Contents

Preface	xv
Theme Coordinators	xvii
T1: Modelling and Simulation	
1. Periodic Oscillations in Methane Reactor: Effects of the Main Operating Parameters <i>Piero Bareschino, Alberto E. Cutillo, Claudio Tregambi, Francesco Pepe, Gaetano Continillo, Erasmo Mancusi</i>	1
2. Modeling and Simulation of Non-Isothermal Ceramic Drying <i>Achilleas L. Arvanitidis, Margaritis Kostoglou, Michael C. Georgiadis</i>	7
3. Numerical study on the solid phase residence time distribution in a counter-current screw extractor <i>Annemarie Lehr, Gábor Janiga, Andreas Seidel-Morgenstern, Dominique Thévenin</i>	13
4. Dynamic modelling of light and temperature effects on biomass growth and biohydrogen production by the photosynthetic bacterium <i>Rhodospseudomonas palustris</i> <i>Bovinille Anye Cho, Brandon Sean Ross, Jan-Pierre du Toit, Robert William McClelland Pott, Ehecatl Antonio Del Rio-Chanona, Dongda Zhang</i>	19
5. Reducing the experimental effort to design pharmaceutical tablet lubrication by model-based design of experiments <i>Francesca Cenci, Gabriele Bano, Charalampos Christodoulou, Yuliya Vueva, Simeone Zomer, Massimiliano Barolo, Fabrizio Bezzo, Pierantonio Facco</i>	25
6. A model-based approach to predict the flowability of directly compressed pharmaceutical blends from individual components <i>Gabriele Bano, Magdalini Aroniada, Yuliya Vueva</i>	31
7. Purification of MIBA by Continuous Distillation <i>Pavan Veldandi, Ralph Cos, David Earp</i>	37
8. Modelling of Organophilic Pervaporation for Separation of Acetone-Butanol-Ethanol Mixture <i>Andras Jozsef Toth</i>	43

- 9. Development of Deep Learning Architectures for Forecasting Distillation Columns Dynamic Behavior of Biobutanol Purification**
Abraham Rodarte de la Fuente, Eduardo Sanchez-Ramirez, Martha Patricia Calderon-Alvarado, Juan Gabriel Segovia-Hernandez, Esteban A. Hernández-Vargas **49**
- 10. Impact of Methanol Synthesis Kinetics on Bulk Production Prediction: an In-Silico Assessment**
Filippo Bisotti, Matteo Fedeli, Carlo Pirola, Giulia Bozzano, Flavio Manenti **55**
- 11. Optimal layout of modular multi-floor process plants using MILP**
P Wrigley, P Wood, S O'Neill, R Hall, S Marr, D Robertson **61**
- 12. Paving the way to multi-case optimization of a steam Rankine cycle for cogeneration in nuclear power plants**
Guilherme Vescovi, Nicolas Alpy, David Haubensack, Catherine Azzaro-Pantel, Pascal Stouffs **67**
- 13. Dynamic modelling of non-isothermal open-cell foam catalyst packings: selective sugar hydrogenation to sugar alcohols as a case study**
Catarina G. Braz, Ali Najarnezhadmashhadi, Vincenzo Russo, Kari Eränen, Henrique A. Matos, Tapio Salmi **73**
- 14. Optimising a wind farm with energy storage considering curtailment and uncertainties**
Flora A. V. Biggins, Jude O. Ejeh, Diarmid Roberts, Aaron S. Yeardley and Solomon F. Brown **79**
- 15. Optimisation of Biofuel and Kerosene Fuel Blends to Support Sustainable Aviation**
Ridab Khalifa, Mohammad Alherbawi, Adel Elomri, Tareq Al-Ansari **85**
- 16. Dynamic Surrogate Modeling for Continuous Processes Control Applications**
Alessandro Di Pretoro, Andrea Tomaselli, Flavio Manenti, Ludovic Montastruc **91**
- 17. Probabilistic machine learning based soft-sensors for product quality prediction in batch processes**
Max Mowbray, Aaron Hicks, Harry Kay, Sam Kay, Amanda Lane, Cesar Medonza, Philip Martin and Dongda Zhang **97**
- 18. Property Estimation Method for Cannabinoids and Terpenes Using Machine Learning**
Laura A. Vergara, Hector J. Hortúa, Gustavo A. Orozco **103**

- 19. Kinetic modelling of γ -linolenic acid production by *Cunninghamella echinulata***
Ziqi Song, Alexander Rogers, Bovinille Anye Cho, Keju Jing, Dongda Zhang **109**
- 20. Techno-economic and environmental analysis of pyrolysis process simulation for plastic (PET) waste**
Muhammad Shahbaz, Ahmed AlNouss, Gordon Mckay, Hamish Mackey, Tareq-Al Ansari **115**
- 21. Monte Carlo Simulation of the Mechanical Processing of Bulk Materials with Fluctuating Compositions - Compositional Probability Density**
Karim Khodier, Tobias Krenn, Lisa Kandlbauer, Lisa Tatschl, Renato Sarc **121**
- 22. Determination of the burst pressure of pillow plates using finite element methods**
Alexander Zibart, Bernhard Spang, E.Y. Kenig **127**
- 23. A hybrid multi effect distillation and double reverse osmosis system for most economical brackish water desalination**
O.M.A. Al-hotmani, Mudhar A. Al-Obaidi, Y.M. John, Raj Patel, and Iqbal M. Mujtaba **133**
- 24. Computational intelligence applied to the mathematical modeling of enzymatic syntheses of biosurfactants**
Alice de C. L. Torres, Rafael A. Akisue, Lionete N. de Lima, Paulo W. Tardioli, Ruy de Sousa Júnior **139**
- 25. A Practical Guide to Coffee Roaster Modelling**
Cameron E. Bolt and Philip L. de Vaal **145**
- 26. Modeling and simulation of anoxic-aerobic algal-bacterial photobioreactor for nutrients removal**
Irina Bausa, Raúl Muñoz, Smaranda Podar, César de Prada **151**
- 27. Gaussian-Process based inference of electrolyte decomposition reaction networks in Li-ion battery failure**
Dr Peter J. Bugryniec, Aaron Yeardley, Aarjav Jain, Nicholas Price, Dr Sergio Vernuccio and Dr Solomon F. Brown **157**
- 28. Energy evaluation of processes for the production of hydrogen from biomass biodigestion under Aspen Plus**
Lokmane Abdelouahed, Fatma Kourdourli, Bechara Taouk, Lionel Estel **163**

- 29. Life cycle optimization of energy systems integrated with carbon capture and utilization**
Iasonas Ioannou, Alex Mercandetti, Gonzalo Guillén Gosálbez 169
- 30. A comparative study of swarm intelligence and artificial neural networks applications in modeling complex reaction processes**
Min Wu, Ulderico Di Caprio, Furkan Elmaz, Bert Metten, Dries De Clercq, Olivier Van Der Ha, Siegfried Mercelis, Peter Hellinckx, Leen Braeken and M. Enis Leblebici 175
- 31. Combined optimization of start-up shutdown and grade transition of a multistage continuous crystallization process**
Jiaxu Liu, Brahim Benyahia 181
- 32. Systematic dynamic modelling of heat exchanger network**
Bertrand Zitte, Isabelle Pitault, Boussad Hamroun and Françoise Couenne 187
- 33. Technical and economic assessment of a castor bean biorefinery to produce renewable aviation fuel: a computer-aided design**
Araceli Guadalupe Romero-Izquierdo, Claudia Gutiérrez-Antonio, Fernando Israel Gómez-Castro, Salvador Hernández 193
- 34. SiCN fibers as advanced materials for electromagnetic shielding in X-band: experiments and computational modelling and simulation**
Heloisa Ramlow, Liangrid Lutiani da Silva, Bráulio Haruo Kondo Lopes, Maurício Ribeiro Baldan, Ricardo Antonio Francisco Machado 199
- 35. Continuous-Time Surrogate Models for Data-Driven Dynamic Optimization**
Burcu Beykal, Nikolaos A. Diangelakis, Efstratios N. Pistikopoulos 205
- 36. Parameter estimation in dynamic metabolic models applying a surrogate approximation**
Rafael D. de Oliveira, Dielle P. Procópio, Thiago O. Basso and Galo A.C. Le Roux 211
- 37. A Benchmark Model to Generate Batch Process Data for Machine Learning Testing and Comparison**
Margarida L.C. Vicente, José F.O. Granjo, Ruomu Tan and Franz D. Böhner 217
- 38. Global warming impact of electric city buses in Chile: Critical stages of their fabrication and use**
Guillermo Valenzuela-Venegas, Daniel Peña-Torres, Franco Lizama-Valenzuela and Melanie Colet-Lagrille 223

39. Sustainable Ammonia Production via Electrolysis and Haber-Bosch Process <i>Gbemisola Ojo, Kyle Camarda</i>	229
40. Optimization for sustainable hydrogen production path <i>Patience B. Shamaki, G.A.C Le Roux</i>	235
41. Development of lactic acid evaporation process model with multi effect evaporator and mechanical vapor recompression system <i>Sujin Cha, Jonghun Lim, Yurim Kim, Hyungtae Cho, Il Moon, Junghwan Kim</i>	241
42. Optimization-Based Framework for Robust Modeling and Design of Kinetic Systems <i>Eduardo Sánchez-Ramírez, Brenda Huerta-Rosas, Juan José Quiroz-Ramírez, Víctor Alejandro Suárez-Toriello, Juan Gabriel Segovia-Hernández</i>	247
43. Optimal Control System For Products Quality from a Deethanizer Column <i>Cristian Patrascioiu, Nawwar A. Rahman, Marian Popescu</i>	253
44. Importance of detailed experimentation in the model based design and scale up of pharmaceutical spray dryers for heat sensitive products <i>P. Martin-Salvador, T. De Beer, A. Kumar</i>	259
45. Process modelling of Direct Air Capture (DAC) of CO₂ using solid amine sorbents <i>So-mang Kim, Grégoire Léonard</i>	265
46. Mechanistic modelling for thrips incidence in organic banana <i>Jean C. Campos, José Manrique-Silupú, William Ipanaqué, Bogdan Dorneanu and Harvey Arellano-García</i>	271
47. A novel approach to modelling trickle bed reactors <i>Bogdan Dorneanu, Norbert Heinzelmann, Klaus Schnitzlein, Harvey Arellano-García</i>	277
48. Alkaline Water Electrolysis Model to Purify GMP grade NaOH Solutions for Biopharmaceutical Manufacturing Processes <i>Yeonghyun Kim, Youngjin Kim, Jae Hyun Cho, Il Moon</i>	283
49. Effect of air dynamics on the discharge of a pharmaceutical powder using the discrete element method <i>L. Naranjo, I. Nopens, T. De Beer, A. Kumar</i>	289

50. Biorefinery modelling is in tatters, and here is why <i>Robert Pujan and Heinz A. Preisig</i>	295
51. Simulation of a Fischer-Tropsch reactor for jet fuel production using Aspen Custom Modeler <i>Alejandro Morales, Gregoire Leonard</i>	301
52. Techno-economic-environmental analysis of a microbial oil production integrated into a bioethanol sugarcane biorefinery <i>Andreza Aparecida Longati, Felipe Fernando Furlan, Roberto de Campos Giordano, Everson Alves Miranda</i>	307
53. Modeling the hydrodynamic sizing and rating of reactive packing in Aspen Plus <i>Andressa Neves Marchesan, Ingrid Lopes Motta, Rubens Maciel Filho and Maria Regina Wolf Maciel</i>	313
54. Simplified Model-based Design of Plate-fin Microdevices with Uniform Flow Distribution at High Flow Rates <i>Osamu Tonomura, Kaori Maenaka, Shinji Hasebe</i>	319
55. CFD-based study of fluid flow and transport phenomena in fixed bed compact reactors <i>Osamu Tonomura, Akihiro Kitagawa, Kazuki Kato, Taisuke Maki, Ken-Ichiro Sotowa</i>	325
56. Multicomponent, nonisothermal VOC adsorption modelling for pharmaceutical effluent purification: effect of operating conditions on bed performance <i>Vasiliki E. Tzanakopoulou, Alexandra Costa, Daniel Castro-Rodriguez, Dimitrios Gerogiorgis</i>	331
57. Hydrogen Separation via Continuous Hydrate Formation <i>Marcelino Artur L. Fernandes, Mariana G. Domingos, Fernando G. Martins, Isabel S. Fernandes, Marcelo F. Costa, Ricardo J. Santos, José Carlos B. Lopes</i>	337
58. Combined particle model and experimental approach for predicting pyrolysis with palm kernel shells <i>Andres Chico-Proano, Michelle Romero, Ricardo A. Narváez C., Boris G. German, Daniel Rivadeneira, George Manos, Lazaros G. Papageorgiou and Eric S. Fraga</i>	343
59. Methanation of CO₂ byproduct from an ammonia plant with green hydrogen <i>Samuel Asante, Mark W. Hlawitschka, Robert Schlesinger</i>	349

60. Uncertainty analysis applied to distillation columns calculations <i>Leonardo O. S. Santana, Ewerton E. S. Calixto, Fernando L. P. Pessoa</i>	355
61. Gas diffusion channels in Li-O₂ batteries: a comparison of wet and flooded electrodes <i>Jean Felipe Leal Silva, Gustavo Doubek, Rubens Maciel Filho</i>	361
62. Techno-economic analysis of flexible AP-X LNG production process under risks and uncertainties <i>Noor Yusuf, Rajesh Govindan, Tareq Al-Ansari</i>	367
63. Modelling and Parameter Fitting of the Dosage of Hydrogen Peroxide in a Photo-Fenton Process <i>Kourosch Nasr Esfahani, Montserrat Pérez-Moya, Moisés Graells</i>	373
64. Optimising the performance of the condensate stabilisation unit in LNG Processes <i>Abdul Aziz Shaikh, Ahmed AlNouss, Tareq Al-Ansari</i>	379
65. Data-driven modelling of full batch distillation cycles based on recurrent neuronal networks <i>Gerardo Brand-Rihm, Erik Esche and Jens-Uwe Repke</i>	385
66. Stackelberg Game Design and Operation of a Non-Cooperative Bi-Level H₂ Supply Chain Under Cournot Equilibrium <i>Jose M. FLORES-PEREZ, Catherine AZZARO-PANTEL, Antonin PONSICH and Alberto A. AGUILAR LASSERRE</i>	391
67. Modelling of Heat-Driven Water Treatment Systems: Multi-Effect Distillation (MED) model in Modelica <i>Miguel Castro Oliveira, Pedro Coelho, Muriel Iten, Henrique A. Matos</i>	397
68. Continuous operation of a solar photobioreactor with linearizing control – A simulation study <i>Joris Sébile-Meilleroux, Mariana Titica, Jérémy Pruvost</i>	403
69. Dynamic Inherent Safety Analysis of a Distillation Column under Simultaneous Design and Control <i>Denis Su-Feher, Efstratios N. Pistikopoulos</i>	409
70. Modeling of Phosphates Slurry Pipelines Through Dynamic Non-Newtonian Fluid Model With Modelica <i>Fatima Ez-Zahra El Hamra, Radouan Boukharfane, Saad Benjelloun, Ahmed Ja and Jean-Michel Ghidaglia</i>	415

71. Techno-Economic Analysis of the Conversion of Waste Plastics to Hydrogen Fuel <i>Ali A. Al-Qadri, and Usama Ahmed</i>	421
72. Evaluating the flexible operation of vacuum-pressure swing adsorption for CO₂ capture from modern gas turbines <i>Mathew Dennis Wilkes, Solomon Brown</i>	427
73. Exergoeconomic assessment of the optimized vapour-recompression assisted column for palm-based fatty acid fractionation <i>Norul M. Sidek, Mohamad R. Othman,</i>	433
74. A Reduced Population Balance Model for Coupled Hydrodynamics and Mass Transfer in Shallow Bubble Column Reactors <i>Menwer Attarakih, Ferdaous Al-Slaihah, Armin Fricke, Hans-Jörg Bart</i>	439
75. Modeling of the crystallization of gypsum produced in the digestion tank of an industrial phosphoric acid manufacturing process <i>Ilias Bouchkira, Abderrazak M. Latifi, Lhachmi Khamar and Saad Benjelloun</i>	445
76. Development of a whole-body physiologically-based pharmacokinetic model for high-dose methotrexate <i>Giuseppe Pesenti, Dario Massari, Marco Foppoli, Davide Manca</i>	451
77. Analysis of an industrial adsorption process based on ammonia chemisorption: model validation <i>Cristian Cardenas, Abderrazak M. Latifi, Cécile Vallières and Stéphanie Marsteau</i>	457
78. CFD modeling and simulation of an ammonia adsorption process <i>Flora Esposito, Cristian Cardenas, Abderrazak M. Latifi and Stéphanie Marsteau</i>	463
79. Polygeneration from sugarcane industries enhanced by functionalizing novel cultivars and excess thermal energy <i>Shoma Fujii, Yuichiro Kanematsu, Yasunori Kikuchi</i>	469
80. Economic optimization of a reactive distillation column with multiple reactive sections for silane production <i>Alcántara-Maciel, Francisco D., Victor E. Casillas-Céspedes, J. Armando López-García, Julián Cabrera-Ruiz, César Ramírez Márquez, J. Rafael Alcántara-Ávila</i>	475

81. A multiscale model of proliferating and quiescent cell populations coupled with cell cycle dynamics <i>Iqra Batoool and Naim Bajcinca</i>	481
82. Multi-objective optimization of the food chain as a support for the development of agricultural sector <i>Jan Drofenik, Klavdija Zirngast, Bojan Pahor, Zdravko Kravanja, Zorka Novak Pintarič</i>	487
83. Optimal CO₂ allocation for enhanced oil recovery operations within carbon utilisation networks in Qatar <i>Razan Sawaly, Ikhlas Ghiat, Abdulkarim Mohamed, Ahmad Abushaikha, Tareq Al-Ansari</i>	493
84. Optimal operation of an evaporator for the controlled production of titania nanoparticles <i>Filippo Tamagnini and Sebastian Engell</i>	499
85. A model-based approach for the prediction of banana rust thrips incidence from atmospheric variables <i>Carlos A. Estrada, José Manrique-Silupú, William Ipanaque, Bogdan Dorneanu and Harvey Arellano-García</i>	505
86. Comparison between 3D numerical simulations and experimental results of a lab-scale liquid-solid fluidized bed <i>Almir G. S. L. Ritta, Renaud Ansart and Olivier Simonin</i>	511
87. Non-process elements in kraft bleach plants: adsorption equilibrium aiming at reducing water consumption <i>Ana M. Sousa, Carolina T. Pinheiro, José Granjo, Licínio M. Gando-Ferreira, Lino O. Santos, Margarida M. J. Quina</i>	517
88. Re-design and scheduling of dairy thermal treatment processes for continuous operation <i>Wei-Fu Tseng and Sandro Macchietto</i>	523
89. Xflow modelling for investigation of fluid structure interaction of artificial reef: application to burial effect <i>Baptiste Oudon, Chanez Belaidi, Jessica Salaun, Arnaud Coutu</i>	529
90. Metamodeling of chemical engineering unit operations using Kriging and prediction error estimation <i>Thibault Delage, Sanaa Zannane and Thibaut Neveux</i>	535

- 91. On the integration of process engineering with metabolomics for the production of muconic acid: the case for *Saccharomyces Cerevisiae***

Preface

This volume of the Computer-Aided Chemical Engineering series puts together a selection of the contributions presented at the 32th European Symposium on Computer Aided Process Engineering (ESCAPE), held in Toulouse, France, from June 12th to 15th, 2022.

This 32th event of the ESCAPE series is a continuation of the conferences under the auspices of the CAPE Working Party of the European Federation of Chemical Engineering (EFCE), and the Société Française de Génie des Procédés (SFGP).

The ESCAPE series serves as a forum to bring together scientists, researchers, managers, engineers, and students from academia and industry, who are interested in CAPE and Process Systems Engineering (PSE). The scientific aim of the symposium is to present and review the latest developments in CAPE and/or PSE. The conference has been organized since 1992, starting with two meetings in 1992 in Denmark and France, and since then having one event annually. Hosting countries to the conference have been Austria (1993, 2018), Ireland (1994), Slovenia (1995, 2016), Greece (1996, 2011), Norway (1997), Belgium (1998), Hungary (1999, 2014), Italy (2000, 2010, 2020), Denmark (1992, 2001, 2015), The Netherlands (2002, 2019), Finland (2003, 2013), Portugal (2004), Spain (2005, 2017), Germany (2006), Romania (2007), France (1992, 2008), Poland (2009), United Kingdom (2012) and Turkey (2021).

The main focus for ESCAPE-32 is on the methodical approaches in process systems engineering with emphasis on uncertainty towards sustainability. The themes of ESCAPE-29 have been selected after a comprehensive discussion with the CAPE Working Party members and the scientific community. The particular topics within these overarching themes have been formulated to allow researchers from CAPE-related sciences to present their results and exchange valuable knowledge and experience. The themes include:

Modelling and Simulation

Coordinators : Iqbal Mujtaba, Jena-Pierre Belaud and Ludovic Montastruc

Product/Process Synthesis and Design

Coordinators: Grégoire Léonard and Laurent Cassayre

Large Scale Design and Planning/Scheduling

Coordinators: Antonio Espuna and Catherine Azzaro-Pantel

On Line Model Based Applications and Control

Coordinators: Miroslav Fikar and Nataliya Shcherbakova

Concepts, Methods and Tools

Coordinators: André Bardow and Pascal Floquet

Digitalization and Artificial Intelligence

Coordinators: Norbert Aspirion, Rachid Ouaret and Stéphane Negny

CAPE Applications Addressing Societal Challenges

Coordinators: Ana Barbosa-Povoa, Raphaële Thery-Hetrex and Marianne Boix

Education in CAPE and Knowledge Transfer

Coordinators: Eric Schaer and Vincent Gerbaud

ESCAPE-32 attracted 467 contributions from four continents (Europe, Americas, Africa, Asia). The papers have been reviewed and 281 selected for publication by the International Scientific Committee together with the help of Theme Coordinators. The selection process involved review of abstracts, review of manuscripts and final selection of the revised manuscript. We are deeply thankful for timely and careful reviews by these Scientists, as well as their invaluable help.

As editors of this special volume, we hope that the contributions in this edition of Computer Aided Process Engineering are excellent illustrations of the current state of the art in their respective field, that it will contribute to the progress in computer aided process and product engineering.

Abstract

Biogas is widely considered as one of the most promising renewable energy resources and the most environmental-friendly energy source. Biogas produced through anaerobic digestion contains many impurities and a high percentage of CO₂. Thus, upgrade and purification of the raw biogas by capturing CO₂ before its application are necessary. In this work a catalytic methanation process of biogas was proposed and numerically analyzed. It appears that sustained periodic oscillations occur in a wide range of operating parameters. A detailed nonlinear analysis is performed, and the information produced can be useful for effective plant design and adequate plant control and operation.

Keywords: Biomethane, Power-to-Methane, fixed bed reactor, periodic oscillations, non-linear dynamics.

1. Introduction

Due to the continuous increase in energy demand and to mitigate environmental problems related to greenhouse gas emissions, the research towards non-fossil and renewable energy sources is continuously increasing (Kapoor et al. 2019). In this respect, production of biomass-derived biofuels has emerged as one of the most promising non-conventional energy resources (Tursi 2019, Mancusi et al. 2021). Among biofuels, biogas from the anaerobic digestion of organic wastes stands out as an attractive way of reducing landfilling while producing energy. However, the CH₄ content in biogas usually reaches about 70% at most, so that it needs to be purified (removal of trace components) and upgraded (removal of CO₂) before utilization. The most used carbon dioxide separation technologies are based on absorption, adsorption, cryogenic distillation, and membrane separation, all of them being highly energy consuming (Zhang et al. 2020). In this work, the upgrading process by direct methanation of biogas is analyzed. Particularly, we envision using surplus electrical energy from renewable sources to produce, via electrolysis, the required hydrogen to be fed, along with the biogas, into the methanation reactor (Bareschino et al. 2020). Methanation enables the conversion of H₂ and CO₂ into methane ranking among the power-to-gas technologies that represent the best solution for the energy storage. Several studies show that methanation has a very high CO₂ conversion degree, close to the removal efficiencies of traditional upgrading techniques (e.g. Mhadmhan et al. 2022). In the present work, the proposed methanation process involves simultaneous biogas upgrading and methane enrichment of the leaving gas. The process is carried out in an adiabatic fixed bed reactor with a nickel-based catalyst, and a recycle loop is used for diluting the inlet reactants concentration, to limit the maximum adiabatic

temperature increase (Bareschino et al. 2021). The effects on the feed temperature and recycling ratio (R) are considered. Periodic oscillations are predicted over a wide range of the investigated parameters. The main cause of the sustained periodic oscillations can be found in the feedback from the mass recycle coupled with the typical phenomena of fixed bed reactors, i.e. the inverse response (Luyben, 2007). Although the maximum temperature reached during the oscillations is limited by the thermodynamic equilibrium, the system temperature oscillates remarkably, with a period of about 10 minutes and in a range of $\pm 150^\circ\text{C}$. This behavior must be avoided to prevent catalyst damage. Non-linear analysis is performed to characterize the stability range of periodic regimes and to identify domains of coexistence of multiple stable regimes. This information can be useful for effective plant design and adequate plant control and operation (Mancusi et al., 2007).

2. Mathematical Model

The biogas upgrading process is carried out in a single adiabatic fixed bed reactor with a nickel-based catalyst. Figure 1 reports a schematic layout of the methanation process under study.

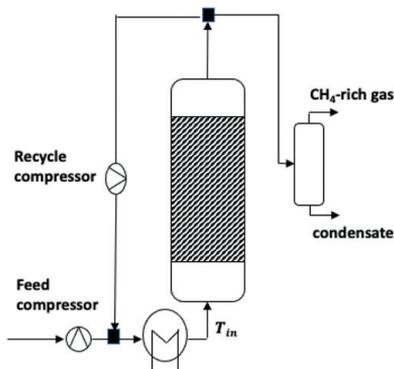

Figure 1 Adiabatic fixed bed methanation with recycle.

The biogas fed to the reactor is produced by anaerobic digestion of food waste. Purified from all impurities (H_2S), it contains CH_4 and CO_2 at 65% and 35% respectively (Tursi, 2019). This stream is enriched with H_2 produced by renewable sources according to a stoichiometric $\text{CO}_2:\text{H}_2$ ratio of 1:4 (R_3 in Tab. 1). The complete CO_2/CO methanation reaction mechanisms for syngas methanation over Ni-based catalyst proposed by Xu and Froment (Xu and Froment 1989) is considered. For readers' convenience, Table 1 summarizes the adopted reactions and associated enthalpy variations.

Table 1 – Reactions scheme and associated standard enthalpies of reactions.

Reaction	ΔH_{298} (kJ.kmol ⁻¹)	
$\text{CO} + 3\text{H}_2 \rightleftharpoons \text{CH}_4 + \text{H}_2\text{O}$	-206	R_1
$\text{CO}_2 + \text{H}_2 \rightleftharpoons \text{CO} + \text{H}_2\text{O}$	41	R_2
$\text{CO}_2 + 4\text{H}_2 \rightleftharpoons \text{CH}_4 + 2\text{H}_2\text{O}$	-165	R_3

To limit temperature increase due to the strong exothermicity of the methanation reactions, the water content in the feed is increased by adopting gas recirculation (Rönsch

et al. 2016). While the presence of water in the feed stream due to recycle shifts the chemical balance towards the products, it is essential to keep the temperature below 600° C and reduce carbon formation (Rönsch et al. 2016). Moreover, since the process is exothermic and reactions R_1 and R_3 take place with increasing volumes, the process benefits from high pressures and low temperatures.

The fixed bed reactor is modeled by a 1D pseudo-homogeneous and adiabatic model (Bareschino et al. 2021). The material balances for each gas component ($i=CH_4, CO, CO_2, H_2, H_2O$) and the energy balance are reported in Table 2 with the initial and boundary conditions:

Table 2 – Governing equations.

Mass Balance	$\varepsilon_g \frac{\partial c_i}{\partial t} = -u_{sg} \frac{\partial c_i}{\partial z} - (1 - \varepsilon_g) \rho_c r_i$
Heat Balance	$(\varepsilon_g \rho_g c_{pg} + (1 - \varepsilon_g) c_{pc}) \frac{\partial T}{\partial t} = -u_{sg} \rho_g c_{pg} \frac{\partial T}{\partial z} - \rho_c \sum_{j=1}^3 \Delta H_{Rj} R_j$
Initial conditions	$c_i(z, 0) = 0, T(z, 0) = T_0$
Boundary conditions	$c_i(0, t) = c_{i,in}, T(z, 0) = T_{in}$

where z is the axial position along each reactor belonging in $[0, L]$, and r_i the rate of consumption or formation of i -species ($i=CH_4, CO, CO_2, H_2, H_2O$) determined by summing up the reaction rates of those species in all the reactions R_j (see Table 1) according to the stoichiometric coefficients (ν) as follows:

$$r_i = \sum_{j=1}^3 \nu_{i,j} R_j \quad (1)$$

The gas superficial velocity (u_{sg}) is calculated as follows:

$$u_{sg}(z, t) = \frac{PM_{in}}{PM} u_{sg,in} \quad (2)$$

where PM is the molecular weight and the subscript in represents inlet conditions. Operating conditions, reactor volumes, and catalyst properties used in the simulations are reported in Table 3.

Table 3 – Parameters values used in the simulations.

Parameter	Value	Parameter	Value
P , bar	15.0	$y_{CO_2,in}$	0.145
T_{in} , °C	280	$y_{H_2,in}$	0.585
L , m	1.5	c_{pc} , J.kg ⁻¹ .K ⁻¹	1100
d_t , m	0.225	ρ_c kg.m ⁻³	2350
$y_{CH_4,in}$	0.27	ε_g	0.4

The method of lines is applied to solve the partial differential equations (PDEs) in two steps: the spatial derivatives are approximated by finite differences over a uniform grid of 200 discretization nodes, and the resulting system of 1200 ODEs is integrated in the

initial value variable (Bareschino et al. 2021). The size of the ODE set is large, but model order reduction techniques are available for future studies (Bizon and Continillo, 2021).

3. Results

The non-linear features of the fixed bed reactor give rise to phenomena such as the inverse response (a temporary behavior contrary to that expected). Figure 2 reports the reactor output according to the legend, for a step decrease (10°C) of the inlet temperature. It is apparent that the first effect observed at the reactor exit is a temperature increase. Since higher temperatures decrease the equilibrium conversion, the temperature increase is followed by an increase in the reactant concentrations. Thus, although the inlet heat exchanger cancels out temperature variations, recycle still provides a feedback.

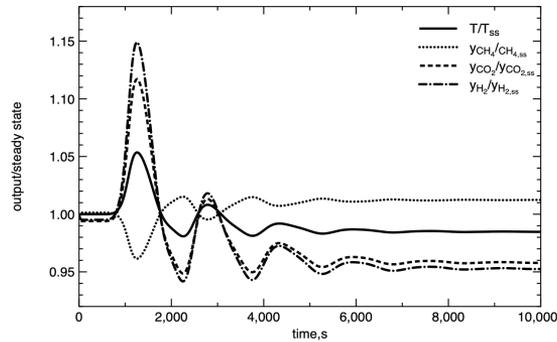

Figure 2 Reactor response to a step decrease of inlet temperature. Subscript ss refers to unperturbed steady-state. Recycle ratio $R=1.6$ whereas the other parameters are those reported in Tab. 3.

The combination of this feedback due to mass recycle and the inverse response can result in sustained oscillatory behavior (Luyben, 2007). Numerical simulations using non-linear dynamical model reproduce periodic oscillations in the reactor. Figure 2 reports a simulation showing time series of the outlet gas temperature and composition.

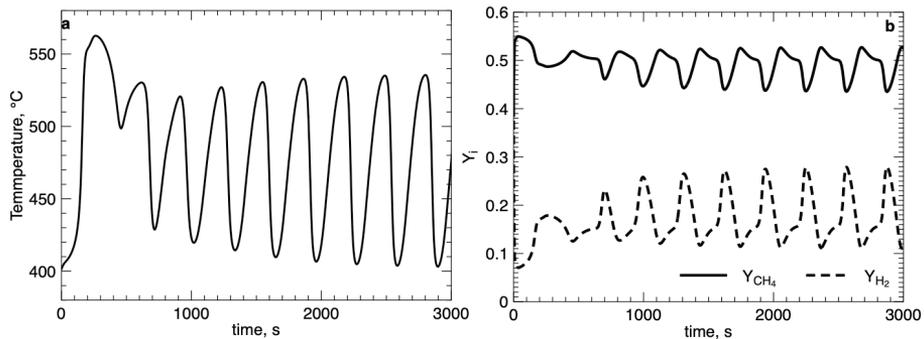

Figure 3 (a) Temperature at reactor exit vs time, (b) CH_4 and H_2 molar fraction at reactor exit vs time for $R=1.6$, whereas the other parameters values are those reported in Tab. 3.

Although the maximum temperature is limited by thermodynamic equilibrium, the system, as it can be seen, oscillates with a period of about 10 minutes and in the range of

$\pm 150^\circ\text{C}$. The amplitude of temperature oscillations is wide, and this could cause thermal stress of the catalyst. We now use a linear analysis to study more carefully the cause of the instability induced by the recycle operation. Close to an operating point, the dynamics of a system are well described by its linearized model. The model of the reactor was linearized numerically at this operating point, yielding a standard linear state space model with 1200 state variables in the form:

$$\frac{dx}{dt} = Jx \quad (3)$$

where J is the Jacobian matrix calculated at the steady state solutions. Computing steady state solution implies solving the nonlinear system of equations as reactor parameters vary (Mancusi et al., 2015). Once the steady state solution was calculated, the eigenvalues are computed by employing the *eig* function in MATLAB.

The largest eigenvalues of J for several values of R were calculated and depicted in Fig. 4. The reactor with no recycle ($R=0$) has a stable stationary response, i.e., all the eigenvalues have a negative real part. As R increases, the real part of the eigenvalues increases until $R=1.5$, where a couple of eigenvalues cross the imaginary axis. In these conditions the stable static regime solution becomes unstable, and periodic oscillations occur due to a Hopf bifurcation (Kuznetsov 1998).

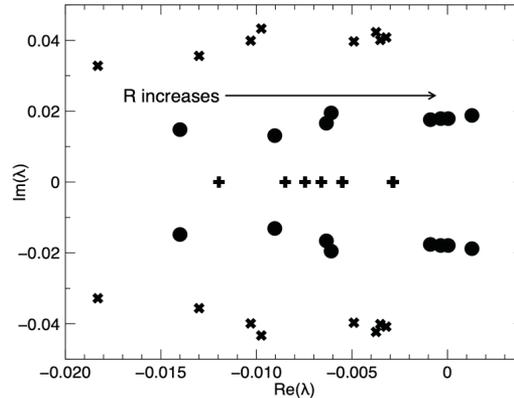

Figure 4 Imaginary and real part of the largest eigenvalues for several values of R .

The effect of the inlet temperature and recycle ratio is addressed by a bifurcation diagram (Fig. 5) where the locus of all Hopf bifurcation points is reported in the plane $R-T_{in}$. In this plot, the lines partition the parameter space into regions characterized by qualitatively similar phase portraits, that is the region characterized by stable steady state and region in which stable periodic oscillations exist (Kuznetsov 1998).

4. Conclusions

The paper reports a dynamical study of an adiabatic fixed bed reactor for the catalytic methanation of biogas. The complete dynamical characterization of a model is very useful to study the existence of periodic regimes and its influence on plant design, control, and operation. For the problem at hand, complex periodic regimes are due to the interaction of feedback induced by the mass recycle and by the inverse response typical of fixed bed reactors. The emergence of periodic oscillations is due to a Hopf bifurcation. The effect

of both the inlet temperature and the recycle ratio was investigated. The knowledge of the global dynamics can be helpful in designing an effective control strategy.

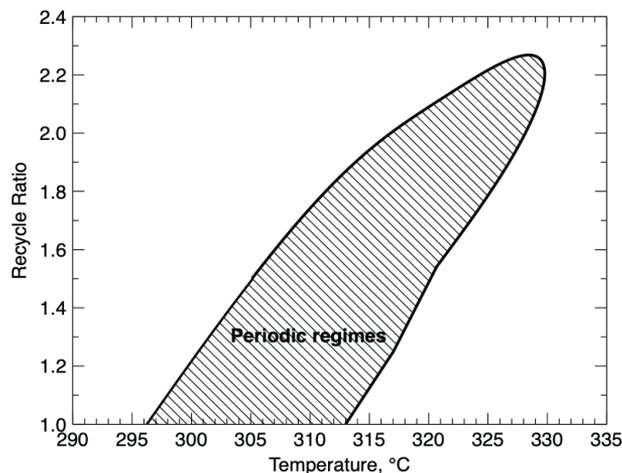

Figure 5 The bifurcation diagram in the R - T_{in} plane.

Abstract

The main objective of this work is to model, simulate and assess the drying behavior of a single ceramic tile which is exposed to the convective flux of air of known humidity, velocity and temperature. The proposed mathematical model is inspired by a moving boundary model which was originally presented by Adrover et al. (2019). More specifically, 1-D mass and heat transfer is assumed along the thickness of the tile. The mechanism of mass transfer inside the material is a combination of diffusion and capillary motion, whereas at the surface moisture is removed through forced convection by the blowing air. Based on this assumption, shrinkage takes place only on one dimension. The model is used to accurately capture the drying behavior of a parallelepiped roof tile for two distinct case studies. Namely, the ideal-shrinkage case and the no-shrinkage case. The proposed modeling approach leads to high quality results with low computational costs. Furthermore, the developed modeling framework can provide the basis for modeling drying for a wide variety of operating conditions and various material properties.

Keywords: Process Modeling, Ceramic Drying, Moving-Boundary Problem

1. Introduction

Drying constitutes an essential step in the ceramic industry consuming large amounts of energy. During this process most of the water that was added in a previous molding step is removed. This step is characterized by significant complexity since heat and mass transfer are coupled processes and take place simultaneously. According to Geankoplis (1993), at first, the wet green body is heated by the blowing air and thus the evaporation initiates. Afterwards, the body's temperature reaches an equilibrium value which implies that the drying rate is constant. At some point, the moisture content at the surface becomes insufficient to maintain the constant rate drying and the drying rate starts decreasing. Accounting to the nature of the process, drying may also be accompanied by dimensional variations which occur due to the moisture removal. Specifically, the total volume variation of the material, in an ideal shrinkage case, should be equal to the removed water's volume. In reality though, this phenomenon is often antagonized by an increase in the body's porosity which is caused by the replacement of the evaporated water by an equal volume of air. Thus, products with differing shrinkage than the ones expected are usually rejected as they often do not meet the required quality standards or there is a high probability of breakage in the subsequent firing step. Furthermore, it is possible that breakage phenomena occur during the drying process itself, especially when the drying

rates are not properly controlled. Consequently, drying is a product quality defining process which makes the knowledge of the evolution of moisture content and linear shrinkage imperative.

Due to the complex nature of the process, drying has been studied extensively through the years. Scherer (1990) presented a comprehensive review in which he explains the mechanisms as well as the various phenomena that take place during drying of porous material. Jarque et al. (2016) combined experimental results and modeling techniques and showed that drying of ceramic roof tiles is a non-isothermal process and that the assumption of an instantaneous increase of the body's surface temperature to the drying air's temperature does not stand well. More recently, a numerical model was developed to describe the drying kinetics of ceramic green bodies by using moisture dependent thermophysical properties (Lauro et al., 2021). In this work a non-isothermal model is proposed to predict the water distribution and shrinkage of a ceramic tile over time.

2. Mathematical description of the model

Air of uniform velocity is assumed to flow over a rectangular ceramic roof tile. The temperature, T_g , and relative humidity, RH , of the blowing air are fixed. The mass and heat transfer inside the tile are assumed to be one dimensional and are described by the corresponding diffusion equations, which in this case, also consider the local shrinkage of the material via a local shrinkage velocity variable, v_s (Adrover et al., 2019). The mass conservation equation is written in terms of the water mass concentration, C_w , and the energy equation is given in terms of the tile temperature T .

$$\frac{\partial C_w}{\partial t} = \frac{\partial}{\partial z} \left[D_{eff} \frac{\partial C_w}{\partial z} - v_s C_w \right] \quad (1)$$

$$\rho C_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \left[k \frac{\partial T}{\partial z} - v_s \rho C_p T \right] \quad (2)$$

Where D_{eff} is the effective diffusion coefficient of the moisture in the porous body and k is the thermal conductivity of the wet tile. Both properties have constant values for the present study.

The local shrinkage velocity, v_s , accounts for the rate at which a specific point of the green body moves and is surmised to be proportional to the diffusive flux of water inside the body.

$$v_s = a \frac{D_{eff}}{\rho_{H_2O}} \frac{\partial C_w}{\partial z} \quad (3)$$

Where a is the shrinkage factor, which is a parameter that lies between 0 to 1. These two marginal values correspond to the no-shrinkage and the ideal-shrinkage scenario respectively. However, since shrinkage is considered, the sample thickness, L , is not fixed and should be measured at any time according to equation (4).

$$\frac{dL}{dt} = v_s |_{z=L(t)} \quad (4)$$

In addition, bearing in mind that volume variations occur during drying and that the shrinkage velocity is a pointwise variable, the local concentration of the solid phase, C_s should be described by:

$$\frac{\partial C_{solid}}{\partial t} = - \frac{\partial [v_s C_{solid}]}{\partial z} \quad (5)$$

Given that, the local porosity of the green body, ε , can be derived from the equation (6).

$$1 = \varepsilon + \frac{C_{solid}}{\rho_{intrinsic}} + \frac{C_w}{\rho_{H_2O}} \quad (6)$$

Where $\rho_{intrinsic}$ is the particle density of the solid and does not include the volume of the pores.

The density and the thermal conductivity of the wet porous body are moisture dependent properties and are calculated through equations (7) and (8) respectively.

$$\rho = C_w + C_s + \varepsilon \rho_{air} \quad (7)$$

$$C_p = \frac{C_{p,H_2O} C_w + C_{p,s} C_s + C_{p,air} \varepsilon \rho_{air}}{\rho} \quad (8)$$

Furthermore, it is assumed that the water evaporation takes place only on the surface of the tile. Hence, the boundary conditions for the mass conservation equation (1) is:

$$-D_{eff} \left. \frac{\partial C_w}{\partial z} \right|_{z=L(t)} = h_m \rho_{da} (H_g^{eq} - H_g) \quad (9)$$

Where h_m is the mass transfer coefficient, ρ_{da} is the dry air density and H_g is the humidity ratio of air which is given by the equation (10).

$$RH = \frac{H_g}{H_g^{sat}} \quad (10)$$

The term H_g^{sat} is the saturation humidity ratio and it is calculated by equation (11).

$$H_g^{sat} = 0.622 \frac{P_{H_2O}^{sat}}{P - P_{H_2O}^{sat}} \quad (11)$$

Where P is the pressure of the air and $P_{H_2O}^{sat}$ is the saturation pressure of water.

The boundary condition of the energy balance equation (2) is given by:

$$-k \left. \frac{\partial T}{\partial z} \right|_{z=L(t)} = h_T (T|_{z=L(t)} - T_g) - \lambda_v D_{eff} \left. \frac{\partial C_w}{\partial z} \right|_{z=L(t)} \quad (12)$$

Where h_T is the heat transfer coefficient and λ_v is the latent heat of vaporization of water. Finally, the specific moisture, W , at the tile - air interface correlates with the equilibrium relative humidity through the Henderson desorption isotherm (Murugesan et al., 2001):

$$RH = 1 - \exp(-17W^{0.6}) \quad (13)$$

The water concentration can be converted to specific moisture through the following transformation:

$$W = C_w / C_{solid} \quad (14)$$

3. Results and Discussion

The above system consists of ordinary differential equations coupled with partial differential equations with moving boundaries. The numerical solution of the model in this form is not trivial. This makes the need of a new, fixed in time spatial variable which exempts the partial differential equations of the moving boundaries and allows the model to predict the position of the boundary as part of the solution. The boundary immobilization technique requires the dimensionalization of the model by utilizing the new fixed-in-time spatial variable $y = z/L(t)$, which lies between 0 and 1.

The transformed model is implemented in the gPROMS™ modeling environment. The following data were used as inputs:

Table 1: Model Data

Model Inputs					
k	1.23 W/(mK)	λ_v	2500 kJ/kg	T_g	273.15 + 60 K
D_{eff}	$6 \cdot 10^{-8} m^2/s$	$\rho_{intrinsic}$	2826 kg/m ³	T_{tile}	273.15 + 25 K
RH	0.50	ρ_{H_2O}	1000 kg/m ³	$C_w _{t=0}$	414 kg _{H₂O} /m ³
h_m	0.01 m/s	ρ_{air}	1.063 kg/m ³	$C_{solid} _{t=0}$	2070 kg/m ³
h_T	60 W/(m ² K)	P	101325 Pa	$L _{t=0}$	0.0187 m

In this work two marginal shrinkage scenarios were examined and compared. In the ideal shrinkage case, where the a parameter is equal to unity, the tile's volume variation from its initial state corresponds to the total volume of the liquid water that has been removed until that time. In other words, no change in the porosity takes place. On the other hand, in the no-shrinkage case, where the a parameter is equal to 0, the moisture migrates towards the body's surface where it evaporates leaving empty pores inside the green body.

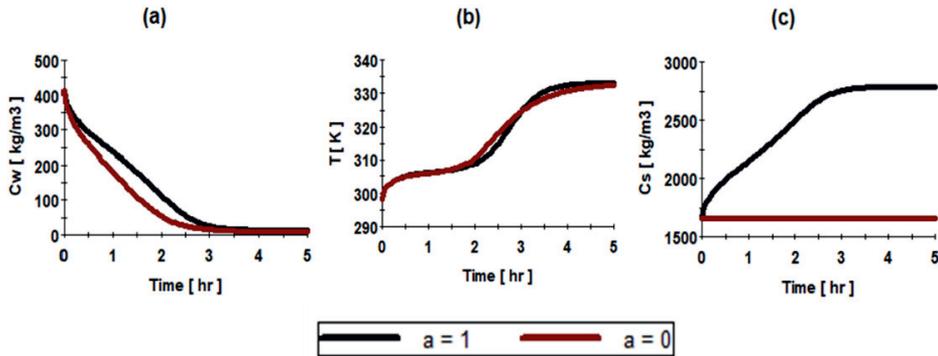

Figure 1: (a) Simulated surface moisture concentration vs time for the two cases (b) Simulated tile surface temperature vs time for the two cases (c) Surface solid concentration vs time for the two cases

Figures 1 and 3 illustrate the comparison between these two case scenarios and how the body shrinkage affects the drying kinetics of the body.

Figure 2 shows the tile shrinkage with respect to time, for the ideal-shrinkage case. It can be observed that the shrinkage stops when drying exits its constant rate period, as stated in the literature (Scherer, 1990; Lauro et al., 2021). As far as the no-shrinkage case is concerned, the tile thickness is fixed to its initial value since no volume variations occur.

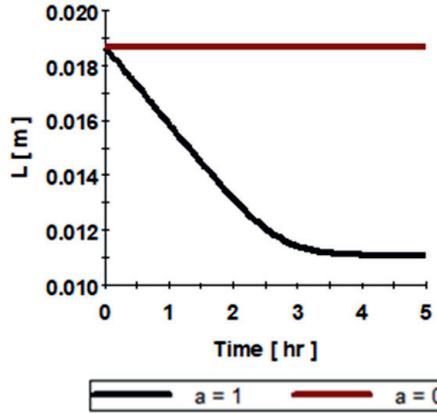

Figure 2: Tile thickness vs time for the ideal-shrinkage case and the no-shrinkage case

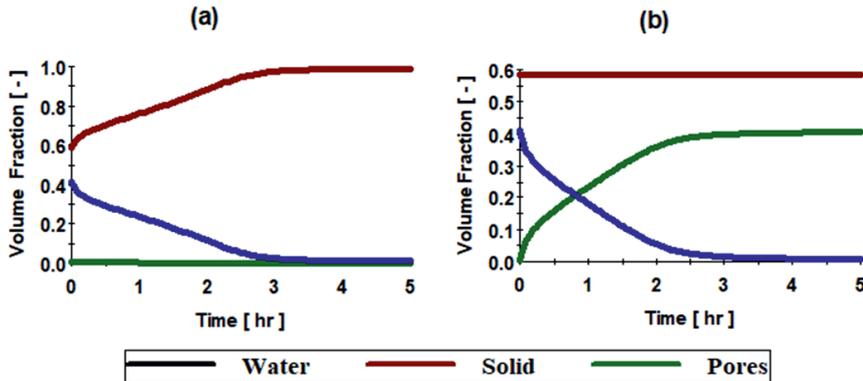

Figure 3: Surface volume fractions of the moisture, solid and the pores for (a) the ideal-shrinkage case and (b) for the no-shrinkage case

As it was stated earlier, when $a = 1$, the green body's volume is decreased by the volume of the evaporated water. In that case, an increase in the local solid concentration is expected along the tile. For the ideal-shrinkage scenario, since no pores are created as drying proceeds, the solid concentration approaches the solid's intrinsic density asymptotically. On the other hand, when $a = 0$, pores with an equal volume as the removed water's are created along the tile. Hence, the solid concentration is not affected. This phenomenon can be displayed in Figures 1c and 3.

Figure 3 presents the graphical illustration of the terms of the right-hand side of equation (6). For the ideal-shrinkage scenario (see Figure 3a), the local solid volume fraction increases with respect to time while the moisture volume fraction decreases. No pores are created. When it comes to the no-shrinkage scenario (see Figure 3b), the solid volume fraction remains fixed to its initial value through the process as no volume variations take place on the body. At any time, the volume of the removed moisture is replaced by an equal volume of air. Thus, the product's porosity increases as drying proceeds.

4. Conclusions

In this work, a 1-D modeling framework is proposed to simulate the drying behavior of a shrinking roof tile. Two marginal shrinkage scenarios were examined. These two scenarios were distinguished by the value of the shrinkage parameter a , which illustrates a key role in the overall analysis. The simulated results confirm the robustness of the model. It is important to note that the above framework can be used to capture the phenomena that accompany drying of a wet tile even for more realistic shrinkage scenarios, i.e., when $a \in (0,1)$, in which the tile's thickness decreases while its porosity increases.

Abstract

The application of a highly efficient continuous counter-current extraction to extract Artemisinin from *Artemisia Annu*a leaves is desirable since Artemisinin is efficiently used as anti-malaria drug. The residence time distribution (RTD) of the solid and liquid phases are most important for understanding this process since they influence the reaction efficiency. This work is devoted to the numerical investigation of the solid-phase RTD in a fully-filled screw extractor by using computational fluid dynamics (CFD). The solid phase is considered as a liquid Eulerian phase with a high viscosity. To track it, the commonly used species model has been implemented in a frozen quasi-steady-state simulation. Validation experiments have been performed by using dry leaves. A very good agreement between numerical and experimental residence times can be observed, with a relative error lower than 12 %. As a next step the model will be extended to predict the RTD in a multiphase flow model including the liquid solvent.

Keywords: computational fluid dynamics (CFD), extraction, residence time distribution

1. Introduction

The implementation of counter-current extraction processes provides advantages compared to the direct current method, since higher final concentrations of the target substance can be achieved in the solvent. Especially in the field of natural product extraction high yields of plant substances are required for drug preparation (Lack, 1985). In this work the solid-liquid counter-current extraction process of *Artemisia Annu*a leaves to gain Artemisinin is investigated. Derivatives of Artemisinin (e.g. artesunate) are increasingly used as efficient anti-malaria drugs (Gilmore et al., 2014). The extraction efficiency of this leaching process is influenced by the contact times between the liquid solvent and the solid plant material. Consequently, the knowledge of the residence time distribution (RTD) of both phases is of particular interest. The RTD is directly linked to the apparatus performance as it is influenced by various process parameters, such as throughput, the rotation speed of the screw, or the process temperature. Its characterization is highly important for many industrial processes such as the continuous production of chemicals, food and pharmaceutical products (Gao et al., 2012). Experimental measurements are the most common way to study the RTD in an apparatus. However, such measurements can be very expensive, especially when considering scale up or plant design. Here, computational fluid dynamics (CFD) may provide a deeper

understanding of the multiphase flow and of the controlling interactions. Chen et al. (2019) used CFD simulation to measure the particle residence time distribution in a fluidized bed by using the species method and the multi-solid method for tracer injection, which are the most common Eulerian methods. While the species method only solves a species transport equation for a numerical tracer, the multi-solid method describes two or more solids as Eulerian phases by considering interactions. Both methods can in principle deliver accurate predictions of the RTD, but the species method needs prior information concerning the diffusion coefficient. Nevertheless, the associated computational time is lower compared to the multi-solid method. This is the reason why several additional studies used the species method for getting the RTD behavior of multiphase flows, e.g. Adeosum et al. (2009), Deshmukh et al. (2009), and Zhang et al. (2015).

In this study the species method is used as well to describe the RTD distribution of the solid phase in a fully-filled screw extractor. The diffusion coefficient is derived from prior experiments. Finally, the numerical results are validated by comparison with experimental data.

2. Mathematical Model

2.1. Mean residence time and variance

The mean residence time and variance can be determined from the residence time distribution (RTD), which is a function of the length of the observed extruder. For measuring the RTD in a device, the stimulus response technique with pulse or stepwise input of tracer is typically used. The tracer concentration is measured by an appropriate device at the outlet of the extruder, leading to concentration curves named $E(t)$ and $F(t)$ curves, also known as normalized residence time distribution function and cumulative exit age distribution function, respectively. Both functions can be transformed into each other following Levenspiel (1999):

$$F(t) = \int_0^t E(t) dt \quad (1)$$

or conversely

$$E(t) = \frac{dF(t)}{dt} \quad (2)$$

The mean residence time τ and the variance σ^2 can be derived from $E(t)$.

$$\tau = \int_0^{\infty} t \cdot E(t) dt \quad (3)$$

$$\sigma^2 = \int_0^{\infty} (t - \tau)^2 \cdot E(t) dt \quad (4)$$

2.2. Dispersion coefficient

The dispersion model is frequently applied to describe back-mixing effects in tubular reactors. For this purpose, an additional axial dispersion coefficient D_{ax} is introduced into a second-order term in the mass balance:

$$\frac{\partial c_{\alpha}}{\partial t} = -u_{ax} \frac{\partial c_{\alpha}}{\partial z} + D_{ax} \frac{\partial^2 c_{\alpha}}{\partial z^2} \quad (5)$$

Implementing the species method in CFD requires the provision of the axial dispersion coefficient as input parameter. It can also be expressed via the dimensionless Bodenstein number Bo , which includes the axial velocity u_{ax} and the length of axial coordinate L .

$$Bo = \frac{2\tau^2}{\sigma^2} \quad (6)$$

$$D_{ax} = \frac{u_{ax}L}{Bo} \quad (7)$$

3. Experiments and Simulation

3.1. Experimental Setup

For validating the CFD simulations three experiments with equal operating conditions have been performed. The employed screw extractor with a total length of 320 mm is shown in Figure 1. The milled dry leaves are introduced as powder on the left-hand side until total filling of one segment is reached. When starting the screw rotation with 1.3 rpm the leaves are transported towards the right side of the device over a total flow length of 260 mm. The RTD during the transport process is controlled by a sampling of leave material at four different locations, marked 1 to 4 in Figure 1. Since only the dry leaves transport in the screw extruder has been considered no compression inside the device occurs. Consequently, the pressure equals atmospheric pressure.

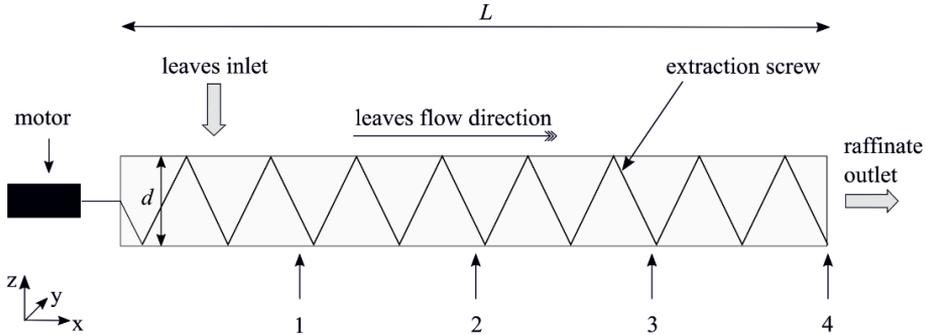

Figure 1: Counter-current screw extractor used for solid RTD experiments with equally distributed sampling points 1-4, $L = 320$ mm, $d = 29.7$ mm

3.2. Numerical Setup

The flow investigation was performed by using the commercial CFD software package StarCCM+ (Simcenter STAR-CCM+ 2019.2.1 Build 14.04.013). The computational geometry corresponds to the configuration used in the experimental setup (Figure 1). A block-structured mesh has been generated with a total number of 830.931 finite-volume cells. According to a previously performed mesh independence study this resolution provides the most accurate results by reducing numerical diffusion. Since only the screw rotates, the domain has been separated into a rotating and a stationary domain. Refinements at the interface between the domains were implemented to accurately capture the occurring leakage flows. As the numerical simulation of solid phases is very complex, the *Artemisia annua* leaves have been modelled as a Newtonian fluid with a very high viscosity of $\eta = 1,000$ Pa·s. Due to the slow rotation of the screw (1.3 rpm) and the high viscosity the resulting flow is laminar. A slip boundary for all walls has been implemented. The CFD simulation considers a completely filled system. The real experiments naturally involve a thin layer of gas phase (air) at the top, but it does not play any significant role for the extraction process. It is therefore neglected in CFD to reduce the computational effort. To adapt the inflow velocity of the leaves in CFD to the experiments an average axial velocity \bar{u}_{ax} has been calculated from experimental data.

$$\bar{u}_{ax} = \frac{L}{\tau_{exp}} \quad (8)$$

To measure the residence time distribution, the species method has been implemented by using the experimentally determined axial diffusion coefficient at the outlet (sampling point 4). First, the flow has been solved for 30 s of physical time until velocities and pressure converged to a specific value to ensure a quasi-steady state. Subsequently, the resulting flow has been frozen, and the species has been initialized and solved as single transport equation in the domain. Further modeling details can be taken from Table 1.

Table 1: Physical models and boundary conditions

Models	Parameter	Value	Unit
Laminar	Density	260	kg/m ³
Liquid	Viscosity	1000	Pa·s
Segregated Flow	Velocity Inlet	4.5×10^4	m/s
2nd order Implicit Unsteady	Time Step	0.5	s
Three Dimensional	Screw rotation	1.3	rpm
	Gravity z	-9.81	m/s ²

4. Results and Discussion

The residence time distributions obtained from the CFD simulation at four sampling points are shown in Figure 2a and compared with the residence time distributions of the first experiment. The RTD curves are similar, but the differences in maxima increase with time. Figure 2b shows the resulting mean residence times of experiments and CFD depending on the sampling points. The numerical results show slightly higher values than the experiments resulting in an error of 7.05 % for sampling point 2, up to 14.65 % for sampling point 4 (Table 2). These errors correspond to a difference in residence time between 0.31 and 1.32 min. Nevertheless, during the independent repetitions of the same experiment, some deviations of the RTD curves have also been observed. They occur due to minute changes of particle size distributions, particle-particle interactions, but also small variations in the screw rotation speed. As the experimental values are not perfectly repeatable a second comparison of numerical residence times is performed by involving three experimental realizations, considering the mean values and their deviations to each other (Figure 3). Here, the numerical mean residence times fit the experimental residence time for sampling points 2 and 3. For sampling point 1 the experimental residence time is slightly higher than the numerical one, by 12 % (Table 3). For sampling point 4 the numerical residence time is outside the experimental range by only 2.48 %. Consequently, the numerical predictions are very close to the experimentally measured values, proving that the CFD model can appropriately predict the residence time.

Table 2: Comparison of numerical results and experimentally measured residence times ($D_{ax} = 1.41 \times 10^{-6} \text{ m}^2/\text{s}$)

Sampling Point	τ_{CFD} (min)	$\tau_{exp,1}$ (min)	error (%) (vs. exp.)
1	1.54	1.74	11.49
2	4.71	4.40	7.05
3	7.88	6.99	13.31
4	10.33	9.01	14.65

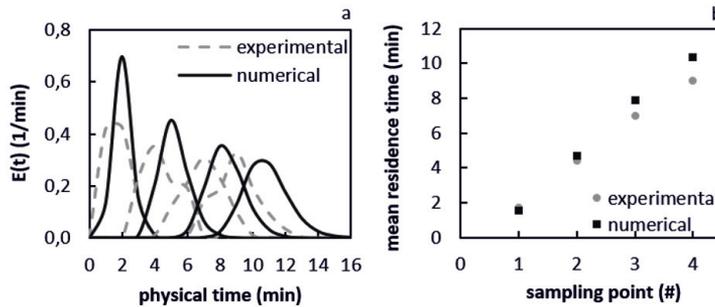

Figure 2: Results of the solid RTD study and comparison between experiments and numerical simulation regarding a) RTD curves at four sampling points, b) mean residence times

Table 3: Numerical mean residence time compared to the deviations observed when repeating the experiments ($D_{ax} = 1.41 \times 10^{-6} \text{ m}^2/\text{s}$)

Sampling Point	τ_{CFD} (min)	$\bar{\tau}_{\text{exp,all}}$ (min)	$\sigma_{\text{exp,all}}$ (min)	error (%) (vs. range)
1	1.54	1.89	± 0.14	12.00
2	4.71	4.94	± 0.47	-
3	7.88	7.77	± 0.68	-
4	10.33	9.58	± 0.50	2.48

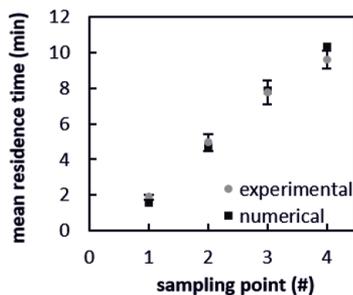

Figure 3: Comparison of the numerical mean residence time with three experimental runs

5. Conclusion and Outlook

In this study the solid residence time in a counter-current screw extractor has been analyzed by using CFD simulations. Since solid-phase RTD experiments show deviations in the resulting mean residence times, the numerical simulations have been first compared to one single experimental trial, then to the average value involving three measurement campaigns. The results show that the CFD mean residence time fits in the range of the experimental observations. The first sampling point shows the largest deviation, with an error of only 12 % (12.6 s). As this is considered an acceptable range, the numerical model with a fully-filled Eulerian phase can appropriately predict the solid RTD of *Artemisia Annua* leaves. Using the frozen quasi-steady-state flow allows short computational times for the implemented species method. This will enable future multiphase flow simulations with liquid and solid phase even closer to the experimental reality.

The numerical representation of the RTDs will then be used to parametrize compartment models (CM) in which the reaction kinetics can be considered with acceptable computational times. This mixed CFD/CM model will be used for the final optimization.

Abstract

Background: Parallel to the impending hydrogen economy, the simultaneous treatment of organic waste and biohydrogen synthesis by the photosynthetic bacterium *Rhodospseudomonas palustris* is a promising renewable energy technology. However, studies so far have been mostly laboratory based with upscaling of the bioprocess still being an open challenge. Therefore, this study investigates two different photobioreactors (PBRs): schott bottle-based and vertical tubular-based PBRs and presents three original contributions to facilitate the biotechnology transfer across PBR scales and configurations.

Study Design: Firstly, a dynamic model is constructed to simulate the complicated influences of light intensity, light attenuation, and temperature, previously not unified for any photosynthetic bacteria to the best of our knowledge. Secondly, perturbation analysis was exploited to identify critical parameters influencing the model accuracy and reliability for across the scale extrapolations. Thirdly, two model parameters: *effective light coefficient* and *biohydrogen enhancement coefficient*, both linked to the PBR's transport phenomena were proposed for recalibrations during bioprocess upscaling predictions.

Major results: By comparing against experimental data, the upscaling prediction accuracy was thoroughly verified for the two investigated PBR scales. As well, the enhancement of biohydrogen production rate by improved culture mixing and gas removal was mechanistically described.

Conclusion: This provides important advances for the efficient design of novel PBRs and future online optimisation for biohydrogen production.

Keywords: Photobioreactor, Biohydrogen production, kinetic modelling, Purple non-sulfur bacteria, Upscaling.

1. Introduction

Renewable biohydrogen is a key biofuel identified as one promising alternative to the conventional fossil-based fuels for providing energy meant for: (i) electricity generation,

(ii) transportation, and (iii) heating [1, 2]. Amongst the several species of photosynthetic microorganisms which can synthesis biohydrogen, the purple-non-sulfur photosynthetic bacterium *Rhodospseudomonas palustris* (hereinafter referred to as *R. palustris*) has been identified as a promising candidate due to: (i) the absence of oxygen-induced nitrogenase repression; (ii) a versatile metabolic repertoire with capabilities of degrading a wide variety of organic substrates including those toxic to other microorganisms; as well as (iii) the continuous synthesis of biohydrogen during all the growth phases, including the stationary phase which is observed to last significantly longer under anaerobic conditions than in cyanobacteria and microalgae species [2]. Despite these benefits, literature investigations have been mostly carried out at the laboratory scale and to a lesser extent at the pilot scale but remains pending industrial scale applications. Although mathematical models can help facilitate the experimental design and process upscaling, two of the most important cultivating factors, namely temperature and light intensity (plus light attenuation herein - the decrease in light transmission due to cellular absorption and scattering within PBRs) have never been unified/coupled in a biokinetic model of any photosynthetic bacteria in general and *R. palustris* in particular. Therefore, this paper aims to: (i) investigate the photoheterotrophic biomass growth and biohydrogen production of *R. palustris* in two different Photobioreactors (PBRs) configuration and scales: schott bottle-based (0.5 L) and vertical tubular-based (1 L) PBRs, (ii) construct an accurate mechanistic model of the bioprocess under the unified influences of temperature, and light intensity, and light attenuation, and (iii) evaluate model's applicability for simulating process dynamics over different scales and configurations of PBRs.

