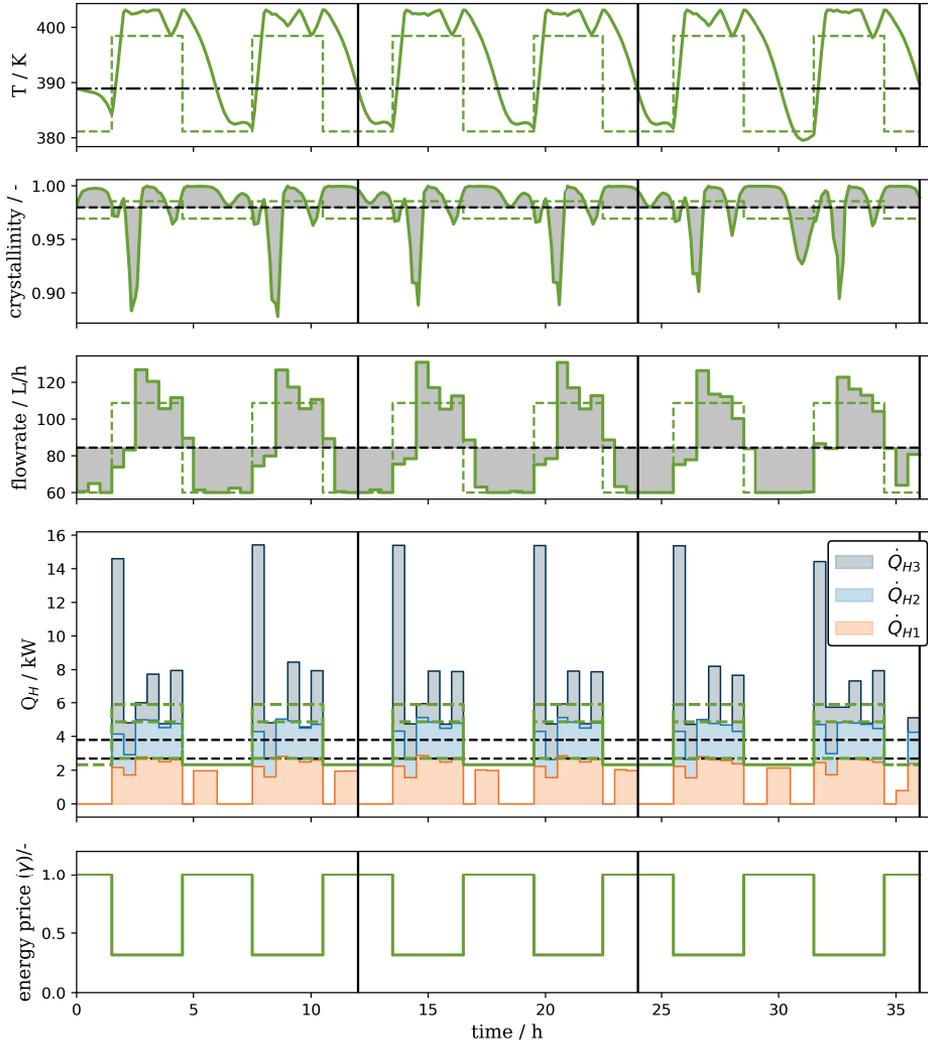

Figure 3: Result of the dynamic optimization with the a varying energy price

The periodic energy price variation leads to a periodic pattern of the operation of the COBR. At a high price of energy, the flow rate is close to its lower bound and the heating power is small. When the price of energy switches to a low value (e.g. after 13.5 h) the heating power of all three heaters reaches a maximum, while the flow rate increases to the mean value. The extensive heating reduces the drop of the product quality which is caused by the low energy input in the high

energy price period. The usage of the third heater is detrimental from an energetic point of view but is compensated by the savings due to the lower price of energy. The temperature is increased and stays close to the steady-state level. One hour after the price change, the flow rate reaches a maximum and slowly drops afterwards. Within that period, the first two heaters have a constant value. The heat input of the third heater oscillates around the static value. The oscillation ends with a maximum in order to store energy in the system before the increase of the price. After the transition to high values of the price of energy, the flow rate is rapidly decreased to the lower bound and the heaters are turned off. In this dynamic transition period, the residual heat is used. Later, to ensure the desired crystallinity, the first heater is turned on again and operated close to the steady-state optimum around the middle of the high energy price period. The variations of the different periodic patterns from each other in the beginning and to the end are caused by the initial and terminal constraints. The benefit of the shown operation in comparison to a static optimal operation can be calculated as an energy cost saving of 32.4% for this scenario. The proposed method is capable to calculate an optimal dynamic schedule assuming perfect knowledge of the variation of electric energy price. The complexity of the calculated purely dynamic operation of the COBR underlines the necessity for the inclusion of the full dynamic plant model in the optimization. Using this method, the optimal operation schedule dependent on the variation of the price of electric power can be investigated.

5. Conclusion

In this work, a flexible operation of a continuous zeolite crystallization process in a COBR is demonstrated. The plant and the model are introduced and the resulting dynamic optimization problem is described. The influence of the finite horizon approximation is further analysed and its influence on the optimized schedule is minimized using end-point constraints and an extended optimization horizon. The dynamic optimization results are presented which show a periodic pattern of operation, following the variations of the price of electric power. The results show a large potential of the adaptive dynamic operation. Further extensions of this work concern including alternative electrical energy inputs, such as sonication or vapour compression technologies and the handling of the uncertainty in the predictions of the variations of the price of energy similar to the approach presented by Leo and Engell (2018) for scheduling problems.

Abstract

This paper presents an efficient Deep Learning (DL) based method for explicit model predictive control (E-MPC) of high-dimensional and/or nonlinear chemical processes for which mathematical E-MPC approaches are difficult to apply. The method uses DL models for off-line development of control laws that accurately approximate the relationship between the optimal values of the control variables to be applied in the next sampling period (SP) as a function of the values of the state variables in the current SP. The training data are generated by solving the MPC problem considering different initial values of the state variables selected using design of computer experiments (DOCE) techniques. The obtained DL-based control laws are then integrated into a closed-loop for online control of the process. A numerical validation procedure is used to evaluate the performance of the developed control laws in terms of their accuracy and computational cost. The method is applied to case studies for which a “direct” application of mathematical E-MPC techniques is difficult due to their high dimensionality and nonlinearity. The results show a high performance of the proposed method and a reduction in the complexity of the solution procedure compared to mathematical E-MPC.

Keywords: Control; Explicit MPC; Chemical Processes; Deep Learning; ANNs.

1. Introduction

MPC is one of the most widely used control methods in engineering because it can efficiently deal with multivariate systems, hard constraints on control and/or state variables, and different types of control objectives, e.g., economic objectives. However, MPC faces the challenge that its expensive online computations require high computational resources: at each SP, MPC solves a dynamic optimization problem (open-loop optimal control) that requires repeated evaluation of a dynamic process model (Karg and Lucia, 2020). Therefore, MPC applications may be infeasible for processes characterized by high dimensionality, nonlinearity, and/or fast dynamics (Rivotti et al., 2012). To overcome this challenge, E-MPC methods - also called MultiParametric MPC - have been developed to solve the MPC problem off-line, providing simple mathematical relationships that describe the future values of the optimal control variables as a function of the current values of the state variables, where each relationship applies only to a specific subregion of the state variables space, called critical region (Chen et al., 2018). These mathematical laws are then used online to drive the process, requiring very little computational time. Although E-MPC methods have been successfully applied in many cases in various engineering fields, they are limited to linear, discrete-time state-space models with moderate dimensionality (Rivotti et al., 2012). Recently, the use of machine

learning has been proposed to extend these limitations by exploiting their universal approximation and dimensionality reduction capabilities to develop accurate and computationally cheap data-driven control laws that approximate the relationship between the optimal future control values and the current state values. For example, Shokry et al. (2016) used multilayer artificial neural networks (ANNs) to develop explicit control laws and applied them to a simple continuous stirred tank reactor (CSTR). Chen et al. (2018) used constrained ANNs to develop control laws that explicitly learn the mathematical constraints of the MPC problem, and applied them to simple linear, discrete-time state-space models. Karg et al. (2020) used ANNs to approximate control laws and applied them to linear, discrete-time state-space models of mass-spring systems. However, most of these methods are tailored to the existence of simple linear discrete-time state-space models to which mathematical E-MPC methods can be easily applied, and also require large amounts of training data. Therefore, in this paper, an efficient DL-based method for E-MPC (DL-E-MPC) of high-dimensional and nonlinear chemical processes is presented, which uses DL models for off-line development of control laws that accurately approximate the relationship between the optimal values of the control variables to be applied at the next SP as a function of the values of the state variables at the current SP. The training data are generated by solving the MPC problem considering different initial values of the state variables selected by DOCE techniques. The obtained DL-based control laws are then integrated into a closed-loop for online control of the process. A validation procedure is used to evaluate the performance of the control laws in terms of i) open-loop response accuracy (i.e., over a SP, without feedback), ii) closed-loop response accuracy (i.e., over the entire control trajectory, with feedback), iii) state accuracy, and vi) online computational cost. The proposed method is applied to two case studies from the literature (Rivotti et al., 2012), to which a "direct" application of E-MPC methods is not possible due to their high dimensionality and/or nonlinearity.

2. Problem statement

In a generic MPC problem (Eqs. (1:3)), a process is controlled over a finite time horizon composed of a number N^{fnl} of equal SP, relying on an accurate process model (Eq. (2)). At each SP $k, k = 1, 2, \dots, N^{fnl}$, the optimal trajectory of the manipulated inputs $[u_{t+1}^*, \dots, u_{t+N_p}^*]$ over a specific prediction horizon N_p is calculated by solving a dynamic optimization problem that considers a desired performance index J (Eq. (1)) and subjected to a set of constraints $g_l, l = 1, \dots, L$ (Karg and Lucia, 2020). The measured values of the state variables at the previous SP, x_{k-1} , are used as the initial conditions for this optimization problem. Then, only the values of the calculated optimal control profile corresponding to the first SP, u_{t+1}^* , are implemented in the real process, and so on. Notice that in Eq. (1), $Q \in R^{m \times m}$ and $\mathfrak{R} \in R^{v \times v}$ represent weight metrics of the objective function J , while \check{r} is the setpoint.

$$\min_{u_{t+1}, \dots, u_{t+N_p}} J = \sum_{k=1}^{N_p-1} (x_{t+k} - \check{r})' Q (x_{t+k} - \check{r}) + \Delta u_{t+k}' \mathfrak{R} \Delta u_{t+k} \quad (1)$$

$$S.T. \quad x_{t+1} = F(x_t, u_t), \quad x \in R^m, u \in R^v \quad (2)$$

$$g_l(x_t, u_t) \leq 0, \quad l = 1, 2, \dots, L \quad (3)$$

$$u_{min} \leq u_k \leq u_{max}, \quad \Delta u_{t+k} = u_{t+k} - u_{t+k-1}, \quad k = 1, \dots, N_p.$$

3. Proposed methodology

Motivated by situations where F (Eq.(2)) is a highly nonlinear and/or high-dimensional model that hinders the application of mathematical E-MPC methods, this paper proposes an efficient DL-E-MPC for such processes, consisting of the following steps:

3.1. Sampling of the initial values of state variables

In the first step, different n^{tr} values of the initial state variables $[x_{0,i}]$, $i = 1, \dots, n^{tr}$, $x \in R^m$ are selected within their expected/feasible variability domain. The selection is done using a DOCE technique that covers the entire variability space of the state variables to obtain information about the control behavior over the whole state domain. In this work, we use a hybrid DOCE technique that combines Hammersley and fractional designs, which generates uniform sampling schemes with very low computational requirements.

3.2. Training and testing data generation by solving the MPC problem

In the second step, the MPC problem is solved n^{tr} times as formulated in Eqs. (1:3) but only over a finite duration $N^{trn} \leq N^{fnl}$, where in each time, one of the previously generated initial state values, $x_{0,i}$, is considered as the initial conditions for the $i - th$ MPC problem. This allows to obtain the optimal closed-loop trajectories of the control inputs $[u_{1,i}^*, u_{2,i}^* \dots, u_{N^{trn},i}^*]$ and the associated trajectories of the state $[x_{0,i}, x_{1,i}, \dots, x_{N^{trn}-1,i}]$, $i = 1, \dots, n^{tr}$. Then, the n^{tr} pairs of control-state trajectories are folded into an input-output dataset in the form of $[x_{t,i}, u_{t+1,i}^*]$, $i = 1, \dots, n^{tr} \times N^{trn}$. Another testing dataset is generated in the same way, as described in Sections 3.1 and 3.2, but in this time, the MPC problem is solved over the entire time horizon N^{fnl} to obtain n^{ts} pairs of optimal closed-loop control-state trajectories, i.e., $[u_{1,i}^{*ts}, u_{2,i}^{*ts}, \dots, u_{N^{fnl},i}^{*ts}] - [x_{0,i}^{ts}, x_{1,i}^{ts}, \dots, x_{N^{fnl}-1,i}^{ts}]$, $i = 1, \dots, n^{ts}$. These test trajectories are also folded into input-output dataset in the form of $[x_{t,i}^{ts}, u_{t+1,i}^{*ts}]$, $i = 1, \dots, n^{ts} \times N^{fnl}$. The folded test dataset will be used to assess the open-loop accuracy of the control laws, while the n^{ts} test pairs of control-state trajectories will be used to assess their closed-loop accuracy.

3.3. Development of DL-based control laws

In this step, the generated training data $[x_{t,i}, u_{t+1,i}^*]$, $i = 1, \dots, n^{tr} \times N^{trn}$ are used to develop a number of v DL-based control laws $\hat{u}_{i,t+1}^* = \mathcal{F}_{DANNi}(x_t)$ $x \in R^m$, $i = 1, 2, \dots, v$, where \mathcal{F}_{DANNi} is a feedforward deep ANN (DANN) for regression. The selection of the DANNs' structure (number of hidden layers and their respective sizes, type of activation functions, training loss, etc.) and the training algorithm is done by a cut-and-try procedure that seeks for the best compromise between the prediction accuracy and the simplicity of the structure (Shokry et al., 2016). After training the control laws, their open-loop response accuracy is evaluated using the folded test dataset $[x_{t,i}^{ts}, u_{t+1,i}^{*ts}]$, $i = 1, \dots, n^{ts} \times N^{fnl}$ generated in Section 3.2, and an accuracy measure, such as the Normalized Room Mean Square Error (NRMSE) (Eq. (4)), can be calculated for each of the v control laws.

$$NRMSE = 100 \times \frac{\sqrt{\frac{1}{n^{ts} \times N^{fnl}} \sum_{n^{ts} \times N^{fnl}} (u_{t+1,i}^{*ts} - \hat{u}_{t+1,i}^{*ts})^2}}{(u_{max}^{*ts} - u_{min}^{*ts})} \quad (4)$$

where u_{max}^{*ts} and u_{min}^{*ts} are the maximum and minimum values of the control variables in the testing dataset, respectively.

3.4. Online (closed-loop) deployment of the control laws

Finally, the control laws based on DL are integrated into a closed-loop to predict the entire control trajectory starting from arbitrary initial conditions of the state variables: at each SP, the real outputs measured from the process are sent to the control laws to calculate the optimal values of the control variables, which are sent to the actuators to implement them in the process, and so on. The closed-loop accuracy (in terms of NRMSE) of the control laws is evaluated using the n^{ts} pairs of optimal control-state trajectories generated in Section 3.2. This closed-loop NRMSE is calculated for each predicted trajectory individually and then averaged over the n^{ts} trajectories. A third NRMSE is calculated to evaluate the accuracy of the process state variables driven by the application of the predicted control trajectories compared to their exact values calculated by mathematical MPC.

4. Applications

4.1. Case 1: MPC of two connected CSTRs

A series of two CSTRs is considered in which an irreversible reaction $A \Rightarrow B$ takes place (Rivotti et al., 2012), where reactant A is fed into the first reactor and the resulting mixture is then fed into the second reactor. A nonlinear model describing the dynamic relationships between six state variables and two manipulated variables is used to control the process. The state variables include the reactant concentration, temperature, and volume in each reactor, $CA1, V1, T1, CA2, V2, T2$, and the manipulated variables are the heat supplied to the first reactor, η , and the outlet flow from the second reactor, ω . The objective is to bring the controlled state variables, volume and temperature of the second reactor, to their setpoints $V2 = 100 L$, $T2 = 463 c^o$ through manipulating the control variables within their allowable limits: $0.75 \leq \eta \leq 1.1$ and $-0.75 \leq \omega \leq 1.1$, assuming that all state variables are measured and there are no external disturbances (Rivotti et al., 2012). The problem is formulated as in Section 2 with $Q = [1 \ 0; 0 \ 1]$, $R = [0.05 \ 0; 0 \ 0.05]$, $N_p = 10$ and $N^{fnl}=200$ SPs each of 0.1 min.

The proposed method is applied as described in Section 3. A sampling plan of $n^{tr} = 400$ value combinations of the initial state variables is generated, $[CA1_{o,i}, V1_{o,i}, T1_{o,i}, CA2_{o,i}, V2_{o,i}, T2_{o,i}]_{400}$, using the hybrid DOCE technique. Then the MPC problem is solved 400 times over the horizon $N^{trn} = 10$ to obtain the control trajectories $[\eta_{1,i}^*, \eta_{2,i}^* \dots, \eta_{10,i}^*]_{400}$, $[\omega_{1,i}^*, \omega_{2,i}^* \dots, \omega_{10,i}^*]_{400}$ and the associated state trajectories, which are then folded into the input-output training matrix $[CA1_{t,i}, V1_{t,i}, T1_{t,i}, CA2_{t,i}, V2_{t,i}, T2_{t,i}, \eta_{t+1,i}^*, \omega_{t+1,i}^*]_{4000}$. Figure 1-(a) shows the input training data projected onto the space of two state variables, and Figure 1-(b, c) shows the distributions of the output training data, much of which lies at the extremes of the distributions. This is because the MPC problem is solved over a short period of time, N^{trn} , that represents the early period immediately after the initial state where the controller tends to apply allowable extreme control values to quickly stabilize the process. The training set is used to build two DANNs $\hat{\eta}_{t+1}^* = f_{DANN1}^{\eta}(CA1_t, V1_t, T1_t, CA2_t, V2_t, T2_t)$ and $\hat{\omega}_{t+1}^* = f_{DANN2}^{\omega}(CA1_t, V1_t, T1_t, CA2_t, V2_t, T2_t)$. A number of $n^{ts} = 30$ testing optimal closed-loop control profiles are generated, as described in Section 3.2, to evaluate the developed control laws. Table 1 shows the promising performance of the developed control laws in terms of accuracy, which is well below 1% of NRMSE in all cases (open-loop, closed-loop, and states), and the very low online computational overhead required to predict the

control actions in each SP (0.015 s) compared to that of MPC (2.55 s). Figure 2-(a, b) shows the three predicted control trajectories with the highest closed-loop NRMSE (dashed lines) compared to their exact behavior (solid lines), while Figure 2-(c) shows the corresponding state trajectories. The figure again highlights the promising performance of the methodology.

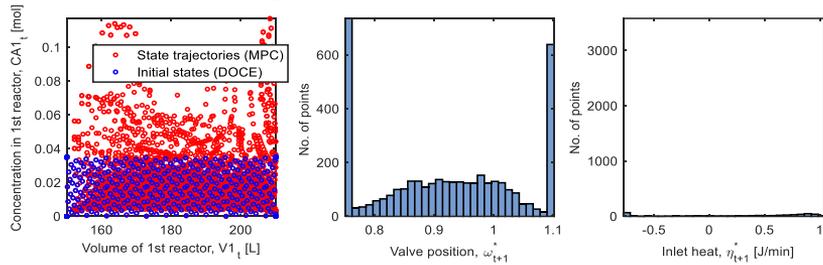

Figure 1. Folded training dataset of the 2-CSTRs case study.

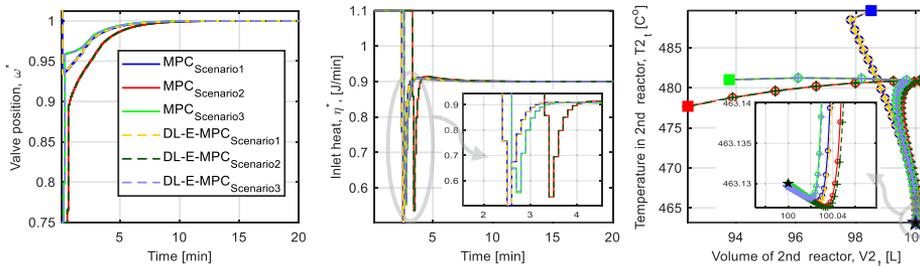

Figure 2. (a,b) Three predicted control trajectories compared to their exact values, and (c) corresponding states trajectories, where squares are initial conditions and star is the setpoint.

4.2. Case 2: MPC of a distillation column

In this case, a distillation column consisting of 30 trays is considered, which is fed with liquid mixtures at the 17th tray (Rivotti et al., 2012). The system is represented by a differential model describing the dynamic relationships between 32 state variables, which include the liquid composition at each tray, y_2, y_3, \dots, y_{31} , distillate composition, y_1 , bottom-product composition, y_{32} , and a control variable represented by the reflux ratio, γ . The goal is to maintain the purity of the distillate at the setpoint, $y_{32} = 0.935$, by manipulating the reflux ratio within its limits $0 \leq \gamma \leq 5$. The parameters of the MPC problem are $Q = 20$, $R = 1 \times 10^{-6}$, $N_p = 15$, and $N^{fnl} = 200$ SPs each of 0.1 min. The method is applied as described in Sections 3 and 4.1 starting by the generation of a sampling plan involving $n^{tr} = 400$ different initial state values $[y_{1,o,i}, \dots, y_{32,o,i}]_{400}$. The MPC problem is, then, solved with $N^{trn} = 40$ to collect the control $[\gamma_{1,i}^*, \dots, \gamma_{40,i}^*]_{400}$ and the related state trajectories. The folded input-output training matrix $[y_{1,t,i}, \dots, y_{32,t,i}, \gamma_{t+1,i}^*]_{16000}$ is used to develop a DANNs-based control law $\hat{\gamma}_{t+1}^* = f_{DANN1}^{\gamma}(y_{1,t,i}, \dots, y_{32,t,i})$, which is assessed using a number of $n^{ts} = 30$ testing control profiles. Table 1 and Figure 3 show the promising assessment results.

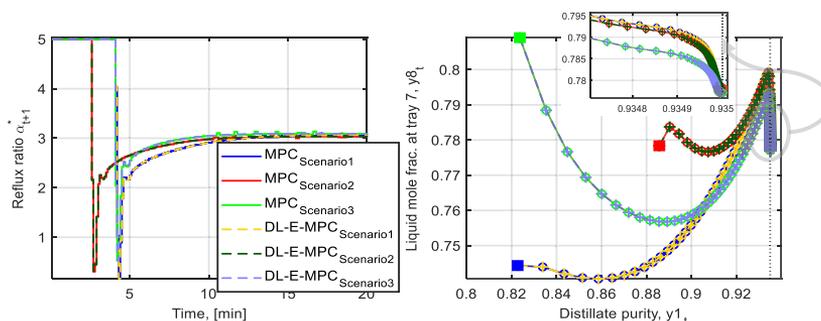

Figure 3. (a) Three predicted control trajectories -with the highest closed-loop NRMSE- compared to their exact values, and (b) corresponding states trajectories, where squares are initial conditions and dotted line is the setpoint.

Table 1. Computational cost and accuracy of the developed DL-based control laws.

		Off-line CPU time (s)*			NRMSE (%)			Online CPU time per SP	
		Training data gen.	Testing data gen.	DANNs training	Open-loop	Closed-loop	Final states	DL-E-MPC	MPC

5. Conclusion

In this paper, we present an efficient DL-E-MPC method for highly nonlinear and/or high-dimensional chemical processes, consisting of four steps and incorporating various tools and techniques, such as DOCE, state-of-the-art dynamic optimization methods, and machine learning techniques. The core of the method is the off-line training of DL models to serve as accurate and computationally cheap control laws, which are then integrated into a closed-loop control scheme to predict the optimal control of the process online. The method is applied to two case studies for which direct application of mathematical E-MPC is difficult. The results are very promising in terms of prediction accuracy (NRMSE less than 1% in all cases) and online computational cost (saving at least 99.4% of computational effort in all cases). Future work will investigate extending the capabilities of the method to handle state constraints, unknown disturbances, and process-model mismatches.

Abstract

Monitoring and control of biological processes is still mainly limited to only a few physical and chemical properties that can be measured online with relatively low efforts. Important parameters and variables of a bioprocess are predominantly determined by offline sampling as they are difficult to accurately measure online. Therefore closed-loop control of those critical process variables poses great difficulties to the bioprocessing industry. To overcome this challenge state estimation techniques can be used. For their proper function they need observable process models, which are still not available for every bioprocess. In this work a first principle based soft-sensor is presented, which allows for real-time estimation of biomass and specific reaction rates for cell growth, substrate uptake, O₂ consumption and CO₂ formation in biotechnological production processes. The proposed algorithm utilizes elemental balancing of the carbon flux alongside the degree of reduction balance to incorporate gross error detection and data reconciliation between the two balances. The functionality of gross error detection and data reconciliation strongly rely on the errors of the used measurements. Most of the recent works employed elemental balancing for state estimation considering only constant measurement errors over time. The high dynamic range during fed-batch operation as well as the carbon evolution and oxygen uptake rates being calculated from several measurements necessitates a proper and dynamic error propagation procedure. We successfully applied an adaptive propagation of measurement uncertainties to substrate limited fed-batch cultivations of recombinant *Escherichia coli*. The novel soft-sensor algorithm led to a reduction of the biomass estimation error from formerly 10.8% to 5.3% NRMSE. Especially the consideration of additional uncertainty derived from supplemented pure oxygen increased data reconciliation effectiveness. In addition gross error detection is more sensitive to better indicate sensor faults or mismatches between carbon and degree of reduction balances. Elemental balancing including true measurement errors and error propagation is a valuable tool to estimate biomass and biomass specific reaction rates of microbial fed-batch processes. The basis on the law of mass conservation rather than on very specific process models makes it a generically applicable soft-sensor with reduced efforts for implementation and measurement needs that can also be used for real-time control purposes.

Keywords: bioprocessing, soft sensor, process analytical technology, elemental balancing, error propagation to measurement uncertainties

1. Introduction

The Process Analytical Technology (PAT) initiative, which was introduced by the FDA in 2002, should ensure the quality of bioprocesses not only for the end product but also throughout the whole pharmaceutical manufacturing process. It facilitates modeling approaches as well as new sensor technologies to monitor and control critical process parameters (CPPs) and critical quality attributes (CQAs) during the process [Hausmann et al. (2017)]. Model-based methods are gaining importance as they are able to increase process understanding and automation as well as guide the decision making [Narayanan et al. (2020)]. A software sensor or short soft sensor is the combination of one or several hardware sensors and a software model to derive new estimated variables from those measurements that are hard or impossible to measure directly or measured at too low frequency [Luttmann et al. (2012), Hausmann et al. (2017)]. Soft sensors can be used to effectively monitor and control fermentation processes, estimate important variables that are hard to measure and deal with the complex and strong nonlinear nature of a bioprocess [Zhu et al. (2020)]. Recent works presented material balance based soft-sensor algorithms for growth rate and biomass estimation [Wechselberger et al. (2013), Sagmeister et al. (2013)]. In simulation studies it was already shown that propagation of uncertainties from the measurements to the conversion rates is advantageous compared to an arbitrarily chosen static error assumption [Steinwandter et al. (2017)]. In this contribution we incorporated a first order uncertainty propagation procedure into an elemental balancing soft sensor and compared reaction rate and biomass estimation accuracies to the static error consideration based on real experimental data of a typical fed-batch bioprocess.

2. Methods

Fermentations with a recombinant *Escherichia coli* BL21 (DE3) were carried out in 3.3 L Labfors 5 bioreactors (Infors, Bottmingen, Switzerland). A minimal medium according to DeLisa et al. (1999) was used. The process design was composed of a batch phase with 10 g L^{-1} glucose as the main carbon source, an uninduced fed batch phase with a predefined exponential glucose feed profile to keep the specific growth rate q_X at a constant level and a production phase with constant feed rate, induction with 1 mM isopropyl β -d-1-thiogalactopyranoside (IPTG) and lowering of the temperature from $37 \text{ }^\circ\text{C}$ to $30 \text{ }^\circ\text{C}$. The pH was controlled with ammonia and H_3PO_4 to 7.0. For offline biomass quantification the dry cell weight (DCW) and the optical density at 600 nm (OD_{600}) were determined. Glucose concentration was measured with the Cedex Bio HT and the Glucose Bio HT photometric assay using hexokinase. Real-Time process control was realized through the Lucullus Process Information Management System PIMS (Securecell, Urdorf, Switzerland) together with MATLAB[®]. The soft sensor algorithm shown in chap. 3 was implemented in a Simulink[®] model connected to the Real-Time environment. MATLAB[®] was also used for data preprocessing for the soft sensor inputs and to compute important process variables. The substrate feed rate F_R was calculated by numeric integration of the feed weight signal combined with a Savitzky-Golay-Filter approach [Savitzky and Golay (1964)]. The Jacobian matrix was also computed in MATLAB[®] using the Symbolic Math Toolbox.

3. Soft sensor

3.1. Calculation of C-molar reaction rates from prime variables

The measured rate vector r_m , which is composed of the rates for substrate uptake r_S , O_2 uptake r_{O_2} and CO_2 evolution r_{CO_2} , can be calculated according to the formulas below under the assumption that the reaction rate is equal to the transfer rate measured. The formulas contain the aeration rates for air $F_{n\text{AIR}}$ and oxygen $F_{n\text{O}_2}$, the substrate feed rate F_R and the measured offgas mole fractions of oxygen $x_{\text{O}_2\text{Gout}}$ and CO_2 $x_{\text{CO}_2\text{Gout}}$. These are called the prime variables which are the inputs to the soft sensor. $x_{\text{O}_2\text{Gin}}$ and $x_{\text{CO}_2\text{Gin}}$ are the mole fractions of oxygen and CO_2 respectively in the gas

intake, which can be calculated from gas flow balancing. Parameters are V_{nM} which is the molar gas volume at standard temperature and pressure, c_S , which is the substrate concentration of the feeding solution and M_S , which is the C-molar mass of the substrate used.

$$r_{CO_2} = \frac{F_{nAIR} + F_{nO_2}}{V_{nM}} \cdot (x_{CGout} - x_{CGin}) \quad (1)$$

$$r_{O_2} = \frac{F_{nAIR} + F_{nO_2}}{V_{nM}} \cdot (x_{OGout} - x_{OGin}) \quad (2)$$

$$r_S = -\frac{F_R \cdot c_S}{M_S} \quad (3)$$

3.2. Unknown rate calculation

Essentially the material balance system can be compactly described in matrix form according to eq. 4. E is the Elemental Composition Matrix where the rows represent the element contents (e.g. carbon, hydrogen, oxygen, nitrogen) and the columns represent the metabolic compounds in the process (e.g. biomass, substrate, metabolic products). r is the corresponding vector of reaction rates. For the further analysis E and r are divided into measured rates r_m with the corresponding subset E_m and non-measured unknown rates r_c with E_c .

$$Er = E_m r_m + E_c r_c = 0 \quad (4)$$

The addition of the generalized degree of reduction balance (DoR) described in Roels (1983) to the equation system leads to an overdetermined system. This enables besides the calculation of the unknown rates also a data reconciliation approach where the accuracy of the calculations can be increased in a least squares manner. For the use case of growth rate estimation in *Escherichia coli* fermentations eq. 5 was derived as a special form of eq. 4 including the C-molar carbon balance as well as the DoR balance yielding in an overdetermined system for growth rate estimation.

$$E \cdot r = \begin{bmatrix} 1 & 0 & 1 & 1 \\ 4 & -4 & 4.113 & 0 \end{bmatrix} \cdot \begin{bmatrix} r_S \\ r_{O_2} \\ r_X \\ r_{CO_2} \end{bmatrix} = 0 \quad (5)$$

Using the Moore-Penrose pseudoinverse of E_c , which can be calculated by $E_c^+ = (E_c^T E_c)^{-1} E_c^T$, the least-squares fit of the unknown reaction rate vector is given by:

$$r_c = E_c^+ E_m r_m \quad (6)$$

3.3. Data reconciliation

Before calculating the unknown rate vector r_c from r_m with eq. 7 a reconciliation procedure can be applied to check the data consistency and detect gross errors. Inserting eq. 7 into eq. 4 leads to eq. 8 with R being the redundancy matrix $R = E_m - E_c(E_c^T E_c)^{-1} E_c^T E_m$ and R_r the reduced redundancy matrix containing only the independent rows of R .

$$Rr_m = 0 \quad (7)$$

The optimal estimate for measured rates \hat{r}_m under rate uncertainty is then formulated with F being the error variance covariance matrix and P being the variance covariance matrix of the residuals

described by $P = R_r F R_r^T$. I is the identity matrix. The detailed derivation of eq. 8 is described in Stephanopoulos et al. (1998).

$$\hat{r}_m = (I - F R_r^T P^{-1} R_r) r_m \quad (8)$$

The test function h computed in eq. 9 provides information about the statistical significance of the result, where h represents the sum of weighted squares of the residual vector $\varepsilon = R_r r_m$. The h -value is computed before the actual data reconciliation and can be evaluated against the χ^2 distribution at the degrees of freedom of R to detect systematic errors in the data to a certain level of confidence as described in Wang and Stephanopoulos (1983).

$$h = \varepsilon^T P^{-1} \varepsilon \quad (9)$$

3.4. Dynamic propagation of uncertainties vs. static error assumption

The definition of the true error variance covariance matrix F reflecting the errors accurately is not trivial. Often, the matrix is assumed to be diagonal with static relative error assumptions meaning that the measurement errors are uncorrelated. However, in many cases the uncertainties are actually correlated to each other resulting in a non-diagonal covariance matrix. A more accurate description of F can be achieved by propagation of uncertainties from the prime variables, which are in this case the inputs substrate mass flow rate F_R , the aeration rates for air F_{nAIR} and oxygen F_{nO2} and the offgas measurements x_{OGout} and x_{CGout} . After computing the Jacobian matrix J of the vector valued function, which describes the mapping from prime variables to the measured rate vector r_m , the first order propagation of uncertainty can be evaluated as shown in Madron et al. (1977):

$$F = J F_{in} J^T \quad (10)$$

with F_{in} being a diagonal error covariance matrix of the input prime variables mentioned above. The uncertainties of the prime variables were derived from the specification data of the equipment used, in particular the balances with an error of 0.1 g, the mass flow controllers with an error of $0.9 \text{ L h}^{-1} + 0.005x$ and offgas analysers with errors for O_2 of $0.1\% + 0.03x$ and CO_2 of $0.025\% + 0.03x$. x denotes the measurement value. In general, Jacobian calculation strongly depends on model correctness and is sensitive to model uncertainties. Here, the model structure is solely based on first principles with the parameters V_{nM} and M_S being well defined and the only source of parameter uncertainty is the substrate concentration of the feed c_S (chap. 3.1). c_S should be accurately measured before fermentation to ensure proper Jacobian calculation.

4. Results & Discussion

Both soft sensor approaches, that were described in chapter 3.4, have been compared on the data of a typical fed batch fermentation with batch phase, uninduced exponential feed and constant feed rate after induction with IPTG at 1.0 d. Fig. 1 shows the reconciled rate estimates for static errors (left) and dynamic error propagation (right). It can be observed, that the growth rate r_X is shifting to negative values utilizing error propagation especially in the late production phase after induction, although the noise level is considerably larger than under static error consideration. In fig. 2 the process results are shown including the biomass measurements and estimates obtained by integration of the growth rate r_X for both approaches. While the biomass estimates in the early growth phase do not differ significantly from each other, they start to deviate later in the production phase where the static error assumption leads to a major discrepancy of estimation and measured biomass with a NRMSE of 10.8% with respect to the DCW as the reference data. However, calculating the biomass under dynamic error propagation leads to more accurate estimates especially in the late production phase and a decrease of NRMSE to 5.3% corresponding to an increase of

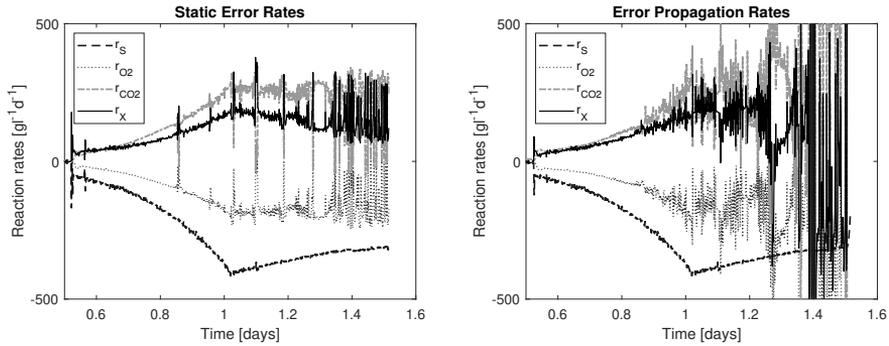

Figure 1: Reconciled rates are shown for both approaches from the start of the fed-batch phase.

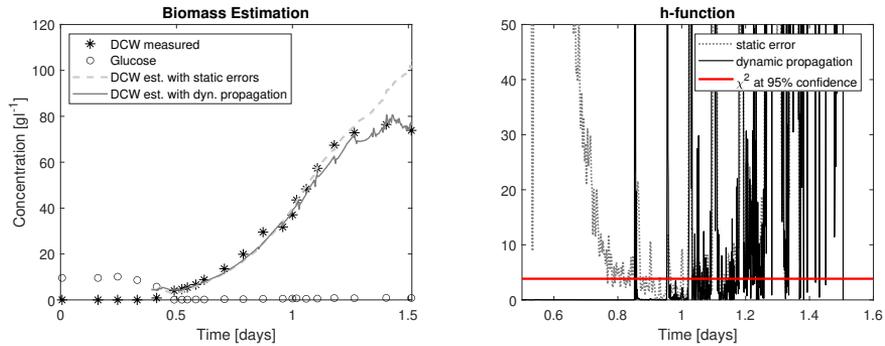

Figure 2: The left plot shows the measured concentrations of DCW and glucose as well as the biomass estimates with static error assumption (NRMSE = 10.8%) and dynamic error propagation (NRMSE = 5.3%). Biomass estimates are obtained by numerical integration of r_x . The right plot shows the value of the h-function for both approaches and the critical χ^2 distribution of 3.84 at a 95% confidence level for a degree of freedom of 1.

Table 1: The error variance covariance matrices F [mol d^{-1}] are shown for both approaches at a process time of 1.5 d.

Static Errors	Dynamic Error Propagation
$F = \begin{bmatrix} 0.485 & 0 & 0 \\ 0 & 0.301 & 0 \\ 0 & 0 & 0.273 \end{bmatrix}$	$F = \begin{bmatrix} 2.6 \times 10^{-5} & 0 & 0 \\ 0 & 3.686 & -3.623 \\ 0 & -3.623 & 3.728 \end{bmatrix}$

accuracy over 50%, which is similar to the improvements observed in Steinwandter et al. (2017). Fig. 2 also shows the h-function test described in chap. 3.3. Before induction the high static error h-values above the critical χ^2 indicate inconsistencies in between the balances. By incorporating dynamic error propagation the h-value is well below the critical χ^2 indicating a consistent closing of the balances. This is probably because the variance covariance matrix F reflects the true errors much better. A snapshot of both F matrices at the end of the process after 1.5 d is shown in tab. 4. Obviously, assuming static errors, F is just a diagonal matrix with scaled versions of the values itself, whereas covariances are present with error propagation. Here, the variance of r_s is very low

($2.6 \times 10^{-5} \text{ mold}^{-1}$) compared to r_{O_2} and r_{CO_2} , such that r_{O_2} and r_{CO_2} are much more influenced by the data reconciliation than r_S .

5. Conclusion & Outlook

The goal of this contribution was to investigate, whether the dynamic propagation of measurement errors has a positive impact on the accuracy of data reconciliation in a microbial fed-batch process. We propose the usage of dynamic error propagation from prime variables in order to estimate the reaction rates. The effectiveness of the data reconciliation procedure is increased as the error variance covariance matrix reflects the true variances more accurately leading to better estimates of the rates and biomass concentration. The prerequisite for that is, that the uncertainties of the prime variables are known, which could be derived from the sensor and equipment specification data. However, the soft sensor presented here has some limitations, that should be addressed. One major limitation is the assumption of steady state substrate concentration, meaning that the whole substrate feed is assumed to be taken up by the cells instantaneously neglecting potential substrate accumulation. This steady state assumption holds well enough, when the specific substrate uptake rate q_S is significantly below the maximum substrate uptake capacity q_{Smax} and the cell growth is substrate limited. In the case of substrate excess, where cells take up substrate near at q_{Smax} , the C-balance does not close properly anymore and the rate estimates become inaccurate. Therefore, the soft sensor is not applicable to the batch phase, to high feed pulses or whenever overfeeding occurs. Furthermore, the soft-sensor is not considering cell death leading to overestimation of cell mass especially in late production phase. Despite those limitations, we believe that elemental balancing is a solid foundation for soft sensors in bioprocessing. The generic first principle nature of elemental balancing improves transferability and generalizability of the algorithms. Limitations as mentioned above should be tackled by targeted and reasonable extensions of the elemental balance system with reaction kinetics and model based state estimation techniques.

Abstract

This study presents a novel application of multivariate iterative learning control (ILC) to the continuous, chromatographic ion-exchange purification of biopharmaceuticals for consistent and reliable production. The ILC algorithm used was based on a linearized model of the retention times of two compounds as functions of the starting and ending values of a linear salt gradient. Simulations of an ion-exchange purification process were used to identify the non-linear model behavior and thus suggest an appropriate linearization of the model for use in the ILC. Two control configurations were compared: one using direct inversion of the resulting linear model, and another using a least-squares, quadratic-criterion objective function for optimal control in conjunction with the model. The result was an ILC configuration based on a simple model with parameters that only required 3 experiments to compute, that was capable of controlling the retention times of two compounds simultaneously. This leads to more reliable and flexible operation of continuous and integrated biopharmaceutical purification in the future, and serves as a foundation for further development of other ILC-based control strategies within biopharmaceutical purification.

Keywords: preparative chromatography, ion-exchange, simulation, iterative learning control, model-based control

1. Introduction

Production of biopharmaceuticals has traditionally been performed in batch mode. However, as societal pressures for cheaper pharmaceuticals increase along with the need for faster development of new pharmaceuticals, research within the field has shifted towards development of flexible, integrated and continuous manufacturing processes that allow for consistent product quality (Zydney, 2015; Gronemeyer et al., 2014; Jungbauer, 2013). The purification, or downstream processing, of biopharmaceutical manufacture is of particular importance due to the high requirements for purity in the finished pharmaceutical, as well as the desire to recover as much of the desired product as possible. This has given rise to a need for monitoring and control during continuous downstream processing, so that a desired yield and purity of the biopharmaceutical can be maintained.

The core of many downstream processes for biopharmaceutical production is chromatography. While it is inherently a batch process, chromatography has been adapted for continuous and integrated processing in several ways, often operating in parallel with other chromatography columns in a cyclic fashion (Jungbauer, 2013). This cyclic batch-wise operation makes iterative learning control (ILC) a prime candidate for control of chromatography steps in continuous downstream

processes. Hailing from the field of robotics, ILC is a control technique that is used to improve the operation of processes that repeat over time based on the information gathered from previous process runs (Moore, 1993). It has been successfully applied to control the temperature trajectory of batch reactors (Lee and Lee, 2007), and more recently to single-input-single-output (SISO) control of the retention time of a protein in an ion-exchange (IEX) chromatography column (Holmqvist and Sellberg, 2016). In this latter study, an approach based on direct model inversion was used in which the retention time was modelled as a function of the time duration of the elution step, where the separation of the protein from other molecules takes place. Finally, another direct-inversion SISO ILC application has been done on the loading of columns in periodic counter-current (PCC) chromatography (Löfgren et al., 2020).