2. Methodology

2.1. Mechanistic model construction

The photo-heterotrophic biomass growth, substrate consumption and biohydrogen production under the influences of light intensity, light attenuation, and temperature are simulated with Equations (1) to (3). The biomass growth (Equation 1) assumes negligible cell death and replete amount of substrate (i.e., > 20 mM at the end of each batch) with the rate of substrate consumption described in Equation (2). The biohydrogen production model (Equation 3) is an extension of the Luedeking-Piret model with the incorporation of temperature and light intensity influences on the linear dependence of biomass growth rate and instantaneous biomass concentration. The first square brackets on the Right-Hand-Side of Equations (1) and (3) simulates the monotonic increase of microbial activity by temperature which does not exceed the optimal operational value (i.e., 313.15 K) for *R. palustris* biomass growth [3]. Assuming the absence of photoinhibition for light intensities not higher than 200 W m^{-2} [4], photolimitation and photosaturation are the main photo-mechanisms captured from the Aiba model as represented by the second square brackets on the Right-Hand-Side of Equations (1) and (3).

2.2. Dynamic parameter estimation

Generally, the model parameter estimations were solved by weighted nonlinear least-square regression. However, due to the high nonlinearity, the entire process was decoupled into two steps with step I: estimating biomass growth and substrate consumption model parameters, and step II: estimating biohydrogen model parameters while fixing the optimal solution of step I. Due to stiffness and nonlinearity, orthogonal collocation over finite elements in time was used to discretise the differential equations, then solved with the interior point solver, IPOPT through the open-source interface Pyomo, within Python version 3.7 programming environment.

$$\frac{dX}{dt} = \mu_{max} \cdot \left[A \cdot \exp\left(-\frac{E_a}{RT}\right) \right] \cdot \left[\frac{\frac{I_0}{(\tau \cdot X) \cdot L} \cdot (1 - e^{-(\tau \cdot X) \cdot L})}{\frac{I_0}{(\tau \cdot X) \cdot L} \cdot (1 - e^{-(\tau \cdot X) \cdot L}) + k_s} \right] \cdot X \quad (1)$$

$$\frac{dS}{dt} = -Y_{XS} \cdot \frac{dX}{dt} - m \cdot X \quad (2)$$

$$\frac{dH_2}{dt} = \alpha_{max} \cdot \left[A_{H_2} \cdot \exp\left(-\frac{E_{a,H_2}}{RT}\right) \right] \cdot \left[\frac{\frac{I_0}{(\tau \cdot X) \cdot L} \cdot (1 - e^{-(\tau \cdot X) \cdot L})}{\frac{I_0}{(\tau \cdot X) \cdot L} \cdot (1 - e^{-(\tau \cdot X) \cdot L}) + k_{s,H_2}} \right] \cdot X \quad (3)$$

where X , S and H_2 , are the biomass concentration (g L^{-1}), substrate concentration (mM) and biohydrogen production (mL) respectively, μ_{max} and α_{max} are the maximum specific growth rate (h^{-1}) and maximum specific production rate (h^{-1}) respectively, $\mu_{max} \cdot A = A'$ (h^{-1}) and $\alpha_{max} \cdot A_{H_2} = A'_{H_2}$ (h^{-1}) are the pre-exponential factors which are lumped for identifiability purposes, E_a and E_{a,H_2} are the activation energies (J mol^{-1}), R the is universal gas constant ($8.3145 \text{ J mol}^{-1}\text{K}^{-1}$), T is the absolute temperature (K), I_0 is the incident light intensity (Wm^{-2}), τ ($\text{m}^2 \text{ g}^{-1}$) is the light absorption coefficient, L (m) is the light path length, Y_{XS} and m as the substrate yield coefficient (mmol g^{-1}) and maintenance coefficient ($\text{mmol g}^{-1} \text{ h}^{-1}$), respectively.

2.3. Parameter perturbation analysis

The parameters in the mechanistic model are grouped into three classes: Class I (i.e., Y_{XS} and m) for reaction conversion related parameters, Class II (i.e., k_s , k_{s,H_2} and τ) for light intensity associated parameters, and Class III (i.e., A' , E_a , A'_{H_2} and E_{a,H_2}) for temperature associated parameters based on expert knowledge (e.g., Class I are well-known to great accuracy from microbiological studies meanwhile the same is not true for Class III). Input parameter uncertainties are assigned to each Class, then probabilistic sampling with Latin Hypercube Sampling was carried out, and the effects on the model's prediction uncertainty was propagated by Monte Carlo simulations.

2.4. PBR large scale simulations

The frequencies of local light/dark cycles are the only factor influenced by the PBR's transport phenomena on biomass growth rate. This effect was simulated in our recent study [5] by introducing one additional parameter (i.e., *effective light intensity coefficient*, η) which is larger than 1 if the PBR's culture mixing is intensified thereby leading to Equation (4). As the biohydrogen production rate is known to be a function of the PBR's biohydrogen partial pressure since this reaction is reversible, another parameter (i.e., *biohydrogen enhancement coefficient* ϕ) is added into Equation (6) to affect the overall hydrogen production rate as per the influence of biohydrogen removal rate and gas-liquid mass transfer.

$$\frac{dX}{dt} = A' \cdot \exp\left(-\frac{E_a}{RT}\right) \cdot \left(\frac{\frac{I_0}{(\tau \cdot X) \cdot L_L} \cdot (1 - e^{-(\tau \cdot X) \cdot L_L})}{k_s \left(\frac{1}{\eta}\right) + \left(\frac{I_0}{(\tau \cdot X) \cdot L_L} \cdot (1 - e^{-(\tau \cdot X) \cdot L_L})\right)} \right) \cdot X \quad (4)$$

$$\frac{dS}{dt} = -Y_{XS} \cdot \frac{dX}{dt} - m \cdot X \quad (5)$$

$$\frac{dH_2}{dt} = \phi \cdot A'_{H_2} \cdot \exp\left(-\frac{E_{a,H_2}}{RT}\right) \cdot \left(\frac{\frac{I_0}{(\tau \cdot X) \cdot L_L} \cdot (1 - e^{-(\tau \cdot X) \cdot L_L})}{k_{s,H_2} \left(\frac{1}{\eta}\right) + \left(\frac{I_0}{(\tau \cdot X) \cdot L_L} \cdot (1 - e^{-(\tau \cdot X) \cdot L_L})\right)} \right) \cdot X \quad (6)$$

3. Results and discussion

3.1. Dynamic parameter estimation results

Table 1 lists the obtained parameter values while the orange line in figure 1 shows the model fitting result after the step I of the parameter estimation for 100 Wm^{-2} and 200 Wm^{-2} at 35°C and 30°C , respectively with the remainder (i.e., 200 Wm^{-2} at 35°C and 40°C) not shown due to fitting similarities.

Table 1: Model parameter estimates and literature validation.

Parameters	Estimated	Parameters	Estimated
Step-one optimisation		Step-two optimisation	
$\mu_{T=303.15 \text{ K}}$ (h^{-1})	0.159	$\alpha_{T=308.15 \text{ K}}$ (h^{-1})	81.0
$\mu_{T=308.15 \text{ K}}$ (h^{-1})	0.185	$\alpha_{T=313.15 \text{ K}}$ (h^{-1})	106.0
$\mu_{T=313.15 \text{ K}}$ (h^{-1})	0.225	k_{s,H_2} (Wm^{-2})	500.0
k_s (Wm^{-2})	500.0	A' (h^{-1})	8.30×10^3
τ ($\text{mm}^2 \text{ g}^{-1}$)	90.8	E_a (J mol^{-1})	2.74×10^4
Y_{XS} (mmol g^{-1})	9.66	A'_{H_2} (h^{-1})	1.01×10^{10}
m ($\text{mmol g}^{-1} \text{ h}^{-1}$)	0.0140	E_{a,H_2} (J mol^{-1})	4.78×10^4
$\alpha_{T=303.15 \text{ K}}$ (h^{-1})	56.9		

3.2. Results of parameter perturbation analysis

Figure 1 shows the uncertainty bands and average percentage uncertainty over the process trajectory to be lowest and highest for Class I parameters (not shown) and Class III parameters respectively. This suggests that the model is highly sensitive to changes of Class III parameters but is less responsive to Class I parameters. Therefore, it is necessary to design more experiments for the accurate identification of temperature associated parameters meanwhile it is unsafe to update these Class III parameters during model-based process online optimization considering the high level of prediction uncertainty that can be introduced into the model output. Conversely, Class II parameters only showed a similar magnitude of model uncertainty when their input uncertainty was around 20% thereby indicating the model to be robust in their mild changes. Hence, Class II parameters are the ideal candidates to be re-estimated during online operation if the model is used for dynamic process optimisation.

3.3. Results of PBR large scale simulation

Figure 2 (a) to (c) shows that the model can well predict substrate consumption and hydrogen production in the large scale PBR with the calibrated transport phenomena associated parameters being $\eta = 4.515$ and $\phi = 1.945$. The η was observed to be higher than that reported in the literature [5] (i.e., 0.25 to 3.625) thereby implying a better light utilisation efficiency in the upscaled PBR which can be associated to the enhanced transport phenomena (i.e., better culture mixing that promotes a more frequent light/dark cycling). The obtained ϕ implies that the maximum specific H_2 production rate was almost doubled due to a decrease in the PBR's partial pressure which facilitates biohydrogen synthesis. Similar observations were reported in the literature [6] whereby a 12% increase in the biohydrogen productivity of *Rhodobacter sphaeroides* ZX-5 was attained when the total pressure at the PBR's headspace was decreased from 1.082×10^5 to 0.944×10^5 Pa.

Figure 2 (d) to (f) shows the biomass, substrate and biohydrogen models to be sensitive to the transport phenomena associated parameters. This implies: (i) they tune all of the state variables during any re-calibration process for the prediction of a different PBR scale and configuration, and (ii) can be updated during process online optimisation for scenarios such as a sudden disturbance of the PBR operation (e.g., random failure event

of the mixing pumps in the PBR) since their sensitivities were relatively low in comparison to Class III parameters.

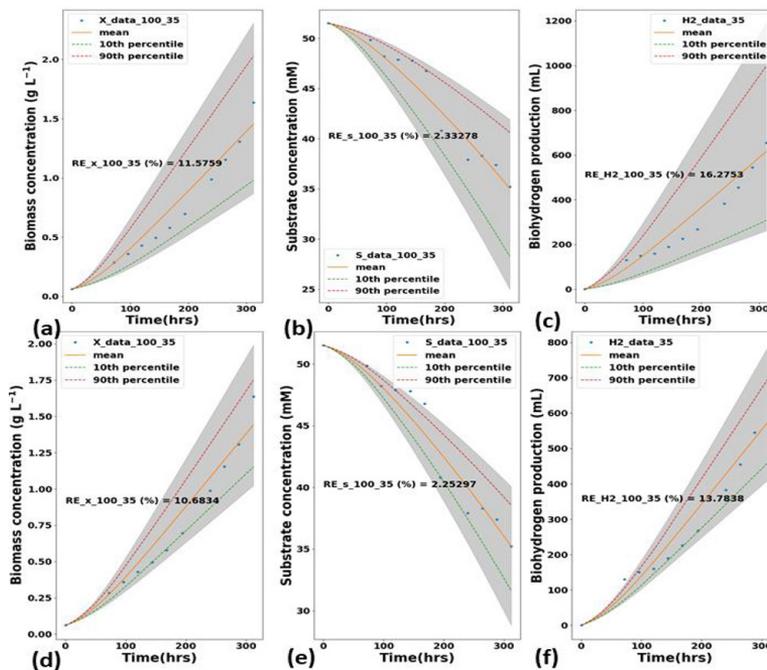

Figure 1: Perturbation analysis for input uncertainties of (a) to (c) 4% for class III, (d) to (f) 20% for class II. The mean, 10th and 90th percentile, and %RE for 100 Monte-Carlo simulations. Also, (a) to (c) and (d) to (f) are state variables corresponding to the biomass, substrate and biohydrogen models respectively

4. Conclusion

In this paper, a mechanistic model capable of simulating the photoheterotrophic biomass growth and biohydrogen production by the photosynthetic bacterium *R. palustris* under the unified influences of light intensity, light attenuation and temperature was developed. Model-based upscaling capabilities via two transport phenomena dependent parameters, η and ϕ embedded into the mechanistic model was possible after re-calibration. By using experimental data from a small (0.5 L) and large (1 L) scale photobioreactors (PBRs), the model prediction accuracy was thoroughly verified for both intra and across-scale predictions. Whilst perturbation analysis revealed temperature, light and transport phenomena associated parameters to be sensitive, the first should be identified and fixed during online model-based process optimisation meanwhile the second and last are more suitable to be updated. Amongst the investigated PBR scales, the enhanced biohydrogen production rate in the large scale PBR was attributed to the superior culture mixing and gas removal performance, and was mechanistically described for the first time. This provides important advances for the efficient design of novel PBRs and future online optimisation for biohydrogen production.

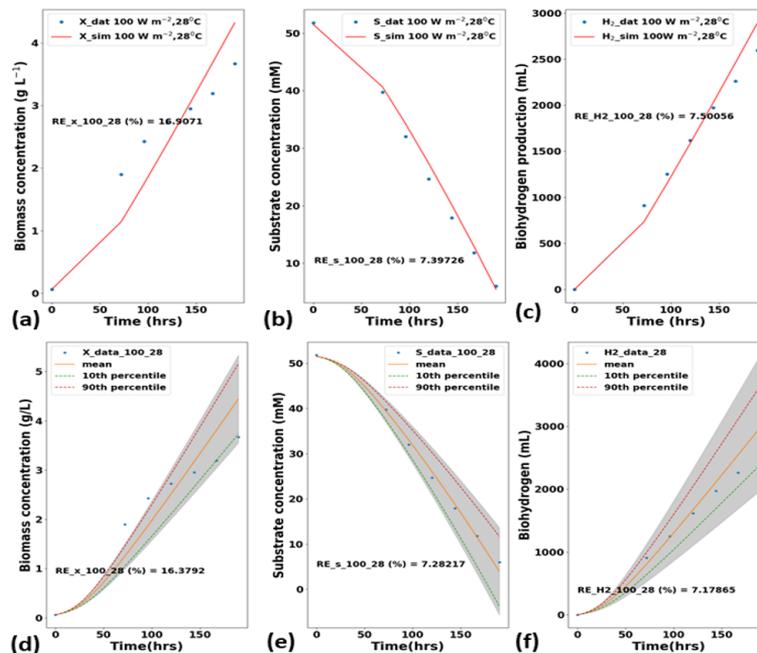

Figure 2: Simulation result of the large scale PBR: (a) to (c) and perturbation analysis (d) to (f) of 20% for transport phenomena associated parameters. The mean, 10th and 90th percentile, and %RE for 100 Monte-Carlo simulations. Each fitting is accompanied by the percentage relative error (%RE). Also, (a) to (c) and (d) to (f) are state variables corresponding to the biomass, substrate and biohydrogen models respectively.

Abstract

In oral solid-dosage manufacturing through direct compression, lubrication is used to enhance powder flowability and the ejection of the tablet from the die. However, lubrication can negatively impact tablet quality attributes such as tablets hardness or dissolution. In order to facilitate the selection of an appropriate lubrication extent, different models describing the relation between compaction performance and process conditions may be used. In particular, the extension of the Kushner and Moore model proposed by Nassar et al. (Nassar et al., 2021, *Int. J. Pharm.*, **592**, 119980) allows predicting tensile strength over a wide range of tablets solid fraction and powder blending time values. The main drawback of this model is that it requires a large number of experiments for parameter estimation. This results into a significant consumption of active pharmaceutical ingredient (API), which may be scarce and considerably expensive. In this study, model-based design of experiments is used to reduce the required experimental effort for the identification of the model parameters. We propose a novel procedure that is able to reduce parameters uncertainty while minimizing the number of required experiments. Results based on a simulated case-study demonstrate the effectiveness of the approach.

Keywords: model-based design of experiments; pharmaceutical engineering; quality by design; oral solid-dosage manufacturing

1. Introduction

In tablet manufacturing, while dry or wet granulation facilitates compaction and flow properties by converting fine powders into agglomerates (Šantl et al., 2011), direct compression improves powder manufacturability only through lubrication. Accordingly, lubrication is a crucial step: an excessive usage of lubricant may degrade tablets properties, like disintegration and dissolution, thus prejudicing the correct absorption when they are ingested by the patients. Many lubrication models have been proposed to aid the product development in tablets production through direct compression. Kushner and Moore (2010) developed a model which relates tensile strength and lubrication at the fixed solid fraction of 0.85. Recently, Nassar et al. (2021) introduced two additional parameters to the abovementioned model to describe the effect of solid fraction when it varies in a wide range of values. Despite the satisfactory predictive power, a considerable amount of experiments is needed for model parameters identification. In the industrial practice the experiments are usually carried out in a suboptimal, and consequently

ineffective, manner, based on trial-and-error approaches. The typical experimental procedure goes through the preparation of up to 7-9 blends with different lubrication extents, in which one powder blend is first prepared with a specific lubrication extent, and then a compression profiling is performed to produce tablets with different solid fractions. While changing compression pressure to have different solid fractions is not an issue, preparing a considerable number of blends (i.e., a considerable number of lubrication extents) leads to an excessive usage of API, which is expensive and may not be available in the required quantity during drug development.

In this work we adopt model-based design of experiments (MBD_{oE}; Asprey and Macchietto, 2000), which is a science driven method to select optimal experimental conditions yielding the maximum information content for the purpose of parameters estimation. In order to minimize the number of blends to be prepared, a novel approach is proposed based on a two-step optimization: first the optimal solid fractions are found for every possible value of lubrication extent (i.e., blend); then, the lubrication extent providing the most informative experiment is selected.

2. Materials and methods

The efficacy of the proposed MBD_{oE} procedure is demonstrated through numerical simulations (Figure 1): (1) a proper model describing the lubrication process is selected, together with preliminary parameters guesses; (2) based on model equations and parameters, MBD_{oE} provides the design of the most informative experiments; (3) optimal experiments are executed in the process, which in this study is simulated through a digital model; (4) optimal data are available to update parameters estimates. This procedure is iterated until satisfactory parameters precision and model predictive power are obtained.

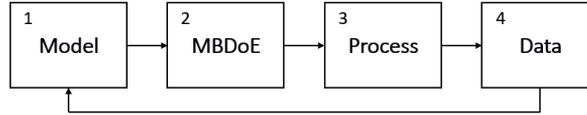

Figure 1 Workflow to validate the MBD_{oE} procedure through numerical simulations.

2.1. Lubrication model

The compression performance in the tablet press is quantified in terms of tablets tensile strength (ts , MPa), which is related to powder lubrication extent and to tablets solid fraction (sf , -) through the extended Kushner and Moore equation proposed by Nassar et al. (2021):

$$ts/ts_{sf=0.85,0} = (1 - \beta) + \beta \exp(-\gamma k) \quad (1)$$

$$ts_{sf=0.85,0} = a_1 \exp(b_1(1 - sf)) \quad (2)$$

$$\beta = a_2(1 - sf) + b_2 \quad (3)$$

where Eq. (1) represents the original Kushner and Moore (2010), while Eqs. (2) and (3) introduce the dependence of tensile strength from solid fraction.

Five parameters (θ) must be identified in this model: a_1 [MPa], a_2 [-], b_1 [-], b_2 [-] and γ [dm^{-1}]. Two variables can be manipulated in the experiments to estimate those parameters, namely solid fraction and lubrication extent.

2.2. Model-based design of experiments and global sensitivity analysis

MBD_{oE} aims at finding the optimal experiment conditions $\phi_{\text{opt}} = [sf_{\text{opt}}, k_{\text{opt}}]^T$ in terms of solid fraction and lubrication extent in such a way as to estimate the model parameters

with minimum uncertainty. This is performed by solving an optimization problem which maximizes the information obtained by the experiment, which is evaluated through the Fisher information matrix (FIM), $\mathbf{H}_{\hat{\theta}}$ (Box and Lucas, 1959):

$$\mathbf{H}_{\hat{\theta}}(\hat{\theta}, \phi) = \frac{1}{\sigma_y^2} \mathbf{S}(\hat{\theta}, \phi)^T \mathbf{S}(\hat{\theta}, \phi), \quad (4)$$

where \mathbf{S} is the sensitivity matrix whose elements are:

$$s_{sf,k}(\hat{\theta}, \phi) = \left[\frac{\partial ts}{\partial a_1}(\hat{\theta}, \phi), \frac{\partial ts}{\partial b_1}(\hat{\theta}, \phi), \frac{\partial ts}{\partial a_2}(\hat{\theta}, \phi), \frac{\partial ts}{\partial b_2}(\hat{\theta}, \phi), \frac{\partial ts}{\partial \gamma}(\hat{\theta}, \phi) \right]_{sf,k}, \quad (5)$$

the decorator symbol ($\hat{\cdot}$) indicates estimated quantities, ϕ is the design vector which collects inputs variables, i.e. $\phi = [sf, k]^T$, and $\hat{\theta}$ are the estimated parameters. In this study, the information content is maximized through a D-optimal strategy (Pukelsheim, 1993) which minimizes the volume of the parameters uncertainty region:

$$\phi_{\text{opt}} = \underset{\phi}{\text{argmax}} \{ \det[\mathbf{H}_{\hat{\theta}}(\hat{\theta}, \phi)] \} \quad (6)$$

Note that, to avoid the dominance of some variables or parameters due to different scales, data are pre-treated through a division by a reference value (e.g., the mean value of each variable) and the parameters are estimated with scaled data and indicated with capital letters, i.e. $\hat{\theta} = [\hat{A}_1, \hat{B}_1, \hat{A}_2, \hat{B}_2, \hat{\Gamma}]^T$.

Considering that MBDofE calculations rely on sensitivity indices and that parameters with negligible influence on the response tend to have higher uncertainty, a preliminary global sensitivity analysis is performed. Sobol's method (Saltelli et al., 2008) is applied, estimating first-order ($S_{\text{main},i}$, $i=A_1, \dots, \Gamma$) and total-order ($S_{T,i}$, $i=A_1, \dots, \Gamma$) sensitivity indices with a latin-hypercube sampling strategy. In particular, 8000 resamplings are performed in the entire parameters domain whose ranges are shown in Table 1.

Table 1 Lower and upper bounds for model parameters used in global sensitivity analysis.

Parameter	Lower bound	Upper bound
A_1	0	5
B_1	-7	-2
A_2	0	5
B_2	0	5
Γ	0	5

2.2.1. Two-step MBDofE

With a classic MBDofE, input variables are freely varied inside their domain; therefore, in each iteration of the MBDofE procedure ϕ_{opt} may have different k_{opt} , which corresponds to the preparation of different powder blends after one compression point. However, the number of blends that should be prepared (i.e., the changes in powder lubrication extent) should be minimized for operational reasons. To reach this goal, we adapt the MBDofE procedure by developing a two-step optimization. At first, experimental domains of the input variables are specified: sf varies in the continuous range [0.65, 0.90], while k can take on integer values in [90, 2000] dm. Then, the following optimizations are performed:

- a possible value of k is fixed and the optimization (6) is solved to get N_{SF} optimal values of sf ; the set of N_{SF} solid fractions for the same lubrication extent is named "profile"; this procedure is repeated for every possible value of k ;
- among all calculated profiles, the one maximizing the objective function in (6) is selected as the optimal experiment to be executed ($\phi_{\text{opt}} = [sf_{\text{opt},1}, \dots, sf_{\text{opt},N_{SF}}, k_{\text{opt}}]^T$).

In general, the same values of $sf_{\text{opt},i}$ and k_{opt} can be obtained by solving (6) multiple times; however, since the objective is to reduce the experimental burden, replications of similar optimization results are avoided by imposing that the optimal values differ by at least 150 dm for k and 0.04 for sf . This allows to better explore the experimental domain, which is advantageous in case of process-model mismatch.

In order to have sufficient experimental data for model calibration, the two optimization steps are iterated $N_K = 4$ times, thus obtaining N_K profiles. For each profile, $N_{SF}=5$ optimal solid fractions are calculated.

In both optimization steps, results depend on the quality of the parameters estimates $\hat{\theta}$ used in (6), but usually “true” parameters estimates are not available at the beginning of the experimental campaign and parameters guesses $\hat{\theta}_{\text{guess}}$ must be used. In this study, we choose guesses based on historical data. Indeed, the datasets of five different formulations named A, B, C, D and E (for details, see Nassar et al., 2021) are available. Since they comprise a considerable amount of data points, the estimated parameters are treated as “true values” ($\theta_A, \theta_B, \theta_C, \theta_D, \theta_E$ respectively) and reliable initial guesses are obtained by setting $\hat{\theta}_{\text{guess}} = \text{mean}(\theta_A, \theta_B, \theta_C, \theta_D, \theta_E)$.

2.3. Process

In this study, we represent the process through a digital model of the historical formulation A, which is made of equations (1)-(3) and “true” parameters θ_A . Noise is added to the in-silico data to mimic experimental and measurement errors. In particular, given that specific solid fractions are difficult to be achieved in the physical system, pseudo-random noise is added to $sf_{\text{opt},i}$, $i = 1, \dots, N_{SF}$ to reproduce experimental errors (the mean sf error is 0.01). Furthermore, pseudo-random noise is added also to the values of ts generated by the digital model to reproduce a ts error variance of 0.02.

2.4. Global sensitivity analysis

First-order and total-order sensitivity indices are calculated in the selected domain of sf values for three different given lubrication extents, namely 90 dm, 800 dm, 2000 dm. Results (Figure 2) show that:

- at low lubrication extents ($k=90$ dm in Fig 2.a), the most influential parameters are \hat{A}_1 , \hat{B}_2 and \hat{B}_1 , while at medium and high lubrication extents ($k=800$ dm and $k=2000$ dm in Fig 2.a) the influence of \hat{B}_2 on the response is dominant;
- parameter \hat{A}_2 has always little influence on the response (Fig 2.b); therefore, it is expected to have higher uncertainty when the model is calibrated with experimental data. However, S_{T,\hat{A}_2} is not constantly equal to zero, thus this parameter cannot be set to a nominal value;
- the summation of the total effects (omitted for sake of conciseness) is almost always higher than 1, suggesting a high level of interaction among parameters at every sf and k value, which in turn complicates the unique identification of parameters.

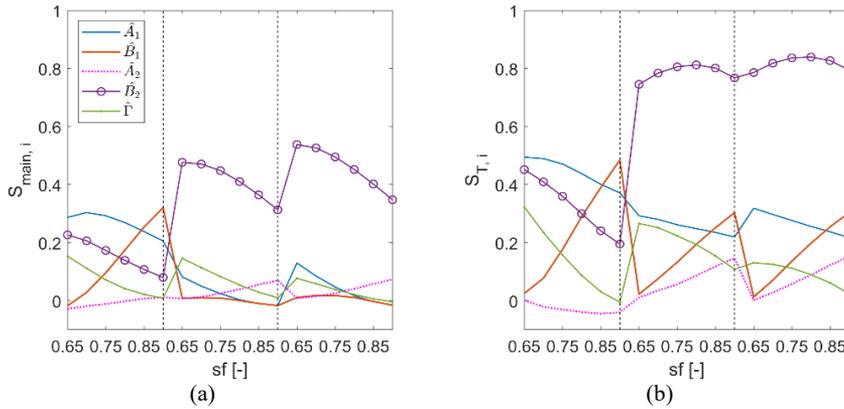

Figure 2 Global sensitivity analysis on model (1)-(3). Two types of sensitivity indices are shown: (a) main effects; (b) total effects. They are calculated for three different lubrication extents: 90 dm, 800 dm and 2000 dm (separated by vertical black dotted lines).

2.5. Design of optimal experiments

By applying the two-step MBDofE procedure, the following optimal lubrication extents are obtained: 90 dm, 2000 dm, 718 dm, 1849 dm. Since the process is affected by experimental and measurement errors, four replicates are generated in silico for every optimal solid fraction level.

Optimal profiles are used to identify model parameters, whose precision is assessed through a t-test (Table 2). Moreover, model validation is performed by calculating the tensile strength absolute error (*ts* AE) with the historical dataset A in the domain of the MBDofE optimization, i.e. with *k* in [90, 2000] dm. As suggested by the process experts, the desired model predictive power is a percentage of at most 5% of data points with a *ts* AE exceeding 0.25 MPa.

Table 2 Results of model calibration performed with an increasing amount of optimal profiles generated in silico. Parameters estimates are shown together with 95% confidence intervals ($\hat{\theta}_i, \pm 100(1-\alpha)\%CI$); CI are not calculated when the FIM is ill-conditioned. Parameters precision is assessed through a t-test; estimates not satisfying the t-test are indicated with an asterisk (*).

no. k_{opt}	$\hat{\theta}_i, \pm 100(1-\alpha)\%CI$				
	\hat{A}_1	\hat{B}_1	\hat{A}_2	\hat{B}_2	$\hat{\Gamma}$
2	0.14*	-4.82*	0.92*	1.00*	0.63*
3	0.15±0.03	-4.81±0.41	0.72±0.44*	0.79±0.23	1.26±0.58
4	0.15±0.03	-4.81±0.40	0.71±0.37	0.80±0.19	1.21±0.53

The t-test for parameters precision show that two optimal profiles do not allow to obtain statistically sound parameters estimates; a considerable improvement is achieved by adding the third profile, since all parameters except for \hat{A}_2 pass the t-test. The higher uncertainty of this parameter is likely due to the scarce influence on the response, as revealed by GSA (Section 2.4). The addition of the fourth optimal profile significantly improves the quality of \hat{A}_2 , which passes the t-test; moreover, and the fourth optimal profile slightly improves the precision of parameters \hat{B}_2 and $\hat{\Gamma}$ (their 95% CI are smaller) and brings negligible differences in terms of parameters estimates and intervals for \hat{A}_1 and \hat{B}_1 . Moreover, three optimal profiles allow to attain the desired model predictive

performance (Fig. 3), leading to a reduction of the experimental effort by more than 50% with respect to the standard industrial practice.

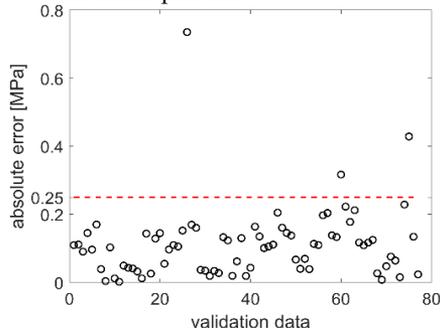

Figure 3 Tensile strength absolute error when the model is calibrated with three optimal profiles.

3. Conclusions

Lubrication models are used in the pharmaceutical industry to aid the design of lubrication processes, which in turn are crucial to facilitate tablets manufacturability and to ensure the desired product quality. Precise model parameters are required to the scope, but they are usually obtained with an excessive amount of experimental data, which implies a considerable API usage (thus, high costs) and time-consuming experimental campaigns. We solve this issue by proposing a novel MBDoE procedure that allows to select the most informative experiments for the purpose of parameters estimation. Moreover, the proposed MBDoE approach is able to minimize the change in lubrication extent, thus the number of blends to be prepared, through a two-step optimization: first, solid fraction values are optimized for every lubrication extent, thus providing multiple profiles of optimal sf ; among them, the profile maximizing parameters precision is selected as the best experiment to be performed. We demonstrate that it is efficient in reducing the experimental effort by more than 50% with respect to the standard industrial practice, with considerable savings in terms of API and time for the experimentation. Indeed, three optimal blends instead of the typical 7-9 are sufficient to obtain both statistically sound parameters estimates and the desired prediction quality. However, with three optimal profiles a higher uncertainty has to be accepted for parameter \hat{A}_2 , which is likely due to the small influence of this parameter on the model response.

Abstract

In oral solid dosage (OSD) forms manufacturing, understanding and characterizing the flowability of pharmaceutical formulations is pivotal since product and process performance directly depend on this property. Therefore, whenever a formulation change occurs during drug development, the impact on powder flowability must be quantified to address any potential effects on the manufacturability or critical quality attributes of the final product. Current industrial practice relies on extensive experimentation to address this problem, resulting into a significant consumption of active pharmaceutical ingredient (API), which is expensive and scarce during the early stages of drug development.

In this study, we propose a mixing rule model that can be used to predict the flowability of pharmaceutical blends from the flowability of the individual components. The model is validated with 35 different powder blends consisting of common APIs and excipients used for directly compressed pharmaceutical formulations. Results show that, by measuring the flowability of the pure API and only 6 binary mixtures, the mixing rule model can be used to predict the flowability of directly compressed pharmaceutical blends containing the API without further experiments. For a new pharmaceutical product, the reduction in experimental effort using this modelling approach can translate to ~80% reduction of API consumption, depending on the formulated product and the API physical properties.

Keywords: quality by design; pharmaceutical manufacturing; mixing rules; OSD

1. Introduction

Understanding powder flowability is critical to the success of several unit operations involved in the manufacture of oral solid dosage (OSD) forms (Prescott and Barnum, 2000). The performance of feeders, blenders, tablet presses and capsule fillers depends, among other factors, on the flow properties of the formulation = (Osorio and Muzzio, 2013). Nevertheless, measuring and predicting powder flowability from the individual components of the formulation is notoriously a difficult task (Seville et al., 2000), especially for powders with small particle size and uncontrolled size and shape distributions (Leung et al., 2017).

Despite this complexity, attempts to predict the flowability of multi-component mixtures of solids have appeared in the literature. These attempts can broadly be categorized in two groups: empirical approaches based on statistical models (Hildebrandt et al., 2019; Barjat et al., 2021) and approaches based on the granular Bond number (Capece et al., 2015; Giraud et al., 2021). In the former case, powder flowability was predicted from both bulk and particle properties of the individual components using multivariate regression techniques, latent variable models, support vector regression models or a combination thereof (Barjat et al., 2021). In the latter case, specific flow properties of the powder mixture such as the flow function coefficient (ffc) were correlated to bulk and particle properties of the individual components via the Bond number, which quantifies the relative balance between gravitational forces and attractive interparticle forces such as the van der Waals forces.

Both these approaches have limitations. From one side, the prediction fidelity of statistical models depends on the size and the range of composition and bulk/particle properties included in the calibration dataset. The models currently available cover only a small range of powder flow characteristics observed in pharmaceutical OSD forms, and therefore have limited applicability for industrial applications, independently of the manufacturing platform considered (direct compression, dry or wet granulation). On the other side, the approaches based on the granular Bond number, although promising, require some input measurements that are not routinely collected in an industrial environment (e.g., particle surface energy), and often show a low prediction fidelity. Their applicability is therefore limited, since the additional effort to retrieve the required input measurements does not often justify their resulting low prediction fidelity.

In this study, we develop a pragmatic mixing rule model to predict the flowability of pharmaceutical blends from the individual components. We constrain our study to formulations that are suitable to direct compression as the chosen manufacturing platform for the final OSD product. Under this assumption, we identify a restricted set of components and composition ranges for the formulations which are relevant in an industrial context, and we quantify the prediction fidelity of the proposed modelling approach with experimental data.

2. Materials and experimental methods

2.1. Materials

Experiments were performed using blends composed of the following materials:

- microcrystalline cellulose (MCC) as Avicel PH102 (FMC Corporation, USA);
- anhydrous lactose as lactose Supertab 21AN (DFE Pharma, Germany);
- croscarmellose-sodium as Ac-Di-Sol (FMC Corporation, USA);
- magnesium stearate as LIGAMED MF-2-V (Peter Greven, Germany)
- monohydrate crystalline lactose as Pharmatose 200M (DFE Pharma, Germany) (used as surrogate API)
- micronized paracetamol (Mallinckrodt Pharmaceuticals, USA).

All materials were used as received by the vendors. Binary and ternary mixtures containing Pharmatose 200M as API (formulation A) and micronized paracetamol (formulation B) were prepared spanning the range of composition reported in Table 1. These components and composition ranges were selected based on current state-of-the art for directly compressed pharmaceutical formulations in an industrial environment.

Table 1. Materials used in this study and composition ranges used for the ternary mixtures.

Material	Grade	Range (%w/w)
API	n/a	[5,40]
MCC	Avicel PH102	[10, 90]
Lactose anhydrous	SuperTab 21AN	[15, 70]
Croscarmellose sodium	Ac-Di-Sol	Fixed at 3%
Magnesium stearate	LIGAMED MF-2-V	Fixed at 1%

Binary blends and ternary blends were prepared for the two formulations at different compositions according to the ternary plots shown in Figure 1.

2.2. Blend preparation (pre-lubrication)

2.3. The blends were prepared using 3L bin blender (Sino Pharmaceutical Equipment Development Co, Ltd). All excipients and the API were transferred into the blender after screening through 1.0 mm sieve, and then mixed at 20 rpm for 20 min.

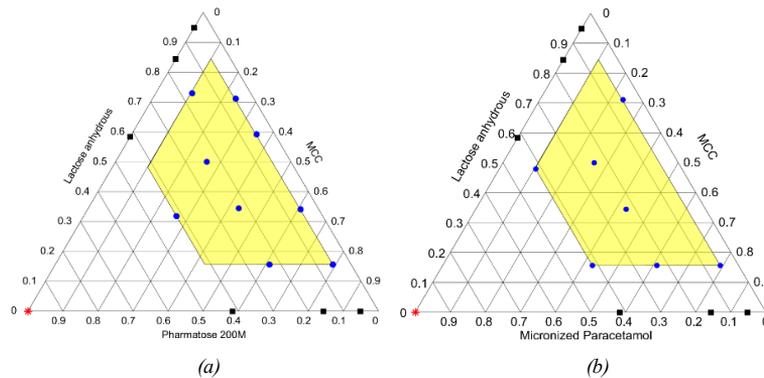

Figure 1. Powder blends prepared for this study using (a) Pharmatose 200M as surrogate API and (b) micronized paracetamol as API. Red stars are pure components, black squares binary blends and blue circles ternary blends. The shaded area represents the formulation design space of interest.

2.4. Blend lubrication

Magnesium stearate (MgSt) was added to the pre-lubricated blends in the amount of 1% w/w in the 5L bin blender. The mass of the non-lubricated blend required to achieve 40% head space and the lubrication time were calculated respectively from the blend bulk density, and according to the relationship proposed by Kushner (2012), by setting a target lubrication extent equal to 100 dm.

2.5. Flowability measurements

Powder flowability was measured using a Brookfield shear cell tester (Amtrek, USA). Prior to the analysis, all blends were pre-conditioned at 20 °C/50% RH for 24h. Flow function tests were performed for each blend using a standard (volume = 266 cm³) cell.

3. Proposed modelling approach

We aimed to construct a mixing rule model that could predict the following properties of the powder blend:

- slope and intercept of the flow locus;
- fill bulk density

using these properties of the individual components as inputs. From the slope and intercept of the flow locus, we derived the flow function coefficient at a consolidation endpoint = 3 kPa. This value is often used in industry to assess the flowability behaviour of the blend according to the classification system reported in Schulze (2008).

Most of the APIs and excipients that are used in pharmaceutical development are fine, dry and uncharged powders. In this scenario, previous studies (Capece et al., 2015; Giraud et al., 2021) have shown that the flowability of the mixture is dominated by inter-particle cohesive forces such as the van der Waals forces. Based on this assumption, we used statistical-mechanical arguments developed for mixture of fluids to propose a functional relationship between the property of the solid mixture and the individual components.

For a mixture whose pair intermolecular potential energy as a function of distance between the pair ($u_{ij}(r)$) can be described as:

$$u_{ij}(r) = \epsilon_{ij} f\left(\frac{r}{\sigma_{ij}}\right), \quad (1)$$

the following mixing rules can be derived to describe the molecular volume σ^3 and the molecular energy ϵ of the mixture:

$$\sigma^3 \propto \sum_{i=1}^N \sum_{j=1}^N w_i w_j \sigma_{ij}^3 \quad (2)$$

$$\epsilon \propto \frac{\sum_{i=1}^N \sum_{j=1}^N w_i w_j \epsilon_{ij} \sigma_{ij}^3}{\sigma^3}. \quad (3)$$

Here, σ_{ij} is intermolecular interaction distance between molecules of component i and j , ϵ_{ij} is the interaction energy parameter, N is the number of components in the mixture and w_i is the mass fraction of the i -th component. For a mixture of solids, we assumed that the property of the mixture can be described as a sum of two terms: 1) a term that depends on the molecular volume of the mixture σ^3 (zero-interaction term), and 2) a term that depends on the product (molecular energy) \times (molecular volume) $\epsilon \sigma^3$ (first-order interaction term). Leveraging on the mixing rules developed by Van der Waals for fluids and their statistical mechanics interpretation (Van der Waals, 1873; Kwak and Mansoori, 1986), and considering the analogy with our assumptions, we formulated the following mixing rule for a generic property ϕ_m of the mixture:

$$\phi_m = \sum_{i=1}^N w_i \phi_i + \sum_{i=1}^N \sum_{j=1}^N w_i w_j \sqrt{\phi_i \phi_j} (1 - k_{ij}) \quad (4)$$

where k_{ij} is a binary interaction parameter (BIP) for the pair of components i and j that needs to be fitted from experimental data of the binary mixture, and ϕ_i is the property of the i -th component of the powder blend. The first term on the right-hand side of Eq. (4) is the zero-interaction term, while the second term is the first-order interaction term. Note the analogy between the first and second term of Eq. (4) and the "b" and "a" term in the van Der Waals equation of state for mixture of fluids.

Eq. (4) sets the structural relationship between the property of the mixture and the individual components. In order to use it, binary interaction parameters must be estimated for each pair of components of the mixture. For the formulation considered in Table 1, this requires estimation of the binary interaction parameters $k_{API,MCC}$, $k_{API,Lac}$ and $k_{MCC,Lac}$, with $MCC =$ Avicel PH102 and $Lac =$ Lactose SuperTab21AN. Note that, for a specific property of the mixture, only the first two parameters depend on the API, and therefore need to be estimated from experimental data when a new product is considered. The binary interaction parameter $k_{MCC,Lac}$ can be estimated only once and then used for any formulation containing those two components.

3.1. Software

The models presented in this study were coded in MATLAB R2020b. All simulations were performed on an Intel Core i7-5600U CPU@2.60GHz processor with 16.0 GB RAM.

4. Results

The BIPs were estimated from the binary mixtures reported in Figure 1 (black square points) for each binary system API-excipient or excipient-excipient. The parameter estimation was performed using a maximum likelihood estimator (Johansen and Juselius, 1990). The estimated values of the BIPs for the slope and intercept of the flow locus and for the fill bulk density are reported in Table 2. Model predictions were validated against the experimental data obtained for the ternary mixtures reported in Figure 1 (blue circles). Note that these mixtures were chosen in order to cover the design space of mixtures of industrial relevance (yellow area in Figure 1). The same plot shows the classification ranges for the flow behavior of the mixture according to the ffc values reported in Schulze (2008). Good agreement between the model predictions and the experimental observations was obtained for both formulations.

Table 2. Estimated value of the binary interaction parameters for the two formulations considered in this study. PT = Pharmatose 200M. MCC = Avicel PH102. Lac = Lactose SuperTab21AN. APAP=micronized paracetamol.

Binary interaction parameter	Value for slope of the flow locus [-]	Value for intercept of the flow locus [-]	Value for fill bulk density [-]
$k_{PT,MCC}$	3.648	0.085	0.753
$k_{PT,Lac}$	-0.861	1.756	0.830
$k_{APAP,MCC}$	-9.575	4.695	1.061
$k_{APAP,Lac}$	-8.897	3.497	2.387
$k_{MCC,Lac}$	3.107	0.720	1.306

The classification of the flow behavior of the blend was predicted correctly by the model for all blends apart from a single blend with micronized paracetamol (blend #3), where the blend was categorized as cohesive rather than very cohesive. However, the model prediction was still within the experimental error for the specific blend.

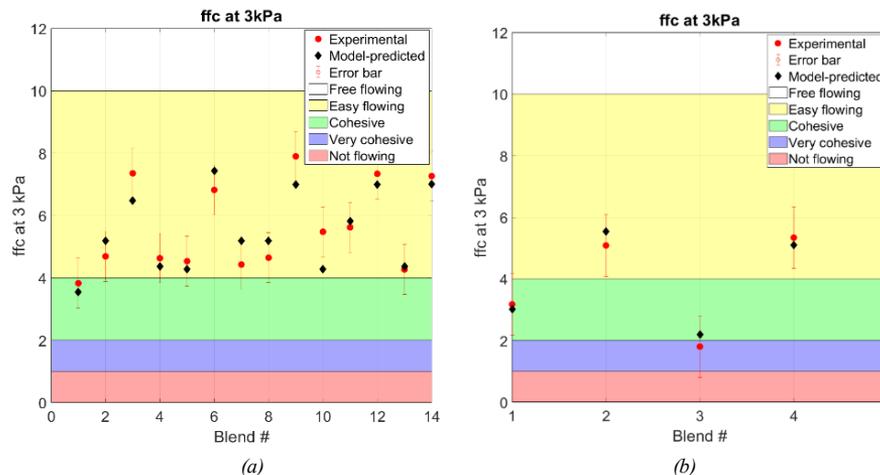

Figure 2. Model predictions Vs experimental values of the flow function coefficient at 3kPa consolidation endpoint for (a) formulation A (API: Pharmatose 200M) and (b) formulation B (API: micronized paracetamol).

Figure 3 shows the parity plots predicted vs experimental for the fill bulk density. Good prediction fidelity was obtained for both formulations; however, the model seemed to systematically underestimate the bulk density of the formulation containing micronized paracetamol. Investigation on this behavior is ongoing and the study will be further corroborated with additional experimental data for model validation. Overall, the model was able to consistently predict the behavior of the ternary blends with just binary and pure API data used as model inputs. Whenever a minor or major change of the formulation occurs, the model can be used to assess any impact on the flow behavior without additional experiments.

5. Conclusions

In this study, we developed a simple, yet effective, mixing rule model to predict the flowability of multi-component pharmaceutical powder blends that are suitable for direct compression. The model requires an upfront experimental characterization of the flowability of the pure API and 6 binary mixtures, and can then be used to predict the flowability of any ternary blend whose ingredient compositions fall within pre-defined ranges relevant to a direct compression

manufacturing route in an industrial environment. Whenever a minor or major change in the formulation composition occurs during the drug development process, the model can be used to predict the impact on the blend flowability without requiring any further shear cell experiments.

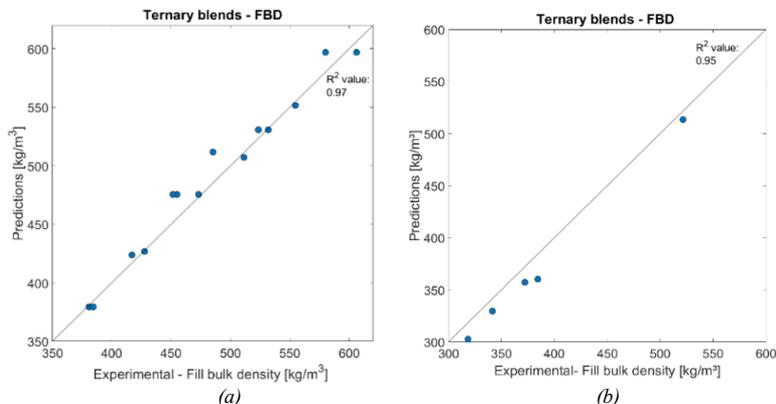

Figure 3. Model predictions Vs experimental values of fill bulk density for (a) formulation A (API: Phartamose 200M) and (b) formulation B (API: micronized paracetamol).

For some OSD products, where several alterations of the formulation composition might occur, this can translate into a reduction of up to 80% of API consumption for blend flowability assessment. Future work will focus on testing the methodology with additional APIs and excipients (e.g., mannitol) with different particle properties in order to define the range of validity of the underlying assumptions of the proposed approach.

Abstract

MIBA (Methyl Iso Butyryl Acetate) is an intermediate used in the pharmaceutical industry and is generally produced in small scale batch processes making it expensive to produce. This study was to look at the potential for a continuous process for the manufacture of MIBA, with the aim to improve yields and hence reduce costs., with the initial stage of the work focused on the purification of the MIBA product, this being required at high levels of purity, typically in excess of 99 weight %. Vacuum distillation column models were built using both AVEVA's PRO/II Simulation and AVEVA Process Simulation process modeling tools with the feasibility of separations assessed using PRO/II's Ternary VLE tool. This study investigated achieving high purities of MIBA by using different column configurations modelled in AVEVA PRO/II Simulation and AVEVA Process Simulation. This paper summarizes the methods and findings of this study.

Keywords: MIBA, Distillation, Simulation, modeling, Ternary Plots.

1. Introduction

The component Methyl Iso Butyryl Acetate (MIBA) has good demand in Pharmaceutical Industry across the world. Most of the manufactures are synthesizing MIBA in batch processes and as a result the cost of the product is high. So, in this work we tried to design a single continuous distillation unit. This is a challenging problem because the properties of the components involved in the reaction are not well known. It is a general method that MIBA is synthesized by the reaction of Methyl Acetoacetate with Iso Butyryl Chloride in the presence of Calcium Hydroxide and Ammonium Chloride. In the reaction the main byproducts are Acetamide and water. In this work the reaction part of the process is not considered for simulation. Rather, the focus is on removing Acetamide and water to produce 99.9 wt% MIBA by means of a continuous distillation process.

2. Simulation of continuous distillation of MIBA

2.1. Simulation using AVEVA PRO/II Simulation Software

In this simulation the following feed composition and conditions were used:

Table 1. Feed stream composition and condition

Stream Name		FEED
Temperature	C	80
Pressure	MM HG	133.488
Total Molar Rate	g-mol/hr	1384.401
Total Mass Rate	KG/HR	125
Stream Phase		Liquid
Thermodynamic system		NRTL
Total Weight Comp Fractions		
ACETAMIDE		0.0739
MIBA		0.8561
WATER		0.07
Total Weight Comp. Rates		
	KG/HR	
ACETAMIDE		9.2323
MIBA		107.0159
WATER		8.7518

A rigorous distillation column unit operation with 13 trays, reboiler and condenser is used to model the separation. The feed enters at the bottom. This is to make the distillation equivalent to the configuration in a batch distillation. The pressure of the column is maintained at 4 mmHg. The thermodynamic method used is Non-Random Two Liquid (NRTL). When the simulation model is run the top product purity achieved was 92.7 wt% MIBA, but this purity is not of sufficient quality for use in practical applications. The objective is to reach 99.9 wt% purity. An attempt has been made to improve the purity by changing several parameters for the column, but none of them achieved the desired purity. The MIBA composition profile versus the tray number, as illustrated by Figure 1, reveals a peak composition MIBA in the upper stages below the condenser. Resulting from this observation a side draw was added at tray 3 and this produced 99.9 wt% pure MIBA stream. The stream details of the top product and side draw are shown in Table 2.

2.2. Simulation using AVEVA Process Simulation Software

The same approach as mentioned in 2.1 has been followed to simulate the Distillation operation using AVEVA Process Simulation Software with identical results. The initial results without side draw are shown in Figure 2., and the process flow diagram with side draw is shown in Figure 3.

2.3 Application of Ternary plots

The separation has been analyzed with PRO/II's Ternary Plot tool confirming the obtained results through a conceptual analysis. The ternary plot analysis of the initial process flowsheet with 92 wt% pure MIBA is shown in Figure 4. The ternary plot analysis of the modified process flowsheet with 99.9 wt% pure MIBA is shown in Figure 5.

Table 2. Product stream composition and condition

Stream Name		SIDEDRAW	TOP PRODUCT
Temperature	C	56.501	0.653
Pressure	MM HG	5.246	4
Total Molar Rate	g-mol/hr	650	576.954
Total Mass Rate	KG/HR	92.853	22.643
Stream Phase		Liquid	Liquid
Thermodynamic system		NRTL	NRTL
Total Weight Comp. Fractions			
ACETAMIDE		0.0008	0
MIBA		0.9981	0.6182
WATER		0.0012	0.3818
Total Weight Comp. Rates			
ACETAMIDE	KG/HR	0.074	0.0002
MIBA		92.672	13.9982
WATER		0.107	8.6447

Figure 1. Weight fraction of MIBA from top tray to bottom tray

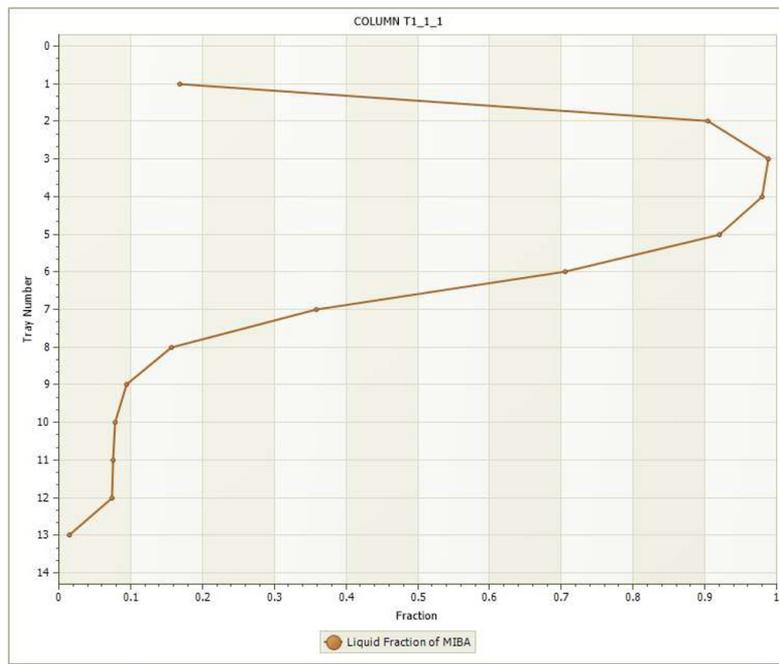

Figure 2. MIBA synthesis initial process flowsheet using AVEVA Process Simulation software

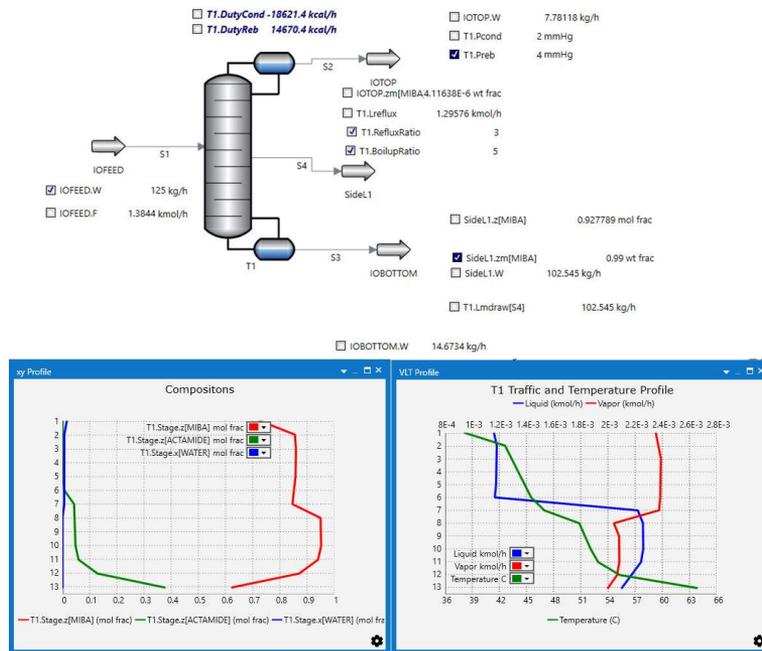

Figure 3. 99.9 wt% MIBA modified process flowsheet using AVEVA Process Simulation software

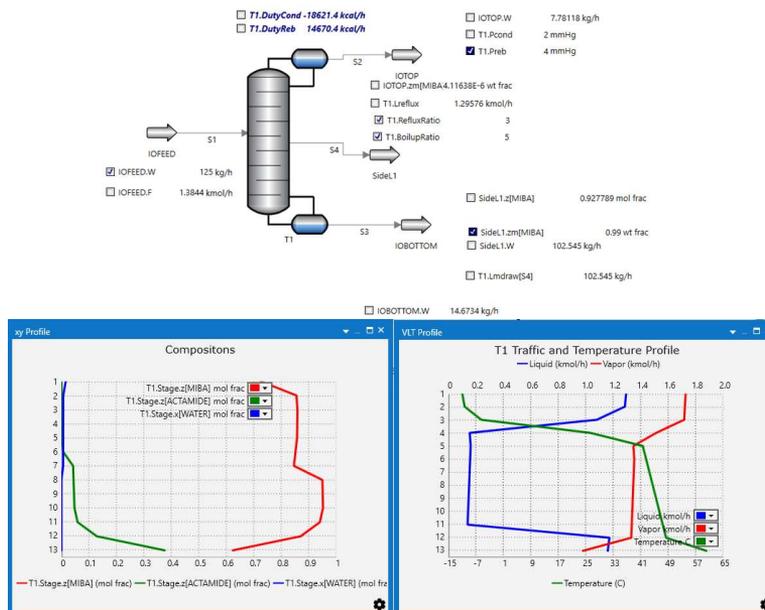

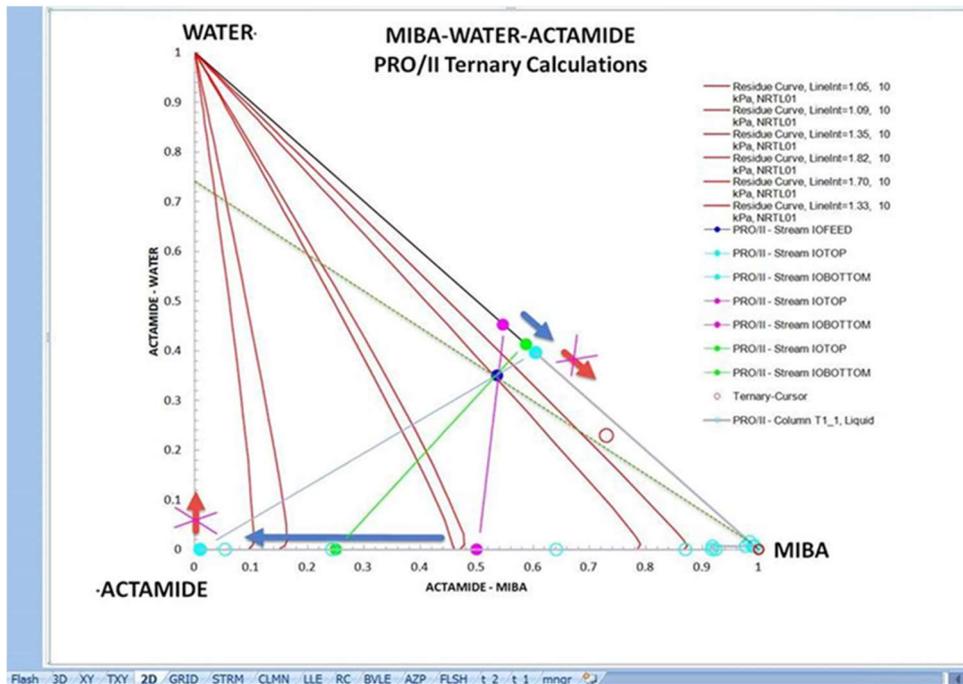

Figure 4. Ternary Plot for Base Flow diagram

The intention is to gain a 99 wt% pure MIBA distillate. But this is not achievable, it is infeasible. As the feed is a ternary system composed of MIBA, ACETAMIDE and water, we used the PRO/II Ternary Plot tool that allows to analyze the thermodynamic behavior along with the operational process specifications.

The filled dots represent stream compositions, the marine circles represent the column profile for the extreme solution when 60 mol% MIBA is obtained. This allows to analyze the separation statement. We can see the residue curves in red. According to separation theory for ternary systems, two requirements describe the solution:

- Distillate, bottoms and feed compositions form a straight line.
- Distillate and bottoms compositions must lie on the same residue curve.

This defines the separation region for a given feed. The chart below shows the feed as the blue dot. If we want the blue feed to separate into a pure MIBA composition then the bottoms must be resulting somewhere along the dotted green curve, it would be somewhere in the upper left section. This is due to requirement a).

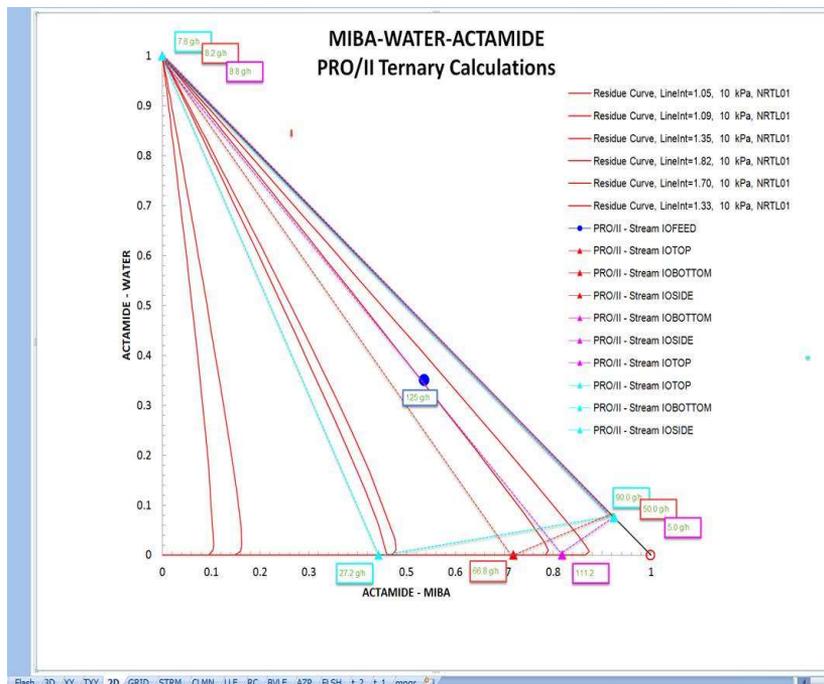

Requirement b) shows that a bottoms composition in that section is infeasible:

The column can be solved for the distillate/bottom composition pairs in pink, green, and marine. The arrow shows that as we move the specification for the distillate's MIBA from pink to marine, we also push the bottom's ACETAMIDE towards 100 wt%.

The point is that the residue curve does not extend upwards (the crossed out red arrow on lower left corner). Hence, there is no way a bottoms product can be gained that would be in the upper left section. The pure ACETAMIDE node (the chart's lower left corner) limits the MIBA distillate to the marine blue fraction of 0.6, i.e. 60 mol%.

Below is a plot with various side draw rates (90, 50, 5 g/h), all at 99 wt% MIBA (ca. 92 mol%), and the resulting top and bottom purities and rates. In case of side draws, the feed is located in the gravity center of the triangle that can be spanned by the top, side and bottom composition (the dotted lines). It is a simple mass balance.

Figure 5. Ternary Plot for 99.9 wt% MIBA Flow diagram

Conclusion

In this work a continuous distillation process has been proposed for purifying MIBA. Simulation has been carried out using AVEVA PRO/II Simulation software and AVEVA Process Simulation Software. The results from the standalone flowsheet have been verified with ternary plots feature available in both the software. The location of side draw plays an important role in achieving 99.9 wt% MIBA. The data used and the predicted performance of the distillation columns should be validated by experimental analysis.

Modelling of Organophilic Pervaporation for Separation of Acetone-Butanol-Ethanol Mixture

Andras Jozsef Toth, ^{*,a}

^a*Department of Chemical and Environmental Process Engineering, Műegyetem rkp. 3., Budapest, 1111, Hungary
andrasjozsefth@edu.bme.hu*

Abstract

The motivation of the research is based on separation problem from fermentation industry, that is Acetone-Butanol-Ethanol solvent residue removal from its aqueous solutions. Pervaporation is a novel, promising technology for the separation of complex, azeotropic mixtures. Within pervaporation membrane category, organophilic pervaporation was investigated. In this work, laboratory experiments were performed with commercially available test membranes at different temperatures conditions. The separation factor and total organic fluxes were determined as well. It was found that, the separation factor and fluxes were inversely proportional to the feed butanol concentration. The laboratory results were consistent with literature studies. Using partial fluxes, semiempirical pervaporation models were fitted. Exponentially improved model version of Rautenbach pervaporation model (Szilagyi and Toth, 2020) was investigated in the case of binary mixtures. The aim of this work was to extend the observations of organophilic pervaporation model to more complex mixture. It can be observed that, the exponentially Rautenbach model describes accurately the transport process of organophilic pervaporation. Thus, it is possible to implement further studies in process simulator environment.

Keywords: Parameter estimation, Organophilic pervaporation, Acetone-Butanol-Ethanol mixture.

1. Introduction

During the ABE (A: Acetone, B: N-butanol, E: Ethanol) fermentation, Acetone, N-butanol and Ethanol are mainly produced, other components may be e.g. organic acids (butyric acid, acetic acid) (Kollarik, 2018). There are several possibilities for the separation of fermentation products. The most common solutions are distillation adsorption, liquid-liquid extraction, stripping, reverse osmosis, pervaporation (Valentinyi et al., 2018). The latter two methods fall within the scope of membrane procedures. The advantages of membrane operations are that they are generally energy efficient, flexible operations and do not require the addition of foreign (organic) substances to improve the separation. Any fouling and scaling during the process must be prevented. Furthermore, the membrane operations are environmentally beneficial because they do not produce significant additional waste (Haaz and Toth, 2018).

Pervaporation is a membrane operation in which the mixture to be separated evaporates to the low-pressure side of the membrane and the separation between the components through the membrane is carried out by the principle of sorption-diffusion. Vacuum pump is mostly used to achieve the low vapor pressure on the permeate side. Depending on the

permeable component, two types of pervaporation are distinguished: hydrophilic and organophilic pervaporation (Baker, 2012). The “sorption-diffusion” model is the most accurate to describe pervaporation in bilayer composite membranes, so the separation process of pervaporation can be derived from the sorption-diffusion principle (Wijmans and Baker, 1995). The industrial application of pervaporation has become more widespread in recent decades due to its lower energy consumption compared to traditional separation techniques (distillation, absorption, etc.). In the case of the products of ABE fermentation, the actual task is the problem of separating the quaternary mixture of Acetone - N-butanol - Ethanol - Water. Only organophilic pervaporation is possible, not hydrophilic because dilute aqueous solutions must be separated. Table 1 introduces some organophilic pervaporation membranes treating the products of ABE fermentation.