When separating a target protein from a known impurity by means of ion-exchange, it would be useful to control the retention times of both the target compound and the impurity. This increases the magnitude of the problem to a multiple-output system with increased complexity, which requires a careful choice of model to obtain the desired control. The purpose of this study was to use in-silico simulation of IEX chromatography to develop a control approach based on a linear model of the retention times of two proteins as a function of a set of process inputs. The result was a multiple-input-multiple-output (MIMO) ILC that made use of a quadratic-criterion objective function in conjunction with a linear map from beginning and ending values of a linear salt gradient, to the retention times of the two proteins. The choice of ILC is motivated by the repetitious nature of chromatographic purification steps, and by that ILC hinges on the process returning to its initial conditions between each control action (Longman, 2000), which in this study was achieved by the regeneration and equilibration steps following the elution. The efficacy of the ILC was demonstrated by running a simulated sequence of chromatography processes and letting the ILC correct for a simulated disturbance to the process inputs. To the authors' knowledge, application of MIMO ILC to chromatographic purification of biopharmaceuticals has not previously been presented.

In the following section, a brief background of the IEX chromatography process is provided along with the strategy for formulation of a linear process model by means of in-silico simulation. This section is followed by a description of the ILC algorithm and the least-squares, quadratic-criterion objective function used in conjunction with the model, along with the results of the simulated and controlled sequence of chromatography processes. Finally, some concluding remarks and suggestions for future studies will be made.

2. Simulations and model formulation

In liquid chromatography, substances in a liquid, mobile phase, are separated based on interactions with a solid, stationary phase. In ion-exchange chromatography, these interactions take place between ionically charged substances in the mobile phase and ligands on the stationary phase. Ion-exchange liquid chromatography with linear gradient elution is commonly performed in a five step process, as illustrated by Figure 1. In the first step, the load step, a certain volume of a mixture of a product and its impurities is loaded onto a chromatography column. The product binds to the stationary phase along with any other ionically charged impurities. Any substance that does not bind to the column is washed out in the wash step by a low salt concentration buffer solution, hereafter called buffer A. In the elution step, the column is loaded with a mixture of buffer A and buffer B, which is a solution with a high salt concentration. The percentage of buffer B in the mobile phase is increased linearly over the duration of the elution step, and as the concentration of salt in the column increases, the molecules bound to the column release and are eluted at different rates. The result is that the substances in the mixture have different retention times. Following the elution step, the column is regenerated by loading it with 100% buffer B and then equilibrated with 100% buffer A, to ensure that the column is restored to its initial conditions before the next sample is loaded and the process can be repeated.

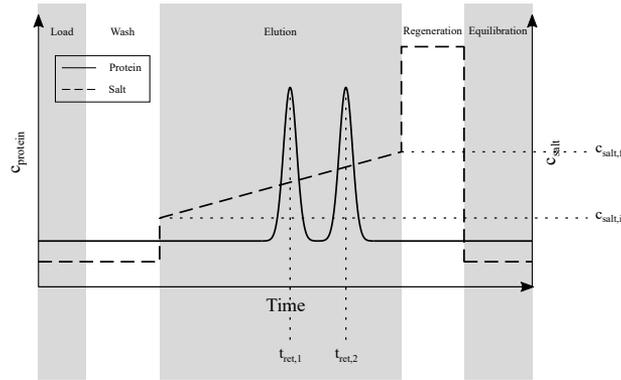

Figure 1: The ion-exchange purification process and its steps.

In an elution step with fixed time duration, the initial and final salt concentrations of the gradient are what determine the retention times of the substances. In a real chromatography process, the salt concentration during the elution step is controlled by two pumps, one each for buffer A and B, and the percentage of the flowrate that is driven by each pump. The initial and final percentages of buffer B, $x_{B,i}$ and $x_{B,f}$, are thus directly manipulable values by the process and were chosen as the control signals for this study. To control the retention times of the two compounds, $t_{ret,1}$ and $t_{ret,2}$, using model-based ILC, a model using $x_{B,i}$ and $x_{B,f}$ as inputs was needed.

To evaluate the relation between the retention times and $x_{B,i}$ and $x_{B,f}$, response surfaces were generated in-silico by modelling and simulating the mass transfer in a chromatography column. The mass transfer along the column in the z -direction can be described with a convection-dispersion model along with an adsorption term:

$$\frac{\partial c_i}{\partial t} = -\frac{F}{A\varepsilon} \frac{\partial c_i}{\partial z} + D_{app} \frac{\partial^2 c_i}{\partial z^2} - \frac{(1-\varepsilon_c)}{\varepsilon} \frac{\partial q_i}{\partial t} \quad (1)$$

where c_i is the concentration of component i in the mobile phase, F is the volumetric flowrate of the mobile phase, A is the cross-section area of the column and D_{app} is the apparent dispersion coefficient. ε and ε_c are the total porosity and column void fraction, respectively, and q_i is the concentration of component i in the stationary phase. The change in q_i can, in turn, be modelled by means of the Langmuir mobile phase modulator:

$$\frac{\partial q_i}{\partial t} = k_{kin,i} \left(B_i c_i c_s^{-\beta_i} \left(1 - \sum_{j=1}^N \frac{q_j}{q_{max,j}} \right) - q_i \right) \quad (2)$$

where β_i is a parameter that describes the ion-exchange characteristics, c_s is the salt concentration in the mobile phase, q_j is the concentration of compound j in the stationary phase and $q_{max,j}$ is its maximum possible concentration in the stationary phase. $k_{kin,i}$ and B_i are lumped parameters that describe the adsorption kinetics and equilibria. (Karlsson et al., 2004)

The response surfaces were generated by creating lists of $x_{B,i}$ and $x_{B,f}$ ranging from 0 to 100 and recalculating them to salt concentrations c_s . The above model was then simulated for each combination of initial and final salt concentrations. The simulations were carried out in Python by discretizing the space dimension (the length of the column) into 100 finite volumes, thus reformulating the partial-differential model into a system of ordinary differential equations (ODEs) using the finite-volume method. The second-order derivative in space, i.e., the dispersion term, was discretized using a 3-point central derivative approximation, while the first-order derivative in

space, i.e., the convection term, was discretized using a 2-step backwards derivative approximation (Shyy, 1994). The system of ODEs was then solved using the backward-differential formula (BDF) method in the Python SciPy library. The retention times were found by taking the solution at the column outlet and finding the maximum values of the peaks using the first and second order derivatives of the concentration data (Felinger, 1998).

As the response surfaces in Figure 2 show, the retention volumes for both peaks decreased as both $x_{B,i}$ and $x_{B,f}$ increased. In particular, the response surfaces showed that the model could be linearized in the zone $0 \leq x_{B,i} \leq 40$ and $20 \leq x_{B,f} \leq 100$ and yield marginal errors. Thus, the model was linearized around a set of inputs $\mathbf{x}_B^d = [x_{B,i}^d, x_{B,f}^d]^T$ that yielded a desired separation between peaks, by means of a finite-difference derivative Jacobian matrix:

$$\mathbf{G} = \frac{\partial \mathbf{F}(\mathbf{u})}{\partial \mathbf{u}} = \begin{bmatrix} \frac{t_{ret,1}(\mathbf{x}_B^{pert,1}) - t_{ret1}(\mathbf{x}_B^d)}{\varepsilon} & \frac{t_{ret,1}(\mathbf{x}_B^{pert,2}) - t_{ret1}(\mathbf{x}_B^d)}{\varepsilon} \\ \frac{t_{ret,2}(\mathbf{x}_B^{pert,1}) - t_{ret2}(\mathbf{x}_B^d)}{\varepsilon} & \frac{t_{ret,2}(\mathbf{x}_B^{pert,2}) - t_{ret2}(\mathbf{x}_B^d)}{\varepsilon} \end{bmatrix} \quad (3)$$

where \mathbf{F} denotes the non-linear model and \mathbf{G} denotes the linearized model as a 2×2 matrix. $\mathbf{x}_B^{pert,1}$ and $\mathbf{x}_B^{pert,2}$ each denote a set of inputs \mathbf{x}_B where either $x_{B,i}$ or $x_{B,f}$ are perturbed by a small value ε . Smaller values of ε result in a locally more accurate \mathbf{G} , but depending on the variations in slope of the function \mathbf{F} this may not be desirable. In this case, as seen in Figure 2, the slope is almost linear in all directions in the zone of interest and thus the choice of ε was assumed to be less important. For the controller as detailed in the next section, \mathbf{G} was computed around the point $x_{B,i} = 10$, $x_{B,f} = 30$ for $\varepsilon = 3$, which was deemed small enough since $x_{B,i}$ and $x_{B,f}$ range from 0 to 100. The retention times at this point were 19.7 and 25.8 minutes for the left and right peak, respectively, and were used as set points for the controller.

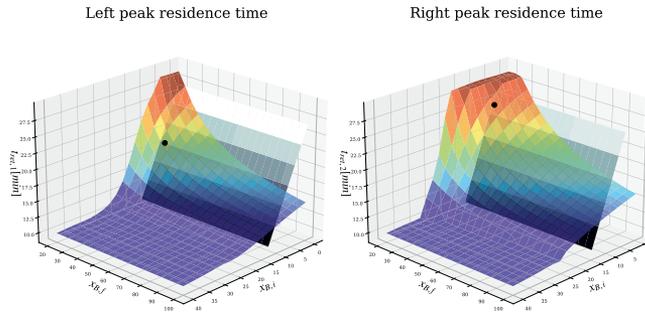

Figure 2: Response surfaces (jet) from the simulations of the chromatography process. The retention times of the first (left) and second (right) peak are plotted as functions of the initial ($x_{B,i}$) and final ($x_{B,f}$) proportions of buffer B in the linear gradient, along with the linearization (grey) around the point $x_{B,i} = 10$, $x_{B,f} = 30$ (black).

3. Control algorithm

In order to maintain a desired process output \mathbf{y}_d in a repeating process, the following ILC algorithm can be used (Lee and Lee, 2007; Holmqvist and Sellberg, 2016):

$$\mathbf{u}_{k+1} - \mathbf{u}_k = \mathbf{K} \mathbf{e}_k \quad (4)$$

where the control inputs \mathbf{u} on process cycle k are updated for the following cycle $k + 1$ based on the error $\mathbf{e}_k = \mathbf{y}_d - \mathbf{y}_k$, i.e., how the process output \mathbf{y} deviates from the desired output. \mathbf{K} , in turn,

is a learning filter that can be designed in different ways depending on the system to be controlled. In this study, the learning filter was designed using the model-based approach detailed by Lee and Lee (2007), in which the following quadratic-criterion objective function is used:

$$\min_{\mathbf{u}_{k+1}} \|\mathbf{e}_{k+1}\|_{\mathbf{Q}}^2 + \|\Delta\mathbf{u}_{k+1}\|_{\mathbf{R}}^2 \tag{5}$$

The objective function has a penalty term for changes in process input on cycle $k + 1$, and for process errors \mathbf{e}_k , weighted by the positive-definite matrices \mathbf{Q} and \mathbf{R} . The solution to the objective function becomes:

$$\mathbf{K} = [\mathbf{G}^T \mathbf{Q} \mathbf{G} + \mathbf{R}]^{-1} \mathbf{G}^T \mathbf{Q} \tag{6}$$

The benefit of using quadratic-criterion-based ILC, or Q-ILC, is that it becomes possible to apply damping to the control action by penalizing changes to the process input, which in turn allows for robust control of processes with less precise model estimations or with disturbances to the process dynamics and outputs. For the purposes of this study, \mathbf{Q} was selected to a 2x2 identity matrix \mathbf{I} , and \mathbf{R} to $r\mathbf{I}$, where r was a scalar value. With this selection of weighting matrices, the damping of the controller could be increased by increasing the value of r , while the special case $r = 0$ resulted in a direct inversion controller, $\mathbf{K} = \mathbf{G}^{-1}$. This latter choice would result in a complete elimination of the process error on the following cycle for perfect process models (Lee and Lee, 2007).

To test the proposed process control configuration, a sequence of 12 chromatography cycles were simulated. On cycle 3, a disturbance to the process inputs was introduced by increasing the salt concentration in buffer B by 10%. The sequence was run with both direct inversion ($r = 0$) and Q-ILC ($r = 0.5$). The results, displayed in Figure 3, show that the direct inversion approach failed to correct for the error on cycle 4, instead overshooting the set points. It failed to correct for the overshoot perfectly on cycle 5 as well and undershot them, only landing stably on the set points on cycle 6 and onwards. Even in an in-silico study with perfect repeatability, the direct inversion controller proved to be slightly unstable due to the imperfect process model, which caused this "bouncing" behavior.

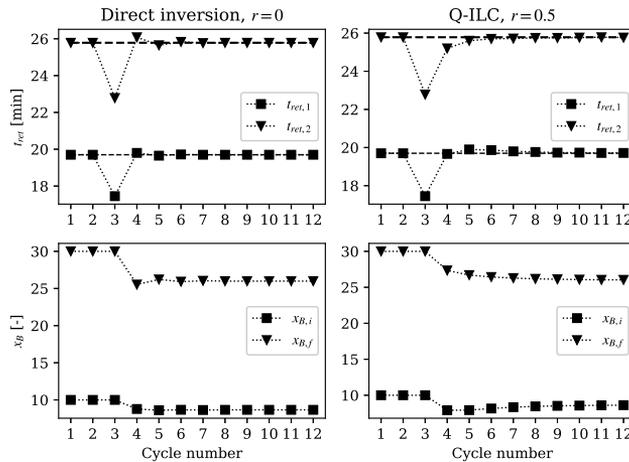

Figure 3: The 12-cycle controlled sequence. The direct inversion (left) sequence showed an overshoot when correcting for the disturbance on cycle 3, stemming from an imperfect process model estimation. The Q-ILC approach (right) displayed no overshoot of the first peak, but instead showed coupling behavior between the two peaks.

Q-ILC with $r = 0.5$, on the other hand, proved to avoid the overshoot of the first peak, but took 2 cycles to restore to the setpoint. Additionally, it overshoot the second peak on cycles 5 and 6. This is likely due to coupling between the two retention times, and could be remedied by some form of decoupling, i.e., by reparametrizing the control inputs into decoupled control inputs by means of a decoupling matrix, \mathbf{D} (Waller et al., 2003). If \mathbf{D} is chosen carefully, this would make it possible to adjust each peak individually without shifting the other. In a real case, Q-ILC would be useful due to variations in the process dynamic caused by ambient conditions or human error, or to compensate for stochasticity in the outputs caused by the UV detectors used to measure the presence of biopharmaceuticals and impurities at the outlet of the column. Thus, decoupling would also be crucial in a real case.

4. Concluding remarks

The successful application of multivariate, model-based ILC using a quadratic-criterion objective function to a simulated chromatographic separation contributes to the field of biopharmaceutical purification by providing a method of maintaining the desired separation when disturbances are applied to the process. Of particular note is the simple model estimation, which resulted in a functioning controller while requiring only 3 experiments to compute. For the purposes of this study, a single model estimation was performed with three simulated experiments. This single model estimation may be particularly suitable for repetitious chromatography steps in continuous downstream processes, where the goal is to improve the consistency of product quality and thus any disturbances to the system can be expected to happen slowly and in the long term. However, the model-based approach can be modified to fit any desired process and its dynamics, for example, non-linear dynamics or additional process inputs/outputs. Thus, the proposed control approach provides a solid starting point for control of other cyclically repeating process operations in biopharmaceutical purification. To further examine the efficacy of the Q-ILC, practical studies are required. Thus, the application of this controller to a real process is a natural next step.

Abstract

This work presents the application of modifier adaptation with quadratic approximation (MAWQA) to the production process of hydrophobically modified ethoxylated urethanes (HEUR) by reactive extrusion in a simulation study. A plant-model mismatch in the conveying rate in the twin-screw extruder model as well as a mismatch in the reaction kinetics are investigated. These uncertainties result from a limited availability of experiments for the chemical system and the extrusion system during the up-scaling to production size. It is shown that the application of MAWQA can drive the plant to the true economic optimum after about 25 set-points and satisfy the constraints for both cases even under the presence of noise in the inputs and measurements. These 25 set-point changes take about 2 hours which makes this method applicable for frequent product changes.

Keywords: RTO, MAWQA, Reactive Extrusion, Model-Based Control, Plant-Model Mismatch

1. Introduction

Hydrophobically modified ethoxylated urethanes (HEUR) are a group of polymers mainly used as rheology modifiers in paints and coatings as reported by Reuvers (1999). These rheology modifiers are conventionally produced in batches of several cubic meters and directly formulated with water within the same vessel. This production process takes multiple hours per batch. Within the SIMPLIFY project, the transition to a continuous production of these paint thickeners by reactive extrusion on a twin-screw extruder is investigated, which offer numerous advantages. This transition significantly reduces the time and costs associated with cleans and allows a fully electrified production using renewable energy sources. To operate the process at the economic and ecological optimum, an advanced process control strategy is required. Applying classical model-based control methods such as conventional real-time optimization would lead to suboptimal performance as the optimal set-point of the model does not coincide with the optimal point of the real process due to the plant-model mismatch. This plant-model mismatch is caused due to the limited availability of experiments to determine the chemical and rheological system. Especially relevant in the case of the production of HEUR is the high sensitivity to traces of moisture in the reaction system, decreasing the reproducibility of the experiments. Considering the model of the extrusion system, errors can occur during scale-up to a bigger extruder. To overcome this mismatch, we suggest the application of modifier adaptation with quadratic approximation (MAWQA) for the reactive extrusion process. This method extends the method of iterative optimization using plant and model gradients Gao and Engell (2005) and Marchetti et al. (2009) by a quadratic approximation of the cost and constraint functions (Gao et al. (2016)). This extension increases the robustness for noisy

process data and simplifies the estimation of real plant gradients in practice. An example for a successful implementation of MAWQA in an industrial environment was reported by Gottu Mukkula et al. (2020). This method is suitable for the reactive extrusion process as the main requirements are met: The process can be safely probed and exited, reaches steady state within five minutes and the cost and constraint function can be measured. For the production of paint-thickeners, the off-spec product produced during the probing phase can be blended in other products minimizing waste. In the following the model for the twin-screw extruder, the chemical system and the applied control method are presented. Afterwards the application of this method to the case of a plant-model mismatch in the reaction model and a mismatch in the extruder model are investigated.

2. Models and Method

2.1. Twin-Screw Extruder Model

The extruder model used in this work is based on a mechanistic twin-screw extruder model developed by Eitzlmayr et al. (2014). The approach has been extended by a singular perturbation approach for the pressure description by Cegla and Engell (2021) so that it can be used in efficient optimization algorithms. This model accounts for different flow patterns within the extruder caused by different screw geometries. It discretizes the extruder into finite volumes in which the polymerization reaction is occurring, in this case 29. The finite volumes are connected by internal flows caused by a pressure difference or by the rotation and geometry of the screw. The conveying capacity for a given screw element must either be determined experimentally or approximated from the knowledge of their geometry and therefore is prone to errors. With the progressing polymerization reaction in the extruder, the viscosity of the processed material increases, amplifying the energy dissipation and affecting the internal flows. Due to this strong coupling of the states, the model is highly non-linear. Furthermore, due to the high complexity of the switching of the model when a section is entirely filled, it is not possible to transform the model into a steady state model. Therefore, the steady state is computed by simulation of the model over a long time horizon. By the nature of the model, input multiplicities are not possible. The extruder assumed in this work is a Leistritz 18 mm ZSE MAXX extruder with a length to diameter ratio of 60. The screw concept is consisting of double flighted conveying elements with a pitch of 20mm and a cylindrical die with a diameter of 6 mm and a length of 40mm.

2.2. Kinetic Model

For the production polyurethane paint thickeners, initially a long chained polyethylene glycol (PEG) is reacted with an aliphatic diisocyanate (ISO). Further along the extruder, a short chained mono alcohol (A) is fed to stop the reaction and give the product the hydrophilic properties by end-capping of the formed urethanes. The reaction kinetics are approximated by a differential equation for the weight average molecular weight M_W similar to Verhoeven et al. (2004) and extended by an inhibition term by the reacted mono alcohol A_R . The parameter $M_{w,rep}$ is the molecular weight of a polymer repetition unit and is used to describe the stoichiometry of the end-capping. The maximum achievable molecular weight for a given ratio between ISO and PEG is given by $M_{w,max}$ and can be calculated from the reaction stoichiometry. The parameter k_{inhib} quantifies the effect of reacted mono alcohol on the molecular weight. Transurethanisation is not observed in this temperature range. The reaction system is described by:

$$\frac{dM_w}{dt} = k_0 \cdot \exp\left(\frac{-E_A}{RT}\right) \cdot \left| \frac{M_{w,max} - M_w - [A_R] \cdot k_{inhib}}{M_{w,max} - [A_R] \cdot k_{inhib}} \right| \quad (1)$$

$$\frac{d[A]}{dt} = -\frac{d[A_R]}{dt} = [A] \cdot \left(\frac{2M_{w,rep}}{M_w} - [A_R] \right) \cdot k_{0,alc} \cdot \exp\left(\frac{-E_{A,alc}}{RT}\right) \quad (2)$$

The melt behaves quasi-Newtonian. The temperature influence of the viscosity is described by an Arrhenius approach, the influence of the molecular weight is described by a power law. The exponent 3.4 is chosen as exponent as reported in literature being applicable for linear polymers such as polyurethanes (Verhoeven et al. (2004)). Summarizing, the viscosity is described by:

$$\eta(T, M_w) = \eta_0 \cdot M_w^{3.4} \cdot \exp\left(\frac{-E_A}{RT}\right) \quad (3)$$

2.3. Modifier Adaptation with Quadratic Approximation

The basis for the MAWQA method is the extension of the steady state optimization problem by contributions for the differences of the plant and model gradients multiplied by the change in the input u for the objective function and the constraint function as proposed by Gao and Engell (2005) and Marchetti et al. (2009). F_m denotes the plant model, J the cost function, G the constraint function, y the model output, the indices m and p denote the model and plant respectively:

$$\min_u J_m^{ad,k}(\hat{y}, u) \quad (4)$$

$$s.t. \hat{y} = F_m(u) \quad (5)$$

$$G_m^{ad,k}(\hat{y}, u) \leq 0. \quad (6)$$

The adapted cost function for the model J_m^{ad} at the k -th time point is therefore:

$$J_m^{ad,k} = J_m(\hat{y}, u) + (\nabla J_p(y_p^k, u^k) - \nabla J_m(\hat{y}^k, u^k))^T (u - u^k) \quad (7)$$

and adapted constraint function for the model G_m^{ad} :

$$G_m^{ad,k} = G_m(\hat{y}, u) + G_p(y_p^k, u^k) - G_m(\hat{y}^k, u^k) + (\nabla G_p(y_p^k, u^k) - \nabla G_m(\hat{y}^k, u^k))^T (u - u^k). \quad (8)$$

To robustly determine the plant gradients and to improve the optimization, Gao et al. (2016) proposed the approximation of the plant cost and constraint functions J_m and G_m with the set of inputs \mathbf{u} by quadratic functions with the set of parameters P :

$$\min_P \sum_{i=1}^n (J_p(u^i) - J_Q(u^i, P))^2 \quad J_Q(u, P) = \sum_{i=1}^{n_u} \sum_{j=1}^{n_u} a_{ij} u_i u_j + \sum_{i=1}^{n_u} b_i u_i + c. \quad (9)$$

This two quadratic function can then be analytically derived with respect to the inputs to calculate the plant cost gradient ∇J_p and plant constraint gradient ∇G_p for equation (7) and (8). The prediction quality is described by ρ_m^k for the adjusted optimization problem (4) and by ρ_Q^k of the quadratic approximation for both the cost and constraint function for a single constraint:

$$\rho_m^k = \max \left\{ \left| 1 - \frac{J_m^k - J_M^{k-1}}{J_p^k - J_p^{k-1}} \right|, \left| 1 - \frac{G_m^k - G_m^{k-1}}{G_p^k - G_p^{k-1}} \right| \right\} \quad \rho_Q^k = \max \left\{ \left| 1 - \frac{J_Q^k - J_Q^{k-1}}{J_p^k - J_p^{k-1}} \right|, \left| 1 - \frac{G_Q^k - G_Q^{k-1}}{G_p^k - G_p^{k-1}} \right| \right\} \quad (10)$$

For the case that $\rho_Q^k < \rho_m^k$, the quadratic model is used to calculate the next input:

$$\min_u J_Q(u, P) \quad (11)$$

$$s.t. G_Q(u, P) \leq 0 \quad (12)$$

$$(u - u^k)' \cdot \text{cov}(\mathbf{u}^k) \cdot (u - u^k) \leq \gamma^2 \quad (13)$$

Equation (13) constrains the inputs to the validity range of the quadratic approximation to prevent extrapolation and can be tuned by the distance parameter γ . For the case that the new input is an exploration step and not improving the cost function, u^k will not be updated.

3. Results

3.1. Initialization of the method

The method is initialized with 12 set-points which are distributed using Latin hyper cube sampling and 3 set-points for the computation of the finite differences to get a good coverage of the search space and to have $\frac{(n_u+1)(n_u+2)}{2}$ sample points as required for the quadratic approximation. The nominal plant optimum is at a throughput of 20 kg/h, a rotation speed of 200 RPM and a barrel temperature of 132 °C with a total specific energy demand of 163.36 kJ/kg. Gaussian noise with a standard deviation of 0.25 kg/h is added to the throughput and with a standard deviation of 1.5 kg/mol on the measurement of the product molecular weight. The rotational speed and the individual barrel temperatures are assumed noise free as these are precisely controlled by feedback control. The throughput is bounded between 5 and 20 kg/h, the rotation speed between 200 and 600 RPM, and the barrel temperature between 120 and 160 °C. A combined economic and ecological cost function is used aiming at the minimization of the energy input required to produce a given quantity of product. The contributions to the energy inputs are the mechanical energy input that is provided by the motor, the heat input provided by the heating blocks and the required cooling energy provided by the cooling system of the block. The process constraint is a minimum molecular weight of the product of 55 kg/mol to fulfil the desired rheological properties of the HEUR. The validity range of the quadratic model is constrained with $\gamma = 1$ and the model is trained on the 12 inputs closest to the last-set point.

3.2. Mismatch in the extruder model

In this section, an mismatch in the extruder model is assumed additional to the noise described in the last subsection. The conveying capacity of all extruder elements is assumed to be 20% higher in the model than in the plant. A higher conveying capacity causes a shorter residence time as less material is present in the screw section and it is transported faster out of the extruder. This causes the model optimum to be very conservative in the satisfaction of the molecular weight constraint.

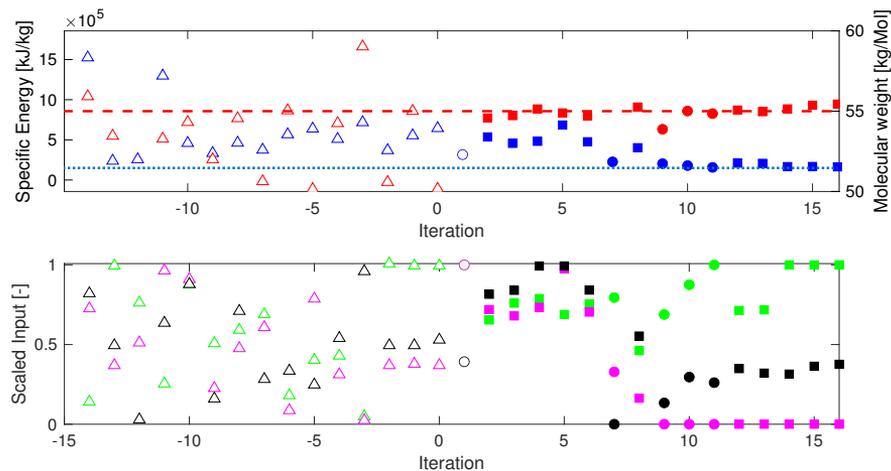

Figure 1: Results for the application of the method with an plant-model mismatch in the conveying capacity of the screw. \triangle denotes the initial probing steps, \circ denotes improvement steps and \square indicates exploration steps. The inputs are scaled within the bounds of the optimization problem. Filled symbols mark steps computed from the quadratic approximation, empty symbols mark steps based on the extended model. Red indicates the molecular weight, blue the specific energy consumption, green the throughput, magenta the rotation speed and black the barrel temperature.

The results of the application of the MAWQA method are shown in Figure 1. After the initial probing, the method uses the gradients determined by finite differences in the extended optimization problem to determine the first improving set-point. Both rotation speed and throughput are set to the upper limit while the barrel temperature is set close to the optimum. Although the cost function is improved, due to the high noise in the measurement the prediction of the finite differences for the constraint function, the resulting set-point does not satisfy the constraints. Therefore from the next iteration on, the quadratic approximation is used for optimization and significantly reduces the constraint violation. Between iterations five and ten, the method is driving the plant to its true optimum by decreasing the rotation speed from the upper limit to the lower limit. These big changes can be explained by the low sensitivity of the molecular weight and the specific energy use to the rotation speed. This low sensitivity can be explained physically as with the screw design used here, most of the residence for the reaction is generated by the back-pressure zone of the die and not in the upstream screw elements. Furthermore in a 18mm extruder, the dominant introduction of energy is via the electrical heating, especially for polymers with a high melt flow index like the investigated HEUR. At iteration 10 the true plant optimum is reached with satisfaction of the constraints. As the presented method depends on the random initial probing, the method was repeated 10 times showing similar or better performance.

3.3. Mismatch in the kinetic model

In this section, the method is applied for the case of a plant-model mismatch in the reaction kinetics. The same noise as in the first case is present. The pre-exponential factor k_0 for the polymerization reaction is assumed to be 10% lower in the model. With this mismatch, the result of a conventional steady state optimization would be very conservative as more residence time would be provided and a more viscous product would be produced, increasing the specific energy consumption. The results obtained using MAWQA for this case are shown in Figure 2.

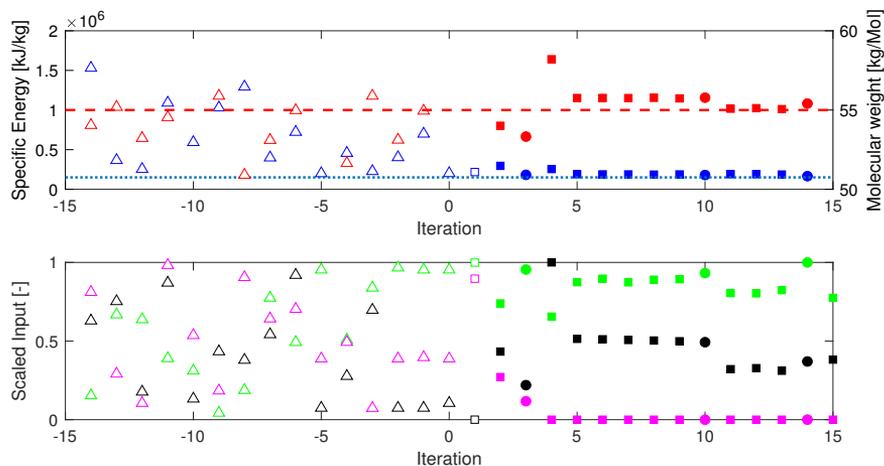

Figure 2: Results for the application of the method with an uncertainty in the reaction kinetics. Δ denotes the initial probing steps, \circ denotes improvement steps and \square indicates exploration steps. The inputs are scaled within the bounds of the optimization problem. Filled symbols mark steps computed from the quadratic approximation, empty symbols are based on the extended model. Red indicates the molecular weight, blue the specific energy consumption, green the throughput, magenta the rotation speed and black the barrel temperature.

After probing, the first evaluation is performed by solving the extended optimization problem with the gradients computed by finite differences. Similar to the other presented case, the resulting set-point results in a low specific energy use, but a very low molecular weight caused by moving the temperature to the lower bound. As in the first case, after the first iteration the model quality of the quadratic approximation was at every point superior to the extended model. In the following steps the rotation speed is decreased and the barrel temperature increased. Worth mentioning here is the fact that after the fifth iteration the constraints are fulfilled at a cost function value close to the optimum, the next improvement is the 10th iteration. Therefore, it might be worthwhile to base the evaluation process of a solution not only on the cost function but also on the constraint violation. This change would influence the range of validity of the quadratic approximation in equation (13).

4. Conclusion

In this work, the benefits of the application of MAWQA to the production of HEUR in reactive extrusion are shown. For both investigated cases of a mismatch in the structure of the model as well as a mismatch in the reaction kinetic the controller drives the plant to the true optimum after a maximum of 10 iterations. These 10 iterations and the 15 initial probed set-points in total correspond to a total duration of about two hours operation time. This makes this method suitable for a flexible production with frequent product changes. In the situation of few product changes but a discontinuous production, which is the case for a day shift production, this method can be initialized with the quadratic models of past shifts with a similar product. Using this information, the required iterations can be reduced to a minimum and no further time consuming initialization is required in the regular operation. Furthermore on a long term, the information of the quadratic models can be used to detect and to quantify effects such as wear in the production process. In our future work, we will experimentally apply the method proposed here to the real reactive extrusion system. Furthermore, different approaches for the selection of the points for the quadratic approximation and the use of more optimization variables will be investigated.

Abstract

Independently of the implemented heat exchange technology for industrial applications, it is necessary to apply an optimization routine to obtain the best heat exchanger design according to an objective function. This work presents a design and optimization environment for heat exchangers where the total annual cost is used as an objective function. Eight metaheuristic algorithms are employed to carry out the optimization procedure independently: Cuckoo Search, Differential Evolution, Grey Wolf Optimizer, Jaya Algorithm, Particle Swarm Optimization, Univariate Marginal Optimization Algorithm, and Whale Optimization Algorithm. Three different types of heat exchangers are contemplated: shell-and-tube heat exchanger, plate fin heat exchanger and plate heat exchanger. The performance of each optimization algorithm is assessed for each kind of exchanger.

Keywords: heat exchanger optimization, optimization environment, metaheuristic optimization.

1. Introduction

Heat exchanger devices are applied to exchange thermal energy between two or more fluid streams or to supply heating and cooling services in industry. Different technologies are available, some examples of heat exchangers configurations include double pipe, shell-and-tube, finned-tube, plate-fin, plate or spiral plate (Thulukkanam, 2013). The heat exchanger technology is selected according to different criteria, such as, operational conditions, available space, physical properties of the fluids, among others.

Three types of heat exchangers are considered: shell-and-tube heat exchanger (STHE), plate-fin heat exchanger (PFHE), and plate heat exchanger (PHE). STHEs are the most versatile, being able to operate at high temperatures and pressures. Also, they have a good heat transfer area-to-volume ratio. PFHEs are categorized as compact heat exchangers because of their high heat transfer area-to-volume ratio. They are conformed by a series of flat plates and layers of corrugated fins and its main use is in gas-to-gas systems. PHE are flexible devices; its heat transfer area can be modified by adding or removing plates. Regardless of the heat exchanger technology, it is necessary to produce an optimal design according to an objective function. Some common optimization objectives are the minimization of the heat transfer area, total annual cost, the entropy generation, or the maximization of the effectiveness. The optimization process is not a trivial task. All design methods available, independently of the heat exchange technology, contain non-

linear, non-continuous and non-differentiable equations which results in complex optimization problems (Onishi et al., 2013). The resulting optimization problems depends on continue and discrete variables that increase the complexity. There is plenty of different gradient-based optimization algorithms. Gradient-based algorithms tend to fast converge, but most of times converge in a local optimum in non-convex optimization problems. On the other hand, metaheuristic algorithms employ two search mechanisms known as exploration and exploitation, increasing the probability to converge in the global optima (Yang, 2014).

Metaheuristic optimization algorithms are employed to produce the best heat exchanger design. The user can choose between eight optimizer options; these are Cuckoo Search (CS) (Yang and Suash Deb, 2009), Differential Evolution (DE) (Storn and Price, 1997), Grey Wolf Optimizer (GWO) (Mirjalili et al., 2014), Jaya Algorithm (JA) (Venkata Rao, 2016), Particle Swarm Optimization (PSO) (Kennedy and Eberhart, 1995), Univariate Marginal Optimization Algorithm (UMDA) (Larrañaga and Lozano, 2001), and Whale Optimization Algorithm (WOA) (Mirjalili and Lewis, 2016). The design and optimization environment is designed in a modular way, all the codification was done in Python. The total annual cost (TAC) is used as objective function. Specific constraints are employed for each type of heat exchanger.

2. Heat exchanger design and optimization environment

This section explains how the design and optimization environment works, which is designed in a modular way. Different modules that perform specific task interacts with each other to obtain the best heat exchanger design. Once the optimization procedure is finished, the most relevant variables are shown. Six modules are involved, these are: the *Main* module, the *Optimizers* module, the *OptProblem* module, the *DesignMethods* module and the *Costing* module. Figure 1 shows how the modules are interlinked.

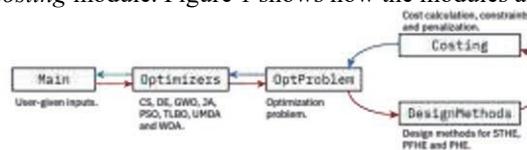

Figure 1. Modular configuration of the design and optimization environment.

2.1. Main module

The *Main* module is the only one the user can directly interact with. The user provides the different parameters for the design and cost calculation of the heat exchanger, and for optimization procedure. The required parameters regarding the design of the heat exchanger are the type of heat exchanger (STHE, PFHE or PHE), the inlet and outlet temperatures of the cold and hot fluids, the physical properties of the fluids. For the cost calculation it is necessary to introduce the interest rate, the number of operating hours per year, the electricity cost per 1 kWh, the value of the Chemical Engineering Plant Cost Index (CEPCI), and the value of the factors for the construction and operating conditions. Regarding to the metaheuristic optimization routine, it is necessary to select the optimization algorithm to be used, indicate the upper and lower bounds for each decision variable, specify the number of iterations and individuals (solutions) produced per iteration, and the number of experiments (only if the user requires to obtain statistical information such as the standard deviation, median, mean, and minimum value). Once all this information is given, the design and optimization procedure can be carried out.

All the information that the user provides is distributed to the other modules. The *Main* module directly interacts with the *Optimizers* module, which receives all the information regarding the optimization procedure.

2.2. Optimizers module

After the user introduce all the necessary information and runs the environment, the *Main* module calls the *Optimizers* module. The *Optimizers* module contains the codes of the eight metaheuristic optimization algorithms that can be employed to optimize the selected type of heat exchanger. The included metaheuristic algorithms are CS, DE, GWO, JA, PSO, TLBO, UMDA and WOA. The value of parameters used by Lara-Montaño et al. (2021) were employed in this work.

This module generates all solutions according to the chosen optimization algorithm. It takes as inputs the parameters involved in the optimization procedure and is linked with the *OptProblem* module which in turn is linked to the *DesignMethods* and *Costing* modules. The outputs of the *Optimizers* module is the best solution i.e. the best heat exchanger design and its total annual cost (value of the objective function).

2.3. Modules that define the optimization problem

The module *Optimizers* contains the optimization problem that depend on the selected heat exchanger. This module takes as inputs the decision variables on which each optimization problem depends. The value for the objective function for each design is the output. The module is divided in two parts. In the first part a heat exchanger design is calculated from the decision variables provided by the *Optimizers* module, this occurs in the *DesignMethods* module. The second part consist of obtaining the value of the evaluation of the objective function for each heat exchanger design produced.

The *DesignMethods* module contains the equations, variables and parameters involved in the design methods of STHEs, PFHEs and PHEs. The Bell-Delaware method is implemented to design STHEs, the details of this design methodology can be found in Shah and Sekulic (2003). The procedure to design PFHEs is taken from Mishra et al. (2009) and Rao and Patel (2010). Finally, the methodology to design PHEs is obtained from Kakaç et al. (2002).

The *Costing* module receives information from the *DesignMethods* module and calculates the operating cost (C_{op}) given by the cost of pumping, and the fixed cost (C_f) that mainly depends on the value of the heat transfer area. Then, the total annual cost, which is employed as objective function, is calculated by the addition of the (C_{op}) and (C_f). The (C_{op}) is computed according to Towler and Sinnott (2012). The (C_f) for STHEs and PHEs is calculated according to Smith (2005), whereas for PFHE it is computed as shown in Towler and Sinnott (2012). Also, the *Costing* module implements the constraints for each optimization problem and applies a penalization if any constraint is not satisfied. The value of the total annual cost is sent back to the *Optimizers* module that produce potentially new heat exchanger designs in each iteration. Once the optimization procedure finishes, the results are printed and exported. The results are the relevant variables and parameters of the heat exchanger design, the operation cost, fixed cost, total annual cost, the statistical results, and the best value of the objective function found.

3. Case studies and optimization problems

Two case studies are considered. The first case study, for STHE and PHE, involves methanol with a flow rate of 27.8 kg/s and inlet and outlet temperatures of 95°C and 40°C, respectively. The other fluid is sea water with a flow rate of 68.9 kg/s and inlet and outlet temperatures of 25°C and 40°C, respectively. In the second case study, for PFHE, both

fluids are air. The hot fluid has an input and output temperature of 240°C and 171°C, respectively and a flow rate of 0.8962 kg/s.

The cold fluid has an input and output temperature of 4°C and 79.5°C, respectively and a flow rate of 0.8296 kg/s. A project lifetime of 20 years, an interest rate of 5%, 8,000 operating hours per year, an electricity cost of 0.1 kWh and a CEPCI equal to 686.7 (Jenkins, 2021) are used.

Eleven decision variables are involved in the design of a STHE, seven in the PFHE and eight in the PHE. Upper and lower boundaries for continuous decision variables are shown in Table 1. The allowed values for discrete variables are shown in Table 2.

For STHE the pressure drop in shell side, ΔP_s and tube side, ΔP_t must be lower or equal to 70,000 Pa. The fluid velocity in tubes must be found between 1 m/s and 3 m/s (Caputo et al., 2008). And the ratio between the inner diameter of the shell and the length of tubes (D_s/L) must be lower or equal to 15. For PFHE the maximum allowed pressure drop in hot side, ΔP_h , and cold side, ΔP_c , are 300 Pa and 2,000 Pa, respectively (Rao and Patel, 2010). For PHE the maximum allowed pressure drop is 70,000 Pa in both sides.

The three optimization problems were solved using all the optimization algorithms. In Lara-Montaño et al. (2021) it is determined through a sensitivity analysis that 50 individuals are required, these are values for the number of individuals and iterations used. To obtain statistical information 30 experiments were run per optimization problem and optimization algorithm.

Table 1. Bounds for continuous design variables.