Table 1 Organophilic membranes separating ABE fermentation products (Feed, total organic flux and separation factor values)

Membrane type	Feed [wt%]			Total organic flux [kg/m ² h]	Separation factor [-]			Reference
	A	B	E		A	B	E	
PDMS/ceramic	0.6	1.2	0.2	1.21	34.6	20.0	6.5	Liu et al., 2014
PDMS	1.1	1.0	10.2	58.60	4.7	11.6	2.7	Liu et al., 2005
PEBA	0.6	1.9	0.7	0.03	5.1	12.4	3.5	Liu et al., 2005
PDMS filled with s. (60wt%)	7.0	15–20	1.0	0.91	7.0	20.0	1.0	Huang and Meagher, 2001
PDMS/ceramic	0.6	1.1	0.2	1.05	30.0	18.0	5.0	Liu et al., 2011
PDMS filled with s. (65wt%)	0.5	1.0	0.2	0.28	40.0	70.0	10.0	Zhou et al., 2011
PDMS filled with s. (50wt%)	3.0	10.0	1.0	0.12	44.0	70.0	5.2	Qureshi et al., 2001
TOA LM with PP s.	0.8	1.5	0.5	0.02	220.0	275.0	80.0	Thongsukmak and Sirkar, 2007

Studying Table 1, it can be seen that PDMS-based membranes are the most common in practical application. The aim of this research work is to investigate the quaternary Acetone - N-butanol - Ethanol - Water test mixture and the parameter estimation for semiempirical pervaporation model.

2. Material and methods

The measurements were performed on CM Celfa Membrantechnik AG P-28 membrane apparatus with the effective membrane area of 28 cm². On the permeate side, constant 13.33 mbar vacuum was provided with VACUUMBRAND PC2003 VARIO vacuum pump. Measurements were performed under isothermal conditions at three different temperatures (303, 318 and 328K) with an organophilic PDMS type membrane (Sulzer PERVAP 4060). The starting compositions of the 500 mL feed mixtures were 0.4 wt% Acetone, 0.8 wt% N-butanol and 0.1 wt% Ethanol. The rest of the test mixtures were water. The permeate was collected in liquid nitrogen-cooled traps and the compositions were analyzed by SHIMADZU GCMS-QP2010 gas chromatograph and Hanna HI 904 Karl Fischer coulometric titrator (Toth, 2015).

Appropriate computer modelling is an essential tool for designing and optimizing separation processes, which requires models that describe the processes as well as possible. Among the pervaporation models found in the literature, the used model

(Szilagyí and Toth, 2020) was based on Rautenbach's sorption-diffusion model. The model defines the process of pervaporation in the following steps.

- adsorption of the component in the selective layer of the membrane,
- diffusion of the component through the membrane material,
- desorption of the target component on the steam side.

The basic equation of this model is (J : partial permeate flux) (Szilagyí and Toth, 2020):

$$J_i = \bar{D}_i^* \exp \left[\frac{E_i}{R} \left(\frac{1}{T^*} - \frac{1}{T} \right) \right] \left(\frac{p_{i1} - p_{i3}}{p_{i0} \bar{y}_i} \right) \exp(x_{i1}^B) \quad i = (1, \dots, k) \quad (1)$$

First the parameters of the model must be estimated based on measured data. These parameters are the activation energies (E_i) and the reference transport coefficients (\bar{D}_i^*), and the B parameters that shows the concentration dependencies of the transport coefficients. Transport coefficient depends on the temperature in an Arrhenius type exponential way. The liquid activity coefficients can be calculated with different vapor-liquid equilibrium models or with the Wilson equation (Haaz and Toth, 2018). The estimations are completed with the STATISTICA® program environment. The verification can be obtained with objective function, that is minimized the deviation of the modelled and the measured values (Toth et al., 2018).

$$OF = \sum_{i=1}^n \left(\frac{J_{i,measured} - J_{i,modelled}}{J_{i,measured}} \right)^2 \quad (2)$$

Partial pressures (p_{i0}) are calculated according to the Antoine equation (Haaz and Toth, 2018).

3. Results and discussion

The most valuable component during the separation is N-butanol, so the parameters evaluating the separation was plotted as a function of this. Figure 1 shows the separation factors at 303K. Total organic fluxes at 303, 318 and 328K can be seen in the Figure 2.

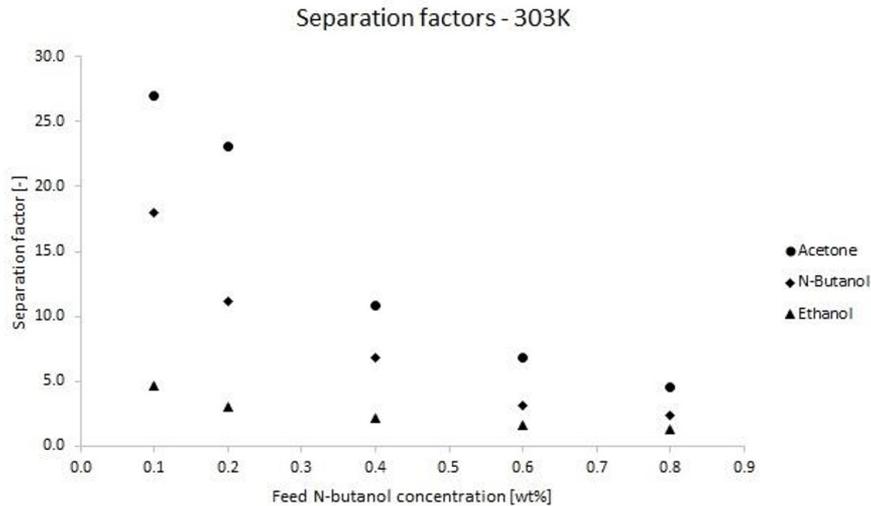

Figure 1. Separation factors of ABE mixtures in a function of feed N-butanol content in weight percent with Sulzer PERVAP™ 4060 membrane

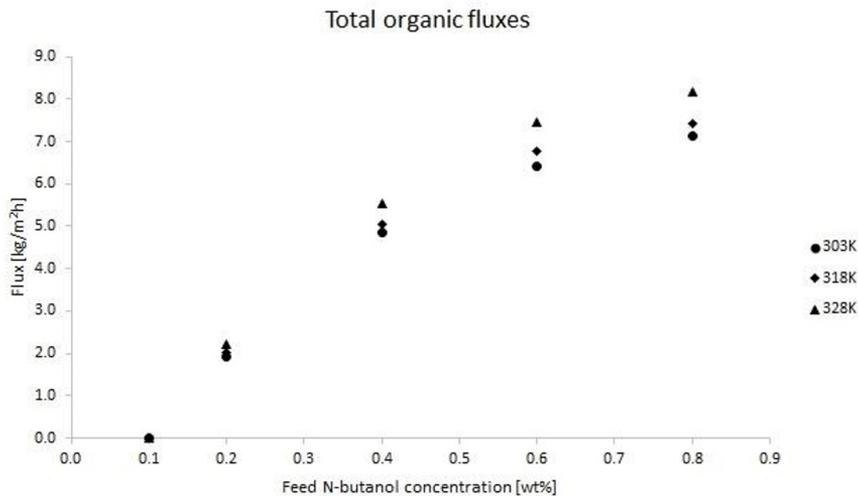

Figure 2. Measured total organic fluxes of ABE mixtures in a function of feed N-butanol content in weight percent with Sulzer PERVAP™ 4060 membrane

Figure 1 and Figure 2 show that the fluxes are inversely related to the separation factors as a function of the N-butanol feed concentration. Higher temperatures resulted in higher flux and separation factor values. In order of magnitude, the order is: Ethanol < N-butanol < Acetone, which is in agreement with the literature (Kujawska et al., 2015). Figure 3, Figure 4 and Figure 5 show the comparison of the measured partial fluxes with the model at 303K.

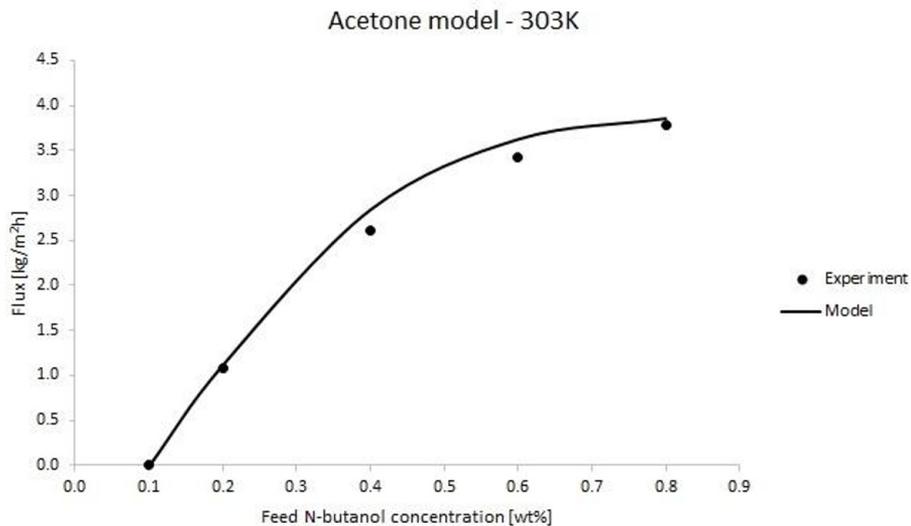

Figure 3. Measured partial Acetone fluxes of ABE mixtures compared to Acetone fluxes calculated with pervaporation model at 303K in a function of feed N-butanol content in weight percent

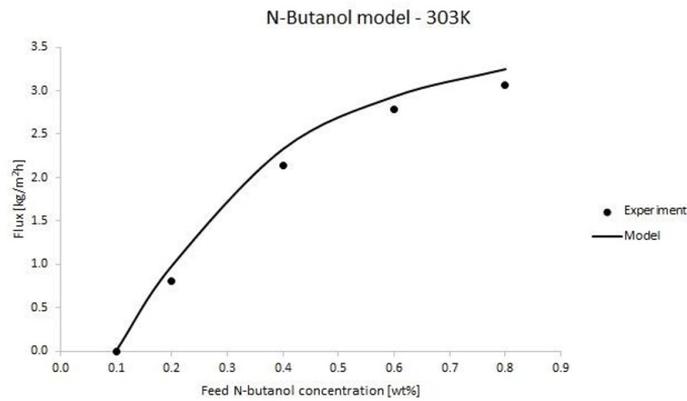

Figure 4. Measured partial N-butanol fluxes of ABE mixtures compared to N-butanol fluxes calculated with pervaporation model at 303K in a function of feed N-butanol content in weight percent

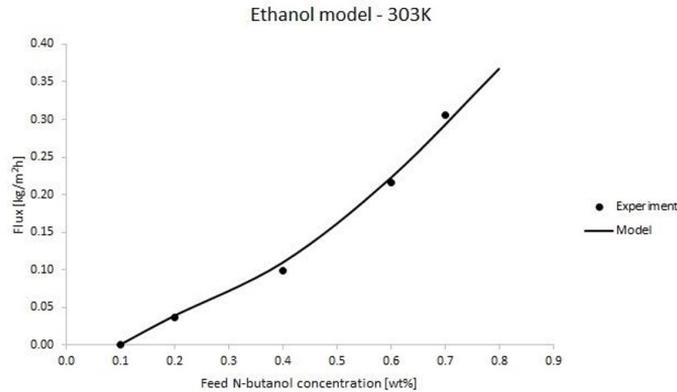

Figure 5. Measured partial Ethanol fluxes of ABE mixtures compared to Ethanol fluxes calculated with pervaporation model at 303K in a function of feed N-butanol content in weight percent

It can be seen that, in the case of the pervaporation model good agreement is found at the lower and also at the higher feed N-butanol content between the measured and calculated values. The reason for the better fit of the supplemented model probably lies in the concentration dependence of the transport coefficient. The results of the laboratory measurements suggest that the transport coefficient is also concentration dependent. The minimized objective functions and estimated values for transport coefficients, activation energies and B parameters of the pervaporation model are shown in Table 2. It can be seen, the low OF values also confirm the accuracy of the model.

Table 2 Estimated parameters for Acetone - N-butanol - Ethanol - Water mixture with Sulzer PERVAP™ 4060 membrane and objective functions

	Acetone	N-Butanol	Ethanol	Water
\bar{D}_i [kmol/m ² h]	0.034	0.193	0.003	65821
E_i [kJ/kmol]	18075	34298	43943	35637
B [-]	257.12	-30.45	624.12	-15.42
OF [-]	0.012	0.031	0.025	0.106

4. Conclusions

In this study, organophilic pervaporation works in the literature related to the separation of ABE fermentation products was presented. Laboratory experiments were performed at three different temperatures. It was found that the separation factors and the fluxes are inversely proportional to the N-butanol feed concentration. The results are in good accordance with literature studies. It can be observed that the Rautenbach model with exponential exponent precisely describes the transport process of organophilic pervaporation. This publication was supported by NTP-NFTÖ-21-B-0014, MEC 140699, OTKA 128543, OTKA 131586 and TKP2020 National Challenges Subprogram.

Abstract

In recent years, Artificial Neural Networks (ANNs) have received special attention to a widespread application in the field of engineering, biology, energy, and finance. Within the ANN design, several factors play a major role in the correct prediction of the process, such as the number of internal layers, the number of neurons, the number of used features, the training algorithm, the activation function, the number of epochs, among many others. Considering datasets of an intensified distillation column generated by Aspen Plus Dynamics at different operation conditions, here we bring clarity in the field with different architectures of ANNs to abstract the dynamics of both an intensified and conventional distillation process that separates an effluent coming from fermentation producing acetone, butanol, and ethanol (ABE) for spark-ignition purposes. Our results highlight that a one-layer neural network can represent the dynamics of an intensified column to forecast the concentration of acetone, butanol, and ethanol. Remarkably, the linear activation function overperforms the tangent hyperbolic as activation functions. Ultimately, we found that the reflux ratio and reboiler duty are key features to reconstruct the full dynamics of the intensified column.

Keywords: Deep Learning, ABE purification, LSTM, Biobutanol.

1. Introduction

The use of liquid biofuels such as ethanol and butanol has been presented as an important advance due to their origin from biomass fermentation and their low emission levels (Ribeiro et al., 2007). One of the processes by which it can be obtained is ABE fermentation from biomass, this process produces a mixture composed of acetone, butanol, and ethanol which creates a challenge in trying to reduce the energy in the separation process (González-Bravo et al., 2016). The use of new design approaches for the control, modeling, and simulation of chemical processes has allowed the development of intensified processes, seeking a radical change in the unit operations used to meet current needs under the development of a sustainable process (Sánchez-Ramírez et al., 2017). The dividing wall column (DWC) allows to reduce energy and capital costs due to the reduction of equipment since the separation of the mixture would be carried out in one column and not in two, in addition to the fact that shorter piping and electrical currents

are required (Gómez-Castro et al., 2008). Dynamic properties are an important issue in DWC since apparently dynamic behavior can be greatly reduced. Although it has been shown that control sequences can be better than conventional distillation sequences so you can have total annual cost savings as good dynamic performance (Rewagad & Kiss, 2012). Furthermore, there is not any preliminary work reported involving the processing of mixtures with a high degree of complexity relative to thermodynamic modeling. Deep learning models can learn extremely complicated patterns from a large amount of data without much manual expertise so they can be used for a large number of applications where their structure is constituted by several hidden layers that allow transforming the input data several times before producing the output, so it is possible to manipulate their architecture to obtain better output values without overfitting (López-Tapia et al., 2021). The use of Long short-term memory (LSTM) ANNs in time series prediction may offer more efficient and effective alternatives for highly complex multivariate systems (Ookura & Mori, 2020). The main objective of this study is to optimize the ANN architecture that models the dynamics behavior of a DWC comparing the activation function, the optimizers that minimize the Mean Squared Error (MSE), and analyzing the increase in the number of hidden layers based on the AIC (Akaike Information Criterion) value. Finally, the manipulable variables that have a greater weight on the system modeling while maintaining a good prediction of the output data will be identified.

2. Methodology

Data generation. The datasets are obtained from a simulation software Aspen Dynamics, this simulation is performed in a closed-circuit test where a set point was implemented in the composition of each component of the mixture to be separated (Acetone-Butanol-Ethanol), in this way three setpoint changes were performed, and tuned at the same time, thus producing time-varying operational datasets. Simulations of 100 hours were performed using a sampling time of 0.4 hours. The feed stream considers a mixture of acetone, butanol, ethanol, and water in proportions of 0.3018, 0.1695, 0.0073, and 0.5214 wt%, respectively. The datasets were subdivided into the first 24 hours for training and the rest for testing. The data manipulation is done in the Python 3.8 programming language where use is made of the PANDAS library which is ideal for data analysis.

Neural Network basic elements. An artificial neural network (ANN) is a distributed computing scheme inspired by the structure of the human nervous system. The architecture of a neural network is formed by connecting multiple elementary processors, being an adaptive system that has an algorithm to adjust its weights to meet the performance requirements of the problem based on representative samples. Eq. 1 and 2 represent the equivalent model of the synaptic connections in a k neuron.

$$u_k = \sum_{j=1}^m w_{kj} x_j \quad (1)$$

$$y_k = \varphi(u_k + b_k) \quad (2)$$

where the vector x_j is the set of input signals, w_{kj} is the set of synaptic weights of neuron k , u_k is the linear combination of the weighted inputs, b_k is the polarization and y_k is the output signal of the neuron. The activation function φ serves the purpose of limiting the output range of the neuron and can be linear or nonlinear. In this study, we compare the performance of the functions Linear, ReLU, and Tanh. To obtain a good minimization of the loss function, the choice of the optimizer will be compared from a defined activation function to obtain a good prediction of the time series thanks to its convergence speed and its generalization speed (Manickam et al., 2021). The optimizers compared are

Adaptive Moment Estimation (ADAM), Root Mean Square Propagation (RMSP), and Stochastic Gradient Descent (SGD).

LSTM modeling. Recurrent Neural Networks (RNN) are distinguished in that they have at least one or more feedback loops that have a profound impact on the learning capability of the neural network. The LSTM is a special type of RNN that can learn long-term dependent information making considerable progress in problems related to time series analysis. This type of network needs a higher computational power because it has feedback based on a time step (Hochreiter & Schmidhuber, 1997). In this study, a step of 5 is used for the feedback, with which it is possible to have a good prediction for a large amount of data.

Model Selection. Optimal architectures of the neural network model can be found by minimizing the MSE concerning the variation of the number of hidden neurons (Shin et al., 2020).

$$MSE = \frac{\sum_{i=1}^n (y_i - \bar{y}_i)^2}{n} \quad (3)$$

where n is the number of data points, y_i is the actual value and \bar{y}_i is the value estimated by the ANN. Given a collection of models for a dataset, AIC estimates the quality of each model, relative to each of the other models. Hence, AIC provides a value for model selection. It deals with the trade-off between the goodness of fit of the model and the complexity of the model. AIC does not provide a test of a model in the sense of testing a null hypothesis, so it can tell nothing about the quality of the model in an absolute sense. If all the candidate models fit poorly, AIC does not give any warning of that. The formula for AIC depends upon the statistical model. A lower AIC value means that a given model describes the data better than other models with higher values.

$$AIC = N \log(MSE) + \frac{2MN}{N - M - 1} \quad (4)$$

N is the number of data points, M is the number of unknown parameters.

The normalization was performed using Eq. 5 to transform all feature values into an interval of $[0,1]$, mathematically speaking y_i refers to the data values, $\min(y_i)$ is the minimum value and $\max(y_i)$ refers to the maximum value. Increasing the efficiency of the algorithm by reducing fluctuations.

$$y_{scaled} = \frac{y_i - \min(y_i)}{\max(y_i) - \min(y_i)} \quad (5)$$

3. Results

From the DWC system, were considered as manipulable variables the reflux ratio, side streamflow, and reboiler heat duty. In the Linear activation function and the RMSP optimizer, an analysis of the impact of these manipulable variables was performed; first, the ANN was fed with the three manipulable variables the result is shown in blue color line in Figure 1(a), then the reboiler duty input to the ANN was inactivated and the predictive capability of the ANN was measured with the input only of the reflux ratio and the side stream flow the result is shown in orange color line Figure 1(a), also the analysis of inactivating the reflux ratio to the ANN and feeding the ANN reboiler duty and the Side streamflow the result is shown in Figure 1(a) green color line and finally inactivating the side-stream flow feed to the ANN and feeding the ANN with the Reboiler duty and ratio the results are shown black line Figure 1(a). According to these results, it can be observed that the one that showed the worst behavior was the one that deprived the Reboiler duty feeding, and the ones that showed the best results were on the one hand the

one that feed the three manipulable variables and the ones that deprived the side streamflow feeding and the reflux ratio. The one that showed the best result for 5 neurons was the one feed with the reflux ratio and the reboiler duty.

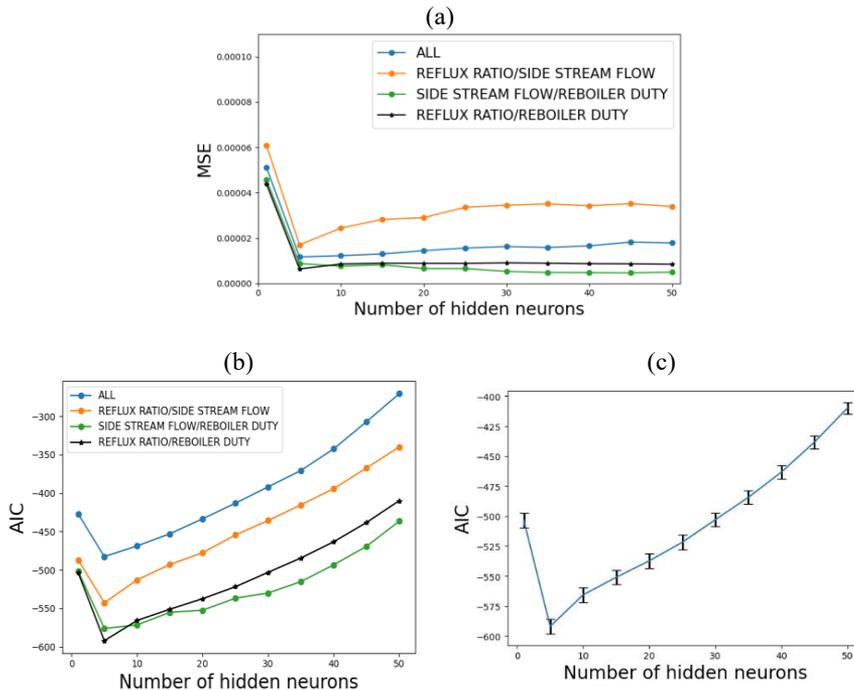

Figure 1. ANNs with one single hidden layer (a) Effects of the input manipulable variables on MSE; (b) AIC value comparison for input manipulable variables; (c) Best value of AIC is for Reflux ratio/Reboiler duty.

The ANN RMSP optimizer is analyzed for the three manipulable variables; Reflux ratio side streamflow and reboiler duty. The black-colored line in Figure 1(b) was the one that showed the lowest value of the AIC for 5 hidden neurons which is the one that was fed only with the Reflux ratio and the Reboiler heat duty. An error analysis was performed only for the one showing the lowest AIC shown in Figure 1(c).

According to the analysis performed to the different hyperparameters, the final topology of the ANN shown in Figure 2(b) was configured, where the manipulable variables that showed the greatest influence in the modeling of the DWC dynamics, as well as the perturbed variables, are feed to the ANN and only one layer of neurons is used, achieving a good prediction in the output variables, the composition profiles of Acetone, Ethanol, and Butanol. With the architecture shown in Figure 2(b), a good prediction was achieved for the system shown in the diagram in Figure 2(a), the results obtained by ANN show a good fit to the data simulated by Aspen Dynamics for the mass fraction of Acetone, Ethanol, and Butanol (see Figure 3). Table 1 summarizes the methodology that gave the best results in the ANN configuration.

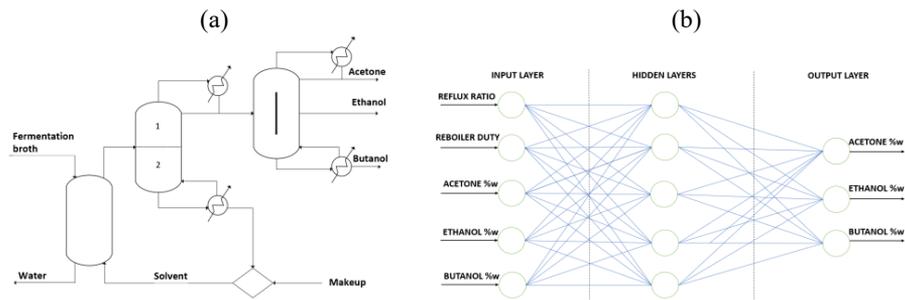

Figure 2. Artificial neural network final architecture. (a) Study case; (b) Final ANNs architecture.

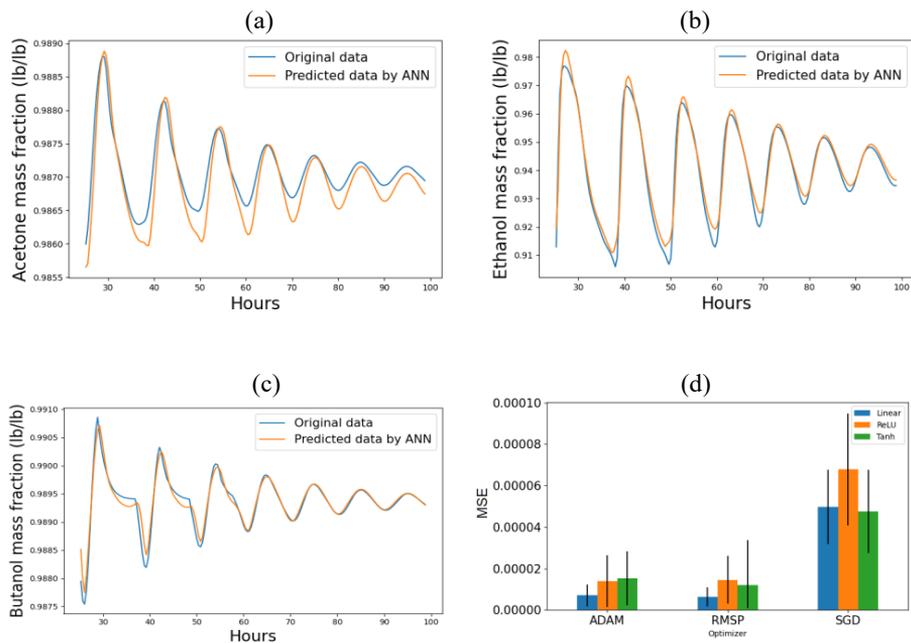

Figure 3. Comparison between the predicted and actual a) acetone, b) ethanol and c) butanol mass fraction; d) MSE values for activation functions and optimizers.

Table 1. ANN Configuration Summary.

Percentage of training data	24%	Activation function	Linear
Percentage of test data	76%	Optimizer	RMSP
Feedback step	5	Key Features	Reflux ratio/ Reboiler heat duty
Number of input features	5	MSE value	6.396095×10^{-6}
Type of neurons	LSTM	AIC value	-591.96
Number of hidden layers	1	Activation function	Linear
Number of hidden neurons	5	Optimizer	RMSP

4. Conclusions

The architecture of the ANN was optimized to obtain good forecasting of Acetone, Butanol, and Ethanol in a dividing wall column. A major result in our study is that we found that to have a good data prediction it is not necessary to consider the three manipulable variables. Results show that it is only necessary to consider two: the reflux ratio and the reboiler heat duty. This would have an impact on future work by implementing only two controllers for the three perturbed output variables of the DWC system, which would reduce the operating cost considerably by having fewer controllers and with a low number of neurons in the ANN structure.

Abstract

Kinetic modelling covers a key role in process simulation and design. Recently the methanol sector is assisting a remarkable enhancement due to its applications as fuel, solvent, and precursor as shown in Bozzano and Manenti (2016). The increasing number of patents, the market prospects, and recent research witness this renewed interest. However, despite this rate in developing and improving technologies, the kinetics modelling does not follow these trends. The methanol synthesis chemical paths, the intermediates, and the real role of the active sites are nowadays still unclear. However, process engineering requires reliable models to estimate the methanol synthesis rate, hence, to design and size the reactor and downstream equipment. Currently, the most used kinetics are Graaf and Vanden Bussche - Froment's models which in any case show some shortcomings and weaknesses. Starting from these premises, the need for updated kinetics is clear. This work aims at comparing and highlighting the impact of different kinetic models (1) original Graaf (or-GR), (2) Vanden Bussche - Froment (VBF), and (3) refitted Graaf (ref-GR) on the methanol synthesis configuration for different feedstocks through an in-silico assessment. The general simulation flowsheet includes the single-stage PFR for the methanol synthesis, the condensation step, and recycle loop for the unreacted syngas. The comparison with industrial data proves that the ref-GR model predicts better than the original Graaf model as in Graaf et al. (1988), while the VBF, Vanden Bussche and Froment (1997), tends to overestimate methanol production. The validation exploits industrial data published in the literature.

Keywords: kinetics comparison, methanol reactor, process simulation, industrial comparative case studies, Lurgi and ICI technologies

1. Introduction

As highlighted in recent publications by Bisotti (2021), and Bozzano and Manenti (2016), the methanol molecule has been gaining increasing interest for twenty years as in Olah's wishes for the methanol economy anticipating the energy transition period. Although the technology is shifting towards milder operating conditions decreasing pressure and optimizing catalyst formulation, the kinetic steps, species role and interaction with active sites, and consequently modelling appear to lack a comprehensive catalytic path description for CO and CO₂ hydrogenation over CZA catalysts. The different kinetic models (Table 1) reflect this fragmented framework where carbon source and kinetic scheme are not uniform. The methanol synthesis is essentially limited to three different reactions: CO and CO₂ hydrogenation, and (reverse) water-gas shift reaction. Looking at

the table, with few exceptions, these models were proposed more than 20 years ago, hence, a kinetic parameters robust refit would be beneficial as demonstrated in Bisotti et al. (2021) for the or-GR model. They decided to refit the Graaf model since several authors use regardless Graaf's and VBF's models showing good accuracy with industrial and/or experimental observations. Hence, or-GR and VBF models are considered as industrial benchmark for methanol synthesis modelling, as proven in Mäyrä and Leiviskä (2018). In this work, adopting the ref-GR model, we would show the impact and the different predictions in methanol synthesis for or-GR, ref-GR and VBF models furtherly corroborating observations/conclusions proposed in previous work, Bisotti et al. (2021).

Table 1 – Main kinetic models available in the literature.

Model (year)	Source	Model reactions
Villa et al. (1985)	CO	$\text{CO} + 2\text{H}_2 \rightleftharpoons \text{CH}_3\text{OH}$ $\text{CO} + \text{H}_2\text{O} \rightleftharpoons \text{CO}_2 + \text{H}_2$

Skrzypek et al. (1991) Askgaard et al. (1995) Vanden Bussche-Froment (1996) Kubota et al. (2001)	CO ₂	$\text{CO}_2 + 3\text{H}_2 \rightleftharpoons \text{CH}_3\text{OH} + \text{H}_2\text{O}$ $\text{CO}_2 + \text{H}_2 \rightleftharpoons \text{CO} + \text{H}_2\text{O}$

2. Methods

The in-silico assessment consists of two different steps: (1) comparison of the methanol production and reactants conversions using three different kinetic models, syngas quality, and operating conditions; (2) industrial case studies. For the first task, the analysis is performed in Aspen Hysys[®] V11 using a PFR followed by a cooling step (up to 25°C) and flashing unit where liquid products and light gas are separated. The recovered syngas is then recycled back to the reactor feed after a re-compression as in Figure 1. The fresh syngas make-up and recycled syngas temperatures are set to 225°C. Pressure drop is estimated using the Ergun model already implemented in Aspen Hysys[®]. The PFR length is subdivided into 100 segments (the default value is 20). The recycle function settings impose low errors in the molar flow and stream composition, the adjust guarantees the residual error for the feed stream (FEED) lower than 0.02%. Since, we aim at comparing kinetic models for industrial applications, we choose conventional feed compositions or at least close to industrial among the one proposed in Leonzio (2020). For the second task, reactor design/configuration and flowsheet are assigned in accordance with the analyzed industrial technologies (i.e., Lurgi and ICI). For the industrial plant data, we refer to Chen et al. (2011) and Froment et al. (1995) which report the process schemes and equipment details for the Lurgi and ICI technologies, respectively. We focused our attention on such technologies since they cover almost 90% the installed reactor technology worldwide, as proven in Bozzano and Manenti (2016).

3. Sensitivity analysis to the feed composition and pressure

The sensitivity analysis aims at comparing the methanol production using the three kinetics under different operating conditions: 50-75 bar is a typical operating window for the MegaMethanol technology and 70-90 bar range is a standard in other technologies such as Lurgi and ICI. To further test the kinetics, different feed compositions are considered. Such compositions are petro-syngas, COG, and bio-syngas in Leonzio (2020) and reported also in Bisotti et al. (2021). The petro-syngas is representative for conventional syngas from natural gas (i.e., steam methane reforming), the COG for syngas from coke gasification that in China is still the main carbon source to chemicals, and bio-syngas for emerging biosources such as biogas and biomasses. The implemented Lurgi reactor specifications, including feed temperature, are the same reported in Chen et al. (2011). As purge ratio, we assumed that 10% of the recycle loop is removed. Figure 1 depicts the implemented reactor flowsheet, while Figure 2 gathers the simulations results.

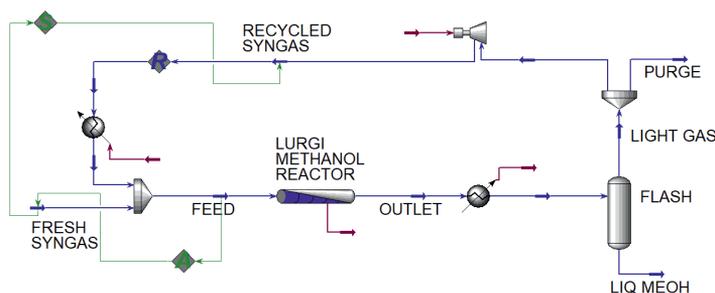

Figure 1 - methanol synthesis complete configuration.

The results show that the ref-GR is like the VBF model in predicting the methanol production and reactant conversions meaning that the robust refit procedure modified the kinetic parameters forcing the or-GR to move closer to the VBF. Since the or-GR tends to underestimate the methanol productivity, the refit induced an increment in the CO₂ and H₂ conversion as depicted in Figure 2 (2A)-(2C). Furtherly, it is noticeable that VBF and ref-GR predicts larger methanol production with regards to the or-GR which never overcomes 3 ton/h. This is one of the main Graaf's model shortcoming already emerged. Moreover, the ref-GR exhibits a strong pressure dependence in the methanol production, on average moving from 50 bar to 90 bar there is +35% increment, while or-GR and VBF is almost flat regardless the operating pressure. Generally, the ref-GR behavior is comprised the VBF and or-GR predictions (except for the petro-syngas feedstock). These have been already discussed in Bisotti et al. (2021). However, considering the order of magnitude of the simulation results is possible to state that the ref-GR and VBF predictions are quite similar both in terms of methanol production (4.5 ton/h vs 3.7 ton/h respectively). Instead, it is quite evident that the discrepancies are magnified looking at COG and bio-syngas feedstocks. Under such conditions, using the VBF model, the methanol production is one order of magnitude larger than the one predicted with ref-GR as in Figure 2 (1B)-(1C). Finally, the reactants conversions point out that the VBF implies larger H₂ and CO₂ consumptions. This is due to: (1) the VBF tends to overestimate the methanol production as proven in Bisotti et al. (2021) and (2) the CO₂ is the only direct hydrogenation path considered, hence, as expected, higher CO₂ conversion are strictly related to the suppressed CO hydrogenation which push the water-gas-shift equilibrium towards CO₂ production which is then converted into methanol.

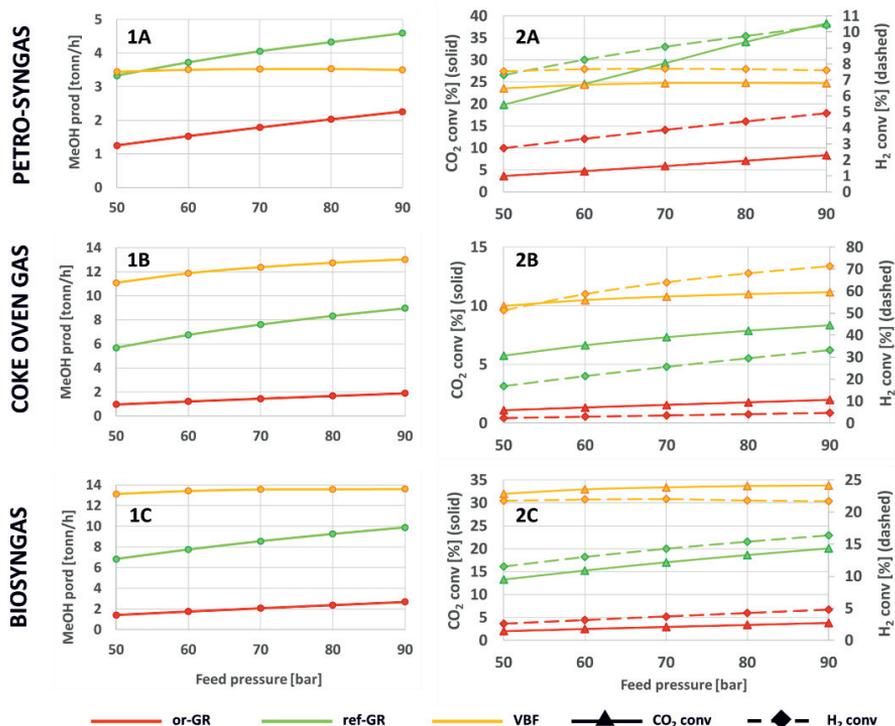

Figure 2 - sensitivity analysis results: (1) methanol production and (2) CO₂ and H₂ conversions for different feedstocks (A) petro-syngas, (B) COG, and (C) bio-syngas. For the conversion chart CO₂ conversion is the solid line (left y axis) and H₂ conversion is the dashed one (right y axis).

4. Industrial case studies

The industrial case studies include the Lurgi Boiling Water Reactor (BWR) and the fixed adiabatic beds gas-quenched reactor (formerly ICI, nowadays Johnson Matthey). The Lurgi and ICI technologies are described in Chen et al. (2011) and Froment et al. (1995) and depicted in Figure 3 and Figure 4 respectively. The cited works report further details such as the reactor specifications, feed composition, and operating conditions. Simulations results are graphically depicted in Figure 5 (BWR Lurgi) and Figure 6 (ICI).

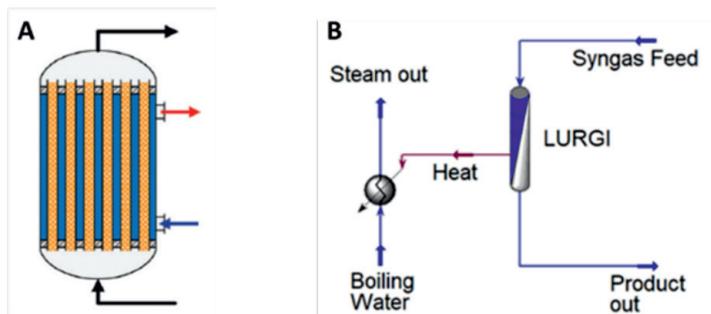

Figure 3 - Lurgi BWR technology: (A) reactor configuration and (B) simulation flowsheet

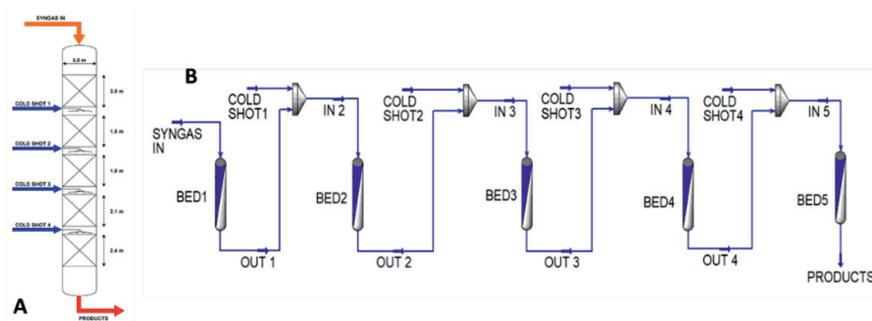

Figure 4 - ICI technology: (A) reactor configuration and (B) simulation flowsheet

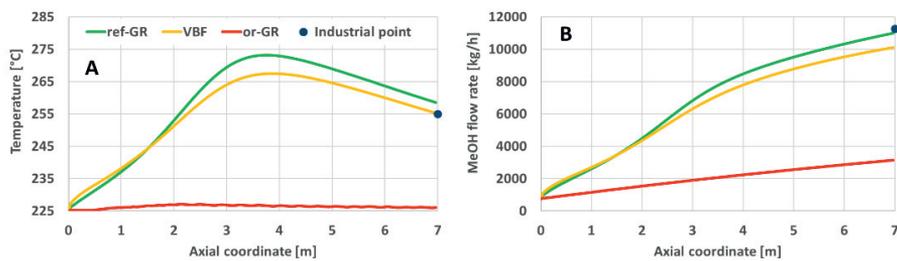

Figure 5 - Lurgi BWR reactor results: (A) temperature profile and (B) methanol production using or-GR (red solid line), ref-GR (green), and VBF (yellow). The blue dots are the experimental data.

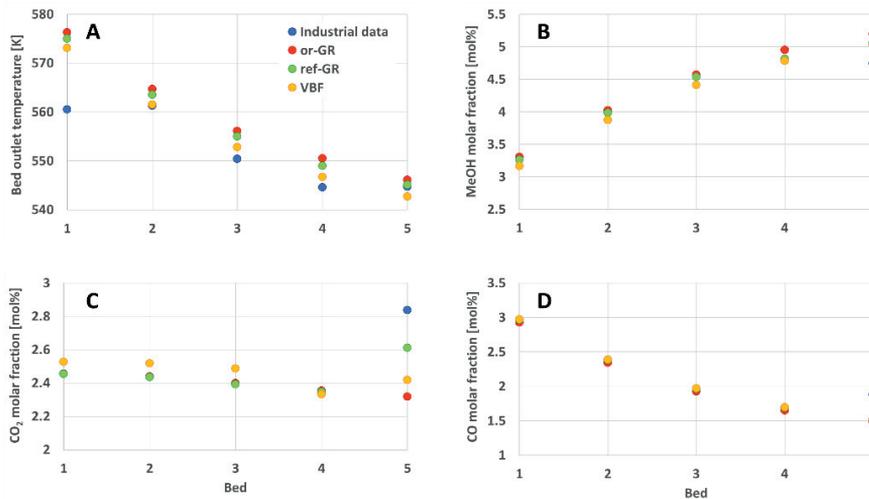

Figure 6 - ICI reactor results: (A) bed outlet temperatures, (B) methanol, (C) CO₂, and (D) CO molar fractions in the outlet mixture using ref-GR (green dots), or-GR (red) and VBF (yellow). The blue dots are the industrial data.

The industrial case studies results show that the ref-GR kinetic better predicts the methanol production in the Lurgi reactor while the predicted outlet temperature is close to the industrial value. Similarly, also for the ICI technology it is possible to appreciate that the ref-GR is based on an accurate kinetic model since it enables to catch both methanol and CO_x molar fractions, and the outlet temperatures. Specifically, VBF and ref-GR have similar deviations with regards to the industrial data, however, the ref-GR model is the only one catching the final CO₂ amount. In Figure 6, the hydrogen content is not reported since industrial data are not available. Concerning the ICI technology neither of the considered kinetic models can correctly predict the products mixture and outlet temperature values for the first and second adiabatic beds. This may be due to the presence of mass transfer limitation which may occur where temperature is larger than 275°C. It is not possible to characterize this aspect using simulation software such as Aspen Hysys. The VBF model presents similar accuracy even though it is not as accurate as the ref-GR in predicting the methanol production, for instance, in the Lurgi technology VBF underestimates the methanol production for almost 1.0 ton/h. The or-GR exhibits the worst accuracy meaning that it does appear as a suitable kinetic model for the methanol synthesis reactor simulation and validation.

5. Conclusions

This work demonstrated that kinetics affect the reactor predictions. Furtherly, it proved that in process simulation environment (Aspen Hysys[®]) the or-GR is not a suitable model to properly design the methanol synthesis reactor. Conversely, the ref-GR guarantees accuracy, and it is more precise of the VBF in the analyzed case studies. Hence, it is possible to state that ref-GR solved the shortcomings emerged in the or-GR and it is a potential candidate as reliable alternative for industrial and simulation purposes.

Abstract

Off-Site Modular Construction (OSMC) research has been a growing research area over the past two decades driven by low productivity levels in construction (Bock 2015). Some of the chemical plant industry has started analyzing small modular chemical plants. Some work has been achieved in automating earlier parts of the small modular chemical plant design process such as automated database creation and selection of equipment. However, a layout optimization methodology has not been applied to OSMC industrial process plants. Plant layout is an important step in the plant design process (Moran 2017). Methods have been made to proposed to optimize the plant for different requirements. Requirements have been modeled in a mathematical programming model as constraints such as connectivity, pumping, safety, pipe routing, multi-floor arrangements, etc., to establish the optimal cost and safe plant layouts.

This paper proposes to develop and utilize a MILP mathematical layout optimization model to help design and construct modular process plant. The main considerations are the module sizes for transport requirements and factory handling. Data from previous research was utilized and run through the new modular optimization model. The previous research layout results were compared to the new modular layouts process plant optimization to compare how modularization may affect the design of industrial process plants. The results demonstrate that building a plant in road transportable, factory built could enable equipment to be located closer together due to advanced factory manufacturing processes as assembly and tools are more accessible than building stick built plants.

Keywords: MILP, mathematical layout optimization, off site modular construction, industrial process plants,

1. Introduction

Off-Site Modular Construction (OSMC) research has been a growing research area over the past two decades driven by low productivity levels in construction (Bock 2015). Productivity is higher in factories when compared to a stick-built site due easier access to superior tools, methods and learning. This has spawned the development of small, factory built, rapidly deployable and flexible process plants (Seifert et al. 2012) to take advantage of the gains in OSMC productivity. This is a rapidly growing area in Chemical process plant research (Bielenberg and Palou-Rivera 2019). Research has shown that OSMC can provide 20% savings in cost and up to 50% savings in scheduling, providing reductions in risk and finance (Mignacca et al. 2018). The same work performed in a factory may be

8x more efficient and cost effective than performing work in situ according to a study in shipbuilding (Barry 2009).

Plant layout is an important step in the plant design process (Moran 2017) where requirements are taken into consideration for layouts. Requirements can take the form of process flow connectivity, pumping, safety, pipe routing, multi-floor arrangements, etc., to establish the optimal cost and safe plant layouts. Three core approaches have been applied to optimising costs of plant layouts: Heuristics and Metaheuristics, Mathematical optimisation along with Rule based expert systems. Some work has been achieved in automating earlier parts of the small modular chemical plant design process such as automated database creation and selection of equipment, however, a layout optimization methodology has not been applied to OSMC industrial process plants (Eilermann et al. 2018).

In plant layout literature, heuristics were first utilised in the plant design problem to arrange equipment. Mathematical approaches were then developed using Mixed integer (Nonlinear) Programming (MINLP) and (MILP) and techniques (MINLP) or graph partitioning (Ejeh, Liu, and Papageorgiou 2019b) for pumping and floor construction costs, financial risk and safety. Pipe routing and other safety methods were developed (Ejeh, Liu, and Papageorgiou 2019b) along with methods to solve larger problems. Ejeh et al., expanded the optimisation model with considerations for tall equipment items that span across floors and the availability of predefined production sections (Ejeh, Liu, and Papageorgiou 2018) and an updated model accounting for fire and explosion risk (Ejeh, Liu, and Papageorgiou 2019b). In another work, three improvements are added over the previous methods: an extension for multi-floor equipment items to extend above the maximum possible number of levels, the choice of an available number of floors fewer than the maximum amount essential for any equipment item and Integer cuts to improve the efficiency (Ejeh, Liu, and Papageorgiou 2019a).

This work builds upon the previous work of (Patsiatzis and Papageorgiou 2002) by extending the problem to consider process plant systems for OSMC and road transportable modules.

2. Problem Description

This work aims to obtain the optimal system layout for equipment in modules constrained for OSMC and transport. The factory-built road transportable requirement for this work is a key requirement. Requirements for EU transport are outlined in Table 1, (Barrot 2019).

	No permit (1)	Long term permit (2)	Corridor (3) (except Germany)
Width	3 m	3,5 m	4,5 m
Overall length	24 m	30 m	40 m
Overall height	Directive 96/53/EC	4,2 m	4,4 m
Weight	Directive 96/53/EC	80 tonnes	100 tonnes
Axle load: Beam axle	Directive 96/53/EC 12 tonnes	12 tonnes 15 tonnes	12 tonnes 15 tonnes

Table 1 – EU road transport requirements (Barrot 2019)

In this section, the extension of the optimisation model will be considered with the addition of module cost. An outline of the modular process plant layout problem and the fundamental assumptions are provided in this section for the mathematical model formulation. If equipment items extend above the available module height, these are identified a suitable vertical module and located outside the module stack. Equipment items are assumed as a cuboid. The geometrical centres are utilized for rectilinear distances between equipment in the x-y axis. A position on the equipment height is determined for the vertical distances/connections. Every equipment item is permitted to rotate in 90 angles in the x-y plane unless constrained. Equipment items could be built on platforms to increase the work off site. A trade off study would be required to assess these criteria. The problem description is as follows

Provided to the Model:

- A set of N process plant equipment items, i, j, size: (width, height, depth)
- Directed connections between items
- Module size (width, height, depth)
- NF number of modules
- a set of K available modules for layout with module height, MH;
- Connection points height on items h
- Costs of connections and modules connection, Cci j, pumping (horizontal, Chi j, and vertical, Cvi j), land purchase (LC) and construction (FC1, FC2) cost data;
- Additional margin space between items
- Module Positions (fixed)
 - i j, pumping (horizontal, Ch
 - i j, and vertical, Cv
 - i j), land purchase (LC) and construction (FC1, FC2) cost data;

Determined by the Model

- Positions of items
 - Rotations of items
 - Number of modules used
 - Cost of connections
 - floor area;
- so as to minimise the total plant layout cost

2.1. Model Formulation

Binary variables V_{ik} and Z_{ik} , Integer variable NF, and Parameter H from (Patsiatzis and Papageorgiou 2002) are altered to represent modules rather than floors.

Assuming construction and piping installation costs can be reduced 20% by constructing modules in factories (Barry 2009)(Mignacca et al. 2018), FC1&FC2 and connection costs C_{ij} are reduced by 20%.

2.2. Non overlapping of Items with module bounds

A lower and upper bound must be imposed on the equipment coordinates to ensure they remain within the module dimensions depending on its current rotation. Assuming that all modules are positioned at the origin and distances are calculated by taking their relative position into account:

$$x_v + l_i \leq W_k + M(1 - m_k), \quad \forall v \in V, \forall k \in K \quad \text{Equation 1}$$

$$y_v + d_i \leq H_k + M(1 - m_k), \forall v \in V, \forall k \in K \quad \text{Equation 2}$$

Considering if items can move in the z axis:

$$z_v + dv \leq D_k + M(1 - m_k), \forall v \in V, \forall k \in K \quad \text{Equation 3}$$

and $(x_{uv}, y_{uv}, z_{uv}) = (0, 0, 1)$ respectively.

2.3. Rectilinear distance between connected items

The rectilinear distance in the x-axis between item i and j can be calculated by the absolute value of D_{xij} and is considered for the set of connected items, $f(i; j)$ 2 Eg, where D_{xij} is defined by:

$$R_{ij} - L_{ij} = x_i + \sum_{k \in K} V_{ik} m_{xk} - x_j - \sum_{k \in K} m_{jk} m_{xk}, \forall (i, j) \in f_{ij} \quad \text{Equation 4}$$

$$A_{ij} - B_{ij} = y_i + \sum_{k \in K} m_{ik} m_{yk} - y_j - \sum_{k \in K} m_{jk} m_{yk}, \forall (i, j) \in f_{ij} \quad \text{Equation 5}$$

Considering the rectilinear in the z-axis:

$$U_{ij} - D_{ij} = [z_i + \sum_{k \in K} m_{ik} m_{zk}] - [z_j + \sum_{k \in K} m_{jk} m_{zk}], \forall (i, j) \in f_{ij} \quad \text{Equation 6}$$

2.4. Objective function

Given that the unit cost of a connection between i and j is c_{ij} and the cost of a module is given by g_k , minimise the following objective function,

$$\begin{aligned} Of = & \sum_{(i,j) \in E} c_{ij} TD_{ij} + C_{ij}^v D_{ij} + C_{ij}^h (R_{ij} + L_{ij} + A_{ij} + B_{ij}) + C1 \cdot NF + FC2 \cdot NF \cdot FA \\ & + LC \cdot FA \end{aligned} \quad \text{Equation 7}$$

All continuous variables in the formulation are defined as non-negative. Total layout cost (eq. 21), subject to floor constraints (eqs. 1 - 3, 5 - 9), multi-floor equipment constraint (eq. 4), distance constraints (eqs. 10 - 14), area constraints (eqs. 15 - 20), equipment orientation, non-overlapping and layout constraints

3. Results and Discussion

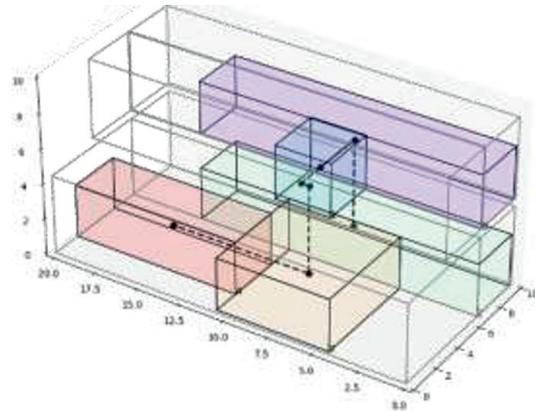

For the case study, the five-unit instant coffee process (Patsiatzis and Papageorgiou 2002) was chosen.

3.1. 2 Module stack

The results for the 3 layer module stack can be seen in Figure 1.

	x	y	z
Percolator	7.9	7.85	5
Cyclone	7.9	4.7	5
Spray Dryer	7.9	7.85	0
Press	7.45	3.15	0
Drier	15.3	3.15	0

Figure 1 - Locations of equipment for 2 floor module

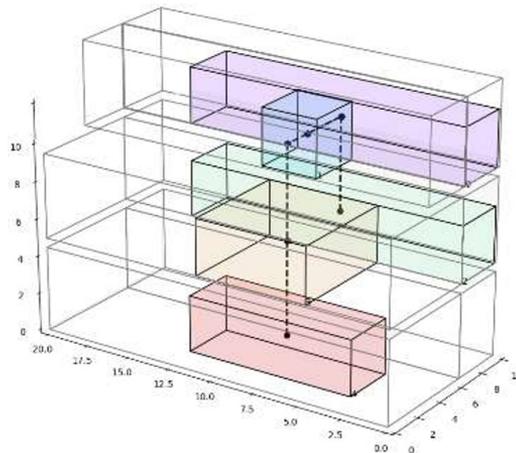

Assuming construction and piping installation costs can be reduced 20% by constructing modules in factories (Barry 2009)(Mignacca et al. 2018), construction of the module stack (FC1&FC2) reduces to 26624rmu and connection costs decrease to 12374rmu. The total plant cost is 77184rmu a 6.3% decrease compared to the original stick-built site. Land costs stay the same at 13340rmu. However, pumping costs increase to 24846rmu a 3.6% increase of the total original costs of 82366rmu.

3.2. 3 Module stack

The results for the 3-layer module stack can be seen in Figure 2.

	x	y	z
Percolator	7.9	7.85	10
Cyclone	7.9	4.7	10
Spray Dryer	7.9	7.85	5
Press	7.9	3.15	5
Drier	7.9	3.15	0

Figure 2 - Locations of equipment for 3 floor modules

Again, assuming 20% reduction in construction and piping installation, construction of the module stack (FC1&FC2) increases to 39936rmu. Connection costs are 13863rmu. In this instance, pumping costs decrease to 12854rmu, a 41% decrease on the original pumping costs of 21909rmu. Land costs stay the same at 13340rmu. The total plant cost is 79992rmu, a 2.9% decrease compared to the original stick-built site.

Although the construction costs have increased by 13312rmu (a 50% increase) the reduction in pumping costs is 11992rmu. The operators of this plant would therefore see significant savings if running the plant for over a year.

4. Conclusions

A layout optimisation model was introduced to consider off site manufacture and transport of process plant systems. Although operational pumping costs may increase slightly due to the requirement to locate equipment items in modules (more constrained), construction costs for structures and piping costs can be decreased. The results showed that this reduction provides an overall benefit when comparing OSMC to stick built process plants on the smaller scale plants analysed here.

Future work would be to increase the process plant system size to see how it copes with larger models. A more detailed analysis is required on the construction of modules, this would require the involvement and collaboration with civil engineering and infrastructure experts.

Abstract

The current global climate situation requires adequate energy technologies and systemic solutions to reduce CO₂ emissions to reach the carbon neutrality target by 2050. Cogeneration in nuclear power plants can provide a low-carbon source of process heat. These plants are in most cases optimized only for electricity production, which is the case for Pressurized Water Reactors in France. A significant asset of cogeneration units is that they can efficiently switch from electricity-only production to hybrid heat and power production. In this context, the objective of this work is to assess the benefits of performance optimization for a multi-case operation applied to Rankine cycle system design. The key for such an optimization is to minimize the exergetic losses that change from one operational mode to another. As a proof of concept of the multi-case optimization relevancy for a steam-water cycle, a seasonal variation of the heat sink temperature is considered as it induces several operating modes for the cycle, even for electricity-only production. The model of the system developed in the Modelica environment with the ThermoSysPro library is first presented. The formulation of the optimization problem involves dimensional parameters as optimization variables to maximize the global efficiency of the cycle. Three cases are then simulated: minimal condenser pressure, maximal condenser pressure and a seasonal variation profile of condenser pressure. Multi-case optimization allows improving the mean operating efficiency of the cycle in the considered heat-sink temperature range, compared to an optimization focused on a single operating point. The relative efficiency gain obtained for a narrow condenser temperature range is about 0.5 %. While the gain is modest, this demonstrates the interest for the concept of partial regimes modelling in support of a multi-case optimization, which should be rather emphasized for a cogenerating Rankine cycle, for which operational modes will be much more different. Further developments on the model and the study of a cogeneration case constitute a natural perspective of this work.

Keywords: Modelica simulation, Optimization, Cogeneration, Rankine cycle, CO₂ reduction.

1. Introduction

The energy transition has become a cornerstone of the global response to climate change. In order to avoid nature's irreversible turning point, extremely challenging goals are being set for reducing greenhouse gas emissions to zero by 2050, and limiting the rise in global temperatures to 1.5 °C (IEA, 2021). The role of nuclear energy is very relevant in that context, since nuclear power plants (NPP) do not emit CO₂ during electricity production. Alongside with the growth of renewables, which have an intrinsic variability, the need for flexibility in power systems increases. The combined production of electricity and heat in power systems contributes to grid stability and security, dealing with supply-demand fluctuations and load following transients. The heat produced during a decrease in electricity supply has several potential applications depending on the available temperature levels, such as hydrogen production, thermal storage (for further shifted electricity production when the demand becomes higher), and district heating. Hence, cogeneration in power plants has a key role in decarbonisation of the energy systems in the long term (Taibi et al. 2018).

In this work, a seasonal temperature variation is used as a proof of concept for the multi-case optimization approach, which could be useful in the design of cogenerating systems. The dimensional characteristics of the cycle are optimized considering the whole temperature profile, instead of a single operation case with the extreme or average temperature values. The assessment of this case study will provide better insights in a real cogeneration case, with a larger range in temperature variations to which the cycle is submitted, so that more significant efficiency improvements could be achieved.

2. Rankine cycle model

The case study considered is a Nuclear Power Plant (NPP) equipped with a 540 MW Small Modular Reactor (SMR). In the secondary circuit, saturated steam exits the steam generator at 45 bar, is expanded in the turbine group, releasing heat through the condenser to the cooling circuit before being pumped back to the steam generator as liquid water. In the cooling system, sea water is pumped to the condenser, where it extracts heat and flows back to the sea in an open system configuration.

The secondary circuit of the NPPs is usually a Rankine cycle containing a reheater and several preheaters. However, the reference case for the present work contains only one preheater and no reheat. Even if this cycle is significantly simplified, this choice facilitates the calculations and numerical convergence of the model, and is not restrictive for the goal of this work.

Figure 1 shows the case study, which consists of the secondary circuit of the SMR-PWR. The system was modeled using Dymola software (Dassault Systèmes 2021) and the ThermoSysPro library (EDF 2021). These tools are capable of simulating system models comprising physical components from several engineering domains (Brück 2018).

The cycle in Figure 1 was designed with the standard ThermoSysPro components. In order to validate the Rankine model developed in Dymola, the CYCLOP (Cycle Optimization) tool was used (Haubensack, Thévenot, and Dumaz 2004). This tool is being developed by the CEA and its accuracy has already been proven with real operation data of NPPs. Table 1 shows the results obtained with Dymola, compared to CYLOP, for the steady-state design operation for two values of the condenser pressure, i.e. 50 and 100 mbar.

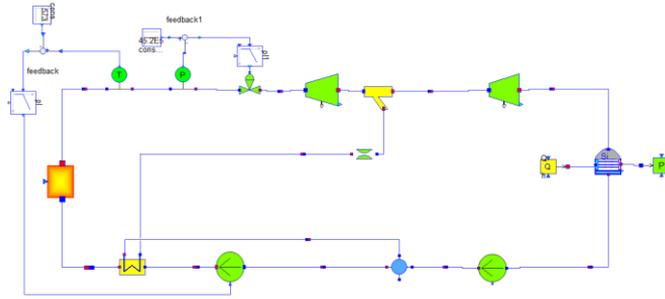

Figure 1: Rankine cycle model, designed with ThermoSysPro library in Dymola.

For these two design conditions, the results show that Dymola model is capable of obtaining optimized values very similar to CYCLOP results for different nominal conditions, hence validating a single case optimization process with Dymola.

Table 1: Validation of Dymola cycle in design conditions. Where η is the cycle efficiency, $T_{in,sg}$ is the steam generator inlet temperature, P_{ph} and Q_{ph} are the pressure and mass flow of steam entering the preheater, respectively. The relative error between cases is presented.

Design Value	50mbar			100mbar		
	CYCLOP	Dymola	Rel. Error	CYCLOP	Dymola	Rel. Error
η	0.3306	0.3306	0	0.3141	0.3140	-3.2E-04
$T_{in,sg}$ (°C)	150.00	150.01	6.7E-05	150.00	150.01	6.7E-05
P_{ph} (mbar)	5436	5436	0	5436	5437	1.8E-04
Q_{ph} (kg/s)	46.99	47.02	6.4E-04	42.77	42.79	4.7E-04

3. Seasonal temperature variation of cold source

In a water-cooled condenser, typical of a Pressurized Water Reactor (PWR), the pressure is defined by the available temperature of the cold source. Consequently, temperature variations of the cooling water in the vicinities of the NPP affect the electricity production, since the efficiency of the Rankine cycle (secondary circuit) is dependent on the condenser pressure. This effect is shown in Figure 2.

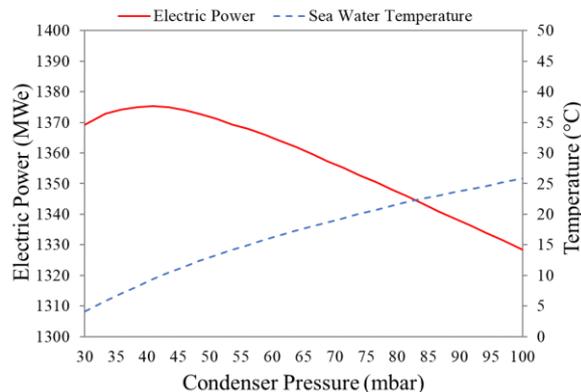

Figure 2: Electrical power production sensibility to cold source temperature. Adapted from (Grand 2014). Courtesy of the author.

As the condenser pressure decreases, due to a reduction in cooling water temperature, the production of electricity increases, as expected by the Carnot efficiency. However, there is an inflexion point beyond which electrical power begins to drop with a further decrease in condenser pressure. This effect is highly influenced by the increase in irreversibilities along the turbine during off-design operation. Indeed, the increase in condenser pressure causes an increase of turbine outlet swirl velocities, generating losses, which degrade cycle efficiency, reinforcing the Carnot tendency. In addition, the reduction in condenser pressure increases turbine outlet volumetric flow, which increases kinetic losses, contradicting the ideal Carnot cycle efficiency trend.

Temperature variations occur seasonally, and their amplitude depends on the geographic location of the plant. Table 2 shows the monthly temperature averages for sea water used as a cold source in the nuclear power plant located in Blayais, France.

Table 2: Average values of sea temperature, with corresponding condenser pressures, in Blayais, France (Weather Spark 2021).

Month	T_{sea} (°C)	P_{cond} (mbar)	Month	T_{sea} (°C)	P_{cond} (mbar)
January	11	44,99	July	20	73,88
February	11	44,99	August	21	77,91
March	11	44,99	September	20	73,88
April	13	50,38	October	17	62,85
May	15	56,32	November	15	56,32
June	18	66,36	December	13	50,38

The water used for cooling the three 900 MW reactors of this NPP undergoes a temperature variation from 11 to 21°C, with a yearly average of 15.4°C. In order to assess the electricity production efficiency and optimize the cycle for the seasonal temperature variation, the exhaust loss effect must be considered in the turbine model.

In order to account for off-design conditions, the turbine model available in ThermoSysPro library was then modified to include the exhaust loss as a function of last stage exit velocity (1) adapted from (Spencer, Cotton, and Cannon 1974). This loss has been chosen since it has considerable influence on the cycle efficiency in part-load operation.

$$\Delta h = 3.901 \cdot 10^{-8} V_s^4 - 4.515 \cdot 10^{-5} V_s^3 + 1.954 \cdot 10^{-2} V_s^2 - 3.447 V_s + 2.28 \cdot 10^2 \quad (1)$$

In this expression, Δh is the enthalpy loss due to the exhaust-pressure loss, and V_s is the velocity of steam leaving the last stage blades. In order to assess the operation at off-design conditions, a pressure variation was imposed to the condenser, in a cycle designed for a condenser pressure of 57.63 mbar. For comparison, the same cycle was re-optimized at every pressure with CYCLOP tool, which does not account for the irreversibility effects. The results from the Dymola simulations in Figure 3 include the inflexion point seen in Figure 2, which is influenced by the exhaust loss in the turbine. As expected, the cycles simulated at rated conditions with CYCLOP follow the Carnot efficiency trend, which increases as the condenser temperature (and pressure) decreases. These results support the Rankine model developed in Dymola regarding the operation in off-design conditions.

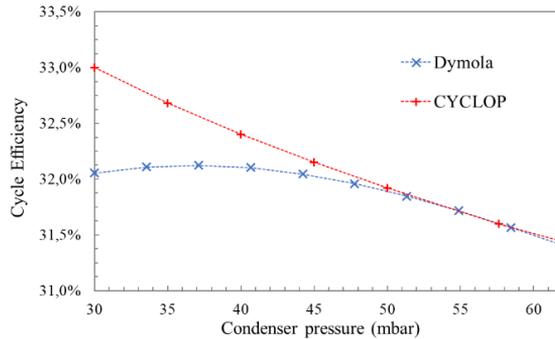

Figure 3: Efficiency of Rankine cycle with exhaust loss in non-rated conditions (Dymola) and the design efficiency of each condition (CYCLOP).

4. Optimization

The optimization module available in Dymola was then used to optimize the Rankine model for the multi-case scenario given by the temperature profile of Table 2. The Simplex method was used with six optimization variables, given by dimensional characteristics: the Stodola coefficients of the turbines (Cooke 1984), the exhaust area of the turbine’s last stage and a coefficient for pump head characteristic curve (for both the high-pressure and low-pressure sections). The multi-case optimization was compared to the performance of cycles optimized for the minimal and maximal temperatures (Figure 4).

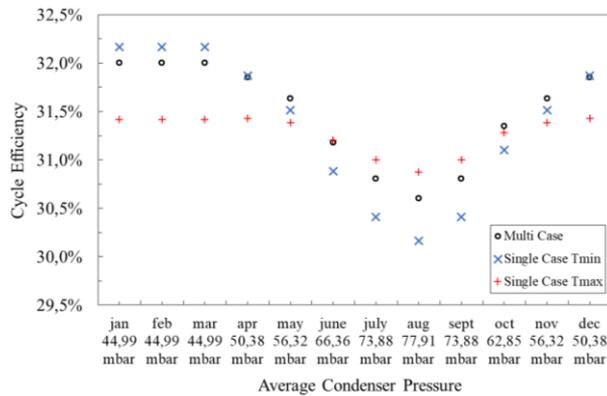

Figure 4: Multi-case optimization result for the Rankine cycle submitted to a seasonal variation of cold source temperature. A comparison is made with the cycle optimized for the minimal and maximal temperatures.

The multi-case results do not give the best efficiency values at minimal and maximal pressures. However, it increases the average efficiency of the cycle with respect to the single-case extreme-temperature optimizations. Table 3 shows the respective average efficiency.

The multi-case optimization presented the highest annual average efficiency for the Rankine cycle. This demonstrates the interest in considering the different operation scenarios during the optimization, instead of a single-case approach. The results obtained indicate that even if the cycle is optimized for the average temperature (of the seasonal

variation), the efficiency obtained is lower than the multi-case performance. This methodology allowed a relative gain of 0.41%, 0.67% and 0.06% with respect to the single case optimizations for the minimal, maximal and average temperatures, respectively.

Table 3: Average values of Rankine cycle efficiency for the different optimization approaches.

Average Efficiency (12 months)	Single Case	Single Case	Single Case	Multi
	Tmin	Tmax	Tavg	Case
	0,3135	0,3127	0,3146	0,3148

5. Conclusion

The presented work is a proof of concept of the methodological feasibility of the multi-case optimization approach. First, the case study was presented and the optimization was validated using two nominal conditions as a reference. The turbine model was then modified to include the exhaust loss effect, which has a considerable influence on cycle efficiency. A literature example was then used as a reference for supporting the behavior of the modified turbine model. For a seasonal temperature variation, relative efficiency gains of 0.41% and 0.67% were obtained through the multi-case optimization of the Rankine cycle, in comparison to the cycle optimized only for the minimal or maximal temperatures. When the cycle was optimized for the average value of the seasonal variation, the efficiency was still slightly lower than with the multi-case optimization result. In a cogeneration situation, with temperature variations that might be much more significant, this methodology should further improve the efficiency of combined heat and power production.

Abstract

A comprehensive multiphase model was developed for a trickle bed reactor with solid foam packings. Three-dimensional dynamic mass and energy balances in the three phases of heterogeneously catalysed reaction systems were implemented, and the mass and heat transfer resistances in the gas-liquid and liquid-solid phases and inside the pores of the catalyst were included in the model. Hydrogenation of arabinose and galactose mixtures on a ruthenium catalyst supported by carbon-coated aluminium foams was applied as an industrially relevant case study for the multiphase model. The kinetic parameters were estimated with confidence intervals within 10% error, indicating a good accuracy of the parameters, and the model results present a good adjustment to the experimental values. Finally, a sensitivity analysis on several model parameters demonstrated that the model could be applied to industrially sized reactors and various multiphase catalytic systems.

1. Introduction

In the context of increasing energy costs and future stringent environmental regulations for industrial production, structured catalysts play an essential role in designing more energy-efficient chemical reactors. In recent years, several advances in this field have been taken, with diversified structured catalysts being invented and studied in detail, such as monoliths, fibres, solid foams as well as structures prepared by 3D printing.

For three-phase catalytic systems (solid catalyst, gas phase, and liquid phase), open-cell foams have been investigated as suitable alternatives for catalytically active reactor packings because of their advantageous structural properties. The structures of pores and struts in open-cell foams provide high porosity (75-95%) and high specific surface area, allowing radial liquid flow and high local turbulence, which result in enhanced mass and

heat transfer. Axial and radial mixing are improved by the high pore tortuosity of solid foams, ensuring the even distribution of the gas and liquid phases, which is critical for a maximum product yield (Stemmet *et al.* (2008), Mohammed *et al.* (2014), Twigg *et al.* (2002)).

In this work, an advanced mathematical model of a three-phase catalytic tubular reactor was developed for solid foam packings and implemented in the *gPROMS[®] ModelBuilder 7.0* software. The two-dimensional gas, liquid and solid phase mass and energy balances include individual terms such as internal diffusion, gas-liquid and liquid-solid mass transfer, and intrinsic kinetics. Furthermore, the gas and liquid flows are described by axial and radial dispersion terms along with liquid hold-up and pressure drop expressions.

The hydrogenation of arabinose and galactose mixtures on a ruthenium catalyst supported by carbon-coated aluminium foams was applied as an industrially relevant case study. The kinetic parameters of the reaction were estimated using experimentally obtained concentrations of arabinose, galactose, arabitol and galactitol in a continuously operating tubular reactor (Figure 1) with a diameter of 11 mm and bed length of 33 mm, equipped with an open-cell aluminium foam with a pore density of 40 PPI. The experiments were conducted at varying operating conditions, with temperatures between 90 and 120 °C and arabinose-galactose molar ratios of 1:1 and 1:2. The experimental methods are explained in detail in a previous study by Najarnezhadmashhadi *et al.* (2020).

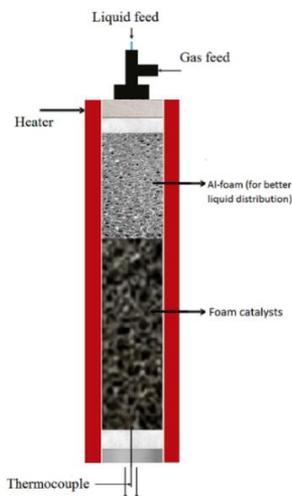

Figure 1 – Continuous tubular reactor system: trickle bed with cylindrical solid foam packing.

2. Model development

Modelling of trickle bed reactors is a very challenging and complex problem. In addition to the description of the flow pattern and the intrinsic reaction kinetics, mass and heat transfer effects must be accounted for accurately calculate the concentrations and temperatures inside the reactor tube. Heat and mass transfer resistances can appear at the gas-liquid and liquid-solid interfaces, as well as inside the pores of the catalyst layer. These resistances are more pronounced for lower fluid velocities (lower Reynolds, Sherwood, and Nusselt numbers) of the fluids inside the reactor. This is the case for many organic reactions applied in the production of fine and speciality chemicals and

ingredients in dietary products, where reactions are slow and long residence times are necessary to obtain high reactant conversions. On the other hand, internal mass and heat transfer resistances can be significant too, depending on the ratio between the reaction and diffusion rates, and, particularly, the thickness of the catalyst layer. Typically, internal mass and heat transfer resistances in the catalyst pores are negligible in structured reactors with thin catalyst layers such as 50 μm or less. However, these resistances might become prominent for rapid reactions and slow diffusion rates.

It was assumed that the reactions proceeded in the porous catalyst layer exclusively. Hence, the reactants diffuse first into the solid catalyst, after which they react on the active centre on the surface of the solid catalyst. Figure 2 illustrates the scheme of the system considered in the present work.

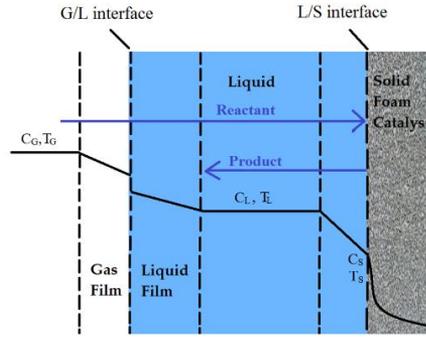

Figure 2 – Interaction of kinetic, mass and heat transfer effects in the three-phase system: gas, liquid, and solid foam catalyst. Adapted from Najarneshadimashhadi (2021).

2.1. Advanced model for continuous trickle bed reactors with open-cell foam packings

The model for the tubular reactor enables the calculation of the axial and radial concentration and temperatures profiles in the gas and liquid phases, as well as within the catalyst active layer by solving the dynamic mass and energy balances simultaneously for the gas, liquid, and solid phases. The model considers intrinsic kinetics, gas-liquid mass and heat transfer, internal diffusion inside the catalyst pores, heat conduction within the reactor and inside the catalyst pores, and the flow description by axial and radial dispersion. These essential features are combined with up-to-date correlations for liquid hold-up, mass transfer coefficients, axial and radial dispersion coefficients and pressure drop. The energy balances for the tubular trickle bed reactor are presented in equations (1)-(3). Because the catalyst layers are very thin ($< 10 \mu\text{m}$), and the reactor and particle coordinates are quite different in the model, a dimensionless coordinate, $x = r_p/R_c$, is used in the mass and heat balances of the solid phase, where R_c is the catalyst layer thickness, and r_p is the distance from the catalyst centre to its surface. The mass balance equations and the correlations implemented in the reactor model are described in detail by Najarneshadimashhadi (2021).

Gas phase

$$\begin{aligned} \frac{dT_G(t, z, r)}{dt} = & - \frac{h_{G,L} a (T_G(t, z, r) - T_L(t, z, r))}{\varepsilon_G \rho_G(z, r) C_{p,G}} - \frac{\partial(u_G(z, r) T_G(t, z, r))}{\partial z} + \left(\frac{\lambda_{z,G}}{\varepsilon_G \rho_G(z, r) C_{p,G}} + D_{z,G} \right) \frac{\partial^2 T_G(t, z, r)}{\partial z^2} \\ & + \left(\frac{\lambda_{r,G}}{\varepsilon_G \rho_G(z, r) C_{p,G}} + D_{r,G} \right) \frac{1}{r} \frac{\partial T_G(t, z, r)}{\partial r} + \left(\frac{\lambda_{r,G}}{\varepsilon_G \rho_G(z, r) C_{p,G}} + D_{r,G} \right) \frac{\partial^2 T_G(t, z, r)}{\partial r^2} \end{aligned} \quad (1)$$

Liquid phase

$$\begin{aligned} \frac{dT_L(t, z, r)}{dt} = & + \frac{h_{G,L} a (T_G(t, z, r) - T_L(t, z, r))}{\varepsilon_L \rho_L C_{p,L}} - \frac{u_L \partial T_L(t, z, r)}{\partial z} + \left(\frac{\lambda_{z,L}}{\varepsilon_L \rho_L C_{p,L}} + D_{z,L} \right) \frac{\partial^2 T_L(t, z, r)}{\partial z^2} \\ & + \left(\frac{\lambda_{r,L}}{\varepsilon_L \rho_L C_{p,L}} + D_{r,L} \right) \frac{1}{r} \frac{\partial T_L(t, z, r)}{\partial r} + \left(\frac{\lambda_{r,L}}{\varepsilon_L \rho_L C_{p,L}} + D_{r,L} \right) \frac{\partial^2 T_L(t, z, r)}{\partial r^2} - \frac{\lambda_p}{\varepsilon_L \rho_L C_{p,L} R_c^2} \left(\frac{\partial T_L(t, z, r, x)}{\partial x} \right) \Big|_{x=1} \end{aligned} \quad (2)$$

Solid catalyst phase

$$\frac{dT_S(t, z, r, x)}{dt} = \frac{\lambda_p}{\varepsilon_p \rho_p C_{p,p} R_c^2} \left(\frac{\partial^2 T_S(t, z, r, x)}{\partial x^2} + \frac{s}{x} \frac{\partial T_S(t, z, r, x)}{\partial x} \right) + \frac{1}{C_{p,p}} \sum r_j(t, z, r, x) (-\Delta H_r) \quad (3)$$

The boundary conditions for the energy balances are presented below. The closed-closed boundary conditions of Danckwerts were applied at the reactor inlet and outlet in gas and liquid phases. In the solid phase, the energy balance is coupled to the bulk liquid balance through the boundary condition, which states that the heat flux through the liquid film is equal to the heat flux in/out to/from the catalyst particle.

	Entrance	Outlet	Center	Wall
Gas phase	$T_G^in = T_G(t, r) \Big _{z=0} - \frac{D_{z,G}}{u_G(z, r)} \frac{\partial T_G(t, r)}{\partial z} \Big _{z=0}$	$\frac{\partial T_G(t, r)}{\partial z} \Big _{z=L} = 0$	$\frac{\partial T_G(t, z)}{\partial r} \Big _{r=0} = 0$	$\frac{\partial T_G(t, z)}{\partial r} \Big _{r=R} = 0$
Liquid phase	$T_L^in = T_L(t, r) \Big _{z=0} - \frac{D_{z,L}}{u_L} \frac{\partial T_L(t, r)}{\partial z} \Big _{z=0}$	$\frac{\partial T_L(t, r)}{\partial z} \Big _{z=L} = 0$	$\frac{\partial T_L(t, z)}{\partial r} \Big _{r=0} = 0$	$-\lambda_L \frac{\partial T_L(t, z)}{\partial r} \Big _{r=R} = h_w (T_L(t, z) \Big _{r=R} - T_w)$
	$T_S^in = T_S(t, r, x) \Big _{x=0}$	$\frac{\partial T_S(t, r, x)}{\partial z} \Big _{z=L} = 0$	$\frac{\partial T_S(t, z, x)}{\partial r} \Big _{r=0} = 0$	$-\lambda_S \frac{\partial T_S(t, z, x)}{\partial r} \Big _{r=R} = h_w (T_S(t, z, x) \Big _{r=R} - T_w)$
Solid phase	Particle center		Particle surface

3. Modelling results and discussion

The dynamic model for trickle bed reactors equipped with cylindrical solid foam packings was applied to describe the catalytic hydrogenation of arabinose and galactose mixtures as a representative case study. The kinetic parameters of the highly selective arabinose (A) and galactose (G) hydrogenation to arabitol and galactitol are presented in Table 1. The activation energies and pre-exponential factors for the process were estimated with a 95 % confidence interval below 10 % error, indicating a good accuracy of the estimated parameters.

Table 1 – Parameter estimation results.

Parameters	Estimated Value	95 % Confidence interval
<i>Ea_A</i>	5.32×10^4	0.36×10^4
<i>Ea_G</i>	5.48×10^4	0.37×10^4
<i>k_{ref,A}</i>	5.24×10^{-7}	0.31×10^{-7}
<i>k_{ref,G}</i>	5.31×10^{-7}	0.30×10^{-7}

Figure 3 compares the experimental and calculated conversion values, of both arabinose and galactose, as a function of the reaction temperature. The model is able to predict the sugar conversions successfully, the average relative deviations being maximally about 16 %. The experimentally recorded sugar conversions displayed in the figures are averages from multiple samples. The selectivity toward sugar alcohols was always very high, typically exceeding 95%.

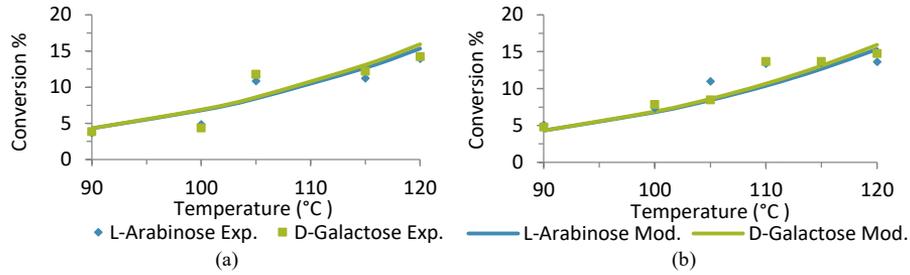

Figure 3 – Experimental and model values for the conversion of sugar mixtures as a function of the temperature. Inlet molar ratio (a) 1:1, (b) 1:2.

Figure 4 (a) and (b) present the arabinose concentration and the liquid-phase temperature axial and radial profiles for different reactor lengths. The conversion increases in line with the reactor length. The radial profiles in the conversion of arabinose were not observable because local conversions are very small. The temperature inside the reactor tube does not vary significantly because the reactor radius is very small. Higher temperature profiles are observed for higher reactor radiuses, Figure 4 (c).

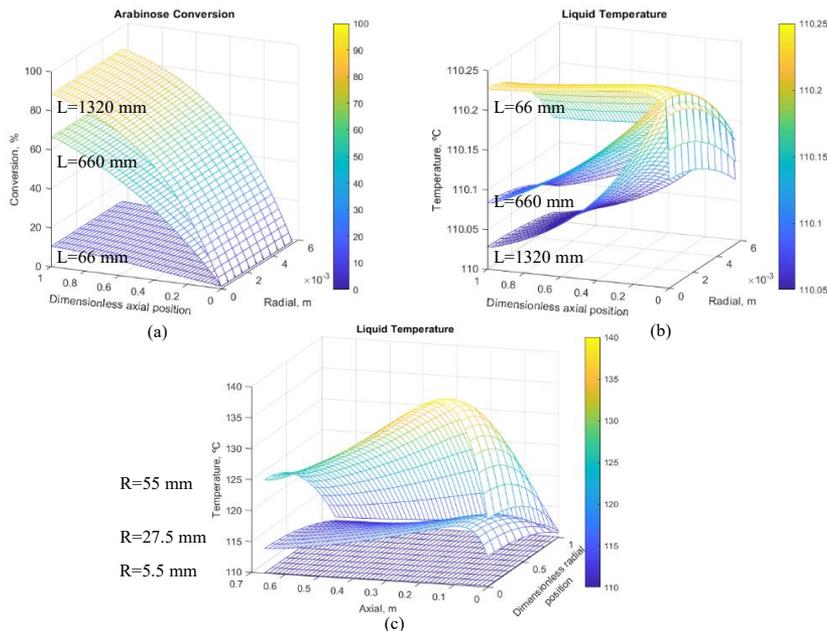

Figure 4 – Arabinose conversion (a) and liquid temperature (b) as a function of the reactor length, and liquid temperature as a function of the reactor radius for L=1320 mm (c).

The capabilities of the model proposed were tested through a sensitivity analysis on the effect of the catalyst layer thickness on the concentrations (galactose) and temperature profiles inside the catalyst pores, for $k_{ref,i} = 25 \times k_{ref,i}^{estimated}$. Analysing Figure 5, it is possible to conclude that, as the washcoat thickness increases, so do the concentration gradients and temperature in the catalyst layer. These results also demonstrate the flexibility of the generalised model, which can simulate both ideal cases, where there are no internal transfer limitations, and systems dominated by high intraparticle transport

limitations. These properties demonstrate that this model is suitable for use in other chemical systems.

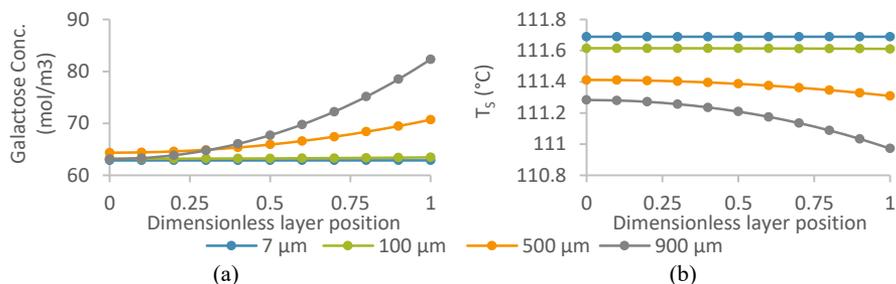

Figure 5 – (a) Galactose and (b) temperature profiles in the washcoat in the middle of the reactor ($z = 0.033\text{m}$), for $k_{ref,i} = 25 \times k_{ref,i}^{estimated}$

4. Conclusions

A comprehensive dynamic model for three-phase catalytic tubular reactors with solid foam packings considering all the main chemical and transport effects occurring in the system was developed and implemented successfully in the very modern software. The kinetic parameters of the model were estimated with good accuracy by non-linear regression analysis. The sensitivity analysis demonstrated that the model could predict the effect of different reactor dimensions, as well as the kinetic and transport phenomena included in the advanced multiphase reactor model. It is possible to conclude that this modelling approach can be applied to industrially sized reactors and various reactive multiphase catalytic systems, which are of fundamental and industrial interest.

Abstract

In this work, we present a scenario-based stochastic optimisation (SBSO) model to schedule a wind farm with battery storage (BS) and a hydrogen electrolyser (HE) considering curtailment and uncertainties in generation and market prices. We compare cases with BS only, HE only, and a combination of the two. We apply Markov Chain (MC) and Gaussian Process (GP) techniques to generate wind curtailment and electricity price scenarios, respectively, capturing their inherent uncertainties. The model then assesses the economic benefits of incorporating BS and/or HE alongside wind generation and their scheduling as a function of curtailed and non-curtailed wind. The results can be used to determine the suitability of such systems for the purposes of maximising profits and making optimal use of curtailed generation. Results show that HE increases mean income and curtailed wind utilisation significantly more than BS. However, by combining the two, wind curtailment can be reduced by 95%.

Keywords: Wind farm, Battery storage, Hydrogen electrolysis, Curtailment, Stochastic optimisation

1. Introduction

Energy storage technologies (EST) can facilitate the decarbonisation of energy systems and lead to more sustainable futures. Battery storage (BS) has been found to improve power quality in electrical grids (Das et al., 2018) – particularly with high renewable energy penetration – and hydrogen storage (HS) can also replace fossil fuels in heating, industry and shipping (Gielen et al., 2019). Operating these technologies alongside renewables allows for the adoption of variable electricity sources (IRENA, 2019) and a means to use otherwise curtailed generation. However, in order to do so optimally, the scheduling of these ESTs must further take into account uncertainties relating to renewable generation, curtailment and market prices due to their unpredictable nature.

There are a number of recent studies optimising the scheduling of renewable energy - energy storage systems under uncertainties, specifically wind-hydrogen systems. Xiao et al. (2020) consider uncertainties in wind generation and electricity price and present a scenario-based stochastic optimisation (SBSO) model which evaluates financial risk. They find that a hydrogen electrolyser (HE) can increase the value of a wind system, the extent of which depends on hydrogen price. Yu et al. (2019) and Mirzaei et al. (2019) present SBSO models which minimise operation costs of a system with wind generation and HS, the latter study also considers demand response (DR). Both of these papers consider uncertainties in wind generation, whilst Yu et al. (2019) also considers uncertainties in demand. The efficacy of these models at reducing the risk of uncertainties

is demonstrated. Finally, Cao et al. (2020) present a SBSO model to minimise operation costs of an intelligent parking lot with HS and renewable generation. They present a Pareto set of solutions for different levels of risk aversion. These studies highlight the value of SBSO models for scheduling wind-hydrogen systems under uncertainties. However, they do not consider curtailed wind, which is an important issue as renewable penetration increases, nor do they consider other forms of energy storage, such as BS.

Several studies address using curtailed wind for an HE. For example, Yan et al. (2018) explore different approaches for handling curtailed wind. They find that investing in an HE is both a profitable and environmentally friendly approach. However, they do not consider uncertainties in wind power or electricity price. Shams et al. (2021) present a machine learning model to predict curtailed power which is used for an HE and BS. However, they optimise from a system operator point of view rather than that of an investor. On the other hand, Jiang et al. (2019) present a chance-constrained model that optimises the size of a wind-hydrogen system from an investor's perspective. Their methodology allows flexibility for the decision variables to not satisfy the constraints at a given probability level; thus adverse conditions can be accounted for. However, they do not model different curtailment or electricity price scenarios nor do they incorporate BS.

In this work we consider an investor's point of view, and present an SBSO which schedules a wind farm with HE and BS. We optimise their usage to maximise income, considering curtailment and uncertainties in wind generation, curtailment and electricity price. We compare case studies with HE and BS, HE only, BS only and no storage (NS). From this we determine the optimal choice for a wind farm owner to maximise income and utilise the maximum amount of curtailed wind.

2. Model Description

Wind curtailment occurs when generation exceeds demand, and generators are instructed to reduce, or sometimes halt, power export. At time t , in scenario, i , total wind generation can be divided into two categories: curtailed wind, $w_{t,i}^c$, which cannot be exported, and non-curtailed wind, $w_{t,i}^n$, which is available to export. The electrolyser can be powered using curtailed, $e_{t,i}^c$, or non-curtailed wind, $e_{t,i}^n$. Likewise the battery can be charged using curtailed, $c_{t,i}^c$, or non-curtailed wind $c_{t,i}^n$. The discharged power from the battery can be exported to the grid $d_{t,i}^n$ or curtailed $d_{t,i}^c$. It is assumed that at times when wind generation is not curtailed, $w_{t,i}^c = 0$, discharged battery is also not curtailed, $d_{t,i}^c = 0$. However where there is wind curtailment, it is assumed that discharged power cannot be exported to the grid, $d_{t,i}^n = 0$, and is also curtailed.

The objective function is given in Equation 1 and maximises revenue due to selling non-curtailed power in the day-ahead market (first term), selling hydrogen (second term) and minimises losses due to using curtailed wind (third term). The day-ahead price at time, t , and scenario, i , is $p_{t,i}^{da}$, p^h is hydrogen price and η^e is electrolyser hydrogen conversion efficiency. The cost of using curtailed wind, p^c , is neglected in most models, which assume that curtailed wind is free. This assumption is overly simplistic and not realistic, hence we consider p^c here.

$$\max \sum_{t,i=0}^{T,I} (w_{t,i}^n + d_{t,i}^n - c_{t,i}^n - e_{t,i}^n) p_{t,i}^{da} + (e_{t,i}^n + e_{t,i}^c) \frac{p^h}{\eta^e} - (e_{t,i}^c + c_{t,i}^c) p^c \quad (1)$$

The constraints are given in Equations 2-10. Equation 2 sets the lower limits on the battery charging and discharging powers and the power going to the electrolyser, where \underline{e} represents the minimum power required for hydrogen production. Equations 3 and 4 set the upper limits; the upper bound on $d_{t,i}^n$ is set such that discharged power can only be exported when there is no wind curtailed. Equation 5 prevents the sum of curtailed and non-curtailed powers exceeding the maximum limits.

$$c_{t,i}^n, c_{t,i}^c, d_{t,i}^n, d_{t,i}^c \geq 0, \quad e_{t,i}^n, e_{t,i}^c \geq \underline{e} \quad \forall t, i \quad (2)$$

$$c_{t,i}^n, c_{t,i}^c \leq \bar{c}, \quad d_{t,i}^c \leq \bar{d}, \quad e_{t,i}^n, e_{t,i}^c \leq \bar{e} \quad \forall t, i \quad (3)$$

$$\text{if } w_{t,i}^c = 0: d_{t,i}^n \leq \bar{d}, \quad \text{else: } d_{t,i}^n \leq 0 \quad \forall t, i \quad (4)$$

$$c_{t,i}^n + c_{t,i}^c \leq \bar{c}, \quad d_{t,i}^n + d_{t,i}^c \leq \bar{d}, \quad e_{t,i}^n + e_{t,i}^c \leq \bar{e} \quad \forall t, i \quad (5)$$

Equations 6 and 7 set limits on the battery's capacity, $x_{t,i}$, and ensure that it is equal to the capacity at the previous time period plus any charging/discharging in the current time period, respectively. The charging and discharging efficiencies are η^c and η^d , respectively, and are equal to 90%.

$$\underline{x} \leq x_{t,i} \leq \bar{x} \quad \forall t, i \quad (6)$$

$$x_{t,i} = x_{t-1,i} + (c_{t,i}^n + c_{t,i}^c)\eta^c - \frac{d_{t,i}^n + d_{t,i}^c}{\eta^d} \quad \forall t, i \quad (7)$$

Equation 8 prevents the battery from being simultaneously charged and discharged. In Equation 9 the curtailed generation and discharge is greater than or equal to the curtailed power used for charging and powering the electrolyser. Equation 10 ensures that when there is no wind curtailed there is also no curtailment of discharged battery. M is a very large positive co-efficient which allows curtailed discharge to take on any value, satisfying previous constraints, when there is non-zero curtailed wind.

$$(c_{t,i}^n + c_{t,i}^c)(d_{t,i}^n + d_{t,i}^c) = 0 \quad \forall t, i \quad (8)$$

$$w_{t,i}^c + d_{t,i}^c \geq c_{t,i}^c + e_{t,i}^c \quad \forall t, i \quad (9)$$

$$Mw_{t,i}^c - d_{t,i}^c \geq 0 \quad \forall t, i \quad (10)$$

3. Scenario Generation

A range of scenarios are generated to represent possible outcomes of the uncertain parameters, in this case wind generation, curtailment and electricity price. Three wind power profiles are randomly generated from Drax Power Ltd (2021), by adding noise from a Gaussian centred around each data point with a mean equal to that point and a standard deviation $0.25 * \text{data point}$. This wind data is scaled such that the farm has a maximum output of 20 MW. Five curtailment profiles are then generated using a MC with probabilities of moving between states 'curtailed' and 'not-curtailed' determined using historic data, and initial state 'not-curtailed'. When the state is 'curtailed', the percentage of wind power curtailed is determined by randomly selecting from historic data. The 'not-curtailed' wind profile is the difference between this and the original wind profile. Three price profiles are created using Gaussian Process (GP) techniques as described in Yeardley et al. (2021); the first profile is an ordinary GP, and the other two are created using a novel hybridisation method which combines Gaussian Processes with K-means clustering and hierarchical cluster.

A summary of the scenario generation procedure is shown in Figure 1. Each of these scenarios is input into our SBSO model which optimises the scheduling our of energy storage for cases with HE and BS, HE only, BS only, and no storage (NS). The input parameters for the storage for each of these cases is shown in Table 1. Finally, it is assumed that hydrogen can be sold at a price of £3.50/kg and the cost of curtailed wind is £0.01/kWh.

Table 1: Input storage parameters for each case considered.

	\underline{e} (MW)	\bar{e} (MW)	\bar{c}, \bar{d} (MW)	\underline{x} (MWh)	\bar{x} (MWh)
HE + BS	0.04	2	2	1.6	8
HE	0.04	2	0	0	0
BS	0	0	2	1.6	8
NS	0	0	0	0	0

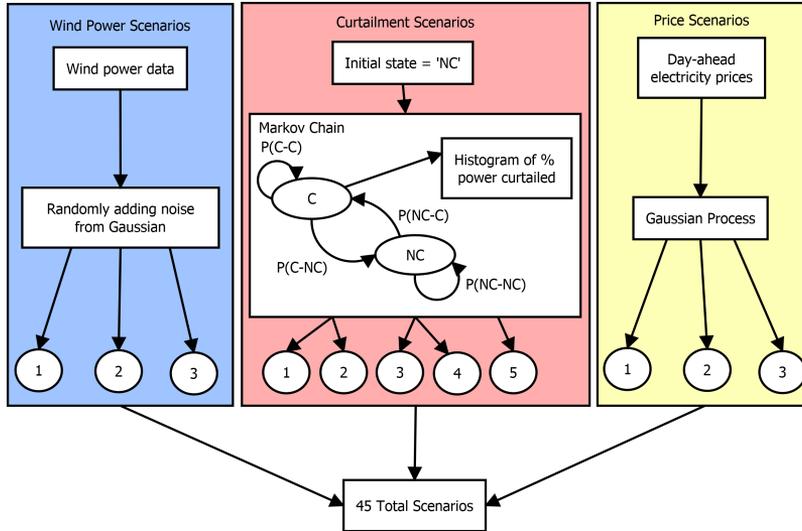

Figure 1: Scenario generation diagram

4. Results and Discussion

In Table 2 the mean income and percent of curtailed wind utilisation, across all scenarios, are shown for the different case studies, along with their standard deviations. It can be seen that the inclusion of storage increases both the mean expected income and curtailed wind utilisation. In particular, the HE is able to increase the values of these more than the BS. However, the combination of both is the most effective of the case studies presented here. Additionally, the inclusion of storage reduces the standard deviation of mean expected income. This is since storage adds flexibility; for instance, when wind generation is low and curtailment is high, additional revenue can still be achieved due to selling hydrogen and discharged power from the BS.

Figure 2 shows the optimised daily power profiles for each case study for Scenario 6. This scenario was chosen because there is a large amount of wind curtailment, occurring between 4:00 and 14:00 (8 and 28 in Figure 2), and shows how the scheduling of the storage responds to this. Wind generation is indicated by the red lines; wind power that is directly imported or curtailed is shown by a solid area, power used for the HE: a dashed area, and power used for or discharged by the BS: a dotted area. Non-curtailed wind may be exported, along with non-curtailed discharge from the BS (indicated by a dark blue area); alternatively, it may be consumed by the storage (green area). Curtailed wind (and BS discharge) is used to power the HE and/or BS (although the BS cannot simultaneously charge and discharge) and is indicated by a white area.

In the case of NS, we can see that all curtailed wind is wasted. By adding BS, we are able to use some of the curtailed wind, however, once the BS is fully charged we cannot use it anymore. The

Table 2: Mean and standard deviation of daily income and percentage of curtailed wind utilised across all scenarios for each case study.

	Mean income (£)	Standard deviation (£)	Curtailed wind usage (%)	Standard deviation (%)
HE + BS	4989	222	0.949	0.029
HE	4870	300	0.679	0.034
BS	4311	629	0.165	0.037
NS	4208	689	0.0	0.0

BS also allows a greater amount of power to be exported in the evening when electricity prices are typically higher (34 - 38 in Figure 2). By adding HE we are able to use a greater proportion of the curtailed wind. Furthermore, under the conditions specified here, it is economical to self-consume and import power for the HE. By combining BS and HE we are able to utilise the most curtailed wind and maximise power used for the HE; at 10:30 and 12:00 (21 and 24 in Figure 2), there are two peaks above the red line which indicate curtailed BS discharge powering the HE. As shown in Table 2 this case generates the highest mean income across the different scenarios. Hence we conclude that of the cases explored here, a combination of BS and HE is optimal for both maximising income and utilising the maximum curtailed wind.

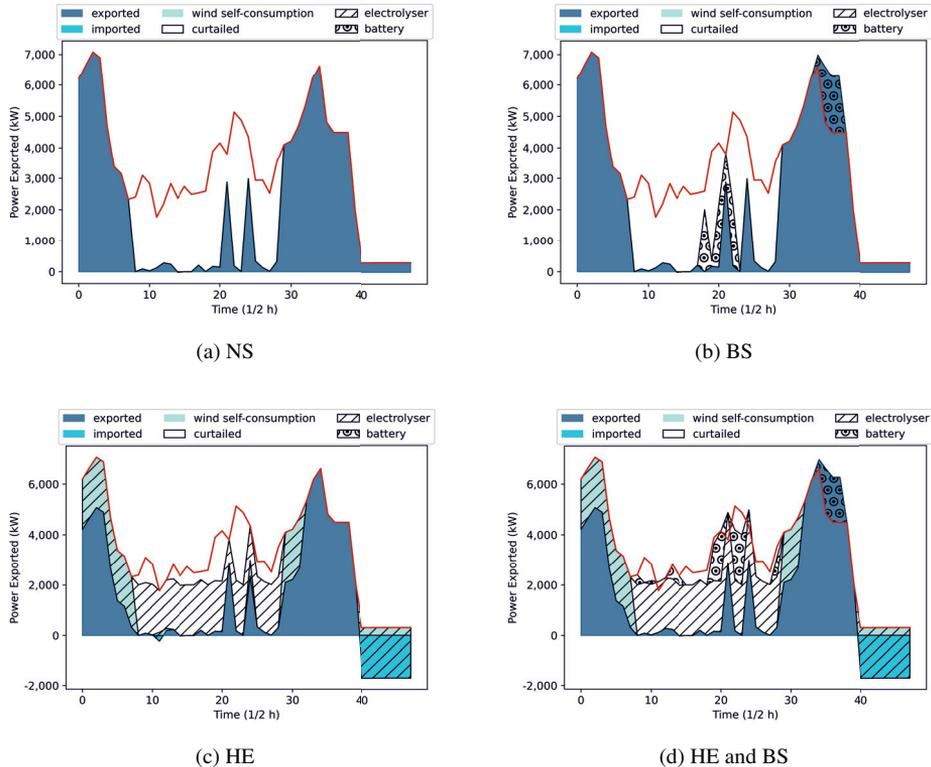

Figure 2: Daily power profile for Scenario 6, for each case study. Red line indicates total wind generation.

5. Conclusion

A scenario-based stochastic optimisation (SBSO) model is presented to schedule a wind farm with battery storage (BS) and a hydrogen electrolyser (HE) under uncertain conditions and considering curtailment. We generate wind curtailment and electricity price scenarios using Markov Chain (MC) and Gaussian Process (GP) techniques, respectively, to model a range of possible outcomes. We compare daily mean predicted income and utilisation of curtailed wind with BS only, HE only, both BS and HE, and no storage (NS).

We find that HE increases mean income and curtailed wind utilisation significantly more than BS. However, by combining HE and BS curtailed wind utilisation increases from 68% to 95%, compared with HE alone. At times when curtailed wind is greater than the HE maximum power, it can also be used to charge the BS; then at times when curtailed wind is lower than this maximum power, it can be additionally powered by discharging the BS. Future work will consider capital and operational costs of these technologies, as well as varying their sizes, ratios and hydrogen price.

Abstract

The aviation industry supports the world economy, contributing US\$ 2.7 trillion to global the gross domestic product. However, aviation raises environmental concerns, where the industry has a 12% share of CO₂ emissions within the transportation sector. Therefore, the International Civil Aviation Organization (ICAO) suggested the implementation of Carbon Offsetting Scheme for International Aviation (CORSIA) as a market-based measure to mitigate CO₂. The CORSIA scheme may increase the operational costs by setting a carbon price on every extra tonne of CO₂ beyond the baseline limits. In order to reduce operators' obligations, the integration of reduction measures such as Sustainable Aviation Fuels (SAF) may reduce the cost associated with offsetting requirements. As such, a multi-objective optimization model is presented in this study to identify optimal blending ratios of jet biofuels with conventional kerosene fuel for multiple aircrafts and destinations. The model considers the operators fuel cost, carbon price and renewable credit under CORSIA; aiming to minimize the total fuels' associated costs. In addition, the model is implemented in a case study considering three fuel categories. The results indicate that Jatropa-based jet fuel, within the current tested data, is a preferable synthetic fuel to be blended with Jet-A at a maximum margin of 50%. Fuel prices highly influenced the results of the model. Whereas other factors including carbon prices, fuels' lifecycle emissions, and supplied fuel quantity may directly or indirectly impact the process of incorporating SAF as an integrated mitigation tool under CORSIA.

Keywords: CORSIA, Carbon Policy, Aviation, Sustainability, Mitigation.

1. Introduction

The airline industry has not only influenced global mobility, it has also contributed US\$3.5 trillion to the global gross domestic product (GDP). In 2019, the aviation sector created over 87.7 million jobs and facilitated 4.5 billion boarding passengers on the world's airlines. During the pandemic, the economic contribution from the aviation sector reduced to US\$1.7 trillion, eliminating 46 million jobs supporting the industry (ATAG, 2020). As a mode of transportation, the aviation sector contributes 12% of the total CO₂ emissions produced from transportation (IEA, 2019). It is reported that in the next 15 years, the demand for transportation will double (Airbus, 2019), thus increasing CO₂ emissions from the sector. As a consequence, the IATA suggested four CO₂ mitigation techniques: market-based measures (MBM), alternative fuels, technological enhancement, and operational modifications. The International Civil Aviation Organization ICAO proposed the "Carbon Offsetting Scheme for International Aviation

(CORSIA)" as an applicable methodology of global MBM techniques to support aviation environmental goals.

1.1. CORSIA

During the 39th assembly, the ICAO announced CORSIA as a global offsetting scheme for international flights, with an applicable methodology of a combinatorial approach, beginning with a 100% sectorial approach and moving to a 100% individual approach (IATA, 2019). Fuels classified as CORSIA's Eligible Fuel (CEF) should have the capability of achieving a minimum 10% emission reduction compared to Jet-A, determined by life cycle assessment (LCA) of the fuel. The integrability of SAF, technological improvement, and operational enhancement within a CORSIA framework can help minimize the cost of carbon, support IATA's goal of reducing carbon emissions, and invest in research or through the implementation of SAF (Staples et al., 2018). The acceleration on developing drop-in fuels seems the most suitable substitute for Jet-A, in which its implementation may require minimum or no design modification of the engine or fuel system. These fuels can be synthesized from biomass for example, through production pathways of Fischer-Tropsch (FT), Hydroprocessed Ester Fatty Acid (HEFA), Hydrothermal Liquefaction (HTL), Alcohol to Jet (ATJ), and Direct Sugars to Hydrocarbons (DSHC) or commonly known as Synthesized Iso-paraffins (SIP) (Stratton et al., 2010).

1.2. CORSIA Associated Models

Optimization techniques can predict the influence of SAF in minimizing carbon emissions and support managerial decisions. Jiang & Yang (2021) discussed the correlation between SAF and SAF's policies from an operational decisions perspective, comparing carbon tax and SAF quota. Sharma et al. (2021) investigated CORSIA by examining technologically innovative factors and the related emissions through regression techniques. Sharma et al. (2021) developed a minimization model of aviation emissions using Vensim. Chao et al. (2019) modified the Fleet-level Environmental Evaluation Tool (FLEET) and created multiple emissions scenarios. The modified model was integrated with the SAF lifecycle assessment to evaluate SAF development economically and environmentally. Whereas, this study presents a multi-objective optimization model to select optimal blending ratios based on carbon price, fuel price and lifecycle emissions. The model is applicable to multiple data entries considering different types of aircrafts and multiple destinations through the incorporation of key parameters, such as, aircraft fuel consumption rate, number of passengers and distance travelled.

2. Methodology

2.1. Mathematical optimization model

A mathematical model was developed to select and set the blending ratios of viable SAF's and Jet-A under CORSIA as presented in Table 1. The model was solved using CPLEX OPL considering two assumptions. The model assumed that the Trips Number ($TN_{k,j}$) is a ready-prepared aircraft schedule and that the blending ratio does not vary for different trips on the same route. The model aimed to minimize the cost of investing and operating fleets using certain SAF and the cost of emissions under CORSIA framework. It also considers the reward provided to operators utilizing SAF.

Table 1: Mathematical formulation of blend ratio selection of biofuel and Jet-A.

Sets, Decisions Variables, and Parameters	
Sets	Parameters
k: is the aircraft type	Pr: Price of fuel f (\$/MJ.)

j: is the routes f: is the fuel	CPrice: Price of carbon (\$/kgCO ₂) Ef_f: Amount of CO ₂ produced per MJ of fuel f. LCA_f: Lifecycle Analysis value of fuel f.
Decision Variable BR_{f,k,j}: Blending ratio of fuel f on aircraft k and route j.	TN_{k,j}: Number of trips of aircraft type k on route j. Pax_{k,j}: Number of passengers using aircraft type k on route j. CR_k: Consumption rate using aircraft k (M.J./Pax.km). LHV_f: Lower Heating Value of fuel f (M.J./liter) Supply_f: The amount of supplied fuel f (liter) FCF: Fuel Conversion Factor (0.0718 kgCO ₂ /MJ for Jet-A). GF: Growth factor of carbon (20%). NFC: Net cost of jet fuel. CTax: Carbon taxing cost. RCredit: Reduction credit, representing a reclaimed value of reduced emissions from the offsetting requirements.
Objective Function	
Min NFC + CTax – RCredit	
Where:	
NFC = $\sum_f \sum_k \sum_j FuelConsumption_{f,k,j} * P_f$	
CTax = $CPrice * GF * \sum_f \sum_k \sum_j OperatorsEmissions_{f,k,j}$	
RCredit = $CPrice * FCF * \sum_f \sum_k \sum_j FuelConsumption_{f,k,j} * (1 - \frac{LCA_f}{89})$	
OperatorsEmissions = $\sum_f \sum_k \sum_j FuelConsumption_{f,k,j} * Ef_f$	
FuelConsumption = $\sum_f \sum_k \sum_j Pax_{k,j} * TN_{k,j} * CR_k * D_j * BR_{f,k,j}$	
Constraints	
$\sum_f BR_{f,k,j} = \begin{cases} 1 & TN_{k,j} \neq 0 \\ 0 & TN_{k,j} = 0 \end{cases} \quad \forall k, j$	The blending ratio of fuels f utilized by assigned aircraft k on route j should add up to 100%.
$BR_{f=1,k,j} \geq 0.5 \quad TN_{k,j} \neq 0, \quad \forall k, j$	A minimum blending ratio of 50% should be allocated to Jet-A utilized by aircraft k on route j.
$\sum_k \sum_j Pax_{k,j} TN_{k,j} CR_{k,j} BR_{f,k,j} / LHV_f \leq Supply_f \quad \forall f$	For each fuel, the total amount of the consumption by all aircraft k and all route j should not exceed
$\sum_{f=2}^F \sum_k \sum_j FuelConsumption_{f,k,j} * FCF * (1 - \frac{LCA_f}{89}) \geq 0.1 \sum_{f=1}^F \sum_k \sum_j FuelConsumption_{f,k,j} * Ef_f$	The total SAF fuels utilized by all aircraft k associated with route j should pertain to a minimum of 10% emissions reduction from the total fuel consumption.

2.2. Case study

Aside from the conventional Jet-A, data of two biofuels including jatropha and algae-based fuels, were obtained to test and validate the developed model. Previous literature referenced a well-to-wheel (WTW) approach to account for GHG emissions of jatropha and algae fuels as studied by Alherbawi et al. (2021a) and Fortier et al. (2014), respectively. CORSIA specifies that these values shall be compared to the lifecycle emissions of 89 gCO₂/MJ of conventional jet fuel, as referenced by the ICAO (IATA, 2019). Jatropha lifecycle emissions values were collected from Alherbawi et al. (2021a). Whereas Fortier et al. (2014) performed an LCA using a WTW approach to study algae-based jet fuel's environmental performance. The study analyzed two pathways: the Hydrothermal Liquefaction (HTL) and the wastewater treatment plant (WWTP) HTL. The study also compared the results to previous LCA values of bio-jet fuels. Table 2 shows the average emissions for the two selected fuels. Fuel prices were collected to evaluate the additional costs associated to clean fuels for airlines operators.

Algae and jatropha jet fuel prices were obtained based on the minimum selling price of jet biofuels (Alherbawi et al., 2021b). The fuel prices were presented in USD per energy equivalent units of (MJ) based on the lower heating value (LHV) and density characteristics for each biofuel (Azami & Savill, 2017), and for jet-A as specified by Chevron Products Company (2007). In 2019, biojet production was estimated with 140 million liters per year, the production is assumed to be shared between Jatropha and Algae as in Table 2 (Renewable Energy Agency, 2021).

Table 2: Selected fuels' price, quantity, and characteristic.

Fuels	Price (\$/MJ)	Supplies (Million L)	LHV (MJ/L)	LCA emissions (gCO_{2eq}/MJ)
Jatropha	0.026	70.000	39.0	37.95
Algae	0.031	70.000	38.0	61.38
Jet-A	0.015	87.625*	34.7	89.00

* Jet-A supplied fuel amount was assumed.

The associated direct emissions of Jet-A, jatropha, and algae synthesized fuels are defined based on their emissions factors of 3.16, 2.81 (Carels et al., 2012), and 3.7 (kgCO₂/kgfuel) (Ponnusamy et al., 2014), respectively. Implementing CORSIA requires setting a growth factor value by the ICAO to specify the increase in the emissions compared to a baseline of 2020 for each country. The tested scenario assumed a growth factor of 20% and a carbon price tax of 3 \$/kgCO₂.

Table 3: Selected aircraft types and fuel consumption rates.

Type of Aircraft	Consumption Rate (MJ/Pax/km)
Airbus A320-200	0.7814
Airbus A330-200	1.0802
Airbus A380	1.1357

The scenario was developed with three aircraft types as summarized in Table 3 along with their consumption rates. It was assumed that the operators have a ready flight schedule associated with a specific aircraft type and an average number of passengers on board. The number of trips and passengers per aircraft on each route and the associated traveled distance are illustrated in Table 4 and Table 5.

Table 4: Trips number per an aircraft type on a specific route

Type of Aircraft	Trips Number			Passengers		
	Route	Route	Route	Route	Route	Route
	1	2	3	1	2	3
Airbus A320-200	0	0	46	0	0	180
Airbus A330-200	77	0	0	220	0	0
Airbus A380	0	22	0	0	320	0

Table 5: Trips destinations and distances.

Route	Doha-Kuwait	Doha-London	Doha- Miami
Distance (km)	572	5240	12340

3. Results

The results illustrated Figure 1 indicate that the model selected kerosene and jatropha to create an optimal blend. Algae is excluded from the blend in the current scenario, which is possibly due to its higher price as compared to Jet-A and jatropha fuels. The first route was assigned a 100% jet-A to minimize the overall fuel associated costs, while the SAF blend comes is introduced from the second route to satisfy the minimum emission reduction constraints. However, as the distance travelled increases, the subsequent emissions also increase, which require more SAF to be blended to restrict the emissions within the defined margins. As such the third route was associated with a 50:50 Jet-A and jatropha blended fuels. The initial run of the model suggested a cost of approximately 1.5 million U.S.\$. Along with fuel price, the supplied fuel quantity, fuel emission factor, and emissions reduction capability also influenced the optimal blending ratio and the SAF selection. In addition, an increasing carbon tax is expected to further promote the integration of SAF with higher blending ratios. In such case, airlines can shift to SAF with reasonable blending ratios to satisfy the environmental targets without compromising the economic gains.

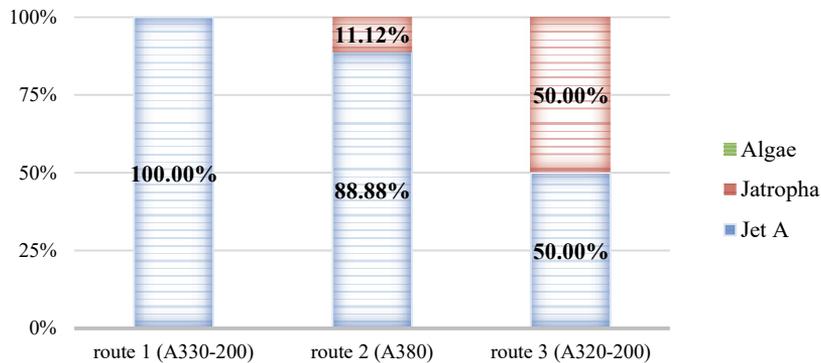

Figure 1: Results of the optimal fuel blending ratios for selected routes.

4. Conclusion

CORSIA promotes the integration of SAF to mitigate the environmental impact of air travel. The policy framework incentivizes operators utilizing SAF by providing a reduction reward function that allows operators to reclaim some of the offsetting carbon emissions. However, a 100% shift can be more challenging due to the high price of SAF as compared to Jet-A, leaving operators required to maintain a higher blending ratio for Jet-A utilization on fleets, as the results reflect a 100%, 88.88 %, and a minimum of 50% Jet-A utilization. It is expected that SAF blending ratios will be further promoted with the expected increase in carbon tax. However, more efforts are required to produce cheaper SAFs and reduced life cycle emissions to reach a full transition to clean fuels.

Abstract

With the increasing amount of data to quickly process, surrogate modeling has become a topic of major interest in process engineering during the last decades. Recently, black-box models have gained renewed interest as effective tools to reduce the computational effort and to enhance the solution of optimization algorithms. Among the surrogate model applications, scheduling and control problems are getting particular attention in the last years. However, when dealing with dynamics, the majority of literature works concern batch processes to be modeled within the corresponding residence time interval. With the purpose to extend the established procedures to continuous operations, in this research work the surrogate modeling procedure of a dynamic non-isothermal CSTR reactor is discussed and analyzed in detail. The modeling phase was carried out for the temperature and concentration with different sampling size and techniques by means of the software ALAMO[®]. After the open-loop model was built and validated, the related closed loop configuration has been tested by means of a conventional PID controller implementation. The controller has been properly tuned on both models in order to compare the performances. The obtained trends show good agreement with those of the rigorous model both for open loop and closed loop performances. More importantly, the implemented surrogate model requires reduced calculation time thanks to the explicit input-output variable correlations. In conclusion, the proposed dynamic surrogate modeling approach for process control applications has proved to be effective and provided reliable results. Moreover, the computational time was reduced by an order of magnitude and the best compromise between the performances and accuracy can be detected.

Keywords: data-driven modeling, design of experiment, process control, ALAMO

1. Introduction

Nowadays, the exponential increase of the available computational performances is leading the entire engineering domain towards a more and more data-driven approach. With respect to phenomenological models, data-driven models sometimes allow a smoother calculation, lower computational effort and better convergence of optimization algorithms. In the process engineering domain, the impact of data processing in the digitalization transition can be detected in particular in the growing interest towards surrogate modeling. Initially conceived to compensate the lack of phenomenological models, surrogate modeling for chemical processes has become a topic of major interest in the Process Systems Engineering and it is studied and exploited to considerably reduce

the computational effort for complex systems modeling as well as for optimization (Bhosekar and Ierapetritou, 2018; McBride and Sundmacher, 2019).

The majority of surrogate modeling related research works addresses steady state models to derive input-output variables correlations without the need to solve all the units of the system. During the last years, the interest towards this approach is nevertheless involving dynamic systems as well (Di Pretoro et al., 2022). When dynamic models are analyzed, the literature studies mainly refers to batch operations to be modeled over the related residence time interval (Shi and You, 2015; Shokry et al., 2020). The purpose of this work is then to extend the surrogate modeling activity to continuous processes and suggest a preliminary approach that could be suitable for this scope. Moreover, once completed the modeling phase, we are interested as well in comparing the rigorous and data-driven model closed-loop performances for a conventional PID feedback control strategy.

The selected case study is a simple non-isothermal CSTR reactor and its thorough description is addressed in the next section as well as the control strategy one. Section 3 refers to the different approaches proposed for the surrogate modeling procedure and the obtained results are then discussed in section 4. Finally, some conclusions of general validity and possible perspectives and developments are commented in the last section.

2. Case study

This section introduces first the selected case study, i.e. a non-isothermal CSTR reactor, along with its model equations and parameter values. The second part of the section is focused instead on the feedback control strategy and on the parameters tuning approach.

2.1. The non-isothermal CSTR reactor

The continuous process selected for the surrogate modeling procedure is a conventional non-isothermal CSTR reactor, with constant inlet and outlet overall flowrates, where a first order reaction occurs according to the kinetic scheme:

$$k = k_0 \cdot \exp\left(-\frac{E_a}{R \cdot T}\right) \quad (2)$$

The set of differential equations required for the phenomenological modeling of the system consists of mass and heat balances as follows:

$$\frac{dC_A}{dt} = \frac{Q}{V} \cdot (C_{A,in} - C_A) - k_0 \cdot \exp\left(-\frac{E_a}{R \cdot T}\right) \cdot C_A \quad (3)$$

$$\frac{dC_B}{dt} = -\frac{Q}{V} \cdot C_B + k_0 \cdot \exp\left(-\frac{E_a}{R \cdot T}\right) \cdot C_A \quad (4)$$

$$\frac{dT}{dt} = \frac{Q}{V} \cdot c_p \cdot (T_{in} - T) - \frac{\Delta H_r}{\rho \cdot c_p} \cdot k_0 \cdot \exp\left(-\frac{E_a}{R \cdot T}\right) \cdot \frac{UA}{\rho \cdot V \cdot c_p} \cdot (T_j - T) \quad (5)$$

All physical properties and system parameters are listed in Table 1.

Process parameter	Value	Unit
Q/V	1	1/s
$C_{A,in}$	0.98	mol/m ³
k_0	$7.2 \cdot 10^{10}$	1/s
E_a/R	8750	K
T_{in}	304.2	K
ΔH_r	$5 \cdot 10^4$	J/mol
$U \cdot A$	$5 \cdot 10^4$	W/K
$\rho \cdot c_p$	239	J/(m ³ ·K)

Table 1 – Process operating conditions and reactor parameters

2.2. Control strategy and tuning

This section introduces the control strategy employed for the aforementioned case study. As already explained, given the constant inlet and outlet flowrates, no level control is accounted for while the reactor temperature is controlled by manipulating the coolant temperature in the jacket. For this purpose, a conventional PID control was used according to the characteristic equation:

$$u(t) = u_s + K_C \cdot \left(e(t) + \frac{1}{\tau_I} \cdot \int_0^t e(\tau) \cdot d\tau + \tau_D \cdot \frac{de(t)}{dt} \right) \quad (6)$$

Where $e(t)$ is the error, K_C is the proportional gain, τ_I and τ_D the integral and derivative time constant respectively. As concerns these controller parameters, both for phenomenological and data-driven models, they were tuned so that they minimize the objective function given by:

$$F_{obj} = w_1 \cdot CA_{max} + w_2 \cdot ISE + w_3 \cdot OS + w_4 \cdot ST \quad (7)$$

where w_i is the relative weight of each term, CA_{max} is the maximum control action, ISE is the Integral Square Error, OS is the OverShoot and ST is the Settling Time.

3. Methodology

The surrogate modeling procedure was carried out based on different approaches better detailed in the following subsections.

In any case, the dataset used for temperature and concentration dynamic trends is the same and it was derived by means of the Latin Hypercube Sampling (LHS) function already implemented in MatLab®. The key difference between this approach for control of continuous processes and those available in the literature is that sampling should be performed over the [time]x[manipulated variable] domain for a time interval long enough to achieve the new steady state conditions.

Figure 1 a and b show respectively the results obtained for reactor temperature and reactant concentration for coolant temperature step perturbation of different magnitude.

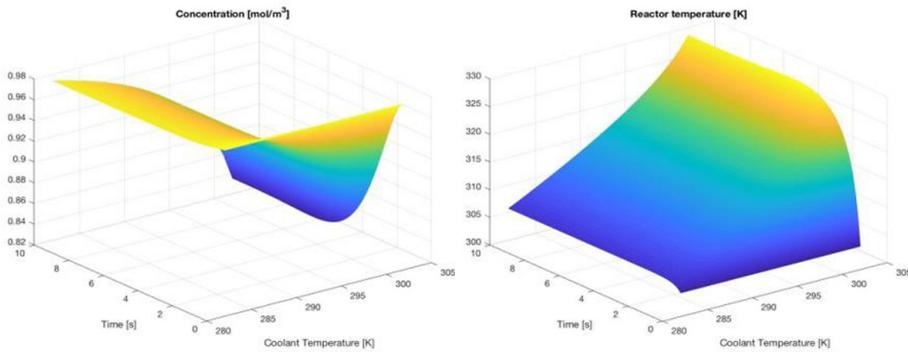

Figure 1 – a) Concentration and b) reactor temperature response vs coolant temperature and time

A time interval equal to 10 seconds was found in order to achieve the new steady state conditions for both variables and every step perturbation size.

3.1. Surrogate modeling with ALAMO[®]

The first two approaches for surrogate modeling exploit the dedicated software ALAMO[®]. This tool performs surrogate modeling based on Response Surface Methodology by using selected interpolating base functions. In this study, mixed polynomial, logarithmic and exponential functions were selected for the regression. Datasets with different size have been imported and the related performances in terms of model accuracy and computational time required to solve the dynamic model over the 10s time interval have been recorded as later discussed in the results section.

The main difference between the two is related to the sample density. In particular, as pointed out in the next section, the model obtained with the conventional LHS sampling shows some discrepancies at the proximity of the domain boundaries and is not able to exactly represent the steady state behaviour. That is why, in the second approach, the sample density was doubled in proximity of the 10 s boundary, so that the steady state points have a higher weight on the objective function minimized by the software.

3.2. First order response regression

The third approach is based on the pre-selection of a polynomial function for the controlled variable whose coefficients are obtained by means of a regression minimizing the relative error with respect to the data sampling. Given the temperature behaviour (cf Figure 1b) a suitable candidate as response surface is a first order response function as:

$$T_r = f(T_j) \cdot (1 - A \cdot e^{-B \cdot t}) + C \quad (7)$$

The advantage of using this expression lies on the fact that, for high values of the time variable, it exhibits a steady state behaviour that is exactly what is experienced by the system under study. This procedure was implemented with a MatLab[®] dedicated script. The results for these three approaches, along with the related advantages and inconveniences are discussed in the next section.

4. Results

4.1. Modeling

This first subsection addresses the performances of the modeling procedure from a computational point of view. Although results are showed for the first approach, the same remarks both from a qualitative and a quantitative perspective are valid for the others.

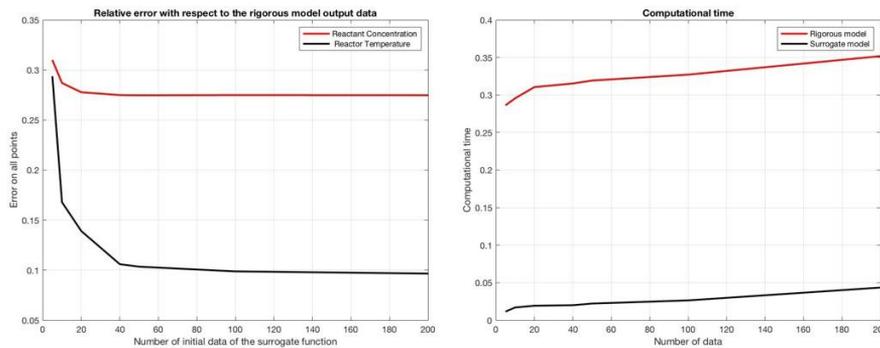

Figure 2 – a) Relative error [%] and b) computational time [s] vs dataset sample size

Figure 2a presents the mean relative error for concentration and temperature while Figure 2b compares the solution of the dynamic model over the 10 s time span for the rigorous and surrogate model respectively. As it can be noticed, for this specific case study, the relative error decreases almost exponentially with the sample size and achieves a stable value of about 0.1 % for a dataset with more than 40 points. On the other hand, the computational time, that is one order of magnitude lower than that of the rigorous model, follows an almost linear trend with respect to the sample size.

From this first analysis, we can observe the considerably higher performance of surrogate model with respect to ODE system from a computational perspective and that a good compromise between accuracy and computational time can be obtained for a number of points in the range 40-60.

4.1.1. Closed-loop response

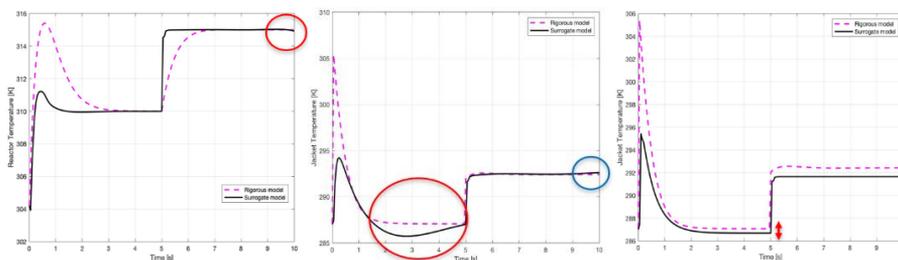

Figure 3 – Controlled/manipulated variable for the three approaches

Once the surrogate models according to each of the three approaches have been derived, their closed-loop response to two sequential 5 K perturbations on the inlet reactor temperature have been tested. Figure 3 shows, for each of them, the controlled or manipulated variable behaviour according to the one that is more significant for the model performances.

As it can be noticed, in the first case, the model is able to reproduce with some inaccuracies the dynamic trend by respecting the settling time and the overshoot for the second perturbation in particular. However, in proximity of the second steady state, the curve starts dropping down to the impact of the exponential term of the obtained analytical function. In order to mitigate this behaviour, the second approach increases the number of points in proximity of the domain boundary. In this case, the steady-state issue has been fixed but the cost to pay is a higher inaccuracy in the central part of the time domain, in particular for the manipulated variable trend as showed in Figure 3b.