Heat exchanger	Design variable		Lower bound	Upper bound
STHE	Diameter of shell	D_s	300 mm	1,000 mm
	Baffle spacing at center	L_{bc}	$0.2D_s$	$0.55D_s$
	Baffle spacing at the inlet and outlet	L_{bo}, L_{bi}	L_{bc}	$1.6L_{bc}$
	Tube-to-baffle diametrical clearance	δ_{tb}	$0.01d_o$	$0.1d_o$
	Diametrical clearance of shell-to-baffle	δ_{sb}	$0.01D_s$	$0.1D_s$
	Outer diameter of tube bundle	D_{otl}	$0.8(D_s - \delta_{sb})$	$0.95(D_s - \delta_{sb})$
PFHE	Heat exchanger length in cold size	L_{cold}	0.1 m	1 m
	Heat exchanger length in hot size	L_{hot}	0.1 m	1 m
	Height of fin	H	2 mm	20 mm
	Fin thickness	F_t	0.1 mm	2 mm
	Lance length of the fin	l	1 mm	10 mm
PHE	Horizontal distance between ports	L_h	0.3 m	0.7 m
	Vertical distance between ports	L_p	1.1 m	2 m
	Port diameter	D_p	0.1 m	0.4 m
	Plate thickness	P_t	0.001 m	0.0003 m
	Plate pitch	P	0.0015 m	0.005 m
	Enlargement factor	E_f	1.15 m	1.25 m

Table 2. Allowed values for discrete variables

Heat exchanger	Design variable		Allowed values
STHE	Outer and inner tube diameter	d_o, d_i	Taken from Flynn et al. (2019)
	Tube pitch	P_t	[1.25 d_o , 1.5 d_o]
	Tube layout angle	TL	[30°, 45°, 90°]
	Baffle cut	B_c	[25%, 30%, 40%, 45%]
	Number of tube passes	s	[1, 2, 4]
PFHE	Fin frequency	n	[200, 201, ..., 1,000]
	Number of fin layers in hot side	N_h	[2, 3, ..., 40]
PHE	Chevron angle	D	[30°, 45°, 50°, 60°, 65°]
	Number of plates	N_p	[2, 3, ..., 700]

4. Results

Table 3 shows the statistical results after 30 experiments for each optimization problem and optimization algorithm. DE and GWO have the best performance in the design optimization of a STHE. These optimization algorithms produce the smaller SD, they can obtain the best design at least in one experiment, and according to the median in most of the experiment converge about the best design. WOA, PSO and UMDA present the worse performance according to the produced SD. PSO do not has a good performance, but it was able to find the STHE design with the minimum cost in at least one experiment.

Table 3. Statistical results

Heat exchanger	Statistical variable	CS	DE	GWO	JA	PSO	TLBO	UMDA	WOA
STHE	Mean (USD/year)	12,899.59	12,862.28	12,873.76	13,365.17	13,142.55	13,266.87	13,237.23	13,890.98
	Median (USD/year)	12,892.48	12,860.52	12,862.92	13,178.23	12,931.32	13,174.19	13,120.50	13,294.01
	SD (USD/year)	27.81	6.44	13.15	311.91	534.86	271.60	448.81	1,067.88
	Minimum (USD/year)	12,866.71	12,860.34	12,860.64	12,871.41	12,860.31	12,951.26	12,865.27	12,892.19
	Mean (USD/year)	2,266.49	2,221.56	2,227.36	2,290.75	2,232.46	2,231.20	2,276.12	2,249.30
PHE	Median (USD/year)	2,271.82	2,222.59	2,226.54	2,289.67	2,304.05	2,227.85	2,299.17	2,402.80
	SD (USD/year)	36.41	2.12	3.57	50.74	119.98	5.24	66.44	243.65
	Minimum (USD/year)	2,225.11	2,221.19	2,221.19	2,231.03	2,221.19	2,221.19	2,237.31	2,221.19
	Mean (USD/year)	3,969.98	3,969.97	3,969.97	3,969.97	3,995.01	3,969.97	3,997.30	3,969.97
	Median (USD/year)	3,973.55	3,969.97	3,969.97	3,975.38	4,080.23	3,969.97	4,012.79	3,969.97
PFHE	SD (USD/year)	7.76	0.00	0.00	9.51	447.08	0.00	35.96	0.00
	Minimum (USD/year)	3,969.97	3,969.97	3,969.97	3,969.97	3,969.97	3,969.97	3,976.86	3,969.97

Regarding to the optimization problem where the best design for a PHE must be obtained, PSO and WOA have the worst performance, but both algorithms are able to converge in the best solution in at least one experiment. DE, GWO and TLBO have the best performance, these algorithms produce the smaller SD, and their median is close to the minimum value for TAC found.

Even though PSO and UMDA have the worst performance to find the best design of a PFHE, due their large SD, they can obtain the best design in at least one experiment. That is, in at least one experiment these algorithms converge in the neighborhood of the best solution. In this optimization problem all the algorithms can obtain the best design, and most of them have a produce a median close to the minimum value found for the TAC.

The more complex optimization problem is the one that involves the design of a STHE. This optimization problem produces relatively large SD while using multiple optimization algorithms. The best overall optimization algorithms are DE and GWO. The values found of the decision variables for the best designs of the heat exchangers are presented in Table 4.

5. Conclusion

The presented design and optimization environment for heat exchangers can find the best design, using the TAC as objective function, for STHE, PFHE, and PHE. Currently, it is limited to heat exchangers with no phase change. Although multiple metaheuristic optimization algorithms are implemented, DE has the overall best performance independently of the heat exchanger that requires to be optimized. Thus, according to the results, DE is the most recommended optimization method for the non-linear mixed-integer models representing the heat exchangers. The environment also supports the

execution and statistical analysis of multiple experiments as a tool of analysis for the obtained results.

Abstract

The decarbonization of industrial utility systems is an important step to reduce greenhouse gas emissions. Decarbonization can be enabled by sector coupling, which can also enhance system flexibility of low-carbon utility systems. However, exploiting sector coupling efficiently for the design of low-carbon utility systems is complex and, therefore, best addressed by mathematical optimization. Recently, the open-source framework SecMOD was introduced for the linear optimization of multi-energy models with adjustable spatial and temporal resolution. SecMOD considers environmental impacts by fully integrating life cycle assessment. In this work, we optimize a sector-coupled utility system supplying electricity, heating, and cooling. For this purpose, we extend SecMOD to allow mixed-integer decisions. Further, we investigate the benefits of a pumped thermal energy storage system consisting of a high-temperature heat pump, heat storage, and an organic Rankine cycle. We identify trade-offs in system design by comparing a least-cost design to a design with minimal greenhouse gas emissions. Combining heat pumps and heat storage is economically and environmentally viable and leads to synergies between sectors. However, the reconversion of stored heat to electricity cannot compete with alternatives, such as battery storage.

Keywords: utility systems; decarbonization; MILP; pumped thermal energy storage; sector-coupling

1. Introduction: Low-carbon industrial utility systems

Industry significantly contributes to overall economic value added but is also subject to high greenhouse gas emissions, leading to an increase in climate change. Hence, beyond the traditional search for cost reductions, improvements now also aim increasingly at low-carbon energy supply (Ringkjøb et al. 2018). Integrating low-carbon electricity from renewable sources is vital to reduce greenhouse gas emissions. While renewable energy is increasingly integrated in the electricity sector, its contribution to supply heat has stagnated. Sector-coupling may help to bridge this gap and lead to synergy effects between sectors (Guelpa et al. 2019).

Pumped thermal energy storage (PTES) systems can strengthen sector-coupling by addressing volatility in electricity supply to flexibly provide electricity and heat (Dumont

et al. 2020): During high feed-in of renewable energy converters, PTES systems convert electricity into heat and store heat that can not be used immediately. The stored heat can then either fulfill a heat demand or be re-converted to electricity at a later time. In this way, PTES systems can contribute to a secure and low-carbon energy supply.

The need to consider volatile electricity supply of renewables, sectoral interaction, and environmental aspects leads to highly complex systems. To cope with this complexity, effective energy systems are usually designed based on mathematical modeling and optimization. Hence, the above-mentioned challenges need to be addressed when designing optimization methods and software frameworks. Although many models have been developed for the transition to low-carbon energy systems, reusability is limited when these models are not openly available (Pfenninger et al. 2018). Generalized and modular open-source software frameworks ensure reusability and, hence, contribute to accelerating transparent research. For this purpose, the object-oriented framework SecMOD was recently introduced that considers energy conversion, transport, and storage (Reinert et al. 2022).

In this work, we apply SecMOD to a case study of an industrial utility system providing electricity, heating, and cooling. First, we introduce the general formulation of SecMOD and discuss how we integrate life cycle indicators as an objective function. To model the utility system as a mixed-integer linear program (MILP), we modify SecMOD to account for integer decisions, such as the modelling of part-load behaviour. We then identify trade-offs between the least-cost design and the design with the lowest overall greenhouse gas emissions. Two energy supply scenarios are considered: with and without grid supply. In these scenarios, we examine to what extent sector-coupling by a PTES system can contribute to the optimal design of the utility system.

2. Method: Utility system optimization considering life cycle indicators

In this Section, we present the general problem statement of SecMOD (Reinert et al. 2022). We then discuss the integration of life cycle assessment (LCA) into the energy system optimization and further specify how SecMOD is implemented.

Generally, the problem statement of SecMOD is as follows: Given

- a potentially spatially and temporally resolved exogenous energy demand,
- a set of components to convert and store energy,
- and additional constraints (such as emission limits),

find the energy system that minimizes the objective function (e.g., total annualized cost or overall annual global warming impact) and cover the energy demands in each time step. As decision variables, we consider the capacity expansion of energy converters and storage components and respective component operation.

In this work, we extend the framework formulation to a mixed-integer linear program (MILP). The MILP optimization considers discrete component expansion and integer decisions, e.g., to model part-load behavior. We optimize and evaluate the system using the LCA methodology, standardized in ISO 14040:2006 and ISO 14044:2006. LCA quantifies the impacts of a component or system on the environment over the whole life cycle. In contrast to classical optimization of utility systems, we extend all component models by life cycle inventories (LCIs). Here, we employ the LCI database ecoinvent 3.5 (Wernet et al. 2016). Each LCI quantifies the material and energy flows needed to build and operate the component. We model the direct inputs and outputs of component operation using piecewise-affine functions to reflect part-load efficiencies.

For the optimization, the impacts of the infrastructure and operation are calculated by multiplying the LCIs with the respective environmental impact of each energy or mass

flow. The environmental impacts are determined using the Environmental Footprint 2.0 methodology recommended by the European Commission (Joint Research Center 2010). Due to space limitations, this work only reports on the impact category “climate change”, quantifying the global warming impact (GWI). The optimization problem is implemented in Python using Pyomo (Bynum et al. 2021; Hart et al. 2011) and is solved using Gurobi (Gurobi Optimization 2021), employing the branch-and-cut algorithm. The time-series aggregation module by Hoffmann et al. (2020) is integrated to decrease the number of time steps for time-dependent variables. The SecMOD code and documentation are publicly accessible (Reinert et al. 2022).

3. Case Study: Integrating pumped thermal energy storage in a utility system

The utility system assessed in this study (Figure 1) was first published by Voll et al. (2013) and extended by Baumgärtner et al. (2019). The system satisfies temporally resolved demands for electricity, heating, and cooling. Import is possible for grid electricity and natural gas, each associated with specific costs and environmental impacts. Overproduction of electricity may occur at no costs or revenues to account for curtailment. However, overproduction of heat or cooling is not allowed.

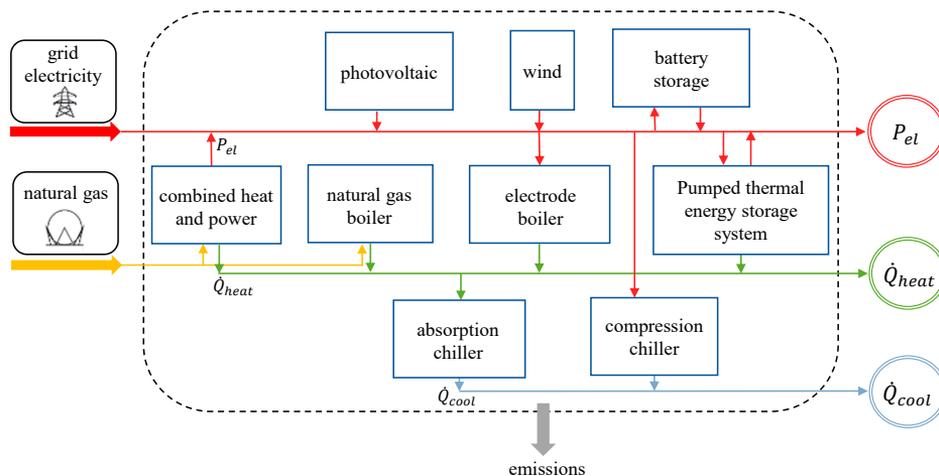

Figure 1- Simplified structure of the utility system providing electricity, heating, and cooling supply (extending on Voll et al. (2013)). For chillers, boilers, and the combined heat and power engine, multiple units can be employed, accounting for scaling effects.

The utility system consists of the components shown in Figure 1. Combined heat and power engines (CHP) and the electricity grid provide electricity. We further add wind turbines, battery storage and photovoltaic systems, as modeled in Baumgärtner et al. (2021). Heat can be provided by the CHPs, an electrode boiler, or a natural gas boiler. Cooling power is provided by absorption chillers or compression chillers, respectively. In addition to the existing components, we further model a PTES system as an emerging technology. The PTES system consists of a heat pump (based on Baumgärtner et al. (2021)), sensible heat storage with water as storage medium (Baumgärtner et al. 2019), and an organic Rankine cycle (ORC) (based on Stoppato and Benato (2020), Tartièrre and Astolfi (2017), and Tillmanns et al. (2022)). The heat storage unit can supply heat directly or feed the ORC for the reconversion to electricity, thereby adding additional flexibility.

Scaling effects during sizing are taken into account by allowing small, medium, and large components for the chillers, boilers, and CHP. The components have different specific costs and part-load behavior. For all units, sizing can be chosen continuously between the minimum and maximum component size.

We consider one year of operation, aggregated to six typical days with hourly resolution. As clustering technique for temporal aggregation, we use k-medoids. We optimize the system for two scenarios: Firstly, we consider the system given above (current system) and optimize it by an economic and an environmental cost function. The economic cost function is the total annualized system cost. As environmental objective, we minimize the overall annual GWI. The annual GWI considers the whole life cycle of the system components. For this purpose, the impacts from construction are annualized over the unit life time without discounting. Secondly, we model the utility system as a stand-alone system where electricity cannot be imported from the grid to evaluate sector-coupling in volatile energy systems on a small scale.

4. Results: Economically and environmentally optimal energy supply structure

Figure 2 shows the annual supply of electricity, heating, and cooling for the current and stand-alone utility system for all scenarios. The optimality gap is less than one percent.

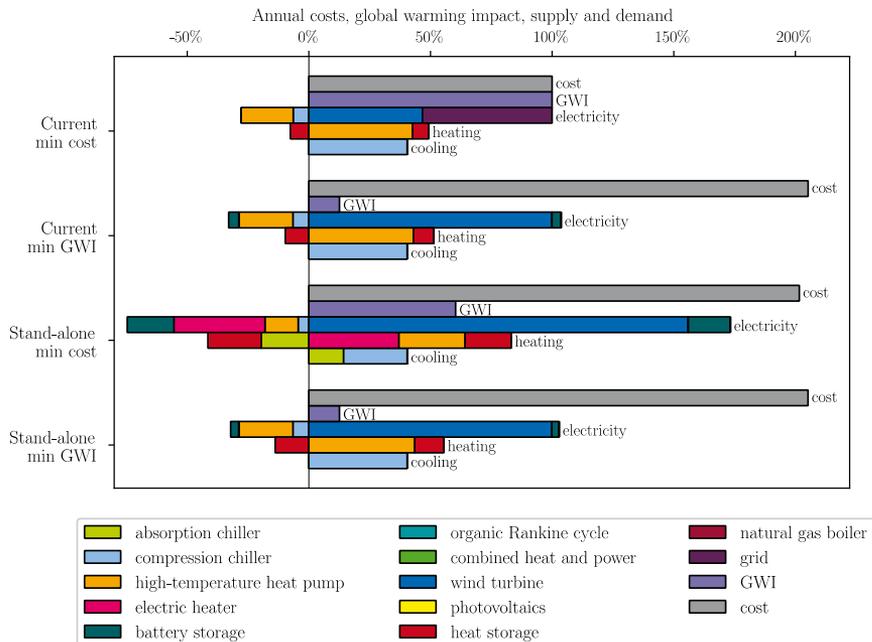

Figure 2 Annual electricity, heating, and cooling supply and endogenous demand in the current and stand-alone utility system for the cost-optimal and environmentally optimal cases. All energy flows are normalized by the electricity flow in the case “current min cost”. Further, the annualized cost and global warming impacts (GWI) are shown normalized by the case “current min cost”.

The current cost-optimal system provides electricity partly by the grid and partly by wind turbines. However, the minimal-GWI system fully relies on wind electricity. Except the current cost-optimal system, all systems store both electricity and heat to decouple supply

and demand. The PTES system as a whole is not used in any case: While some components of the PTES system - high-temperature heat pump and heat storage - are used in all systems to couple the electricity and heating sectors, the organic Rankine cycle is never used to provide electricity. Cooling is provided mainly by a compression chiller in all cases.

The environmentally optimized designs are similar in the current and stand-alone systems, as the supply of grid electricity is associated with relatively high environmental burdens and therefore not used even when available. A comparison of the stand-alone systems shows that the environmentally optimal system is near-optimal regarding cost, as the cost are less than 2 % higher than in the cost-optimal case. However, their resulting utility supply is rather different: While heat provision is slightly cheaper by combining a heat pump and an electric boiler, the environmentally optimal system employs a heat pump only. Similarly, the cost-minimal system operates the absorption chiller, whereas the environmental optimization uses the compression chiller only. In the stand-alone cost minimization, stored heat is used to provide cooling by the absorption chiller, as storing heat and using the heat directly for cooling is cost-efficient. Alternative routes that exploit the low costs of heat storage are inferior, for example, to provide cooling by combining the PTES system and the compression chiller. Overall, the studied PTES system is outperformed by other available flexibility options and therefore not employed as a whole to flexibly provide electricity.

5. Conclusions

In this work, we optimize an industrial utility system using the SecMOD framework. To account for part-load behavior in utility systems, we extend SecMOD to a MILP formulation. We show trade-offs between economically and environmentally optimal designs for a grid-integrated and a stand-alone utility system. While a significant trade-off is found between cost and GWI for the grid-integrated scenario, the trend is different in the stand-alone system: At comparably low cost, the environmentally optimal system has a five times lower GWI than the cost-optimal system.

The results further confirm that sector-coupling and energy storage are essential for industrial decarbonization. Especially in the stand-alone scenario, we observe high synergies between sectors. Regarding pumped thermal energy storage as a system of components to enhance flexibility, we find that some components (heat pump and heat storage) of PTES system are economically and environmentally viable in all cases. However, reconversion to electricity is neither economically nor environmentally competitive for the studied system.

We hope that our results can contribute to understand trade-offs in utility systems and hence help realizing environmental improvements that can be achieved cost-efficiently.

Abstract

The design and operation of distributed energy systems (DES) have often been modelled as linear optimisation problems. Although DES are increasingly connected to existing alternating current (AC) distribution networks, state-of-the-art DES modelling frameworks use oversimplified approximations which either exclude network constraints or overlook the inherent three-phase unbalance present in distribution networks. This can lead to poor designs which amplify network operational issues and result in greater costs to both the network and consumers/producers. This study presents a new modelling framework for DES design, which incorporates unbalanced optimal power flow within DES models for the first time. Furthermore, Robust Optimisation is included in this detailed modelling framework to ensure design feasibility under worst-case scenarios. Results show that previous frameworks tend to either overestimate or underestimate objectives when compared with the DES model combined with unbalanced power flow. Robust scenarios demonstrate that the new combined model is capable of closing the gap between objectives when compared with a linear DES-only model, albeit with different designs that do not violate grid constraints during baseline operation. These results suggest that this detailed framework can be utilised for DES design and network planning, as it produces more robust designs which can potentially help avert operational issues.

Keywords: Distributed Energy, Distribution Network, Unbalanced Power Flow, Robust Optimisation, Nonlinear Programming.

1. Introduction

With persisting efforts to integrate more renewable energy resources and improve network resilience, a global growth in community DES and microgrids has been predicted. Designing DES requires the consideration of many constraints, and these are best assessed using optimisation models. Mixed-Integer Linear Programming (MILP) models have been commonly used to design DES. However, with the increasing integration of DES into existing AC distribution networks, the linear DC power flow approximations used in these models do not accurately represent complex network constraints. Several studies have attempted to bridge this gap by incorporating AC optimal power flow (OPF) models for balanced networks with DES design, which are labelled DES-OPF models (De Mel et al., 2021; Mashayekh et al., 2017; Morvaj et al., 2016). Comparisons have shown that solutions from DES-only frameworks can be infeasible with respect to the network. Despite these efforts, all existing studies assume that the overall network is balanced, which is a characteristic of transmission networks. In reality, most DES are connected to unbalanced distribution networks, particularly in European radial distribution networks (Ma et al., 2020). The impacts of considering phase

unbalance in distribution networks and DES design simultaneously have not been investigated before, despite the potential implications on network longevity, integration of renewable resources, and costs to the prosumers. A few studies have incorporated network unbalance within DES operational models. However, the significant gap observed in DES design should also be addressed, as a robust DES design can help alleviate operational issues in advance. Furthermore, despite the growing number of studies on designing and operating DES under uncertainty using techniques such as Robust Optimisation (RO) and Stochastic Programming (Mavromatidis et al., 2018a), detailed DES-OPF models are notably absent from such frameworks. This could be due to the increased complexity of these models, both to formulate and solve. This study aims to bridge these gaps by advancing the modelling framework previously presented by the same authors (De Mel et al., 2021) to incorporate unbalanced power flows within DES design for the first time, and the uncertainty of key inputs using RO (Li et al., 2011). RO was chosen as it can assess worst-case scenarios without assuming probability distributions. Overall, the study contributes to more realistic DES design and operation by improving system feasibility and robustness.

2. Methodology

The bi-level model used in this study first determines the binary topology of the DES design using an MILP, followed by a nonlinear programming (NLP) model which re-optimises the design under unbalanced network constraints (De Mel et al., 2021). Such a strategy is used as it avoids the need to solve a large, nonconvex Mixed-Integer and Nonlinear Programming (MINLP) model, which is difficult to converge and computationally costly. The combined model is labelled DES-UPF. The overall objective, which minimises total annualised cost for a DES with houses $i \in \mathbf{I}$ operating in time $t \in \mathbf{T}$, is transformed to its robust counterpart (Z) to consider uncertainty in electricity and gas prices. A polyhedral uncertainty set (Bertsimas and Sim, 2004) has been chosen for its balanced conservativeness and linearity in the MILP, where an auxiliary variable v_0 and an adjustable sizing parameter Γ_0 are introduced to the reformulation:

$$\min Z$$

$$Z - \left(\left(\sum_{i \in \mathbf{I}, t \in \mathbf{T}} a \bar{P}_t^{\text{grid}} E_{i,t} \right) + \left(\sum_{i \in \mathbf{I}, t \in \mathbf{T}} b \bar{C}^{\text{gas}} H_{i,t} \right) + C^{\text{IN,OM}} - I \right) - v_0 \Gamma_0 \geq 0 \quad (1)$$

$$v_0 \geq a \hat{P}_t^{\text{grid}} E_{i,t} \quad \forall i \in \mathbf{I}, t \in \mathbf{T} \quad (2)$$

$$v_0 \geq b \hat{C}^{\text{gas}} H_{i,t} \quad \forall i \in \mathbf{I}, t \in \mathbf{T} \quad (3)$$

where a and b are scalars, \bar{P}_t^{grid} and \bar{C}^{gas} are nominal values of electricity and gas prices, \hat{P}_t^{grid} and \hat{C}^{gas} are their respective perturbations, $E_{i,t}$ and $H_{i,t}$ are variables for electricity and heat produced and/or bought, $C^{\text{IN,OM}}$ represents all other investment and operational costs, and I is the income generated. Uncertainty associated with demands and irradiance exist in the right-hand side coefficient of the associated constraints, and therefore can be represented by the following generalised counterpart:

$$x_{i,t} - \varepsilon \hat{c}_{i,t} \leq \bar{c}_{i,t} \quad \forall i \in \mathbf{I}, t \in \mathbf{T} \quad (4)$$

where $x_{i,t}$ is a variable, $\bar{c}_{i,t}$ is the nominal value of the uncertain parameter, $\hat{c}_{i,t}$ is the perturbation, and ε represents the parameter controlling the size of the uncertainty, which is $\varepsilon \in [0,1]$ for a polyhedral set with one uncertain parameter in the constraint. Note that the sizing parameters can be used to control the level of conservativeness in the decision, i.e., the higher the value taken by the sizing parameter, the more conservative the decision will be. As the upper bounds of the two sizing parameters, Γ_0 and ε , are different, Γ_0 is

fixed to its upper bound and multiplied by ε to ensure that the conservativeness is varied by the same amount across the constraints.

The NLP includes nonconvex constraints to calculate the active P_n^α and reactive Q_n^α power at each phase $\alpha = \{A, B, C\}$ and node $n \in \mathbf{N}$, connected to branch $(n, m) \in \mathbf{L}$:

$$P_{n,t}^\alpha = V_{n,t}^\alpha \sum_{m \in \mathbf{N}} \sum_{\varphi \in \{a,b,c\}} V_{m,t}^\varphi (g_{mn,t}^{\alpha\varphi} \cos(\theta_{n,t}^\alpha - \theta_{m,t}^\varphi) + b_{mn,t}^{\alpha\varphi} \sin(\theta_{n,t}^\alpha - \theta_{m,t}^\varphi)) \quad \forall n \in \mathbf{N}, t \in \mathbf{T} \quad (5)$$

$$Q_{n,t}^\alpha = V_{n,t}^\alpha \sum_{m \in \mathbf{N}} \sum_{\varphi \in \{a,b,c\}} V_{m,t}^\varphi (g_{mn,t}^{\alpha\varphi} \sin(\theta_{n,t}^\alpha - \theta_{m,t}^\varphi) - b_{mn,t}^{\alpha\varphi} \cos(\theta_{n,t}^\alpha - \theta_{m,t}^\varphi)) \quad \forall n \in \mathbf{N}, t \in \mathbf{T} \quad (6)$$

where $g_{mn}^{\alpha\varphi}$ and $b_{mn}^{\alpha\varphi}$ are conductance and susceptance derived from the real and imaginary parts of the complex phase admittance matrix Y , as shown below:

$$Y = \begin{bmatrix} Y_{11}^{ABC} & \dots & Y_{1n}^{ABC} \\ \vdots & \ddots & \vdots \\ Y_{n1}^{ABC} & \dots & Y_{nn}^{ABC} \end{bmatrix} \quad (7)$$

Each element of Y represents a 3×3 matrix, obtained using line parameters and the Approximate Line Model (Grigsby, 2018). The Y submatrices at the transformer primary and secondary connections have been obtained from Chen et al. (1991). The DES and UPF are linked at load (house) nodes, where active and reactive power injections occur at the respective phase, while injections at the other phases remain zero.

3. Case study

A modified version of the IEEE European Low Voltage Test Feeder (IEEE, 2020) has been considered as a realistic unbalanced three-phase test case. A reduced version of the 906-node test feeder is used to demonstrate the proposed framework, as presented in Figure 1, with 22 of the 55 loads and associated key network connections. A Wye-Wye transformer is considered at the slack node, i.e., the point at which the local network is connected to the wider grid. It is assumed that all the consumers in this network are opting to install distributed energy resources, which include solar PVs, lithium-ion batteries, and boilers. All loads are assumed to have a constant power factor of 0.95.

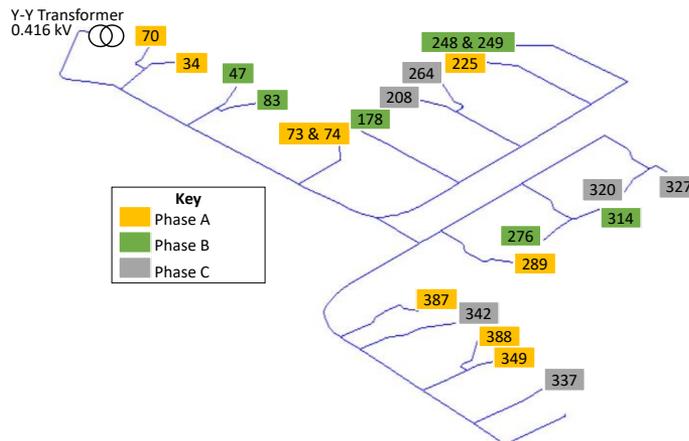

Figure 1. The subset of loads and branches from the IEEE European LV Test Feeder which are used in this study. Note the unequal number of loads connected to each phase.

Averaged demand and irradiance data for four representative seasonal days have been discretised into hourly timestamps. Other inputs include renewable energy generation and export tariffs, day and night electricity purchasing prices, available roof area (35 m²) for PV installation, available volume (0.5 m³) for battery installation, and technology performance parameters and capital costs. Solar irradiance, heat and electricity demand, and pricing are considered as the subset of uncertain inputs. These have been identified by Mavromatidis et al. (2018b) to have the most influence on model outputs, via Global Sensitivity Analysis. As the DES lifespan is considered to be 20 years, harsh daily and seasonal variations are likely to be dampened when averaged over several years. Therefore, overall uncertainty intervals of 20%, 10% and 25% have been assumed for demands, irradiance, and pricing, respectively.

4. Results and Discussion

The MILP and NLP models are solved on Pyomo (Hart et al., 2011) using CPLEX (IBM, 2019) and CONOPT (Drud, 1985), respectively. The overall deterministic NLP contains 386,404 continuous variables and 627,169 constraints, with 4,312 fixed binary variables determined by the MILP.

4.1. Deterministic scenario

Table 1 presents the results for the deterministic scenario, where four models are evaluated: 1) DES-only which represents the MILP, 2) DES-DPF containing the DC power flow approximation, 3) DES-OPF containing balanced AC OPF, and 4) DES-UPF with unbalanced optimal power flow.

Table 1. Comparison of deterministic results for four models.

Breakdown	DES only (MILP)	DES-DPF	DES-OPF	DES-UPF
Objective (£)	21,297	21,297	23,692	21,840
% Difference (Objective)	-	0	11	3
Grid electricity (£)	4,962	4,962	4,876	4,917
PV investment (£)	19,422	19,422	17,789	18,915
PV operation (£)	1,375	1,375	1,259	1,339
Boiler investment (£)	3,359	3,359	3,359	3,359
Boiler operation (£)	13,804	13,804	13,804	13,804
Battery investment (£)	64	64	148	95
Battery operation (£)	27	27	62	39
Export income (£)	6,368	6,368	3,548	5,681
Generation income (£)	15,348	15,348	14,058	14,947
<i>Time taken (s)</i>	<i>23</i>	<i>91</i>	<i>353</i>	<i>1,968</i>

Voltage violations are detected in both DES-OPF and DES-UPF as a consequence of higher power injections from the prosumer due to high generation. The DES-DPF fails to detect this due to the assumption that voltages always remain at nominal values. Significant differences in objective values and designs are observed in DES-OPF when compared with DES-UPF, suggesting that the former overestimates both cost and design for this type of network. This overestimation is a result of a higher number of violations detected in DES-OPF across the network, as all loads are assumed to be connected to a balanced network represented by a single phase. On the other hand, the unbalanced model is capable of distinguishing voltage violations at specific phases and remedying them, rather than reducing PV capacity across most of the network. While the DES-UPF

objective has a low percentage difference when compared with that of DES-only, more prominent design differences can be observed, especially with respect to battery investment as larger batteries reduce network violations. Note that the high computational time recorded in Table 1 for DES-UPF is mostly used for model building on Pyomo, while only approximately 20% of the total time is used by the solver.

4.2. Robust scenario

Figure 2 summarises the percentage differences observed between the DES-only (MILP) model and DES-UPF at different levels of conservativeness. As conservativeness increases, the objective values achieved become more similar, as seen in Figure 2a. Despite these small differences in total annualised costs, Figure 2b shows that differences in design remain prominent at each level. Further tests show that fixing the design as predicted by the MILP would result in greater costs when unbalanced network constraints are included, due to solar power curtailment resulting in loss of export income. The consistently higher battery capacities chosen by the DES-UPF once again help minimise costs while reducing network violations. It is evident that the differences in objectives between the MILP and fixed DES-UPF design reduce as the levels of conservativeness increase. This suggests that MILP designs, despite the lack of detailed network constraints, may be practically feasible with respect to the network if uncertainty is considered with high levels of conservativeness in these formulations, while being less computationally expensive.

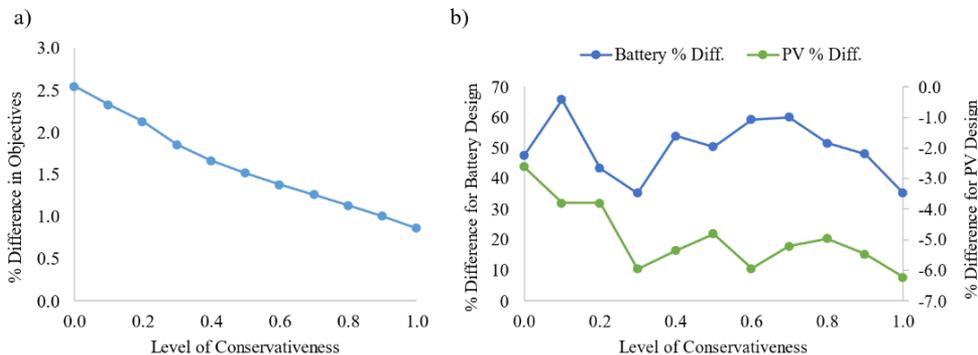

Figure 2. Percentage differences observed with respect to different levels of conservativeness (ϵ) in a) objective values, and b) installed battery and PV capacities.

5. Conclusion

The modelling framework proposed in this work incorporates more realistic power flow constraints associated with unbalanced distributed networks for the first time, to which DES have been increasingly connected. It also uses Robust Optimisation techniques to optimise under uncertainty, which has not been included in detailed and combined models before. The framework is tested using an unbalanced feeder and compared with state-of-the-art models, including DES combined with balanced AC power flow (DES-OPF). Results demonstrate that assuming the network is balanced can lead to oversized DES, much higher capital costs, and less income. They also confirm the unsuitability of DC approximations, as this model fails to detect any network violations. It is evident that the DES-UPF framework proposed in this paper achieves more robust designs at a slightly higher cost when compared to the globally optimal DES-only model. Results also suggest that DES-only and DES-UPF solutions could converge at higher levels of

conservativeness, emphasising the need to consider uncertainty in the design phase. The significantly higher computational expense of this model, compared with state-of-art DES-OPF, poses a major limitation to evaluating larger and more realistic test cases with higher nodes and branches. Therefore, decomposition techniques would be essential to improve the efficiency of this framework and further increase its utility. Other improvements include the addition of more transformer connections and network infrastructure to study potential mitigation strategies at the operational stage. Finally, the study emphasises the need for more investigations using high-fidelity models to obtain locally optimal but more robust DES designs while considering existing infrastructure and networks. This would give both network operators and prosumers greater confidence in implementing DES, and jointly address the need for more renewable energy resources.

Abstract

This paper proposes a novel optimization algorithm for constrained black-box problems, where the objective function and some constraints are computed by a simulation code. The basic idea of the optimization algorithm, referred to as SCR (Surrogate-CMAES-RQLIF), is to (i) build separate Kriging surrogates for the objective function and black-box constraints, (ii) use the global search algorithm CMAES to find the global optimum region of the surrogate, (iii) use the recent algorithm RQLIF to refine the search locally, (iv) use all the points sampled by RQLIF and additional points within the optimal region located by CMAES to update the surrogate model. Tests on 46 constrained and unconstrained test problems show that SCR outperforms the benchmark algorithms in terms of fraction of problems solved, specially at low function evaluations (< 300).

Keywords: process optimization, surrogate-based optimization, Black-box optimization, Global optimization.

1. Introduction

A vast range of process engineering and economic problems [1] can be tackled as black box optimization problems where the objective function and the constraints are computed by a simulation code (e.g., flow sheeting software, CFD code, etc). The simulation code works as a noisy and computationally expensive black-box function called by the optimization algorithm. In such optimization problems gradient information are not available so gradient-based algorithms are not suitable, and it is necessary to rely on derivative-free methods [2]. Moreover, simulations codes are computational expensive making it necessary to reduce the number of black-box function evaluations. Thus, an efficient derivative-free algorithm is required to optimize these simulation codes with a limited number of function evaluations, this can be done by creating a surrogate model of the simulation code.

The goal of this paper is to present a novel derivative-free, surrogate-based global optimization algorithm called SCR which is well suited for black-box problems with general nonlinear constraints. The problem that we consider is of the form

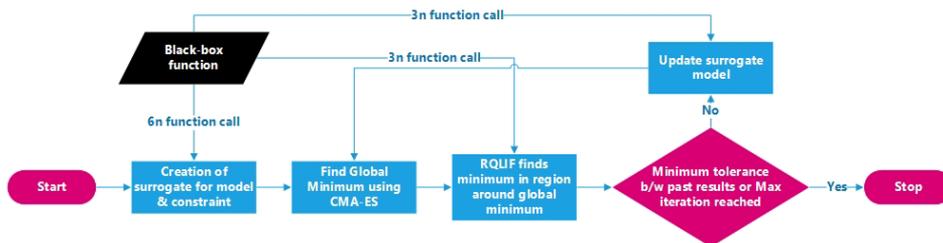

$$\begin{aligned} \min_{x \in \mathbb{R}^n} & f(x) \\ \text{s. t. : } & lb \leq x \leq ub \\ & h(x) = 0 \\ & g(x) \leq 0 \end{aligned}$$

where lb , ub are the bounds, g is the vector of inequality constraints, h is the vector of equality constraints and f is the objective function. One or all the functions may be nonlinear, nonconvex, computationally expensive, non-smooth and noisy black-box functions (e.g., computed by a process simulation code).

2. SCR algorithm

SCR (Surrogate-CMAES-RQLIF) is a surrogate based derivative-free optimization algorithm which is suitable for problems with expensive and possibly noisy black-box functions. The flowchart of SCR is provided in Figure 1 and summarized below in four steps.

- 0) Initially $6n$ (where n is the number of optimization variables) random points are generated using latin hypercube.
- 1) Separate Kriging surrogate models of the black box problem and its constraints are created using the Matlab based Kriging toolbox DACE [3].
- 2) The surrogates of the objective function and constraints are then used by the evolutionary algorithm CMAES [4] to find the global minimum of the constrained surrogate model. The constraints and objective surrogates are combined in CMAES using the quadratic penalty approach.
- 3) If the optimum found by CMAES is relatively close to the best solution found in the previous iterations (i.e., there is the need of performing a local search in that region), the local search algorithm RQLIF [5] is called with a limit of $3n$ black-box function evaluations. RQLIF is a hybrid implicit-filtering-model based (using a regularized quadratic model) algorithm specifically developed for expensive black-box functions and tested on a wide range of test and engineering problems.
- 4) At the end of the RQLIF run, the surrogate models are updated by adding the points tested by RQLIF along with $3n$ new points found using latin hypercube. The algorithm stops if RQLIF reaches the convergence tolerance on the search step length, or the maximum number of black-box evaluations is reached. If none of these stopping criteria is met, the algorithm begins a new iteration from Step 2.

3. Assessment of SCR performance on test functions

The Matlab implementation of SCR was tested in comparison with two well-known derivative free algorithms: NOMAD [6] and CMAES [4]. These algorithms were selected from many other alternatives (see [7] for a review) as they are widely used and very effective, as reported in literature [5] [8]. Furthermore, both these algorithms use different strategies, NOMAD samples points on an adaptive mesh grid using direct search methods

while CMAES uses an evolutionary optimization strategy with covariance matrix adaptation.

The tests were carried out on 25 unconstrained nonlinear test problems taken from [9] and 21 constrained nonlinear test problems taken from GLOBALlib and Floudas' Collection [10]. These test problems feature 2-13 real variables and up to 17 constraints. Each run of each algorithm was repeated ten times starting from initialization points was found using Latin Hyper Cube Method. The average results of the ten runs are used to plot the performance profiles reported in Figure 2. The performance parameter shows the fraction of problems solved within a certain tolerance “ τ ”, as defined by [11], with the maximum allowed budget of black-box function evaluations.

Figure 2 shows that SCR outperforms the benchmark algorithms in terms of fraction of problems solved for both constrained and unconstrained problems. The figure also shows that SCR performs quite well at low function evaluations (< 300) in terms of fraction of problems solved and solution quality.

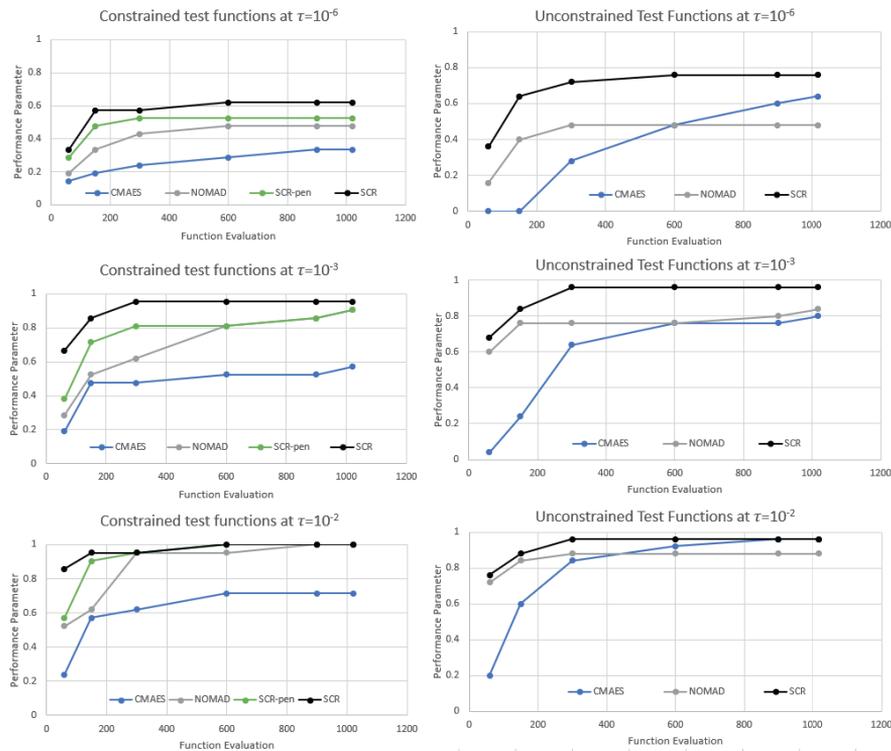

Figure 2: Comparison of SCR with benchmark algorithms

Figure 2 reports the performance of a modified version of SCR (called SCR-pen) which generates directly the surrogate of the penalized function (obj. function + penalty term proportional to the quadratic violation of constraints). Compared to directly generating the surrogate of the penalized objective function (SCR-pen), the strategy of SCR of generating separate surrogates for the black-box function and each of its constraints (g and h) leads to the following main advantages: (i) the surrogates are more accurate since the constraint functions do not have steep valleys/curvatures like those of the quadratic penalty term, (ii) the surrogate generation algorithm and the optimization algorithm do

not incur in ill-conditioning problems caused by the quadratic penalty term outside the feasible region.

4. Optimization of a CO₂ Purification Unit

SCR was applied to the techno-economic optimization of a CO₂ Purification unit (CPU) developed for the purification of CO₂ captured from a Cement Plant [12]. The CPU scheme is reported in Figure 3 and it is based on a patent by Air Products [13], in the version published by [14]. The CPU model was developed in Aspen Plus® and its convergence needs 10-20 seconds depending on the input conditions. The optimization problem is to minimize the total annual cost (sum of annualized capital cost and operating costs) subject to four main nonlinear inequality constraints: (i) the recovery of CO₂ should be greater than 95%, (ii) the purity of CO₂ should be greater than 98%, (iii) the oxygen in the outlet stream should be less than 75 ppm, and (iv) the mole fraction of nitrogen in the outlet stream should be less than 3%.

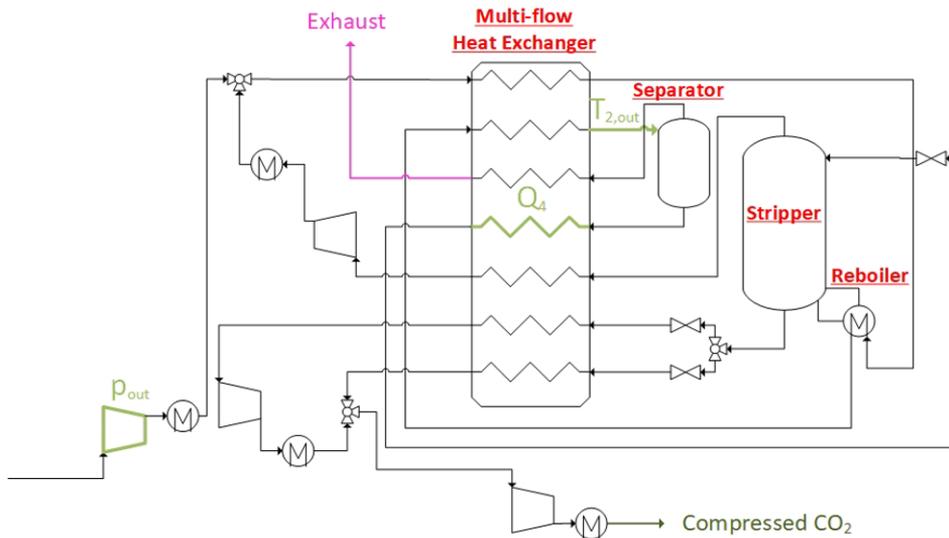

Figure 3: Scheme of CO₂ purification unit (CPU)

The process variables that are optimized (shown in green in Figure 3) are (1) p_{out} , the compressor outlet pressure, (2) Q_4 , the heat absorbed by the liquid stream coming from the separator and going to the stripper, and (3) $T_{2,out}$, the temperature of the inlet stream of the separator.

Figure 4 shows the convergence plot (objective function value of the best-found solution as a function of the number of simulation runs) of SCR and NOMAD. The figure indicates that SCR is able to find a good solution with only 50 simulation calls, and further improving it with the successive 150 calls. However, NOMAD was able to find a similar solution after 400 calls. The comparison of the yearly capital cost of each component and the total yearly operational cost of the CPU for the optimized case for SCR and NOMAD is provided in Table 1. The values of the main process parameters affected by the optimization process are shown in Table 1.

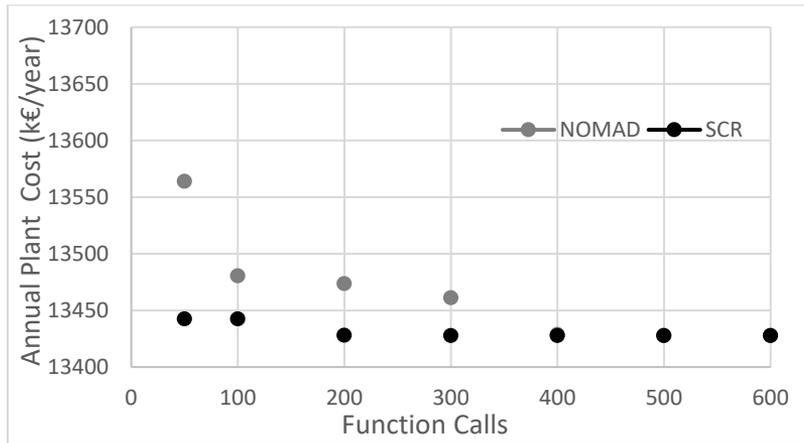

Figure 4: Comparison between SCR and NOMAD for the considered case study

Table 1: Main process parameters and the yearly cost of CPU components optimized with SCR and NOMAD

	SCR	NOMAD
p_{out} (bar)	38.3	37.7
$T_{2,out}$ ($^{\circ}C$)	-44.3	-44.6
Q_4 (kW)	564.8	562.3
CO ₂ Recovery (captured CO ₂ /inlet CO ₂)	95.00%	95.00%
Purity (mol. conc. of CO ₂ in captured stream)	99.99%	99.99%
Oxygen conc. in captured stream (ppm)	7.26	7.13
N ₂ +AR conc. in captured stream	2.95E-06	2.88E-06
Total Area of main HX (m ²)	892.6	948.2
Compressor power (kW)	11206.2	11171.2
Costs		
Annualized compressors cost (k€/year)	5678	5664
Annualized Intercoolers cost (k€/year)	305	305
Annualized Heat Exchanger cost (k€/year)	865	900
Other Equipment cost (k€/year)	126	125
Yearly Operational Cost (k€/year)	6453	6433
Total yearly cost	13428	13428

5. Conclusion

SCR is a surrogate based derivative free algorithm which is well suited for black-box optimization problems with expensive function evaluations. SCR creates surrogate model of the black-box problem and its constraints to accelerate convergence and handle the noise. Performance profiles of SCR compared with two well-known optimization algorithms (CMAES & NOMAD) indicate that SCR provides good quality solutions in limited number of functional evaluations on a large set of benchmarking test problems.

When applied to a real engineering black-box optimization problem, the optimization of a CO₂ purification process, SCR needs about half simulation runs (about 200) compared to NOMAD to find the same optimum solution.

Abstract

Due to the volatile nature of renewable energy sources, balancing electricity generation and consumption in electric power systems becomes more challenging with an increasing share of renewable generation technologies. A promising option to face fluctuations in the electricity grid is demand-side management (DSM), the adjustment of electricity consumption driven by varying electricity prices. To assess the environmental impacts of DSM, the holistic method of life cycle assessment can be applied. In literature, life cycle assessment of DSM receives increased attention. However, the goals of operating DSM are not consistently reflected in the definition of the functional unit. In our view, the goals of DSM include both the original products of a process as well as the flexible electricity consumption. So far, no approach exists that considers both goals in the functional unit.

This work aims to close this gap by developing an approach that jointly considers products and flexibility in the functional unit of DSM. We compare DSM with a steady-state operation of the process as a reference system, given that both systems provide the same products. Furthermore, we expand the reference system with energy storage technologies, which enable short- and long-term flexibility in electricity consumption. We demonstrate the proposed approach on the switchable chlor-alkali electrolysis, using hourly electricity prices and emission factors. Our findings show that comparing the switchable electrolysis to the reference system indicates only small differences in the environmental impacts. Thus, the results indicate that the flexible operation of the chlor-alkali electrolysis has comparable environmental impacts as integrating electricity storage.

Keywords: functional unit, flexibility, chlor-alkali electrolysis

1. Introduction

The integration of renewable energies into the electricity grid aims to reduce greenhouse gas (GHG) emissions. However, due to the volatile nature of renewable energies, the temporal mismatch between demand and supply of electricity is likely to increase. This mismatch can be reduced by demand-side management (DSM) - the load management of

processes or appliances to reduce the overall energy costs (Warren, 2014). To analyze if DSM is suitable to stabilize the electricity grid while avoiding significant environmental impacts, the environmental assessment of DSM is necessary. Currently, the environmental impacts of DSM receive increased attention in literature (e.g., Schäfer et al., 2020). For the environmental assessment of DSM, the method of life cycle assessment (LCA) can be applied. LCA is a holistic method, covering potential environmental impacts over the entire life cycle of a product system (International organization for standardisation, 2021). The LCA is conducted by comparing DSM with a reference operation mode. For this comparison, it is essential that both modes of operation provide the same functions, e.g., the production of a certain product. These functions are defined and quantified by the functional unit. However, concerning the environmental assessment of DSM, the functional unit differs in literature. Some studies focus on the products of the DSM and consider the flexible electricity consumption as a secondary benefit to reduce process costs (Walzberg et al., 2019). Other studies consider the grid service due to the flexible electricity consumption as the only function, especially when non-industrial DSM is considered (Milovanoff et al., 2018). In the environmental assessment of industrial DSM, the products should be integrated into the functional unit since they are essential for downstream processes. Furthermore, considering the importance of system services to the electricity grid, the flexible electricity consumption of DSM should also be included in the functional unit.

In this work, we present an approach to integrate both the products and the flexible electricity consumption in the functional unit of DSM. The approach is introduced and applied to the switchable chlor-alkali electrolysis, which is a potential DSM process in the chemical industry.

2. LCA of demand-side management processes

The proposed approach aims to assess environmental impacts of DSM via a comparative LCA, in which products and flexible electricity consumption are included in the functional unit. Since industrial processes usually supply downstream processes, we define a constant supply rate of the products in the functional unit. Therefore, the DSM system generally needs an additional product storage to enable a constant supply rate. The reference system for comparison comprises the conventional steady-state operation, providing a constant supply of products. However, since the steady-state operation cannot provide a flexible electricity consumption, the reference system is expanded with energy storage units. To consider different time periods of flexibility, short-term as well as long-term storage technologies are used for the expansion. The power and capacity of these storage units depend on the flexibility defined in the functional unit. Since DSM is assessed, we define the flexible electricity consumption by the DSM as the required flexibility. But quantifying this flexibility is challenging because it depends on the flexible power that the DSM can provide and the duration of provided flexibility. Thus, we propose the following four-step approach to determine the environmental impacts of the DSM and the reference system while guaranteeing the same flexibility (Figure 1):

1. To quantify the flexibility of the DSM, the operation profile of the process is required. For this, the operation of the DSM process is optimized while minimizing operating costs. The time horizon of this optimization covers one year so that seasonal variations in DSM are considered. The time resolution of the optimization should be defined in accordance with the ramping constraints of the DSM. From the results of this optimization, the electrical load profile of the DSM process is obtained. The derivative of this load profile, i.e., the

marginal electricity consumption, characterizes the flexibility of the DSM. In the functional unit, flexibility is defined as the potential to provide the same flexibility as the DSM, thus the potential to operate with the same marginal electricity consumption.

2. In the reference system, the steady-state operation and the storage capacities need to be designed so that they can provide the products and flexibility as stated in the functional unit. For this, an optimization minimizing design and operational costs of the reference system is conducted. Since the reference system should provide the same flexibility as the DSM system, the derivative of the electrical load profile is predefined for the reference system by the derivative of the DSM system as obtained in Step 1. The same derivative results in the same shape of the electric load profile. Although the shape of electricity consumption is predefined, it does not restrict the total amount of consumed electricity, i.e., there can be a constant offset in electricity consumption between the DSM and the reference system. The amount of the constant offset depends on the process and storage efficiencies. Furthermore, the constant offset enables the assessment of different DSM types such as load shifting, peak clipping, or valley filling.
3. Subsequent to the design optimization, the reference system can provide the same flexibility as the DSM. However, the restriction of the derivative of electricity consumption can lead to a suboptimal economic operation of the reference system. Economically, the reference system would probably be operated differently due to the diverse efficiencies and ramping constraints of the storage technologies. Thus, an optimization minimizing the operational costs of the reference system with the design results of step 2 is conducted while providing the same supply rate as defined in the functional unit.
4. As a last step, the life cycle impact assessment of both systems is conducted. For this, the respective operation determined in Steps 1 and 3 is applied to calculate the environmental impacts in each time step. These impacts are accumulated for one year of operation. Furthermore, the construction and disposal impacts of the production and storage facilities are included to consider the complete life cycle of both systems. The construction impacts of each component are proportionally

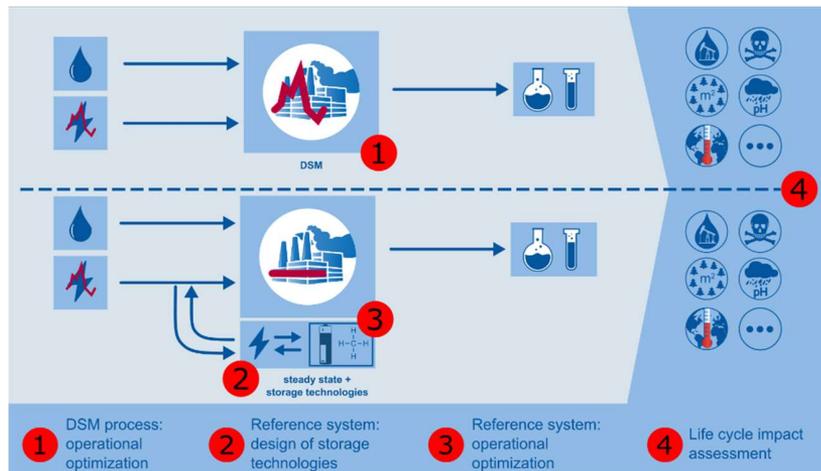

Figure 1: Life cycle assessment of demand-side management (DSM) with proposed four step approach.

allocated to one year, depending on the lifetime of the component. Finally, the impacts of operation and construction are added, and both systems are compared.

3. LCA of the switchable chlor-alkali electrolysis

The presented approach is applied for the environmental assessment of the switchable chlor-alkali electrolysis. Chlor-alkali electrolysis is an essential process in the chemical industry, producing the bulk chemicals chlorine and sodium hydroxide. The switchable chlor-alkali electrolysis can apply DSM by utilizing a bifunctional electrode which allows changing operation between two different modes (Brée et al., 2018). The standard mode converts a brine solution into chlorine, sodium hydroxide, and hydrogen (H₂-mode). The typical electricity consumption ranges between 2.1 and 3.0 kWh per kg of produced chlorine. The second mode requires oxygen as an additional input and suppresses the hydrogen production (O₂-mode). This mode consumes around 30% less electricity. When switching between these modes, cleaning the electrolysis cell is necessary to avoid oxyhydrogen reaction. The cleaning leads to downtimes in the production. Therefore, to enable a constant supply of products, the electrolysis is capable of overproduction, and a small intermediate storage for the products is integrated into the system.

The mathematical model of the switchable chlor-alkali electrolysis is adapted from Roh et al. (2019). The model is formulated as a mixed-integer linear program (MILP). Since the downtimes due to the cleaning of the electrolysis cell do not represent the controllable flexibility of the DSM, the downtimes and the overproduction are neglected for the determination of the flexibility in the functional unit. The supply of products defined in the functional unit is 1 kg chlorine and 1.128 kg sodium hydroxide per hour over the time horizon of one year. The produced hydrogen is assumed to be burned for supplying heat to other processes, which is often applied in the chemical industry (Jörissen et al., 2011). Therefore, a heat supply is also defined in the functional unit by multiplication of the produced hydrogen and its lower heating value.

In the reference system, the H₂-mode is chosen as the steady-state process since it is the conventional process of the chlor-alkali electrolysis. Because the H₂-mode consumes more electricity than the O₂-mode, the DSM application represented by the switchable chlor-alkali electrolysis is peak-clipping. The short-term storage technology considered for the system expansion of the reference system is a vanadium redox flow battery. This type of battery was chosen because it allows a separate design of storage power and capacity. For long-term storage, the power-to-methane-to-power technology is considered. This technology consists of water electrolysis, a methanation plant, a methane storage tank, and a natural gas turbine. Although this technology is immature, it is one of the most promising options for long-term storage of electricity without being regionally bounded (Jülch, 2016).

The exogenous electricity price is obtained from Bundesnetzagentur | SMARD.de (2020) and represents the German electricity prices on the wholesale market in 2019. The electricity price is increased by 1.5ct/kWh, representing levies and taxes for the energy intensive industry. For the environmental assessment, the hourly grid mix emissions are calculated with emission factors of the generation technologies provided by ecoinvent 3.6 (Wernet et al., 2016) and the hourly mix of generating technologies, which is also obtained from Bundesnetzagentur | SMARD.de (2020). The environmental impacts of the chlor-alkali electrolyzer construction are integrated by the work of Jung et al. (2014). For the calculation of the vanadium redox flow battery's construction impacts, the modelling of Weber et al. (2018) is applied. Construction impacts of the water electrolysis are taken from Baumgärtner et al. (2021). All other construction impacts are modeled with the life

cycle inventory database ecoinvent 3.6 (Wernet et al., 2016). The considered life cycle impact assessment method is Environmental Footprint 2.0, which is recommended by the European Commission's Joint Research Center (Sala et al., 2014).

4. Results of the switchable chlor-alkali electrolysis

The operational optimization of the switchable chlor-alkali electrolysis shows that the electrolysis operates more often in the H₂-mode during the year (from 22.7% to 73.6% per month, 56.4% annual average, see Figure 2). The O₂-mode is the preferred mode during January and February, since the electricity price in these months is higher than in the summer. The DSM results in a seasonal variation of electricity demand, which is represented in the functional unit and favors a system expansion with long-term storage in the reference system. Actually, the power-to-methane-to-power facility provides all the flexibility with a charging power of 0.47 kW, discharging power of 0.16 kW and a methane storage of 25.94 kg, representing an electrical storage capacity of 360.29 kWh.

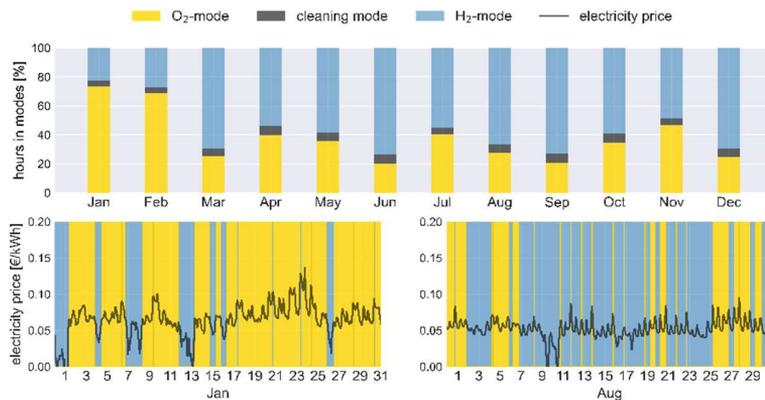

Figure 2: Operation overview of the switchable chlor-alkali electrolysis for the complete year (top plot) and detailed operation for January and August (bottom plots).

The results of the life cycle impact assessment show that DSM of the switchable chlor-alkali electrolysis leads to similar environmental impacts compared to the reference system in all impact categories except human toxicity (non-cancer). The reasons for the similar environmental impacts are the high impacts of sodium chloride and electricity in the operation of the electrolysis. Impacts due to construction are mostly negligible in comparison to the impacts of process operation. However, the impact in human toxicity (non-cancer) is remarkably higher for the reference system, because of the high impact of storage construction in this category. As the results are mostly in the range of impact assessment uncertainties, no recommendations for operating the chlor-alkali electrolysis can be given. However, the results indicate that applying DSM for the chlor-alkali electrolysis has comparable environmental impacts as integrating storage technologies into the grid to match the electricity supply with its demand.

5. Conclusions

In this paper we propose an approach to assess the environmental impacts of DSM via LCA by integrating flexibility in the functional unit. The approach enables a comparison between applying DSM and the utilization of storage technologies to provide flexibility. We demonstrate our approach on the environmental assessment of the switchable chlor-alkali electrolysis. The environmental impacts of the switchable chlor-alkali electrolysis

and the reference system are mostly in the range of impact assessment uncertainties. However, the results indicate that applying DSM for the chlor-alkali electrolysis has comparable environmental impacts as integrating storage technologies.

Abstract

This study presents a systematic methodology for process synthesis based on superstructure optimization, which identifies the optimal configuration of a biorefinery to produce high value chemical and biochemical products, by maximizing product profits and minimizing process energy costs and the investment costs. The case study employed agave bagasse as a feedstock. The results indicated that furfural production is the best option, followed by lactic acid production as the second best and, ethanol, ethylene glycol and diethylene glycol production was the third best option, relying on the objectives previously mentioned. The optimization was performed using a variant of genetic algorithms with multi-objective approach (Gamultiobj), through a COM® interface linking the computational tools such as, Aspen Plus and MATLAB, which allowed to perform a rigorous energy balance calculation employing the proper thermodynamic models.

Keywords: superstructure, optimization, agave bagasse, genetic algorithms.

1. Introduction

The production of biofuels and/or high value chemical products derived from lignocellulosic biomass is one of the alternatives that has been studied and developed in recent years (Ren et al., 2009). These chemical compounds can be produced from a variety of non-food crops, such as lignocellulosic residues from agriculture, forestry, and food industry, which has a direct impact on reducing dependence on fossil resources. Lignocellulosic biomass is mainly composed by three biopolymers: cellulose, hemicellulose, and lignin. The cellulose and hemicellulose fractions can be subjected to diverse chemical and/or biological processes and a wide variety of compounds can be obtained. There is great interest in proposing new optimal industrial processes that use lignocellulosic biomass as feedstock, with the purpose of producing high value chemical compounds and/or biofuels, through production platforms called biorefineries.

A superstructure represents all possible pathways by synthesizing distinctive alternatives at different stages of the processing network to optimize a series of possible processing approaches (Quaglia et al., 2015). This methodology has been widely used to optimize multi-criteria processing alternatives, for example, to select the optimal pathway for the conversion of microalgae to biodiesel (Rizwan et al., 2013), among others. Although the results were promising in terms of different parameters such as economic and environmental, the study did not cover other aspects, such as rigorous energy balances

analysis, which is a paramount aspect that must be included in the multidimensional analysis for finding optimal (bio)process routes.

The optimization task in process synthesis employing superstructures is another issue to solve. Some computer-aided tools have been employed to solve that kind of problems, but it is necessary to represent and develop the mass balance process model and most of the time, energy balance is rarely included (Rizwan et al., 2013). On the other hand, the use of ActiveX-OLE(COM)[®] technology allows the implementation of an interface between MATLAB R2017a[®] and Aspen Plus V.8.8[®] (Darkwah et al., 2018; Ponce-Rocha et al., 2021). The utilization of the NSGA-II algorithm is a well-established multi-objective evolutionary algorithm, which has been successfully implemented in a wide range of applications (Punnathanam and Kotecha, 2016). Matlab [®] offers a suite focused on multi-objective optimization (Gamultiobj) to create a set of points on the Pareto front. Gamultiobj uses a controlled and elitist genetic algorithm (a variant of NSGA-II). Moreover, Aspen Plus[®] provides a suitable environment for robust process simulation. Thereby, the objective of this research was to create and implement, a new methodology based on a genetic algorithm for the optimization of superstructures, integrating two computational programs through an interface: Aspen Plus (AP) and Matlab. This allowed the use of a rigorous thermodynamic approach by combining computer-aided tools, to find the best configuration of a biorefinery considering different processing routes to obtain high value biofuels and chemical products. Expanding how process synthesis has mostly been performed so far.

2. Methodology

The proposed methodology includes the collection of data such as, potential process routes to transform lignocellulosic biomass. The methodology was used to identify the optimal route for processing one or several chemical products on a commercial scale from agave bagasse, since it is a natural residue from the production of tequila and mezcal in some regions of Mexico. The processed agave bagasse used in this study was 1000 kg/day. The costs used in the economic evaluation were based on the current commercial price available (Alibaba, 2021). The thermodynamic model employed in this work was NRTL, while the parameters were obtained from Wooley and Putsche (1996). The compounds that were not found in the aspen plus database were generated using published experimental data and using group contribution approach.

2.1. Superstructure generation

Five major processing sections are included in the superstructure: feedstock, pretreatment, hydrolysis, fermentation, separation and/or purification (see Fig. 1).

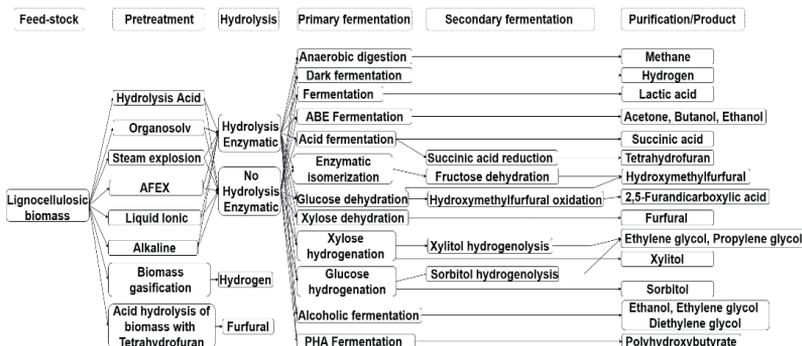

Fig. 1 Biorefinery superstructure to produce diverse chemical products.

The different production routes of biofuels and/or chemicals from lignocellulosic biomass were developed and simulated in Aspen Plus® through a superstructure. Aspen Plus was selected for its versatility and thoroughness for obtaining the results of mass balances and energy requirements, in addition to the availability of appropriate thermodynamic models. Aspen Plus and Matlab were connected to use the optimization suites available in Matlab. The optimization technique used in this work was based on stochastic multi-objective evolutionary methods.

2.2. Superstructure objective function

The multi-objective optimization problem was formulated to maximize the profit per day (GAN) and minimize the energy consumption per day (Q), given by:

$$\min(-GAN, Q) = f(x_{BM}, x_{sugars}, x_{sec-product}) \quad (1)$$

$$GAN = \sum_{i=1}^n (P_i * CV_i) - CB * BM - \sum_{j=1}^m MP_j \quad (2)$$

$$Q = \sum_{k=1}^p C_{vapor} * Q_{in_k} + C_{water} * Q_{out_k} \quad (3)$$

where P_i is the amount of product obtained in kg/day, CV_i are the selling prices of product obtained in USD/kg, CB is the cost of feedstock in USD/kg, BM is the processed biomass (1,000 kg/day) and MP_i is the cost of reactants and additives of each process in USD/kg. Q_{in} and Q_{out} are the amount of energy to be supplied and removed from the equipment respectively in kJ/day, C_{steam} and C_{water} are the cost of steam and cooling water, respectively, in USD/kg.

The multi-objective function is formulated in terms of decision variables as the treated mass fractions distribution in each section considered in the superstructure, that is, the mass fractions of fed biomass, mass fractions of the pretreatment, enzymatic hydrolysis, and fermentation stages. Optimization of the superstructure was performed using a stochastic multi-objective evolutionary method (Gamultiobj®), where population sizes of 100 individuals, 15 generations, crossover fraction 0.8, and a feasible adaptive mutation fraction were used. The implementation of the COM® interface used the computational tools Aspen Plus V.8.8® - Matlab R2017a®. The investment costs estimation was also included as a decision variable and calculated with the Guthrie method, to obtain an approximate investment cost for each of the scenarios to be considered. So, this parameter will be a decision criterion for an optimal biorefinery route.

3. Results

3.1 Optimal product and its processing route.

Table 1 presents a summary of the scenarios obtained by the optimizer, including GAN (product profit per day), Q (energy cost per day), IC (investment costs) and the result of the multi-objective function; in addition to the products obtained for each scenario, where the production of furfural is common for all the scenarios. Fig. 2a illustrates the optimal results in a 3D plot, Fig. 2b presents a ternary plot that illustrates the scenarios among the three objectives mentioned above. The optimal process flow diagram of the optimal processing route is shown in Fig. 2c. The results shown in Table 1 indicate that the processing route presented in Fig. 2c leads to the highest GAN (393.73 USD/day) of all the candidates, having a minimum cost of energy expenses (13 USD/day) and a minimum in the investment costs (3,230,000 USD). The optimal processing route for furfural

production consists of direct treatment of agave bagasse by acid hydrolysis with tetrahydrofuran.

Table 1 Results of superstructure optimization.

Scenario	Multi-objective function	GAN (USD/day)	Q (USD/day)	IC (USD)	Products
A	1,114.47	1,237.51	123.04	150,744,112	furfural, HMF, FDCA
B	380.73	393.73	13.00	3,230,000	furfural
C	408.53	521.92	113.39	249,740,863	furfural, HMF, FDCA
D	575.94	692.92	116.98	143,792,625	furfural, HMF, FDCA
E	1,092.27	1,215.31	123.04	150,694,121	furfural, HMF, FDCA
F	467.48	582.63	115.15	249,740,863	furfural, HMF, FDCA
G	611.67	731.53	119.86	149,839,974	furfural, HMF, FDCA
H	894.81	1,016.99	122.18	146,775,251	furfural, HMF, FDCA
I	861.94	983.44	121.50	148,226,897	furfural, HMF, FDCA

Nomenclature: HMF = hydroxymethylfurfural; FDCA = 2,5-Furandicarboxylic acid

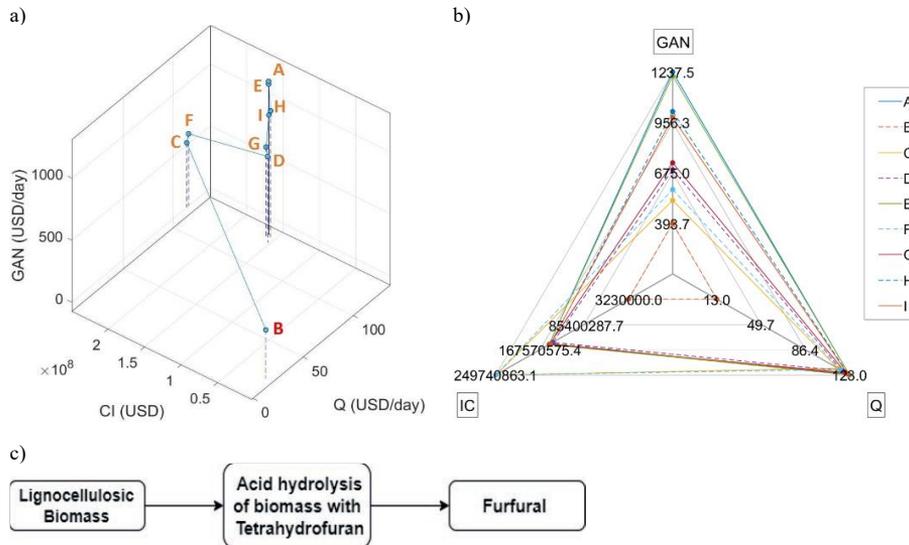

Fig. 2. a) 3D plot of the optimal processing scenarios, b) Ternary plot of optimal processing scenarios, c) Optimal processing route for agave bagasse.

3.2 Suboptimal products.

A subsequent optimization was performed not considering furfural production by acid hydrolysis with tetrahydrofuran in the superstructure, to find the second-best process configuration. Fig. 3a and 3b show the 3D plot and the ternary graph, respectively, where the optimal scenarios are illustrated. The process flow of the optimal processing route is shown in Fig. 3c that correspond to lactic acid production. The process layout includes a steam explosion, enzymatic hydrolysis, fermentation and separation and purification stage. The results indicated that is possible to have a profit of 939.70 USD/day, energy expenses (Q) of 26.13 USD/day and an IC of 6,187,109 USD.

In the same direction, a third optimal scenario was determined eliminating the furfural and lactic acid production processes of the superstructure. The results showed that the

third best option was the production of ethanol, ethylene glycol and diethylene glycol, including a pretreatment stage using steam explosion, followed by an enzymatic hydrolysis and fermentation stages. The profit (GAN) was 178.49 USD/day, with an energy cost (Q) of 13.75 USD/day and an IC of 8,339,205 USD. Fig. 4a-4b shows the obtained optimal scenarios in a 3D and ternary plots, respectively. Fig. 4c illustrates the process flow diagram of the optimal processing route for ethanol, ethylene glycol and diethylene glycol production.

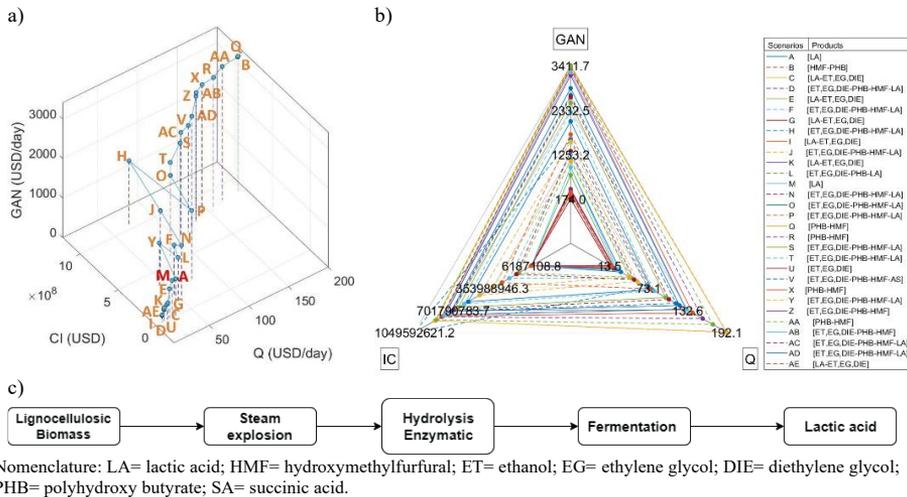

Fig. 3. a) 3D plot of the suboptimal processing scenarios by eliminating the furfural production process, b) Ternary plot of the suboptimal processing scenarios by eliminating the furfural production process, c) Second optimal processing route for agave bagasse: lactic acid production.

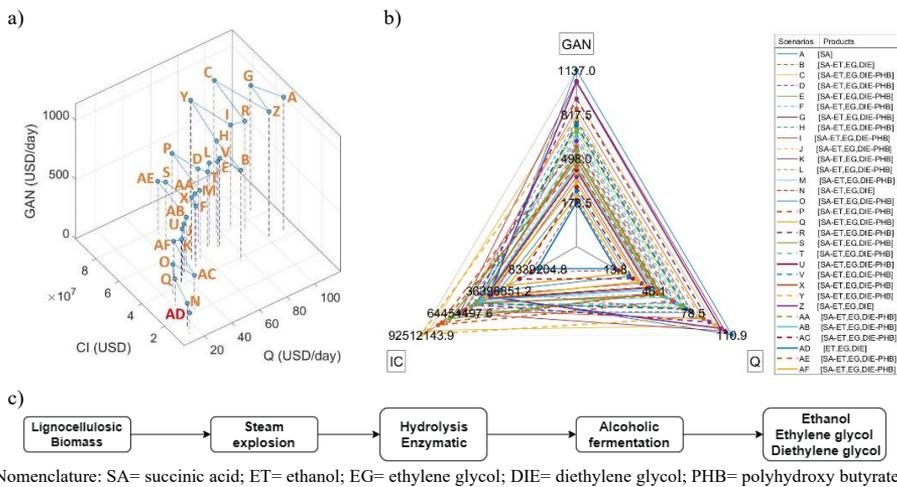

Fig. 4. a) 3D plot of the suboptimal processing scenarios by eliminating the furfural and lactic acid production process, b) Ternary plot of the suboptimal processing scenarios by eliminating the furfural and lactic acid production processes, b) Third optimal processing route for agave bagasse: ethanol, ethylene glycol and diethylene glycol production.

4. Conclusion

In this study, a new methodology for process synthesis with a superstructure approach was performed, in which different optimal process routes to produce high value chemicals were determined using agave bagasse lignocellulosic biomass as feedstock. The methodology involves a multi-objective optimization, maximizing profit, minimizing energy requirements, and including the lowest capital cost in the selection criteria. The integration of the Aspen Plus and Matlab computer-aided tools showed several advantages, one of them being that there was no need to explicitly introduce the equations representing each of the processes considered in the superstructure, such as mass and energy balances.

In addition, the simulation of the superstructure in Aspen Plus allowed to calculate the thermodynamic properties, through equations of state and solution models that consider the non-idealities of the mixtures involved in the phase equilibria and the interactions of components; in this way, a rigorous approach was used, avoiding disregarding important data in the synthesis of processes.

Different process scenarios were obtained in which the three decision criteria were satisfactorily fulfilled: maximization of total profit, minimization of energy expenses and the investment cost, permitting to obtain feasible process routes for the conversion of agave bagasse into a high value chemical product, such as the production of furfural, as first option, as second option the production of lactic acid and, as third option the production of ethanol, ethylene glycol and diethylene glycol.

Renewables-Based Multigeneration System for District Energy Supply

Houd Al-Obaidli, Rajesh Govindan, Tareq Al-Ansari*

College of Science and Engineering, Hamad Bin Khalifa University, Doha, Qatar
talansari@hbku.edu.qa

Abstract

District energy systems (DES) provide electric and thermal energy from a central plant to a developed area through underground distribution networks. Fossil fuels are widely used as a primary energy source in DES. In 2021, energy-related CO₂ emissions from residential and commercial buildings reached 10% worldwide. In this paper, a renewables-based multigeneration system is proposed as a sustainable alternative for DES. The conventional system is based on a gas-fired combined cycle turbine and an absorption cooling system (ACS). The proposed renewables-based system utilises biomass and solar thermal energies and an ACS to provide district electricity, heating and cooling. A stochastic optimisation approach based on multi-objective generic algorithm (MOGA) is used to support the process modelling and identify the optimal pre-defined configurations based on their proximity to the Pareto curve. A techno-economic assessment is performed to compare the levelised cost of energy (LCOE) and evaluate the anticipated environmental footprint reduction. Results show that although the LCOE of the proposed system is higher than the conventional system, the reduction in CO₂ emissions converts directly into annual savings in districts covered by a carbon tax regime.

Keywords: Carbon tax, Multigeneration, Optimisation, Renewable energy, Techno-economic assessment.

1. Introduction

DES is one of the vital infrastructural elements of any modern urban development. It enables the efficient supply of critical utilities such as electricity, cooling and heating to contemporary residential and commercial districts. Conventional district supply entails fossil fuels as a primary energy source, such as coal, oil, and natural gas. Currently, residential and commercial buildings contribute 10% of the global carbon emissions. Therefore, renewable energy sources are now targeted for DES integration to enhance the environmental performance of the sector (Lake *et al.*, 2017; IEA, 2021). Recently, several studies featured renewable energy integration into DES. Al-Obaidli *et al.* (2020) designed a renewables-based multigeneration system to supply electricity, heating, cooling and freshwater. The study's main objective was to assess the energetic and exergetic efficiencies of the system compared to conventional supply methods. Hou *et al.* (2018) evaluated expansion strategies for existing conventional DES through demand-side management efficiencies and the use of renewable technologies. The study found that a potential reduction in CO₂ emissions between 6% and 8% was possible. Cheng *et al.* (2020) investigated the cost impact of CO₂ emissions and renewable energy targets in two real-world districts in China using a mixed-integer linear programming model (MILP). The study found that the average cost of reducing carbon emissions by 40% is 66 \$/tCO₂,

while the average cost of achieving 25% renewable energy penetration is 65 \$/MWh. Chen et al. (2021) proposed a 100% renewable energy DES for 30 different regions in China. The optimal portfolio for each district was determined based on economic performance and geographical features. The study identified the feasibility of the proposed system based on current market conditions with an average payback period of 6 years. Whilst earlier studies may have looked at various indicators (cost, emissions, etc...) individually, they have not attempted to find the optimal solutions based on these indicators combined.

This paper aims to develop a techno-economic assessment and optimisation tool for evaluating renewables-based DES compared to conventional supply systems. The MOGA process is used as a trade-off mechanism between LCOE and life-cycle emissions (LCE) and Net present project valuation (NPV) is performed subsequently for the identification of project profitability. The main objective is to couple the techno-economic evaluation and the trade-off analysis using MOGA in order to compare and evaluate the pre-defined configurations with the baseline for DES application.

2. Methodology

A case study was built for Al-Khor and Al-Thakira district, located in the North-East of Qatar. It is the closest residential district to the Ras Laffan industrial city (RLIC), which houses some of the world's most extensive natural gas processing and liquefaction facilities. Over the last 30 years, the district has witnessed cycles of growth and decline in both population and commercial activities due to peaking and diminishing project and construction work in the nearby RLIC. According to the 2020 census, the population total was 140,453, nearly 28% less than the population in 2010 (PSA, 2021). By dividing the total energy production over the total population, it is estimated that the average energy consumption per capita in Qatar is 17,307 kWh per annum. A DES is designed to supply electricity, heating and cooling for the district where commercial supply requirements are assumed to be equivalent to the residential energy requirements. Meanwhile, industrial requirements are excluded from this study. Table 1 provides the design specifications of the DES system.

Table 1. Design specifications of DES system (EIA, 2020).

Technology	CF (%)	Unit capacity (MW)	Number of units	Plant capacity (MW)
CCGT	56.6	430	3	1,290
PV	24.9	350	7	2,450
CSP	43	900	2	1,800
BIGCC	58.4	90	11	990
BECCS	49.8	90	13	1,170

Figure 1 depicts the DES system potential configurations. Renewables-based DES system using biomass and solar technologies is considered. Four technologies are envisaged: photovoltaics (PV) with battery storage, concentrated solar power (CSP) with thermal storage, a carbon-neutral biomass integrated gasification combined cycle (BIGCC) and a carbon-negative bioenergy with carbon capture and storage (BECCS) (Namany, 2019). A conventional system based on a natural gas-fired combined-cycle gas turbine (CCGT) is also included as a baseline configuration for comparison purposes. Since a PV-only

configuration cannot supply the required thermal energy for heating, a hybrid system will be considered and evaluated.

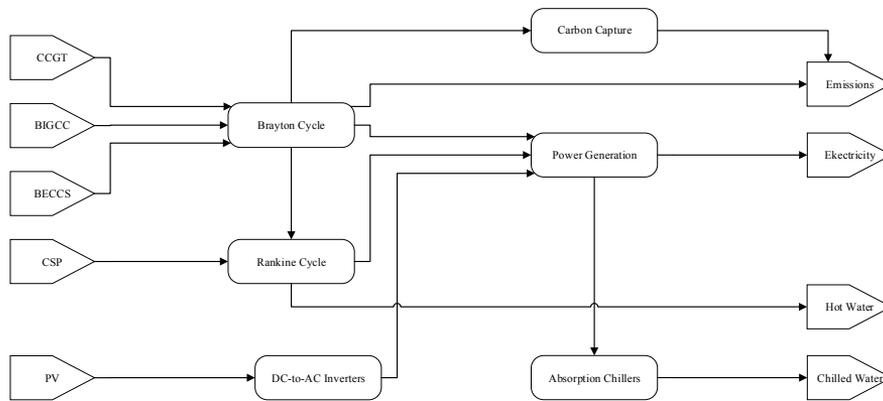

Fig. 1. DES block diagram.

A techno-economic assessment is performed based on the levelised cost of energy and life-cycle emissions. The LCOE is defined as lifetime costs over lifetime energy produced and is calculated using Eq. (1).

$$LCOE = \frac{CC + TOC \times DF}{E_{prod} \times DF} \quad (1)$$

The capital cost (CC) is the product of the plant's nameplate capacity by the capital cost rate, the total operating cost (TOC) is the sum of fixed (FOC) and variable operating costs (VOC), and E_{prod} is the annual energy production. The discount factor (DF) is determined using a facility lifetime of 24 years and a discount rate of 6.5%. Technology-specific cost and LCE parameters are listed in Table 2. Natural gas fuel cost is added to the VOC of CCGT only.

Table 2. Cost and LCE data (EIA, 2020; IPCC, 2014; Namany, 2019).

Technology	CC rate (\$/kW)	FOC rate (\$/kW)	VOC rate (\$/MWh)	LCE (gCO ₂ eq/kWh)
CCGT	1,084	14.1	2.55	490
PV	1,755	31.27	-	48
CSP	7,221	85.4	-	27
BIGCC	4,468	132.82	-	-
BECCS	5,865	146.32	-	(65)

A multi-objective genetics algorithm is used to determine the optimal Pareto frontier. The two competing objectives of the optimisation problem are:

$$\text{minimise } \sum_i c_i x_i$$

$$\text{minimise } \sum_i e_i x_i$$

where c_i is the unit LCOE per technology, e_i is the unit LCE per technology, and x_i is the technology fraction of the portfolio. The optimisation problem is subject to the following constraints:

$$\begin{aligned} \sum_i x_i &= 1 \\ 0 \leq x_i &\leq 1 \end{aligned}$$

The net present value is calculated using Eq. (2).

$$NPV = -CC + AP \times DF \quad (2)$$

The annual profit (AP) is determined by subtracting the TOC plus carbon taxes from the annual revenues.