Finally, the first order regression performances were tested. The obtained trend exhibits good agreement with the rigorous model one both in terms of transient quality and steady state behaviour. However, an offset with respect to the actual steady state values can be noticed due to the fact that the functional form of the surrogate model has been fixed and includes, as a function of time, the exponential term only.

5. Conclusions

As a first result, the study shows that surrogate modeling to describe continuous processes dynamics is possible and effective by means of the currently available tools. In particular, the obtained model is able to describe the system performances both in open- and closed-loop behaviour. However, although the most critical aspects such as transient peaks and steady state value are correctly described, the accuracy of all points in the perturbation time interval is not always ensured. To deal with these inaccuracies different modeling and sampling approaches can be employed according to the specific parameter of interest. As concerns the computational aspects, with respect to the set of differential equation, the model obtained by means of the proposed procedure exhibits a solution time over the defined time span that is lower by an order of magnitude and a relative error lower than the 0.5 %. Moreover, it allows to detect the best compromise between solution accuracy and computational time in terms of sample size for the specific case study.

In conclusion, the research work shows good potential for continuous process modeling by means of data-driven approach and it is worth a deeper investigation in terms of both modeling strategies and sampling in order to become a well-established tool in the process systems engineering domain and also further applications in different research fields.

Abstract

Statistical machine learning algorithms have been widely used to analyse industrial data for batch process monitoring and control. In this study, we develop a three-step methodology to identify, visualize and systematically reduce data dimensionality for the construction of robust soft-sensors for end-product quality prediction. The approach first employs partial least squares to screen the entire dataset and identify critical time regions and operational variables, then adopts multiway partial least squares to construct a latent space descriptive of the existing batches. Nonlinear estimators are then constructed from the reduced latent space to estimate final product quality, which is able to express model uncertainty. Specifically, in this study, we explore the performance of Gaussian processes. Innovations of this approach include the ease of data visualisation and ability to identify major operational activities within the factory, as well as robustly predict end-quality. To highlight efficiency and practical benefits, an industrial consumer goods product manufacturing process was presented as an example and the soft sensor was successfully constructed and cross validated. Furthermore, the accuracy, reliability, and interpretability of the soft-sensor is discussed, tested and shown to generalise well.

1. Introduction

The operation of nonlinear, uncertain batch processes is a well established domain of research within process systems engineering. Batch process data tends to consist of rank-3 tensorial datasets which are highly dimensional. Further, given that the process is batch, it tends to be the case that operation's primary concern is to ensure that end-quality is kept on specification (meaning that one typically only has a single measurement of the desired qualities of a given batch). As a result, the construction of end-quality predictive models for process monitoring and operation is a highly complex process, requiring identification of different dynamical regimes (handling of non-stationarity in the data) and highly dimensional data points that typically exhibit multicollinearity. This is combined with the fact that operational data is often reasonably limited (at least relative to the era of big data) and the identification of physical mechanisms (mathematically) is extremely challenging. Conventionally, the problem has been handled by various dimensionality reduction techniques (see e.g. Wold et al. (2009)). However, proper quantification of the uncertainties associated with latent variable models is challenging as discussed in Zhang and Garcia-Munoz (2009).

As a result, in this work we consider the development of probabilistic latent variable models, which can naturally quantify the uncertainty of their prediction. This is important because not only is the nature of end-quality prediction in batch processing of high uncertainty, but such quantification can help inform operation of the batch to mitigate waste and reduce inefficiencies.

2. Methodology

2.1. Model construction with rank-3 tensorial input data

In this work, we assume the availability of a dataset, $\mathcal{D} = \{\mathcal{X}, Y\}$, composed of N batch runs, with J process variables recorded at T discrete time intervals, such that $\mathcal{X} = [X_1, \dots, X_N]^T \in \mathbb{R}^{N \times J \times T}$ and $Y = [y_1, \dots, y_N] \in \mathbb{R}^{N \times n_y}$, where n_y represents the number of process qualities one would like to monitor. In this work, we would like to identify a predictive mapping expressed as follows:

$$\mathbf{y} = f(X, \theta) \quad (1)$$

where $\theta \in \mathbb{R}^{n_\theta}$ are the parameters of the functional mapping, $f(\cdot, \theta)$, defined generally. The input data, \mathcal{X} , represents a rank-3 tensorial dataset, which generally poses challenge to constructing classical predictive models. A number of techniques exist to handle such data (that all aim to obtain a rank-2 tensorial representation), including convolutional neural networks, and a number of tensorial analysis approaches as outlined in Sun and Braatz (2020). Further, it is common in the paradigm of batch processing for datasets to exhibit multi-collinearity, such that the problem of identifying the mapping (in Eq. 1) is ill-posed. As a result, in this work, we use the method developed in Hicks et al. (2021) with inspiration from Nomikos and MacGregor (1995, 1994) to construct a reduced latent representation of a batch, such that the dataset \mathcal{X} can be well described by $Z = [\mathbf{z}_1, \dots, \mathbf{z}_N]$, where $\mathbf{z}_i \in \mathbb{R}^{n_z}$ and $i \in \{1, \dots, N\}$. This reduced latent representation, Z can be used for model construction as outlined subsequently. Specifically, we propose to identify Z via multi-way projection to latent structures (MPLS), which can be thought as a special case of projection to latent structures (PLS). Essentially, the additional component of MPLS (relative to vanilla PLS) is the transformation (or unfolding) of a rank-3 tensorial dataset via a functional transformation, f_{unf} , to obtain a rank-2 matrix. In this work, we use time-wise unfolding, which may be defined as $f_{unf} : \mathbb{R}^{N \times J \times T} \rightarrow \mathbb{R}^{N \times JT}$. Having obtained an unfolded representation of the dataset, $\hat{X} = f_{unf}(\mathcal{X})$, one can then identify Z that correlates with the variables one desires to predict via PLS:

$$\begin{aligned} \hat{X} &= ZP^T + E \\ Y &= UQ^T + F \end{aligned} \quad (2)$$

where $P \in \mathbb{R}^{JT \times n_z}$ are the *input loadings*, which project \hat{X} to the input latent space; $Q \in \mathbb{R}^{n_y \times n_u}$ are the *output loadings*, which project Y to the output latent space; $U = [\mathbf{u}_1, \dots, \mathbf{u}_N]^T \in \mathbb{R}^{N \times n_u}$ are the *output scores*; and, $E \in \mathbb{R}^{N \times JT}$ and $F \in \mathbb{R}^{N \times n_y}$ quantify the information loss from projecting both \hat{X} and Y to their respective latent spaces. The latent spaces themselves are related via a linear regression, which enables formation of a predictive model (which together with an unfolding mechanism enables identification of a model of the form of Eq. 1).

Although PLS is a linear decomposition, the relationship expressed within the latent spaces can often be nonlinear. This means that PLS may inherently underfit the modelling problem at hand. Further, approximation of the model uncertainties is a difficult problem given that the typical methods for uncertainty estimation do not consider the indirect relationship of model input and output via the latent structures. This was studied in Zhang and Garcia-Munoz (2009). To handle these two facets, we propose to a nonlinear estimation from the latent space, U to the target Y , to identify a model which naturally expresses predictive uncertainty via probabilistic inference. A suitable estimator is discussed in the following.

2.2. Nonlinear Estimators for Probabilistic Inference and Gaussian Processes

Here, we briefly formalise a general introduction to nonlinear estimators which lend naturally to probabilistic inference. Specifically, we can consider probabilistic inference as the construction of a conditional probability distribution function over predictions, \mathbf{y} , given a model input, \mathbf{z} . In this case, we would like to identify a prediction as follows:

$$\mathbf{y} \sim p(\mathbf{y}|\mathbf{z}, \cdot) \quad (3)$$

Specifically, we consider the use of Gaussian processes (GPs), the high level intuition for which is provided in the following. The use of GPs is particularly appealing as the predictive distribution constructed (in Eq. 3) expresses both aleatoric (arising due to the underlying process) and epistemic (due to a lack of information) uncertainties in closed form. In short, GPs operate within a nonparametric, Bayesian inference framework. The idea here is to (instead of identifying a fixed model structure and number of parameters) simply exploit the statistical relationships within the data to identify a function, $f: \mathbb{R}^{n_z} \rightarrow \mathbb{R}$, (i.e. an infinite dimensional weight vector) such that we can make predictions, $\mathbf{f} = [f(\mathbf{z}_1), \dots, f(\mathbf{z}_N)]$, where $f(\mathbf{z}_i) \in \mathbb{R}$, by simply querying the function at given model inputs, Z . Formally, however, GP models are a subset of stochastic process models (SPs). SPs define a probability model over a collection of random variables, such that any finite subset of the random variables have a joint distribution - meaning they are often identified as a distribution over functions. When this joint distribution is assumed Gaussian, one obtains a GP. A GP is fully specified by a mean, $\mathbf{m}(\cdot)$, and covariance function, $k(\cdot, \cdot)$. Many covariance functions exist, but all are constituted by some hyperparameters, which we define generally as $\boldsymbol{\lambda}$, such that the covariance function may be denoted $k(\mathbf{z}, \mathbf{z}'; \boldsymbol{\lambda})$. Selection of the covariance function, and the associated hyperparameters, defines the behaviour of the GP in function space, otherwise known as the *prior*, $p(\mathbf{f}|Z, \boldsymbol{\lambda})$:

$$\begin{aligned} f(\mathbf{z}) &\sim p(\mathbf{f}|Z, \boldsymbol{\lambda}) \\ p(\mathbf{f}|Z, \boldsymbol{\lambda}) &= \mathcal{G} \mathcal{P}(\mathbf{m}(\mathbf{z}), k(\mathbf{z}, \mathbf{z}'; \boldsymbol{\lambda})) \end{aligned} \quad (4)$$

The mention of a prior, leads us nicely into discussion regarding probabilistic inference in GPs. As mentioned, inference leverages a Bayesian framework, which allows us to directly exploit the statistical relationships in data to infer $f(\mathbf{z}_i) \approx y \in \mathbb{R}$ (i.e. a product end-quality). Therefore, we may write a variant of Bayes' rule for inference of a latent coordinate at the training points in GPs as follows:

$$p(\mathbf{f}^j|Y^j, Z, \boldsymbol{\lambda}) = \frac{p(Y^j|Z, \mathbf{f}, \boldsymbol{\lambda})p(\mathbf{f}|Z, \boldsymbol{\lambda})}{p(Y^j|Z, \boldsymbol{\lambda})} \quad (5)$$

where $Y^j \in \mathbb{R}^N$, $j \in \{0, \dots, n_y - 1\}$ denotes the j^{th} column of Y ; $p(\mathbf{f}^j|Y^j, Z, \boldsymbol{\lambda})$ is known as the *posterior* predictive distribution; $p(Y^j|Z, \mathbf{f}, \boldsymbol{\lambda})$ is the likelihood (formalised as conditional to the covariance function hyperparameters); and, $p(Y^j|Z, \boldsymbol{\lambda})$ is the marginal likelihood. Due to the dependence on $\boldsymbol{\lambda}$, it is important to properly identify $\boldsymbol{\lambda}$. This is achieved by maximisation of the marginal log-likelihood, $p(Y^j|Z, \boldsymbol{\lambda})$. If a homoscedastic Gaussian additive noise model is chosen in construction of the likelihood term, and given that Gaussians are closed under both conditioning and marginalisation, we can construct the *posterior* exactly as a Gaussian distribution, such that at a new test point \mathbf{z}^* , a posterior predictive distribution over function values, f^* , may be constructed as:

$$p(f^*|Y^j, Z, \mathbf{z}^*, \boldsymbol{\lambda}) = \mathcal{N}(\mu(\mathbf{z}^*; Y^j, Z, \boldsymbol{\lambda}), \sigma(\mathbf{z}^*; Y^j, Z, \boldsymbol{\lambda})) \quad (6)$$

As GPs are multiple-input, single-output models, if one has an n_y dimensional latent representation of desired process qualities to predict, then n_y separate GP models can be constructed with the

predictions aggregated as follows:

$$\begin{aligned}
 \boldsymbol{\mu}(\mathbf{z}^*; Y, Z, \cdot) &= [\boldsymbol{\mu}_1(\mathbf{z}^*; Y^0, Z, \cdot), \dots, \boldsymbol{\mu}_{n_y}(\mathbf{z}^*; Y^{n_y-1}, Z, \cdot)] \\
 \boldsymbol{\Sigma}(\mathbf{z}^*; Y, Z, \cdot) &= \text{diag}(\boldsymbol{\sigma}_1^2(\mathbf{z}^*; Y^0, Z, \cdot), \dots, \boldsymbol{\sigma}_{n_y}^2(\mathbf{z}^*; Y^{n_y-1}, Z, \cdot)) \\
 p(\mathbf{y}^* | \mathbf{z}^*, \cdot) &= \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}) \\
 \mathbf{y}^* &\sim p(\mathbf{y}^* | \mathbf{z}^*, \cdot)
 \end{aligned} \tag{7}$$

2.3. Contribution

By integrating the concepts outlined in this Section, one can identify a reduced latent representation of the batch trajectory, which correlates to the desired end-qualities to predict. By constructing nonlinear estimators from the latent space, Z , one can make predictions given a new test batch, $X^* \in \mathbb{R}^{1 \times J \times \hat{T}}$, as follows:

$$\mathbf{y}^* \sim p(\mathbf{y}^* | f_{unf}(X^*)P, \cdot) \tag{8}$$

Given, we identify our mapping from the latent space to end-batch quality as a Gaussian process, we can write $\mathbf{y}^* \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, which describes both the expected end-quality given the trajectory information of the batch, as well as a variance which is quantitative of the aleatoric and epistemic uncertainty associated with the prediction.

3. Case Study

3.1. Consumer goods product-quality prediction

The work developed in this paper focuses on product quality prediction in batch processes. The feasibility and performance of the proposed soft-sensors is assessed by predicting the viscosity of a consumer good product with data obtained from a production plant. This data belongs to two different product specifications with similar processing procedure. Specifically, the data was generated from real-time monitoring of the process as well as one off-line measurement of end-viscosity. These measurements are performed with a rheometer, and can take upwards of 20 min to be completed, which can potentially make errors irreversible. As is demonstrated subsequently, a possible solution is to substitute periodical off-line viscosity measurements with on-line final viscosity prediction using live process data.

3.2. Datasets

The first dataset used to develop the soft-sensor belongs to the first product specification. It comprises 30 individual batches that follow the same recipe, and have the same target viscosity. Deviations from the set target are due to operation errors and uncertainty in the final viscosity measurements. This dataset was used to train all the models. In the first instance, model performance was assessed using leave-two-out cross-validation on dataset α . Two further datasets, β and γ , were used for testing. Dataset β originates from the specification as dataset α and has 16 batches, while dataset γ belongs to a different product specification and is composed of 11 batches. Hence datasets β and α represent the same process. As for dataset γ , test predictions assess the generalisation capacity of the model, since γ belongs to a different specification of product.

To ensure that all datasets could be used for prediction, heterogeneity was standardised via a process of batch alignment and critical time regions and process variables were selected to constitute \mathcal{X} (for the respective datasets). This was conducted via the framework outlined in Hicks et al. (2021), which is based on finding datapoints that correlate strongly with the process quality one would like to predict. For all datasets, critical data regions were identified such that $J = 8$ and $T = 300$, reducing the datasets from an original dimensionality of 7000 measurements of 30 different process variables.

3.3. Metrics for Model Selection and Evaluation

The evaluation and comparison of the different models' performance was based on the following metrics that are required to quantify the quality of the predictive distribution constructed by the models. The accuracy of the models was calculated with the mean average percentage error (MAPE) with respect to the real viscosity as seen in Eq. 9:

$$MAPE = \frac{|y - \mu(X^*, \cdot)|}{y} \times 100 \quad (9)$$

where $|\cdot|$ denotes the absolute value; y is the real viscosity measurement and $\mu(\mathbf{z})$ corresponds to the mean of the predictive distribution over viscosity values given a latent coordinate, \mathbf{z} , as predicted by the models constructed in this work. The scaled coefficient of variation, σ_c , is denoted:

$$\sigma_c = \frac{c\sigma(\mathbf{z})}{\mu(X^*, \cdot)} \times 100 \quad (10)$$

where $c \in \mathbb{R}$ is defined to quantify the normalised spread of potential viscosity values observed under the predictive distribution modelled, with a given probability (i.e. $c = 3$ indicates the spread of potential viscosity with probability 0.997); $\sigma(X^*, \cdot) = \sqrt{\Sigma(X^*, \cdot)}$ is the standard deviation of the predictive distribution identified. In the region of the latent spaces that one has data, this should be reflective of the aleatoric uncertainty of the data generation process and e.g. represent variability in the measurement of viscosity and operational error. For the underlying process it has been estimated that this aleatoric uncertainty should be in the range of $\sigma_c = 26\%$. The final metric used in this work, is the coverage probability, CP :

$$CP = \mathbb{P}(|y - \mu(\mathbf{z})| \leq c\sigma(\mathbf{z})) \quad (11)$$

As in Zhang and Garcia-Munoz (2009), CP is defined with c and hence the inequality should be satisfied with a hypothetical probability (i.e. $c = 3$ indicates $CP = 0.997$, as used in this work).

4. Results and Discussion

Given the nonparametric nature of Gaussian process models, determination of model structure primarily considered the number of latent variables used with the MPLS model input latent space. The results of the cross validation for the model are expressed by Fig. 1. From Fig. 1, one can see the optimal number of latent variables (PCs) in the latent space is around 2. At this PC, there is the lowest validation MAPE ($\approx 10\%$), $\sigma_c \approx 26\%$, which well represents the expected variation of the process, and $CP = 0.95$, which considering the finite number of predictions is close to the hypothetical value desired.

The results obtained in model testing are displayed by Table 1. The results demonstrate the ability of the model identified to obtain impressive predictive accuracy (via low MAPE $\approx 10\%$) and identify predictive distributions, which well represent the aleatoric and epistemic uncertainties (quantified via $CP \approx 0.9$). The framework has particular utility, because it is able to identify predictive uncertainties (innately) in closed form. Further, combining Bayesian inference with latent space modeling, interpretability is provided in the form of both the uncertainty prediction, but also clustering and loading type analyses, which together are able to jointly inform operators when the process is displaying dynamical regimes not commonly observed (i.e. when operational error is present) and for what reason. This enables efficient process monitoring and an online indicator if operators should take action and how best to take it.

5. Conclusions

In this work, we have provided a framework for the identification of a robust soft sensor for end-quality prediction in batch processes. The soft sensor is able to well identify a predictive

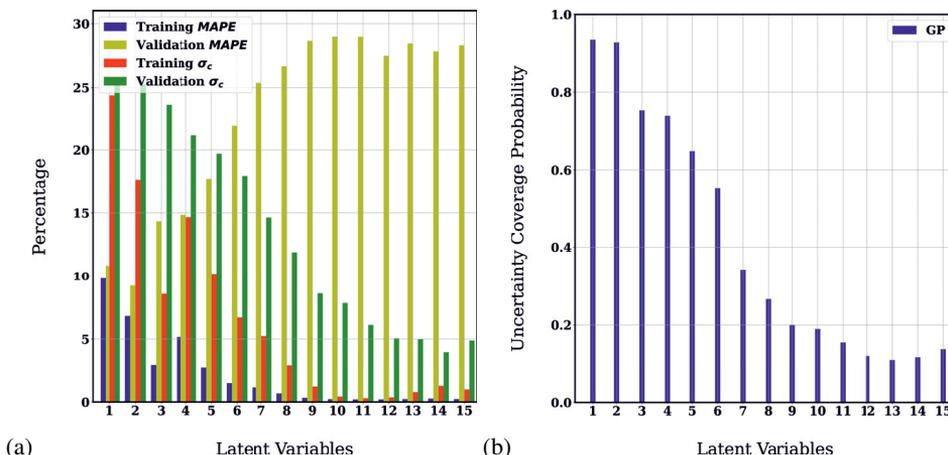

Figure 1: a) Average training and validation MAPE (bar 1 and 2, respectively) and σ_c (bar 3 and 4, respectively) over all cross validation folds as latent variables are added to the MPLS latent space. b) Evolution of coverage probability with the addition of latent variables.

Table 1: Results of predictive tests on datasets β and γ .

Dataset	MAPE (%)	σ_c (%)	CP
β	10.0	22.46	0.88
γ	11.4	22.90	0.83

distribution that quantifies both the expected end-quality (quantified via MAPE in the region of 10% on both validation and test predictions), as well as a closed form uncertainty prediction, which represents the underlying process variation and epistemic uncertainty of the model (quantified via the coverage probability and coefficient of variation). Combining both Bayesian inference and latent space modelling enables interpretability of the predictions, and could help inform operators if and how to take action. We hope to implement this framework to a real process in the scope of process monitoring.

Abstract

Nowadays, medical cannabis has great importance as a coadjuvant in the treatment of some pathologies as glaucoma, rheumatoid arthritis, HIV, Alzheimer's, asthma, cancer, chronic pain that is difficult to control, Crohn's disease, epilepsy, multiple sclerosis, insomnia, and Parkinson's; additionally, cannabinoids and terpenes have important properties that need to be considered and studied in a deeper way to understand the way these compounds work. The main goal of this study is to develop a new hybrid methodology based on both contribution groups and machine learning algorithms. In this particular case, the study is focused on estimating properties of cannabinoids and terpenes whose experimental information is really scarce and, in most cases, not yet reported. To do so, a database of hundreds of thousands of molecules which includes different thermodynamic properties have been considered. Our method is able to estimate different properties such as: boiling point, melting point, vapor pressure, viscosity, and vaporization enthalpy. Machine learning algorithms have been used to establish the contribution of every functional group and its prediction capability has been compared with other well-known methods like the Joback and Reid (1987) method, Constantinou and Gani (1994) method, among others. One of the major findings of the present study is the fact that the current estimation methods are not adequate enough for cannabinoids and terpenes, so there is an important need to find new and more precise ones that allow to improve the accuracy in the groups as well as to extend the predictions to a bigger set of chemical groups. This study clearly shows the importance and utility of the machine learning methods in one of the most relevant chemical engineering areas such as the properties estimation one. This study clearly shows the benefits of machine learning techniques in chemical engineering applications.

Keywords: Property Estimation Method, functional groups, Machine Learning, Neural Networks, Cannabinoids.

1. Introduction

In the last years the interest in studying the cannabis plant has increased notoriously in different fields due to the different pharmaceutical properties of several of its chemical compounds, for instance it is known cannabinoids are of great importance as coadjuvants in the treatment of different pathologies as cancer, epilepsy, and multiple sclerosis Abyadeh et al. (2021). Besides cannabinoids, cannabis plants also contain several compounds such as flavonoids, fats, and terpenes. The latter have biological properties that make them potential mechanism against different diseases, including cancer chemo preventive effects, antimicrobial, antifungal, antiviral, and antiparasitic activities Paduch et al. (2007). Despite the great range of applications, the thermodynamics properties of

cannabinoids and terpenes are difficult to find in the literature or in specialized databases. Therefore, as a first cheap and fast alternative predictive tool such as the based ones on group contribution methods can be used in order to estimate them based on experimental data of other molecules, in particular due to their importance in the crystallization and distillation process it is relevant to study properties such as melting and boiling points, densities, viscosities, among others. This work is aimed to study the melting point of several cannabinoids and terpenes using a group contribution strategy along with machine learning techniques. The basic idea when using group contribution methods, once a set of chemical groups is defined, all molecules belonging to the database are split accordingly allowing to establish a system of algebraic equations. Finally, an optimization method is used in order to minimize the error between predictions and experimental data. Several contribution methods have been proposed for different purposes in the property's estimation field. One of the most famous was proposed by Joback and Reid (1987), this method is able to estimate critical points, melting temperature and normal boiling temperature, it is commonly used for relatively simple molecules and is based on 41 molecular groups. Additionally, Constantinou and Gani (1994) made the estimation of critical properties of pure organic compounds, which due to its sophistication promises better results than Joback's method, as the estimation is performed at two levels: the basic level that uses contributions from first-order groups, and the next higher level that uses a small set of second-order groups having the first-order groups as building blocks. The predictions, first and second order approximations, are based on the molecular structure of the compounds, and is able to make the distinction between isomers. Recently, other studies unified the group contribution methods with artificial neural networks. For instance, Valderrama et al. (2015) created this type of hybrid method for the estimation of the density of ionic liquids. For this purpose, an experimental database of 399 data for 100 ionic liquids was used for the network training. In order to discriminate between different isomers, the molecular mass and the structure of the molecule were given as input variables. Additionally, Gharagheizi et al. (2011) proposed an artificial neural network-group (ANN-GC) contribution method in order to determine surface tension of pure compounds at different temperatures and pressures. They used 4700 data belonging to experimental surface tension values of, approximately, 750 chemical compounds and 151 functional groups at different conditions. Although several methods have been proposed, none of them is able to reproduce the experimental data of cannabinoids or terpenes, additionally since the experimental information is scarce for these compounds it is certainly to propose a methodology to estimate them, in this particular a hybrid strategy of group contribution methods along with machine learning techniques and a big set of experimental data will be used. The manuscript will be presented as follows, first in the computational section, the database generation for and the group contribution method is described, second the neural network algorithms are presented, third the results are presented and finally the conclusion and future work is presented. The code and the best predicted model will be available after publication.

2. Methodology

2.1. Database features

In order to build the machine learning algorithms, a database with the property data was needed to train the method. To do so, an open database available on the U.S. Environmental Protection Agency (EPA) was used, this database contains the chemical name, the Simplified Molecular Input Line Entry Specification (SMILES) and different chemical and physical properties such as the melting point, the boiling point among many

others. This database has, approximately, 700,000 compounds with their respective melting point, as it is the property being studied. Additionally, the database created has the functional groups present in each compound, which are group of atoms that have their specific characteristics and contribute to the properties of the compound. The functional groups were obtained using RDKit, a library created for Python, which prints the functional groups of each compound based on its SMILES. Additionally, to evaluate the model a database of 50 cannabinoids and terpenes was generated, the information was obtained from the Cannabis Compound Database Version 1.0, a freely available electronic database containing detailed information about small molecules found in Cannabis sativa, Cannabis indica and Cannabis hybrids (Cannabis Database). The functional groups of the cannabinoids and terpenes were also found using RDKit and the compounds SMILES. Finally, it is important to mention that, as this was the database used for the evaluation of the model, the melting point was not included in it.

2.2. Machine learning algorithms

In this subsection, we introduce the concept of Artificial Neural Networks (ANN), and the process of its training and evaluation. ANN was inspired by the structure and functions of biological neurons, and it generally consists of an input layer where data is fed, the hidden layers standing for the internal structure of the model where information goes through until arrive at the output layer Schmidhuber (2015). Each layer comprises neurons that transmit the information downstream to connected neurons belonging to other layers. The previous layer acts as an input for the next one after applying nonlinear activation on it, and finally propagates the current result to the following layer. In a vector notation we have Wang et al. (2020):

$$h_{i+1} = W_{i+1}l_i + b_{i+1}; \quad l_{i+1} = f(h_{i+1}) \quad (1)$$

where l_i is the input row vector of the $i - th$ layer, W_{i+1} and b_{i+1} are the weights and biases trainable parameters, h_{i+1} is the intermediate vector after linear transformation, and f is the activation function. The goal of training an ANN is to minimize the difference between the predicted value given by the output layer $\hat{y} = f_{W,b}(h)$ and the ground truth y . The minimization is described through the loss function L , by optimizing the parameters W and b . In regression tasks Schmidhuber (2015), it is common to use L as the mean squared error (MSE), the mean absolute error (MAE) or the Huber loss (H):

$$MSE = \frac{1}{N} \sum (y - \hat{y})^2, \quad MAE = \frac{1}{N} \sum |y - \hat{y}|, \quad H_\delta(y, \hat{y}) = \begin{cases} 0.5(y - \hat{y}), & |y - \hat{y}| \leq \delta \\ \delta(|y - \hat{y}| - 0.5\delta), & \text{other } w \end{cases} \quad (2)$$

where N stands for the number of samples. The aforementioned functions will be adapted to this work. Following the chain rule, one could transmit gradients of the trainable parameters in the $i - th$ layer from the $(i + 1)th$ layer. During backward propagation the parameters are updated, then forward propagation is performed again. This is repeated until the loss function achieves the desired precision and thus, the NN is trained and ready to make predictions. Two types of artificial neural networks are implemented in this work: deep Feedforward Neural Networks (FNN) and Convolutional (Conv1D). The FNN described above does not have cycles contained within it and the connections between layers and the information flow are straightforward, while the Conv1D is a structured network with multiple sets of weights (filters) that "slide" or convolve across the input-space to analyze distance-pixel relationship opposed to individual node activation in the FNN Schmidhuber (2015). On the other hand, the dataset is split in training 70%, validation 15%, and test 15% sets. The first set is used to train the ANN, while the

validation and test set contain unseen values, relevant for testing the performance of the model. The latter can be achieved using a metric that in most of cases is similar to the loss function shown in Eq.(2) or thought the coefficient of determination (R^2) Hortúa et al. (2020):

$$R^2 = 1 - \frac{\sum_i(\hat{y} - y_i)^2}{\sum_i(y_i - \bar{y})^2}, \quad (3)$$

where \bar{y} is the average of the true parameters and the summations are performed over the entire test set. R^2 ranges from 0 to 1, where 1 represents perfect inference. R^2 will be used in this work as metric for measuring the performance of the NN models. Finally, a downside behind of the standard NNs is that they are sensitive to the training process and the hyper-parameter choices, finding different set of weights each time they are trained, which in turn produce different predictions and high variance. An attempt approach to reduce this variance is to train multiple models instead of a single one and to combine the predictions from these models. This is called ensemble learning and it helps to reduce the variance of predictions and can also result in better performance Tao (2019).

3. Analysis

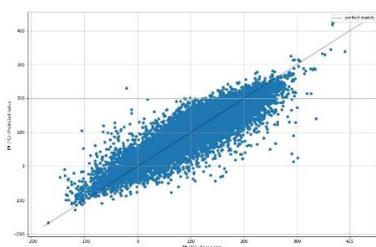

In order to predict the melting point in terms of the establish chemical groups, we started with single NN regression models. First, we built in TensorFlow a FNN consists in four dense layers with 256, 128, 64 and 1 neurons, followed by an ELU activation function, a Batch Normalization in order to optimize and accelerate the convergence, and a Dropout layer (with a rate of 0.1), for regularization purposes. Here, we adopt Adam as the optimizer, and a learning rate decay with 0.01 in its initial value, with a factor of 0.8 during each 10 epochs. On the other hand, the conv1D architecture comprises of four convolutional layers of 64, 32, 32, 16 filters, then a MaxPool layer is used to reduce the dimensions of the feature maps, followed by four dense layers of 256,126,64 and 1 neurons. As before, each layer is followed by an ELU activation function, Batch Normalization and Dropout (rate 0.1).

Table 1. Performance for different models in terms of R^2

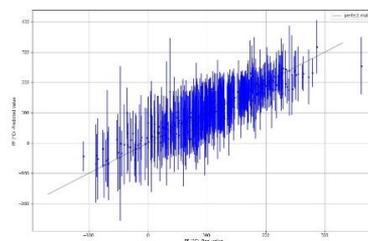

Metric/Model	Ensemble			Single		
	MSE	MAE	Huber	MSE	MAE	Huber
R^2 -FNN	0.88	0.84	0.84	0.83	0.82	0.82
R^2 -Conv1D	0.87	0.87	0.87	0.81	0.80	0.83

The results of the performance for both, FNN and Conv1D for different loss functions are reported in the right hand side of the Table 1. As we observed, both models seem to work well, reaching a decent coefficient of determination value. FNN model trained with MSE is the best model that we obtained through all single NN experiments, and the behavior for predicting unseen instances can be seen also in Fig.1a. Finally, we also worked with ensembles of Neural Networks (BNN) in order for including variances during the inference process, and improve the estimates for predictions. The schema for these ensembles with either FNN or Conv1D are displayed in Fig.(2)-(3) respectively. For these ensembles we added at the top of the models, an Average-layer which provides of an unique neuron for predicting the melting point. Furthermore, we could extract the information from the top-before layer to get the outputs for all the models in the ensemble and thus, to be able to compute the standard deviation for the predicted values. As we can

see in the left part of the Table 1, the ensemble models outperform the results that we have obtained in the single scenario. Indeed, we achieved coefficient of determination around 0.8 for the FNN ensemble trained with MSE loss function. The prediction for the test dataset can be also seen in Fig.1b. Here, we observed not only a better accuracy in the predictions, but also, we acquired new information about the uncertainty of those estimations. One of the main analysis that we can get from the ensemble models, is that there is a huge variance for chemical groups with melting points around 10-100 Celsius degrees, basically because of the few dataset in this range. Also, we can argue that five models in the ensemble is not good enough, and it requires more single NN for yield better results in terms of variability. These additional remarks along with the use of models which provide uncertainties such as Bayesian Neural Networks Hortúa et al. (2020) or Gaussian Processes are tools that we are proposing for a future work.

(a) Predicted values against true values for a single FNN model.

(b) Predicted values for an ensemble consisting of 5 FNN models.

Figure 1. Predicted vs true values for the best experiments found for a single and ensemble NN

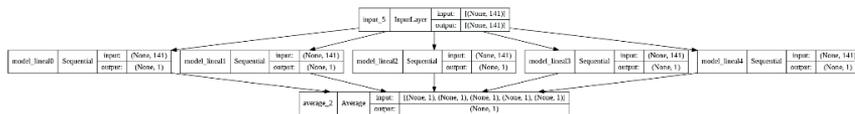

Figure 2. NN architecture used in the work based on ensembles of several NN Fully-connected models.

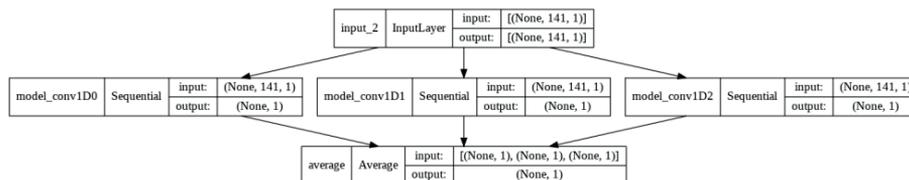

Figure 2. NN architecture used in the work based on ensembles of several NN convolutional models.

Table 2. Prediction provided by the ensemble FNN model for different cannabinoids

Compound Name	Predicted Value (°C)	Reported value (°C)	Standard Deviation
Mircene	-70.0	<-10.0	48.4
Apha-pinene	-30.8	-62.0	26.8
Menthol	87.0	36.0-38.0	36.0
Cannabidiol	152.4	66.0	39.2
Cannabigerol	152.3	49.0-52.0	36.4
Beta-pinene	-53.1	-61.5	35.4
Limonene	-45.8	-74.0	35.8

Table 2 summarizes the predictions for some of the studied cannabinoids, not previously used by the algorithm. Standard deviations are also reported. As shown: i) qualitatively speaking the model is able to predict positive and negative melting points, however, it still needs a lot of improvement in compounds such as cannabidiol, one of the most important in the current processes; ii) the obtained standard deviations are very high, indicating that a pre-treatment process is certainly necessary to improve the model.

4. Discussion and Conclusions

In this paper, we have explored several machine learning techniques for estimating the melting point property in chemical compounds. We contrasted two main approaches: the use of trained single NN models based on FNN and Convolutional layers, along with ensembles comprised of those single NN. We have found that these ensembles outperform single NN, and additionally provide uncertainties in its predictions. The best model found in this paper comes from the ensemble of FNN trained with MSE loss function, reaching a $R^2 = 0.88$. Even if the results are good enough and promising, we observed that the variance for the models built so far is huge. This effect can be associated with either a noisy dataset or because of few instances in the dataset for some temperature ranges. In order to overcome this issue, we suggest for future work, a strong reprocessing method before feeding the data into the NN model, and also the use of more robust techniques such as Bayesian Neural Network in order to get the aleatory and epistemic uncertainties which give a clearer picture about the huge variability in the predictions. Finally, we are currently working on improving the accuracy of this model as well as determining more thermodynamic properties of interest in the cannabinoid extraction process.

Abstract

Microbiological production of γ -linolenic acid (GLA) via a temperature-shift strategy has been found to shorten the batch cultivation period, improve GLA yields and reduce the operational cost. However, the underlining biochemical mechanistic phenomena are highly complex and challenging to model, thus hindering commercial upscaling applications of this fermentation technology. To bridge this gap, a dynamic model capable of simulating biomass growth, substrate consumption, and GLA biosynthesis of *Cunninghamella echinulata* for a wide temperature range was proposed for the first time. Once the model parameters were identified, the model's high simulation accuracy was demonstrated against data from a small scale 1L bioreactor. It was found that the optimal temperatures for biomass growth and GLA production were 37 °C and 14 °C, respectively. Model aided upscaling to a 5L bioreactor with a two-stage temperature-shift strategy showed a 69.6% increase in GLA production, which was verified experimentally. Therefore, this presents a significant advance for the upscaling of GLA production biotechnology from laboratory to pilot scale.

Keywords: fermentation; kinetic modelling; γ -linolenic acid; temperature-shift; process upscaling.

1. Introduction

The polyunsaturated fatty acid (PUFA), γ -linolenic acid (C18:3n-6, GLA), is widely utilised within the pharmaceutical and nutraceutical industries due to its outstanding value for treating diseases. As an essential precursor for the biosynthesis of several prostaglandins, GLA is an essential fatty acid with proven anti-inflammatory and anti-cancer effects (Wan, 2009). However, with the body unable to manufacture its own (Somashekar et al., 2003), GLA must be assimilated through the consumption of poultry, beef, pork or egg yolk, or else as a dietary supplement.

Plant seeds such as borage, black currant, evening primrose, and hemp have been used as commercial sources of GLA oil (Tanticharoen et al., 1994). However, cultivating these plants requires large swathes of arable land owing to their seeds low intracellular GLA

content. In contrast, a promising alternative source: the oleaginous fungus *Cunninghamella echinulata* (*C. echinulata*), possesses a much higher GLA content, and is simpler to cultivate (i.e., traditional fermentation). Taken together, this marks the fungus as an economically competitive source of GLA for large-scale production.

Temperature-shift: an approach where the operating temperature is switched during cultivation to increase the accumulation of the targeted metabolite has been reported to influence the intracellular PUFAs content of fungal species (Jang et al., 2005).

However, whilst *C. echinulata* is oleaginous fungi, the optimal temperature for biomass growth, lipid production, and product accumulation might differ significantly between strains. Hence, it is valuable to investigate the optimal temperature-shift strategy for industrial GLA production with *C. echinulata*. Moreover, model-based design of experiments is considered an effective tool to accomplish bioprocess scale-up from laboratory to pilot and industrial scale (Zhang et al., 2015).

Therefore, this work aims to: (i) investigate the effect of temperature on the *C. echinulata* biomass growth and GLA production through the construction of a rigorous kinetic model; (ii) evaluate the performance of the temperature-shift strategy when up-scaling the fermentation processes from a 1L to 5L bioreactor; (iii) evaluate the predictive accuracy and sensitivity of the kinetic model over different bioreactor scales.

2. Methodology

2.1. Experimental setup

In our lab, *C. echinulata* X-15 was a screened high-yield strain, which was maintained on potato dextrose agar (PDA) plates at 4 °C and transferred every 3 weeks to PDA plates. The culture was grown at 28 °C for 2 days and then stored at 4 °C until fermentation. GLA fermentation was carried out in 1L bioreactors (Infors-2015 Bioprocess controller, Netherland) containing 0.7L of medium and cultivated at different temperatures (14 °C, 28 °C, and 37 °C) with 10% (v/v) of the seed culture without pH controlled. In the two temperature-shift experiments, GLA fermentation was carried out in a 5L bioreactor (Infors-2015 Bioprocess controller, Netherland) containing 3.5L of medium, ultimately switching the temperature from 37 °C to 14 °C at either 168 hours or 96 hours. All the control conditions were the same as those in the single temperature experiments, and all cultivation experiments were performed in triplicate and analysed individually.

2.2. Kinetic model construction

2.2.1. Model structure identification

The Contois model accounts for the effect of cell flocculation and diffusional barriers that arise in high-density cell cultures. Thus, the Contois model was adopted in this study to describe biomass growth. Equation (1) simulates the total biomass growth rate, and Equation (2) simulates the fat-free biomass growth rate, assuming that the fat-free biomass growth rate is proportional to the total biomass growth rate.

$$\frac{dX_T}{dt} = \mu_m \cdot \frac{C}{K_{co} \cdot X_T + C} \cdot X_T - \mu_d \cdot X_T \quad (1)$$

$$\frac{dX_B}{dt} = k_0 \cdot \frac{dX_T}{dt} = k_0 \cdot \left(\mu_m \cdot \frac{C}{C + X_T \cdot K_{co}} \cdot X_T - \mu_d \cdot X_T \right) \quad (2)$$

Where X_T is total biomass concentration (g L^{-1}), C is glucose concentration (g L^{-1}), μ_m is the maximum specific growth rate (h^{-1}), μ_d is the specific cell death rate (h^{-1}), K_{co} is the half-saturation constant and k_0 is the ratio of fat-free biomass to total biomass (g g^{-1}).

$$\frac{dC}{dt} = -Y_{C0} \cdot \left(\mu_m \cdot \frac{C}{K_{co} \cdot X_T + C} \cdot X_T - \mu_d \cdot X_T \right) - m \cdot X_T \quad (3)$$

Equation (3) simulates glucose consumption rate, where Y_{C0} is the yield coefficient from glucose to biomass (g g^{-1}) and m is the biomass specific maintenance coefficient ($\text{g g}^{-1}\text{h}^{-1}$).

Finally, GLA accumulation was simulated by adapting the Luedeking-Piret equation to include a novel GLA consumption term which is used to describe the decay stage of GLA in experiment shown in Equation (4).

$$\frac{dX_G}{dt} = k_m \cdot \left(\mu_m \cdot \frac{C}{C + K_{C0} \cdot X_T} \cdot X_T - \mu_d \cdot X_T \right) + k_n \cdot X_T - k_d \cdot \frac{1}{C + K_p} \cdot X_T \quad (4)$$

Where k_m is the growth-dependent synthesis constant (g g^{-1}), k_n is the growth-independent synthesis constant ($\text{g g}^{-1}\text{h}^{-1}$), k_d is the specific GLA decay rate ($\text{g g}^{-1}\text{h}^{-1}$) and K_p is the saturation product constant (g L^{-1}) for GLA decay.

2.2.2. Simulating temperature effects

In order to investigate the temperature dependence of each kinetic parameter, seven parameters were modelled as a function of temperature (μ_m , K_{C0} , Y_{C0} , K_0 , k_m , k_d and K_p), whilst the remaining three parameters (m , μ_d , k_n) were considered temperature independent. The positive or negative temperature dependence was captured by either Equation (5), or Equation (6) (Laidler, 1984), respectively, where the former is simply the standard Arrhenius equation.

$$\theta_i = A_i \cdot \exp\left(\frac{B_i}{T}\right) \quad (5)$$

$$\theta_i = C_i - A_i \cdot \exp\left(\frac{B_i}{T}\right) \quad (6)$$

Where A_i , B_i and C_i in the above equations are specific parameters to be fitted for each kinetic parameter θ_i and T is the temperature in Kelvins K. Thus, two or three constants describe each of the seven temperature-dependent parameters.

2.3. Parameter estimation method

The 24 parameters required by the model were estimated by formulating the nonlinear least-squares optimisation problem defined by Equation 7, identifying parameter vector parameters θ by minimising the objective function (Del Rio-Chanona et al., 2015):

$$\min_{\theta} E(\theta) = \sum_{n=1}^{np} \left[\frac{(X_{Tn} - X_{Ten})^2}{X_{T_{emax}}^2} + \frac{(C_n - C_{en})^2}{C_{emax}^2} + \frac{(X_{Bn} - X_{Ben})^2}{X_{B_{emax}}^2} + \frac{(X_{Gn} - X_{Gen})^2}{X_{G_{emax}}^2} \right] \quad (7)$$

Where X_{Ten} , C_{en} , X_{Ben} and X_{Gen} are the measured concentrations of biomass, substrate, fat-free biomass and GLA respectively, at each sampling time n . Whilst, X_{Tn} , C_n , X_{Bn} and X_{Gn} are the respective concentrations computed by the model at each sampling time n , and $X_{T_{emax}}$, C_{emax} , $X_{B_{emax}}$ and $X_{G_{emax}}$ are the maximum measured concentrations and np is the number of sampling points.

This derivative-based nonlinear programming problem (NLP) was solved by adopting the parameter estimation framework widely employed. Given the high nonlinearity and stiffness of the system, the differential system of equations was discretised by direct transcription by orthogonal collocation into a series of nonlinear algebraic equations. The NLP was then solved using the interior point nonlinear optimisation solver IPOPT (Wächter & Lorenz T. Biegler, 2006).

2.4. Sensitivity analysis

Although the solution to a parameter estimation problem may provide point estimates that agree with the data instantaneously, questions about model stability remain unaddressed. Therefore, model sensitivity to parameter uncertainty was investigated by resampling each parameter in turn with all others fixed, simulating the state variable trajectories each

time. These trajectories were then aggregated into the propagated uncertainty bounds shown later. All the model parameters were assumed to be distributed uniformly between a lower bound (P_{min}) and an upper bound (P_{max}) centred on the mean (P_{mean}), defined as follows:

$$P_{min} = (1 - \%Variation) * P_{mean} \quad (8)$$

$$P_{max} = (1 + \%Variation) * P_{mean} \quad (9)$$

In total, Latin Hypercube Sampling (LHS) of the input space selected 200 parameter samples. All code was executed in Python version 3.7 using the *SMT 1.0.0*, *SciPy* libraries and *NumPy*.

3. Results and discussion

3.1. Results of model construction

Table 1: Parameters values with different operation temperatures

T (°C)	μ_m (h ⁻¹)	K_{CO} (g L ⁻¹)	Y_{CO} (g g ⁻¹)	K_0 (g g ⁻¹)	k_m (g g ⁻¹)
14	0.115	41.345	1.420	0.700	0.01160
28	0.164	49.586	1.307	0.780	0.003085
37	0.218	55.000	0.591	0.901	0.001173
	k_d (g g ⁻¹ h ⁻¹)	K_p (g L ⁻¹)	μ_d (h ⁻¹)	m (g g ⁻¹ h ⁻¹)	k_n (g g ⁻¹ h ⁻¹)
14	0.00352	25.013	0.0017	0.00498	0.00013814
28	0.00480	34.277	0.0017	0.00498	0.00013814
37	0.00727	37.888	0.0017	0.00498	0.00013814

The values of the parameter estimates are shown in Table 1.

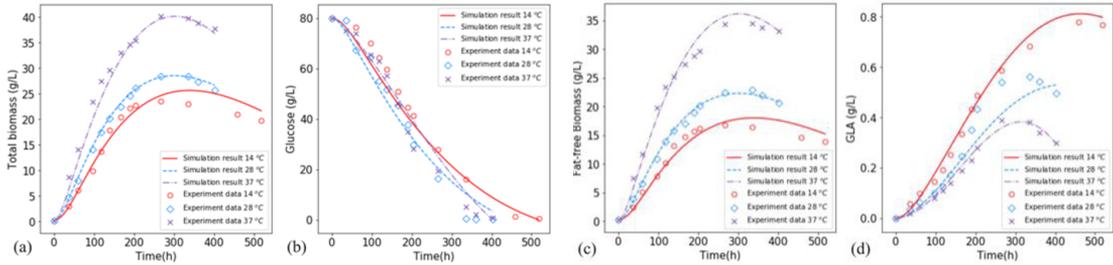

Figure 1. Experimental results and simulation fitting results for (a) total biomass, (b) glucose, (c) fat-free biomass and (d) GLA.

From Figure 1, it is evident that the model accurately captures the bioprocess dynamics over the different operating temperatures, with the state variables' mean relative percentage error falling within 20%. Furthermore, features observed experimentally are successfully described by the proposed model structure. However, whilst the model struggles to fit the GLA decay stage at 28 °C, the error remains relatively small.

3.2. Model sensitivity analysis

For a more comprehensive comparison of the model's sensitivity to each parameter, the mean relative percentage deviation (MRPD) was measured between the lower and upper bound for each state variable and operating temperature.

The result of MRPD indicated that the model is more sensitive to B_i than either A_i or the remaining temperature-independent parameters, an expected result given that B_i modifies the exponent of the temperature-dependent parameters. Of these, the MRPD is largest for

B_{μ_m} , $B_{K_{CO}}$ and $B_{Y_{CO}}$ in decreasing order, and therefore contribute most to model uncertainty.

3.3. Effects of temperature on bioprocess kinetics

The effect of temperature on *C. echinulate* fermentation was studied by inspecting the temperature correlations captured by fitting Equations (5) and (6).

Table 2. The coefficient of determination (R^2) of the optimal parameters fitting as functions of temperature and the obtained constant (A , B and C).

Parameter	R^2	A	B	C
μ_m	0.99	590.58	-2457.29	N/A
K_{CO}	0.98	1239.43	-966.81	N/A
K_0	0.96	18.41	-942.62	N/A
k_m	0.99	5.58E-16	8813.01	N/A
k_d	0.93	62.24	-2808.45	N/A
K_p	0.98	7670.33	-1640.48	N/A
Y_{CO}	0.99	5.60E+10	-7655.47	1.67

From Table 2, it can be seen that the majority of the kinetic parameters follow the standard Arrhenius relationship between 14 °C and 37 °C. However, whilst k_m and Y_{CO} exhibit the same trend overall, k_m decreases exponentially from the offset, unlike Y_{CO} which remains relatively static from 14 °C to 28 °C before plummeting over 28 °C to 37 °C. Since Y_{CO} is associated with the efficiency with which glucose is utilised to synthesis biomass constitutes, the sudden drop in Y_{CO} indicates that high temperatures deactivated the overflow metabolism that previously produced by-product.

3.4. Design of a temperature-shift strategy

A two-stage temperature-shift strategy promises to maximise GLA yield, given the different optimum temperatures for *C. echinulata* biomass growth and GLA accumulation. The bioreactors were operated at 37 °C to maximise biomass density in the first stage before dropping to 14 °C to maximise GLA accumulation in the second stage. The scale-up factor is not taken account in the work since the dynamic influence of scaling up from 1L to 5L can be neglected.

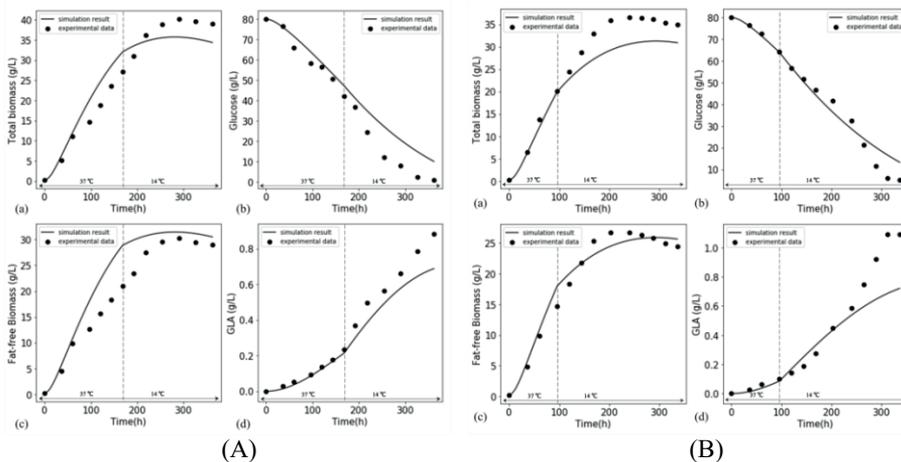

Figure 2. The experimental results and model prediction results for (a) total biomass, (b) glucose, (c) fat-free biomass and (d) GLA of temperature-shift strategy at 168hr (A) and 96 hr (B) in 5L fermenter.

Figure 2 compares the model predictions and corresponding experimental results when employing the chosen temperature-shift policy. The state variables were predicted accurately within 30% error in both cases. Of particular success was the upscaled temperature-shift experiment, which despite being a first for *C. echinulata*, achieved a GLA concentration of 1323 mg L⁻¹, a 69.6% increase over 780 mg L⁻¹ attained by the fixed temperature culture at 14 °C.

4. Conclusion

In this work, a temperature-dependent biokinetic model capable of simulating the fermentative biomass growth and GLA biosynthesis of *C. echinulata* was proposed for the first time. Using experimental data from a 1L bioreactor, the biokinetic parameters were identified and the prediction accuracy verified over a wide temperature range from 14 °C to 37 °C. Higher cultivation temperatures around 37 °C were found to benefit cell biomass growth, whilst GLA accumulation favoured lower temperatures around 14 °C. Thus, a two-stage temperature-shift strategy was designed and tested by optimising biomass growth and GLA biosynthesis of *C. echinulata* for the first time. Compared to fixed temperature cultivation at 14 °C, the optimised two-stage temperature shift strategy increased GLA production by 69.6% when verified experimentally. The proposed biokinetic model's high predictive accuracy when up-scaling the bioreactor from 1L to 5L demonstrates the model's reliability for continued scale-up of the biotechnology. However, further studies on the impact of scale-dependent transport phenomena such as mixing induce shear rate, aeration and eddy size is recommended to improve the upscaling predictions.

Abstract

The intensive use of plastic in modern society has accumulated a significant and damaging quantity of plastic waste. The management of plastic waste is challenging due to its un-degradable nature and increasing polluting impact on land, water, and air systems. Polyethylene terephthalate (PET) is one of the most important plastic types used and constitutes a large fraction of plastic waste. The pyrolysis thermochemical conversion process is an important technique used to convert the PET into value-added products such as char, oil and gas. This study develops a process simulation model for the pyrolysis of PET plastic to convert into char, bio-oil and gas. The process flow sheet model is developed using the Aspen Plus V11[®] and the impact of pyrolysis temperature and pressure on the production of char, pyrolysis oil and gas are investigated, where a techno-economic-environmental feasibility is also conducted using Aspen Plus built-in features. Furthermore, an optimisation is applied, where three sets of optimum operating parameters other than base case are generated through maximising the generation of each pyrolysis product. The base case demonstrates pyrolysis gas, char and oil production approximately at 330 kg/h, 490 kg/hr and 180 kg/hr, respectively at a temperature of 450 °C and 1 bar. The gas production is favourable at a high temperature of more than 450 °C, in contrast to oil and char. The techno-economic evaluation demonstrates the optimised capital and operating costs are obtained at a lower temperature with maximum yields of char and oil at 53% and 28%, respectively. Moreover, the increase in temperature to optimise gas production demonstrates enhancement in the gas quality and reduction in capital cost compared to the base case in addition to a reduction in environmental emissions (86 kg/h CO₂ emissions). In conclusion, this study provides a baseline for the utilisation of the pyrolysis process to convert PET into value-added products.

Keywords: PET, Aspen Plus, Char, Pyrolysis, Techno-economic-environmental analysis.

1. Introduction

As the global population increases, more waste streams are generated, for which effective waste management remains an issue. The most critical waste in municipal solid waste (MSW) is plastic waste, produced 99% from fossil fuel sources. Since the introduction of plastic in 1950, approximately 8.3 billion tons of plastic litter have been accumulated, and only 567 million tons have been recycled. More than 5 billion are disposed through landfill and only about 756 million tons recycled respectively (hub, 2019). The plastic production was approximately 393Mt/year in 2016, and it is expected to double in the

next 20 years (Lebreton and Andrady, 2019). The disposal of plastic waste is a salient issue as the degradation of plastic takes many years if it is disposed through landfilling and emits toxins upon incineration. The state of Qatar generates approximately 1.5 kg/capita/day, which is higher than the average global waste generation approximated at 3kg/capita/day (Miandad et al., 2017). It has been reported that the current 2.5 million population of Qatar produces approximately MSW of 4000 ton/day. Furthermore, plastic waste was approximately 8.8% of the total MSW in Qatar in 2006 (Al-Maaded et al., 2012), and later increasing to 13% (Hahladakis and Aljabri, 2019). The consumption of plastic is approximately 240000 ton, consisting of various plastics such as HDPE, LDPE, PP, PET, PS, and others, where PET is one of the most important types of plastic, and is used for packaging, especially for beverages and water bottles (Hahladakis and Aljabri, 2019).

The PET has a 14% share in total plastic waste in Qatar. Although PET is one of the plastic types that can be recycled, it is generally landfilled or incinerated (Hahladakis and Aljabri, 2019), noting that incineration of PET results in greenhouse gas emissions. In contrast, its conversion into value added products such as syngas, char and bio-oil through gasification and pyrolysis represent sustainable pathways (Anuar Sharuddin et al., 2016). There has been much work conducted in the pyrolysis of plastics domain (Anuar Sharuddin et al., 2016). For instance, the pyrolysis of PET in a fixed bed reactor yielded liquid oil and gaseous fuel in a ratio of 23.1% and 76.1%, respectively (Çepelioğullar and Pütün, 2013). Most studies demonstrate that the pyrolysis of PET produces yields of oil and gaseous products in the range of 24-40 wt% and 52-77 wt%, respectively, which renders PET as an attractive plastic for pyrolysis (Anuar Sharuddin et al., 2016). Although the pyrolysis of PET is well-investigated, very few studies have reported a techno-economic and environmental analysis and feasibility, especially for a Qatar case study. As such, this study aims to develop a process simulation model for the pyrolysis of PET for the generation of bio-oil, char and gas products, integrated with a sensitivity and optimisation of process parameters to maximise the yield. Furthermore, the study details a techno-economic and environmental analysis to investigate the investment and sustainable potential of PET pyrolysis.

2. Methodology

The approach followed for the process development begins with the pyrolysis model of plastic feedstock using Aspen Plus software. The proximate and ultimate analyses of PET presented in Table 1 are used to define the raw plastic feedstock (Oh et al., 2018). The base pyrolysis model is then evaluated in terms of economic and environmental performance. The base case is further optimised by means of sensitivity analyses to identify the optimum operating conditions that maximise the generation of bio-oil, char and gas products. The optimum operating conditions are then utilised to benchmark the different simulation models.

Table 1: Proximate and ultimate analyses of biomass feedstock as received basis (Oh et al., 2018).

Proximate Analysis	MC	VM	FC	Ash	
	0.2	87.2	12.6	0	
Ultimate analysis	C	H	N	S	O
	61.2	5.1	0	0	33.7

The current model is configured by considering the assumptions of; steady state operation, uniformity in heat and mass transfer, zero tar formation, and kinetic-free equilibrium as depicted in the study of AlNouss et al. (2021). The property package and equation of state PR-BM is selected for flowsheet development due to its applicability for hydrocarbon and refinery process (Shahbaz et al., 2020). The pyrolysis model illustrated in Figure 1 begins with an RYIELD reactor linked with calculator block to convert the feedstock attributes into conventional components based on the ultimate analysis as given in Table 1 (Shahbaz et al., 2021). The effluent stream enters the pyrolysis reactor simulated as RGIBBS to produce the pyrolysis main products. The process propagates based on Gibbs free energy minimisation by selecting the Gibbs equilibrium reactor (AlNouss et al., 2020). The hot product is then cooled prior entering a separator to flash out the pyrolysis gases. The remaining stream enters a solid separator to remove the char from the bio-oil liquid product.

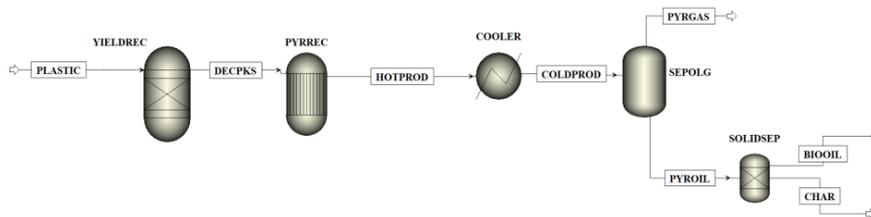

Figure 1: Aspen Plus model for plastic (PET) pyrolysis.

The techno-economic and environmental evaluation of the model is conducted using Aspen's built-in economic and environmental impact assessment features to estimate the capital, operating, and raw material costs for all cases in addition to CO₂ emissions. Moreover, the sensitivity analyses for the pyrolysis temperature and pressure are conducted to study their effect on the product yields. The pyrolysis temperature is varied between 150 and 850 °C at a constant pressure of 1 bar to cover the whole range of conventional pyrolysis process and find the optimum parameters for all three types of products including char, oil and gas. Whereas, the pressure is varied between 1 and 10 bar to observe the effect of different pressure models on the products yield by maintaining the temperature constant at 450 °C. The optimum values and static figures from the sensitivity analyses are then evaluated to benchmark their economic and environmental impact performance relative to the base case.

3. Results and discussion

The results of different PET (plastic) pyrolysis analysis are discussed in this section. The sensitivity analyses of pyrolysis reactor operating conditions illustrated in Figure 2 demonstrate the variation in the different product yields. From Figure 2, char production decreases from 527 kg/hr to 366 kg/hr with the increase in pyrolysis temperature from 150 to 850 °C. A similar trend is deduced for pyrolysis oil with increase in pyrolysis temperature. Whereas the gas generation is in direct relation with the elevation of pyrolysis temperature hence its production increases from 181 kg/hr to 633 kg/hr. The increase in pyrolysis temperature yields an increase in the gaseous product from 181 to 633 kg/h. The higher generation of gas relative to oil and char products from the pyrolysis of PET at a higher temperature of 500 °C is also noticed in other studies (Çepelioğullar and Pütün, 2013). In another study, the gas yield was about 53.13 % for PET pyrolysis (FakhrHoseini and Dastanian, 2013). Whereas, the increase in pressure demonstrates an

increase in the bio-oil production from 192 to 213, and a decrease in the gaseous and char yields from 317 and 489 to 303 and 483, respectively. The domination of gas and char yields as compared to oil at 1 bar of pressure is due to the higher fixed carbon and lower volatile content in PET plastic (Anuar Sharuddin et al., 2016). Based on the trend depicted in Figure 2, three optimum parameters sets are found for each type of product to provide flexibility for making decision in upscaling and applications listed in table 2.

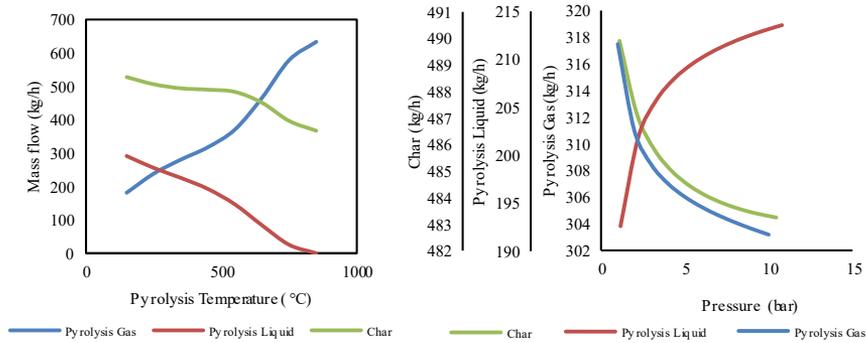

Figure 2: Sensitivity analyses trends for temperature and pressure of pyrolysis reactor.

The results from the sensitivity analysis are then utilised to evaluate the economic and environmental performance of three cases as summarised in Table 2. Optimised case 1 is expected to have higher bio-oil and char yields. Whereas, optimised case 2 is expected to demonstrate higher gaseous product yield while optimised case 3 is expected to demonstrate higher bio-oil yield.

Table 2: Optimum parameter cases for Pyrolysis of PET.

Case	Base	Optimised 1	Optimised 2	Optimised 3
Pyrolysis Temperature (°C)	450	150	750	150
Pyrolysis Pressure (bar)	1	1	1	10

The results of the economic benchmark for the different optimised cases are illustrated in Figure 3. The process is analysed based on the capital cost, operational cost, and total annualised cost in millions USD (M\$). The base case illustrates the highest capital cost (3.421 M\$), while the optimised case 2 illustrates the highest operating cost (2.255 M\$) and overall annualised cost. The higher operating cost in optimised case 2 is due to the higher heating load to operate the reactor at 750 °C. The total annualised cost is slightly higher for optimised case 2 because of the extra heating load. The optimised case 2 also demonstrates the highest in terms of gaseous product yield approximated at 59%. The higher heating yield of gas at high temperature is due to higher carbon conversion and endothermic reactions as evident from the lower volatile matter and higher carbon content (Anuar Sharuddin et al., 2016). Whereas, the highest bio-oil and char yields are achieved in optimised case 3 with values of 28% and 53%, respectively. Although pyrolysis is usually performed at a lower pressure of 1 bar, investigation of higher pressure pyrolysis is to determine the maximum pyrolysis oil.

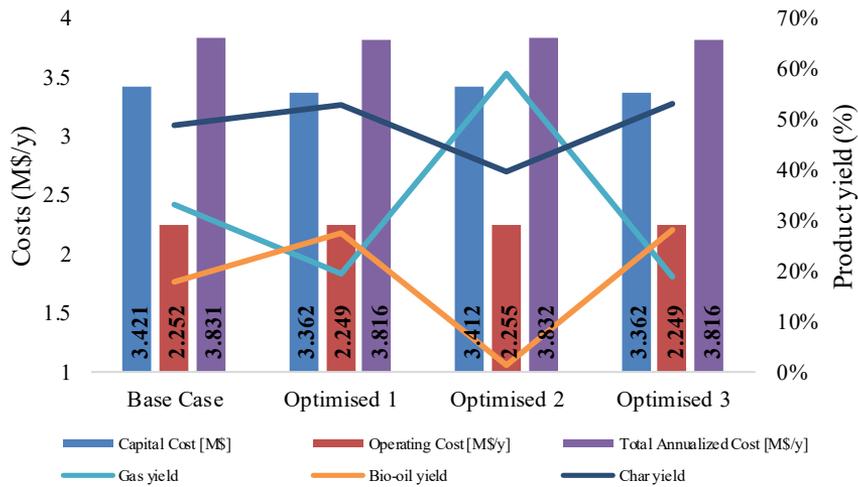

Figure 3: Techno-economic results of PET pyrolysis process.