3. Results and Discussion

Average US wholesale electricity price, Henry Hub natural gas spot price, and EU ETS CO₂ price data were used. Table 3 presents the LCOE for each of the configurations.

Table 3. LCOE results.

Configuration	Power generation mix	LCOE (\$/MWh)
A	CCGT	48
B	PV	89
C	CSP	254
D	BIGCC	103
E	BECCS	153
F	50% PV + 50% BIGCC	108
G	50% PV + 50% BECCS	129

Figure 2 presents the trade-off chart between LCOE and LCE. The different configurations create an artificial Pareto front. It is noted that the baseline configuration provided the lowest cost, and configuration E provided the lowest emissions. The points that lie on the Pareto front are considered "optimal", and the points that lie outside are considered "suboptimal" relative to the optimisation objectives at hand.

From Figure 2, configuration E was chosen from the set of non-dominating solutions (B, F, D, G, and E) to perform the comparison with the baseline case. MOGA was applied, and 700 solutions were identified. Most of the MOGA solutions lie on and between configurations B and E, creating a Pareto front starting from configuration B through configurations F, D, and G to configuration E. This means that all of these configurations are optimal, and configuration C is suboptimal. Configuration A was not evaluated as part of the optimisation run and is only presented for comparison purposes.

The wholesale electricity price follows the LCOE of the power mixture in the case of market equilibrium. This study assumed that the average wholesale electricity price would rise from 40 to 200 \$/MWh. Figure 3 provides the NPV for all the configurations.

It is noted that configuration A provided the highest NPV, and configuration C provided the lowest NPV. It is also noted that the optimal configurations are not necessarily the configuration with the highest NPV.

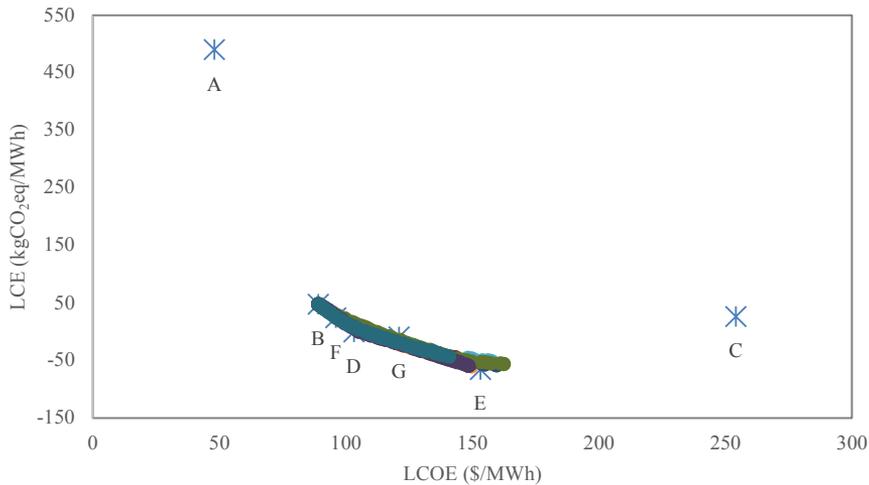

Fig. 2. LCOE and LCE trade-off chart.

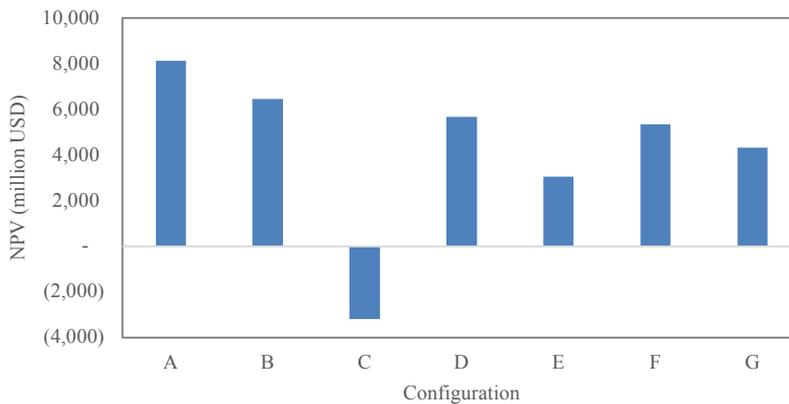

Fig. 3. Net present asset valuation results.

A sensitivity analysis for the CO₂ price is performed on the two profitable configurations, as shown in Figure 4. It is noted that when CO₂ price exceeds 240 \$/tCO₂, the selected non-dominating optimal configuration also becomes the most profitable one since carbon taxes limit the profitability of configuration A as CO₂ price increases. On the other hand, configuration E is positively influenced by rising CO₂ market prices.

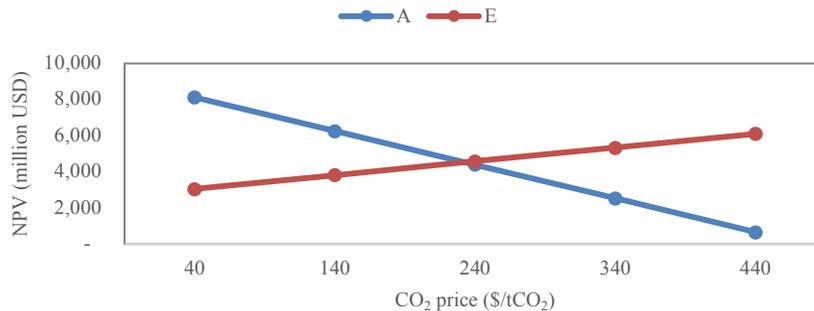

Fig. 4. Sensitivity analysis of CO₂ price impact on NPV.

4. Conclusions

A techno-economic assessment was conducted to evaluate an alternative DES for Al-Khor and Al-Thakira district in Qatar. The renewables-based configurations were compared to a conventional natural gas-fired combined cycle in terms of LCOE and LCE. The results were characterised by a Pareto front where CCGT had the lowest Levelised cost and BECCS had the lowest emissions. Several renewable energy configurations had the best trade-off between cost and emissions and only configuration C (CSP) was sub-optimal. Moreover, carbon-neutral and carbon-negative configurations provide a significant advantage in carbon taxes compared to the conventional system especially in a volatile carbon market. NPV provides a good indication of project profitability; however, when it comes to emissions, CO₂ prices would need to increase by more than six times the current levels for the renewable energy-based DES systems to present a more favourable NPV.

Abstract

Designing a new product requires information from the business and physical domains, which implies integrating business decision tools with process and material simulation processes to form an overall workflow. The integration involves coupling the business workflow management systems with analysis tools, optimisation and decision support systems, which require process simulations and an integrated data transfer service. The process simulation, in turn, will in general model multiple layers of time scales and thus is also in need of data transfer between different solvers. Here we discuss the main components in the light of a coating-design project.

Keywords: Computational engineering, multi-scale modelling, applied ontology

1. Project Background

The Horizon 2020 project VIPCOAT constructs an innovation platform for new active protective coatings based on materials modelling and optimisation. The project's application is coatings for the aerospace industry, and its objective is to introduce novel approaches for corrosion protection by active inhibiting pigments as nano-additives. VIPCOAT is to support end-users in developing new and effective corrosion barriers for metal surfaces, deploying environmentally friendly technologies, and, in parallel, provide a decision support system for business integration. VIPCOAT implements a multi-layer digital structure to enable the open innovation process of the production processes and the design of value-adding product chains. VIPCOAT uses a conceptually new idea, namely a Pareto chain along a value-adding B2B2B (business-to-business-to-business) sequence enabling collaborative, transparent decision processes. The approach builds on multi-criteria optimisation (MCO) and implements a set of decision tools that allow for exploring the individual Pareto fronts interactively.

Usually, coatings contain several components. Primarily the coating matrix is the material that makes up the coating itself. In addition, several additives are mixed in, protecting from UV, giving colour, and inhibiting corrosion in coating defects. When producing a paint, one has several objectives: purpose-related performance, the toxicity of the involved materials, and costs of production and application. Typically, these objectives are not possible to satisfy simultaneously. Also, with

having different components, usually, several suppliers are part of the production process. Therefore, it is natural that each member of the suppliers and customers has another set of objectives. And each member is affected by all of those being close to them in the process. Consequently, if one has to define *optimality*, one is confronted with multiple, incompatible business-related objectives or KPIs (Key Performance Indicators). Hence, overall, one deals with two levels of multi-objective optimisation problems: the lower one is the product, the upper the multi-player business layer. The project will create a digital platform for coating formulation, development and optimization, which could serve as a computational coating marketplace.

The VIPCOAT platform will comprise a collection of physics and data-based materials models, a data space, and an associated ontology-driven service that enables a smooth and simple data transfer between Business Decision Support Systems (BDSS), and the MoDeNa software orchestrator. For this purpose, the team develops new semantic network-based technologies and approaches to ensure an automatic data exchange for multi-scale simulations and multi-level material and business software components. These semantic technology developments are aligned with the Elementary Multiperspective Material Ontology (EMMO), cf. Francisco Morgado et al. (2020), in line with a series of efforts coordinated through activities of the European Materials Modelling Council (EMMC ASBL) and the Innovation Centre for Process Data Technology (Inprodat e.V.).

2. Business-to-Business process level

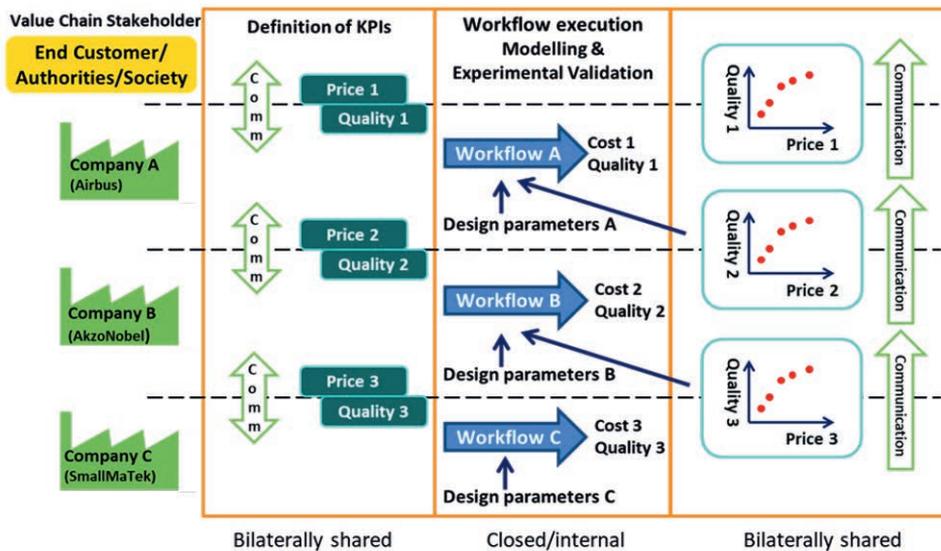

Figure 1: Business-to-Business-to-Business approach implemented in VIPCOAT. Bilateral communication starts the processes, followed by business internal developments and ending in an open access to Pareto-optimal product variants to be used in decision making upstream the production chain.

The VIPCOAT approach supports collaborative decision making along with production and/or value-added chains, using a conceptually new idea: the Pareto chain along Business-to-Business-to-Business (B2B2B) value-added chains as pictorially presented in Figure 1. The value-added chain goes from the bottom to the top. On the bottom, in VIPCOAT SmallMaTek (SMT) producing inhibiting pigments, Company C has some production capabilities associated with costs. As high quality and low cost are almost always contradicting goals, the capabilities to deliver products upstream the value chain are best described using a Pareto front of the best possible compromises.

For a company B downstream, in VIPCOAT represented by AkzoNobel, the best possible compromises form a sub-space of the Companies B opportunities and thus enter their design space for fabrication for company A, in VIPCOAT represented by Airbus. Therefore, we have a B2B2B environment in which collaborative decision making on top of transparent decision processes will make a lot of sense. In VIPCOAT, this is directly supported by the concept of a Pareto chain of interactive decision tools, designed as interactive explorers of the individual Pareto fronts. One Business executes a development and/or production process, supported by materials modelling to be described next, internally. Thus the internal cost structure is kept confidential and the transparent part of the B2B2B relation is the Pareto front of prices and associated product variants.

3. Business internal process level

One of the project's main objectives is to reduce the number of experiments, or in other words, replace experiments with predictions based on a physical model of the experimental setup. The first step is thus to design and discuss a model topology using the minimal graphical language we defined (Preisig (2021, 2014)). The topology captures all the fundamental structural assumptions. It represents the physical process as a network of primitive capacities (base entities, control volumes), a minimal set of extensive quantities and a set of mechanisms on how entities interact. Since it is a hierarchical representation, it also shows the assumed mereology of the model. The topology reflects all the main assumptions: what parts of the system are considered, which ones exhibit capacity effects, if they show significant gradients in the intensive quantities, if they are constant or dynamic or event-dynamic or not, how they link up to other capacities and exchange extensive quantity, what exchange is considered relevant, the exchange mechanism, and the resource environment. It should be noted, that the topology does not include geometrical information, like the shape of a capacity, also called a control volume.

Our Process Modelling software (ProMo) defines an application-focused ontology that defines the fundamental entities and their mathematical representation. The mereological information is encoded into the model's hierarchical tree. The internal nodes in the tree, we term composite entities. Replacing parts of the topology, usually composite entities, by surrogates generates the skeleton of the workflow. In the case of the coating process, as shown in Fig. 2 it is the two gray boxes that may be replaced by a surrogate solving the input relations in a separate task, a PDE solver like OpenFoam, while the leaching process is solved involving molecular modelling on which we do not expand in this exhibition. When running a workflow, the different tasks do exchange data, in our case this would be reading salinity, but also transferring information about the simulation of the coating and the simulation of the material and its inhibition. The same applies with the interaction of the coating and the leaching process simulations. Since ProMo maps information of the variables and the relations via OWL into a triple store, and the model provides the vectors of information exchange between the blocks, the interoperability problem can be solved using the approach described below. Finally, the task factory generates the simulation code for a solver environment like MatLab or an orchestrator that executes the developed workflow.

The green area in Figure 2 is reflecting only part of the story. In ProMo the access to a data taken from an external database is a controlled process. Figure 3 shows how ProMo maps the variables and equations into an EMMO-extended ontology. Once the model is established, the intertask communications is established over the SOFT/DLITE interoperability framework. ProMo maps the variables and equations into an EMMO-extended ontology. Once the model is established, the intertask communications is established over the SOFT-DLITE framework.

4. Interoperability

SOFT/DLITE (Hagelien et al., 2017) (Mir et al., 2020) represents information exchange between a data source and sink as a pipeline that process output data from the producer into a form that is

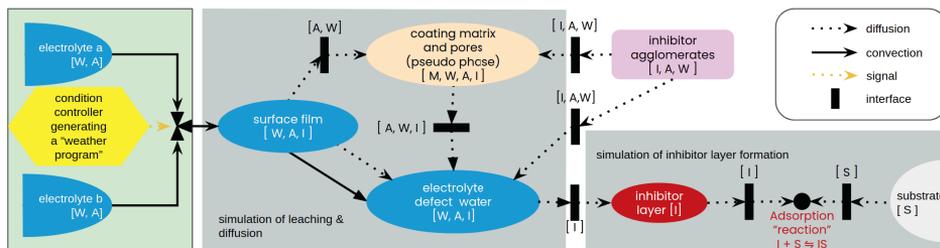

Figure 2: A simplified topology of a coating with inhibitor-loaded nano particles. Replacing the two grey boxes by surrogates providing an input/output solution in a separate task, one has the structure of the workflow.

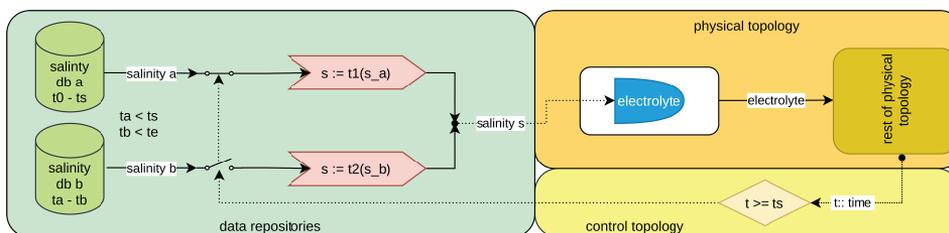

Figure 3: The ProMo view on how the salinity is read from two data sources. The database a covers the first part of the time period, while the database b is used to fill in the remainder.

suitable input to the consumer. Metadata schemas and ontologies capture the description of the data's intent and their meaning (semantics), which can be used in conjunction with specialised data readers for data extraction (Schembera, 2021) (Fig. 4). The next step is to augment high-level semantic artefacts with domain-specific knowledge. EMMO aligned mid-level and domain ontologies can be employed to document concepts such as processes and properties/quantities semantically (Horsch, 2021). Data and metadata need to be represented as knowledge graphs, employing semantic technology standards such as RDF, RDFS, and OWL.

EMMO-aligned mid-level and domain ontologies can also support platform interoperability between VIPCOAT and other infrastructures, particularly those developed within *H2020 NMBP* projects and, in the future, projects supported from the *Horizon Europe CLA resilience and data* lines of funding. Moreover, the EMMC ASBL focus areas and task groups help coordinate a series of ongoing development efforts in this direction. This technology operates at a comparably high level and requires at least the developers of platforms and tools to be familiar both with ontology-based research data management and with the philosophy underlying the EMMO. In contrast, the second line of development of semantic artefacts, equally endorsed by EMMC ASBL, operates at a lower level and is more accessible to domain experts: Based on the terminology of the Review of Materials Modelling (RoMM), the MODA (Model Data) describe simulation workflows, which permits textual descriptions, and is supported by the OSMO's ontology version of MODA (Horsch et al., 2020, 2021). An alignment between semantic artefacts from these two lines of work is not always straightforward because they rely on knowledge graphs that are differently structured. Previous work by Klein et al. (2021) discusses how graph transformation crosswalks can be used to transpose MODA/OSMO representations of simulation workflows, for which annotation and data ingest are comparably easy, into EMMO-aligned mid-level ontologies that are best suitable for platform interoperability in line with EMMC ASBL recommendations.

In the present framework, the mapping property *mapsTo* ensures that the semantics of metadata

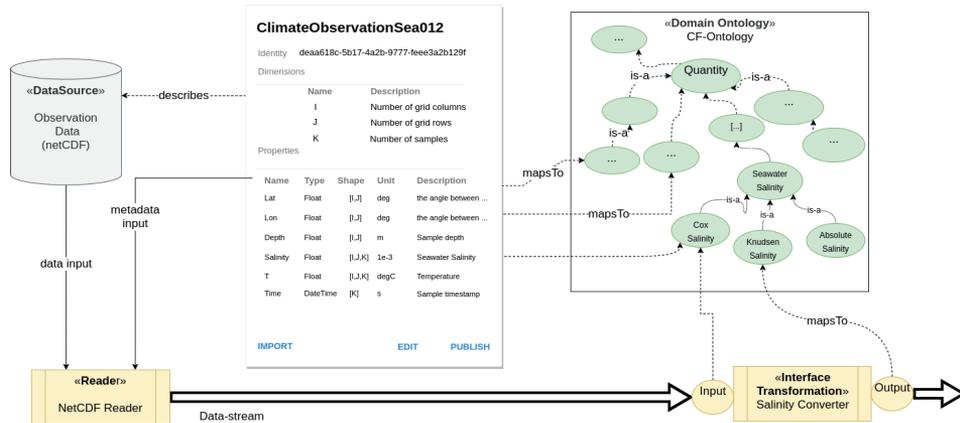

Figure 4: Schematic overview. The key components of the semantic interoperability platform are business data, a business data reader or writer, a metadata representation, domain ontologies, and interface transformations (equations) that connect different ontologies. The interoperability platform will analyse the use case and give the user options to select between multiple semantic pipelines or manually manage the pipeline pathways.

properties are aligned with domain ontology concepts, cf. Fig. 5. Similarly, a data model will represent the schema of application-specific data input on the consumer side. A data ingest system or file format generator using the metadata produces information that the data consumer can interpret. Mapping the metadata schema to the domain ontology concepts captures the semantics of the information. The SOFT/DLite generates the pipeline for the data transfer between the systems, recognising the semantic interpretation and syntactic representations.

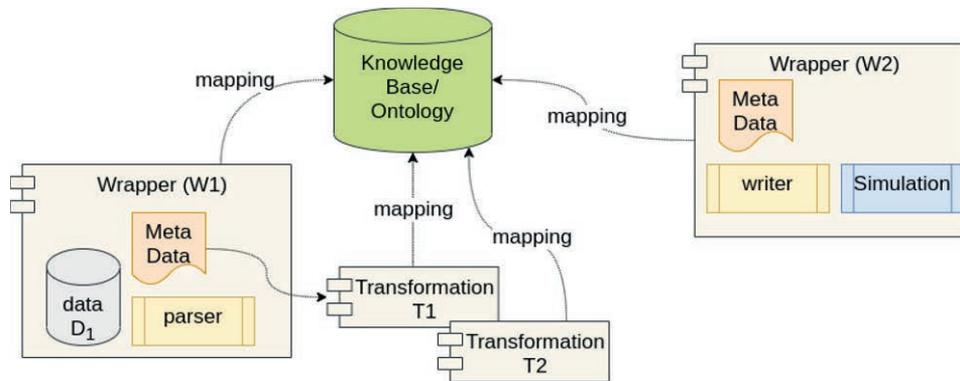

Figure 5: Data resources, data sinks, transformations and simulation packages connect to the Knowledge Base via mappings between the metadata representation of the business data and domain ontology concepts. Dependent on the data model on the receiving side of the information, a pipeline is constructed based on the semantic knowledge of the data and transformations. A pipeline can be constructed from Data resource D_1 in Wrapper W_1 through the interface transformations (T_1 and T_2) to the construction of the syntactic input representation for the simulation tool in W_2 : $W_1 \rightarrow T_1 \rightarrow T_2 \rightarrow W_2$

In the trivial case, the pipeline will only transfer data only. In a more complex scenario, semantic differences between data sources and data sinks require transformations to be taken from an ontology. The ProMo software (see Section 3) is already aligning the equations and variables to

EMMO domain ontologies and can therefore be plugged directly into the SOFT/DLite pipelines. Graph-search algorithms find all possible paths that define the pipeline. The end-user is responsible for selecting the most appropriate pathway if multiple exist, closing the connection through mappings and defining new transformations. In addition, the interoperability platform also manages the representation of the information in terms of differences in units (unit systems) and data shape/dimensionality. Unit conversions transformations can usually be inferred automatically, but strategies for managing differences in dimensionality (extrapolation, interpolation, averaging, machine learning-based methods, etc.) needs to be manually determined.

5. Conclusion

We demonstrate a new approach to a complex business-integrated product design on the example of active-protective coatings for the aeroplane industry. We introduce a new approach to interrelate three daisy-chained industries, two producers and one end-consumer. The new business-to-business environment implements a complex two-level workflow that links the business workflow with the physical simulation workflow, involving all three business partners in forming the final product performance. On the business level, we employ business-process-modelling (BPM) software Camunda and the NTNU's Process Modelling suite (ProMo) to model and generate simulation workflows executed in the MoDeNa platform. The team approaches the data integration of the various software using ontology-based technologies, generating the application interfaces automatically for the different components, providing access to a shared data space and Petri-net based technology for synchronisation.

Abstract

Livestock manure is one of the most abundant agro-wastes worldwide. Most of the manures are landfilled or composted to produce fertilizers, which raises concerns associated with the possible pollution of air and contamination of groundwater. Meanwhile, Hydrothermal liquefaction (HTL) is attracting growing attention to valorise wet wastes as an alternative to anaerobic digestion to produce value-added energy products. Livestock manures differ in terms of their composition, availability, and cost; therefore, an optimal blending of multiple livestock manures for liquefaction is expected to yield biocrude with distinct properties and contribute to process efficiency improvement. As such, this study evaluates the effect of different blending ratios of five typical livestock manures on the yield of biocrude and biochar, as well as the process environmental burden in terms of water consumption and CO₂ emissions. Aspen Plus® software is used to simulate the liquefaction process and to develop a mathematical optimization model to determine the optimal blending scenarios that satisfy adopted technical and environmental preferences. A weighted normalised decision metric is then used to minimise the gap between the solutions for the multiple objectives. The model suggested the optimal manures blend to be (50%, 26%, 14%, 5%, 5%) for cattle, camel, horse, poultry, and sheep manures, respectively. This study provides an insight into enhancing HTL process efficiencies through a careful selection of feedstock blends.

Keywords: Livestock manure, Liquefaction, Blending ratio, Biocrude, Simulation.

1. Introduction

Millions of tonnes of livestock manure are generated each year worldwide. While the uncontrolled decomposition of manure results in severe pollution of the environment and contamination of water resources. Meanwhile, Hydrothermal liquefaction (HTL) is becoming an increasingly attractive alternative to anaerobic digestion in terms of converting wet wastes into multiple fuels. In HTL, carbonaceous materials are converted to various energy products at high temperatures and pressure, just like crude oil is formed underground. The HTL process can directly liquefy manure into biocrude oil without the need for an energy-intensive drying procedure. HTL is typically performed at a temperature ranging from 250 °C to 400 °C, for a residence time of 15-60 minutes, and with an operating pressure ranging from 4 to 25 MPa (Chen et al., 2019). Biocrude is the major product of hydrothermal liquefaction. It is an oil with a lower oxygen content (10-20%) and a higher net heating value than pyrolysis oil (Peterson et al., 2008). In addition

to bio-crude, the HTL process also produces an aqueous phase-rich liquid product, biochar, and syngas.

There are significant differences in the composition of livestock manures, which have a direct significant impact on the biocrude characteristics and yield (Li et al., 2018). Livestock manures differ not only in composition, but also in availability and cost; therefore, an optimal blend of multiple livestock manures for liquefaction will likely yield biocrude with distinct properties and enhance processing efficiency.

It has been reported previously that manure can be used to produce biocrude (Chen et al., 2018; Xiu et al., 2010; Yin et al., 2010). However, the HTL of livestock manure blend is relatively new and requires thorough investigations to improve the process outcomes. As such, the purpose of this study is to explore the effects of different blending ratios of five typical livestock manure such as cattle, camel, horse, poultry, and sheep manures on the yield of biocrude and biochar, as well as the process' environmental burden in terms of water consumption and CO₂ emissions. Using Advanced System for Process Engineering (ASPEN PLUS) software, the liquefaction process is simulated, and a mathematical optimisation model is developed to determine the best blending scenarios that satisfy the adopted technical and environmental preferences.

This research sheds light on possible means for the improvement of HTL process efficiencies by carefully selecting feedstock mixtures. The synergistic effect of animal manure blends in HTL demonstration projects would serve as a roadmap for future use of livestock manure blends.

2. Methodology

2.1. Process Modelling

ASPEN PLUS V.10 is used to model a 250,000 tonnes/year hydrothermal liquefaction plant, considering isothermal and steady-state conditions. All manures are defined based on their proximate and elemental analyses as presented in **Table 1** (Akyürek et al., 2021; Al-Ansari et al., 2020; Chong et al., 2019; Whitely et al., 2006; Zhou et al., 2020). The manure streams are initially fed into a blending reactor, in which they are converted into conventional components based on their moisture and elemental composition using a Fortran code to ensure a mass balance of the conversion. The blended stream is then fed into a hydrolysis reactor along with additive water to create a slurry. For this purpose, a Fortran code is developed to estimate the amount of water required to dilute the solids mass concentration in the slurry to 20%. The mixture is then pumped to 100 bar using two consecutive high-performance pumps into the main HTL reactors, where the process is conducted at 100 bar and 350°C.

Table 1. Proximate and elemental analyses of studied livestock manures.

Analysis	Camel manure	Cattle manure	Horse manure	Poultry manure	Sheep manure
Moisture content (%)	58	85	40	40	50
Fixed carbon (%)	22.74	10.11	12.06	13.31	15.56
Volatile matter (%)	60.51	57.18	77.80	63.58	57.30
Ash (%)	16.73	32.69	10.12	23.09	27.13
Carbon (%)	37.11	27.61	39.53	36.67	33.14
Hydrogen (%)	4.07	3.48	4.99	5.33	4.48
Nitrogen (%)	2.27	1.88	0.70	3.54	2.65
Sulphur (%)	0.24	0.41	0.47	0.73	0.37
Oxygen (%)	39.54	33.91	44.16	30.61	32.21

In the first HTL reactor, the maximum biocrude yield and the minimum hydrochar yield are restricted using a Fortran code based on a correlation adapted from Zhong and Wei (2004) considering feedstock's composition, while the composition of biocrude and hydrochar is adapted from Pedersen et al. (2017) and Lentz et al. (2019) respectively. In the second HTL reactor, the composition of syngas is calculated based on thermodynamic approach via minimising Gibb's free energy. Besides, a hydrocyclone is used to recover hydrochar, while fluids are separated using a three-stage flash unit obtaining syngas, biocrude, and an aqueous phase. A simplified HTL process flow diagram is illustrated in **Figure 1** (Alherbawi et al., 2021).

The syngas composition is then calculated in an "RGibbs" reactor via the minimisation of the Gibbs' free energy. The process is conducted at 350 °C and 100 bar (Al-Ansari et al., 2020). In addition, solids are collected using a hydro-cyclone, while a three-stage flash drum is utilised to split the remaining stream into three phases: gas, biocrude and an aqueous phase.

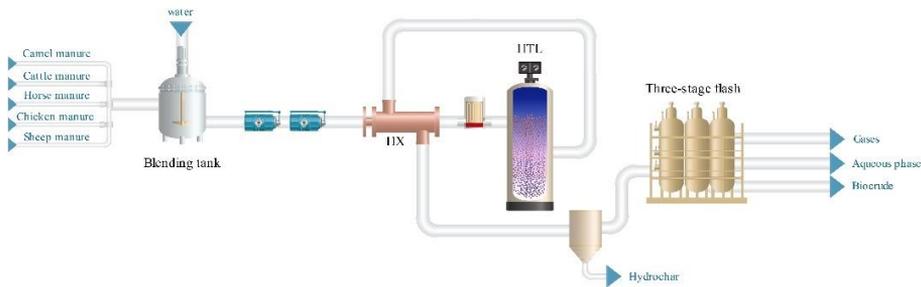

Figure 1. A simplified HTL process flow diagram using manures blend.

2.2. Optimisation Model

A mathematical optimisation model is developed in ASPEN Plus using the objective functions illustrated throughout Equations (1-4) and the constraints in Equations (5-6). Four objectives are adopted to facilitate selecting the optimal blending ratios of the five different manures for the HTL process. The first two objectives concerning the technical aspect of the process aim at maximising the yields of biocrude and hydrochar, while the other two objectives concerning the environmental aspect aim at minimising the water consumption and CO₂ emissions. In addition, the blending is constrained to satisfy 100% of the plant capacity, with a minimum of 5% of each manure utilisation and a maximum of 50% considering the possible limited supply of the manure.

Objective functions:

$$\text{Total biocrude yield } (Z_1) = \text{Max } \sum_{i=1}^5 BC_i X_i \quad (1)$$

$$\text{Total hydrochar yield } (Z_2) = \text{Max } \sum_{i=1}^5 HC_i X_i \quad (2)$$

$$\text{Total water consumption } (Z_3) = \text{Min } \sum_{i=1}^5 W_i X_i \quad (3)$$

$$\text{Total CO}_2 \text{ emissions } (Z_4) = \text{Min } \sum_{i=1}^5 E_i X_i \quad (4)$$

Constraints:

$$\sum_{i=1}^5 X_i = 1 \quad (5)$$

$$0.5 \geq X_i \geq 0.05 \quad (6)$$

Where: X_i : blending ratio % of manure (i).
 BC_i : biocrude relative yield, in tonne per tonne of manure (i).
 HC_i : hydrochar relative yield, in tonne per tonne of manure (i).
 W_i : water relative consumption, in tonne per tonne of manure (i).
 E_i : process emissions, in tonne CO₂ per tonne of manure (i).
 $i=1-5$ represent manure types, whereby: 1: Camel manure, 2: Cattle manure, 3: Horse manure, 4: Poultry manure and 5: Sheep manure.

Each optimisation function is solved independently, whereas the normalised weighted decision metric presented in Equation (7) is used to achieve a solution that relatively satisfies the four adopted objectives. Solving the goal function facilitates minimising the gap between the initial solution and the optimal solution for the different objective functions. Whereby it deals with each objective function independently and generates a single solution, in contrast to multi-objective problems that generates multiple solutions through trade-off between objectives.

$$Goalfunction = Min \sum_{j=1}^4 \omega_j \left| \frac{I_j - Z_j}{Z_j} \right| \quad (7)$$

Where, I_j is the initial solution for objective (j) assuming $X_i=100\%$, while Z_j is the optimal solution for objective (j) represented earlier in Equations (1-4). Besides, ω_i is the relative weight of objective (j), which is assumed to be equal for the four objectives in this study.

3. Results and Discussion

3.1. Model outputs

The products yield and environmental burden of the process considering a single manure feed in each run are illustrated in **Figure 2**. The highest biocrude yield is achieved using horse manure feedstock with a relative yield of 0.23 tonne biocrude per tonne of wet feedstock, while the lowest biocrude yield is achieved using cattle manure, which is possibly due to its low volatile matter and the extremely high ash and moisture contents. However, the highest hydrochar yield is obtained when camel manure is used as feedstock as its fixed carbon is the highest overall. Nevertheless, the HTL of cattle manure does not require any additive water, whereby its moisture content is sufficient to create a slurry. Whereas both, horse and poultry manures required the highest amount of water with 2:1 water to feedstock ratio. Besides, the HTL of horse manure is responsible of the highest CO₂ release, which is possibly due to its high carbon and oxygen contents.

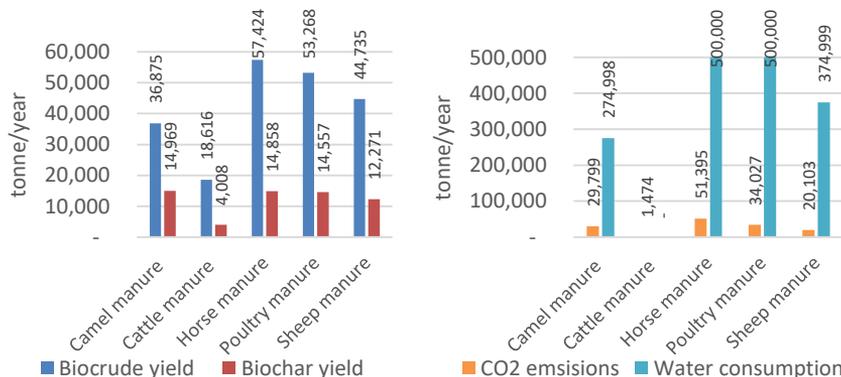

Figure 2. HTL process yield and environmental burden for different manure feedstocks.

3.2. Optimisation model

As indicated in the previous section, different livestock manure feedstocks are associated with distinct product distributions and exert different levels of burden on the environment. As such, considering the technical and environmental aspects of the HTL process, the optimisation model to investigate the optimal blending ratios of manures generated the results presented in **Figure 3**.

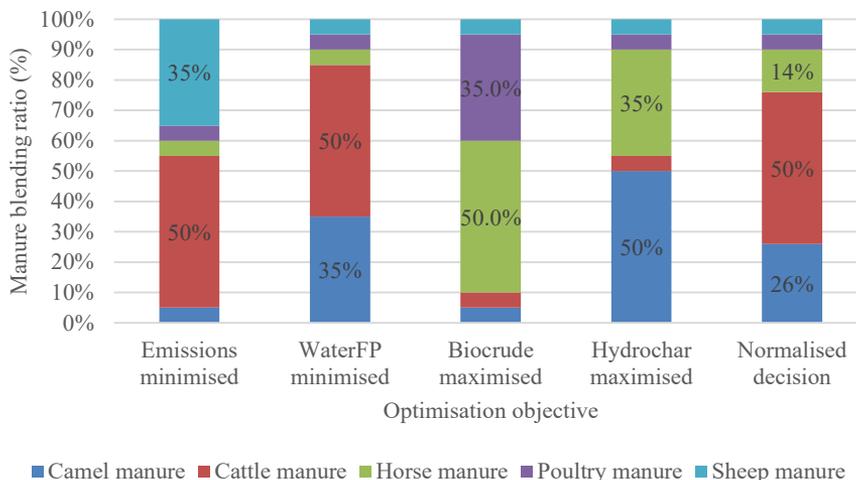

Figure 3. Optimal manures blending ratio considering different objectives.

As far as emissions reduction is concerned, cattle manure and sheep manure are granted 50% and 35% shares, respectively. Whereas the remaining three manures are given the minimum 5% threshold blending ratio. While to minimise the water consumption, both cattle manure and camel manure were selected with 50% and 35% blending ratios, respectively. However, to fulfill the yield objective, the model suggested horse and poultry manures be mainly used to maximise biocrude yield, while the model suggested mainly involving camel manures and horse manures for optimal hydrochar generation. Nevertheless, the weighted normalised decision metric indicated an optimal blending ratio of 50%, 26%, 14%, 5%, and 5% for cattle, camel, horse, poultry, and sheep manures respectively, which is believed to relatively fulfill all four objectives. The said blending ratio results in 31,765 tonne/year of biocrude and 9,289 tonne/year hydrochar, while the system in this scenario consumes 184 ktonne of water and produces 18 ktonne of CO₂.

4. Conclusion

In this study, the influence of different livestock manures feedstocks on HTL process yield and the environmental burden is modeled and studied in ASPEN PLUS. Whereas the optimal blend of different manures is investigated with respect to four objectives including, maximising biocrude and biochar yield and minimising water consumption and CO₂ emissions. The final weighted normalised decision metric suggested the optimal manures blend to be (50%, 26%, 14%, 5%, 5%) for cattle, camel, horse, poultry, and sheep manures respectively. While this study provides an insight on the impact of different feedstock on process efficiencies, it is to be expanded by considering the economic aspect of different blending scenarios, as well as the availability of different manures.

Abstract

This work considers the problem of minimizing economic losses due to system-wide production systems, where different subsystems share hard coupling constraints. The hard coupling constraints need to be tightly controlled, and it is important that it is done in a way that the overall system remains close to optimal in the time it takes for the much slower optimization layer to implement the required input changes. The particular application that we study is a large-scale subsea gas-lifted oil production network, where different subsystems have a local objective and the shared constraint can be a common compressor, but the method has general applicability to any system with time-scale separation between control and optimization layers.

Keywords: Production Optimization, Self-optimizing Control, Active Constraint Control.

1. Introduction

Determining optimal operation of a large and complex process and production system, such as an oil and gas production system, is a challenging task. Decomposing the process into several subprocesses/subsystems is usually recommended since optimizing a small system is practically less complex. Thus, decomposition strategy requires each local process system/cluster/subsystem to have a local optimizer to ensure local optimal process operation. This decomposition strategy is also responsible for coordinating these subsystems to achieve system-wide optimal process operation. The optimal process operation involves making decisions in real-time to meet production goals. This is typically done in the context of real-time optimization (RTO) using process models and real-time measurements. RTO is developed based on mathematical concepts, and with it, production performance improved.

In the 80s, there was an increasing interest in replacing model-based numerical solvers with a simple feedback loop, named feedback-optimizing control. The idea is to translate the economic objective into process control objective by finding a function of the controlled variables (CVs), and when it is held constant, it leads to the optimal adjustment of the manipulated variables (MVs) (Morari et al., 1980). Twenty years later, Skogestad (2000) introduced the concept of self-optimizing control (SOC). In SOC, when the optimum lies at some constraints, we use active constraint control where the available MVs tightly control the constrained variables. The idea of tight active constraint control is one of the primary motivations of this work to ensure the feasibility and obtain a (near-) optimal process operation.

2. Problem Statement

Consider the following steady-state optimization problem of N different subsystems.

$$\min_{\mathbf{u}} J(\mathbf{u}, \mathbf{d}) = \sum_{i=1}^N J_i(\mathbf{u}_i, \mathbf{d}_i) \quad (1a)$$

$$s. t. \quad g(\mathbf{u}, \mathbf{d}) \leq \mathbf{0} \quad (1b)$$

where $\mathbf{u}_i \in \mathbb{R}^{n_{\mathbf{u}_i}}$ denotes the MVs for subsystem i , $n_{\mathbf{u}_i}$ is the number of MVs in subsystem i , and $\mathbf{u} = [\mathbf{u}_1 \ \dots \ \mathbf{u}_N]^T$, $\mathbf{d}_i \in \mathbb{R}^{n_{\mathbf{d}_i}}$ denotes the disturbances in subsystem i , $n_{\mathbf{d}_i}$ is the number of disturbances in subsystem i , and $\mathbf{d} = [\mathbf{d}_1 \ \dots \ \mathbf{d}_N]^T$, $J_i: \mathbb{R}^{n_{\mathbf{u}_i}} \times \mathbb{R}^{n_{\mathbf{d}_i}} \rightarrow \mathbb{R}$ is a function denoting the local objective of subsystem i , $g: \mathbb{R}^{n_{\mathbf{u}}} \times \mathbb{R}^{n_{\mathbf{d}}} \rightarrow \mathbb{R}^{n_g}$ is a function denoting the inequality constraints. n_g is the number of constraints.

The Lagrangian function of problem (1) is

$$\mathcal{L}(\mathbf{u}, \mathbf{d}, \lambda) = \sum_{i=1}^N J_i(\mathbf{u}_i, \mathbf{d}_i) + \lambda^T g(\mathbf{u}, \mathbf{d}) \quad (2)$$

where $\lambda \in \mathbb{R}^{n_g}$ is the shadow price/ Lagrange multiplier of active constraints $g(\mathbf{u}, \mathbf{d})$.

The goal of problem (1) is to determine optimal MVs to achieve system-wide steady-state optimal operation. Our motivation is to solve problem (1) using a feedback control structure that handles changing active constraints.

One possible approach is primal-dual feedback-optimizing control that can eliminate the need for a numerical solver (Krishnamoorthy, 2020; Dirza et al., 2021). Moreover, this approach is flexible in handling active constraint changes. This method has a central coordinator acting as a central constraint controller in a slow timescale in the upper layer. However, this approach has no near-optimal performance strategy due to the non-performing upper layer. There are many practical reasons why the central constraint controller may fail to update the Lagrange multipliers. For example, when the disturbance occurs much faster than the sampling time of the central constraint controller. Another example is when constrained variables from a local system are not updated on time since the optimizer of the other local system may need a numerical solver. This solver requires time to solve the optimization problem. Having different types of local optimizers is normal since every subprocess is unique. In addition, having a central constraint controller in a very slow timescale leads to a longer transient. Constraint violation may occur during this transient. These imply that it is essential to have a good pairing of a (primal) MV to a constrained variable. Thus, “*a systematic pairing procedure is necessary to determine which MV should be paired with a constrained variable such that the pairing minimizes the loss most (near-optimal performance)*”. Finally, this procedure is necessary for selecting the primal MV in primal-dual with direct constraint control proposed by Dirza et al., 2022.

3. Systematic Pairing Formulation

To pair the constrained variables with the right MV, we propose a pairing procedure based on MV’s sensitivities to its local disturbances, assuming no saturation issues in the possible MVs, no back-off problem, and equal value of constraints - MVs gain.

Meanwhile, the remaining MVs control their self-optimizing control variables. To describe this proposal, we consider an Indirect control problem formulation.

Without losing the generality, we consider a case where we have two MVs (i.e., $u_1 \in \mathbb{R}^1$ and $u_2 \in \mathbb{R}^1$), and we want to control the gradient of the Lagrange function w.r.t its input, denoted by $\mathcal{L}_{\mathbf{u}}(\lambda, \mathbf{u}) \in \mathbb{R}^{2 \times 1}$, and the active constrained variable, denoted by $g(\mathbf{u}) \in \mathbb{R}^1$, where λ is Lagrange multiplier for constraint function $g(\mathbf{u})$, and $\mathbf{u} = [u_1 \ u_2]^T$. $\mathcal{L}_{\mathbf{u}}(\lambda, \mathbf{u})$ consists of $\mathcal{L}_{u_1}(\lambda, u_1) \in \mathbb{R}^1$ and $\mathcal{L}_{u_2}(\lambda, u_2) \in \mathbb{R}^1$.