The results of the environmental impact benchmark and gas quality for the different optimised cases are illustrated in Figure 4. The techno-environmental evaluation demonstrates optimised environmental emissions at a lower temperature of around 150 °C for the optimised cases 1 and 3 compared to the base case with 106 and 101 kg/h CO₂ emissions, respectively. However, the quality of pyrolysis gas is decreased with almost no hydrogen content. Moreover, the increase in temperature to 750 °C of optimum gas production (optimised case 2) demonstrates the best enhancement in the gas quality and the lowest environmental impacts approximated at 86 kg/h CO₂ emissions.

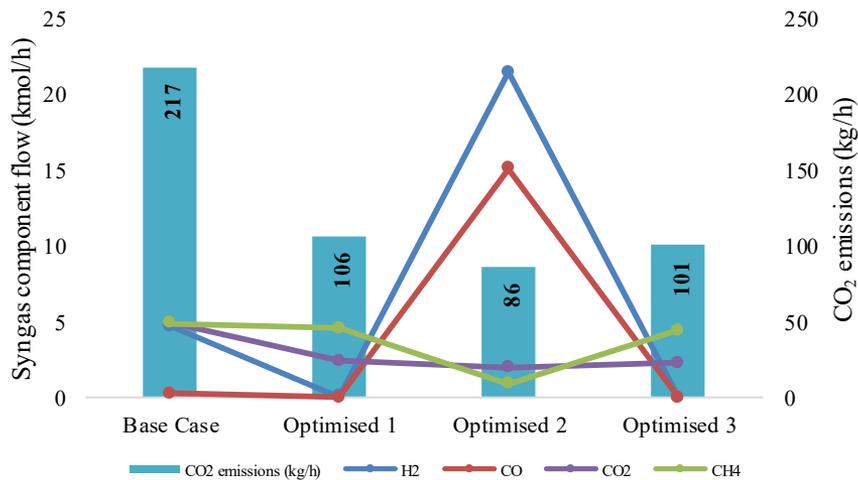

Figure 4: Techno-environmental results of PET pyrolysis process.

4. Conclusion:

The generation of value-added products such as char, oil and gas from the waste plastic (PET) don't contribute to effective PET plastic management only, however it can result

in environment and economic benefits. For this purpose, a process simulation model for the pyrolysis of PET is developed through Aspen Plus. The sensitivity and optimisation of process parameters such as temperature and pressure are conducted to maximise production. The outcomes indicate that the increase in pyrolysis temperature results in an increase in the gaseous product yield from 181 to 633 kg/h. The other two products; bio-oil and char, decrease from 291 and 527 to approximately 0 and 366 kg/h, respectively. The three optimised sets of temperature and pressure are found to maximise the yield of each pyrolysis product. The higher temperature favours the gas production, while oil generation is found to be maximum for higher pressure. The base case illustrates the highest capital cost (3.421 M\$), while the optimised case 2 illustrates the highest operating cost (2.255 M\$), and overall annualised cost with lowest environmental impact (86 kg/h CO₂ emissions). In conclusion, this study provides a basis for techno-economic-environmental feasibility which can support policy makers in making decisions as related to the conversion of PET to value added products.

Monte Carlo Simulation of the Mechanical Processing of Bulk Materials with Fluctuating Compositions – Compositional Probability Density

Karim Khodier^a, Tobias Krenn^a, Lisa Kandlbauer^a, Lisa Tatschl^a, Renato Sarc^a

^a*Chair of Waste Processing Technology and Waste Management, Montanuniversitaet Leoben, Franz-Josef-Strasse 18, 8700 Leoben, Austria*

Abstract

Compositions are omnipresent in process engineering, and often directly interact with process performance. In this work, a Monte Carlo based approach for considering their impact in the case of fluctuating compositions is presented. Based on experimental data, the first component – a model for the compositional probability density is targeted. A variety of descriptive approaches that involve parametric and non-parametric density estimations is discussed. Finally, for a D -dimensional composition, a multivariate Gaussian kernel density estimation for a bijective projection on $D-1$ linearly independent statically constrained coordinates in combination with boundary reflection is presented as a suitable approach.

Keywords: Monte Carlo simulation, kernel density estimation, compositional data, mixed solid waste, reflection

1. Introduction

Process engineers are dealing with compositions all the time. Examples are the chemical compositions of petroleum or combustion gases, but also compositions in terms of particle size fractions' shares. These compositions do not only describe product properties, but also affect the performance of individual processing steps. For example, the share of hydrogen in the reacting gas affects the kinetics of CO-methanation (Kopyscinski, 2010).

Some of these compositions are highly variable. This is especially the case when the input material stream to a process is (untreated) mixed solid waste (cf. Khodier et al., 2021).

Despite the waste's variability, its compositions are often only reported in terms of average values. Such information is not sufficient for calculating process optima, as soon as their dependence on the composition is non-linear. At the same time, optimizing waste processing is becoming more important, considering increasing legally required recycling rates, e.g., due to the Circular Economy Package of the European Union (European Union, 2018).

Based on these considerations, a concept was elaborated for calculating stationary optima for the mechanical processing of mixed solid waste (and in general for composition-dependent processes, with variable compositions): a material model and a process model are coupled through a Monte Carlo simulation. The material composition is described through the probability density distribution of compositions. Virtual model batches of material are created randomly, based on the probability density distribution. The condition of the processing product is then calculated, using a model for the individual process. Finally, all virtual processing products are joint, calculating the resulting overall

product condition. Based on this method, a static optimum of the process can be determined, and moreover the theoretical potential of dynamic material-adaptive processing can be evaluated.

Furthermore, a test scheme was designed, for evaluating the accuracy of the method, based on a lab-scale setup with a circular vibratory screen. The scheme consists of three experiments: first, a compositionally variable mixture of three model materials is sampled, taking at least 100 samples, for testing different descriptive approaches for the probability density distribution. Second, a quadratic regression model for the dependence of the screening efficiency on the composition is derived from a Design of Experiments-based test. Finally, five evaluation runs are performed, where compositionally variable mixtures of the model materials are sampled and screened. The expected compositions and amounts of the output streams are calculated using the suggested Monte Carlo approach and validated by a complete manual analysis of the processing products. The first experiment is covered in this paper, discussing a variety of descriptive approaches for the compositional probability density distribution, their advantages and limitations.

2. Experimental Data Generation

For evaluating different methods for describing the compositional probability density distribution, the variability of waste was experimentally simulated by mixing differently composed mixtures of three granular materials: undersize (with respect to the later used screen) gravel, undersize plastic particles, and oversize quadratic paper pieces. The choice reflects the relevance of an undersize fraction's share on one hand, and the negative influence of two-dimensional oversize particles on screening efficiency, due to the partial covering of the screen's perforation on the other hand (cf. Kaufeld et al., 2017).

The mixed material was then placed on a conveyor belt while ensuring a constant height of the flowing bulk. Finally, every fifth second, a sample, with a sampling duration of one second was taken. For designing the sampling process, Pierre Gy's Theory of Sampling, and its application on mixed solid waste (Khodier et al., 2020) were considered. In total 148 samples were taken. Their compositions are shown in Figure 1.

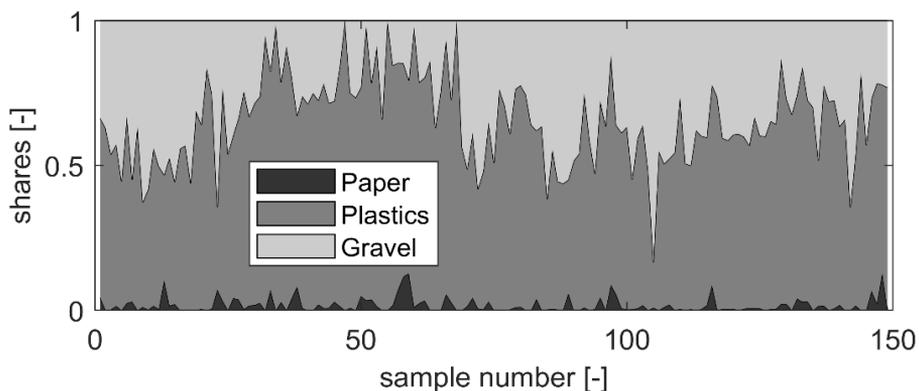

Figure 1: Compositions of the samples.

3. Probability Density Distribution

Compositions are naturally multivariate and constrained: a composition consists of at least two parts, of which each must be zero or positive, and the sum of all parts is constant

(usually 100%). Hence, a D -dimensional composition belongs to a $(D-1)$ -dimensional cartesian subspace of the D -dimensional real space. That subspace is called the D -dimensional simplex (Pawlowsky-Glahn et al., 2015). For three parts, the visualization of this subspace is well known in process engineering: the ternary diagram.

The mathematical nature of compositions must always be kept in mind when working with them. This nature, and also the relevance of correlations in the occurrence of different compositional parts, requires multivariate models for the probability density distribution.

3.1. Parametric Distributions

Parametric distributions describe the probability density through an analytical distribution with a limited number of parameters to be determined. They are hence favourable in terms of compactness and often require fewer individual samples for a reliable model of a population's distribution.

3.1.1. Multivariate Normal Distribution

The most commonly applied parametric distribution is the normal distribution. Its multivariate extension is the multivariate normal distribution. Strictly speaking, it always violates the constraints of the simplex, being positive from $-\infty$ to $+\infty$. Nonetheless, it can be a good approximation, if, e.g., at least 95% of the probability fall within the simplex. For the data at hand, the Henze-Zirkler test from the R-package “MVN” (Korkmaz et al., 2021) was applied, which neglects its multivariate normality. Considering, that multivariate normality requires univariate normality of each individual dimension (Wang, 2015), the univariate non-normality of the Paper fraction according to the Anderson-Darling test (MVN package) is at least one reason for that (Plastics and Gravel are univariate normal each, according to the test).

3.1.2. The Dirichlet Distribution

The Dirichlet distribution is the multivariate extension of the Beta distribution. It is simplicial by nature (i.e., fulfils the constraints of the simplex) and is generated by closing (normalizing to the summation constant) a set of independent, gamma-distributed random variables, with equal scale parameters. Consequently, it is quite inflexible in terms of fitting data, and hence only seldomly applicable for this purpose (Pawlowsky-Glahn et al., 2015).

Due to its inflexibility, in combination with the complexity of finding and applying packages that cover all of parameter estimation, distribution tests, and random number generation, for such a non-mainstream multivariate probability density function, it is not further investigated in this work, which targets finding widely applicable approaches.

3.2. Logarithmic and Log-ratio transformations

Many distributions, like the multivariate normal distribution, do not conform with the constraints of the simplex. For data with a one-sided boundary at zero, e.g., particle sizes, a log-transformation of the data is an often suitable approach. It can also facilitate dealing with compositional data, when the majority of compositional parts are much closer to zero than to one.

The more common approach in the community of compositional data mathematics is applying a so-called log-ratio transformation. For a D -dimensional composition, usually $(D-1)$ such log-ratios are calculated, corresponding to the number of degrees of freedom of the composition, due to the summation constraint. The log-ratios are logarithms of ratios of compositional parts, or products or sums of compositional parts (Greenacre, 2019), with so-called isometric log-ratios being the state of the art (Weise et al., 2020).

In the field of waste management, they have already been applied to waste compositions by Edjabou et al. (2017) and particle size class distributions by Khodier and Sarc (2021). For the data at hand, though, the most significant limitation of log-ratios is obstructive: they are not defined for zeros in the numerator or denominator of the ratio. For multiplicative log-ratios, they are hence not defined, as soon as one compositional part is zero. For the experimental data in this work, log-ratios involving amalgamations still do not solve the issue, since two out of three compositional parts include zeros. While there are zero-replacement approaches to treat that issue (cf. Pawlowsky-Glahn, 2015), their impacts have proven to be problematic, considering that around one third of the samples do not contain paper.

3.3. Non-parametric density estimation

While the compactness of parametric distributions is advantageous, due to the identified issues for the present data and the desired robustness of the modeling approach, non-parametric density estimation was finally targeted, in particular: kernel density estimation, with a multivariate Gaussian kernel.

The general kernel density estimator for the univariate case is shown in Equation (1), where q is the probability density, n is the number of samples, h is the bandwidth, K_i is the kernel function for the sample i , x is the point for which the probability density is estimated and x_i is the value of an individual sample. The kernel function is usually a non-negative, ideally continuous function, which is symmetrical to the origin. A widely applied kernel is the standard normal distribution. The more important choice, though, is the bandwidth, which reflects the amount of smoothing. It is often chosen based on a least-squares evaluation of the kernel density estimation in comparison to the sample data (Nedden, 2012).

$$q(x) = \frac{1}{nh} \sum_{i=1}^n K_i \left(\frac{1}{h} (x - x_i) \right) \quad (1)$$

The multivariate case, using a multivariate Gaussian kernel is shown in Equation (2), where the bandwidth matrix \mathbf{H} corresponds to the covariance matrix of the multivariate normal distribution (Wand and Jones, 1993).

$$q(\vec{x}) = \frac{1}{nh^D} \sum_{i=1}^n \frac{1}{\sqrt{(2\pi)^D |\mathbf{H}|}} \exp\left(-\frac{1}{2} (\vec{x} - \vec{x}_i)^T \mathbf{H} (\vec{x} - \vec{x}_i)\right) \quad (2)$$

3.3.1. Summation constraint

For compositional data, again the constraints of the simplex must be respected. A reliable approach for the summation constraint is a bijective projection of the D -dimensional composition onto $(D-1)$ linearly independent coordinates, as is usually done with the log-ratio transformations. The authors finally decided to follow a pragmatic approach, that does not induce issues with zeros, while the individual projected coordinates have static constraints, being defined from 0 to 1: the first coordinate is the share of one component in the overall composition. The second is the share of another component in the sub-composition that contains all components but the first. Continuing this principle, a defined

representation can be found for all cases, where at least one component is never zero. In this work, the first coordinate is the percentage of paper in the total composition, and the second is the percentage of gravel in the non-paper sub-composition.

3.3.2. Boundaries

While the chosen projection guarantees compliance with the summation constraint, each of the new coordinates is constrained with a minimum of zero and a maximum of 1. An approach for dealing with this in kernel density estimation is so-called reflection, where data is reflected in the boundary (cf. Jones, 1993).

3.3.3. Application on the experimental compositional data

Figure 2 shows the non-normalized histogram of the experimental compositional data and the corresponding bivariate kernel estimate, applying the projection from section 3.3.1 and a lower boundary of -0.00001 and upper boundary of 1.00001 for each dimension. As the Figure shows, the results are promising, while a detailed evaluation is subject to further research.

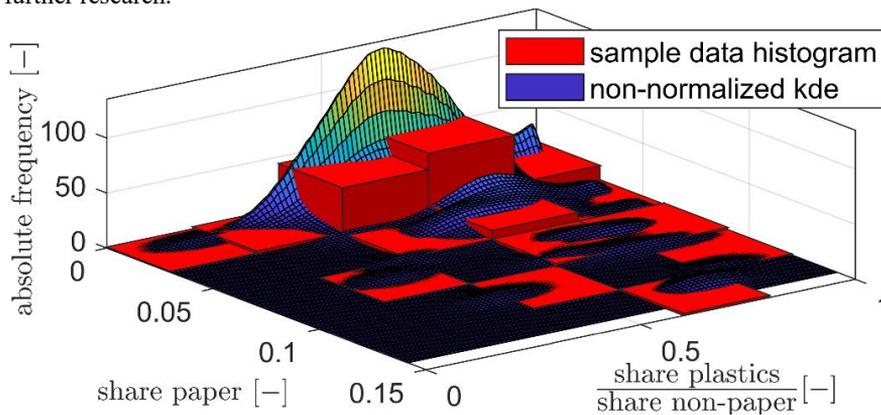

Figure 2: Non-normalized sample data histogram and kernel estimate of the compositional distribution of the experimental data

4. Conclusion and Outlook

There is a variety of approaches for estimating the density distribution of compositional data, including analytical simplicial distributions, non-simplicial distributions of log-ratio transformations and non-parametric density estimations which are adaptable to simplex data. For the investigated data, kernel density estimation, using a multivariate Gaussian kernel, a transformation to shares in sub-compositions and reflection boundaries appears to be a promising approach, and hence may contribute an essential component to the targeted Monte Carlo simulation of the processing of compositionally fluctuating bulks. The in-detail evaluation of the suggested method is still subject to further research. Furthermore, kernel density estimation, using a Dirichlet kernel (Aitchison and Lauder, 1985) is another interesting approach to be considered. Finally, the Monte Carlo approach as a whole will soon be evaluated.

Abstract

Pillow plates are characterised by a high degree of geometrical and manufacturing flexibility, excellent structural strength, hermetic tightness and high thermo-hydraulic efficiency. These advantages open up a wide range of possible applications, and in the last two decades, numerous research studies have been dedicated to the thermo-hydraulic characteristics of pillow plates. In contrast, operational safety of pillow-plate-based equipment has gained limited attention. Due to the lack of design equations, the permissible operating pressure of such equipment is currently determined on the basis of the burst pressure obtained in time-consuming and cost-intensive experiments. In this work, we examine whether the burst pressure can be determined with the aid of finite element simulations. Furthermore, since preliminary studies have shown that the thermal resistance of pillow-plate heat exchangers can be significantly increased if they are fabricated from aluminium instead of stainless steel, we checked whether technically relevant pillow plates can be made of the aluminium alloy EN AW-5083.

Keywords: Pillow plates, Heat exchanger, Finite Element Analysis, Burst pressure

1. Introduction

Along with satisfactory thermal performance, heat exchangers must ensure sufficient operational safety, while both these criteria influence the equipment design. For conventional equipment, such as shell-and-tube heat exchangers, a calculation-based and hence non-destructive verification of the permissible operating pressure is possible by following established regulatory standards, e.g. AD2000 or ASME code. In contrast, pillow-plate-based heat exchangers represent a comparatively novel type of heat transfer equipment that has not yet been fully investigated. Therefore, currently, no appropriate design equations for the determination of the permissible operating pressure exist, mainly because of the high geometrical complexity and variability of pillow plates resulting from the simple fabrication process free of forming tools.

As a first manufacturing step, two superimposed metal sheets are spot-welded by means of a CNC-controlled laser welding machine, allowing the shape and spacing of the welding spots to be arbitrary selected. After welding of the edges and joining the nozzles, the sheets are inflated in a hydroforming process and achieve their characteristic pillow-like shape. The latter ensures high structural strength, which, along with the fully welded, hermetically sealed design, represents one of the main advantages of pillow plates. By arranging several plates in parallel, so-called pillow-plate heat exchangers (PPHX) can be assembled (cf. Fig. 1). These exchangers offer a flow path through the inner channels

of the pillow plates and another flow path through the wavy channels between adjacent plates. The welding spots and the complex, wavy-channel structure cause a periodic disturbance of the boundary layers, resulting in a high thermo-hydraulic performance of PPHX. Along with the planar design, pillow plates can also be shaped cylindrically to be applied as jackets in tempered pipelines and vessels.

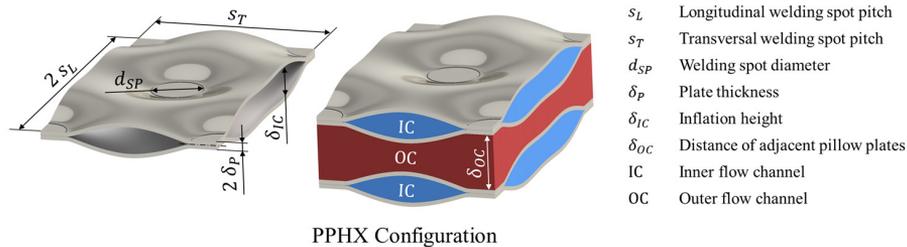

Figure 1. Periodic sections of a pillow plate (left) and of a PPHX composed of two pillow plates (right), adapted from Zibart et al., (2021).

Due to the lack of calculation methods, permissible operating pressure of pillow-plate-based equipment is currently evaluated in dependence on the burst pressure, which has to be determined experimentally by means of expensive and time-consuming burst tests. Previous studies were primarily concerned with the investigation and optimisation of the thermo-hydraulic behaviour of PPHX. Structural mechanics investigations were only carried out by Piper et al. (2015), with the focus on the correct reproduction of the pillow-plate geometry by means of FEM simulations. The burst pressure was determined for only one geometry, while no validation was performed. A comparison with experimental data obtained by the pillow plate manufacturer BUCO Wärmeaustauscher International GmbH showed that the simulations by Piper et al. (2015) significantly underestimate the burst pressure.

This work was aimed at establishing a correct prediction of the burst pressure of pillow plates using finite element methods which can replace experimental burst pressure determination. Furthermore, investigations by Zibart et al. (2021) showed that the thermal resistance of PPHX can be reduced by up to 25% by using aluminium instead of stainless steel. Therefore, in a second step, it was investigated whether technically relevant pillow plates can be manufactured from aluminium with regard to permissible operating pressures and achievable internal channel inflation height.

2. FEM Simulation

The finite element solver ABAQUS (version 2017) by Dassault Systèmes was used, which is well established in both academia and industry. The simulations were carried out in a transient manner with an explicit temporal discretisation. Since large displacements are encountered in the course of simulations, the stiffness matrix depends on geometry. To capture the arising geometric non-linearities, the stiffness matrix is updated in each time increment. In contrast to our approach, Piper et al. (2015) determined the stiffness matrix only once in the initialisation step of the simulation. Consequently, the increase in stiffness of the sheets associated with the formation of the shell-like pillow plate structure could not be captured in the simulations, and this was probably the main reason for the significant underestimation of the burst pressure in that work.

Further non-linearities result from the elasto-plastic material behaviour. In this work, along with the stainless steel AISI304, the most commonly used material for the manufacturing of pillow plates, the aluminium alloy EN AW-5083 was also considered.

Compared to other aluminium alloys, it is characterised by comparatively high strength combined with good forming capabilities. Furthermore, it offers good corrosion resistance and weldability. Thus, no filler material is required for welding, making EN AW-5083 ideally suited for laser welding. The non-linear plastic material behaviour exemplified in Fig. 2 was taken into account in the simulations.

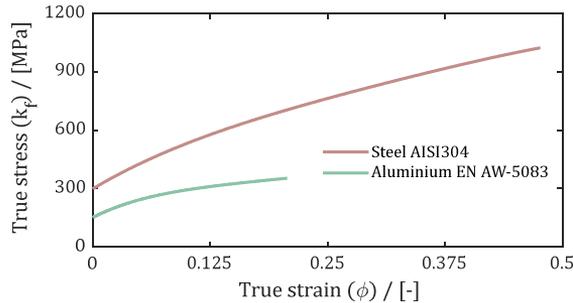

Figure 2. Flow curves of AISI304 and EN AW-5083 (Ostermann, 2007; Barthelmie, 2017).

For both steel and aluminium alloy, the Young's modulus, Poisson's ratio and yield strength, which characterise the linear elastic material behaviour, are summarised in Table 1. The so-called 'Ductile Damage Model' from ABAQUS was used to capture the bursting process in the simulations. The model parameters were fitted in such a way that computational elements completely lose their stiffness when they reach the material-specific elongation at break and are consequently eliminated from the computational mesh. Thus, cracks arise at the most highly stressed locations, which finally leads to the bursting of the pillow plate due to further crack growth. In order to decrease the computational effort, the simulation domain was reduced to the smallest possible characteristic section of a pillow plate, taking into account symmetries with regard to geometry and load. The chosen simulation domain has the dimensions s_L and $0.5s_T$. A mid-cut was performed in the thickness direction of the pillow plate, which separates the two metal sheets along their contact surfaces in the welded areas. The initial state represents a welded but still flat sheet as it is before the hydroforming process. The boundary conditions used are shown in Fig. 3.

Table 1. Elastic material parameters.

Material	Young's modulus / [GPa]	Poisson's ratio / [-]	Yield strength / [MPa]
AISI304	200	0.3	637
EN AW-5083	70.3	0.33	285

Symmetry boundary conditions in x - and y -direction were set at the lateral end faces, while symmetry boundary conditions in z -direction were specified at the free-cut contact surfaces of the plates in the welding spot regions. This causes a blockage of the translation in the respective coordinate direction as well as of the rotations around the other two coordinate axes. The free surface of the plate between the welding spots, which forms the inner channel wall of the pillow plate, was subjected to pressure. For the burst pressure determination, a physical duration time of $t_{max} = 1000$ s with a time step of $\Delta t = 0.001$ s was simulated. Here, the pressure was increased linearly from $p = 0$ bar at $t = 0$ s to p_{max} , which corresponds to t_{max} . At the beginning of each simulation, the burst pressure is not known. Therefore, p_{max} must be determined iteratively, until the condition $p_{max} > p_{Burst}$ is fulfilled and mechanical failure of the pillow plate is encountered. Care

was taken to ensure that p_{max} is only slightly higher than p_{Burst} , so that the strain rates and thus inertia effects are kept as low as possible. To determine the maximum inflation height, the simulation time was increased to $t_{max} = 2000$ s, while keeping the time step at $\Delta t = 0.001$ s. Up to $t = 1000$ s, pressure increases linearly to p_{max} . This is followed by a static phase until $t = 1500$ s, in which pressure is kept constant in order to eliminate inertial effects. In this case, p_{max} was iteratively determined in such a way that bursting during the static phase was avoided. Subsequently, pressure was linearly reduced to $p = 0$ bar at t_{max} in order to remove elastic strains.

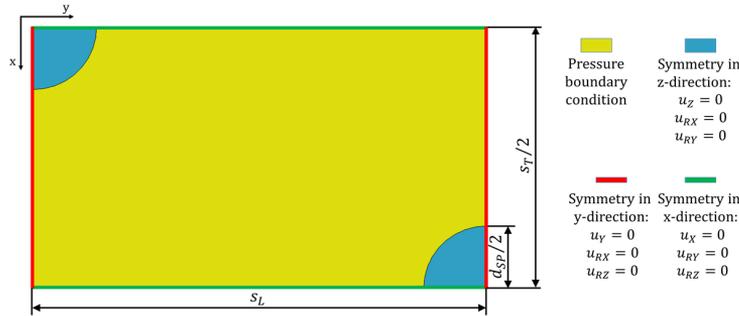

Figure 3. Applied boundary conditions shown on the inner surface of the initially undeformed plate.

Structured hexahedral computational grids were used to achieve a high computational accuracy combined with high computational efficiency. The ABAQUS specific computational element of type C3D8R was chosen, as this element type was proven in the work of Dancette et al. (2012) for the investigation of welding spot failures.

3. Validation

For the validation of the simulations, the pillow plate manufacturer BUCO provided protocols of burst tests carried out for two geometrically strongly different pillow plates. The geometry parameters of these plates are summarised in Table 2.

Table 2. Geometries used for validation.

Case	$2s_L$ / [mm]	s_T / [mm]	d_{SP} / [mm]	δ_p / [mm]	Reference
VAL1	95	55	10	1	BUCO
VAL2	52	30	11	1.5	BUCO

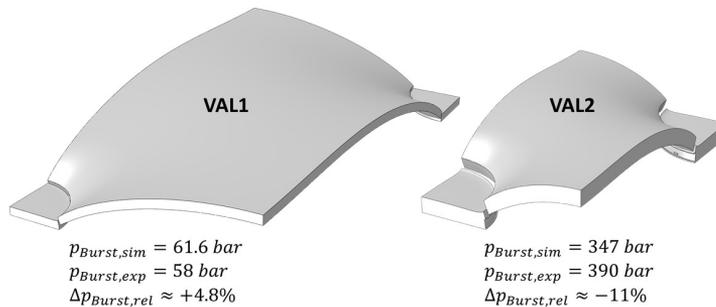

Figure 4. Results of the FEM simulations carried out for VAL1 and VAL2: the deformed geometries for the first time step after bursting of the pillow plates.

Both pillow plates were made of AISI304. The simulation results are illustrated in Fig. 4, showing the deformed plate geometries in the first time step after bursting. For the VAL1 geometry, the simulation with $p_{Burst,sim} = 61.6 \text{ bar}$ shows an overestimation of the experimentally determined burst pressure ($p_{Burst,exp} = 58 \text{ bar}$) of approx. 4.8%. The experimental burst pressure ($p_{Burst,exp} = 390 \text{ bar}$) for the VAL2 geometry is approx. 11% underestimated by the simulation with $p_{Burst,sim} = 347 \text{ bar}$. The agreement between simulated and measured values can be considered satisfactory for both geometries, and hence, the performed FEM simulations are successfully validated.

4. Results

After the successful validation of the FEM simulations, the next step was to investigate whether the aluminium alloy EN AW-5083 would be a suitable material for pillow plates. In this study, welding spot pitches $2s_L$ and s_T matching VAL1 and VAL2 geometries were chosen, while the welding spot diameter ($d_{SP} \in \{10; 11; 12\} \text{ mm}$) and the plate thickness ($\delta_p \in \{1; 1.5; 2\} \text{ mm}$) were varied. The burst pressure was found to increase almost proportionally with increasing welding spot diameter and plate thickness (cf. Fig. 5). This is due to the fact that in the region of the welding spots, the load-bearing material cross-section depends linearly on d_{SP} and δ_p . Furthermore, it can be seen that the burst pressures are significantly higher for smaller welding spot pitches. This stems from the fact that the number of welding spots per unit area increases. Thus, at equal acting pressure, the forces affecting each welding spot become smaller and consequently higher pressures can be withstood. Comparing the results with those of VAL1 and VAL2 geometries, it becomes apparent that the burst pressures are approx. 80% lower than for the counterpart made of AISI304. Considering the significantly lower tensile strength and elongation at break of EN AW-5083, this result is not surprising.

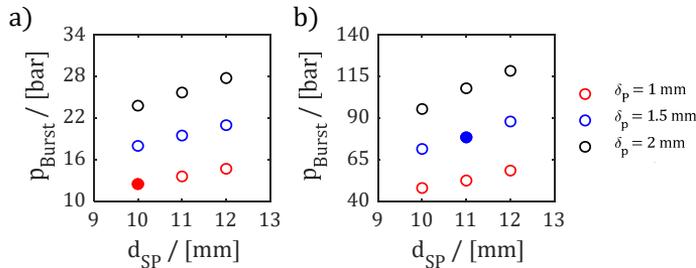

Figure 5. Burst pressure in dependence on the welding spot diameter for $2s_L = 95 \text{ mm}$, $s_T = 55 \text{ mm}$, $\delta_p \in \{1; 1.5; 2\} \text{ mm}$ (a), $2s_L = 52 \text{ mm}$, $s_T = 30 \text{ mm}$, $\delta_p \in \{1; 1.5; 2\} \text{ mm}$ (b); filled circles denote geometries matching VAL1 resp. VAL2.

Fig. 6 shows the maximum achievable inflation height ($\delta_{IC,max}$) for the investigated pillow-plate geometries plotted against welding spot diameter. Comparing Fig. 6a with 6b, it can be seen that $\delta_{IC,max}$ decreases with reducing welding spot pitch, which results from the decreasing free bending length. Furthermore, $\delta_{IC,max}$ decreases with increasing plate thickness due to the growing bending stiffness of the plates. The dependence of the maximum inflation height on the welding spot diameter is much less pronounced than for the burst pressure. It is also visible that the trends are different, namely, for $2s_L = 52 \text{ mm}$ & $s_T = 30 \text{ mm}$, $\delta_{IC,max}$ decreases with increasing d_{SP} , whereas for $2s_L = 95 \text{ mm}$ & $s_T = 55 \text{ mm}$, $\delta_{IC,max}$ increases with increasing d_{SP} . When considering the thermo-hydraulic performance of pillow plates, Piper et al. (2016) showed that the thermo-hydraulic efficiency (heat flowrate divided by required pumping power) for inner channel

flow depends almost quadratically on δ_{IC} . Small values of δ_{IC} mean small effective flow cross-sections, resulting in high flow velocities and thus high pressure drop. For this reason, expansions of $\delta_{IC} < 3 \text{ mm}$ should be regarded as technically irrelevant. Fig. 6a shows that with a welding spot pitch of $2s_L = 52 \text{ mm}$ & $s_T = 30 \text{ mm}$, technically relevant pillow plates can only be realised with a plate thickness of $\delta_p = 1 \text{ mm}$ and a further pitch reduction is not useful. For the remaining pillow plate geometries of this study, which are considered to be technically relevant, a maximum burst pressure of approx. 60 bar was obtained (cf. Fig. 5, for the geometry with $2s_L = 52 \text{ mm}$ & $s_T = 30 \text{ mm}$, $\delta_p = 1 \text{ mm}$, $d_{SP} = 13 \text{ mm}$). According to AD2000, a safety factor of 5 must be taken into account, so that a maximum permissible operating pressure of approx. 12 bar can be achieved with pillow plates made of EN AW-5083. Thus, pillow plates made of aluminium are mainly suitable for low-pressure applications, but can offer significant advantages due to their lower thermal resistance and much lower weight.

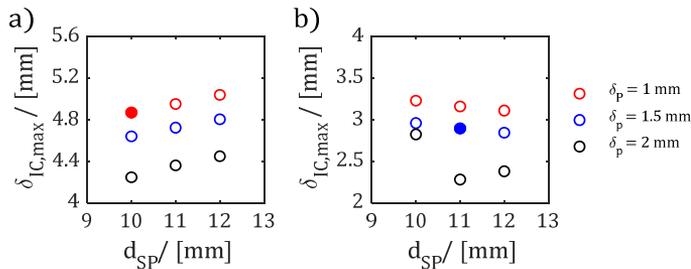

Figure 6. Maximum inflation height in dependence on the welding spot diameter for $2s_L = 95 \text{ mm}$, $s_T = 55 \text{ mm}$, $\delta_p \in \{1; 1.5; 2\} \text{ mm}$ (a), $2s_L = 52 \text{ mm}$, $s_T = 30 \text{ mm}$, $\delta_p \in \{1; 1.5; 2\} \text{ mm}$ (b); filled circles denote geometries matching VAL1 resp. VAL2.

5. Conclusions

It was demonstrated that FEM simulations are suitable for predicting the burst pressure and hence the operating pressure of pillow plates. A validation with experimental data showed a maximum deviation of 11%. Furthermore, it was found that technically relevant pillow plates with a burst pressure of up to 60 bar can be manufactured from the aluminium alloy EN AW-5083, which corresponds to a permissible operating pressure of approx. 12 bar . Thus, pillow plates made of aluminium alloys can be judged as a good alternative for low-pressure applications, providing lower thermal resistance and lower mass compared to steel-made pillow plates.

Abstract

Brackish water desalination is one of the most promising methods to generate freshwater for the community in water-scarce regions. The current research proposes a hybrid Multi Effect Distillation and Thermal Vapor Compression (MED-TVC) and double Reverse Osmosis (RO) system for brackish water desalination for the Jordanian arid and semi-arid regions. In this regard, ten effects MED system was coupled with two permeate and retentate reprocessing designs of RO processes to desalinate brackish water. For this purpose, the model for the hybrid system developed by the same authors in the past has been used for simulation. For a given set of brackish water properties, the indicators such as the freshwater productivity, freshwater salinity, specific energy consumption, and disposed brine flow rate are used to evaluate the performance of the process in terms of economics and environment. The results show that freshwater can be produced from brackish water with high productivity and reduced specific energy consumption and with reduced brine flow rate into the environment compared to seawater desalination.

Keywords: Brackish Water Desalination; Multi Effect Distillation; Reverse Osmosis; Productivity; Specific Energy Consumption; Disposed Brine Flow Rate.

1. Introduction

Jordan is basically suffering from water shortage as it is located in a transitional position between arid and semi-arid climatological zones of mild rainy winter and hot dry summer. Menzel et al. (2007) stated that Jordan has approximately 90,000 km² of the semi-arid region stretching from the upper north of the Jordan basin to the south in the Gulf of Aqaba, and from the Mediterranean coast to the Jordanian Highland / Jordanian Plateau. Furthermore, the growth of population and industrialization besides the climate change and uneven spatial distribution of water resources with over-exploitation of aquifers have increased water demands that possibly would cause future water conflict. In such a complicated situation, the ground and surface water treatments are a long-term and vital solution to the issue of water scarcity specially for those coastal regions such as Red Sea region (Afonso et al., 2004). Furthermore, the wastewater reclamation and reuse is another alternative source of freshwater in arid and semi-arid regions in Jordan (Saidan et al., 2020).

The techno-economic feasibility of instilling RO system to desalinate brackish water in the Zarqa basin, Jordan was investigated by Afonso et al. (2004). This study demonstrated

the success of RO system for providing freshwater. However, the membrane fouling was one of many challenges in the water desalination. In this regard, Walschot et al. (2020) discussed in detail the challenges faced by RO desalination in Jordan despite the increasing utilisation of the process. They stated that RO desalination plants require higher maintenance than thermal desalination plants (due to fouling propensity) besides other environmental concerns. On the other hand, the thermal desalination system such as multi effect distillation is another commercially viable water desalination method which has been extensively used to generate a vast amount of freshwater, but with higher energy consumption and higher investment and operational cost compared to RO system (Filippini et al., 2018). This explains the expansion of water desalination using membrane technology and thermal processes. Jones et al. (2019) confirmed the existence of 16000 desalination plants around the world which use RO process, Multistage Flash (MSF), and MED that share 69%, 18%, and 7%, respectively, to produce 95 million m³/day of freshwater.

The potential of integrating both membrane and thermal technologies in a hybrid system was assessed by several colleagues and demonstrated its robustness to mitigate the drawbacks of individual processes and enhance the overall operation (Filippini et al., 2019). However, the high energy consumption of seawater desalination using the hybrid system still remains a challenge (Al-hotmani et al., 2021). Fera-Diaz et al. (2021) confirmed an intensive specific energy consumption between 14 to 21 kWh/m³ of MED-TVC system for seawater desalination. However, this is not the case for brackish water desalination using MED and RO hybrid system. Thus, it is imperative to analyse the potential of investigating the viability of a hybrid system of MED and double RO processes for brackish water desalination in arid and semi-arid regions in Jordan due to lower salinity of feed water compared to seawater. In other words, this research will introduce a feasible option of water desalination in Jordan compared to seawater desalination. For the first time, this study attempts to assess the feasibility of constructing a hybrid system of MED and permeate reprocessing and retentate reprocessing RO processes to desalinate brackish water in the coastal area of Red Sea in Jordan. The simulation results of this system including the performance indicators will be compared against the results of seawater desalination to evaluate the operational, economic, and environmental perspectives of brackish water desalination.

2. Description of MED-TVC and double RO processes

Fig. 1 shows a schematic diagram of the hybrid system of permeate reprocessing and retentate reprocessing RO processes (PRRO and RRRO) and MED-TVC system to desalinate brackish water. The PRRO process is designed as 20, 15, and 8 of pressure vessels (PVs) in a series where each PV contains eight spiral wound membranes synthesised by Toray, USA (brand: TM820M-400/SWRO of 37.2 m²). The water is fed into PRRO process using a high pressure pump of 85% efficiency. The forward MED-TVC system is designed of ten effects connected to thermal vapor compression (TVC). The combined brine streams of PRRO and MED-TVC are fed for further refining into the third process of RRRO. The temperature of the inlet stream of RRRO process is moderated to a specified temperature using a heat exchanger. The RRRO process is designed to process high flowrate of brackish water in 40, 30, and 16 PVs configuration. The fresh water of RRRO process is combined to the product water of PRRO and MED-TVC to form the final product stream of freshwater. However, the brine stream of RRRO process represents the brine disposal stream back to the environment.

8	Specific energy consumption of RRRO	$E_{s,RO} = \left\{ \frac{[(P_{f(plant)} \times 101325) Q_{f(plant)}]}{\frac{\eta_{pump} Q_{p(plant)}}{3600000}} \right\}$	kWh/m ³

4. Simulation and performance evaluation of the brackish water desalination system using MED-TVC and double RO processes

This section utilises the simulation of MED and double RO process (presented in Figure 1). The brackish water is simultaneously fed to the PRRO and MED-TVC processes at 3000 ppm and 25 °C of salinity and temperature, respectively. The operating pressure and feed flow rate of PRRO process are 50 atm and 5011.2 m³/day, respectively. For both cases of seawater desalination and brackish water desalination, the feed flow rate and brine temperature of MED-TVC system are same (16867.24 m³/day and 40 °C). The brine salinity for seawater is 60000 ppm for inlet salinity 39000 ppm while for brackish water is 4615 ppm for inlet salinity of 3000 ppm. Also, the motive steam of TVC is designed at 8 kg/s, 1300 kPa, and 70 °C of steam flow rate, pressure, and temperature, respectively. The combined brine of MED and PRRO is fed at 50 atm into the RRRO process. However, the inlet brine temperature of RRRO process is moderated to 25 °C using a heat exchanger (Fig. 1).

Table 3 shows the simulation results of desalinating brackish water including the most important performance indicators of the hybrid system of MED-TVC and double RO process. To justify the potential of this hybrid system, the simulation results of treating seawater of 39000 ppm at 25 °C are included in Table 3 for the purpose of comparison. This indicates that brackish water desalination using the hybrid system has a considerable increase of freshwater productivity of 20996.41 m³/day compared to 8516.66 m³/day of seawater desalination. This is an approximate growth of 146% leading to the reduction of

total specific energy consumption by 58.8%. The brackish water desalination of 3000 ppm produces a high quality water of less than 100 ppm compared to 277.87 ppm of seawater desalination of inlet salinity 39000 ppm besides attaining a high water recovery of 95.96%. Moreover, the concern of disposing brine into the environment is significantly reduced by 93.4%, which highlights a merit of brackish water desalination. The simulation results indicate the potential of constructing the proposed design of MED and double RO processes for arid and semi-arid regions in Jordan due to its superiority of producing freshwater of a high productivity compared to seawater desalination. In turn, this would be a cost-effective solution to tackle the issue of water shortage in Jordan.

Table 3. Simulation results of the hybrid system for two types of treated water

Water type	Salinity of feed water (ppm)	Productivity (m ³ /day)	Specific energy consumption (kWh/m ³)	Salinity of fresh water (ppm)	Water recovery%	Disposed brine flow rate (m ³ /day)	Salinity of disposed brine (ppm)
Brackish water	3000	20996.41	6.50	75.06	95.96	882.01	72762
Seawater	39000	8516.66	15.78	277.87	38.92	13361.77	63689.93

5. Conclusions

Water desalination from brackish water source was recognised as one of the most promising methods to produce freshwater in arid and semi-arid regions of water shortage. This research attempted to develop a new option of water desalination in Jordan based on brackish water compared to seawater desalination. Thus, a hybrid system of MED and double RO processes to desalinate brackish water has been introduced and analysed. The associated results confirmed the superiority of the proposed system and it looks very promising option in Jordan. The potential of the proposed hybrid system was assessed via comparing the simulation results with those obtained for seawater desalination. In turn, the proposed hybrid system has water recovery of 95.96% with lower energy consumption of 6.5 kWh/m³ compared to seawater desalination option.

Abstract

Enzymatic esterification reactions of fatty acids with sugars generate non-ionic biosurfactants widely used in food, pharmaceutical and cosmetic industries, because of their high capability to reduce surface and interfacial tensions. In turn, mathematical modeling can be a useful tool, in its different approaches, for the simulation and optimization of enzymatic processes. Particularly, neural and fuzzy approaches are still scarcely evaluated for data of producing sugar fatty acid esters. Thus, this study aimed at using these approaches to model data of enzymatic esterification of fatty acids (oleic and lauric acids) with xylose, catalyzed by immobilized lipase B from *Candida antarctica* (CALB-IM-T2-350) and CALB immobilized on silica magnetic microparticles (SMMPs) modified with octyl groups (CALB-SMMP-octyl) or octyl+glutaraldehyde moieties (CALB-SMMP-octyl-glu). Using Matlab Neural Network Toolbox, five artificial neural networks (ANNs) were trained to predict the reaction rate, one for each type of biocatalyst and acid, obtaining R-squared values greater than 0.97. Furthermore, as an additional effort in neural modeling, two new ANNs were fitted (for two of the biocatalysts), each one of them incorporating, in its inputs, an option referring to the type of acid. R-squared values above 0.98 indicated good predictive capability. To carry out the modeling study by fuzzy inference systems, the Neuro Fuzzy Designer tool from ANFIS (Adaptive Network-Based Fuzzy Inference System) of Matlab was used. Fuzzy models were built for each of the three biocatalysts under study (CALB-IM-T2-350, CALB-SMMP-octyl and CALB-SMMP-octyl-glu), considering as input linguistic variables the type of acid, the temperature, the reaction time and the substrates molar ratio, to predict the conversion of the esterification process. Gaussian membership functions and linear output functions were used, in a Takagi-Sugeno's fuzzy approach. The fuzzy systems parameters were fitted by a hybrid parametric optimization method. The results showed that the fuzzy model outputs were very close to the targets, with RMSE (root mean squared error) values below 0.006. Finally, to demonstrate the potential of fuzzy modeling to optimize processes, response surfaces were built for the conversion of xylose as function of different operating conditions. The fuzzy surfaces indicated that higher values of xylose conversion are reached after 45 h of reaction, temperatures above 50°C, and at substrates molar ratio of 1:0.2 (acid:sugar). Thus, the present work presents, in a broad way, the potential of computational intelligence tools in the study of enzymatic production of biosurfactants.

Keywords: biosurfactants, artificial neural networks, fuzzy logic.

1. Introduction

Sugar fatty acid esters (SFAEs) are surfactants mainly applied in food, pharmaceutical and cosmetic industries (Colla *et al.*, 2010; Khan; Rathod, 2015). From the process point of view, different conditions can be applied to produce biosurfactants by heterogeneous biocatalysts using immobilized lipases. Therefore, the mathematical modeling of enzymatic reactions can be a useful tool for process simulation and optimization. This technique allows the prediction of the effects on the process due to changes in operating conditions, pointing towards factors that most influence the conversion of substrates. In addition, mathematical modeling can be applied in optimization projects, equipment sizing, economic feasibility analysis and scale-up (Nelles, 2001). However, in some situations, when complex phenomenological (white-box) models are not able to fully describe a certain reaction process, the use of black-box or gray-box models can be an interesting choice. Besides, rational exploration of the parametric space of a white-box model can impose a huge load of work (which is usually very time consuming), to guarantee that the set of mechanistic parameters satisfy chemical/biochemical and physical meanings (even more when considering possible correlations between them). Among black-box and gray-box models, stands out Artificial Neural Networks and fuzzy systems. Thus, the present work deals with the mathematical modeling of enzymatic syntheses to produce biosurfactants under two distinct approaches: use of artificial neural networks and the development of a fuzzy model.

2. Methodology

The experimental data for esterification modeling was provided by Lima *et al.* (2016). The dataset was acquired based on the syntheses of xylose esters obtained by esterification with oleic or lauric acid in tert-butyl alcohol. The experiments were conducted under the following conditions: stirring speed of 300 rpm, 72h of reaction, 1g of molecular sieve, acid-xylose molar ratio (substrates molar ratio) of 1:0.2 (base case), load of activity of $37.5 U_E/g_{acid}$ and reaction temperatures of 46°C and 55°C. The biocatalysts employed were immobilized lipase B from *Candida antarctica* (CALB-IM-T2-350) and CALB immobilized on silica magnetic microparticles (SMMPs) modified with octyl groups (CALB-SMMP-octyl) or octyl+glutaraldehyde moieties (CALB-SMMP-octyl-glu).

2.1. Modeling by artificial neural networks (ANNs)

Initially, five ANNs were trained based on xylose concentration data (mM) along time (h), one for each type of biocatalyst and acid. Training targets consisted of the experimental esterification data of sugar consumption rate ($mmol.L^{-1}.h^{-1}$) for both temperatures (46°C and 55°C). Construction and training of neural networks were performed using Matlab Neural Network Toolbox. A two-layer feed-forward network was designed for training, while classical backpropagation learning algorithm was used to adjust the weights and bias. After several tests, the architecture chosen for networks 1, 2, 4 and 5 was one hidden layer of 2 sigmoid neurons, followed by an output layer of a single linear neuron. Network 3, in turn, contained 5 sigmoid neurons followed by an output layer of a single linear neuron. Finally, to further study the potential of neural network modeling, two new ANNs were fitted (for two of the biocatalysts), each one of them incorporating, in its inputs, an option referring to the type of acid. Thus, the data initially used in the fit of networks 1, 2, 4 and 5 were grouped according to the type of biocatalyst, and two new (final) neural networks were obtained (6 and 7, “replacing” networks 1, 2, 4 and 5).

2.2. Modeling by fuzzy systems

To model the process using a fuzzy inference system (FIS), the linguistic input variables chosen were: temperature (T), substrates (acid-sugar) molar ratio (SMR), reaction time (t) and fatty acid type (FA). Xylose conversion was chosen as the output variable. Aiming to improve the quality of the FIS adjustment, further data was added from an interpolation made at 36h.

Matlab fuzzy logic toolbox was used to build the inference systems according to the type of biocatalyst. For each input variable, the respective linguistic values were identified: fatty acid (oleic and lauric), temperature (low and high), reaction time (low, medium and high) and SMR (low, medium and high). All membership functions chosen were Gaussian type. As the ANFIS (Adaptive Network-Based Fuzzy Inference System) tool used to generate the final FIS only supports Takagi-Sugeno fuzzy systems, the output was a linear function of the inputs as shown in Equation 1:

$$f(FA, T, t, SMR)_i = a * FA + b * T + c * t + d * SMR + e \quad (1)$$

Where “a”, “b”, “c”, “d”, and “e” represent fitting parameters.

For each model (or biocatalyst) 36 fuzzy If-Then rules were established based on the combination of the 10 linguistic values (e.g., Equation 2), where f_i is the linear combination described in Equation 1.

$$IF \text{ FA is oleic and T is low and t is low and SMR is low THEN conversion is } f_i \quad (2)$$

For the FIS training phase ANFIS tool was employed. This technique adjusts fuzzy parameters by mapping inputs and outputs based on process data and a feedforward neural network with a hybrid learning technique. In the forward pass, the consequent parameters are calculated by a least square method. In the backward pass, the error is back propagated, and the premises parameters are updated based on the gradient descent method.

3. Results and discussion

3.1. Modeling by ANNs

During the neural networks training to predict the rate of xylose consumption in the biosurfactant synthesis processes, R-quadratic values higher than 0.97 were obtained (from the comparison between the network output and its targets values), indicating a very good performance of the networks. Graphics of enzymatic kinetics were drawn from the output data of the networks. It was verified a very consistent fit of the five ANNs to the experimental data provided.

Figure 1 shows one of the enzymatic kinetics graphs, drawn from the output data of network 3, which refers to the syntheses of xylose laurate catalyzed by CALB-SMMP-octyl at two temperatures. The graph shows the reaction rates calculated from the experimental data and the rates estimated by the neural network modeling (dotted lines).

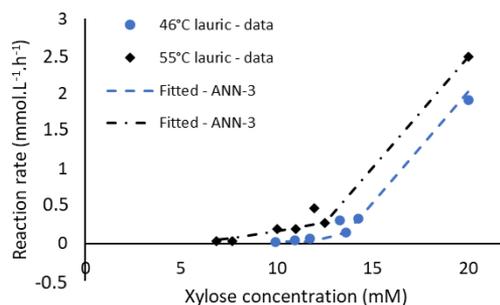

Figure 1: Kinetic modeling of xylose laurate syntheses catalyzed by CALB-SMMP-octyl at two different temperatures (ANN-3).

It can be observed that reaction rate curve at 55°C presented higher reaction rates than for the esterification at 46°C, throughout the profile. Therefore, it is indicated the possibility of acquiring xylose laurate synthesis behavior, reaction rates and sugar concentration by simple interpolation between the curves.

To further study the potential of neural network modeling, the data used in the fit of networks 1, 2, 4 and 5 were grouped according to the type of biocatalyst. Therefore, two new networks were created and trained: ANN-6 (with 5 neurons in the hidden layer, biocatalyst CALB-IM-T2-350, for oleic and lauric acids at 46 and 55°C) and ANN-7 (with 3 neurons in the hidden layer, biocatalyst CALB-SMMP-octyl-glu for oleic and lauric acids at 46 and 55°C). Regression analysis for networks 6 and 7 presented R-squared above 0.98, which suggests very good predictive capability. The kinetic graphs created after training the networks are shown in Figure 2.

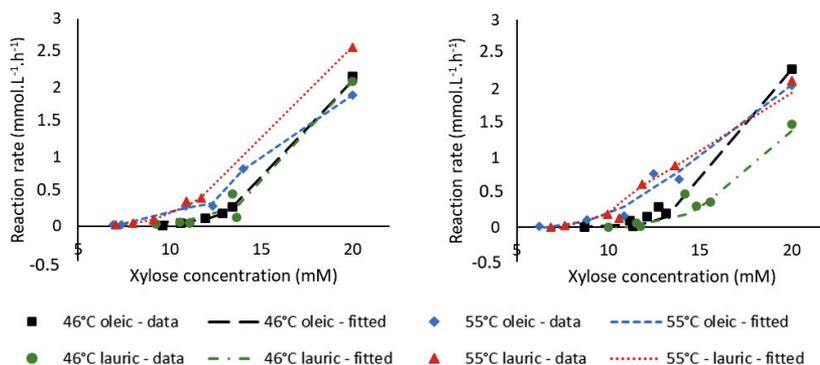

Figure 2: Kinetic modeling of xylose ester syntheses catalyzed by (A) CALB-IM-T2-350 (ANN-6) and (B) CALB-SMMP-octyl-glu (ANN-7) at different temperatures and with two fatty acids.

Once more, the modeled neural networks ANN-6 and ANN-7 presented a good fit to the experimental data. In Figure 2-A, an overlapping of the reaction curves occurred at 46°C for both acids, indicating that there is no influence regarding the type of fatty acid employed when the reaction occurs at this temperature. In general, it was possible to notice higher reaction rates for reactions at 55°C. For the CALB-SMMP-octyl-glu

biocatalyst, indicated in Figure 2-B, the curves at 55°C showed that there was no hard influence regarding the type of fatty acid.

3.2. Modeling by fuzzy systems

The adjustments of the input membership functions and output linear equation parameters of FIS were performed by ANFIS. During the testing phase, root mean squared error (RMSE) values below 0.006 were obtained for all inference systems, proving that the model outputs were similar to the experimental ones (indicating almost perfect fits). Proper graphs of xylose conversion along time were plotted (by fixing the type of fatty acid and the substrates molar ratio in 1:0.2). The graphs in Figure 3 were elaborated considering experimental esterification data and the predicted values by the fuzzy models at 46°C, 50°C and 55°C.

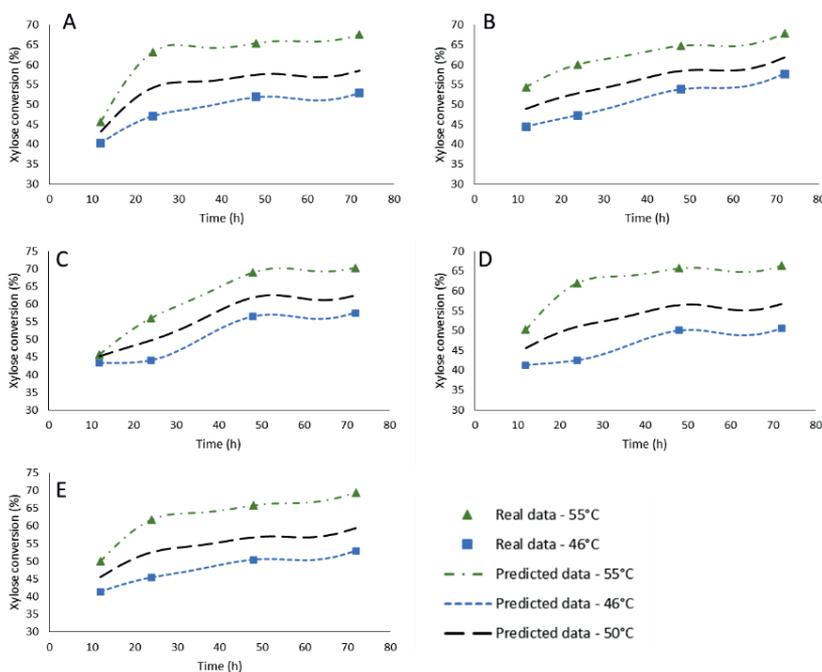

Figure 3: Fuzzy modeling of xylose ester syntheses with (A) oleic acid and CALB-IM-T2-350, (B) lauric acid and CALB-IM-T2-350, (C) oleic acid and CALB-SMMP-octyl-glu, (D) lauric acid and CALB-SMMP-octyl-glu, (E) lauric acid and CALB-SMMP-octyl.

Promising results regarding the modeling of the esterification process, by the fuzzy model, were obtained. It is worth noticing that the intermediate reaction conversion at 50°C was predicted by the fuzzy systems, at which no experimental data was available.

To further demonstrate the potential of fuzzy modeling for optimization of the operating conditions, response surface graphs were built combining the three input variables (temperature, reaction time and the substrates molar ratio) in pairs, for each biocatalyst, separated by fatty acid type. Figure 4 shows the response surfaces from the fuzzy model referred to the CALB-IM-T2-350 biocatalyst.

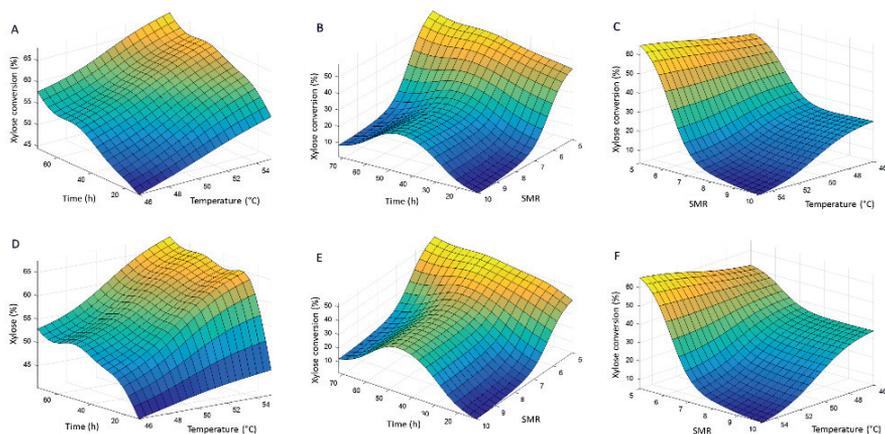

Figure 4: Response surfaces from the fuzzy model referred to xylose esterification with oleic (A, B, C) and lauric (D, E, F) acids by CALB-IM-T2-350.

It is possible to notice similarities between the response surfaces results with those from Lima *et al.* (2016). In general, the highest values of xylose conversion are reached after 45h of reaction, at high temperatures (55°C) and in the lowest condition of SMR (1:0.2 = 5).

4. Conclusions

ANN modeling successfully predicted the behavior of the xylose esterification process in biosurfactant syntheses for three different biocatalysts. All ANNs presented R-squared values higher than 0.97, which was translated to reliable mathematical models for the esterification processes. To expand the computation analysis, fuzzy logic was used to build fuzzy models of the esterification processes. Results point towards an excellent prediction of xylose conversion under experimental conditions, with RMSE values below 0.006, as well as under intermediate temperatures. In addition, it was showed the potential of fuzzy models for optimizing operational conditions as an alternative to the use of regression models in response surface methodologies.

Abstract

It is desired to model the effect of three input features, the LPG flow rate, drum rotation speed and blower speed on the measured temperature profile in a rotating drum coffee roaster of a 30 kg capacity for operator prediction purposes. The performance of a first-principles model of this rotating drum coffee roaster (Schwartzberg, 2002) is compared to the performance of a composite/hybrid empirical model. The hybrid empirical model is composed of two gradient boosted regression trees and an artificial feedforward neural network which predicts two characteristic portions of the measured temperature profile by accurate prediction of the minimum in measured temperature. The first-principles model under-predicts the heat transfer to the coffee beans and as a result over-predicts the minimum temperature point when compared to true data. The relevant root mean squared error (RMSE) between the Schwartzberg model and the true measured temperature of an unseen test set of data is calculated as 23.05 as compared to the RMSE between the hybrid empirical model and the true measured temperature of 9.153. It is recommended that a larger set of data be used to train the empirical model to improve the generalisation of the model to new sets of input features.

Keywords: Coffee roaster, empirical modelling, machine learning, applied modelling

1. Introduction

1.1. Background

The process of converting the green *arabica* coffee bean into the cup of coffee one enjoys involves the roasting process, which brings to light an abundance of coffee flavours. The construction, design, and development of roasters and roaster technology alike is something a company located in South Africa, takes pride specialising in. There is a need for the development of a predictive model which will accurately predict changes in the temperature profile of the coffee beans due to changes in the inputs to the system. The inputs are the LPG (liquefied petroleum gas) flow rate to the burner, the drum rotation speed and the air blower speed. The model will be utilised in manually operated runs to preemptively adjust the inputs in order to shape the desired bean temperature profile, which is strongly correlated to the flavours produced. This paper will focus on the development of a model which generalises well to new sets of input features.

This paper investigates the modelling techniques applicable to the coffee roasting system based on theoretical first-principles (Schwartzberg, 2002) as well empirical (data-driven) methods such as *linear regression*, *decision trees*, *random forests*, *support-vector machines* and *neural networks* implemented using the *scikit-learn* and *tensorflow* python libraries (Géron, 2019). Comparison is

made between models based on performance metrics such as root mean squared error (RMSE) on a validation set of input features.

1.2. The coffee roaster

The coffee roaster of interest consists of a double walled ceramic coated drum, orientated horizontally on a central axis. The drum rotates above an open flame LPG burner. The flame heats the inlet air as well as the drum. Air is drawn through the roaster by an air blower located at the outlet of the roaster. As the air is drawn through the drum, smoke, steam, and chaff is removed from the drum and separated by a cyclone located at the outlet of the roaster. The blower is located at the top of the cyclone in order to separate out the coffee bean outer-skins (otherwise known as chaff) as well as additional solids. The gas separated from the emissions in the outlet is then passed to the stack and released to the environment. It is desired to model the measured bean temperature as a function of the roaster inputs, namely the LPG flow rate to the burner, the drum rotation speed and the blower speed.

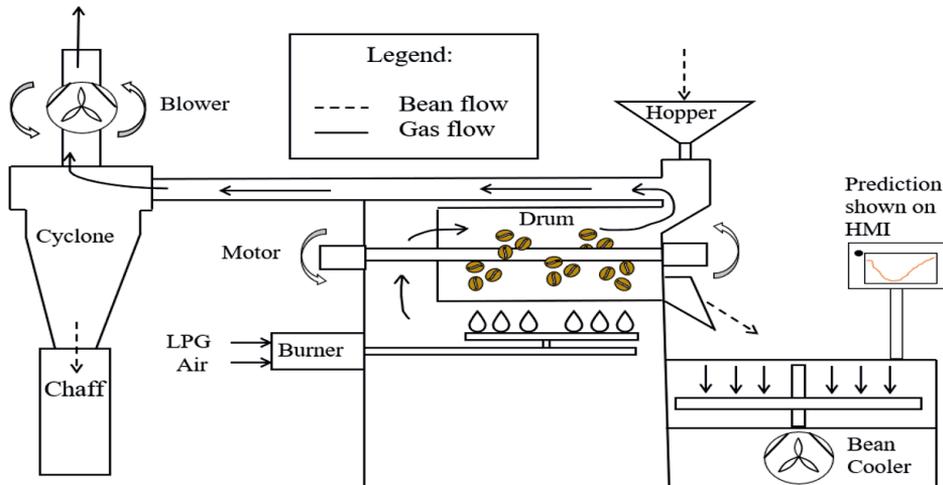

Figure 1: Traditional direct heated drum coffee roaster, adapted from Schwartzberg (2002).

The temperature profile shown in Figure 3 is obtained by measurement of the temperature of the coffee beans within the roaster. One will very quickly observe a local minimum in the curve followed by a steady rise in temperature. This inverse response is as a result of how the roaster is operated. Before the beans are released into the roaster drum through a hopper, the roaster operating temperature is primed to a set-point temperature, measured by a thermocouple located within the drum. At the point in time when the coffee beans are released into the drum (at the point $t = 0$ in Figure 3), the thermocouple within the roaster has reached the steady state priming temperature. As the room temperature beans begin making contact with the thermocouple, heat is transferred from the thermocouple to the beans. It is this dynamic lag of measured temperature which produces the measured temperature profile shown in Figure 3.

1.3. The adapted Schwartzberg model

The following semi-empirical model of the coffee roaster proposes a scalable model for a drum roaster. This model suggested by Palma et al. (2021) builds upon the model suggested by Schwartzberg (2002) by allowing for adjustments as a function of the size of the roaster i.e. the roaster mass and volume. The model can be summarised as follows:

$$\dot{T}_b = \frac{Q_{gb} - Q_{gm} + Q_{bm} + M_{bd}(Q_r + \lambda\dot{X})}{M_{bd}(1+X)c_b} \quad (1)$$

$$\dot{T}_m = \frac{Q_{gm} - Q_{bm}}{M_m c_m} \quad (2)$$

$$\dot{X} = -\frac{k_1}{D_b^2} \exp\left(-\frac{k_2}{T_b + 273.15}\right) \quad (3)$$

$$\dot{H}_e = A \frac{H_{et} - H_e}{H_{et}} \exp\left(-\frac{H_a}{R(T_b + 273.15)}\right) \quad (4)$$

$$T_{go} = \left(T_{gi} - \frac{T_b + FT_m}{1+F}\right) \left(1 - \exp\left(-\frac{h_e A_{gb}(1+F)}{G_g c_{pg}}\right)\right) \quad (5)$$

Nomenclature

A	Arrhenius constant
A_{gb}	air to bean heat transfer surface area
c_b	coffee bean specific heat capacity
c_{pg}	air specific heat capacity
c_m	metal specific heat capacity
D_b	coffee bean diameter
F	ratio of air-metal and air-beans thermal resistance
G_g	air (gas) flow rate
h_e	air to beans heat transfer coefficient
H_a	activation energy
H_e	cumulative heat of reaction
H_{et}	total reaction heat
k_1, k_2	semi-empirical constants
m_b	mass of a single bean
M_{bd}	mass of dry bean batch
M_m	mass of roaster metal
Q_{gb}	heat transfer from the air to the coffee beans
Q_{gm}	heat transfer from the air to the roaster metal
Q_{bm}	heat transfer from the beans to the roaster metal
Q_r	heat production by exothermic reaction
R	universal gas constant
T_b	measured coffee bean temperature
T_{gi}	inlet air temperature
T_{go}	outlet air temperature
T_m	roaster metal temperature
X	coffee bean moisture content
λ	latent heat of vaporisation of water

A notable advantage of the adapted Schwartzberg model is the scalability of the model to different sized coffee roasters. The adapted Schwartzberg model does however not take into account the effect of the drum rotation speed on the measured temperature. This is a considerable disadvantage if the proposed model is to be used for the purposes of process control such as in the case of a model predictive controller. The semi-empirical constants k_1 and k_2 will be chosen as proposed by Schwartzberg (Schwartzberg, 2002).

2. Methodology

Developing a realisable model of the coffee roaster which is multiple input – multiple output in nature can be achieved in one of two distinct approaches. Firstly, a model may be developed which makes use of first principle mass and energy balances in order to determine the effect of the three inputs, namely the LPG flow rate to the burner, the drum rotation speed and the blower speed on the measured temperature within the system. Available literature (Schwartzberg, 2002) will be utilised to simulate the “first-principles” model. Alternatively, measured temperature and input feature data sets may be used to develop empirical regression models which may accurately predict the measured temperature in the coffee roaster. Examples of such modelling techniques include *linear regression*, *random forests*, *decision trees* and *neural networks*. The theory behind the inner workings of these empirical methods will not be covered in this paper. The reader is referred to the excellent introduction to such topics provided by Géron (2019). These two approaches will be assessed and compared in order to determine inaccuracies that exist in either approach.

Data from a 30 kg (capacity) drum roaster is available which contains information about 42 runs (containing a total of 22 149 measurements). The current data acquisition software does not allow for the recording of total bean mass for each roast. As mentioned, the measured bean temperature exhibits a local minimum in temperature. The laws of heat transfer would lead one to believe that this local minimum’s location in time and temperature is strongly correlated to the initial starting temperature of the roast and the total mass of beans being roasted (assuming a constant specific heat capacity of beans for different temperatures and coffee bean species). Accurate prediction of this point in time will allow one to address the non-linear nature of the temperature profile by splitting the empirical model into two characteristic portions.

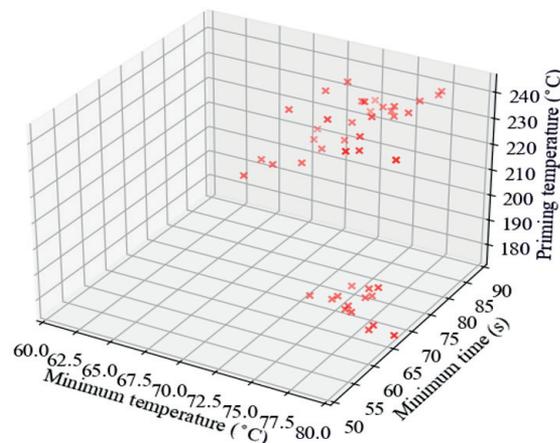

Figure 2: Relationship between the observed minimum temperature of the coffee beans and the associated priming temperature.

Available data from the roaster is plotted in Figure 2 which displays two distinct clusters of data. The first cluster of minimum times occur between 64–73 seconds from the beginning of each respective roast. This cluster is strongly correlated to a set of colder priming temperatures (in the region of 180–190 °C). The second cluster of minimum times occur between 73–90 seconds from the beginning of respective roast and is strongly correlated to a hotter set of priming temperature (in the region of 215–240 °C). A *gradient boosted regression tree* is used to model the relationship

between the priming temperature and the time at which the local minimum in temperature occurs. All the test data will be split into two portions, the “downward” portion (the region with a negative gradient in temperature) and the “upward portion”. A model will be developed for each portion applying the aforementioned regression techniques. The “downward” and “upward” data-sets will be split into training (data used to train the regression models) and test sets (data used to validate the regression models). The performance of each model will be assessed by calculating the RMSE on the relevant validation sets.

3. Results and Discussion

Upon splitting of the available data into the aforementioned “downward” and “upward” data sets, the following regression techniques are made use of: *gradient-boosted regression trees*, *linear-regression*, *support-vector machines*, *random-forests* and *neural networks*. The performance of each model is assessed against a validation data set using the root mean squared error (RMSE), the calculated performance norms are summarised in Table 1.

Table 1: RMSE of each model evaluated for the each characteristic portion.

Model	Downward portion	Upward portion
Linear	18.46	8.428
Gradient boosted regression tree	2.612	5.724
Support-vector machine	12.49	4.386
Random forest	2.659	1.161
Feedforward neural network	6.746	1.150

The results obtained indicate that a composite/hybrid modelling approach can be used to model the coffee roaster. The proposed hybrid model will be selected on the basis of the RMSE performance norms of the relevant models on the validation data set. A *gradient boosted regression tree* will be used to predict the downward portion of the measured temperature up to the predicted minimum time (where the local minimum in temperature is predicted to occur in time by use of an additional *gradient boosted regression tree*), subsequently the upward portion in measured temperature will be predicted by use of a *feedforward neural network*.

A visualisation of the results obtained by predicting the measured coffee bean temperature during roasting as a function of the roaster input features is shown in Figure 3. The supplied input features as shown in Figure 3 did not occur in the training or validation set of data and is typical of a roasting operation, the LPG input is initially maintained at 100% (an artefact of the priming process) before stepping down at a later stage. The empirical model predicts the measured bean temperature exceptionally well on the downward portion by use of a *gradient boosted regression tree*. The *neural network* deviates from the true measured temperature between 80–600 seconds before coinciding with the true temperature, interestingly a considerable reduction in LPG input occurs at 600 seconds. The Schwartzberg model was implemented using the semi-empirical constants and heat transfer coefficient approximations provided by Schwartzberg. The Schwartzberg model seems to model a system in which there is less heat transfer to the beans by the hot air and/or drum. This can be noted by the local minimum in the Schwartzberg model which occurs at a later point in time and at a hotter temperature than the true minimum. The relevant RMSE between the Schwartzberg model and the true measured temperature is 23.05 as compared to the RMSE between the hybrid model and the true measured temperature of 9.153. The RMSE for the hybrid model is surprisingly large when one considers the errors calculated in Table 1. This can be attributed to the size of the data set used (22 149 measurements). Use of a larger data set will allow the hybrid model to generalise with increased accuracy to unseen input features.

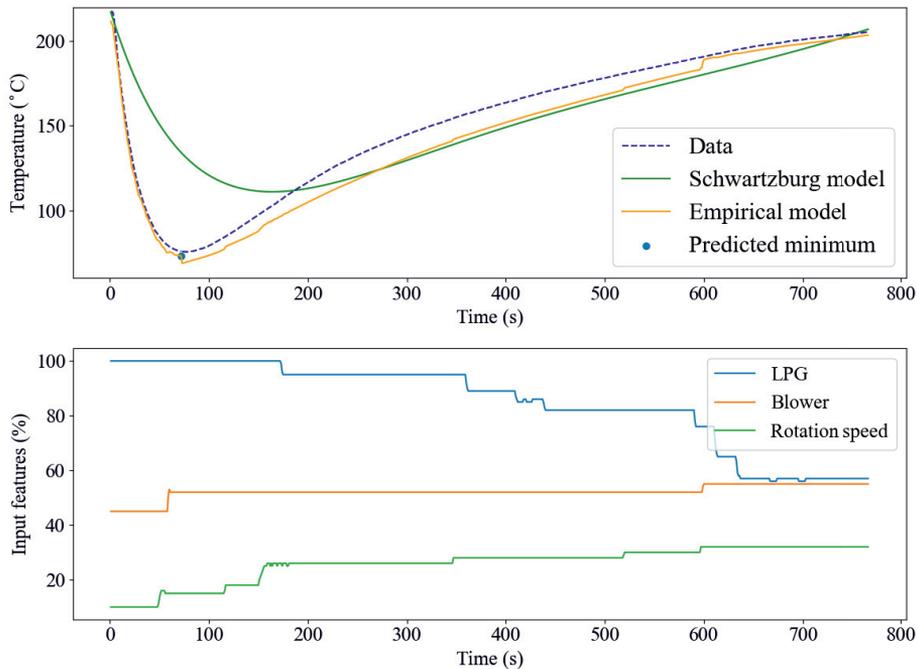

Figure 3: Comparison of the composite empirical model to the first-principles model.

4. Conclusions and Recommendations

The empirical hybrid model has been successfully developed. The empirical model is composed of two *gradient boosted regression trees* and an artificial *feedforward neural network* which predicts two characteristic portions of the measured temperature profile by accurate prediction of the minimum measured temperature. The relevant RMSE between the Schwartzberg model and the true measured temperature of an unseen test set of data is calculated as 23.05 as compared to the RMSE between the hybrid empirical model and the true measured temperature of 9.153. It is recommended that a larger set of data be used to train the empirical model to improve the generalisation of the model to new sets of input features. The methods shown can easily be applied to unrelated physical system modelling problems. The Schwartzberg model does not incorporate the effects of drum rotation speed on the measured temperature. It is suggested that with the development of an accurate model of the coffee roaster, the use of model-based control algorithms such as model-predictive control (MPC) be investigated.

Abstract

The increasing number of microalgae-based applications has contributed for development of new models to describe the complex interactions taking place in mixed algal-bacterial wastewater treatment systems. Mathematical models contribute to system optimization in terms of operation and control. The goal of this work is modeling and simulation of an anoxic-aerobic algal-bacterial photobioreactor with biomass recycling for wastewater treatment. Process model and simulation have developed in dynamic simulation software PROOSIS®. The model was set-up and calibrated with data from a pilot plant treating synthetic wastewater, located in facilities of University of Valladolid. Simulations have shown the capability of mathematical model to predict the removal efficiency of nutrients from wastewater. Removal efficiencies simulated are closely with experimental results ones.

Keywords: Modeling, Optimization, Simulation, Wastewater treatment.

1. Introduction

In recent years, microalgae-bacteria based technologies for wastewater treatment has generated a growing interest in scientific community. Microalgae-based technologies for wastewater treatment were proposed in the 1960s, but till now, remains certain limitations related with their exploitation at industrial scale. The European Directives concerning wastewater treatment processes; efficient gestion of nutrients; and transit to low-carbon economy, have reactivated the interest in microalgae-based technologies and have motivated the development of large number of improvements and applications (Muñoz & Guieysse, 2006).

The costs associated with mechanical aeration represent 45–75% of the total operational costs in conventional wastewater treatment plants (WWTPs) (Chae & Kang, 2013). These costs could be reduced using wastewater treatment systems based in microalgae-bacteria consortia. In addition, the capacity of microalgae to simultaneously remove carbon (C), nitrogen (N) and phosphorus (P) via mixotrophic assimilation represents an important advantage in comparison with aerobic activated sludge or anaerobic digestion technologies in terms of enhanced nutrient recovery.

The increasing number of microalgae-based applications has contributed for development of new models to studying of main processes, factors, and variables affecting microalgae growth in different cultures media, including wastewater (Casagli, et al., 2021), (Sánchez-Zurano, et al., 2021), (Solimeno, et al., 2019). Recently, design and improvement of

facilities for optimization of algae biomass yield and adequate depuration of wastewater has generated a growing interest. In this regard, in (De Godos, et al., 2014), an innovative anoxic–aerobic algal–bacterial photobioreactor configuration with biomass recycling was proposed. The configuration described in (De Godos, et al., 2014) was optimized in (Alcántara, et al., 2015) in order to promote N removal via denitrification and the development of a rapidly settling algal–bacterial population. Within this framework, the goal of this work is modeling and simulation for first time the anoxic-aerobic algal-bacteria photobioreactor for wastewater treatment proposed in (Alcántara, et al., 2015). In this work, simulation results for the concentration of Total Suspended Solids (TSS) and ammonium are presented. These values are used to estimate removal efficiencies in the anoxic-aerobic reactor configuration. Values of TSS and ammonium in effluents are key indicators for an adequate depuration of wastewaters. Process model and simulation have developed in dynamic simulation software PROOSIS®.

2. Materials and Methods

2.1. Plant Description

Experimental data were collected from anoxic–aerobic algal–bacterial photobioreactor configuration with biomass recycling located in facilities of University of Valladolid (Fig. 1). In (Alcántara, et al., 2015), the influence of the Hydraulic Retention Time (HRT), intensity and regime of light supply, and dissolved O₂ concentration (DOC) in the photobioreactor were analyzed in five-stage experimentation.

The aerobic tank (photobioreactor) was an enclosed jacketed 3.5 L glass tank (AFORA, Spain) with a total working volume of 2.7 L. The photobioreactor was continuously illuminated by LED lamps. The anoxic reactor consisted of a gas-tight 1 L polyvinyl chloride tank with a total working volume of 0.9 L maintained in the dark. The synthetic wastewater (SWW) was fed to the anoxic tank and continuously overflowed by gravity into the aerobic photobioreactor.

The algal–bacterial broth was continuously recycled at 3 L/d from the photobioreactor to the anoxic tank. An Imhoff cone with a volume of 1 L and interconnected to the outlet of the photobioreactor was used as a settler. The algal–bacterial biomass settled was recycled from the bottom of the settler into the anoxic tank at 0.5 L/d and wasted 3 days a week to control the algal–bacterial sludge retention time (SRT). A detailed description of the system, microorganisms and culture conditions, experimental design, and analytic procedures is provided in (Alcántara, et al., 2015).

2.2. Experiment Design

The design of the experimentation was conducted based on the hypothesis that algal–bacterial photobioreactors for wastewater treatment can support the oxidation of ammonium (N-NH₄⁺) into NO₂⁻/NO₃⁻, which can then be easily removed through denitrification (using the organic matter present in SWW) under anoxic conditions via internal recycling of the photobioreactor broth (De Godos, et al., 2014). Liquid samples of 100 mL were drawn three times a week from the SWW storage tank, anoxic tank, aerobic tank, wastage, and clarified effluent to monitor the concentration of dissolved N species (total nitrogen (TN), N-NH₄⁺, N-NO₂⁻, and N-NO₃⁻) and biomass concentration, expressed as TSS. The data used for simulations were obtained from previous studies in the Institute of Sustainable Process (University of Valladolid). Data used in this study were collected from May 2014 to July 2014 (corresponding with two experimentation stages with different HRT). Data from Stages I and II were selected, because same conditions of illumination and no oxygen supply are considered in both stages.

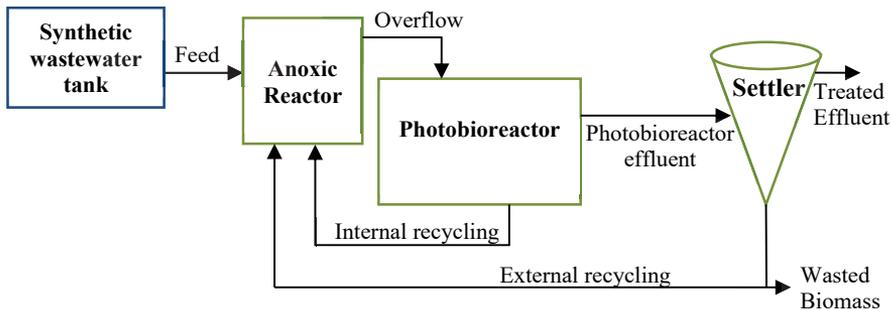

Fig. 1. Schematic of the anoxic-aerobic algal-bacterial photobioreactor configuration

2.3. Modeling

In the last two decades, several microalgae-bacteria models were developed (Reichert, et al., 2001), (Solimeno, et al., 2017), (Solimeno, et al., 2019), (Casagli, et al., 2021), (Sánchez-Zurano, et al., 2021). The review of these models has allowed to choose the model BIO_ALGAE 2 for the present work, since it includes the interactions between microalgae and bacteria, without presenting excessive complexity. Model BIO_ALGAE 2 (Solimeno, et al., 2019) has been used to represent the biochemical reactions and processes that take place in both anoxic and aerobic reactor described in (Alcántara, et al., 2015). Model BIO_ALGAE 2 uses the common nomenclature of the International Water Association models and considers 19 components – 6 particulate and 13 dissolved – implicated as variables in the physical, chemical and biokinetic processes. In (Solimeno, et al., 2017) those components are described, as well as their main role in the processes and their interactions with other components.

Settler model is described using the mass-balance expressions of Takács model (Takács, et al., 1991). Takács model is a multi-layer dynamic model for the clarification and thickening processes. In this work, a 5-layer settler is considered. A description of settler model used in this work can be found in (Bausa, et al., 2021).

Reactors and settler model are coded in dynamic simulation software PROOSIS® (Empresarios Agrupados Internacional, 2021).

2.4. Parameter Estimation

Previous to parameter estimation, a sensitivity analysis is realized with the aim of identify the parameters that have the greatest impact on the model. To this purpose, a subset of the most influential parameters on model outputs was analyzed.

The approach to solve a parameter estimation problem in terms of optimization considers that for each value of the vector of parameters θ (decision variables) the model provides a prediction of the response of the system in each experiment. For this purpose, a set of data samples from inputs $u(t)$ and outputs $y(t)$ of process is needed. The same sequence of process inputs is applied to model. For each time sample t , the prediction error is an indicator of model goodness. The dynamic optimization problem for the start-up optimization can be converted into a nonlinear programming (NLP) problem by means of a control vector parameterization technique and a proper procedure for computing the cost function. In this work, the SNOPT nonlinear programming algorithm has been used in the PROOSIS® dynamic simulation environment to solve the optimization problem. The selected integration method was IDAS. The fair function estimator (Huber, 2014) is used here as a robust objective function J against measurement outliers and gross errors. Dynamic optimization problem reads:

$$\min_{\hat{\theta}} J(\hat{\theta}, \theta) = \sum_{j \in M} c^2 \left[\frac{|\varepsilon_j|}{c} - \log \left(1 + \frac{|\varepsilon_j|}{c} \right) \right] \quad (1)$$

Subject to restrictions (2) and (3)

$$\frac{d\mathbf{x}(t)}{dt} = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t) \quad (2)$$

$$\hat{\mathbf{y}}(t) = \mathbf{g}(\mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t) \quad (3)$$

$$\underline{\boldsymbol{\theta}} \leq \hat{\boldsymbol{\theta}} \leq \bar{\boldsymbol{\theta}}$$

Where $\varepsilon_j = (\hat{\theta}_j - \theta_j) / \theta_m$ represents the error between available process measurements (θ) and their estimated values $\hat{\theta}$ limited between user-defined minimum and maximum values, $c \in \mathbb{R}^+$ is an user defined fitting parameter to tune the slope for large residues, and θ_m is the media of process measurements.

3. Results

The results of sensitivity analysis in both reactors indicated that model outputs are especially sensitive to the maximum specific growth rate of microalgae (μ_{ALG}) and heterotrophic bacteria (μ_{H}), the decay-rate of microalgae ($k_{\text{death,ALG}}$) and heterotrophic bacteria ($k_{\text{death,H}}$), and the mass transfer coefficient for ammonia ($K_{\text{la, NH}_3}$). Limits for decision variables and initial values for optimization were established from similar studies reported in the literature. Values of decision variables resulting from optimization in both reactors are shown in Table 1. The optimized values of μ_{H} and $k_{\text{death,H}}$, are closely related with calibrated values reported in (Solimeno, et al., 2017) and (Casagli, et al., 2021), respectively. Value of $k_{\text{death,ALG}}$ coincide with value used in (Reichert, et al., 2001) and (Solimeno, et al., 2017). In sum, all parameter values are within values ranges adopted in literature for similar facilities. Results of sensitivity analysis and parameter estimation in settler is described in (Bausa, et al., 2021). Data from first 30 days of stage I were used for parameter estimation (corresponding with 14 samples). Validation was performed using data from stage I (days 33 to 47) and stage II (days 47 to 63). Both, parameter estimation, and model validation were performed using 14 samples of data.

Fig. 2 show simulation results for the concentration of TSS. Fig. 2a) and 2b) represent data set used for parameter estimation and for validation in anoxic reactor, respectively. Results for parameter estimation and validation in the aerobic reactor are presented in Fig. 2c) and 2d), respectively. Simulation results show model capability to reproduce dynamic behavior of the system. Fig. 3 presents simulation results for the concentration of ammonium. Fig. 3a) and 3b) represent data set used for parameter estimation and for validation in anoxic reactor, respectively. Results for parameter estimation and validation in the aerobic reactor are presented in Fig. 3c) and 3d), respectively. Although some discrepancies are observed in transient behavior prediction for ammonium concentration, average values (and, consequently, removal efficiencies) are closely with experimental results. Average values for simulated data are compared with experimental values reported in (Alcántara, et al., 2015) at steady state during stage I with the aim of evaluate model capability for prediction. This comparison is presented in Table 2.

Experimental removal efficiency of TSS for anoxic-aerobic configuration during stage I was roughly 98 %, the estimated value for removal efficiency of TSS was 97,7 %. Both experimental and estimated data are consistent with the percentage of reduction established by the European Union (CEE, 1991). Concentrations of ammonium in the effluent are above the maximum concentration permissible for wastewater discharge into the environment according to European Directive 91/271/CEE (CEE, 1991) on discharge of domestic waters. In this context, further research is needed to improve the N-NH_4^+ removal efficiency of the configuration.

Table 1. Values of estimated parameters in anoxic and aerobic reactor

Parameter	Value
μ_{ALG}	0.4 d ⁻¹
μ_H	1.4 d ⁻¹
$k_{death,ALG}$	0.1 d ⁻¹
$k_{death,H}$	0.9 d ⁻¹
$K_{la,NH3}$	22.3 d ⁻¹

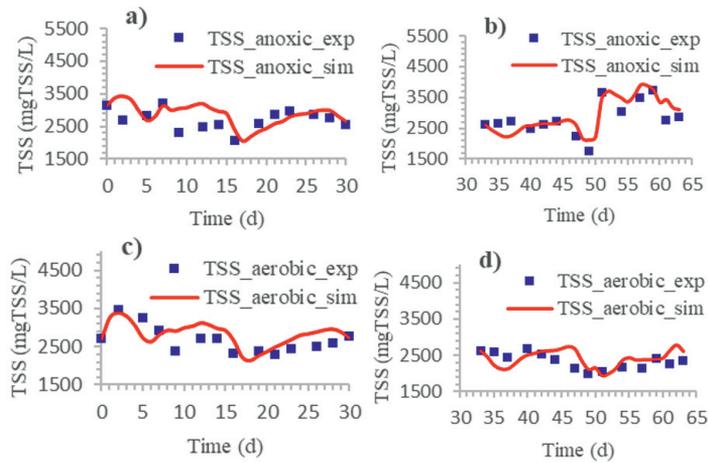

Fig. 2. Experimental and simulated TSS concentration in anoxic and aerobic reactor

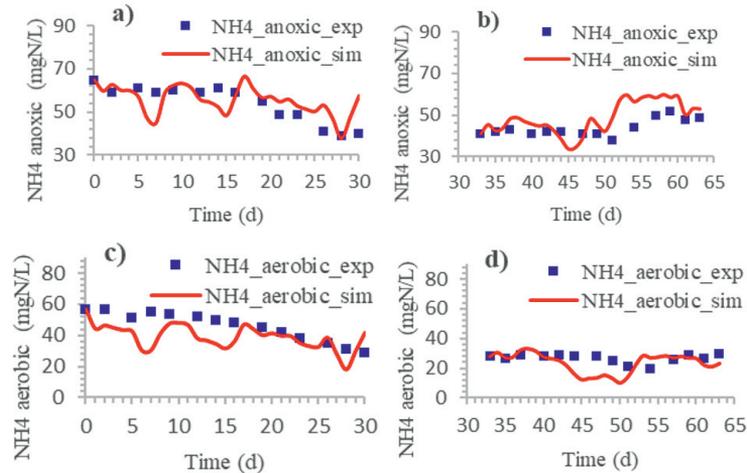

Fig. 3. Experimental and simulated N-NH₄⁺ concentration in anoxic and aerobic reactor

Table 2. Average values ± standard deviations at steady state during stage I

Parameter	Experimental	Simulated
TSS anoxic (mgTSS/L)	2575 ± 160	2627 ± 148
TSS aerobic (mgTSS/L)	2531 ± 191	2392 ± 111
N-NH ₄ ⁺ anoxic (mgTSS/L)	42±1	41.1±4.5
N-NH ₄ ⁺ aerobic (mgTSS/L)	28±1	22.9±7.4

4. Conclusions

In this paper, modeling of anoxic-aerobic algal-bacterial photobioreactor for wastewater treatment is presented. Parameter estimation via optimization is realized to fit experimental and simulated data. The model proved to be effective in reproducing dynamic behavior of different measured variables. Removal efficiencies simulated are closely with experimental results ones. Removal efficiency for total suspended solids is over 95% for experimental and simulation results.

Abstract

Li-ion batteries (LIBs) are widely adopted in EVs and stationary battery energy storage due to their superior performance over other battery chemistries. But LIBs come with the risk of thermal runaway (TR) which can lead to fire and explosion of the LIB. Hence, improving our understanding of TR is key to improving LIB safety. To achieve this, we aim to develop a detailed model of LIB TR, as existing models are oversimplified and often lead to inaccuracies when compared to experiments. To build a realistic representation of the reaction network (RN) for LIB TR, we present a case study on the ethylene carbonate (EC) solvent component of the LIB electrolyte. We use a RN for EC identified from literature to build a micro-kinetic model and optimize it against experimental data. Parameters optimisation and sensitivity analysis for a complex RN is made possible by using Gaussian Processes (GPs). It is found that the only four of the 14 parameters influence the simulation output significantly. Also, this work highlights areas of GP development for improved surrogate modelling of this type of problem. From this the methodology can be scaled to larger networks and can be applied LIB TR models to improve their accuracy, which in turn will help the development of safer LIBs.

Keywords: Thermal runaway, Gaussian Process, Li-ion battery, Reaction network analysis, Robust optimization

1. Introduction

Li-ion batteries (LIBs) have become the favoured electrochemical energy storage device in EVs and stationary applications as they benefit from high energy density and low cost (Keshan et al., 2016). However, they can undergo the rare but hazardous phenomenon of thermal runaway (TR), which through exothermic decomposition can lead to fire and explosion (Wang et al., 2012). Improved battery safety is paramount as the use of LIBs is increasing enormously.

Computational modelling is a proven method to aid the design of safer LIBs (Abada et al., 2016; Bugryniec et al., 2020b,a). However, models used in previous works can be considered oversimplified as they do not consider (1) the multi-pathway and interdependent reaction network (RN) (Wang et al., 2012), or (2) the generation of decomposition products which could be used for chemical hazard assessment. Also, existing models can be limited to the experimental conditions on which they are developed. Hence, there is a desire to build a more detailed model of LIB TR

based on a realistic representation of the RN. In this paper a new approach is developed to meet this goal.

RNs can be developed by inference of reactants and products from experimental observations, or from molecular simulations studies (Campion et al., 2005; Hirai and Jinnouchi, 2021). Micro-kinetic modelling techniques can be applied, which provide a detailed description of the reaction pathways, including each possible elementary step and reaction intermediate. In this approach, the kinetic parameters are typically estimated based on a solid theoretical basis and no a priori assumptions on the rate determining steps are needed (Hermes et al., 2019).

We have previously shown (Milton et al., 2019; Yeardley et al., 2020) that applying Gaussian Processes (GPs) surrogate modelling to LIB modelling is beneficial due to the efficiency of the GP prediction technique (Sacks et al., 1989). Further, as the GP is mathematically tractable it allows sensitivity analysis (SA) and optimisation of the complex RN. The implementation of the GP can be conducted through two main methods. The first, is by fitting the GP to a heuristic fit of the computer simulation, providing information about the error between simulation and experimental data. The second, is to fit multiple GPs to create a direct surrogate model that uses the same input variables as the computer simulation to predict the same outputs as computer simulation.

The aim of this work is to develop a methodology for the efficient generation of realistic RNs of LIB TR, from which the optimal and most influential reaction parameters can be determined. To assess the validity of the aforementioned methodology, an exploratory study has been conducted to analyse the thermal decomposition of ethylene carbonate (EC) as a model component of the electrolyte.

2. Methodology

As stated previously, this work focuses on the RN of EC oxidation decomposition. For this work, the energy diagram from Hirai and Jinnouchi (2021) (containing 3 reaction pathways for the EC decomposition) is used to define the RN. This size of network provides a suitable problem to test and validate our proposed methodology. From the energy diagram a micro-kinetic model can be created. The forward and backward reaction steps are listed in Table 1, for a total of 14 reactions and 8 species, along with the corresponding activation energies of each step. The micro-kinetic model (a.k.a. the full order model or FOM) consists of a system of 8 ordinary differential equations (ODEs) describing the change in concentration of the 8 species. Each ODE is expressed as the algebraic sum of all relevant reaction rates (R_i) corresponding to a given reaction step, where R_i is governed by an Arrhenius equation of the form $R_i = A_i \exp(-E_{a,i}/RT) \prod_j C_j$.

To analyse the RN, and to obtain the optimised frequency factors, GPs are applied. To generate training data for the GP, the desired parameter space of the 14 frequency factors is sampled using Latin Hypercube sampling, which through the FOM, is used to generate 10 000 outputs that are used for training.

The log base 10 of each input variable is taken before being standardised as the bounds of the variables extend over several orders of magnitude. In this research both a GP behaving as a direct surrogate model and a GP predicting a heuristic fit are chosen to analyse the data. A GP is a non-parametric machine learning technique which takes a $1 \times d$ row vector of inputs \mathbf{x} and returns a Gaussian random variable through calculations using the predictive equations shown in Yeardley et al. (2020). The difference between the direct surrogate model and the heuristic fit is the output that the GP predicts. For the surrogate model, numerous GPs are trained to predict the mole ratio every step in temperature. Whereas, the heuristic fit maps the log of the 14 parameters to a single output of interest. This output is the root mean squared error (RMSE) between the experimental and simulated mole ratio over the entire temperature range. In essence, the heuristic fit GP behaves as a blackbox function using training data to predict the RMSE from the log of the

Table 1: Calculated activation energies for the forward and backward reactions of EC decomposition according to the energy diagram from Hirai and Jinnouchi (2021). The notation R_i in brackets identifies each reaction step.

Reaction	Activation Energy (eV)	
	Forward	Reverse
$\text{EC} \longleftrightarrow \text{C}_2\text{H}_4\text{O} + \text{CO}_2$	1.12 (R_1)	1.86 (R_2)
$\text{EC} \longleftrightarrow \text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3$	0.06 (R_3)	1.31 (R_4)
$\text{EC} \longleftrightarrow * \text{C}_2\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3$	0.20 (R_5)	0.37 (R_6)
$\text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3 \longleftrightarrow \text{C}_2\text{H}_3\text{O} + \text{CO}_2 (+ \text{C}_3\text{H}_5\text{O}_3)$	0.84 (R_7)	1.55 (R_8)
$\text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3 \longleftrightarrow * \text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3$	1.08 (R_9)	0.00 (R_{10})
$* \text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3 \longleftrightarrow \text{C}_2\text{H}_5\text{O} + \text{CO}_2 (+ \text{C}_3\text{H}_3\text{O}_3)$	0.21 (R_{11})	1.58 (R_{12})
$* \text{C}_3\text{H}_5\text{O}_3 + \text{C}_3\text{H}_3\text{O}_3 \longleftrightarrow \text{C}_2\text{H}_3\text{O} + \text{CO}_2 (+ * \text{C}_3\text{H}_5\text{O}_3)$	0.84 (R_{13})	1.56 (R_{14})

model parameters

Both methods require GP learning which uses training data to optimise $d + 2$ hyperparameters found in the predictive equations, consisting of Λ , σ_f , and σ_e . This optimisation is completed by maximising the marginal likelihood $p[\mathbf{y}|\mathbf{X}]$ using the ROMCOMMA software library (Milton and Brown, 2019).

The GPs are used for a global sensitivity analysis (GSA) and to optimise the model simulation with respect to the experimental data from Lamb et al. (2015). For this work, we opted to implement a GSA using the variance based Sobol' indices technique (Sobol, 1993, 2001). As previously mentioned, GPs are mathematically tractable, therefore, we can compute the semi-analytic evaluation of complex multi-dimensional integrals resulting in Sobol' indices which measure the contribution to the outputs variance attributable to each input parameter. Hence, to understand how the input parameters impact the model simulations closeness to the experimental data, the GSA required an output that measures said closeness, resulting in a GP predicting the heuristic fit. Additionally, the direct surrogate model is required to be able to optimise the parameters throughout the model simulation as a function of temperature. In this way, the GP is trained to accurately copy the model simulation and is used to make fast, efficient predictions. Thus, the optimisation of model parameters is achieved by minimising the error between the GP predictions and the experimental data. GPs predict a probability distribution presenting the uncertainty in the predictions. Therefore, the optimisation should include constraints where the predicted standard deviation (STD) is limited to be within 2 standardised units from the mean. In this research, we compare both a constrained and an unconstrained GP for parameter optimisation.

3. Results and Discussion

3.1. GP Validation

Both techniques are tested using the 5-fold cross validation technique. The results of which are scrutinised by calculating the error metrics between the GP predictions and the model simulation data. In this work, we conduct a robust validation by calculating three popular error metrics and by plotting figures to provide a visual understanding of the error. Table 2 shows the coefficient of determination (R^2) and the root mean squared error (RMSE) values for each output. Both diagnostics measure a skill score, corresponding to the accuracy of the predicted mean (Al-Taweel, 2018), but with different scales. Further, the predictive distribution is analysed to ensure the GPs are not predicting with over confidence. This is shown by counting the outliers for any prediction where it's true standardised value is outside of the predictions 95% uncertainty distribution. Table 2 presents the outliers of both around the 5% as expected for a normal distribution. However, the two skill scores show the heuristic fit to have a worse accuracy than the direct surrogate

Table 2: Error metrics used to validate the GP models.

GP	R^2	RMSE	Percentage of outliers
Heuristic Fit	0.486	0.486	5.60 %
Direct Surrogate Model	0.931	0.279	5.25 %

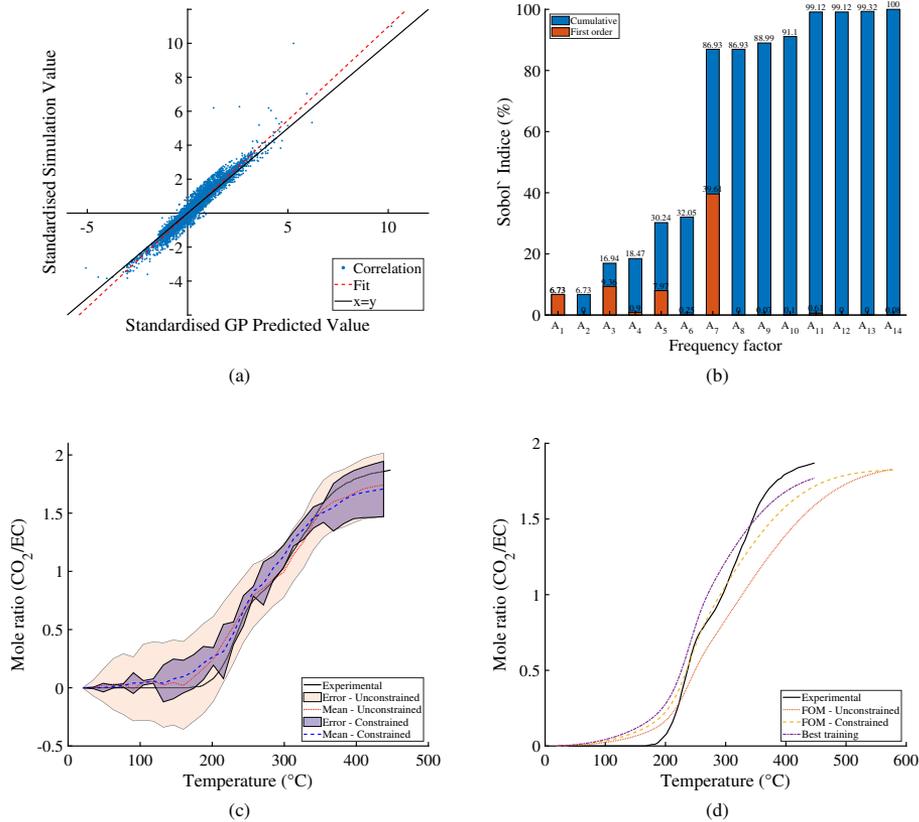

Figure 1: a) Validation, standardised value predicted by GP vs standardised value from FOM simulation, also shown is the linear fit (dashed line, $y = 1.102x - 0.041$ with $R^2 = 0.931$) of the scatter data. b) The cumulative Sobol' indices' overlaid with first order Sobol' indices' for each of the 14 frequency factors, first order totals 65.7 %. c) Optimisation output, GP predicted mean with error bounds (one STD) for scenarios where the STD is constrained and unconstrained. d) FOM output using optimised parameters determined by GP. (Note experimental data is from Lamb et al. (2015))

model as the R^2 is small and the RMSE is large. Further, Fig. 1(a) shows the correlation of GP predictions against the outputs of the FOM in a standardised form. The quality of prediction is shown by the closeness of the fit line to the $y = x$ line, with a coefficient of determination equal to 0.931. However, there are some large residuals, as well as instances of residuals far away from the straight line.

From this, it can be seen that the GP predicting the heuristic fit is satisfactory and appropriate for the calculation of Sobol' indices due to 95% of the true observed values fitting into the predicted distribution. However, the point estimations for the heuristic fit require further work to increase accuracy. Hence, the direct surrogate model is used for a parameter optimisation.

Table 3: Error (RMSE) from predicted output and FOM output (calculated against experimental) for optimised parameters under un/constrained conditions.

Type	GP predicted	FOM
Best training data	-	0.1190
Constrained GP	0.0980	0.1197
Unconstrained GP	0.0821	0.2304

3.2. Sensitivity Analysis

SA of the model output dependent on the 14 frequency factors can be realised by calculation of the Sobol' indices. The first order and cumulative Sobol' indices are presented in Fig. 1(b). From the first order Sobol' indices, it can be seen that the frequency factors relating to the initial decomposition of EC (A_1, A_3, A_5) by the forward reactions R_1, R_3, R_5 are of the most dominant parameters. This is besides parameter A_7 , which is the most dominant and relates to the second stage (forward) reaction from the products of R_2 and leads to the generation of CO_2 . Further, the first order Sobol' indices show that the frequency factors for all the backwards reactions and forward reactions R_9 and above have negligible influence of CO_2 generation.

From the cumulative Sobol' indices in Fig. 1(b) it can be seen that the increase in value is driven by the interactions from the frequency factors related to the first three forward reactions. The backwards reactions, with A_2, A_4, A_6 , have little effect on the increase in indices value. A_7 has a great effect on increasing the cumulative Sobol' indices value, equating to almost 87 % of the total Sobol' indices. Where over 50 % of the value is due to interactions with the first 6 frequency factors. After this, little change is seen in Sobol' indices until A_{11} at which there is an increase to 99 %. From Table 1, the influence of A_{11} can be rationalised by the fact that it is a second stage reaction that leads to CO_2 generation by a relatively low activation energy. Overall, first order Sobol' indices total 65.7 %, thus interaction account for 34.3 %. Hence, it can be seen that the frequency factors relating to R_1, R_3, R_5 and R_{11} , which relate to the forward reaction of the first stage of EC decomposition and the forward reaction of the decomposition of the products from R_5 , have the most influence on predicted output.

3.3. Parameter Optimisation

The best training data, with the lowest RMSE relative to experimental, was chosen from FOM simulations, see Table 3. So the aim is to optimise the GP against experimental data to determine parameters that lead to a smaller RMSE than 0.1190. The results of the direct surrogate model for parameter optimisation are presented in Figs. 1(c) and 1(d). Fig. 1(c) shows the GP predicted mean with STD for two scenarios, where the deviation is (1) unconstrained and (2) constrained. The constraint was applied to minimise the size of the STD around the predicted mean. It can be seen from Table 3 that the unconstrained GP predicts a smaller RMSE than the constrained GP. However, when the optimised parameters from the GP are implemented in the FOM the resulting output (see Fig. 1(d)) leads to RMSEs larger than the GP predicted in both scenarios. Further, the parameters from the unconstrained GP lead to a much larger RMSE than the best training data, while the parameters from constrained GP lead to a similar RMSE to the training data.

It is shown that constraining the GP increases the RMSE of the prediction but leads to a GP that is better at capturing the FOM behaviour. However, as the GPs both predict better than the FOM output for the same parameters it indicates that our surrogate model is not accurately capturing the behaviour of the FOM. This may be due to the slight deviation of the correlation plot from the $y=x$ line (see Fig. 1(a)). Or it may be possible that the FOM is already as close to optimal, due to the large number of starting point considered, and the GP cannot improve on it. To further refine the GP to improve the correlation plot, then the follow can be applied: 1) restricting the training data

to sets with lower RMSE, 2) using both cross-validation and a test set to validate the GP so that there is a data set purely for testing, 3) optimise against experimental data using the continuous ranked probability score to account for uncertainty rather than using the RMSE.

4. Conclusion

The modelling of chemical reactions is usefully for calculating reaction barriers, the effects of catalysts, product yields and analysing theoretical reactions schemes. Here, decomposition of EC is studied using micro-kinetic modelling. A GP approach is applied for SA and optimisation of the frequency factors. The SA shows that most of the error between the simulation output and experimental data comes from 4 of the 14 parameters. The GP, while predicting a mean close to the simulation, currently does not capture the FOM to a standard required to calculate optimised model parameters. This work provides lessons for GP development applicable to RN analysis. It can be used for safer LIB design by applying it to LIB TR models so that the most likely reaction pathway and production of hazardous species can be predicted.

Abstract

Hydrogen is considered as a clean energy carrier that can be produced from several renewable resources. Biomass as an alternative energy resource can be used to produce hydrogen to substitute fossil fuels. The objective of this work is to propose a coupled process modelling under Aspen for H₂ production based on anaerobic digestion for syngas production and methane transformation to hydrogen based on steam reforming (process 1) and partial oxidation (process 2). The modelling was validated with experimental results. The modelling has allowed to establish an evaluation of the energetic performance of each installation with a quantification of the CO₂ production which is considered as greenhouse gas. The feed of the process was set equal to 0.33 l/day of cow manure biomass for both modelling. The results show that the process 1 produced 5.71 l/day of H₂ with an energy efficiency of 82.72% and the emission of the CO₂ is about 12.83 kg per kg of H₂ produced. These values are highly advantageous compared to the second process.

Keywords: biomass, anaerobic digestion, hydrogen, methane, modelling.

1. Introduction

The current production of hydrogen is mainly based on fossil fuels as feedstocks (coal, natural gas, oil, etc.), and 4% is produced by electrolysis of water [1]. Hydrogen could be the fuel of the future because of its high energy content, as well as it presents environmental, economic and social issues, it is considered a clean energy that does not cause air pollution. The production of hydrogen from renewable sources, in particular biomass, instead of fossil fuels, is a green way and shows many advantages due to its availability, abundance and its carbon neutrality.

Anaerobic digestion, also called "methanization", is the transformation of organic materials into a gas rich in methane and carbon dioxide called biogas containing about 20 to 40% of the energy value of the original biomass. It is carried out in the absence of oxygen by a complex microbial community in a closed chamber (digester, fermenter or reactor), and is widely used for the treatment of wet organic waste (80 to 90% moisture) [2,3].

The different hydrogen production techniques are mainly based on syngas and methane reforming techniques, such as (i) steam reforming (methane and steam converted to syngas), (ii) partial oxidation reforming (methane and oxygen converted to syngas), (iii) autothermal reforming (methane, oxygen and steam converted to syngas), (iv) dry reforming (methane and carbon dioxide converted to syngas), (v) bi-reforming (methane,

carbon dioxide and steam converted to syngas), (vi) tri reforming (methane carbon dioxide, steam and oxygen to syngas).

In the light of these considerations, this work is aimed at studying two different processes of hydrogen production from biogas. The two main steps involved in these processes are the production of biogas from biomass by anaerobic digestion and the transformation of the methane produced to produce pure hydrogen.

2. Process modeling in Aspen Plus

2.1. Process description

The main steps in the production of hydrogen from biogas or methane are shown in the Figure 1. The bio-digester model was established and validated by [4]. Steam reforming, partial oxidation reforming and the autothermal reforming models were validated by Hajjaji et al. [5] while the bi-reforming, dry reforming and tri-reforming models were validated by Phan et al. [6].

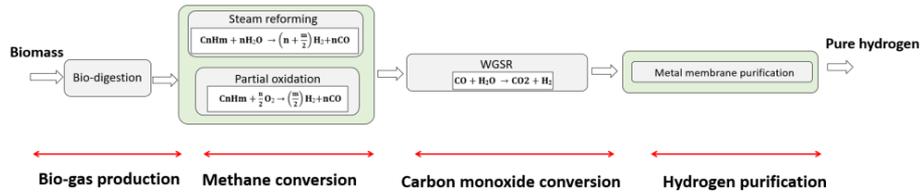

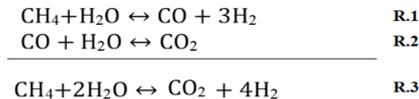

Figure 1: Main steps in the production of hydrogen from biogas or methane

The thermodynamic method selected was NRTL (Non-Random Two Liquid) which is recommended for anaerobic digester simulation [7]. The cow manure is considered as the feedstock with a loading rate of 0.33 l/days. The first step of anaerobic digestion which is the hydrolysis of biomass was not modeled due to complexities such as the difficulty associated with specifying the composition of biomass in terms of its constituents, therefore, the flow for this process is assumed to be pretreated (hydrolyzed) [6,7]. Two streams were produced at the outlet of the digester (i) biogas and (ii) undigested slurry (mixture of solid and liquid phases) which can be used for agricultural purposes.

Steam Reformation of Methane (SRM) is the most industrially applied and commonly used to produce hydrogen in large quantities. This technique consists in reacting methane with steam to produce a synthesis gas, in the presence of a nickel-based catalyst, at a high temperature of 800 to 1000 °C, and at a moderate pressure of about 5 to 25 bars. This transformation is followed by different operations which lead to the production of hydrogen and carbon monoxide, carbon dioxide, methane and water [1,8], as shown in the following reaction system:

The first reaction (R.1) corresponds to the steam reforming, it is endothermic and is characterized by a ratio H_2/CO of about 3 where the second reaction (R.2) corresponds to the conversion of CO, known as the water gas shift reaction, and it is slightly exothermic. A desulfurization pre-treatment is usually applied to the feedstock, to avoid poisoning the catalysts.

The partial oxidation of methane consists in converting hydrocarbons into hydrogen and carbon monoxide in the presence of oxygen, carried out at high temperature from 1200 to 1500°C and at high pressure from 20 to 90 bars. The reaction is exothermic and takes place with or without catalyst depending on the load and the reactor used, this technique remains however much less common than steam reforming because of its high cost. Shell and Texaco processes are the most known, the operating conditions for these two processes involve a temperature of around 1000°C and a pressure of 35 bar [9].

The CO conversion reaction (Water Gas Shift reaction) carries out the conversion of the CO existing in the syngas by reaction with steam, this reaction is also the same in all reforming processes. The WGSR is balanced as follows:

This conversion is carried out in two successive stages, the first the conversion at high temperature which is carried out in HTS reactor (High Temperature Shift) at temperatures between 350°C and 450°C, then, the conversion at low temperature in a LTS reactor (Low Temperature Shift) at temperatures between 200°C and 250°C [10].

Metal membranes operate at high temperature and convert catalytically hydrogen gas into hydrogen atoms that can pass through solids. The atoms recombine on the product side into molecular hydrogen [11]. These membranes operate at temperatures ranging from 300°C to 600°C and the purified hydrogen exits the separator at an atmospheric pressure [8][12].

2.2. Process flowsheet and operating conditions

Several blocks were used to achieve this modelling for both processes. The process 1, for example, is essentially composed of 4 blocks:

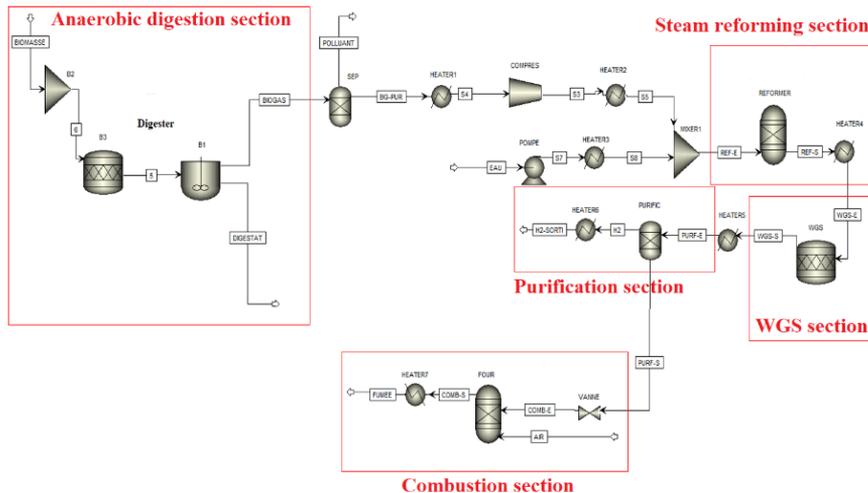

Figure 2: Flowsheet of hydrogen production from biomass via steam reforming
 (i) **Reformer block:** The process feeds the reformer modeled by the RGIBBS model at 973K and 10 atm by methane and steam at high pressure (10 atm). The syngas at the exit of the reformer block (REF-S stream) is cooled to 573K to be returned to the

WGS block. **(ii) The Water Gas Shift block:** The syngas at 573 K and 10 atm is converted by steam into a H₂ and CO₂ rich gas. The WGS reactor is modeled by the RSTOIC with a conversion rate of CO equals 0.98. The (WGS-S stream) from this block is heated to 723 K before being fed into the purification block. **(iii) The purification block:** The purification block is modeled by the Sep model under Aspen plus. The gas leaving the purifier still containing CH₄, CO, CO₂, H₂O and residual H₂ (PURF-S stream) is expanded to atmospheric pressure, to be returned to the combustion block. **(iv) The combustion block:** The combustion furnace is fed with the gas from the purification block to provide heat to the reforming reactor. The global flowsheet in the case of process 1 (coupling with steam reforming) is shown in figure 2.

2.3. Process energy analysis

The energy performance of coupled “anaerobic digestion-reforming” processes has been examined based on several [8,13]:

$$\eta_{biomass} = \frac{D_{H_2} \times LHV_{H_2}}{D_{biomass} \times LHV_{biomass} + W_{compres} + W_{pump}} \quad \text{Eq.1}$$

$$\eta_{biogas} = \frac{D_{H_2} \times LHV_{H_2}}{D_{biogas} \times LHV_{biogas} + W_{compres} + W_{pump}} \quad \text{Eq.2}$$

$$\eta_{methane} = \frac{D_{H_2} \times LHV_{H_2}}{D_{CH_4} \times LHV_{CH_4} + W_{compres} + W_{pump}} \quad \text{Eq.3}$$

With :

D_i : The mass flow rate of i component (hydrogen, biomass, biogas, methane) (kg/s), processes (kg/s), LHV_i : Lower Heating Value of i component (hydrogen, biomass, biogas, methane) (kJ/kg), W_i : Mechanical work of the compressor and pump (kW)

The biomass considered as hydrolyzed cow manure. The LHV of this last was set equal to 12.47 MJ/kg [14].

3. Results and discussion

The simulations of the "DA-Reforming" processes have been modeled on Aspen Plus, these models allow to compare the production of hydrogen from biomass via the coupling of the anaerobic digestion process with the different reforming models.

Table 1: comparison between the two processes

Process	Process 1	Process 2
H ₂ (L/day)	5.57	3.58
$\eta_{biomass}$ (%)	30.58	19.67
η_{biogas} (%)	82.72	47.21
$\eta_{Methane}$ (%)	83.24	53.51
Exhaust gas (L/day)	30.06	33.18
CO ₂ (L/day)	5.2	5.2
kg CO ₂ per kg H ₂	12.83	19.95

The results given by the simulations carried out show that the process 1 "DA-steam reforming" is the most productive of hydrogen, this process has the greatest volume flow in H₂ produced, for a feeding of 0.33 l/day of biomass, we obtained 5.57 l/day of hydrogen produced. The purified biogas containing CH₄ (51.97%), CO₂ (32.07%), H₂O (15.77%), H₂ (0.19%) where the presence of CO₂ and moisture in the biogas is an advantage or the biogas can be used directly, without the removal of steam because it promotes the WGS reaction [7], this reduces energy consumption and improves the ratio

H₂/CO, the biogas is reformed with an excess of steam. Figure 3 shows the mass and energy balance for the two simulations.

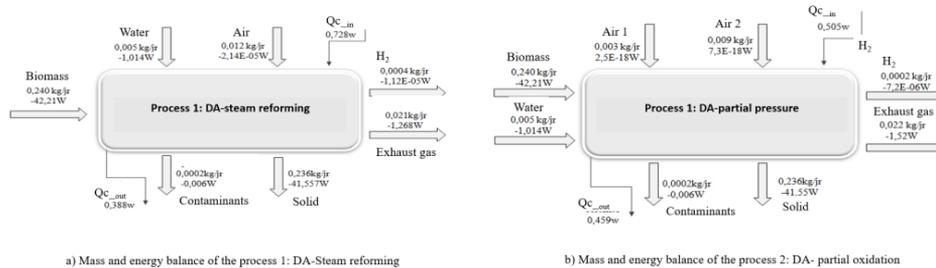

Figure 3: Mass and energy balance for the two process models

based on the energy balance and the different efficiencies shown above, the process1 (DA-steam reforming) has shown more interesting efficiencies compared to process 2 (DA- partial pressure (table 1).

It is necessary to consider the related pollutant emissions for a comparison of the two coupling processes for hydrogen production from biogas. Table 1 presents a comparison between the processes in terms of CO₂ emissions and exhaust gas released into the air from each process at identical temperatures and pressures. The CO₂ emissions per kg of H₂ produced in both processes show that process 1 emits less CO₂ than the process for producing the same amount of H₂. Overall, the amount of CO₂ released is almost the same for both process and equal to 5.2 L/day.

Conclusion

This study focuses on hydrogen production processes from biogas obtained from anaerobic digestion of biomass. The overall process consists of two main steps: (1) biogas production and (2) biogas reforming to generate pure hydrogen adapted from the literature. The important results of this section are summarized in the following points:

- The process 1 coupling DA and a steam reforming section is the most productive of H₂, with a flow of H₂ of 5,57 l/day, for a feed of 0.33 l/day of biomass.
- An energy efficiency η_{biogas} (hydrogen to biogas) of the process1 is about 82.72% which is the highest.
- The process 1 remains significantly interesting compared to process 2 in terms of quantity of CO₂ and gas exhaust released for 1 kg of H₂ produced

This global model can be improved by replacing the hydrogen separators by a purification section based on more efficient models for a better estimation of the energy consumed in the installation. Also, the energy optimization based on the pinch method seems indispensable followed by an exergetic study for each coupling process to calculate the exergetic efficiency and to determine the thermodynamic irreversibility.

Life cycle optimization of energy systems integrated with carbon capture and utilization

Iasonas Ioannou,^a Alex Marcandetti,^a Gonzalo Guillén Gosálbez^{a*}

^a*ETH Zürich, Vladimir-Prelog-Weg 1, 8093 Zürich, Switzerland*

**gonzalo.guillen.gosalbez@chem.ethz.ch*

Abstract

Carbon capture and utilization (CCU) based chemicals' have become an appealing strategy towards more sustainable production patterns. Several previous CCU studies often overlook the variability of renewable power technologies (by assuming average capacity factors) and focus on single technologies. To enlarge the scope of these studies, we optimize location-specific renewable energy systems (ES) clustered with CCU, while accounting for the yearly variability, to evaluate their environmental and economic performance more accurately. Our approach, based on a mixed-integer linear programming (MILP) model, coupled with life cycle assessment (LCA) principles, was applied to evaluate nine locations in the European Union (EU) and considering solar photovoltaics (PV), wind turbines, pumped hydro storage (PHS), and the interactions with the national grid. Overall, our tool could complement future assessments, expanding their scope and boosting the successful industrial implementation of CCU.

Keywords: Life cycle optimization; Energy system; Carbon capture and utilization.

1. Introduction

The fossil-based chemical industry should transition towards a low-carbon future aligned with the Paris climate agreement target (United Nations, 2016). Notably, even though the EU has adopted several policies, the envisioned carbon neutrality goal by 2050 is still beyond reach (European Commission, 2019). Thus, reducing the chemical sector's footprint could aid in achieving the climate mitigation target, which could be attained by replacing fossil-based resources with renewable carbon. Among the proposed alternatives, CCU, which requires large amounts of energy (often via an energy carrier, e.g., electrolytic H₂) to activate the carbon dioxide (CO₂), has received substantial attention (Ioannou et al., 2021). Moreover, by using CO₂ feedstock captured directly from the air –while using low-carbon energy (Deutz and Bardow, 2021)–, CCU could significantly aid the direct atmospheric carbon removal.

Within this general context, the design, location, and operation of the ES, covering the power demand, strongly affect the performance of the low-carbon chemicals (Ioannou et al., 2020). At present, LCA assessments of CCU assume a single power technology, e.g., wind or solar, for H₂ production while overlooking energy storage and links with the power sector. Furthermore, CCU chemicals are often economically inferior relative to their fossil-based counterparts due to their high energy consumption and the low capacity factor of the electrolyzer, which is powered by renewable technologies (Parkinson et al., 2019). Therefore, the variability and availability of renewable power could act as barriers to the successful implementation of CCU.

Here we develop a MILP model to design an ES-CCU cluster, considering nine EU locations, delivering an energy demand at a minimum levelized cost of electricity (LCOE). We integrate the ES with electrolytic H₂, CO₂ capture, and their transformation to methanol (MeOH), benefiting the sector's downstream applications. Our analysis

shows that since the ES's performance can vary significantly within and among countries, an integrated design of the ES-CCU clusters is key to assessing the chemicals' production feasibility and viability accurately.

2. Methods

To carry out our analysis, we developed a network model to design location-specific renewable ES, with energy storage, to minimize the *LCOE*. The latter aim could aid in coping with the variability of renewable technologies while attaining reductions in the cost of the CCU chemicals. The temporal representation is 2015 –on an hourly discretization–, which is adequate for the scope of the current design study. Hence, our model's unique feature is that it explicitly considers the hourly synergetic effects of hybrid ES –and storage– for CCU applications. The proposed methodology is divided into five steps, described briefly in the following sections: (i) selection of location(s), (ii) life cycle inventory generation (LCI) –based on assumptions, process simulation data or other sources–, (iii) model execution to obtain a tailored ES for the location defined in (i), while delivering the hourly power consumption defined in (ii), (iv) techno-economic and environmental assessment, and (v) interpretation of results.

2.1. Locations

We focus on three EU countries and three regions within each of them –Germany: Schwerin, Essen, and Haundorg; Austria: Parndorf, Tulln, and Zwettl; and Spain: Tarragona, Huelva, and Cartagena. Thus, we create a representative sampling to interpret the potential behaviour of the location-specific ES-CCU systems.

2.2. LCI of the CO₂-based MeOH production cluster

We design an ES that supplies the power requirements of a chemical facility, based on CO₂ capture and electrolytic H₂ generation, that produces 11.08 kt y⁻¹ of MeOH, acting as the functional unit. Within this general context, we assume an electrolytic efficiency of 80 % based on the LHV of H₂ and consider the co-product oxygen as a burden-free byproduct. Furthermore, we retrieved from the literature the LCI of the CO₂ hydrogenation to MeOH (González-Garay et al., 2019) and of the direct air capture (DAC) process (Fasihi et al., 2019). Finally, the LCI of raw materials and utility inputs are retrieved from the Ecoinvent V3.5 database (Wernet et al., 2016). Based on the latter, the hourly delivered power should be 10.84MW (amounting to 94.95 GWh y⁻¹), where 10.00MW is consumed for the generation of electrolytic H₂, and the remaining is used to synthesize MeOH and DAC (0.38 and 0.46MW, respectively). Furthermore, the facility will require 9.13 GJ of steam to capture 16.06 kt y⁻¹ of CO₂. The remaining inputs and direct emissions for MeOH production can be found in the original source. A cradle-to-gate LCA is carried out using the global warming (GW) indicator of the ReCiPe 2016 Midpoint (H) methodology (Huijbregts et al., 2017).

2.3. Mathematical model

We briefly describe the ES model, expressing parameters with regular letters and variables with italics. Our model integrates a set of power technologies (solar PV and wind turbines, $i \in I$), exploiting the complementary strengths to design the hybrid ES with storage at minimum *LCOE* –Eq.(1). The *LCOE* is based on the total annualized cost (*TAC*), and the predefined power demand of electrolysis, DAC, and MeOH production ($H_t + D_t$).

$$\min \left(LCOE = \frac{TAC}{\sum_{t \in T} (H_t + D_t)} \right) \quad (1)$$

The TAC considers the costs of purchasing power –from the national grid–, and the capital and operational expenses for installing (i) a PHS facility, with installed capacity S_{max} , (ii) solar PV, with installed capacity $CAP_{i=pv}$ and 3 kW nominal capacity per unit (NCAP), and (iii) wind turbines, with installed capacity $CAP_{i=wind}$ and 3 MW NCAP.

$$TAC = \sum_{t \in T} Grid_t \cdot LCOE_{gr} + Storage_{CAPEX} \cdot crf_s \cdot S_{max} + \sum_{i \in I} ((CAPEX_i \cdot crf_i + OPEX_i) \cdot CAP_i) \quad (2)$$

, where crf is the annual capital charge. The grid interactions and the PHS are necessary to satisfy the ES hourly availability, and thus, cope with the intermittent character of the installed renewables. CAP_i is calculated based on the $NCAP_i$ of the technology i , and the respective number of units –integer variable N_i .

$$CAP_i = NCAP_i \cdot N_i, \quad \forall i \in I \quad (3)$$

We assume that, within the ES lifespan, the annual local solar irradiation and wind speed patterns (obtained by "European Commission: PVGIS tool") will remain constant during the time horizon, and thus, the power generated from a unit i ($NP_{i,t}$) –Eq.(4)–, for 2015 is representative for the upcoming years.

$$NP_{i,t} = f(\text{wind speed, solar irradiation}), \quad \forall i \in I, t \in T \quad (4)$$

The number of renewable units is then connected with the hourly power generation from the respective renewable source – $NP_{i,t}$.

$$P_{i,t} = NP_{i,t} \cdot N_i, \quad \forall i \in I, t \in T \quad (5)$$

An energy balance is defined –Eq.(6)– and expressed in power units since the hourly representation allows us to omit the $\Delta t = 1h$.

$$H_t + D_t + PHS_{ch,t} + \sum_{i \in I} Cur_{i,t} = \sum_{i \in I} P_{i,t} + Grid_t + PHS_{di,t}, \quad \forall t \in T \quad (6)$$

The power demand ($H_t + D_t$) is covered by the renewable technologies ($P_{i,t}$), by purchasing power from the grid ($Grid_t$), and by discharging the PHS ($PHS_{di,t}$). Notably, the PHS capacity may not be sufficient to store the excess renewable power ($PHS_{ch,t}$) at all times. Thus, we consider power curtailment ($Cur_{i,t}$) to the national grid with zero cost. We further constrain the curtailment since it cannot physically exceed the amount delivered from the respective renewable source.

$$Cur_{i,t} \leq P_{i,t}, \quad \forall i \in I, t \in T \quad (7)$$

The PHS stored energy (S_t) at period t is determined from a second balance –Eq.(8)–, including the charging and discharging of power, with an efficiency η_s , and a self-discharge, with a coefficient λ_{di} . Therefore, due to losses by (i) charging-discharging efficiency or (ii) curtailment, the model prioritizes the direct use of renewable power.

$$S_t = (1 - \lambda_{di}) \cdot S_{t-1} + PHS_{ch,t-1} \cdot \eta_s - PHS_{di,t-1} / \eta_s, \quad \forall t \in T > 1 \quad (8)$$

Furthermore, since we consider a yearly base to design the ES –8760 periods–, a periodic condition is necessary to model the storage facility dimensions appropriately.

$$S_{t=1} = S_{t=8760} \quad (9)$$

Subsequently, the highest value of S_t is defined as the maximal amount of stored energy (S_{max}) –Eq.(10)–, which is needed for the cost calculations in Eq.(2).

$$S_t \leq S_{max}, \quad \forall t \in \mathbf{T} \quad (10)$$

We further define the binary variable y_t which restricts the PHS discharging when charging, and vice versa, while an upper bound, C_{ub} , limits both energy flows.

$$PHS_{ch} \leq C_S, \quad \forall t \in \mathbf{T} \quad (11)$$

$$PHS_{ch,t} \leq C_{ub} \cdot y_t, \quad \forall t \in \mathbf{T} \quad (12)$$

$$PHS_{di,t} \leq C_S, \quad \forall t \in \mathbf{T} \quad (13)$$

$$PHS_{di,t} \leq C_{ub} \cdot (1 - y_t), \quad \forall t \in \mathbf{T} \quad (14)$$

Subsequently, we assume that the designed PHS facility must have stored power able to satisfy at least a day of operation $-t_1=24 \text{ h}-$ at all times, whereas we further ensure that in the first period of the year it can deliver power for at least two days of operation $-t_2=48 \text{ h}$. Both of the latter limits affect the PHS design.

$$S_t \geq (H_t + D_t) \cdot t_1, \quad \forall t \in \mathbf{T} \quad (15)$$

$$S_{t=1} \geq (H_{t=1} + D_{t=1}) \cdot t_2 \quad (16)$$

Finally, since the solution for minimum *LCOE* might be degenerate, we apply a post-process step to minimize the GW of the ES (CW_{ES})—Eq.(17)—, subject to not increasing the minimum cost identified by solving Eq.(1). Please note that the GW of the renewable technologies $GW_{i \in I}$ should be adjusted to reflect the location-specific capacity factor.

$$CW_{ES} = (GW_{grid} \cdot \sum_{t \in \mathbf{T}} Grid_t + \sum_{i \in I} \sum_{t \in \mathbf{T}} GW_i \cdot P_{i,t}) / \sum_{t \in \mathbf{T}} (H_t + D_t) \quad (17)$$

3. Results and discussion

Focusing on the *LCOE* (Figure 1, left), we observe that the designed ESs show a substantial economic enchantment in Spain (reduction by 46.2–59.8 %), followed by more moderate improvements in Germany (22.7–42.8 %) when compared to the respective national grid. In contrast, the selected locations in Austria are less appealing (reduction by 2.9–17.3 %). The ESs' benefits emerge mainly due to the high *LCOE* of the national grid—significant in Spain for 2015 and less prominent in Germany and Austria ("eurostat 2016"). Furthermore, local synergies of wind and solar generation, and their storage, significantly influence their lower *LCOE* (see Table 1 and Figure 1, e.g., Cartagena and Schwerin), as also discussed in other studies (Demirhan et al., 2021; Fasihi and Breyer, 2020). For Huelva and Haundorg, the hourly wind speed and solar irradiation characteristics fail to complement each other. Thus, their ES operates without harvesting wind power, while the national grid supplies a considerable share to the ES (12.5 and 19.5 %, respectively). Even though both solar and wind power are being harvested, significant synergies are absent in Essen and the Austrian selected locations. For the latter regions, we observe a significantly lower supply of power from the PHS facility and substantial shares from the national grid—32.4–56.4 %—to attain the required high availability (Table 1).