Assume that we want to control the constrained variables tightly with u_2 , and we consider the disturbance, $\mathbf{d} \in \mathbb{R}^{2 \times 1}$, influences input u_2 . It could be the local disturbance of subsystem 2 or a change of u_2 caused by setpoint changing. This setpoint change may occur due to the changes in subsystem 1. Since λ is constant (due to the non-performing upper layer), and $g_{u_1}(u_1)$ is also in many cases (i.e., resource allocation), we only need to control $J_{u_1}(u_1)$. This formulation can be written as an indirect control problem as follows,

$$J_{u_1}(u_1) = G_{11}u_1 + G_{12}u_2 \quad (3a)$$

$$g(\mathbf{u}) = G_{21}u_1 + G_{22}u_2 \quad (3b)$$

$$u_2 = G_d d + \hat{u}_2 \quad (3c)$$

where G_{11} is the gain from u_1 to $J_{u_1}(u_1)$, G_{12} is the gain from u_2 to $J_{u_1}(u_1)$, G_{21} is the gain from u_1 to $g(\mathbf{u})$, G_{22} is the gain from u_2 to $g(\mathbf{u})$ and G_d is the disturbance gain that influences u_2 .

Fig. 1 illustrates this formulation, where we want to ‘tightly’ control $g(\mathbf{u})$ to reference r_2 directly using a direct constraint controller (DCC). In addition, we also want to find the right u_2 such that u_2 can also contribute to controlling $J_{u_1}(u_1)$ to reference r_1 indirectly or by pairing u_2 with $g(\mathbf{u})$. This control structure has a better ability to control $J_{u_1}(u_1)$ than the other possible structure.

We assume that G_{22} is square and invertible. Otherwise, we can replace the solution with the pseudoinverse. By rearranging Eq. 1 and assuming a ‘perfect’ control $g(\mathbf{u}) \approx r_2$, we obtain $J_{u_1}(u_1) \approx G_{12}G_{22}^{-1}r_2$. Thus, we must choose r_2 such that $r_2 \approx G_{22}G_{12}^{-1}r_1$. According to Skogestad and Postlethwaite (2005), $G_{12}G_{22}^{-1}$ should be small. Usually, it implies that we need to select the pairing that gives the largest G_{22} , where $G_{22} = \nabla_{u_2}g(\mathbf{u})$. However, based on this formulation, selecting the pairing based on G_{22} is insufficient. This formulation shows that we should also consider small G_{12} in addition to large G_{22} in the framework of primal-dual approach with direct constraint control, especially when we have faster disturbances (or non-performing upper layer). Selecting based on G_{12} is then essential and complementary to the common rule.

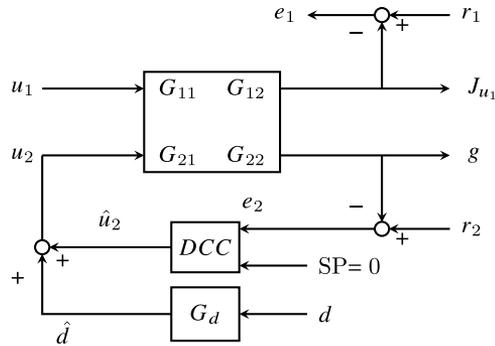

Figure 1: Indirect control problem formulation for systematic pairing

We consider these rules as a near-optimal performance strategy for the primal-dual with direct constraint controls framework (Dirza et. al., 2022).

Defining $\hat{d} = G_d d$, then $G_{12} \approx \frac{\Delta J_{u_1}}{\Delta u_2} \approx \frac{\Delta J_{u_1}}{\Delta(\hat{d} + \hat{u}_2)}$. If one keeps \hat{u}_2 at the same value to control $g(\mathbf{u})$, then a change in \hat{d} can represent any change. Considering Eq. 1c, then $G_{12} \approx \frac{\Delta J_{u_1}}{\Delta \hat{d}}$. Furthermore, assuming that the stationary point is at the local optimum and knowing that J_{u_1} is controlled by u_1 , and J_{u_2} is uncontrolled, then any disturbance on J_{u_1} leads to ΔJ_{u_2} (\mathcal{L}_{u_2} being drifted away from 0). It implies that any disturbance on J_{u_1} leads to the total profit loss ΔJ . Therefore, we can estimate G_{12} as $\frac{\Delta J}{\Delta \hat{d}}$ ($G_{12} \approx \frac{\Delta J}{\Delta \hat{d}}$).

4. Numerical Results

We demonstrate the presented rules in a subsea gas-lifted oil production optimization problem with a fixed gas lift compressor described in Dirza et al. (2022). Moreover, we consider a subsea gas-lifted oil production well network that consists of two wells to provide a better demonstration. Fig. 2 illustrates the case study.

The objective function is to maximize the oil production income while minimizing the cost of the gas lift. The optimization problem is as follows,

$$\min_{\mathbf{w}_{gl}} J = \sum_{i=1}^N (-p_{o,i} w_{po,i} + p_{gl,i} w_{gl,i}) \quad (4a)$$

$$s. t. \quad \mathbf{f}(\mathbf{x}, \mathbf{w}_{gl}, \mathbf{d}) = \mathbf{0} \quad (4b)$$

$$\mathbf{g}(\mathbf{x}, \mathbf{w}_{gl}, \mathbf{d}) \leq \mathbf{0} \quad (4c)$$

$$\mathbf{g}_s(\mathbf{x}, \mathbf{w}_{gl}, \mathbf{d}) = Pow_{gl} - Pow_{gl}^{max} \leq 0 \quad (4d)$$

where $p_{o,i}$, $p_{gl,i}$, and $w_{po,i}$ are the price of produced oil, the cost of gas-lift, and the oil production rate of well i , respectively. Pow_{gl} is the total power consumed by a fixed compressor to inject the sum of gas-lift rate i , and Pow_{gl}^{max} is the maximum available power. The vector $\mathbf{x} \in \mathbb{R}^{n_x}$, and $\mathbf{d} \in \mathbb{R}^{n_d}$ are the vectors of states, and disturbance (i.e., gas-oil ratio) for the entire system. n_x is the number of states. $\mathbf{w}_{gl} \in \mathbb{R}^{n_{w_{gl}}}$ is the vector of inputs for the entire system, where $\mathbf{w}_{gl} = [w_{gl,1} \ \dots \ w_{gl,N}]^T$. Constraint (4b) and (4c) represent model and physical constraints, respectively. We assume that Constraint (4c) is locally managed to maintain the focus of the discussion. Eq. (4a) is additively separable, and eq. (4d) is a linear and hard constraint. The total gas lift rate is supplied by a fixed-efficiency gas lift compressor.

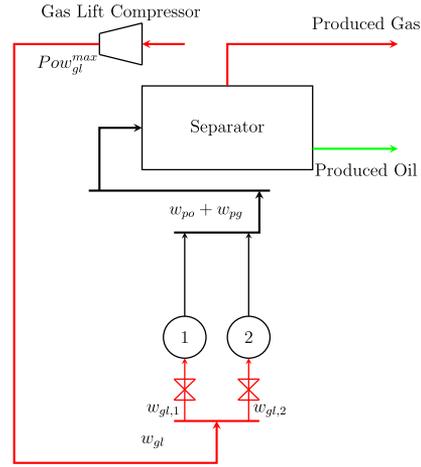

Figure 2: Field illustration

The simulation considers a case where we have a non-performing upper layer (λ is not updated). We show the numerical results of the presented near-optimal performance strategy (Structure 1). As a benchmark, we also show the results of the asynchronous protocol (Structure 0), that the local controllers keep controlling the gradient of the Lagrange function w.r.t input to 0, given any value of the

Lagrange multipliers from the central constraint controllers. In addition, we also show the results of another possible structure (Structure 2).

We solve the steady-state optimization problem (4) to obtain the ‘true’ optimal cost for any considered disturbance cases. We assume that based on historical data, the largest possible error of the disturbance is $\pm 5\%$. The (profit-) loss is the difference between the steady-state cost of structure j to the optimal cost, which can be expressed mathematically as $\Delta J_j = J_j - J^*$, where j is the index of the structure (*i. e.*, $j \in \{0,1,2\}$).

First, we simulate for any possible largest error for Structure 0. The simulation shows that the above case study experiences the largest possible disturbance that happens sequentially starting from $GOR_1 + 5\%$, $GOR_1 - 5\%$, $GOR_2 + 5\%$, $GOR_2 - 5\%$, $Pow_{gl}^{max} + 5\%$, and finally $Pow_{gl}^{max} - 5\%$.

As it can be seen in Fig. 3, Structure 0 fails to satisfy steady-state constraint when either GOR_1 , GOR_2 , or Pow_{gl}^{max} decreases 5% (see time window 18-32 hr, 48-62 hr, and 78-90 hr), which validates the necessity to have a near-optimal strategy in the primal-dual approach.

As mentioned in Section 3, the first general rule is pairing input and active constraint with the largest $G_{22,j} = \nabla_{w_{gl,j}} \mathbf{g}_s(\mathbf{x}, \mathbf{w}_{gl}, \mathbf{d})$. Based on this definition, $G_{22,1} = 3.6740$, and $G_{22,2} = 3.6740$, which corresponds to the assumption of equal value of constraints - MVs gain. This also validates the necessity to have an additional rule to select the pairing that gives the most economic-oriented result.

The additional rule is pairing input and active constraint with the smallest $G_{12,j}$, which one can estimate by calculating $\frac{\Delta J_j}{\Delta GOR_j}$ using the finite difference method. The obtained result is that the smallest $G_{12,1}$ is 1.4441, and the smallest $G_{12,2}$ is 1.4642. According to

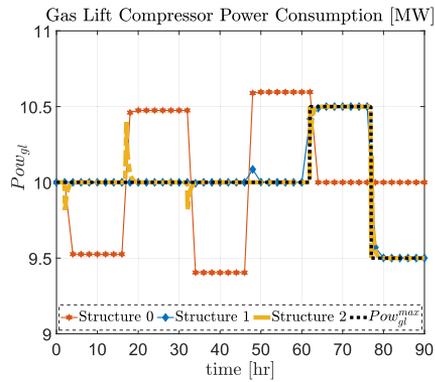

Figure 3: Steady-state constraint satisfaction

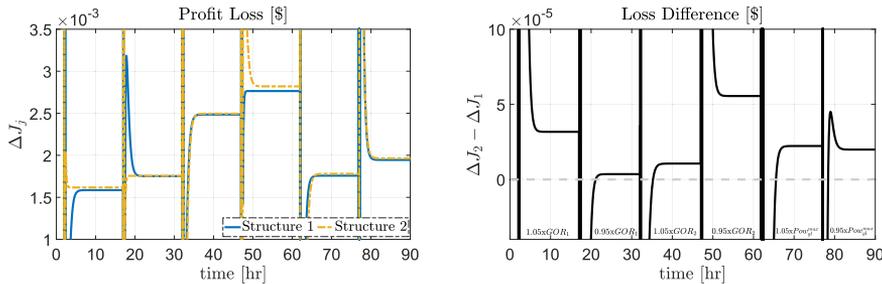

Figure 4: Left figure: Profit loss comparison. Right figure: Loss difference between Structure 1 and Structure 2.

the presented method in Section 3, this result indicates that the most economic-oriented pairing is Structure 1, where we pair the active constraint with $w_{gl,2}$.

Fig. 4 shows the profit loss comparison between Structure 1 and Structure 2, and the right figure shows that, at any possible extreme disturbance, Structure 1 can minimize more the steady-state loss than Structure 2. Additionally, Tab. 1 shows the steady-state profit loss for 24 hours with different extreme disturbance cases.

Table 1: Steady-state profit loss for 24 hours

Structure	GOR_1		GOR_2		Pow_{gl}^{max}	
	+5%	-5%	+5%	-5%	+5%	-5%
0	630.7200	sscv*	751.6800	sscv*	656.6400	sscv*
1	136.3423	151.6720	214.7048	238.8445	151.4331	168.2676
2	139.7161	151.6730	215.0000	243.8771	153.3618	169.9576

sscv*: steady-state constraint violation.

5. Conclusion

In this paper, we have shown that the proposed rule (smallest G_{12}) is complementary to the existing pairing rule (largest G_{22}), especially in the framework of the primal-dual approach. This systematic pairing selection procedure can assist the designer in pairing for economic-oriented constraint control in the primal-dual with direct constraint controls. In addition, this procedure can minimize steady-state loss in the primal-dual framework when we have a non-performing upper layer.

Quality assessment for dynamic, hybrid semi-parametric state observers

Isabell Viedt,^a Jonathan Mädler,^a Leon Urbas^a

^a*Technische Universität Dresden, 01062 Dresden, Germany*

isabell.viedt@tu-dresden.de

Abstract

In modular plants, quality of methods and models must be specifiable, automatically testable and certifiable, if they are increasingly integrated into equipment as a product and an added value. Since the underlying processes are often not completely understood, hybrid and data-driven methods are a promising approach to combine process knowledge and process data for more reliable simulation models. In this paper, the conducted quality assessment utilizes the framework proposed by Mädler et al. (2021) for quality assurance applied to hybrid models. The quality model is revised to include quality factors, criteria and metrics for dynamic, hybrid semi-parametric simulation models. A state observer for the estimation of key process parameters during fermentation is presented as a use case. For this three hybrid models of the fermentation with differing levels of detail are identified and coupled with an extended Kalman filter (EKF). It was found that the quality model can successfully be used to assess quality differences in different types of state observers. The quality model allows a structured and quick assessment and is therefore able to show e.g. the performance improvement of the different hybrid models coupled with an EKF. With the transfer of the quality model to hybrid state observers a broader range of simulations models can be assessed within the framework.

Keywords: Quality assessment, hybrid semi-parametric models, state observer.

1. Introduction

Simulation models as part of software and further as part of smart equipment are envisioned to become increasingly important for smart, modern plant as part of the 4th industrial revolution. Soft sensors or model predictive controllers will be essential parts of the process control and optimization (Kadlec et al., 2009). The quality of those simulation models must be specifiable, automatically testable and certifiable, if they are increasingly integrated into smart equipment. In this context, hybrid modeling approaches are an increasingly popular trend to combine knowledge- and data-driven modeling which makes the models more reliable and precise (Glasse & von Stosch, 2018). With this, it is not only important to assure the quality and correctness of the first principles approach but also process data has to be quality assured.

The remainder of the paper is structured as follows. Section 2 introduces current methods for quality assessment of simulation models and applies it to hybrid, semi-parametric models. In section 3 the case study for the quality assessment in accordance to Mädler et al. (2021) is presented and evaluated in section 4. Section 6 provides a conclusion and further research potential.

2. State of the Art

2.1. Quality assessment of simulation models

To assess the quality of simulation models, different strategies exist in literature (Murray-Smith, 2015). The most commonly used ones are the methods for verification and validation (V&V) presented by Balci and Sargent (Sargent & Balci, 2017). Although the V&V methods provide a wide spectrum of assessment methods, they mainly focus on model accuracy. Sargent and Balci (2017) find that many simulation studies do not consequently apply V&V methods or even disregard them. Therefore, Mädler et al. (2021) discuss the applicability of quality assurance methods from software development to simulation models. To make software quality itself measurable and testable, quality assessment strategies from software development like test-driven-development and quality models in form of FCM models are applied. FCM stands for factor (F), criterion (C) and metric (M). Factors describe the desired abstract attributes of the software.

2.2. Dynamic, hybrid semi-parametric models

With the expansion of the framework presented in Mädler et al. (2021) to the field of hybrid state observers, a short introduction to gray-box modeling, and here specifically dynamic hybrid, semi-parametric models, is given. An overview on hybrid, semi-parametric simulation is shown in Figure 1. Mechanistic models represent a broad class of more transparent models that are usually based on e.g. conservation laws (Glassey & von Stosch, 2018). In contrast, data-driven modeling represents a less transparent modeling framework based exclusively on process data (Glassey & von Stosch, 2018).

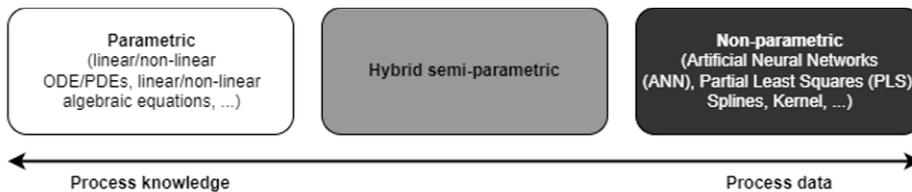

Figure 1: Hybrid, semi-parametric models.

Hybrid semi-parametric models are an example of those gray-box models and combine model structures that are parametric and non-parametric sub-models based on different knowledge sources. Hybrid semi-parametric models have several advantages over traditional mechanistic or data-driven modeling (Bae et al., 2020). Some widely recognized advantages in academia and industry are a broader knowledge base, the transparency of the modeling approach and cost-effective model development (Glassey & von Stosch, 2018). Especially for complex process simulation, a hybrid approach is able to achieve a more accurate and robust estimation (Bae et al., 2020). Existing process data can be used in gray-box models as ML or AI algorithms bridge gaps in the mechanistic modeling approach (Glassey & von Stosch, 2018).

2.3. Functional quality assessment of hybrid, semi-parametric models

When regarding the quality of hybrid semi-parametric models, the structure that combines aspects of parametric and non-parametric modeling has to be considered. So therefore not only quality and correctness of the first principles approach but also the data for non-parametric components of the model have to be equally quality assured. In case of simulation model for smart equipment, the simulation models will rely on continuous integration and continuous deployment strategies (CI/CD) (c.f. Bruckner et al., 2020), which require a high level of transparency and an overview over the quality advancement with time. As presented in Mädler et al. (2021) the first step within the model

development should always be the specification of the purpose and the corresponding requirements. In the next step, a generic FCM model must be adapted or modified regarding the stated purpose. For this framework, the factors and criteria specified within ISO/IEC 25010 are the basis for the generic FCM model. For hybrid models, the adapted FCM model must contain factors, criteria and metrics to equally assess the parametric and non-parametric sub-models (Bae et al., 2020). After determining the target ranges and values for the metrics, the model building can begin. Using the FCM model, the development and quality advancement of the model is tested continuously. If the simulation model fulfills the targets, the user can exit model development successfully.

3. Case study

With the following case study, the framework for quality assessment of hybrid, semi-parametric simulation models is evaluated. The underlying process of the simulation model for the case study is a baker's yeast fermentation and is used for online estimation of biomass concentration c_x and substrate concentration c_s during the process (c.f. de Azevedo et al., 1997) in form of a hybrid state observer.

3.1. Baker's Yeast Fermentation

The underlying process for the use case is a baker's yeast fermentation. The estimated process parameters are in this case the biomass concentration. This process parameter is good quality indicator for the biochemical process of fermentation (De Azevedo et al., 1997). The mechanistic model for the baker's yeast fermentation is obtained from mass balances for all components. The relevant set of model equation for the process of fermentation is shown in the following:

$$\frac{dc_x}{dt} = -\frac{\dot{V}}{V}c_x + (\mu_s^o + \mu_s^r + \mu_E^o)c_x \quad (1)$$

$$\frac{dc_s}{dt} = \frac{\dot{V}}{V}(c_{s,in} - c_s) + \left(-\frac{\mu_s^o}{Y_{X/S}^o} - \frac{\mu_s^r}{Y_{X/S}^r}\right)c_x \quad (2)$$

$$\frac{dc_E}{dt} = -\frac{\dot{V}}{V}c_E + \left(\frac{\mu_s^r}{Y_{X/E}^r} - \frac{\mu_E^o}{Y_{X/E}^{oE}}\right)c_x \quad (3)$$

$$\frac{dc_{O_2}}{dt} = -\frac{\dot{V}}{V}c_{O_2} - OUR + OTR \quad (4)$$

Further, the model includes the oxygen transfer rate (OTR) and the oxygen uptake rate (OUR). For the hybrid, semi-parametric approach of the use case of the case study two different hybrid semi-parametric models are identified. These models combine the parametric approach of the model equations (1) – (4) for the fermentation with a non-parametric approach for the estimation of the specific growth rates $(\mu_s^o, \mu_s^r, \mu_E^o)$. The growth rates are estimated via existing process data.

3.2. Use case

The estimation of the biomass concentration is implemented as a soft sensor which is structured as a non-linear state observer with the state tracking by means of an EKF with the state transition achieved through the hybrid models presented (Auger et al., 2013) in section 3.1. This soft sensor is envisioned to be used in a smart fermenter module during the learning and application phase of the equipment and is shown in figure 2. The use case is the process monitoring (PM) or possibly also online prediction (OP) (Kadlec et al., 2009) of critical process parameters. To achieve the online estimation, the state estimation algorithm of the EKF uses the online measurements of the oxygen

concentration (c_{O_2}) and the carbon dioxide evolution rate (CER). The hybrid state observer structure is shown in figure 2.

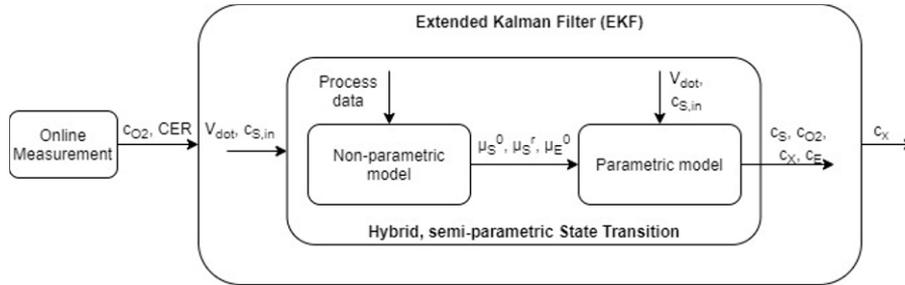

Figure 2: Structure of the hybrid state observer for estimation of biomass concentration.

To show how CI/CD in modular plants (MPs) is applied, the case study shows a fitting of the simulation model in an iterative identification process that represent different quality levels of the state observer. For this, the hybrid model is identified and further quality assessed. After that the actual performance of the soft sensor is compared to the prediction of the quality metric for the simulation model and adapted accordingly. The metrics are able to predict how good the soft sensor will be during operation. The individual cases of the case study are designed to emulate quality differences in the evaluated simulation models and are used to assess the usefulness and accuracy of the semi-automated assessment framework for hybrid semi-parametric simulation models. For the case study, Case 1 will be the version of the state observer that uses the first iteration of the hybrid model for the state transition in the EKF algorithm. To emulate quality differences in the models, different aspects of the model can be modified in the hybrid model. This can be achieved by increasing the noise in the data but also in reducing the size of the data sets or injecting faults into the sets (Kadlec et al., 2009), which affects the accuracy of the non-parametric estimation of the specific growth rates. Inaccurate model parameters, which in this use case is intentional, lead to a less accurate prediction of the model (Case 2). In comparison, Case 3 shows the best quality hybrid model, after two iterations.

3.3. Specified quality model and relevant metrics

To evaluate the quality of the hybrid simulation model, the generic FMC model has to be adapted to the model use case (Table 1). The quality factor functional suitability is described by the criteria functional correctness, appropriateness and completeness. Relevant metrics for the criterion functional correctness are the coefficient of determination (R^2) and the number of domain violations. Another important metric for state observers and is the difference between estimated and measured values (RMSE - Root Mean Square Error), which covers the criterion functional appropriateness. The criterion functional completeness is evaluated by the coverage metric and the model structure metric. The coverage metric describes how the modeling data covers the validity domain of the black-box sub-model and therefore the data quality (Mädler et al., 2021). For the factor reliability the criterion fault tolerance is considered. The corresponding metrics evaluate the model prediction. The metric outlier frequency describes the consistency of the estimated values, which is classified through MAD (Median Absolute Deviation) filter with moving window for more accurate detection. The metric tolerance to fault injection describes how the model reacts to incorrect inputs, which emulates fluctuations during the plant operation. For hybrid models, the metrics have to be able to evaluate both parts of the model. For example, the coverage metric and the data consistency metric can only be applied to the part of the model that is data-driven. Metrics

like the RMSE or R^2 assess the overall quality of the simulation model by evaluating the entire model prediction.

Table 1: FCM model for the quality assessment of hybrid simulation models.

Factor	Criterion	Metric	Equation	Classification	Source
Functional Suitability	Functional Correctness	Prediction consistency	R^2 (determination coefficient)	Prediction quality	Roungas et al, 2017
		Domain violations	Characteristic process boundaries	Prediction quality	Sargent & Balci, 2017
	Functional Appropriateness	Prediction accuracy	RMSE (Root Mean Square Error)	Prediction quality	Montgomery & Runger, 2010
	Functional Completeness	Coverage	Convex hull criterion	Data quality	Mädler et al, 2021
		Model components	Model requirements	Model structure quality	Sargent & Balci, 2017
Reliability	Fault Tolerance	Outlier frequency	MAD filter with moving window	Prediction quality	Roungas et al., 2008
		Data consistency	Error ratio	Data quality	Heinrich et al., 2018
		Fault injection tolerance	Tolerance to fault injection	Prediction quality	Roungas et al., 2008

4. Results and discussion

The quality assessment framework was able to distinguish between the quality differences in the simulation model of the case study. The results, ratings from 0 (insufficient) to 10 (excellent), for the considered metrics during assessment are shown in Table 2.

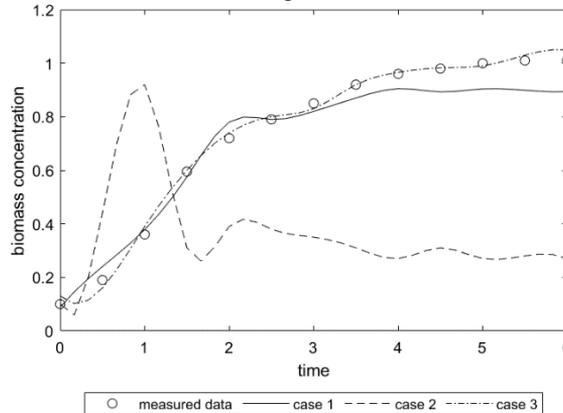

Figure 3: State estimation of the four soft sensors resulting from Case 1 -3.

The assessment shows that the quality model allows easy and automated quality assessment of different model types. With the assessed quality differences in the hybrid, semi-parametric models, the quality of the resulting soft sensor can be predicted. Figure 3 shows the estimation of the biomass concentration with the resulting soft sensors in comparison to measured data. For now, the quality model for the quality assessment only considers the quality factors functional suitability and reliability. In further work it must be expanded to contain factors and criteria to assess attributes like portability, maintainability and performance efficiency of the simulation models to fit the use case of simulation models in smart equipment better. It is envisioned that those simulation models or software components are to be reused in different process scenarios with only minimal necessary adaption.

Table 2: Results of the case study for the model quality.

Factor	Criterion	Metric	Case 1	Case 2	Case 3
Functional Suitability	Functional Correctness	Prediction consistency	8	7	9
		Domain violations	10	3	10
	Functional Appropriateness	Prediction accuracy	8	6	10
	Functional Completeness	Coverage	9	8	9
Reliability	Fault Tolerance	Model components	10	10	10
		Outlier frequency	8	6	10
		Data consistency	8	4	9
		Fault injection tolerance	5	3	8
Aggregated model rating			7,92	5,50	9,38

5. Conclusion

In this paper, the authors show how the in Mädler et al. (2021) presented framework for functional quality assessment can be transferred to dynamic, hybrid semi-parametric state observers. Additional requirements that are necessary for the assessment of dynamic, hybrid semi-parametric models were introduced into the framework. It therefore shows that the generic quality model can easily be adapted and expanded to a new use case and is able to show e.g. the performance improvement of a hybrid state observer over time when the EKF algorithm is coupled with hybrid, semi-parametric model. The flexibility of the generic structure of the quality model allows an easy combinations of metrics that target different parts of the simulation model and make an inclusive view on quality possible. In future work, the quality model must be expanded by further quality factors. The quality assessment must also include factors like portability, performance efficiency and compatibility to meet the requirements for the flexible MP structure.

Abstract

The optimal design of chemical processes is of essential importance for an increased sustainability. However, the resulting non-convex mixed-integer nonlinear programming (MINLP) problems cannot directly be solved to global optimality. Therefore, different alternatives have been proposed, which either build on the application of a simulation-based optimization by means of a metaheuristic or the global optimization of a surrogate model, both requiring extensive simulations. The current work proposes a novel alternative approach for a surrogate-assisted hybrid optimization, which exploits a local deterministic optimization of a full MINLP problem to generate a compact artificial neural network (ANN) model that allows for the direct optimization on a reduced search space. In order to provide a sufficient accuracy of the ANN while targeting the global optimum of the design problem, a tailored mixed adaptive sampling is introduced. Application of the algorithm is illustrated for the optimal design of a distillation-based separation of benzene, toluene, and xylene with different means for energy integration.

Keywords: optimization, artificial neural networks, distillation, energy integration, sampling

1. Introduction

Since downstream processes account for 40 - 90% of the overall expenditures of most chemical plants (de Haan et al., 2020), notably optimization-based design methods for distillation-based processes have received considerable attention. However, the resulting non-convex mixed-integer nonlinear programming (MINLP) problems are usually solved by local optimization techniques, especially in case of rigorous thermodynamic models. To overcome this limitation, different strategies were recently reported, applying machine learning methods for the generation of accurate surrogate models, such as Gaussian processes and artificial neural networks (ANNs), to replace complex parts of the original process model (Nentwich and Engell, 2019) or the overall column models (McBride et al., 2020). Global optimization of ANNs in a reduced-space formulation allows for direct evaluation of full process flowsheets (Schweidtmann et al., 2019). Yet, the application of such methods mandates numerically robust simulation models, some penalizing strategy for constraint violations, and an efficient sampling of the search space, which usually requires a significant number of samples.

The current contribution proposes a different application of ANNs to effectively exploit the reduced search space that is offered by the integration of an efficient local deterministic optimization approach. The ANN creates a mapping of the initial values for a subset of the overall design vari-

ables to verified local optima, which already satisfy all equality and inequality constraints. This results in a significant contraction of the design space and allows for an effective search of the global optimum. The applicability of the ANN-based approach with an adaptive sampling strategy is first verified on several test functions, while the hybrid algorithm is successfully applied to the design of a distillation-based separation of benzene, toluene, and xylene considering different options for energy integration.

2. Methodology

The novel surrogate-assisted optimization procedure comprises a two-level hybrid approach. The lower level is a local deterministic optimization, which solves a full MINLP problem. The top level is an ANN including an adaptive sampling procedure to ensure valid results as well as few sampling points. The structure of the hybrid approach builds on the concept of the memetic algorithm proposed by Skiborowski et al. (2015a), which connects an evolutionary algorithm (EA) and a local deterministic optimization. An overview of the current procedure is depicted in Figure 1, while the main parts are described in the following subsections.

2.1. Artificial Neural Network

As ANN, a multilayer perceptron (MLP) is used to guide the optimal selection of initial values for the local deterministic optimization. Therefore, the MLP maps the initial values to the objective function of the local optimization. In general, the MLP can treat continuous as well as ordinal and nominal integer variables as a simple input vector and processes these through the hidden layers towards a desired output. Since there is no ordered relationship for nominal decision variables, a binary input variable b_i for each decision is considered, according to the concept of one-hot encoding.

For the currently considered case study, which addresses the optimization of a potentially energy-integrated direct column sequence, the input variables comprise the initial number of stages and the feed stage of each column in the superstructure model for the local optimization as well as the decision for the energy integration option, which is treated as four different binary decision inputs (cf. Figure 2). The output represents the total annualized costs (TAC) of the locally optimized process.

The MLP consists of two hidden layers with each neuron having a hyperbolic tangent sigmoid transfer function. As training algorithm, the Levenberg-Marquardt algorithm with Bayesian regularization is used. These specifications were derived based on preliminary tests with a test data set for the column sequence case study. The training and sampling mechanisms, i.e., the top-level of the hybrid optimization approach, are implemented in MATLAB® 2020b with the use of the Deep Learning Toolbox™14.1.

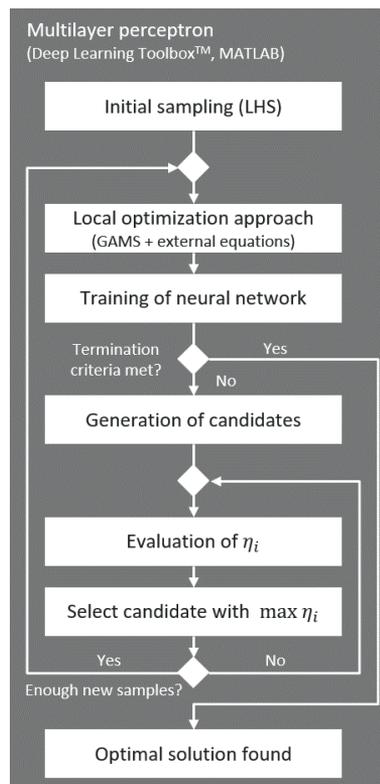

Figure 1: Overview of the surrogate-assisted optimization approach.

2.2. Mixed adaptive sampling

In this work, a mixed adaptive sampling method is applied to generate a reliable model based on the evaluation of the local optimization problems. The overall goal is to gain confidence in the generated results by the local optimization and, at the same time, reduce the number of necessary function evaluations while keeping an adequate model accuracy.

The initial sample points are determined by Latin hypercube sampling (LHS). To ensure that feed locations are within the selected number of column stages, the latter are prioritized and the feed location is considered as a function of the total number of stages. Furthermore, the vertices of the design space are always included in the training set while all other data points are randomly distributed to the training, validation, and test set, in ratios of 80%, 10%, and 10%, respectively.

The subsequently applied mixed adaptive sampling approach successively adds a relative amount of sampling points compared to the already existing samples to the set. In order to select new sampling points, 10,000 candidates are generated by LHS and evaluated based on a combination of different evaluation criteria. The current approach combines the mixed adaptive sampling approach of Eason and Cremaschi (2014), which considers the normalized Euclidean distance ($d_i/d_{i,max}$) as a space filling metric and the normalized jackknife variance ($s_i/s_{i,max}$) as a measure for the model uncertainty, with a normalized expression of the expected improvement criteria EI^{norm} according to Jones et al. (1998), with

$$EI_i^{norm} = \frac{EI_i - \min_i EI_i}{\max_i EI_i - \min_i EI_i}, \quad (1)$$

$$EI_i = (f_{min} - \hat{y}_i) \cdot \Phi\left(\frac{f_{min} - \hat{y}_i}{s_i}\right) + s_i \cdot \phi\left(\frac{f_{min} - \hat{y}_i}{s_i}\right), \quad (2)$$

where f_{min} is the current minimal value of the sampling set, \hat{y}_i is the MLP output at point i , and s_i is the jackknife standard deviation. $\Phi(\cdot)$ and $\phi(\cdot)$ are the standard normal distribution and density function, respectively. The first contribution increases with decreasing predicted values \hat{y}_i while the second contribution increases with increasing standard deviations s_i for the predicted values (Jiang et al., 2020). The resulting combined evaluation criterion

$$\eta_i = \frac{d_i}{d_{i,max}} + \frac{s_i^2}{s_{i,max}} + \cdot EI_i^{norm} \quad (3)$$

provides an effective sampling with a balance between exploration and exploitation of the design space.

The EI criterion favors minima of the predicted target function while maintaining a measure for the prediction uncertainty. This ensures a sufficient accuracy of the surrogate model even if the first two contributions of η_i get outweighed by the EI criterion. After each iteration of the adaptive

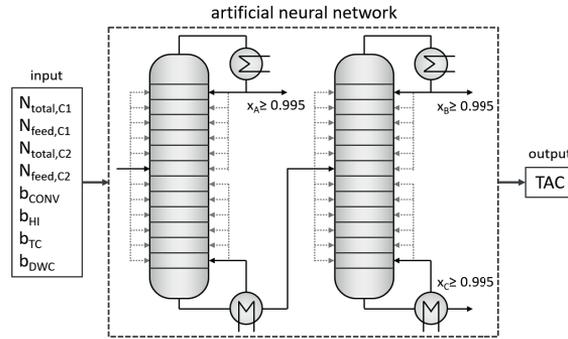

Figure 2: Superstructure of a direct column sequence for three-product separation.

sampling, the termination criteria of the algorithm are checked, i.e., the change in the objective function of the sampling set, the maximum number of iterations, and the maximum number of sample points.

2.3. Local deterministic optimization

By solving a local deterministic optimization problem instead of a simulation problem, the design space of the upper ANN is effectively reduced. For this purpose, a superstructure optimization problem needs to be solved to local optimality. For the current case study, an equilibrium-stage column model with additional correlations for column sizing and costing is solved. The according superstructure for the column sequence is illustrated in Figure 2. The corresponding MINLP problem is solved as a series of successively relaxed nonlinear programming (NLP) problems Skiborowski et al. (2015b) with additional modifications for heat integration, thermal coupling, and an integration of the latter as dividing wall column Waltermann et al. (2020). The local optimization model is implemented in GAMS 34.3.0 and the resulting NLP problems are solved with SNOPT.

3. Results

Prior to the application for the process design example, the functionality of the mixed adaptive sampling is evaluated for simple test functions. Subsequently, the results for the purification of a mixture containing benzene, toluene, and xylene are presented.

3.1. Validation of sampling procedure

To evaluate the functionality of the mixed adaptive sampling approach, three test functions for global optimization, i.e., the Ackley function (Ackley, 1987), MATLAB's Peaks function (Eason and Cremaschi, 2014), and the Six Hump Camel Back function (Floudas et al., 1999), are considered. All test functions have two input variables $x, y \in [-2, 2]$ and one output variable z . For this purpose, a simple MLP is used with a single hidden layer with 15 neurons.

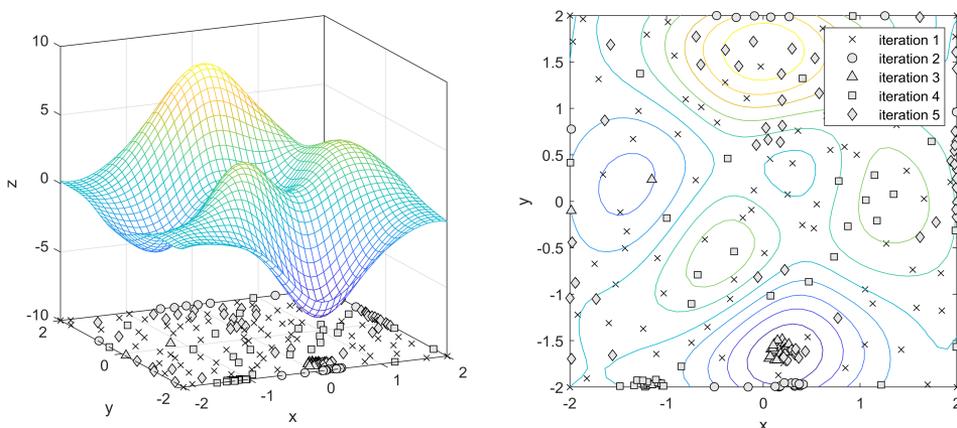

Figure 3: Response surface of the artificial neural network (ANN) representing the Peaks function after five iterations including the sampling locations (left). To increase the clarity, the sample points were added in the $z = -10$ plane and not on the response surface. Corresponding design space representation with contour lines including sampling locations (right).

The representative results for the Peaks function are illustrated in Figure 3. Similar to the work of Eason and Cremaschi (2014), the initial sampling comprised 80 samples followed by a sampling rate of 30% for all consecutive iterations. After five iterations, the response surface of the MLP has an overall mean squared error of about 0.01 but shows a sufficient model accuracy. Especially, the area of the global minimum is tightly covered, which is further highlighted in the contour plot in Figure 3 focusing on iteration three and five. The global minimum is found with a deviation of only 0.015%. Interestingly, a lot of samples are also located on the edges of the design space, which is most likely caused by the tendency to reduce the model variance, while there is also a persistent distribution of samples in a space-filling manner. In conclusion, the mixed adaptive sampling procedures gives a good overall model regression while investigating areas around the potential global optimum to increase the model accuracy in a close vicinity.

3.2. Purification of benzene / toluene / xylene

For demonstration of the approach to optimal process design, the purification of a mixture of $10 \text{ mol}\cdot\text{s}^{-1}$ with 30 mol% benzene, 30 mol% toluene, and 40 mol% xylene into streams with purities of at least 99.5 mol% is investigated. The top-level ANN comprises eight input variables (cf. Figure 2) with $N_{total,C1}, N_{total,C2} \in [20, 80]$ and $N_{feed,C1}, N_{feed,C2} \in [5, N_{total} - 5]$, two hidden layers with five and three neurons, and one output, resulting in 67 parameters (weights and biases). The sampling procedure is carried out with 100 initial samples and a subsequent sampling rate of 25%. For the sake of clarity, Figure 4 (left) shows only the response surface in a reduced design space, illustrating the best solutions in terms of the initial total number of stages in column 1 ($N_{total,C1}$) and column 2 ($N_{total,C2}$) for the heat-integrated process, which is determined as the most economic process configuration. Figure 4 (right) illustrates the overall best solution found in the locally optimized sampling set as well as the feature values and the output of the MLP.

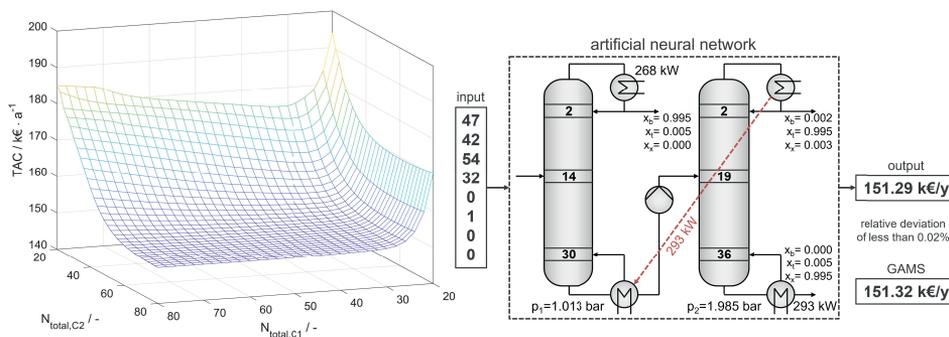

Figure 4: Minimal response surface of the artificial neural network (ANN) for the heat-integrated column sequence in a reduced design space of $N_{total,C1} \times N_{total,C2}$ (left) and the corresponding inputs and output of the ANN for the best found sampling candidate and its locally optimal objective value from GAMS (right).

As indicated in Figure 4 (right), the TAC of 151.32 $\text{k€}/\text{y}$ determined from the ANN is only 0.02% lower than the respective result of the local optimization. The global optimum of the response of the MLP can be determined by a full enumeration of the design space, indicating a potentially reduced objective function value of 149.94 $\text{k€}/\text{y}$, which is, however, less than 1% lower than the previously described local optima in GAMS. In addition to this confirmation of the local optimum, the response surface of the ANN also illustrates a flat optimum in the region of high initial tray numbers, indicating a comparably good convergence of the local optimization approach. While the presented approach does not provide a validation of the global optimum, the combination of local

optimization and the ANN improves the coverage of the design space and strengthens confidence in the quality of the determined solution. Furthermore, the evaluation of a total of 195 converged samples represents only a tiny fraction of the overall number of combinatorial options, which sum up to over 26 million considering the discrete design degrees of freedom that are represented by the features of the MLP.

4. Conclusion

The current work presents a new approach for surrogate-assisted hybrid optimization, which applies an artificial neural network for the regression of a local deterministic optimization approach. Combined with an effective mixed adaptive sampling based on the method of Eason and Cremaschi (2014) and the expected improvement criterion (Jones et al., 1998), an effective search for the global optimum can be conducted for process design problems with MINLP characteristics. The approach is successfully demonstrated for the optimization of a two-column process including different means for energy integration.

Further work will focus on the tuning of the employed hyperparameters, e.g., the architecture of the ANN, the termination criteria, the initial sampling as well as the sampling rate. Additionally, the three parts of the evaluation criterion of new samples can be weighed to actively adjust the ratio of exploration and exploitation in the progress of the iterations. An application to more complex case studies can reveal further advantages and disadvantages of the method and will be part of future research.

Abstract

Flexibility and mobility of modern value chains have created a need for continuous information exchange between involved chain parties. In such process industries, many companies share their manufacturing assets with each other and thereby allow partners to have control over them. In this way, some sensitive essential information about operations and control methods could be leaked from the asset supplier to the user and vice versa. Therefore, such information sharing raises confidentiality concerns between the service provider and its operator. The goal of this work is to apply and evaluate a confidentiality-preserving information sharing model for a time series use case in process industries. There are various ways to maintain privacy of the sensitive information, such as anonymization and encryption. To preserve control for the user and to allow data gathering by the vendor about asset operation, homomorphic encryption methods could be implemented. Homomorphic encryption allows for the preservation of confidentiality of the data while enabling computations on the encrypted data. The main focus of this study is an investigation of homomorphic encryption schemes with multiplicative properties, such as RSA and ElGamal, which can be applied to process data within information exchanges. This research investigates the probabilistic and the deterministic homomorphic algorithms with respective differences in encryption and decryption speeds. This approach is based on the simulation of the use case between asset vendor and asset operator. The confidentiality model of the information exchange sustains the zero-knowledge proof between involved value chain partners. The result implies the adaptability of both methods within the privacy-preserving sharing model. This study is limited to a use case with the application of partial homomorphic cryptosystems in process industries. The outcome highlights the statistical justification of the application of multiplicative homomorphic encryption (MHE) for confidentiality preservation.

Keywords: confidentiality, homomorphic encryption, value chains, process systems, secure information exchange

1. Introduction

Privacy and information security are crucial requisites in industrial systems. Many process systems, including networked and distributed control, could be subject to cyber security attacks. Through such attacks, the perpetrators seek to alter the measurements, steal transmitted information, cause harm to the system, or destabilize it. The perpetrators may also attempt to eavesdrop on time series data, what could help to identify the specific process and to develop an attack mechanism. Moreover, significant flows of sensitive

operation data transferred within supply chains via cloud networks between stakeholders can lead to breaches of information confidentiality.

The purpose of the privacy protection methods is to make the data unreadable and incomprehensible to certain readers or the intruders, whereas the intended recipient is able to decrypt the message. Information confidentiality can be secured using cryptosystems. Key management, computational complexity and resource limitations, random number generation, and the encryption of dynamic data could be recognized as the main challenges of current cryptographic schemes. One group of encryption methods is homomorphic encryption, which can perform computations on the encrypted data without their prior decryption. Here the focus is placed on public key cryptography algorithms, which can solve the problem of key arrangement between the system actors present in symmetric cryptosystems. Two examples of homomorphic encryption with multiplicative properties are ElGamal and RSA cryptosystems. ElGamal public key cryptosystem is based on the complexity of computing logarithms (ElGamal, 1985), whereas RSA (Rivest et al., 1983) is based on the complexity of factoring large integers.

2. Theoretical background

2.1. Multiplicative homomorphic encryption

Homomorphism refers to an encryption's ability to combine the ciphertexts so that they decrypt as if the plaintexts were combined. The procedures for the two homomorphic encryption algorithms with multiplicative properties are described below.

The **Rivest-Shamir-Adleman (RSA)** is an asymmetric cryptographic algorithm that is widely implemented in privacy preserving applications and for authentication of the digital information (Boneh, 1999), such as web traffic security, email encryption and signatures, electronic payment systems, etc. The algorithm is as follows.

Key generation: $n = p \cdot q$, where p and q are random prime numbers.

Totient: $\phi(n) = (p - 1)(q - 1)$.

$\text{gcd}(e, \phi(n)) = 1$ such that $1 < e < \phi(n)$ and e is co-prime to $\phi(n)$.

Congruence relation: $de \equiv 1 \pmod{\phi(n)}$, or $d = (1 + x \cdot \phi(n))/e$ to be an integer.

The *public key* is comprised of (n, e) .

The *private key* consists of p, q , and d .

Encryption: $c = m^e \pmod{n}$.

Decryption: $m = c^d \pmod{n}$.

The **ElGamal** encryption is a probabilistic algorithm of public key cryptography and is based on Diffie-Hellman key exchange. The protocol steps are listed below.

Key generation: publish a large prime p and the generator g of the group Z_p^* .

Compute $A = g^a \pmod{p}$, where $1 \leq a \leq p - 1$. The *public key* is (p, g, A) .

Encryption: choose k from $\{1, \dots, p - 1\}$ to compute the ciphertext:

$(c_1 = g^k \pmod{p}, c_2 = m \cdot A^k \pmod{p})$, where m is a message and $1 \leq m \leq p - 1$.

Decryption: compute inverse x^{-1} of $x = c_1^a \pmod{p}$, from which follows that $m = x^{-1} \cdot c_2 \pmod{p}$.

2.2. Related work

One of the applications of ElGamal encryption was implemented in a networked control system for protecting confidential information passed through devices (Kogiso, 2019). The parameters and signals of a discrete-time linear controller were encrypted to prevent reverse engineering, damage, or information theft. As a result, due to the homomorphic properties of the cryptosystem, the controller could compute the output using encrypted input parameters. Asymptotic stability improvements were performed by adding a dynamic encoder and decoder to the cryptosystem (Teranishi et al., 2020). Another

proposal for implementation of an ElGamal cryptosystem for voting in elections is presented in (Mikhail et al., 2014). The main idea is the secrecy of individual votes while allowing each individual only a single vote. Moreover, the system can exclude non-eligible voters and verify the real outcome. Thus, the tallying of votes can be performed using homomorphic encryption. Another application of MHE was found in protecting DNA data (Thangavel and Varalakshmi, 2018). The ElGamal cryptosystem is used to encrypt the data transmitted via cloud and manage the secure passing of keys between data owner and user. This enhanced implementation of the cryptosystem has an improved authentication and higher resistance to attacks. The RSA cryptosystems are used in cloud networks (Tebaa et al, 2012) and, despite its large computational time, the algorithm can maintain high levels of security.

2.3. Current contribution

The application of multiplicative homomorphic encryption could prove useful for information exchange within value creating chains. Such transfers of information can be observed within collaborations between production process partners. In such interactions, the physical assets and production data could be shared. However, not all parties are willing to fully disclose their process data, operation conditions, and process dynamics. Therefore, to establish a trusted environment and maintain privacy protection of process data or confidential computational formulas, the application of homomorphic encryption is proposed. The implementation of RSA and ElGamal cryptosystems for a use case in process industries is described below.

3. Methodology

3.1. Use case for MHE

Homomorphic cryptographic algorithms can be employed for confidentiality preservation of the information being computed, passed process inputs and outputs, and time-series data generated within production chain.

Much of the data and information transmitted in the process industries can be described by models containing the multiplicative relationship between parameters and variables. The working use case was developed based on a simple multiplicative relationship between the volume of liquid in a tank and its density changing with temperature. To represent the application of homomorphic encryption with multiplicative properties, the use case of computing the liquid volume in the tank from the encrypted values of density is studied. The process equipment is provided by the supplier in a process chain, and it is operated by the user who desires to keep information about the physical properties of the

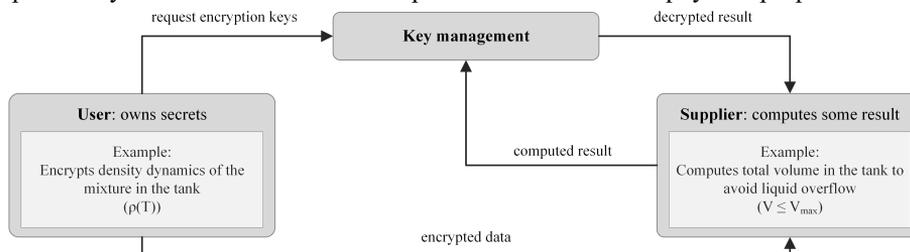

Figure 1. Use case example: information exchange

process materials confidential. The supplier needs to collect essential operation information regarding the process equipment; however, the equipment user can share the information in an encrypted form. Thus, encrypted dynamic density values of the tank mixture are transmitted by the user, and the supplier utilizes them to compute the

corresponding volume in the tank, which is necessary to calculate in order to avoid an overflow in the tank. The protocol of information exchange (Figure 1) between the user and the supplier must sustain a zero-knowledge proof. Using a key management party for generation of a one-time key for each dataset facilitates the confidentiality preserving transfer of data. Therefore, none of the parties are able to reveal the secrets of the other partners, for instance, density dynamics encrypted by the user or computation of the tank volume performed by the supplier.

3.2. Simulation

The data used for the use case are shown in Figure 2 and represent original values of the inverse density dependencies of four substances over temperature. The data used for the generation of the plots are provided by the Dortmund Data Bank (DDBST, 2022). The inverse of density was used to simplify the implementation of the encryption algorithm,

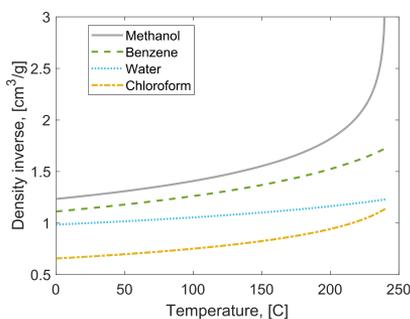

Figure 2. Density inverse profiles

and by directly multiplying the inverse of density by the mass of the liquid in the tank, the operation of division was avoided. To ensure fair evaluation of the encrypted distributions, the algorithms were run for 100 cycles for each liquid and both encryption algorithms using different key generation and encryption constants. To conduct a comparison of the two encryption methods, the encryption parameters were chosen in a manner to have similar ranges of output magnitude.

4. Results and discussion

The goal of this analysis is to perform a statistical evaluation of the encrypted data by identifying patterns from the attacker's point of view. Thus, this does not consider a proof of the strength of encryption algorithms from the perspective of randomness assessment. Instead, the applicability of MHE algorithms to value chains and process related information is analyzed, and the confidentiality level achieved through the implementation of these methods is evaluated.

4.1. Analysis of encryption

The liquids chosen for analysis have different ranges and distributions of density at different temperatures. Methanol has a strong increasing trend, whereas the profile of water has a normal pattern. The profiles of benzene and chloroform also demonstrate similar increasing trends, with a vertical shift between curves. The strategy for analysis of encoded inverse density profiles includes the use of statistical features that are used in similarity assessments of time series data (Nanopoulos et al, 2001). The chances of drawing correlation between encrypted and non-encrypted datasets and identifying the substances is examined based on statistical features.

The comparison between the encrypted datasets for both RSA and ElGamal algorithms was performed using first and second order statistical features. Analyzed first order features include mean value, skewness, and kurtosis. Skewness depicts an asymmetry relative to mean, and kurtosis characterizes the tails of a distribution. Evaluated second order features contain co-occurrence features, such as energy, correlation, and homogeneity. The energy feature reflects the uniformity of the distribution, correlation measures the relationship between neighboring elements of the matrix, and homogeneity describes the probability of closeness to the diagonal in a co-occurrence matrix.

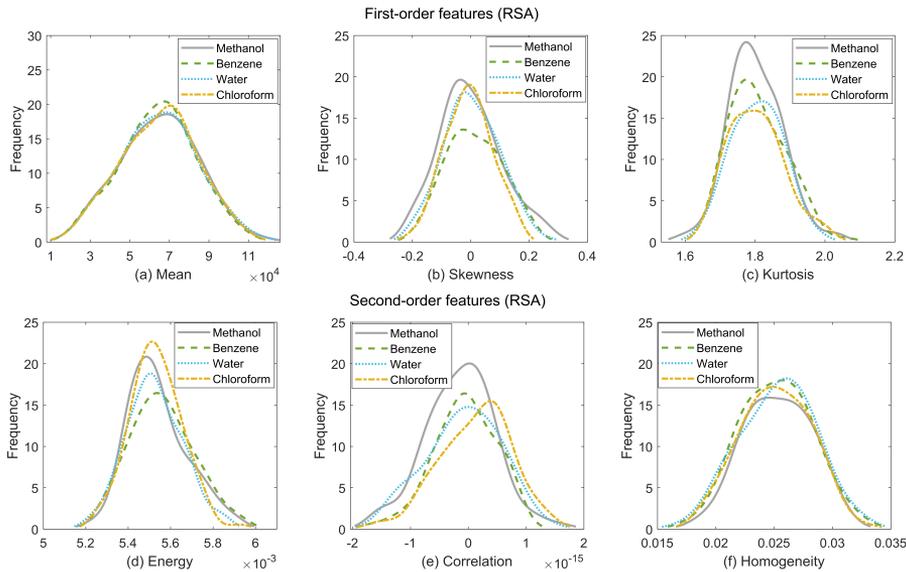

Figure 3. Statistical features of encrypted datasets with RSA algorithm

Figures 3 shows the mentioned first and second order features for datasets encrypted with RSA and Figure 4 depicts the homogeneity of ElGamal implementation. Mainly, the first step in identification of the substances would be to correlate the sequences of distribution peak sizes with the sequence of original datasets from Figure 2. For the RSA encryption,

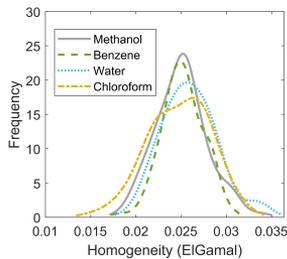

Figure 4. Homogeneity feature

Figure 3 (c) implies that a kurtosis feature applied to the encrypted datasets could reveal the order of liquids, meaning that lower density liquids have higher peaks at the kurtosis distributions. A similar observation could be made from Figure 3 (e) based on the area under the curves of the correlation feature. In comparison, the patterns for the features of datasets encrypted with ElGamal are observed to be different from those with RSA. However, the homogeneity feature in Figure 4 also shows the same arrangement of substances as in the original distribution of inverse densities.

4.2. Inferential statistical comparison

To conduct further evaluations of obtained distributions of statistical features for different substances, a t-test (with $\alpha = 0.05$) was applied to pairs of samples on a per-feature basis. Since the datasets describing statistical features are mostly characterized by normal distribution, a t-test would allow comparison of distributions in each feature to determine whether they could be related to the same population. Table 1 shows the results of null hypothesis (h) and probabilistic significance value (p) for all datasets. When the value of h is 0, the null hypothesis is valid; otherwise, the value is 1. Value of p has a range $[0, 1]$ and higher number designates validity of the null hypothesis.

The t-test concluded that correlation feature distributions of datasets of chloroform density inverse values encrypted with RSA and homogeneity distributions of datasets of water profile encrypted with ElGamal reject the null hypothesis. However, unity values of h have very low probability p . Based on the overall results of t-test, the null hypothesis

was confirmed and it could be inferred that the statistical features are not distinguishable from each other.

5. Conclusion

The aim of this work was to assess the applicability of the multiplicative homomorphic cryptosystems for confidentiality-preserving secret sharing of process-related information. Since RSA and ElGamal cryptosystems are considered to be secure tools for information exchange, they were implemented for the presented use case that includes multiplicative relations within mathematical models of the processes. The statistical features of the encrypted inverse density profiles for four liquids were compared with the original distribution patterns and several correlations between them were found. Some features were identified as revealing for both encryption methods. However, the result of inferential statistical analysis shows that the feature datasets of encrypted values could not be differentiated from each other, thereby proving the usability of multiplicative homomorphic encryption in process industries.

Abstract

In this paper, we describe the PPOPT (**P**ython **P**arametric **O**ptimization **T**oolbox) solver, written in Python. A general-purpose multiparametric package written in Python that features: (i) Efficient and parallel implementations of common multiparametric programming algorithms (strong scaling ≥ 25 cores), (ii) Problem reformulation to reduce the computational overhead and numerical stability, (iii) Multiparametric solution code generation to export solutions in C++, JavaScript, Python, and MATLAB. The speed and scaling behavior of PPOPT are explored with computational studies on the POP problem libraries and with explicit MPC controller design. PPOPT is compared to current state-of-the-art multiparametric solvers. Additionally, an exported solution is benchmarked on various platforms, including embedded processors and desktop computers

Keywords: Multiparametric Programming, Parallel Programming, Explicit Model Predictive Control, Optimization, Operations Research

1. Introduction

We consider the following class of multiparametric programming problem 1, multiparametric Quadratic Programs (mpQP) and multiparametric Linear Programs (mpLP), where $x \in \mathbb{R}^n$, $\theta \in \mathbb{R}^k$ and $A_E, A, A_\theta, F_E, F, H$ are matrices of appropriate dimension and b_E, b, b_θ are vectors of appropriate dimension. Constraint set eq. 1b defines the general equality constraints, similarly eq. 1c defines the inequality constraints, and eq. 1d defines the inequality constraints on the uncertain parameter θ , with eq. 1a defining the multiparametric objective.

$$\min_x f(x, \theta) = \frac{1}{2} x^T Q x + \theta^T H^T x + c^T x \quad (1a)$$

$$\text{s.t. } A_E x = b_E + F_E \theta \quad (1b)$$

$$A x \leq b + F \theta \quad (1c)$$

$$A_t \theta \leq b_t \quad (1d)$$

Multiparametric programming has found renewed interest due to the fact that the model predictive controller (MPC) optimization problem can be reformulated into a multiparametric program (Pistikopoulos et al., 2021). This allows for the generation of explicit MPCs that have found much interest in process control applications (Kiparissides et al., 2011; Sakizlis et al., 2004; Dua et al., 2006; Pappas et al., 2021). Moreover, applications have also been found in scheduling (Burnak et al., 2019), simultaneous design and control (Diangelakis et al., 2017), data science (Tso et al.,

2020), multilevel optimization problems (Avraamidou and Pistikopoulos, 2019), and financial applications (Romanko et al., 2012).

Nearly all of the multiparametric algorithms in the literature are based on serial execution, i.e., the tasks are processed sequentially only one execution thread. Current state of the art multiparametric solvers do not utilize parallel programming techniques, and thus not taking advantage of modern computational hardware. The development of parallel multiparametric algorithms and software implementations has been investigated in the literature, with an initial study being conducted by (Oberdieck and Pistikopoulos, 2016) showing that it is possible to create parallel multiparametric algorithms. However, the scaling with core count was not promising for large core counts.

Motivated by these limitations, PPOPT was developed to scale on large core count systems (≥ 25 cores). Much care has been taken to develop the new parallel algorithms and implementations to achieve good computational scaling. PPOPT has implemented parallel versions of the Combinatorial algorithm, Connected Graph, and Geometric algorithms developed by (Gupta et al., 2011; Oberdieck et al., 2017; Spjøtvold et al., 2006), respectively.

2. PPOPT Features

2.1. Key Points

2.1.1. Parallel Multiparametric Programming

The central feature of PPOPT is the efficient and scalable implementations of multiparametric programming algorithms. Due to limitations of the serial nature of literature algorithms, these needed to be reformulated in a way as to allow for the sub-tasks to be solved independently of each other as well as modifying the data structures being used. The multiparametric programming problem test sets MPQP1, and MPLP1 are used to assess the performance of the considered solvers, a more detailed description for these problem sets can be found in (Oberdieck et al., 2016). A performance comparison is performed in subsection 2.3 on the MPQP1 problem datasets. The scaling of the combinatorial algorithm is studied in Subsection 2.2. In addition, a control application, the generation of explicit MPC, is studied in Section 3.1.

2.1.2. Problem reformulation and Constraint Processing

Performance and robustness considerations require the removal of all redundant constraints at solve time, so PPOPT has a robust set of tools for constraint processing. The primary focus is the removal of strongly and weakly redundant constraints, as the solve time for multiparametric programs with any algorithm scale with the number of constraints, and removing redundant and repeated constraints improves computational stability. Condition number of optimization problems influence the problem (Ordóñez, 2002). As the problem is stated ahead of time, various conditioning methods can be applied that are not applicable for the online case, such as reformulating mpQPs into equivalent multiparametric min-norm problems.

2.1.3. Solution Export

An important application of multiparametric programming is generating Explicit Model Predictive Controllers for optimal control applications. However, there are very few solutions to export explicit multiparametric solutions. This is addressed with PPOPT, as the package can generate code based on the solution of the multiparametric problem. Currently, the solver can generate C++, Python, JavaScript, and MATLAB code. The performance of the exported solutions is explored in Subsection 3.2.

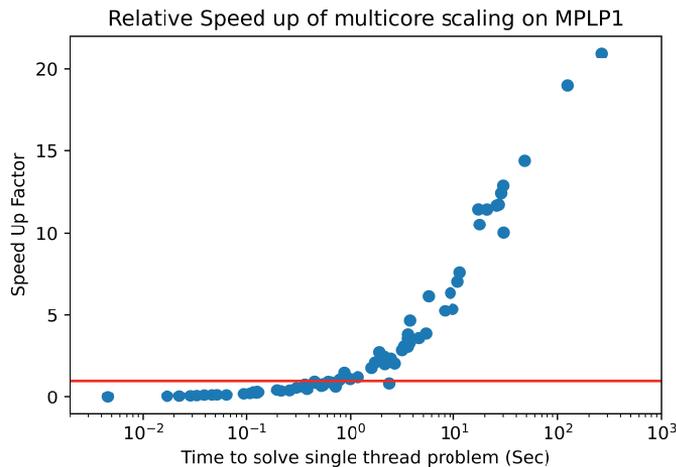

Figure 1: Comparison of single core and multicore solve times

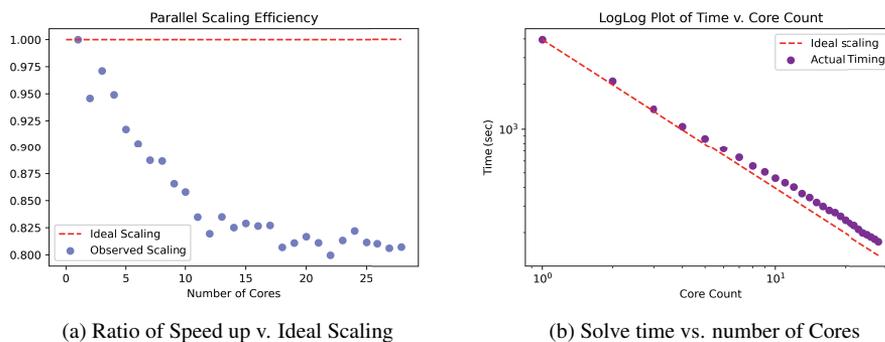

Figure 2: Scaling Study of PPOPT on large scale mpQP

2.2. Case Study: Scaling Analysis of the Combinatorial Algorithm

The scaling behavior of the PPOPT parallel implementation of the combinatorial algorithm (Gupta et al., 2011) is studied for the scaling behavior. A quadratic multiparametric problem was randomly generated such that a solving with a single core becomes computationally burdensome, in the order of an hour. This experiment was run on a single compute node in the Terra Supercomputer (dual Intel Xeon E5-2680 v4 2.40GHz 14-core, 64GB 2400MHz DDR4 RAM, CentOS 7). Here we can see the strong scaling of PPOPT both in terms of scaling efficiency and in a speed-up factor as a function of core count. The multiparametric programming problem considered here has eight optimization variables, four uncertain parameters, and 52 non-redundant affine constraints. This problem took 66 minutes to solve with the PPOPT solver utilizing a single core. In Figure 2b, we see the time scaling behavior of the parallel implementation, scaling nearly ideally with good strong scaling performance, and in Figure 2a, we see the ratio of ideal scaling and observed scaling for this problem, this again show nearly constant strong scaling behavior after 12 cores. With an overall speed-up of 22.7x, the total solve time was reduced to 2.9 minutes from 65.8 minutes, with all 28 cores being used.

A scaling study was carried out on the MPLP1 test set to show scaling performance on solving multiparametric problems with respect to problem-solving time. In Figure 1, It can be seen that problems take less than 1 second to solve that the speed-up factor is less than one. This is due to a fixed overhead of creating multiple python processes to solve the problem in parallel. In the case of solving many simple multiparametric programs, it might make sense to increase parallelization granularity over entire problems instead.

2.3. Case Study: Benchmark Performance on mpQP problems

The performance of PPOPT is tested on the MPQP1 problem sets. Each problem set contains 100 multiparametric problems, each of wide degrees of computational difficulty, with different numbers of constraints, parameters, and optimization variables. A full description of the problem sets can be found in Oberdieck et al. (2017). Here PPOPT will be compared against the POP and MPT3 solvers for the relevant algorithms (Oberdieck et al., 2016; Herceg et al., 2013). This experiment was run on a single compute node in the Terra Supercomputer (dual Intel Xeon E5-2680 v4 2.40GHz 14-core, 64GB 2400MHz DDR4 RAM, CentOS 7). With PPOPT parallel algorithms using all 28 cores, Strong Performance can be observed for PPOPT in Figure 3.

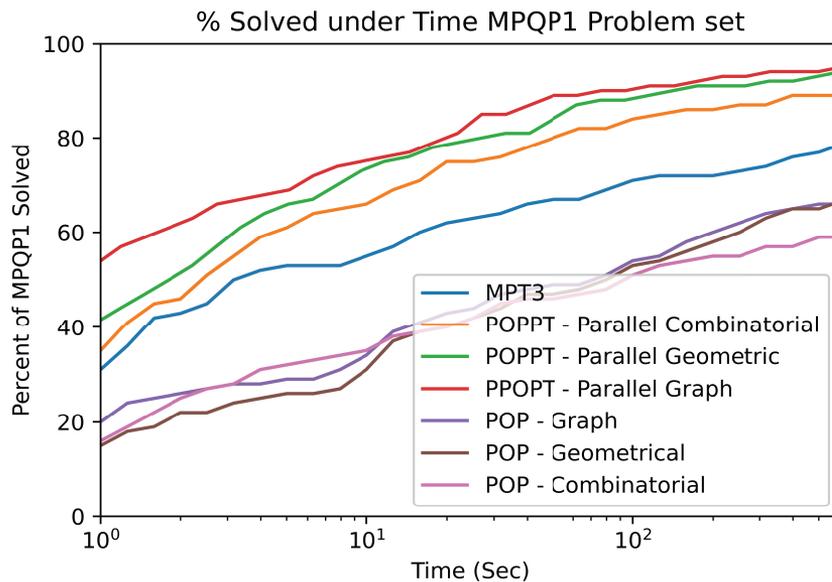

Figure 3: MPQP1 Test Set Performance of PPOPT, MPT3, and POP

3. Applications

3.1. Case Study: Explicit Model Predictive Control

Explicit model predictive control (eMPC) is one of the central applications of multiparametric programming, and thus focus is applied to this application. A computational study is where an explicit model predictive controller is generated for a system with four states, one input, and two outputs with parametric set points with constraints on the state, output and input. The computational study

Table 1: Timing Results of Exported Solution

	C++	Python	Matlab	JavaScript
ESP32	47 uSec	N/a	N/a	N/a
Teensy 4.0	5 uSec	N/a	N/a	N/a
i5-8600K	.3 uSec	8.2 uSec	410 uSec	5 mSec

is the time to solve increasingly larger eMPCs by increasing the control horizon of the eMPC. As can be seen in Figure 4, for larger problems, PPOPT is significantly faster, with a speed-up factor of approximately 15x. Indicating that for the generation of eMPCs, the PPOPT solver would be the faster choice. This computational study was performed on a four core desktop with an i7-4770 with 16 GB of RAM on a Python 3.8 environment for PPOPT and MATLAB 2019a environment for POP and MPT3.

3.2. Case Study: Benchmarking the Real Time Performance of the Exported Solution

PPOPT can export the solution to a multiparametric program as source code with a small included library to run the code. The languages currently supported are C++, Python, JavaScript, and MATLAB. This method was chosen to maximize the portability of the exported solution and allow for modifications in how the solution integrates into the specific environment. A problem with 4 optimization variables, 2 uncertain parameters, 45 constraints, and 87 critical regions was used to benchmark the performance of the exported solution. The exported solution is evaluated on the following hardware: an ESP32, 240Mhz Xtensa LX6 with 520 KiB SRAM, a Teensy 4.0, 600MHz ARM M7, and 1 MiB Ram, and on a desktop 6 core Intel i5-8600k with 32GB DDR4 RAM. As a reference, with Gurobi in Python 3.8 on the desktop system, it takes 800 uSec to solve. Results are summarized in Table 1.

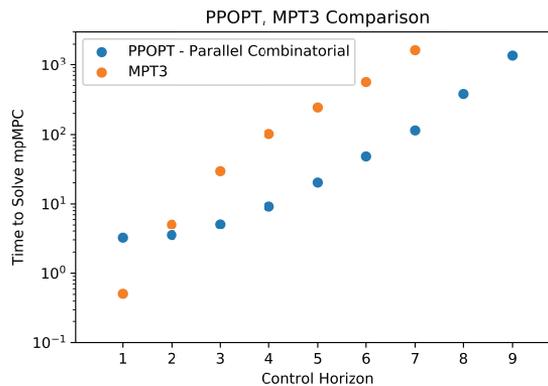

Figure 4: eMPC comparison with PPOPT and MPT 3.1.2

The C++ exported solution is quite fast across all of the hardware evaluated. This is applicable for hard real-time computing optimization problems, even with embedded processors. The indices in the table labeled as N/a cannot be run on the platform, such as MatLab on the embedded processor. While a performance regression was observed for the exported JavaScript solution, the indented application is integrated into a web framework, allowing the end-user to utilize optimization methods without needing an optimization package or license.

4. Conclusions

In this paper, we described PPOPT, the **Python Parametric OPTimization Toolbox**. PPOPT has state-of-the-art implementations of the multiple algorithms implemented to utilize many-core computers to speed up solving multiparametric programming problems. With strong results com-

pared to the state-of-the-art multiparametric solvers. Computational studies on the mpQP1 problem set show superior performance than POP and MPT3. An explicit MPC case study shows an approximate $15\times$ speed up with solving explicit MPCs compared to MPT3. The parallelism scaling of the combinatorial algorithm was explored on large-scale problems showing excellent strong scaling with core count with large scale problems. Additionally, the performance of the exported solution for multiparametric programs was studied on an example solution with different hardware systems showing strong results.

We hope to contribute to many aspects, such as developing and then implementing new scalable algorithms for mpLPs, mpQPs, and the mixed-integer variations of these problems. In addition to completely solving multiparametric programs, a problem type of interest is partially solving the multiparametric program and using this information to speed up the online computational results for large-scale problems.

Improved Sequential Least Squares Programming– Driven Feasible Path Algorithm for Process Optimisation

Yingjie Ma^a, Nan Zhang^a, Jie Li^{a*}

*^aCentre for Process Integration, School of Chemical Engineering and Analytical
Science, The University of Manchester, Manchester M13 9PL, UK*

Abstract

Sequential least squares programming (SLSQP) algorithm has been shown to be useful for driving the feasible path algorithms for process optimisation. However, the existing SLSQP algorithms still need many function evaluations for computationally challenging process optimisation problems. In the current work, we propose several novel strategies to improve both the efficiency and convergence of the SLSQP algorithm. Solving a large-scale process optimisation problem indicates that the algorithm can save computational times by 10-90% with better solutions generated.

Keywords: process optimisation, SLSQP, line search, feasible path, numerical errors.

1. Introduction

Optimisation is a powerful tool to design the best chemical process with the lowest cost or highest profit while satisfying the production requirements and restrictions at the same time (Biegler, 1993). To get optimisation results that can match the real-world production well, it is highly desirable to use rigorous unit operation models. However, this often leads to strongly nonlinear, non-convex or even ill-conditioned large-scale nonlinear programming (NLP) problems, which is hard to solve (Pattison and Baldea, 2014).

The feasible path algorithm is widely used to solve process optimisation problems due to its good convergence, which divides the entire process optimisation problem into a small-scale optimisation problem in the outer level and a large-scale process simulation problem in the inner level (Parker and Hughes, 1981). However, for feasible path algorithms, the simulation needs to be conducted in each iteration, which may suffer from divergence if the models are strongly nonlinear. To tackle with this problem, the pseudo-transient continuation (PTC) modeling approach has been introduced for process simulations, which was reported to be able to improve the convergence of simulations and optimisations significantly (Pattison and Baldea, 2014). However, PTC simulations are much slower than steady-state simulations, making feasible path algorithms less efficient. To improve the efficiency, we proposed a hybrid steady-state and time-relaxation-based optimisation algorithm in our previous work, which combines PTC simulations and steady-state simulations to reduce the times of implementing PTC simulations without degrading the convergence of simulations and optimisations (Ma et al., 2020).

The hybrid algorithm in our previous work (Ma et al., 2020) is driven by a sequential least squares programming (SLSQP) algorithm (Kraft, 1988) that is potential to be more stable than sequential quadratic programming (SQP) algorithm under numerical noise (Schittkowski, 1982). However, due to the lack of wide research, the existing SLSQP

algorithm is less efficient and may generate ascent directions due to the numerical errors in the least squares (LSQ) solver (Lawson and Hanson, 1995) adopted.

With above in mind, in this work, we will develop an improved SLSQP algorithm to drive the hybrid steady-state and time-relaxation-based algorithm. The proposed algorithm uses a formula to initialize the step length during the line search instead of always using full step length as initial values to achieve higher efficiency. Also, some strategies are proposed to improve the convergence of the SLSQP algorithm, such as revising the search directions with a new LSQ solver and relaxing the line search criteria in some iterations. The computational results from solving a challenging large-scale process optimisation problem in the literature indicates that the improved SLSQP algorithm usually generates a better solution with 10-90% less computational time required, compared with an existing SLSQP algorithm.

2. Problem Statement

The NLP problem solved in the current work can be stated as follows:

$$\begin{aligned} \min f(x) & \quad \text{(NLP)} \\ \text{s. t. } h(x) &= 0 \\ g(x) &\geq 0 \\ x &\in R^n, \end{aligned}$$

where $f: R^n \rightarrow R$, $h: R^n \rightarrow R^{m_E}$ and $g: R^n \rightarrow R^{m_I}$ are all twice continuously differentiable functions. We assume both the function values and first-order derivatives are available. When applying the developed SLSQP algorithm to the feasible path algorithm, function values and gradients can be got from equation-oriented simulators.

3. Improved Sequential Least Squares Programming Algorithm

3.1. Sequential least squares programming algorithm

The SLSQP algorithm was proposed by (Schittkowski, 1982), which is to solve a constrained LSQ subproblem in each major iteration to generate a descent direction. The LSQ problem solved at iteration k is shown as follows,

$$\begin{aligned} \min \frac{1}{2} \|R^k d^k - q^k\|^2 & \quad \text{(LSQ)} \\ \text{s. t. } \nabla h^{kT} d^k + h^k &= 0 \\ \nabla g^{kT} d^k + g^k &\geq 0, \end{aligned}$$

where d^k is the search direction to be solved. g^k and h^k are values of constraint functions at iterate x^k , while ∇g^k and ∇h^k are current gradients of inequalities and equalities. R^k and q^k are least squares matrix and observation vector respectively, which are updated during optimisation according to the BFGS formula and an LDL updating algorithm (Fletcher and Powell, 1974).

Line search can be used to guarantee the global convergence of SLSQP algorithm, which is to get a step length α providing a sufficient decrease for the merit function $M(x)$ along the search direction d^k . After a α is obtained, the iterate can be updated using Eq. (1),

$$x^{k+1} \leftarrow x^k + \alpha d^k. \quad (1)$$

A frequently used condition to guarantee the sufficient decrease for constrained NLP is the Armijio condition (Armijio, 1966) as shown in the following Eq. (2),

$$M(x^k + \alpha d^k) \leq M(x^k) + \alpha \rho DM^k(0), \quad (2)$$

where $DM^k(0)$ is the directional derivative of $M(x^k + \alpha d^k)$ along d^k at $\alpha = 0$, and $\rho \in (0, 0.5)$ is a constant. The region of α satisfying the Eq. (2) is shown in Fig. 1.

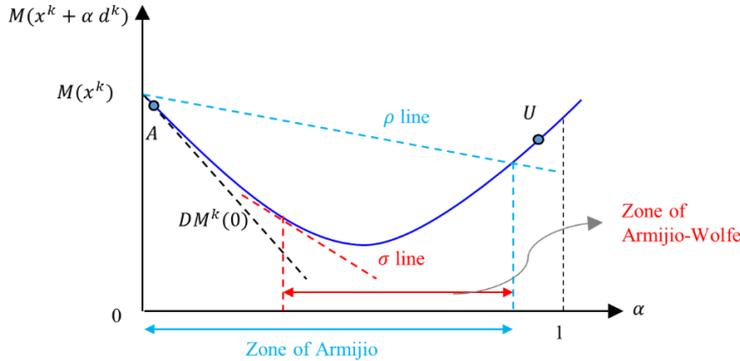

Figure 1 Zones of α in Armijio conditions and Armijio-Wolfe Conditions

The framework of a line search and merit function-based SLSQP algorithm can be described as follows:

Algorithm 1: SLSQP

- Step 1: set $k \leftarrow 0$; give x^0 and evaluate $f^0, g^0, h^0, \nabla f^0, \nabla g^0, \nabla h^0$; assign initial R^k and get q^k ;
- Step 2: solve LSQ subproblem for d^k and check NLP convergence condition. If the solution is found, go to Step 5;
- Step 3: conduct line search to get α satisfying Eq. (2) and to get x^{k+1} ;
- Step 4: evaluate $f^{k+1}, g^{k+1}, h^{k+1}, \nabla f^{k+1}, \nabla g^{k+1}, \nabla h^{k+1}, R^{k+1}, q^{k+1}$ at x^{k+1} ; set $k \leftarrow k + 1$, then go back to Step 2;
- Step 5: return x^k, f^k .

3.2. A new line search algorithm

The backtrack method is usually used for the line search in Step 3 of Algorithm 1, where a full step length is adopted at first and then reduced if it doesn't satisfy Eq. (2). This can achieve superlinear convergence around the optimal point. However, when x^k is far from the solution, the step length satisfying Eq. (2) may be much smaller than one especially for strongly nonlinear problems, so it possibly leads to many unnecessary function evaluations to use full step lengths as initial values for the line search in all iterations. In this work, a formula Eq. (3) from (Fletcher, 2008) that is shown to be efficient for unconstrained optimisation is used here for the constrained NLP problem,

$$\alpha^0 = \min\left(1, \frac{2\Delta M^k}{-DM^k(0)}\right), \quad (3)$$

where ΔM^k is the predicted decrease of the merit function in the current iteration k , which is estimated as $M^{k-1} - M^k$, the decrease of the merit function in the preceding major iteration. The second term in the right hand side of formula (3) is obtained by assuming that the merit function is quadratic with respect to the step length α , while its first term

is to avoid a step length larger than 1. For unconstrained optimisation, α^0 from Eq. (3) will be always 1 when x^k is sufficiently close to solution x^* for a superlinear convergence algorithm, so the superlinear convergence rate of the original algorithm will not be degraded (Fletcher, 2008). For constrained optimisation, although there haven't been a similar proof yet, α^0 are indeed frequently one when x^k is close to optima and not dominated by numerical noise according to our observation.

However, for strongly nonlinear problems, the predicted α^0 from Eq. (3) may be over small and far from the local minimum of the merit function along d^k when x^k is distant from the solution (such as point A in Fig. 1). In such case, if the frequently-used backtrack line search is used and the step length is accepted immediately when it satisfies the Eq. (2), the optimisation may be slow down and/or the approximate Hessian matrix may be polluted by large numerical noise, deteriorating the optimisation. Thus, the Wolfe condition Eq. (4) (Wolfe, 1971) is introduced to avoid an over small α to be accepted,

$$\nabla f(x^k + \alpha d^k)^T d^k \geq \sigma \nabla f(x^k)^T d^k, \quad (4)$$

where $\sigma \in (\rho, 1)$ is a constant. The region of α satisfying both Eq. (2) and Eq. (4) is shown in Fig. 1, which indicates a α satisfying Armijio condition but not Wolfe condition needs to be increased (Step 3.6 in the following Algorithm 2). However, it needs more function evaluations to find a point satisfying both conditions compared with the algorithm enforcing the Armijio condition only. Theoretically, the Wolfe condition doesn't have to be satisfied in the SLSQP algorithm as it is not used in the proof of the global convergence. Thus, we will not check the Wolfe condition if the α satisfying the Armijio condition is not over small judged by Eq. (5),

$$\alpha \geq \tau \alpha^{up}, \quad (5)$$

where $\alpha^{up} \in (0, 1]$ is the smallest α not satisfying Eq. (2) (such as the point U in Fig. 1) and will be updated during the line search. $\tau \in (0, 1)$ is a constant to allow some gap between α and α^{up} , which is set as 0.1 in this work. Overall, the proposed line search algorithm applied to a major iteration k of Algorithm 1 is shown as follows. To avoid the abuse use of indices, we get rid of the index k and use the index i only to represent the iteration in the following Algorithm 2.

Algorithm 2: line search with α^0 predicted and Wolfe condition checked

- Step 3.1: given x^0 ; set $i \leftarrow 0$, $\alpha^{up} \leftarrow 1$, $\rho \in (0, 0.5)$, $\sigma \in (\rho, 1)$, $\tau \in (0, 1)$, $\gamma > 1$;
get an initial step length α^0 from Eq. (3);
- Step 3.2: set $x^{i+1} \leftarrow x^i + \alpha^i d$, and evaluate the merit function $M(x^{i+1})$;
- Step 3.3: if Eq. (2) is satisfied, go to Step 3.5; otherwise, set $\alpha^{up} \leftarrow \alpha^i$;
- Step 3.4: generate an α^{i+1} smaller than α^i ; set $i \leftarrow i + 1$, then go back to Step 3.2;
- Step 3.5: if $\alpha^i \geq \tau \alpha^{up}$ or α^i satisfies Eq. (4), go to Step 3.7;
- Step 3.6: generate $\alpha^{i+1} = \gamma \alpha^i$, set $i \leftarrow i + 1$, then go back to Step 3.2;
- Step 3.7: return α^i , x^{i+1} .

The constants used are $\rho = 0.1$, $\sigma = 0.9$, $\tau = 0.1$, $\gamma = 10$.

3.3. Other improvements

In the existing SLSQP algorithms (Kraft, 1988; Schittkowski, 1982), a powerful algorithm called LSEI (Lawson and Hanson, 1995) are used to solve LSQ subproblems. Although the LSEI algorithm usually works very well, it may generate ascent directions due to numerical errors, which would cause failure of the optimisation. To avoid

divergence, we solve the LSQ subproblem based on a robust commercial solver Gurobi (Gurobi Optimization, 2020) once the LSEI algorithm generates an ascent direction, while in all the other cases, the LSEI algorithm are still used as we find it leads to better performance compared with many other QP and LSQ solvers.

Second, even if a descent direction is generated from an LSQ subproblem, the line search may still fail to find a α satisfying the Armijio condition as function values generated from process simulations suffer from numerical noises. In such case, to continue the algorithm and step out of the noisy region for a better solution, we allow the largest step length α satisfying the following Eq. (6) is accepted,

$$\frac{|M(x^k + \alpha d^k) - M(x^k)|}{M(x^k)} \leq ntol, \tag{6}$$

where $ntol$ is a small value to tolerate noise, which is 10^{-4} here. Eq. (6) is to guarantee the accepted step length will only increase the merit function slightly while the algorithm can still have some progress to have the chance to leave the numerically noisy region. Such condition will only be applied for limited times (here, five times) to avoid the algorithm to run forever when the optimisation cannot escape the region anyway.

4. Case Study

The optimization of a dimethyl ether (DME) production process intensified by dividing wall column (DWC) is used to validate the proposed algorithm, which was first optimized by (Pattison et al., 2016) and later by (Ma et al., 2018; Ma et al., 2020) with better solutions. The problem has 12151 equalities, 17 inequalities and 13661 decision variables in the full model, while it has 122 decision variables, 17 inequalities and one equality in the reduced space when solved by the feasible path algorithm. The objective function to be minimized is a penalty of the cost without a specific unit. The problem is rather challenging to solve not only because of its nonlinearity but more because of its intrinsically ill-conditioning evidenced by that the condition number of the approximate Hessian matrix ranges from $10^{10} - 10^{14}$ in most iterations. In (Ma et al., 2018), an SQP solver was used and the problem has to be scaled by trial and error to be solvable. However, in (Ma et al., 2020), the problem could be solved directly without scaling using an existing SLSQP solver (Kraft, 1988). For a detailed comparison between the existing SLSQP algorithm (Kraft, 1988) (notated as `slsqp`) and our improved algorithm (notated as `i-slsqp`), we conduct the optimisation using `slsqp` and `i-slsqp` from six different initial points on a desktop with 3.20 GHz Intel i7 CPU and 16 GB RAM running 64-bit Windows operating system. The computational results from both algorithms are shown in Table 1.

Table 1 Comparative results from the hybrid algorithm of Ma et al. (2020) and the proposed algorithm

Initial point		1	2	3	4	5	6
Time/s	<code>slsqp</code>	4415	2003	6264	1496	2563	2408
	<code>i-slsqp</code>	469	1173	976	1263	989	2032
Number of simulations	<code>slsqp</code>	2259	923	2373	754	1337	969
	<code>i-slsqp</code>	287	701	527	871	696	1190
Objective	<code>slsqp</code>	125689	125713	125715	125711	125695	125701
	<code>i-slsqp</code>	125708	125687	125712	125705	125683	125690

As can be seen from Table 1, our improved SLSQP algorithm always needs 10-90% less computation time from different initial points than SLSQP. Especially, for the optimisation starting from the first initial point, the computational time is reduced by around one order of magnitude. This is partially because less function evaluations are used in our algorithm as shown in Table 1. The time reduction is also because small step lengths are used during the line search, leading to better convergence of steady-state simulations and hence less number of expensive PTC simulations required. Furthermore, it can be seen that our algorithms usually get better solutions except for the optimisation starting from the first initial point, and the best solution with an optimum of 125683 is also generated from the new algorithm.

5. Conclusion

In this work, we proposed an improved SLSQP algorithm for process optimisation using rigorous models. In the improved algorithm, the initial step length during the line search was calculated from a formula to reduce the number of function evaluations. The Wolfe condition was introduced into the line search to avoid over small step length, but it was not enforced when the step length satisfying Armijo condition was large enough to avoid additional function evaluations. For a better convergence, the LSQ subproblem was solved by our customized solver when the existing LSQ algorithm generated ascent directions. Also, the line search is allowed to accept some step lengths which increase the merit function slightly to tolerate numerical noise from process simulations. One large-scale process optimisation problem from literature shows that the improved algorithm can save computational time by 10-90% with better solutions generated.

Abstract

In a smart chemical plant, knowing the process state at any moment is crucial with impact on aspects such as economic, safety, or control. The information is collected by sensors distributed throughout the plant, responsible for measuring and transmitting the values of temperature, humidity, pressure, among others. The set of devices used in the measurement is called the sensor network (SN). Consequently, their design optimization implies importance and huge capital cost. We propose an intelligent optimization solver based on a Parallel Hybrid Simulated Annealing (PHSA) to solve it. The parallelism is applied at the algorithmic level, following a cooperative model. Among the migration parameters, the replacement criteria have an important role in the PHSA performance. Our main objective is to analyze the PHSA behavior by considering different replacement criteria. The results obtained by PHSA achieve the best-known solution for large and complex SN cases. Furthermore, the parallel HSA exhibits efficient scalability to solve the SN distribution problem.

Keywords: Simulated Annealing, parallel computing, sensor network design; combinatorial optimization; metaheuristics

1. Introduction

In the last decade, the integration of the process control, the operation of the entire plant, and the corporation's business system have been a tendency, which is possible thanks to the rapid advances in cybernetic infrastructure and communications technology that allow the flow of information in real-time. The so-called smart plant aims to maximize the economic profitability of the activity with social responsibility, complying with strict standards on environmental care, occupational health, and safety. Christofides et al. (2007) mention the design of the sensor network (SN) as a key issue to make the smart plant a reality since it provides comprehensive knowledge of the process's current state. The systematic design of the SN in a plant, formulated as an optimization problem, is known as sensor network design problem (SNDP) and consists in determining whether or not each variable should be measured while optimizing the performance. Performance criteria can be classified as criteria associated with the performance of the sensor system itself (Carnero et al. (2018); Kotecha et al. (2008)) or related to indicators of the process for which the instrumentation is designed (Sen et al. (2016); Paul et al. (2015); Sambito (2021)).

The number of possibilities regarding how many variables to measure and the type of the desired performance can achieve a very high order even for small-size plants. Therefore, an important

aspect is related to the choice of the resolution methodology, which can be classified into two main groups: exact methods and heuristics. The analysis of the performance exhibited by exact algorithms (Zhang and Chmielewski (2017); Nguyen and Bagajewicz (2011)) shows that their behavior is very dependent on the particular design problem and its size. In this sense, they are not robust enough to solve a wide range of specifications, nor do they have the possibility of scaling. The most notorious disadvantage is that the optimality guarantee cannot be achieved in many cases, given the excessive computation time they require. This limitation comes mainly from the combinatorial nature of the problem, which results in the impossibility of having polynomial-time algorithms for the cases of practical interest. Therefore, heuristic optimization methods emerge as the most feasible solution alternative to address higher dimensional designs (Hernandez et al. (2019); He and Ma (2014); Panizo et al. (2018)). When many variables have to be measured, the SN design process optimization runtime has been reduced. Consequently, parallelization techniques on the heuristic methods (Talbi (2009)) are used, achieving a substantial improvement in the optimization performance.

In this work, a parallel Simulated Annealing (SA) (Kirkpatrick et al. (1983); Cicirello (2017)) algorithm is proposed to optimize the SNDP. In this model, many hybrid SA algorithms (Hernández et al. (2020)) are launched in parallel and exchanges information to improve the quality solutions and enhance efficiency. Consequently, the main contribution of our research is to develop an intelligent solver based on a parallel HSA algorithm, named PHSA, which intends to support the decision-making during the design of complex sensor networks in a chemical plant. The focus is to increase the efficiency of this solver when large and complex SN cases are addressed. Hence, we formulate the following research questions (RQs): *RQ1*) Does the parallelization of HSA increase its efficiency when we deal with large SN cases?; *RQ2*) What parametric configurations should be used in the proposed parallel algorithm to enhance the solution quality?; and *RQ3*) Is our PHSA design efficient to solve the SNDP?. To answer these RQs, we conduct experiments by applying PHSA to different case studies of incremental size, including a well-known problem in chemical engineering literature.

The remainder of this article is structured as follows. Section 2 explains the SNDP. Section 3 explains our algorithmic proposal. Then, we describe the experimental design and the methodology used in Section 4. We analyze and compare the HSA behavior when solving the SNDP problems in Section 5. Finally, the most important conclusions and future research lines are presented in Section 6.

2. Sensor Network Design Problem

The SNDP is summarized as a problem of finding the minimum cost network that satisfies precision and estimability constraints. Formally, a SNDP solution has to satisfy these constraints for a set of key variable estimates, as stated by Eq 1, where \mathbf{q} is an n -dimensional vector of binary variables such that $q_i = 1$ if variable i is measured, and $q_i = 0$ otherwise, \mathbf{c}^T is the cost vector; $\hat{\sigma}_k$ is the estimated standard deviation of the k -th variable in S_σ obtained by a data reconciliation procedure (Bagajewicz and Sanchez (2000)), and E_l stands for the degree of estimability of the l -th variable in S_E . Furthermore, S_σ and S_E are the set of key process variables with requirements in precision and ability to be estimated, respectively.

$$\min(\mathbf{c}^T \mathbf{q}) \quad \text{s.t.} \begin{cases} \hat{\sigma}_k(\mathbf{q}) \leq \hat{\sigma}_k^*(\mathbf{q}), & \forall k \in S_\sigma \\ E_l \geq 1, & \forall l \in S_E \\ \mathbf{q} \in \{0, 1\} \end{cases} \quad (1)$$

In this formulation, it is assumed that a linearized algebraic model represents plant operation, measurements are subject to noncorrelated random errors, there is only one potential measuring

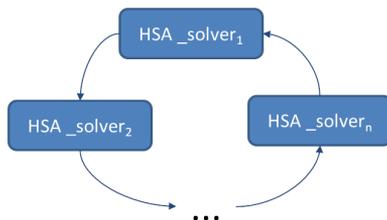

Figure 1: PHSA scheme under ring topology.

device for each variable, and there are no restrictions for the localization of instruments. Regarding degree of estimability constraint, if $E_I=1$, the feasibility of the constraint can be checked by executing a variable classification procedure, which can be accomplished by matrix projection, QR decomposition, or matrix co-optation (Romagnoli and Sanchez (2000); Narasimhan and Jordache (2000)).

3. PHSA solver

In this work, we propose an intelligent parallel solver to optimize the Sensor Network Design problem in chemical plants. This solver is based on the hybrid SA (HSA) introduced in Hernandez et al. (2019). HSA works as the main metaheuristic with a subordinated ad hoc local search, inspired in tabu search with strategic oscillation technique (SOTS), giving rise to the Hybrid Simulated Annealing algorithm. We refer readers to Hernandez et al. (2019) for more HSA details. The proposed parallel HSA (PHSA) follows an Algorithmic-Level Parallel Model (see Talbi (2009)). The PHSA consists of n HSA solvers that are launched in parallel and exchange information to improve the quality solutions and enhance efficiency. Hence, the PHSA design follows a cooperative search strategy. Each HSA solver generates its initial solution S_0 and run an independent HSA. The HSA solvers exchange information related to the search to compute better and more robust solutions regarding migration frequency. Different topologies can be used to do this interchange, but we focus on the ring topology, arising the PHSA_ring (see Figure 1), therefore the HSA solvers are arranged in a logic unidirectional ring. The i^{th} HSA solver sends its current solution S_1 to their $(i+1)^{th}$ neighbor solver in the ring with a certain frequency and following an asynchronous exchange. When the target HSA solver receives a solution (S_2), a replacement criteria is used. In this work, we consider three different approaches: *RC1*) S_2 is accepted with the Boltzmann probability, *RC2*) S_2 is accepted if it is better than the current solution (S_1), *RC3*) S_2 is accepted if it is better than the best-found local solution (S_b).

4. Experimental Design

The PHSA_ring performance is evaluated considering chemical processes of high complexity and size. As a first case study, a simplified ethylene plant was addressed, consisting of 47 units and 82 streams, whose operation is only represented through global mass balances. Secondly, the Tennessee Eastman Process (TEP), Downs and Vogel (1993), a widely considered problem in the chemical process monitoring and control literature was used. Both global and component mass balances are considered in the TEP. The complete system comprises 42 equations that were linearized around the operating point, and a total of 78 variables. Interested readers can gain access to the file containing information about the case studies and the complexity of the set of constraints imposed on all case studies at https://www.ing.unrc.edu.ar/archivos/sndp_cases.doc. In case study 1, a set of 14 required variables with precision constraints on 6 of them is studied. The second case study considers a set of 24 required variables, all of them with precision restrictions. The standard deviation of flow meters is 2% of the corresponding true flow rates for both cases.

To study the performance of this PHSA_ring, we configure each HSA_solver $_i$ as is suggested in Hernandez et al. (2019). Consequently, we use an initial seed temperature $T_s = 900$, the RAND cooling scheme, and the adaptive Markov Chain Length MCLa1. The stop condition of the PHSA_ring is to reach 1,250 iterations. Four PHSA_ring scenarios with 4, 8, 12 and 16 HSA solvers are assessed. Moreover, the three replacement criteria explained in Section 3 are used, and the migration frequency is calculated as a 10% of the HSA_solver $_i$ iterations (1250/#HSA solvers). At least 30 independent executions for each instance and PHSA's configuration and parallel scenarios are necessary due to the stochastic nature of the HSA solver, giving a total of 720 executions (30 runs \times 2 instances \times 3 replacement criteria \times 4 parallel scenarios). This big experimentation allows us to gather meaningful experimental data and apply statistical confidence metrics to validate our results and conclusions. Before performing the statistical tests, we first check whether the data follow a normal distribution by applying the Shapiro-Wilks test. Where the data are distributed normally, we later apply an ANOVA test. Otherwise, we use the Kruskal–Wallis (KW) test. This statistical study allows us to assess whether or not there are meaningful differences between the compared algorithms with $\alpha = 0.05$. To determine these algorithm pairwise differences is by carrying out a post hoc test, as is the case of the Wilcoxon test if the KW test is used.

5. Result Analysis

The solution quality and efficiency of the proposed parallel HSA are assessed taking into account two different stopping criteria: one is based on a maximum number of evaluations (predefined effort), while the other consists in running the PHSA_ring until a given solution is found or the maximum number of evaluations is reached (predefined solution quality). Considering a predefined effort first, we study the PHSA_ring's performance under each replacement criterion in the four parallel scenarios. For a fair comparison, all algorithms used the predefined effort as a cut point. Second, we analyze the parallel performance. We focus on the number of optimum values the PHSA configurations found. Then, we measure the speedup between the serial time (PHSAs using one processor) against the parallel time (PHSAs using 4, 8, 12, and 16 processors) because they run the same underlying algorithm, following the speedup definition given in Alba (2002).

At the beginning, we present the results for both case studies. Table 1 shows the minimum and average solution cost values, the respective standard deviation (SD), and the percentage of times that the best-known solution is found (%Hits) for the PHSA_ring, considering the three replacement criteria and the four parallel scenarios (number of HSA solvers). We observe significant different PHSA_ring's behaviors since only for case study 1 every PHSA_ring variant finds the best-known solution. Furthermore, for this case, the %Hits varies in [10, 56.67], while for the second case, the range is [0, 4]. This difference suggests that the second case needs a bigger predefined effort

Table 2: Total execution times consumed by PHSA_ring, considering the replacement criteria and #HSA solvers.

Replac. Criteria	#HSA Solvers	Case Study 1		Case Study 2	
		Min	Mean \pm SD	Min	Mean \pm SD
RC1	4	180.55	197.23 \pm 23.64	157.14	163.92 \pm 3.06
	8	56.16	68.06 \pm 12.06	47.22	49.47 \pm 0.92
	12	33.37	39.12 \pm 6.69	27.75	28.99 \pm 1.31

	12	33.37	41.98 \pm 7.08	27.89	28.87 \pm 0.55
	16	24.95	29.81 \pm 4.72	21.58	24.44 \pm 3.27

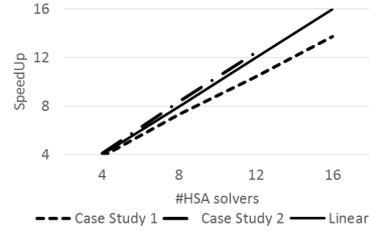

Figure 2: SpeedUp values for PHSA_ring, considering both case studies.

to reach the best-known solution. We follow with the study about the influence of replacement criteria and parallel scenarios from a solution quality point of view. On one side, a statistic and significant difference is observed when the replacement criterion *RC3* is used to solve the two case studies, since the incoming solution is only accepted if it is better than the best local solution. Under this criterion, the lowest cost averages of the solution are found, observing the lowest standard deviations and the highest %Hits. On the other hand, statistically similar behavior is detected when the four parallel scenarios are evaluated. Consequently, the *RC3* enhances the solution quality in every scenario, becoming the best replacement choice for PHSA_ring. In this way, we answer the second research question (*RQ2*).

Now, we proceed with the computational effort through the run-time analysis. Table 2 presents the minimum and average of total execution times and their standard deviations (SD) consumed for the PHSA_ring considering the three replacement criteria and the four parallel scenarios. For both case studies, no statistically significant differences are observed when the total execution time is analyzed, considering the replacement criteria. In other words, the replacement selection only depends on the required solution quality. However, when the parallel scenarios are regarded for this analysis, the reduction in total execution time is noticeable when the number of HSA solvers increases. This reduction loses inertia when going from 12 to 16 solvers since the communication times for 16 HSA solvers are more time-consuming than the search process. A good trade-off between quality and run-time is achieved by PHSA_ring with the *RC3* executed using 8 or 16 HSA solvers to solve complex SNDP cases, answering affirmatively the *RQ3*.

Until now, a predefined effort is given to each algorithm to determine the best one. But from now on, a different scenario is faced in which the computational effort of the algorithms is measured to locate a preset solution. Therefore, the same target solution quality is used as the stop criterion in all algorithms for any given case study. The target cost value depends on the SN case, and their best-known costs are selected for each one as the stopping value for the PHSA_ring variants, to offer a nonbiased scenario produced by an ad-hoc value. This allows to measure the PHSA efficiency through the speedup values, shown in Fig. 2, which are close to linear, showing the efficiency of PHSA to solve the SNDP and answering affirmatively *RQ1*.

6. Conclusions

In this work, we have presented a Parallel Hybrid Simulated Annealing (PHSA) to optimize the design of sensor networks in chemical plants, facilitating the decision-making by providing comprehensive knowledge of the process's current state. The basic underlying search model of the devised PHSA_ring is a set of HSA solvers connected in a ring topology. The availability of

different HSA solvers by cooperating in the process search allows obtaining a powerful parallel algorithm that leads to accurate solutions.

The objective behind the experimentation carried out using sensor networks of different characteristics was to answer our research questions. The objective of *RQ1* was to study the SNDP solution quality. We observed that our PHSA solver found the best-known solution costs. As a consequence, a model based on cooperative self-contained HSA solvers at the algorithmic level resulted in an excellent option to solve this problem. The *RQ2* suggested an analysis of the effect of several parametric configurations on the solution quality. In this sense, different statistical tests proved that the *RC3* allowed significantly enhancing the solution quality. Finally, the *RQ3* led us to assess the PHSA efficiency, considering hit rates and speedup measures. Hence, we confirmed that PHSA held the scalability property because its performance was improved by increasing the number of HSA solvers and the speedup values were close to linear.

Future work will address the resolution of SNDP, where the plant operation model is represented by a set of nonlinear equations. This introduces an additional difficulty to the problem since the feasibility of the solutions is determined by a simulation procedure that involves solving nonlinear optimization problems at a second level. In this scenario, a parallelization strategy turns out to be one of the most promising solving tools.

Abstract

In this paper, a surrogate model is developed from a first-principles model constructed for phosphate ore digestion with a phosphoric acid solution. This model is based on sparse multivariate polynomial interpolation. The main motivation is to reduce the computational time of the first principles model while preserving its properties, namely the monotonicity and positivity of the outputs. The temporal profiles of the concentrations of the different components involved in the liquid phase and in the ore particles, the particle radius and the thickness of the liquid film surrounding the particles are estimated by the developed surrogate model. The inputs to the model are the particle size distribution, the initial acid concentration and the hydrodynamic conditions. A design of experiments method is used to generate the sample points required for the surrogate model and several simulations are performed in the MATLAB environment. Comparison of the predictions of the surrogate model with those obtained by the first-principles model demonstrates the high performance (accuracy and computation time) of the developed surrogate model.

Keywords: Digestion, Shrinking core model, Surrogate model, Sparse polynomial interpolation.

1. Introduction

In process optimization, the mathematical formulation of the problems is very often based on a model described by momentum, heat and mass balance equations as well as thermodynamic and kinetic equations. This first-principles model must be identified and validated with experimental measurements in order to accurately predict the performance of the process to be optimized. However, the process model usually involves many ODEs and PDEs that take time to integrate, making the optimization algorithm very slow when it converges. Therefore, to overcome these problems, high-fidelity surrogate models that compute the required outputs from the inputs faster than the phenomenological model are needed.

In this paper, the objective is to develop an accurate surrogate model from a first-principles model of phosphate ore dissolution in the digestion tank of an industrial phosphoric acid production process (Elmisaoui et al. (2021b)). More precisely, the model allows us to calculate the time-varying profiles of (i) the concentrations of the different components involved in the liquid phase and in the ore particles, (ii) the radius of the particles, (iii) and the thickness of the liquid film surrounding the ore particles. The spatio-temporal profiles of the concentrations in the liquid film are also calculated from the main inputs of the model, i.e., particle size, initial acid concentration and hydrodynamic conditions. The approach used to develop the surrogate model is based on

sparse multivariate polynomial interpolation (Rabhi et al. (2018)) generalized to approximate the variables of interest with vectors of time-dependent values.

2. First-principles modelling of phosphate ore digestion

In order to evaluate the performance of the surrogate modelling approach, the phosphate ore dissolution model previously developed in (Elmisaoui et al. (2021a)) is used. From an industrial perspective, two main phenomena are involved in the digestion tank of the phosphoric acid process: the dissolution of the phosphate ore particles, and the crystallization of gypsum. The last phenomenon is not considered since only pure tri-calcium phosphate (TCP) particles are used. They are attacked with a phosphoric acid solution to produce mono-calcium phosphate (MCP) according to the following reaction:

The conversion rate of the reaction depends on the operating conditions, namely the temperature of the reaction medium, the initial concentration of phosphoric acid, the porosity and size of the phosphate ore particles, the solid/liquid ratio, the hydrodynamic conditions, and the residence time in the digestion tank. In this paper, we set three target parameters: particle size, initial phosphoric acid concentration, and tank stirring speed. It should be noted that a shrinking core model is adopted to describe the dissolution phenomenon where three phases are involved, i.e., the liquid bulk, the liquid film surrounding the particles and the solid phase (Elmisaoui et al. (2021a)). The model is based on the following assumptions: (i) diffusional limitation of the MCP product, (ii) spherical shape of the TCP particles, (iii) reaction occurs on the surface of the particles, (iv) only diffusion takes place in the liquid film. The model equations are presented in Table 1.

Table 1: System of equations describing the dissolution model

Solid phase	$\frac{dX}{dt} = \frac{3M_{TCP}D_{MCP}}{x_{TCP}\rho_s R_0 \delta} (1-X)^{\frac{2}{3}} (C_{MCP} _{r=R} - C'_{MCP})$	
Liquid film	$\frac{\partial C_i}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left(D_i r^2 \frac{\partial C_i}{\partial r} \right); i = H_3PO_4, MCP$	
	$r = R$	$-D_i \frac{\partial C_i}{\partial r} \Big _{r=R} = v_i k_r C_{H_3PO_4} \Big _{r=R}$
	$r = R + \delta$	$C_i \Big _{r=R+\delta} = C'_i$
	Film thickness δ	$\delta = R \left[1 + \alpha \left(\frac{R}{R_0} \right)^{8/9} D_{MCP}^{-1/3} \right]^{-1}$
Liquid bulk	$C'_{MCP} = \frac{3n_{TCP}^0}{V_L}$ and $C'_{H_3PO_4} = C_{H_3PO_4}^0 - \frac{4n_{TCP}^0}{V_L}$	

m_s and R are the mass and the radius of phosphate ore particles, respectively. x_{TCP} is the mass fraction of TCP in the phosphate ore used, M_{TCP} is the molecular weight of TCP, $C_{MCP}|_{r=R}$ and C'_{MCP} are the concentrations of MCP at the solid surface and in the liquid bulk, respectively. k_r is the rate constant, D_i and v_i are the diffusion coefficient and the stoichiometric coefficient of component i , respectively. n_{TCP}^0 is the initial number of moles of TCP in the solid, V_L is the liquid volume in the tank, α is a hydrodynamic parameter calculated from the stirring speed of the tank. Several simulations are performed under the same operating conditions as those used in (Sinirkaya et al. (2010)). Assuming a uniform particle size distribution, the surrogate model will express the conversion rate $X(t)$ as a function of the target variables, namely the initial radius of the phosphate ore particles R_0 , the hydrodynamic parameter α , and the initial concentration of the phosphoric acid solution C_0 as detailed in the next section.

3. Surrogate modelling framework

Black box (non-intrusive) methodology of surrogate modeling consists in performing as few simulations of the system as possible, at well-chosen instances of the three input parameters, then construct a high-fidelity response surface for the outputs. This is done here by means of hierarchical multivariate polynomial interpolation. For example, we denote $\tilde{X}(t)$ (a function of R_0 , α , and C_0) the response surface for the conversion rate output $X(t)$. Basically, $\tilde{X}(t)$ is a linear combination of $R_0^{p_1} \alpha^{p_2} C_0^{p_3}$ for prescribed exponents p_1, p_2, p_3 of small values $0, 1, 2, \dots$. The process we used is adaptive because the exploration of the parameters space is not predefined in advance. We describe it in its generality for d input parameters in $[-1, 1]^d$. Application to general domains is a simple matter of scaling.

We let $S = (s_j)_{j \geq 0}$ be abscissas in $[-1, 1]$ defined by the following recursion:

$$s_{2j-1} = \sqrt{\frac{s_j + 1}{2}}, \quad s_{2j} = -s_{2j-1}, \quad j \geq 2. \tag{2}$$

and $(s_0, s_1, s_2) = (1, -1, 0)$. The sequence S is called an \mathfrak{R} -Leja sequence (Chkifa et al. (2014)). In particular, it satisfies $2s_{2j-1}^2 = s_j$ for all $j \geq 2$. Thanks to this "binary" feature, it is highly relevant for hierarchical polynomial interpolation. Given f continuous on $[-1, 1]$ that we can query on s_0, s_1, \dots one query at a time, we can approximate f using interpolation polynomials $I_0[f], I_1[f], \dots$, with

$$I_n[f] = \sum_{k=0}^n d_k[f] W_k, \quad d_k[f] := \sum_{j=0}^k \tau_{k,j} f(s_j), \tag{3}$$

where W_k are Newton's polynomials associated to S properly normalized, $d_k[f] \in \mathbb{R}$ are the associated Newton coefficients, and $\tau_{k,j} \in \mathbb{R}$ are the so-called barycentric weights, all defined below. Polynomial $I_n[f]$ is the unique polynomial of degree less than n interpolating f at s_0, \dots, s_n . We note that this interpolation scheme is hierarchical, i.e., going from $I_n[f]$ to $I_{n+1}[f]$ requires only the additive update $d_{n+1}[f] W_{n+1}$, which involves a new query of f at s_{n+1} . For instance, $I_0[f] = f(1)$, $I_1[f](x) = f(1) + (f(1) - f(-1))(x - 1)/2$, $I_2[f](x) = I_1[f](x) + (f(0) - I_1[f](0))(1 - x^2)$. It is easily established that this scheme is numerically stable and insensitive machine precision.

Newton polynomials W_k are defined by $W_0 = 1$ and

$$W_k(x) := \prod_{j=0}^{k-1} [2(x - s_j)], \quad k \geq 1, \tag{4}$$

The double sequence of barycentric weights $(\tau_{k,j})_{0 \leq k, 0 \leq j \leq k}$ is defined by

$$\tau_{k,j} = \frac{2}{W'_{k+1}(s_j)}, \quad k \geq 0, \quad j = 0, \dots, k, \tag{5}$$

where W'_{k+1} is the derivative of W_{k+1} . Such polynomials and weights can be easily computed by recurrence (see Appendix).

The generalization of the interpolation scheme to a multivariate setting is straightforward. We simply use tensor product constructions. More specifically, we are given $f : [-1, 1]^d$ continuous which can be queried on any x in $[-1, 1]^d$, and then we approximate using $I_\Lambda[f]$, with

$$I_\Lambda[f] = \sum_{k \in \Lambda} d_k[f] W_k, \quad d_k[f] := \sum_{j \leq k} \tau_{k,j} f(s_j), \tag{6}$$

where $\Lambda \subset \mathbb{N}^d$ are sets of indices. The interpolation nodes s_j , the Newton polynomials W_k , and the barycentric weights $\tau_{k,j}$ are now indexed in \mathbb{N}^d and defined by:

$$\begin{aligned} s_j &:= (s_{j_1}, \dots, s_{j_d}) & j &= (j_1, \dots, j_d) \\ W_k(x) &:= W_{k_1}(x_1) \times \dots \times W_{k_d}(x_d) , & k &= (k_1, \dots, k_d) , \\ \tau_{k,j} &:= \tau_{k_1,j_1} \times \dots \times \tau_{k_d,j_d} & x &= (x_1, \dots, x_d) \end{aligned} \quad (7)$$

where $j, k \in \mathbb{N}^d$ and $x \in \mathbb{R}^d$. The nodes s_j are in $[-1, 1]^d$, the polynomials W_k are multivariate, and for $\tau_{k,j}$, it is assumed that $j \leq k$ coordinate-wise.

The multivariate polynomial $I_\Lambda[f]$ is the unique polynomial of the form $\sum_{k \in \Lambda} a_k x^k$ (with $a_k \in \mathbb{R}$ and $x^k := x_1^{k_1} \dots x_d^{k_d}$) interpolating f on the grid $\{s_j\}_{j \in \Lambda}$. Only one condition has to be assumed on Λ , it is *lower*, i.e. if $k \in \Lambda$ and $j \leq k$ then $j \in \Lambda$ (Figure 1). The interpolation scheme is hierarchical, the change from $I_\Lambda[f]$ to $I_{\Lambda \cup \{l\}}[f]$ only requires the additive update $d_l[f] W_l$ which involves querying f at the new interpolation node s_l . Of course, we assume that the lower structure of Λ is preserved by considering only eligible $l \notin \Lambda$. The design of experiments and the response surface are entirely determined by Λ that, in practice, we construct one multi-index k at a time. We start with $\Lambda = \{\mathbf{0}\}$, $d_0[f] = f(1, \dots, 1)$ (we recall that $s_0 = 1$) and $I_\Lambda[f] = f(1, \dots, 1)$, then enrich Λ by exploring the eligible indices l and adding the most appropriate one.

Eventually, the $I_\Lambda[f]$ proxy of f will consist on a list of values $\{d_k[f]\}_{k \in \Lambda}$ associated to keys k in Λ . Any query $f(x)$ of f is simply replaced by the proxy $I_\Lambda[f](x) = \sum_{k \in \Lambda} d_k[f] W_k(x)$.

This scheme is fast and easy to implement for the following reasons: (i) the $\tau_{k,j}$ weights (see Eq. (5)) can be computed in an offline step, (ii) the weights $\tau_{k,j}$ are fast to compute once $\tau_{k,j}$ are known, (iii) the queries $f(s_l)$ of f are computed as needed, then stored, (iv) the coefficients $d_l[f]$ are computed as needed, then stored, (v) the Newton polynomials are fast to compute for any x . The generalization to vector-valued functions f is straightforward. Given $f : x \in [-1, 1]^d \rightarrow \mathbb{R}^n$, the analysis and formulas above are unchanged, the only difference being that $d_k[f]$ is a vector in \mathbb{R}^n and no longer a scalar.

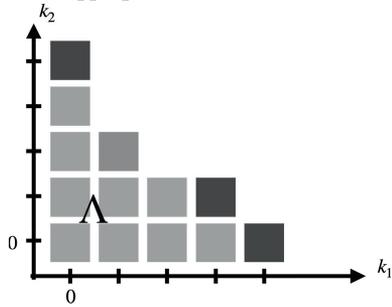

Figure 1: Schematic representation of the interpolation algorithm

4. Application of sparse polynomial interpolation in dissolution modelling

To build the surrogate model, sparse polynomial interpolation is implemented within the algorithm developed by (Chkifa et al. (2014)). Having previously fixed the bounds of the parameters, which constitute the domain of the surrogate model, the first step corresponds to the generation of the sampling points. These are chosen to be sufficiently distributed by means of a design of experiment (*DoE*) approach. Thus, the sparse polynomial interpolation model is fitted to the first-principles model.

To ensure the accuracy of the surrogate model, a comparison between its predictions and those produced by the first-principles model is performed using the root mean square error (RMSE). The rest of the construction of the surrogate model depends heavily on the accuracy of the validation. Indeed, if the accuracy of the surrogate model is good enough, then we can stop the procedure. Otherwise, an increase in the number of sample points is necessary, and the previous steps must be repeated. It is noteworthy that sampling points are generated and distributed by a max-min approach, while the min and max values correspond to the limits set previously (Quirante et al. (2015)).

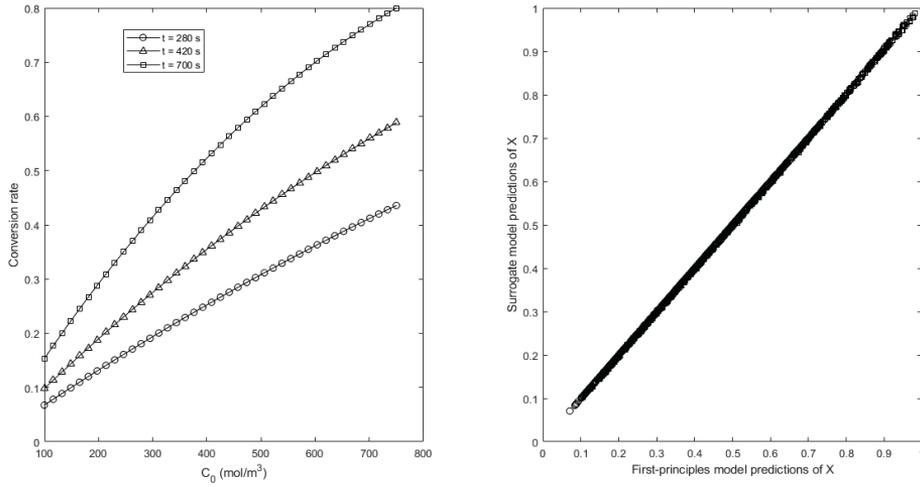

Figure 2: (a) Conversion rate versus initial concentrations at different dissolution times, (b) Comparison of the models' predictions

5. Results and discussions

To use the *DoE* to generate the sampling points, the input data intervals R_0, C_0 and α were defined, with respect to the operating conditions as follows: $[R_{min} = 500, R_{max} = 1000]m$, $[C_{0min} = 100, C_{0max} = 750]mol/m^3$ and $[\alpha_{min} = 2.7, \alpha_{max} = 4.3]$. The values of the target variables are then converted to be between -1 and 1, with respect to the ranges set previously. Thus, the surrogate model developed to describe the conversion rate can be expressed in a $[-1, 1]^3$ domain as $X(R_0, C_0, \alpha) = f(\xi_{R_{min}, R_{max}}(R_0), \xi_{C_{0min}, C_{0max}}(C_0), \xi_{\alpha_{min}, \alpha_{max}}(\alpha))$, where ξ is the affine function used to reduce the variable intervals to the interval $[-1, 1]$, i.e., $\xi_{a,b}(t) = -1 + 2(t - a)/(b - a)$. The MATLAB environment is used to construct the polynomials of the substitution model. Figure 2 (a) shows the conversion rate profiles at various initial concentrations and different dissolution times predicted by the surrogate model using ten sampling points. The values of the remaining target variables are taken as the mean values of the considered intervals, i.e., $\alpha = 3.9225$, and $R_0 = 750\mu m$. Figure 2(b) shows the comparison between the first-principles predictions and those of the surrogate models.

It is found that the surrogate model predicts the conversion rate very well at various initial concentrations and time points. Moreover, the predicted conversion rate increases with the initial concentration of phosphoric acid, and as the dissolution mechanism progresses, the conversion rate also increases. Furthermore, the average error between predicted values is negligible, demonstrating that the surrogate model accurately captures the behavior of the first-principles model.

To assess the accuracy of the surrogate model, the RMSE is calculated for different numbers of sampling points generated and used in the interpolation. It is worth noticing that for the three target variables considered, the RMSE values decrease with increasing number of sampling points. A high precision of the model can therefore be easily obtained (i.e., large number of sampling points) while guaranteeing a very low computation time. The latter is about 13 times lower for the surrogate model with ten sampling points than for the first-principles model. This ratio can be even higher when all side reactions and components involved in the digestion of ore particles are taken into account.

Table 2: Values of RMSE for the conversion rate

Sampling points	R_0	C_0	α
5	2.0110^{-2}	1.0410^{-2}	6.8810^{-5}
10	2.4510^{-4}	5.4210^{-5}	6.7310^{-5}
100	1.9510^{-4}	2.4410^{-5}	4.8710^{-5}

6. Conclusions

In this work, the development of a surrogate model for a phosphate ore digestion model was presented and simulated in the MATLAB environment. The high-dimensional adaptive hierarchical polynomial interpolation used demonstrated its reliability and efficiency in predicting the target variables, namely, the phosphate ore conversion rate, the concentration of reactants in the liquid phase and in the liquid film surrounding the particles. This modelling approach was able to correctly capture the behavior of the dissolution mechanism with high accuracy and a significant reduction in computational time, demonstrating the power of the surrogate modelling approach. Future work will focus on the development of surrogate models for the overall digestion tank model (coupling of dissolution and crystallization models) and their use in real-time optimization of phosphoric acid process performance.

Appendix : Newton polynomials and barycentric weights

Intrinsically, computing sequence S (see Eq.(2)) is straightforward, $S = (1, -1, 0, \cos(\pi/4), -\cos(\pi/4), \cos(\pi/8), -\cos(\pi/8), \cos(3\pi/8), -\cos(\pi/8), \dots)$. Evaluating the Newton polynomials $W_k(x)$ (see Eq.(4)) and computing barycentric weights $\tau_{k,j}$ (see Eq.(5)) is fast (logarithmic complexity in k). We have $W_1(x) = 2(x-1)$, $W_2(x) = 4(x^2-1)$ and $W_3(x) = 8(x^2-1)x$. In general, we use $W_{2N-1}(x) = W_N(2x^2-1)/(2x)$ and $W_{2N}(x) = 2(x-s_{2N-1})W_{2N-1}(x)$ for any $N \geq 2$. Then, by simple derivation rules, it can be verified that $\tau_{0,0} = 1$, $(\tau_{1,0}, \tau_{1,1}) = (1/4, -1/4)$ and $(\tau_{2,0}, \tau_{2,1}, \tau_{2,2}) = (1/8, 1/8, -1/4)$. Then given $N \geq 2$,

- for $k = 2N - 1$,

$$\left. \begin{array}{l} \tau_{k,0} = \tau_{N,0}(s_k + 1) \\ \tau_{k,1} = \tau_{N,0}(s_k - 1) \\ \tau_{k,2} = \tau_{N,1} 2s_k \end{array} \right| \begin{array}{l} \tau_{k,2j-1} = \tau_{N,j}(s_k - s_{2j}) \\ \tau_{l,2j} = \tau_{N,j}(s_k + s_{2j}) \\ j = 2, \dots, N \end{array} \quad (8)$$

- for $k = 2N$,

$$\left. \begin{array}{l} \tau_{k,0} = \tau_{N,0}/2 \\ \tau_{k,1} = \tau_{N,0}/2 \\ \tau_{k,2} = \tau_{N,1} \end{array} \right| \begin{array}{l} \tau_{k,2j-1} = \tau_{N,j}/2 \\ \tau_{k,2j} = \tau_{N,j}/2 \\ j = 2, \dots, N \end{array} \quad (9)$$

Abstract

This work explores data analytics in the development of optimization methodology for global optimization, as applied through decomposition methods and cutting plane algorithms. Cutting planes are treated as data populations, generated at each iteration, population elements are renewed based on the incumbent solution. The current contribution explores qualitative aspects studied in the previous, essentially attempting to expand the affinity norm to temporal sets of data in full and low dimensional spaces. The separation problem is examined using clustering techniques and is tested against a library of quadratic and box constrained optimization problems, that feature varying sparsity and density patterns. The affinity metric was formed, to efficiently evaluate overlapping cutting planes, noting significant improvement in performance. In continuation of these results, normal vector clustering examines the direction of the hyperplanes, by utilizing the cosine similarity of the normal vectors. Temporal data approach aims to prevent repetitions of chosen sub spaces within rounds. Temporal data outperformed the affinity metric approach on the largest problem tested, for tight elimination criteria. Normal vector clustering accelerated the algorithm beyond previous work, in the first round, but failed to further close the duality gap. Overall, analytics are found to dramatically improve the duality gap and the quality of the solution, consistently in all the problems tested. In conclusion, the geometrical interpretation of the dual space holds the most promising lines for future work.

1. Introduction

Convergence to the global optimum in non-convex quadratic programming, at a large scale is an NP-hard problem, and an ongoing challenge in the field of optimization, with various applications. State-of-the-art global solvers employ the Branch&Cut algorithm, with additional classes of computationally light relaxations. Polyhedral relaxations are commonly fused with strong quadratic ones, such as semidefinite and co-positive relaxations. Innovations by Baltean-Lugojan et al. (2019) focus on a generic and effective outer approximation method, suitable for semidefinite relaxations. Their work tackles the computational complexity of the semidefinite relaxation, through the use of low dimensional cutting planes, while maintaining tight bounds. The key element

of the referenced work is the decomposition of high-dimensional cutting planes into their low-dimensional counterparts, taking advantage of the problem's sparsity pattern. This results in a combinatorial explosion of available cutting planes for the separation problem and thus novel selection measures were introduced, based on feasibility violation and improvement of the objective function.

2. Problem description and mathematical formation

The optimization problem consists of a non-convex quadratic boxed function and its linear constraints.

$$z_{qp} = \min_x \{x^T Q x + c^T x \mid Ax \leq b, x \in [0, 1]^N\} \quad (1)$$

where N -variable vector $x, A \in R^{p \times N}$ and $Q \in R^{N \times N}$ represents an indefinite symmetric matrix. Relaxations and reformulation techniques are employed, to tackle Eq(1), as proposed in Sherali and Fraticelli (2002). A new symmetric matrix $X_{ij} \forall i, j$ (lifted variable) is formed to replace the quadratic term $x_i x_j$. The lifted variable is defined as $X = x x^T$ and the quadratic term transforms to $Q \bullet X = \text{Tr}(Q^T X) = \sum_{i,j} Q_{ij} X_{ij}$. Then z_{qp} is lower bounded by,

$$z_{qp}(B) := \min_{x, X} \{Q \bullet X + c^T x \mid Ax \leq b, x \in [0, 1]^N \text{ and } (x, X) \in B\} \quad (2)$$

parametric on any convex set B , which includes all sets of (x, X) , that add valid constraints to the $z_{qp}(B)$ relaxed quadratic problem. The positive semidefinite constraint (PSD), used to create new cuts, derives from the semidefinite relaxation (SDP) $X = x x^T$ to $X \geq x x^T$, or equivalently $\begin{bmatrix} 1 & x^T \\ x & X \end{bmatrix} \geq 0$, Sherali and Fraticelli (2002); Qualizza et al. (2012). The reformulation-linearization technique (RLT) compliments the SDP relaxation, by adding linear, triangular constraints to the optimization problem, Anstreicher (2009), for $0 \leq X_i, X_j \leq 1$. In the first round, convex set B , consists of just the RLT constraints. For (X^*, x^*) , being the initial solution of the relaxed problem, the augmented matrix $\begin{bmatrix} 1 & x^{*T} \\ x^* & X^* \end{bmatrix}$ is formed. Applying eigen-decomposition, provides violations of the feasible set. The number of feasibility violating cuts t , is equal to the negative eigenvalues of the matrix and each violation corresponds to a PSD constraint that is added to the Master problem $v_k^T \cdot \begin{bmatrix} 1 & x^T \\ x & X \end{bmatrix} \cdot v_k \geq 0, \forall k \in \{1, \dots, t\}$.