Compared to the national grids, the designed ESs provide significant GW benefits in all locations (Figure 1, middle). Putting these reductions into perspective, the designed ESs in Spain reduce the GW by 79.3-90.6 %, 64.4-86.5 % in Germany, and 37.8-59.6 % in Austria. The latter improvements are attained via high renewables share in the hybrid ES, i.e., 43.6 to 94.7 % in Zwettl and Cartagena, respectively (see Table 1, accounting for both the direct and indirect –via PHS– use of renewable power). Notably, the high shares of grid power at Essen and in the three locations in Austria lead to a more moderate GW improvement, which influences the CCU performance –as discussed next. Finally, we observe high power losses for most regions due to the charging-discharging and curtailment (Table 1). The model's scope could be expanded to investigate alternatives with a lower curtailment, which we will leave as future work.

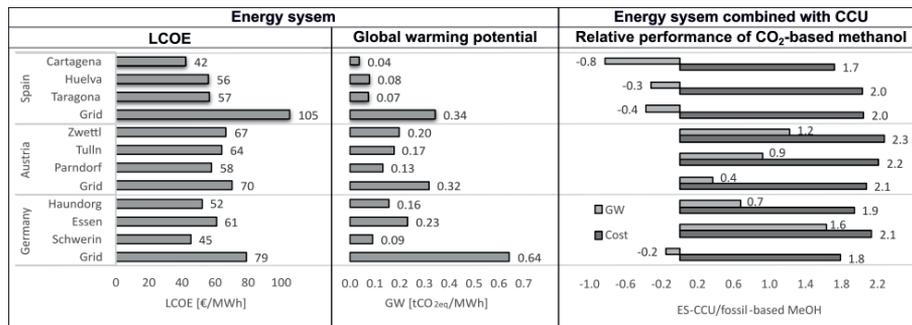

Figure 1. *LCOE* (left) and *GW* (middle) of the designed ESs compared to the national grid –for 2015. Notably, in 2019 the Spanish grid showed a lower *LCOE* compared to 2015 (17.1 % less), whereas the reported *LCOE* for Germany's and Austria's grid increased by 5.7 and 10.12 %, respectively, within the same period ("eurostat 2016"). On the right, we provide the relative cost and *GW* of the CO₂-based MeOH compared to the conventional counterpart.

Table 1. ES delivered power shares as a percentage of the total. The percentage of stored renewable energy is the same as in the ES, e.g., 13.6/86.4 % of solar/wind for Cartagena.

Country	Region	ES delivered power shares in %				ES losses as an additional %	
		Solar	Wind	PHS	Grid	Curtailed	PHS losses
Spain	Cartagena	9.7	61.9	23.1	5.3	17.7	6.1
	Huelva	43.6	0.0	43.9	12.5	8.2	11.5
	Tarragona	40.9	14.6	32.9	11.5	9.4	8.7
Austria	Zwettl	20.1	20.7	2.8	56.4	1.5	0.8
	Tulln	18.6	27.9	4.8	48.7	3.0	1.3
	Parndorf	15.9	38.2	11.3	34.6	4.6	3.0
Germany	Haundorg	42.8	0.0	37.7	19.5	3.3	9.9
	Essen	17.0	40.5	10.1	32.4	4.8	2.7
	Schwerin	20.9	47.3	21.2	10.6	9.6	5.6

Finally, green MeOH production based on the designed ESs (Figure 1, right) is economically unappealing in all selected locations, due to the vast power consumption for H₂ production. Furthermore, we show that in two areas, Essen and Zwettl, the *GW* of the MeOH is even higher –by 1.6- and 1.2-fold, respectively– compared to the fossil-based counterpart, and thus, the investigated CCU application is unfavourable. The latter burdens emerge due to the high shares of grid power in the ES. Compared to the benchmark, a lower *GW* for the green MeOH is observed in the remaining regions, indicating a successful application due to the effective utilization of atmospheric CO₂.

Finally, we observe negative GW values for MeOH (on a cradle-to-gate) in Schwerin, Cartagena, Huelva, and Tarragona, due to the better performance of their ESs.

4. Conclusions

Here we addressed the integrated design of power mix and CCU plants within a single cluster. In seven out of nine locations, we found that carbon footprint reductions (compared to fossil methanol) can be attained via CO₂-based methanol when location-specific hybrid ES powers the production. Our results highlight the benefits of hourly synergetic effects of renewable ES, while providing a roadmap for assessing CCU chemicals more accurately. An optimal and cost-effective integrated design of ES-CCU clusters, predominantly based on renewables, could help overcome the renewable's inherent variability. Notably, our assessment highlighted that even though a renewable-based ES can provide significant benefits compared to the national grid, these might be, in cases, insufficient to make CCU environmentally appealing.

Abstract

This study investigated two artificial intelligence techniques, Swarm Intelligence(SI) and Artificial Neural Networks(ANN), aiming to overcome the difficulties of simulating complex processes with unknown reactions and intermediates. These techniques are incorporated in reaction modeling via mass balances and reaction kinetic models. The accuracy and the applicability of the resulting models from ANN and SI were compared in the trained semi-batch reactors and the new continuous flow reactors. The ANN-based model is recommended when the extrapolation is unnecessary, and the data is high in volume and variety at the applied space. In this case, no profound reaction knowledge is required. Otherwise, the SI-based model should be employed, which provides detailed information of the target process and is constrained by physical meaning parameters.

Keywords: swarm intelligence, artificial neural networks, hybrid models, semi-batch reactors, continuous flow reactors

1. Introduction

The modeling and simulation of a chemical process are vital for digitization in the modern chemical industry, where the reaction process plays a significant role. The duty of downstream processes can be reduced dramatically if a substantial improvement in reaction controls is achieved. An optimal process design can be achieved by using accurate models, resulting in reducing working time and human errors. However, the modeling of the reaction process is complicated to perform, especially when it includes complex reactions that have not yet been studied earlier. The white-box (first-principle), black-box (data-driven), and grey-box (hybrid) approaches all have got decent performances in chemical reaction process modeling (Rojnuckarin et al., 1993; Xie et al., 2018; Babanezhad et al., 2020). Depending on the knowledge of the target process and the available data, the optimal modeling approach differs. Nowadays, people spend much time searching for the appropriate methods, and the inappropriate use of Artificial Intelligence(AI) techniques is one of the greatest threats because most chemical engineers have limited training in computer science and data analysis (Dobbelaere et al., 2021). This paper gives insights about which method is suitable according to the limited data at

hand by modeling unknown reaction processes via two AI techniques from different data scenarios. The data scenarios were analyzed by 4V characteristics - Volume, Velocity, Variety, and Veracity (Anagnostopoulos et al., 2016). The data volume refers to the involved data quantity, and the low data volume can lead to unreliable derived information. The data velocity shows the speed of getting and feeding new data. The data variety is the diversity of data, and the data veracity defines the data accuracy and precision.

The data coming from two different reactors are employed in this study, namely the Continuous Flow Reactor(CFR) and the Semi-Batch Reactor(SBR). The model aims to predict the time profiles of the process outputs (concentrations, temperatures). Because of a limited amount of CFR data, the kinetic model is trained using only the information coming from SBR. It contains a higher amount of data with a greater variety. This approach is possible since the model focuses only on the common chemical reactions for both CFRs and SBRs. The SBR and CFR models are developed taking mass and heat balances into account. The model of SBR is divided into fed-batch and batch subsections, and the CFR modeling is through a series of continuous stirred tank reactors.

Swarm Intelligence(SI) and Artificial Neural Networks(ANN) are the two AI methods applied in this paper. SI is a class of heuristic optimizers utilized to tune the parameters of a system. They are a sub-field of AI inspired by the social behavior of animals and other living beings. The collaboration of simple individuals performs the optimization task. Each individual has the freedom to move within the parameter search space, and its movement is affected both by its own experience and the experiences of the other group components (Chakraborty and Kar, 2017). The applications of SI algorithms have been popular in recent years. Schlueter et al. (2009) applied the ant colony optimization successfully in the design and control of wastewater treatment plants. ANNs are inspired by the biological neurons and their structures in the human brain. They have been widely applied in chemical engineering. Schweidtmann et al. (2019) proposed a hybrid modeling approach with ANN for the deterministic global process optimization. The available applications of SI and ANN in the open literature have proven their strong abilities in developing or improving the models. This paper compared these two techniques in modeling complex reaction processes from different data scenarios, aiming to offer insights about which method is suitable according to the limited data at hand for chemical engineers.

2. Methodology

The data employed in this paper for the training of the models was generated from experiments performed on SBRs. The available data were sorted into five scenarios representing the problems or situations in reality. The causes of these problems are usually safety requirements, device restrictions, or time limitations when collecting data in the chemical industry, resulting in challenges in data volume, velocity, variety, and veracity (Chiang et al., 2017). The data volume is represented by n , and the data velocity (s) is the number of measured points in one minute in this case. Commonly, the measurements from plants are restricted to a specific range or even a certain point, which can lead to low data variety. The mean chi-squares (χ^2) were calculated to assess the variety quantitatively, and a lower χ^2 indicates a wider variety. For the utilized data, the data veracity of all scenarios is considered equal. Among the available five data scenarios, Scenario 1 was considered the baseline to achieve a vision for the lower or higher volume, velocity, and variety. The two modeling approaches by ANN and SI integrated with Arrhenius equations were performed with different data scenarios as shown in Figure 1.

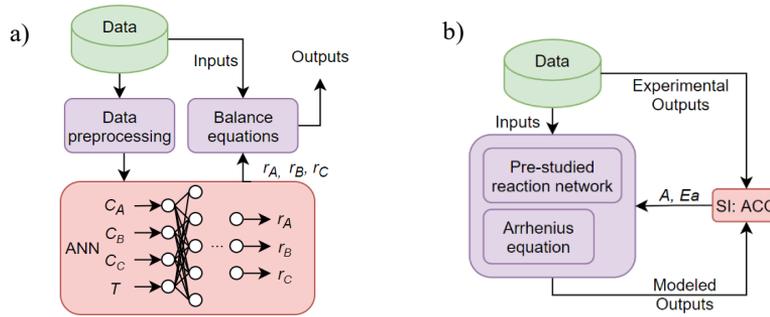

Figure 1: Modeling approaches: a) Artificial Neural Networks(ANN): The preprocessing of the available data is necessary. Each model is trained with an optimal ANN architecture for each data scenario; b) Swarm Intelligence(SI): Based on the possible reaction networks and Arrhenius equations, the related parameters for the model are determined by minimizing the error between modeled and experimental results through SI.

In the ANN approach (Figure 1a), it is necessary to preprocess the data because of the existing high noise and the indirect inputs/outputs. A Savitzky-Golay filter was applied firstly to the generated data from Raman spectra. Its inputs are molar concentrations (C_A, C_B, C_C) and temperatures (T), and the outputs are the reaction rates (r_A, r_B, r_C). The molar concentrations of the components were calculated from the mass weights obtained from Raman spectra. For each data scenario, an optimal ANN architecture was obtained by searching the number of layers and the neuron number of each layer. 70% of the data is utilized to form the training set, while the remaining 30% are used for the validation set. The inputs/outputs were both scaled to the range from 0.00 to 1.00 before feeding into the model. The searching regions of the hidden layer number and the neuron number of each hidden layer are up to 5 and 50, respectively, and the activation function is “tanh”. A $\lambda_1 = 10^{-5}$ L1 regularization term is also utilized to avoid overfitting. The developed reaction model was then combined with the material balance equations to simulate both SBRs and CFRs. There is no need for reaction knowledge in this approach, while the knowledge is compulsory for the following SI approach (Figure 1b).

Table 1: Possible reaction pathways for the SI approach

No.	Reaction	Reaction rates	Remarks
1	$A + B \leftrightarrow C$	$r_1 = A_1 e^{-\frac{Ea_1}{RT}} C_A C_B - A'_1 e^{-\frac{Ea'_1}{RT}} C_C$	r : reaction rate
2	$B + C \leftrightarrow D$	$r_2 = A_2 e^{-\frac{Ea_2}{RT}} C_B C_C - A'_2 e^{-\frac{Ea'_2}{RT}} C_D$	A : frequency factor
3	$A + E \leftrightarrow F$	$r_3 = A_3 e^{-\frac{Ea_3}{RT}} C_A C_E - A'_3 e^{-\frac{Ea'_3}{RT}} C_F$	Ea : activation energy
4	$A + C \leftrightarrow G$	$r_4 = A_4 e^{-\frac{Ea_4}{RT}} C_A C_C - A'_4 e^{-\frac{Ea'_4}{RT}} C_G$	R : gas constant
5	$A + B \leftrightarrow H$	$r_5 = A_5 e^{-\frac{Ea_5}{RT}} C_A C_B - A'_5 e^{-\frac{Ea'_5}{RT}} C_H$	T : temperature
6	$I + B \leftrightarrow J$	$r_6 = A_6 e^{-\frac{Ea_6}{RT}} C_I C_B - A'_6 e^{-\frac{Ea'_6}{RT}} C_J$	C_i : i concentration

Table 1 gives the pre-studied possible reactions from the open literature. The parameters (A_s, Eas) are determined by minimizing the error between modeled and experimental results through SI. R is the gas constant, and T is the temperature. Only three components (A, B, C) were tracked among the ten components listed in the table because of the limited reliable information derived from Raman spectra. The applied objective function is the

normalized mean squared error adding the $\lambda_1 = 10^{-5}$ L1 regularization term. The SI algorithm used in this paper is Ant Colony Optimization(ACO) (Riadi, 2014).

3. Results

The five data scenarios are shown in Figure 2, and the corresponding values indicating data volume, velocity and variety are listed in the following:

- 1) Baseline ($n=1083$, $s=1 \text{ min}^{-1}$, $\text{mean}(\chi^2)=227$);
- 2) Less volume, same velocity, more variety ($n=361$, $s=1 \text{ min}^{-1}$, $\text{mean}(\chi^2)=37$);
- 3) More volume, same velocity, less variety ($n=1805$, $s=1 \text{ min}^{-1}$, $\text{mean}(\chi^2)=288$);
- 4) More volume, more velocity, less variety ($n=2163$, $s=2 \text{ min}^{-1}$, $\text{mean}(\chi^2)=441$);
- 5) Less volume, less velocity, more variety ($n=365$, $s=0.2 \text{ min}^{-1}$, $\text{mean}(\chi^2)=64$).

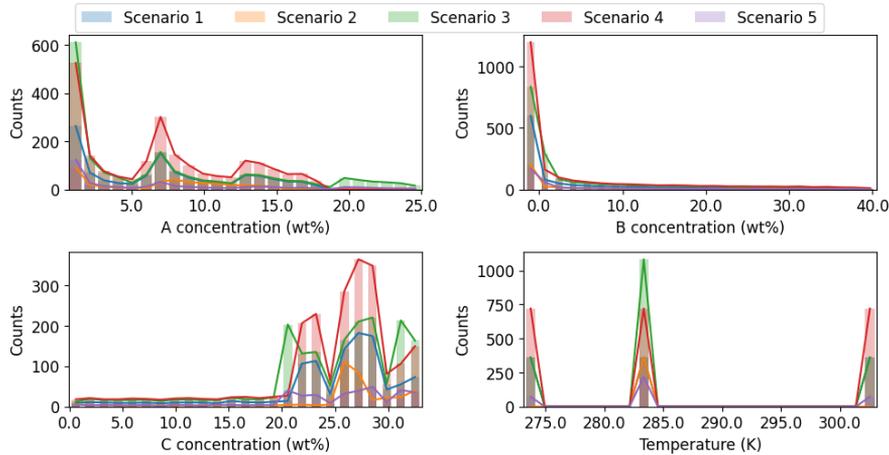

Figure 2: Data distribution of different scenarios. The x-axes are the data ranges, and y-axes are the data amount in each bin. The total number of bins is 25. Scenario 1): Baseline; 2): Less volume, same velocity, more variety; 3): More volume, same velocity, less variety; 4): More volume, more velocity, less variety; 5): Less volume, less velocity, more variety.

Data volume, velocity, and variety are correlated with each other in this case, while their importance for different applications is diverse. The highest amount in this paper is contained in Scenario 4 with 2163 samples, but its data variety is lower, meaning the data majority is in a certain range. It can be seen from Figure 2 that for A concentrations, almost no data in the range from 20.0 to 25.0 in Data scenario 4. Data scenarios 2 and 5 have similar data volumes, while their velocities differ, leading to different data varieties. The imbalanced data is common for all data scenarios, especially for B concentrations and temperatures.

In the ANN approach, a unique architecture of MultiLayer Perceptron(MLP) was employed for each scenario. The optimal architecture was searched using the “keras-tuner Hyperband” algorithm (Li et al., 2018). For all data scenarios, the input neurons are 4 and the output neurons are 3. The resulting optimal structures for scenario 1-5 are: 1) 19-5-36; 2) 8-22-13-5-41; 3) 6-33-12-23; 4) 28; 5) 41-5-35, where the k^{th} position from left is the neuron number of the k^{th} hidden layer. From the optimal trained structures, it can be concluded that an ANN trained with a higher data amount results in a lower amount of hidden layers, because the training of ANN parameters with more data is more efficient. For those with more than one hidden layer, the number of neurons usually increases first and then decreases, increases again, overcoming the difficulties from the imbalance data.

The final models were trained with 1,000 epochs with optimal ANN structures. The training processes are shown in Figure 3a, and all of the final losses were in the magnitude of 10^{-3} .

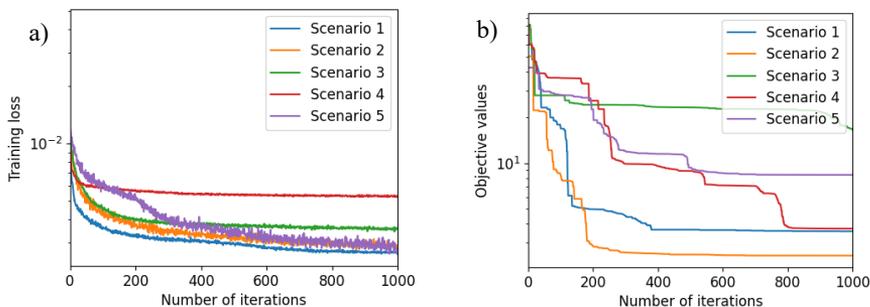

Figure 3: The training process: a) Artificial Neural Networks(ANN): The loss function is the mean squared error with the L1 regularization term, and the used optimizer is “Adam”; b) Swarm Intelligence(SI): The objective values are the sum of the normalized mean square errors and the L1 regularization term.

Scenarios 1, 2, 5 with the greater variety surpass the others. However, the data set with the highest amount (Scenario 4) returns a high loss function value without any significant improvement after the 200th training iteration. This number for the other scenarios is over 600. It can be discussed that a large amount of data but with a low variety does not help the ANN training and can even lead to unfavorable overfitting.

Figure 3b shows the progress of the parameter search executed using the ACO algorithm. The total number of parameters (A_i, Ea_i) is 24 for 6 possible reversible reactions, and the literature study of similar reactions determined their search boundaries. For each scenario, 1,000 iterations were performed and 30 ants were employed to obtain the optimal A s and Ea s. The decreasing of the objective values is stepped because ACO used the same particle until it found another outperforming one, requiring a large number of iterations to mitigate this phenomenon. Within the limited iterations, the training of Scenario 3 ended the earliest with the highest objective value and the least accurate model. Scenario 2 is superior to the others due to the greatest variety. Compared to the ANN approach, fewer efforts were put on the data processing, but more efforts were given to the chemistry reaction study. If the target reactions are already well-studied, this approach is suggested because of less pre-stage work and more delivered information. However, inappropriate assumed reactions can lead to totally different pathways from reality for the unknown complex reactions. The ANN approach can give more insights into unconsidered reaction routes.

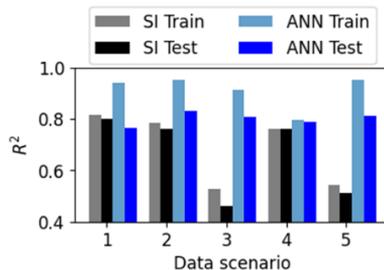

Figure 4: R^2 score of different data scenarios with SI and ANN approaches in semi-batch reactors. The training results were based on mentioned data scenarios. The SI/ANN test results were calculated from a brand-new test set.

The determination coefficients (R^2) of ANN and SI models are shown in Figure 4. The training results were from the data scenarios mentioned above. A brand-new data set of SBR gave the testing results. The ANN approach outperforms the SI approach for most data scenarios. In Scenario 1, the SI obtains a slightly higher R^2 for the testing set, which

shows the strong approximation ability of ANN for the same reactors. In the further stages, the obtained models from different scenarios were applied as the reaction model of a flow reactor. Unexpectedly, ANN models for CFRs gave $R^2 < 0.5$ because their temperatures are out of the ranges of the training data. The SI-based models with $R^2 > 0.8$ showed their advantages for extrapolating since the involved parameters are related to the physical meanings and are temperature independent.

4. Conclusions

This paper applied and compared two artificial intelligence techniques, the SI approach with ACO integrated with Arrhenius equations and the ANN approach with MLP to model complex reaction processes. The ANN model is recommended when the data is high in volume and variety at the applied space, where no profound reaction knowledge is required. The data variety is more important than other data characteristics, especially when the data amount reaches a certain level, such as 300 in this paper. However, the ANN approach is sensitive to the applied region and may be inappropriate for extrapolations. The SI model can provide more detailed information for straightforward extrapolations to other reactors.

Abstract

Continuous pharmaceutical campaigns may exhibit extremely short operating windows. As a result, the impact of the start-up and shutdown on both costs of production and environmental footprint is extremely important. In this paper, a systematic model-based dynamic optimization strategy was developed to address the combined start-up, shutdown and grade transition of a multistage combined cooling and antisolvent continuous crystallizer. Firstly, the optimal shutdown process was addressed, and several scenarios were considered. Subsequently, a combined start-up and shutdown optimization aimed at the maximization of on-spec production based on the maximization of the steady-state operating window for a fixed total manufacturing schedule. It was shown that 5510.2 g of on-spec products can be obtained during an operating window of 800 minutes, which, compared to the non-optimized scenario, corresponds to a 10% increase in production along with a significant reduction of wastes. In addition, the optimization of grade transition was also considered to improve the dynamic performance and flexibility of the process and helped reduce the transition time from 38.5 minutes to 2.7 minutes.

Keywords: Dynamic Optimization, MSMPR, Start-Up, Shutdown, Grade Transition, combined start-up and shutdown optimization

1. Introduction

Continuous manufacturing is increasingly considered as the most flexible option for pharmaceutical manufacturing (Mascia et al., 2013). Despite its great advantages, such as lower costs and increased productivity, the achievement of the full potential of continuous pharmaceutical manufacturing is still hindered by technical challenges such as the lack of optimal strategies to operate the plant during dynamic transitions, particularly under short operation windows (Benyahia et al., 2018). Hence, the development of systematic and rigorous strategies to optimize start-up, shutdown, and grade transition of single processes and integrated continuous pharmaceutical processes is critical to minimize wastes and further enhance resilience and cost efficiency.

Most upstream pharmaceutical processes require at least one crystallization unit, which is adopted as the key purification technology. Various model-based and model-free techniques have been developed to optimize and control crystallization processes (Nagy et al., 2020; Parekh et al., 2018). Typically, there are three types of widely used continuous crystallization technologies namely mixed suspension mixed product removal (MSMPR) crystallizers, plug flow crystallizers, and continuous oscillatory baffled crystallizers. A systematic optimization of the start-up, to minimize the time required to

reach steady state, has already been investigated and multiple decision variables and optimization strategies have been already implemented, including the optimization of discrete profiles of the jacket temperatures, antisolvent flow rates, seeding policies, initial state of the crystallization vessels, and several discretization methods (Liu & Benyahia, 2022). However, despite the importance of shutdown optimization and its significant impact on the cost and environmental performance of continuous pharmaceutical processes, given the large amounts of wastes generated at the end of unoptimized operation, the problem has been seldom reported in the literature.

In this work, a systematic optimization of the shutdown of a multistage continuous crystallization process was developed to maximize on-spec production by manipulating and adopting different discretization methods for the jacket temperatures and antisolvent flow rates. With the experience gained from previous start-up optimization (Liu & Benyahia, 2022), an effective optimization approach was proposed to optimize a scenario that combines start-up, steady-state, and shutdown. The optimal operating profiles of the control variables were identified in the case of the cooling and antisolvent crystallization of Aspirin in a three-stage MSMPR crystallizer. To enhance process flexibility and resilience, the problem of optimal grade transition of the crystal product is also considered to pave the way for the optimal operation of future continuous pharmaceutical processes focused on multiproduct manufacture. Optimal grade transition which has been widely investigated in the polymer industry to produce different product grades inherent to dynamic market demand (Wang et al., 2000, Benyahia et al., 2011). However, it has never been addressed in the context of continuous pharmaceutical manufacturing. In the current scenario, the product grade is associated with different targeted mean crystal sizes. The optimal grade transition aims at improving the flexibility of the multistage continuous crystallization process by minimizing the transition time based on a dynamic optimization approach which manipulates a set of decision vectors in a similar way as in the start-up and shutdown optimization.

2. Material and Method

2.1. Process model

As a case study, the crystallization of Aspirin (acetylsalicylic acid, ASA) in ethanol (solvent) and water (antisolvent) was used to demonstrate the dynamic optimization strategies. The dynamic mathematical model of the continuous crystallization process, which consists of the population balance model based on the standard method of moment, as well as the energy and mass balances, was developed under a set of assumptions as clearly discussed elsewhere (Liu & Benyahia, 2022). The model was modified to capture the shutdown procedure and allow additional decision options for the optimization problem. The full set of modified equations will not be presented here for the sake of brevity.

2.2. Formulation of the optimization problem

A three-stage MSMPR crystalliser was used, and the operating profiles of the antisolvent flow rate, jacket temperature were used as decision vectors based on several discretization methods. Several shutdown scenarios were developed to maximize on-spec production under both fixed and optimized total shutdown time. The shutdown process starts when the fresh feed to the first MSMPR is stopped. The operation profile of antisolvent and jacket temperature at each stage are used as decision variables for the optimization. When

a vessel undergone a complete shutdown, the antisolvent flow rate is also switched off as well as the flowrate of the coolant to the jacket. The combined process involves the start-up, steady state and shutdown. The start-up part has already discussed in great details in the previous work (Liu & Benyahia, 2022). For sake of brevity, only the mathematical formulation of the optimal shutdown is introduced here which can be described by the generic optimization problem shown below:

$$\begin{aligned}
 & \max_{T_{J,i,j}, F_{AS,i,j}, \Delta t_{i,j}} M_{OS} \\
 \text{s.t.} \quad & \dot{x} = f(x, y, u, p, t) & x_{t=0} = x_0 \\
 & 0 = g(x, y, u, p, t) \\
 & C1: 0 \leq F_{AS,i,j} \leq 20 \\
 & C2: 25 \leq T_{J,i,j} \leq 40 \\
 & C3: 0.5 \leq \Delta t_{i,j} \leq 8 \\
 & C4: \sum t_{1,j} \leq 8 \\
 & C5: \sum t_{2,j} \leq 15 \\
 & C6: \sum t_{3,j} \leq 21 \\
 & C7: \omega_{as,i} \leq 70\% \\
 & C8: S_i(t) \geq 1 \\
 & i = 1, 2, 3, j = 1, 2, \dots, n_d
 \end{aligned}$$

M_{OS} is the overall on-spec production during shutdown, the Decision variables are the vectors of discrete jacket temperatures and antisolvent flow rates, and time intervals ($T_{J,i}, F_{AS,i}, \Delta t_i$). The $\omega_{as,i}$ is the antisolvent mass ratio and n_d is the number of discretization point considered the same for all vessels.

For the shutdown optimization the initial conditions were set at the steady-state values. Based on the optimization problem above, several optimization scenarios were developed. The jacket temperature of the i th stage and j th time intervals were regarded as the decision variables in Scenario 1 (Constraints: C2 and C8), and antisolvent flow rate were regarded as decision variables in Scenario 2 (Constraints: C1, C7 and C8). The combined optimization of jacket temperature and antisolvent flow rate are considered in Scenario 3 (Constraints: C1, C2, C7 and C8). In these three cases, the shutdown time was fixed as 30 minutes. The discretisation method of the time intervals is also important, and as such, Scenario 4 was developed based on the combination of several decision vectors including jacket temperatures, antisolvent flow rates and time intervals (C1-C8). In scenario 4, the shutdown time is not fixed. Constraints C1-C3 represent the upper and lower bounds of the decision variables. C4-C6 are the linear constraints for the shutdown of each stage. C7 is a nonlinear constraint which is used to keep the antisolvent mass ratio

in each stage below 70% which is dictated by the prediction capability of the polynomial model of the solubility. C8 is a critical nonlinear constraint used to help avoid dissolution at all stages.

To address the optimization problem with different product requirements, a on the problem of optimal grade transition was also developed. Here, the optimization is designed to shift from a mean particle size of $417 \mu\text{m}$ to $300 \mu\text{m}$. This is considered to present the case where 2 different pharmaceutical products are required to have different dissolution profiles which may be encountered in the context of multiproduct or on-demand continuous manufacture. The combined manipulation of jacket temperatures, antisolvent flow rates and discretisation method was adopted to address the optimal grade transition problem. The objective is to minimize the transition time which in turn minimizes wastes and enhances operation flexibility. The full description of the optimization problem will not be presented here for the sake of brevity, but overall, it can be formulated in a similar way as the optimization problem described above.

3. Result and Discussion

The optimization problem was solved using a combination of a genetic algorithm and a deterministic method (SQP algorithm form MATLAB). The optimization results for the shutdown optimization are shown in table 1. It can be clearly seen that the total on-spec product mass collected during shutdown increases with the increased number of decision variables (increased degree of freedom). The scenario which combines the jacket temperatures and antisolvent flow rates gave the maximum on-spec product mass within the 30-minute shutdown time. The fourth scenario, with the shutdown time extended to 42 minutes which very close to the considered upper bound of the shutdown time, demonstrated additional gain in production capacity but on the expenses of a large shutdown time.

Following the successful shutdown optimization, the dynamic optimization of the overall campaign was developed to optimize the combined start-up, steady-state and shutdown to maximize on-spec production over a fixed continuous manufacturing window. The jacket temperature, antisolvent flow rate, seeding policies and discretisation method were all used as decision variables. The optimal mean crystal size and on-spec product profiles obtained with the resulting optimized operation profiles (Figure 2) are shown in Figure 1.

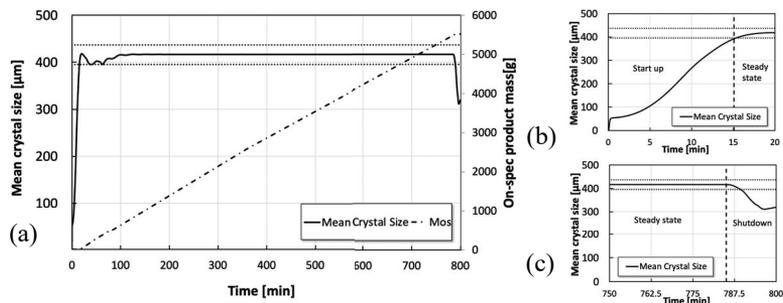

Figure 1. Dynamic profile of the mean crystal size, (a) On-spec production and mean crystal size over the whole process. (b) Mean crystal size during start-up and (c) Mean crystal size during shutdown.

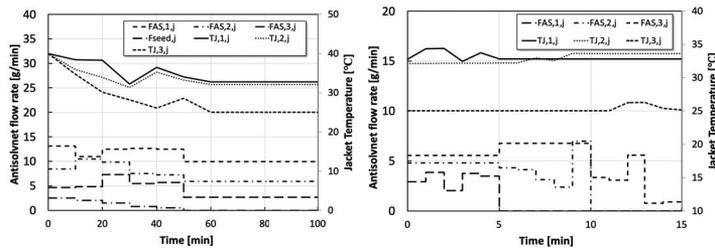

Figure 2. Optimal operating profiles during start-up and shutdown.

Compared to the shutdown process (scenario 4: 42 minutes shutdown and scenario 3: 30 minutes shutdown), in the integrated process optimization, the shutdown is shortened to 15 minutes and less on-spec product mass is collected during this period. When the total operating window is fixed as 800 minutes, shorter shutdown time will prioritise a production rate at the steady-state operating conditions which is higher than the one associated with the shutdown optimization. In other words, longer shutdown time will increase yield of the shutdown process, but shorter shutdown time will increase the production over the fixed total operating window. It is worth mentioning that the maximum on-spec production does not mean to rule out completely the shutdown optimization. It can be observed in figure 1 (c), that the shutdown starts at 785 minutes, and on spec products are still generated until the mean crystal size dropped below the 5% lower bound.

Table 1. Summary of the optimal shutdown results.

Scenario	1	2	3	4
M_{OS} (g)	177.6	205.6	208.0	216.7

Figure 2 shows that that the jacket temperature varies more significantly that in the case of the shutdown which tends to indicate that it is more sensitive to a variation in the antisolvent flowrates. In the shutdown, there are small variations in the jacket temperature which may be associated with the need to maintain the supersaturation at a lower level when a large amount of antisolvent is added. The addition of antisolvent has a conflicting effect as it increases supersaturation but also causes dilution of the system.

In the case of grade transition shown in Figure 3, the operation conditions associated with the second steady state (second product grade) were performed as a single step change for all manipulated variables to generate the base case scenario for the grade transition problem. With the optimal profile, the transition time was shortened from 38.49 minutes to 2.68 minutes, and a total of 290.3 g of the second grade on-spec products were collected.

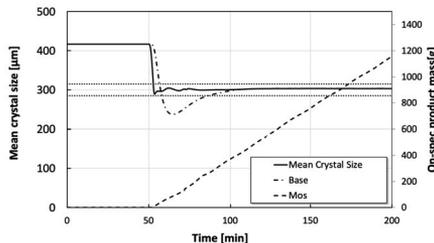

Figure 3. Performance of the optimized grade transition vs base case scenario.

4. Conclusion

The shutdown, combined start-up and shutdown and grade transition scenarios were optimized through a systematic model-based approach. To maximize on-spec production during the shutdown period, several strategies were implemented including discretized jacket temperature, antisolvent flow rate and discretization. Overall, antisolvent showed a more significant impact on the production, and additional on-spec products can be collected by slightly extending the shutdown time.

The dynamic optimization of the whole production process, which combines start-up, shutdown, and steady-state, were developed to maximize on-spec product mass by manipulating the jacket temperatures, antisolvent flowrates, seeding policies along with various discretization methods. With the optimized operation profile, 5510.2 g of on-spec products can be collected over a fixed operating window of 800 minutes. The problem of optimal grade transition was also addressed based on a similar dynamic optimization strategy which demonstrated a significant improvement of process flexibility by minimizing transition time by more than 90% which allows the minimization of wastes and maximization of on-spec production of different product grades.

Abstract

A systematic way to compute the finite dimensional dynamic model of the counter current heat exchanger network based on the graph theory is proposed. This contribution focuses to the serial interconnection of heat exchanger. The proposed models are build from the elementary block composed of two compartments corresponding to the hot and cold streams. The method is based on the graph based input-output representation of the convective heat flux between the heat exchangers.

Keywords: Heat exchanger network, Dynamic modelling, Graph theory

1. Introduction

Modelling and simulation are essential tools for the design of heat exchangers (HE) and Heat Exchangers Networks (HEN) (Roetzel et al. (2020)). Typical HE and HEN design approaches are primarily based on steady-state models. They are suitable for HENs retrofitting, upgrades and for estimating optimal steady-state operating points. However, dynamic performance of HEN has also to be explored in order to improve flexibility and controllability properties of HEN (Yang et al. (2021)) as well as their energy efficiency.

Roetzel et al. (Roetzel et al. (2020)) cited several mathematical models for transient analysis of heat exchangers: (i) the lumped parameter model, (ii) the distributed parameter model and (iii) the cell model. The first model is a systemic approach wherein the HE is considered as a single box; each fluid in the whole HE has a uniform temperature which is used to calculate the heat transfer through the partition wall and the energy balance involves only the inlet and outlet temperatures. The second model is an infinite dimensional model for which the HE space must be discretized (Michel and Kugi (2013)). The latter, also called lumped-distributed parameter model, consists in dividing the HE space into many elements along its length and applying the lumped method to each element (Correa and Marchetti (1987)). All the models were used for a better understanding of HE behaviour and the model building methods were discussed for small systems with simple topology like HE that are not nearly as large as district heating or heat networks. In addition, energy balances were written based on temperatures as state parameters and do not separate the convective and heat transfer parts, which makes it impractical to use them for scalable and extensible HENs.

For this purpose, we propose a systematic way to compute the finite dimensional dynamic model of a network of counter-current heat exchangers based on graph theory. This method gives the dynamic model in an iterative way and is well suited for modification of the network topology. The obtained model is given in a structure form that can be also used for control purposes.

2. Model formulation

This contribution focuses to the serial interconnection of heat exchangers. The proposed models are built from the elementary block named i composed of two well stirred compartments corresponding to the hot and cold streams as shown in Figure 1. Notations h, \bar{h} stand for specific enthalpies and Q, \bar{Q} for mass flows of the two streams. The indexes in and out stand for inlet and outlet flows resp. In this paper, we considered these two compartments were separated by a wall without heat accumulation for pedagogical purpose. However, this assumption could be overcome using mean heat capacities including both the fluid and wall properties as described in Correa's paper annex (Correa and Marchetti (1987)).

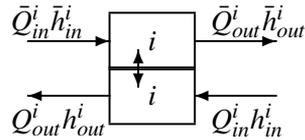

Figure 1: Elementary block i with enthalpy flows

The method is based on the graphic input-output representation of two heat exchangers in series with $[i]$ and $[j]$ elementary blocks, resp. as shown in Figure 2. The arrows are the convective inlet or outlet flows. They are also the edges of the graphs linked to the matter convection. The nodes of the matter and energy graphs are (i) the grey circles which represent the connections of the input and output convective fluxes (grey nodes without matter and energy accumulation) and (ii) each compartment where energy accumulation occurs. There are two graphs, since there are one hot and one cold streams by compartment, but they are treated simultaneously in order to implicitly take into account the heat transfer through the block partition walls (the heat transfer is represented in the block and the edge does not appear in the graph representation). The general construction of the model is based on the adjacency matrix of the convective graphs based on the material and energy balances. With this method, dynamic models of block series can be easily obtained. One of the main advantage of this approach is its modularity as the network can be extended as much boxes (representing a single or network heat exchangers) and streams as needed. So it can be used for network retrofitting or upgrade. Furthermore this modelling method gives structured matrices for which mathematical network analysis can be easily applied and used for control purposes such as dynamic energy assessment approach.

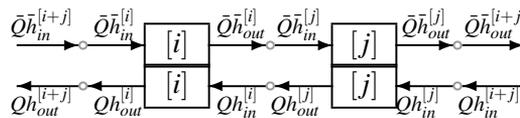

Figure 2: Two heat exchangers or two heat exchanger networks in series

The main assumptions for the modelling of blocks are the following:

- (a) The compartments are perfectly stirred.
- (b) The two streams remain in liquid phase.
- (c) The pressure P, \bar{P} in the compartments as well as the mass densities ($\rho, \bar{\rho}$), the heat capacities (c_p, \bar{c}_p) and the mass flow rates (Q, \bar{Q}) are constant.
- (d) There is no heat accumulation in the block partition wall and no heat exchange with the environment.
- (e) The global heat transfer coefficient λ and the volumes V, \bar{V} are constant and equal for all the compartments.

With the previous assumptions, the mass balances in each block are reduced to the equalities of the inlet and outlet mass flow rates, that for brevity we denote as \bar{Q} et Q :

$$0 = \bar{Q}_{in}^i - \bar{Q}_{out}^i \quad 0 = Q_{in}^i - Q_{out}^i$$

and the enthalpies are defined as $H = \rho V h(T)$, $\bar{H} = \bar{\rho} \bar{V} \bar{h}(\bar{T})$

Proposition 1 *With assumptions (a) to (e), the energy balances in an elementary block 1 write as:*

$$\begin{cases} \frac{d}{dt} \mathbb{H}^1 &= -\lambda (I_1 \otimes A_t) \mathbb{T}^1 - \frac{Q}{\rho V} \mathbb{A}_1 \mathbb{H}^1 - \frac{\bar{Q}}{\bar{\rho} \bar{V}} \bar{\mathbb{A}}_1 \mathbb{H}^1 + \mathbb{B}_1 \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^1 \\ \bar{H}_{in}^1 \end{bmatrix} \\ F_{out}^1 &= \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \mathbb{C}_1 \mathbb{H}^1 \end{cases} \quad (1)$$

where $\mathbb{H}^1 = \begin{bmatrix} H^1 \\ \bar{H}^1 \end{bmatrix}$, $\mathbb{T}^1 = \begin{bmatrix} T^1 \\ \bar{T}^1 \end{bmatrix}$ and $\begin{bmatrix} H_{in}^1 \\ \bar{H}_{in}^1 \end{bmatrix}$ are the enthalpy state, temperature and input enthalpy vectors resp. F_{out}^1 is the output enthalpy flow vector. \otimes stands for the Kronecker product. Matrices are as follow: $A_t = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$, $\mathbb{A}_1 = ((I_1 - S_1) \otimes A_c)$, $\bar{\mathbb{A}}_1 = ((I_1 - S_1^T) \otimes \bar{A}_c)$ with $I_1 = 1$, $S_1 = 0$, $A_c = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}$ and $\bar{A}_c = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$, $\mathbb{V} = \begin{bmatrix} (\rho V)^{-1} & 0 \\ 0 & (\bar{\rho} \bar{V})^{-1} \end{bmatrix}$, $\mathbb{B}_1 = \begin{bmatrix} B & \bar{B} \end{bmatrix}$ with $B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$, $\bar{B} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$, $\mathbb{C}_1 = \begin{bmatrix} C \\ \bar{C} \end{bmatrix}$ with $C = \begin{bmatrix} 1 & 0 \end{bmatrix}$, $\bar{C} = \begin{bmatrix} 0 & 1 \end{bmatrix}$,

The indexes t and c stand for heat transfer through the partition wall and for convection, resp. The matrices B_c et \bar{B}_c are null in this case but not for several blocks in series. The proof is trivial in this case. It suffices to write the energy balances and identify the matrices.

3. Model of two interconnected blocks

The objective of this section is to show on a simple case how the systematic modelling is constructed. For this purpose, we consider two elementary HEs composed of one block each as shown in Figure 3.

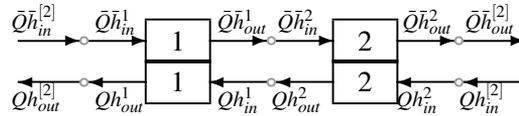

Figure 3: Two elementary HEs composed of one block each in series

Proposition 2 *With assumptions (a) to (e), the system of energy balances for 2 blocks in series writes as:*

$$\begin{cases} \frac{d}{dt} \mathbb{H}^{[2]} &= -\lambda (I_2 \otimes A_t) \mathbb{T}^{[2]} - \frac{Q}{\rho V} \mathbb{A}_2 \mathbb{H}^{[2]} - \frac{\bar{Q}}{\bar{\rho} \bar{V}} \bar{\mathbb{A}}_2 \mathbb{H}^{[2]} + \mathbb{B}_2 \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^{[2]} \\ \bar{H}_{in}^{[2]} \end{bmatrix} \\ F_{out}^{[2]} &= \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \mathbb{C}_2 \mathbb{H}^{[2]} = \begin{bmatrix} Q h_{out}^{[2]} \\ \bar{Q} \bar{h}_{out}^{[2]} \end{bmatrix} \end{cases} \quad (2)$$

with $\mathbb{H}^{[2]T} = [H^1 \quad \bar{H}^1 \quad H^2 \quad \bar{H}^2]$, $\mathbb{T}^{[2]T} = [T^1 \quad \bar{T}^1 \quad T^2 \quad \bar{T}^2]$. The matrices are given by: $\mathbb{A}_2 = ((I_2 - S_2) \otimes A_c)$, $\bar{\mathbb{A}}_2 = ((I_2 - S_2^T) \otimes \bar{A}_c)$ with I_2 the 2×2 identity matrix, $S_2 = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$, $\mathbb{B}_2 = \begin{bmatrix} 0_2 & \bar{B} \\ B & 0_2 \end{bmatrix}$, $\mathbb{C}_2 = \begin{bmatrix} C & 0_2^T \\ 0_2^T & \bar{C} \end{bmatrix}$ with $0_2^T = \begin{bmatrix} 0 & 0 \end{bmatrix}$.

Proof First let us consider two systems of energy balances as written in Proposition 1, the first for the block 1 and the second for the block 2. After vector and matrix concatenations, considering the global state vector $\mathbb{H}^{[2]}$ and the temperature vector $\mathbb{T}^{[2]}$ as written in Proposition 2 and denoting by \mathbb{O} the zeros matrices when the size is not specified, we can immediately write:

$$\begin{cases} \frac{d\mathbb{H}^{[2]}}{dt} = -\lambda \begin{bmatrix} (I_1 \otimes A_r) & \mathbb{O} \\ \mathbb{O} & (I_1 \otimes A_r) \end{bmatrix} \mathbb{T}^{[2]} - \frac{Q}{\rho V} \begin{bmatrix} \bar{A}_1 & \mathbb{O} \\ \mathbb{O} & \bar{A}_1 \end{bmatrix} \mathbb{H}^{[2]} - \frac{\bar{Q}}{\bar{\rho} \bar{V}} \begin{bmatrix} \bar{A}_1 & \mathbb{O} \\ \mathbb{O} & \bar{A}_1 \end{bmatrix} \mathbb{H}^{[2]} \\ + \begin{bmatrix} \mathbb{B}_1 \\ \mathbb{O}_{2 \times 2} \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^1 \\ \bar{H}_{in}^1 \end{bmatrix} + \begin{bmatrix} \mathbb{O}_{2 \times 2} \\ \mathbb{B}_1 \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^2 \\ \bar{H}_{in}^2 \end{bmatrix} \\ F_{out}^1 = \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} [\mathbb{C}_1 \quad \mathbb{O}_{2 \times 2}] \mathbb{H}^{[2]}, \quad F_{out}^2 = \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} [\mathbb{O}_{2 \times 2} \quad \mathbb{C}_1] \mathbb{H}^{[2]} \end{cases} \quad (3)$$

Clearly the first right hand side term of (3) is equal to first right hand side term of (2). In order to write the other terms, let us consider the interconnection matrix A_d for the enthalpy flows. The matrix elements are 1 if a grey node links two enthalpy flows, 0 else. By premultiplying on both sides the flow equality equations by ρV , $\bar{\rho} \bar{V}$ for flow related to Q , \bar{Q} respectively, we obtain:

$$\begin{bmatrix} QH_{in}^1 \\ \bar{Q}\bar{H}_{in}^1 \\ QH_{in}^2 \\ \bar{Q}\bar{H}_{in}^2 \\ QH_{out}^{[2]} \\ \bar{Q}\bar{H}_{out}^{[2]} \end{bmatrix} = \overbrace{\begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}}^{A_d} \begin{bmatrix} QH_{out}^1 \\ \bar{Q}\bar{H}_{out}^1 \\ QH_{out}^2 \\ \bar{Q}\bar{H}_{out}^2 \\ QH_{in}^{[2]} \\ \bar{Q}\bar{H}_{in}^{[2]} \end{bmatrix} = \begin{bmatrix} A_{dlu} & A_{dru} \\ A_{dl4} & \mathbb{O}_{2 \times 2} \end{bmatrix} \begin{bmatrix} QH_{out}^1 \\ \bar{Q}\bar{H}_{out}^1 \\ QH_{out}^2 \\ \bar{Q}\bar{H}_{out}^2 \\ QH_{in}^{[2]} \\ \bar{Q}\bar{H}_{in}^{[2]} \end{bmatrix} \quad (4)$$

A_d is intrinsic to the series of two HEs independently on their sizes.

- Computation of the inputs of the 2 subsystems that become global input variables. We have:

$$\begin{bmatrix} QH_{in}^{[2]} \\ \bar{Q}\bar{H}_{in}^{[2]} \end{bmatrix} = A_{dru}^T \begin{bmatrix} QH_{out}^1 \\ \bar{Q}\bar{H}_{out}^1 \\ QH_{out}^2 \\ \bar{Q}\bar{H}_{out}^2 \end{bmatrix} = \begin{bmatrix} QH_{in}^2 \\ \bar{Q}\bar{H}_{in}^2 \end{bmatrix} \quad (5)$$

- Computation of the internal inputs: They are given by:

$$QH_{in}^1 = A_{dlu_1} [QH_{out}^1 \quad \bar{Q}\bar{H}_{out}^1 \quad QH_{out}^2 \quad \bar{Q}\bar{H}_{out}^2]^T \quad (6)$$

$$\bar{Q}\bar{H}_{in}^2 = A_{dlu_4} [QH_{out}^1 \quad \bar{Q}\bar{H}_{out}^1 \quad QH_{out}^2 \quad \bar{Q}\bar{H}_{out}^2]^T \quad (7)$$

where A_{dlu_1} and A_{dlu_4} are the first and fourth line of A_{dlu} respectively.

Inserting the expressions of the internal outputs with respect to global state vector, we obtain the following relations for the internal inputs:

$$\begin{bmatrix} H_{out}^1 \\ \bar{H}_{out}^1 \\ H_{out}^2 \\ \bar{H}_{out}^2 \end{bmatrix} = \overbrace{\begin{bmatrix} \mathbb{C}_1 & \mathbb{O}_{2 \times 2} \\ \mathbb{O}_{2 \times 2} & \mathbb{C}_1 \end{bmatrix}}^{\mathcal{C}_2} \begin{bmatrix} \mathbb{H}^1 \\ \mathbb{H}^2 \end{bmatrix} \implies \begin{cases} QH_{in}^1 = QA_{dlu_1} \mathcal{C}_2 \mathbb{H}^{[2]} \\ \bar{Q}\bar{H}_{in}^2 = \bar{Q}A_{dlu_4} \mathcal{C}_2 \mathbb{H}^{[2]} \end{cases} \quad (8)$$

Let us rewrite the following terms in (3): $\begin{bmatrix} \mathbb{B}_1 \\ \mathbb{O}_{2 \times 2} \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^1 \\ \bar{H}_{in}^1 \end{bmatrix} + \begin{bmatrix} \mathbb{O}_{2 \times 2} \\ \mathbb{B}_1 \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^2 \\ \bar{H}_{in}^2 \end{bmatrix}$ in order to recompose with respect to internal and global inputs. We have :

$$\begin{bmatrix} \mathbb{B}_{11} & \mathbb{O}_2 \\ \mathbb{O}_2 & \mathbb{B}_{12} \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^1 \\ \bar{H}_{in}^1 \end{bmatrix} + \begin{bmatrix} \mathbb{O}_2 & \mathbb{B}_{12} \\ \mathbb{B}_{11} & \mathbb{O}_2 \end{bmatrix} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^2 \\ \bar{H}_{in}^2 \end{bmatrix}$$

where $\mathbb{B}_{11}, \mathbb{B}_{12}$ are the first and second column of \mathbb{B}_1 , that are respectively B and \bar{B} .

So for the global inputs, the last right hand side term of (2), we can identify that

$$\mathbb{B}_2 = \begin{bmatrix} \mathbb{O}_2 & \mathbb{B}_{12} \\ \mathbb{B}_{11} & \mathbb{O}_2 \end{bmatrix} = \begin{bmatrix} \mathbb{O}_2 & \bar{B} \\ B & \mathbb{O}_2 \end{bmatrix}.$$

Finally, for stream Q , let us add the convective term in (3) and the term on internal inputs and replace H_{in}^1 by the formula given in (8), we obtain:

$$-\frac{Q}{\rho V} \begin{bmatrix} \mathbb{A}_1 & \mathbb{O} \\ \mathbb{O} & \mathbb{A}_1 \end{bmatrix} \mathbb{H}^{[2]} + \frac{Q}{\rho V} \begin{bmatrix} \mathbb{B}_{11} \\ \mathbb{O}_2 \end{bmatrix} H_{in}^1 = -\frac{Q}{\rho V} \begin{bmatrix} \mathbb{A}_1 & \mathbb{O} \\ \mathbb{O} & \mathbb{A}_1 \end{bmatrix} \mathbb{H}^{[2]} + \frac{Q}{\rho V} \begin{bmatrix} \mathbb{B}_{11} \\ \mathbb{O}_2 \end{bmatrix} A_{dlu_1} \mathcal{C}_2 \mathbb{H}^{[2]}.$$

It remains to show that $\begin{bmatrix} \mathbb{A}_1 & \mathbb{O} \\ \mathbb{O} & \mathbb{A}_1 \end{bmatrix} - \begin{bmatrix} \mathbb{B}_{11} \\ \mathbb{O}_2 \end{bmatrix} A_{dlu_1} \mathcal{C}_2 = \mathbb{A}_2$. It can be checked that $A_{dlu_1} \mathcal{C}_2$ is equal to the third line of \mathcal{C}_2 . So $\begin{bmatrix} \mathbb{B}_{11} \\ \mathbb{O}_2 \end{bmatrix} [0 \ 0 \ 1 \ 0] = \begin{bmatrix} \mathbb{O}_{2 \times 2} & A_c \\ \mathbb{O}_{2 \times 2} & \mathbb{O}_{2 \times 2} \end{bmatrix}$. So $\begin{bmatrix} \mathbb{A}_1 & \mathbb{O} \\ \mathbb{O} & \mathbb{A}_1 \end{bmatrix} - \begin{bmatrix} \mathbb{B}_{11} \\ \mathbb{O}_2 \end{bmatrix} A_{dlu_1} \mathcal{C}_2 = \left((I_2 - S_2) \otimes A_c \right)$.

The same computation can be made for stream \bar{Q} .

- Computation of the global outputs. From the equations (4) and (8), we have:

$$F_{out}^{[2]} = \begin{bmatrix} QH_{out}^{[2]} \\ \bar{Q}\bar{H}_{out}^{[2]} \end{bmatrix} = A_{dld} \begin{bmatrix} QH_{out}^1 \\ \bar{Q}\bar{H}_{out}^1 \\ QH_{out}^2 \\ \bar{Q}\bar{H}_{out}^2 \end{bmatrix} = \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \underbrace{A_{dld} \mathcal{C}_2}_{\mathbb{C}_2} \mathbb{H}^{[2]}. \text{ It is easy to check that } \mathbb{C}_2 = A_{dld} \mathcal{C}_2 = \begin{bmatrix} C & \mathbb{O}_2^T \\ \mathbb{O}_2^T & \bar{C} \end{bmatrix} \text{ This ends the proof. } \blacksquare$$

This method can be iteratively used in order to obtain models for HE with i blocks.

4. Model of Heat Exchanger Network interconnection in series

The objective of this section is to give the model of two series interconnected HENs as shown in Figure 2. The results are given without proof.

As in the previous section, we do not present the graphic representation of matter flows since the graph is trivial and leads to equality of matter flows with two flows only: Q and \bar{Q} . However, as soon as mixer or splitter units will be consider this matter graph representation will be important to analyse.

First the model of a HE composed of i blocks in series is given by:

Proposition 3 *With assumptions (a) to (e), the system of energy balances for a heat exchanger composed of i blocks in series writes as:*

$$\begin{cases} \frac{d}{dt} \mathbb{H}^{[i]} &= -\lambda (I_i \otimes A_T) \mathbb{T}^{[i]} - \frac{Q}{\rho V} \mathbb{A}_i \mathbb{H}^{[i]} - \frac{\bar{Q}}{\rho V} \bar{\mathbb{A}}_i \mathbb{H}^{[i]} + \mathbb{B}_i \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_{in}^{[i]} \\ \bar{H}_{in}^{[i]} \end{bmatrix} \\ F_{out}^{[i]} &= \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \mathbb{C}_i \mathbb{H}^{[i]} = \begin{bmatrix} Qh_{out}^{[i]} \\ \bar{Q}\bar{h}_{out}^{[i]} \end{bmatrix} \end{cases} \quad (9)$$

with $\mathbb{H}^{[i]}, \mathbb{T}^{[i]}$ are the enthalpy and temperature $2i$ vectors of the i -blocks HE resp. The matrices are given by: $\mathbb{A}_i = \left((I_i - S_i) \otimes A_c \right)$, $\bar{\mathbb{A}}_i = \left((I_i - S_i^T) \otimes \bar{A}_c \right)$ with S_i the upper shift $i \times i$ matrix and

I_i the $i \times i$ identity matrix, $\mathbb{B}_i = \begin{bmatrix} 0_{2i-2} & \bar{B} \\ B & 0_{2i-2} \end{bmatrix}$, $\mathbb{C}_i = \begin{bmatrix} C & 0_{2i-2}^T \\ 0_{2i-2}^T & \bar{C} \end{bmatrix}$ with 0_{2i-2} the $2i-2$ zero vector.

Now let us consider the series of the i -blocks HE with a j -blocks HE or HEN. We have for the representation of the system of energy balances:

Proposition 4 *With assumptions (a) to (e), the system of energy balances for the global system composed of two systems of the form (9) in series (the first of size i and the second of size j) writes:*

$$\begin{cases} \frac{d\mathbb{H}^{[i+j]}}{dt} = -\lambda(I_{i+j} \otimes A_i) \mathbb{T}^{[i+j]} - \frac{Q}{\rho V} \mathbb{A}_{i+j} \mathbb{H}^{[i+j]} - \frac{\bar{Q}}{\rho V} \bar{\mathbb{A}}_{i+j} \mathbb{H}^{[i+j]} + \mathbb{B}_{i+j} \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_m^{[i+j]} \\ \bar{H}_m^{[i+j]} \end{bmatrix} \\ F_{out}^{[i+j]} = \mathbb{V} \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \mathbb{C}_{i+j} \mathbb{H}^{[i+j]} \end{cases} \quad (10)$$

with $\mathbb{H}^{[i+j]T} = \begin{bmatrix} \mathbb{H}^{[i]T} & \mathbb{H}^{[j]T} \end{bmatrix}$, $\mathbb{T}^{[i+j]T} = \begin{bmatrix} \mathbb{T}^{[i]T} & \mathbb{T}^{[j]T} \end{bmatrix}$ and the notations are the same as previously using $i+j$ instead of i .

The generalization of this approach when heterogeneous blocks parameters are considered can be easily deduced. Consider the $i \times i$ heat transfer parameter diagonal matrices Λ_i with notations $\lambda_{i,k}$ for the k^{th} element. Since volume of compartment can be different for the blocks, the previous (2×2) matrix \mathbb{V} has to be indexed by the number of the block: \mathbb{V}_n for the n^{th} block. Let us consider the block diagonal matrix \mathbb{W}_i with \mathbb{V}_n on the diagonal for the n^{th} block and the matrix $W_i^T = [\mathbb{V}_1 \quad \mathbb{V}_2 \quad \dots \quad \mathbb{V}_i] = \mathbf{1}_{2i}^T \mathbb{W}_i$ with $\mathbf{1}_{2i}$; the $2i$ vector of 1. The matrix \mathbb{W}_i is a $(2i \times 2i)$ matrix while the matrices W_i and W_i^T have the same dimensions as \mathbb{B}_i and \mathbb{C}_i , resp. Finally let us denote the Hadamard product as \odot .

Corollary 4.1 *With assumptions (a) to (d), the system of energy balances for a heat exchanger composed of i blocks in series writes as:*

$$\begin{cases} \frac{d\mathbb{H}^{[i]}}{dt} = -(\Lambda_i \otimes A_i) \mathbb{T}^{[i]} - Q \mathbb{W}_i \mathbb{A}_i \mathbb{H}^{[i]} - \bar{Q} \mathbb{W}_i \bar{\mathbb{A}}_i \mathbb{H}^{[i]} + \left(\mathbb{B}_i \odot W_i \right) \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \begin{bmatrix} H_m^{[i]} \\ \bar{H}_m^{[i]} \end{bmatrix} \\ F_{out}^{[i]} = \begin{bmatrix} Q & 0 \\ 0 & \bar{Q} \end{bmatrix} \left(W_i^T \odot C_i \right) \mathbb{H}^{[i]} = \begin{bmatrix} Q h_{out}^{[i]} \\ \bar{Q} \bar{h}_{out}^{[i]} \end{bmatrix} \end{cases} \quad (11)$$

5. Conclusion

The proposed systematic way of modelling series coupling of heat exchangers or heat exchanger networks has the advantage to have intrinsic matrices (with only 1 and 0 as elements) such \mathbb{A}_i , \mathbb{B}_i and \mathbb{C}_i . The perspective is to extend this method to parallel interconnections in order to model collectors or distributors. The genericity of the proposed structured dynamical model can be easily implemented as a computer aided process engineering.

Abstract

2020 has been identified as the worst year in the history of the aviation sector. Now, this sector faces its sustainable economic recovery; one of the alternatives to reach this is the use of renewable aviation fuel. Aviation biofuel is produced from several biomasses through different processing routes, which are technically feasible, but still not economically competitive with its fossil counterpart. In this context, biorefineries are an interesting processing scheme to produce aviation biofuel. Therefore, in this work the computer-aided modelling of a biorefinery for the conversion of castor bean plant (stems, leaves, husk and kernel) to produce biojet fuel is presented. The biorefinery is simulated in Aspen Plus, including mechanical pressing of kernel, pyrolysis of press cake, gasification, pyrolysis, fermentation of stems and leaves, transesterification and hydrotreating of vegetable oil. The fermentation stage produces bioethanol, which is fed to the alcohol-to-jet process; also, the gasification produces biohydrogen, used into the hydroprocessing. In this biorefinery, products as biochar, biogases, bio-oil, biohydrogen, bioethanol, biodiesel, light-gases, naphtha, green diesel and biojet fuel are obtained. The assessment of the biorefinery considers the calculation of economic (total annual cost and net gross profit of products), environmental (CO₂ emissions from electricity and steam), and energetic indicators (total energy invested in the processing, and total energy delivered by products). Based on results, the main factors affecting the TAC are the steam requirements (48.6 %) and the raw material cost (22.5 %); biojet fuel represents 35.4 % of the net gross profit. Also, in this scheme 4.97 ton CO₂ per kg of products are generated, and 5.49 kW are invested per kW of energy delivered by products. This biorefinery can be further improved by process intensification to reduce energy consumption.

Keywords: biorefinery scheme, castor bean plant, biojet fuel, computer-aided design.

1. Introduction

The pandemic caused by the accelerated spread of SARS-CoV2 virus has affected all economic sectors. In particular, the aviation sector has suffered a dramatic decreasing in its operation, mainly due to the social isolation measures and border closure. According to the International Air Transport Association, in 2019 the net profit of the sector was 26.4 billion USD, while in 2020 this indicator drops to -137.7 billion USD (IATA, 2021). In spite of a slight improvement during 2021, this sector is facing its sustainable economic

recovery, for which one of the alternatives is the use of renewable aviation fuel. The aviation biofuel can be produced from different biomasses through several processing routes; these processes are technically feasible, but still not economically competitive with its fossil counterpart (Gutiérrez-Antonio et al, 2021). In this context, the conversion of complete biomasses through a biorefinery scheme is a promising alternative to produce renewable aviation fuel, bioenergy and value-added products. According to the literature, the production of biojet fuel through a biorefinery scheme has been proposed for microalgae, *Jatropha curcas* fruit, sugarcane, soybean, waste cooking oil, rice straw (Romero-Izquierdo et al, 2021). Nevertheless, the conversion of castor bean plant is still missing in the literature; this study is relevant in México, since it is the energetic crop with major productive potential (Gutiérrez-Antonio et al, 2021). Thus, in this work the computer-aided modelling of a biorefinery for the conversion of castor bean plant to produce biojet fuel is presented. The complete castor bean plant is processed, which includes stems, leaves, husk and kernel. The biorefinery is simulated in Aspen Plus V.10, considering mechanical pressing of kernel, pyrolysis of press cake, gasification, pyrolysis and fermentation of stems and leaves, as well as transesterification and hydrotreating of vegetable oil.

2. Modelling and simulation of castor bean plant biorefinery

The biorefinery feedstock is castor bean plant, which consist of stems (38.8 wt %), leaves (14.4 wt %), husk and kernel (seeds, 46.8 wt %). The composition of stems and leaves includes cellulose (47 wt %), hemicellulose (28 wt %), and lignin (25 wt %); the husks consist of cellulose (4 wt %), hemicellulose (5 wt %), lignin (36 wt %), proteins (24 wt %), and other compounds (31 wt %). The feed stream is assumed as 3,531,954.98 kg/h of castor bean plant; this flowrate is obtained from an average yield for castor bean seed (1.41 ton/ha/year) and assuming 10.286 million ha available for its cultivation (Romero-Izquierdo, 2020). To generate biojet fuel and value-added products, the biorefinery consist of 4 internal processing zones: oil extraction (Z1), pyrolysis of stem, leaves, husk and press cake (Z2), lignocellulosic residues treatment (Z3), oil processing and purification of products (Z4). The structure of the biorefinery is shown in Figure 1. Zone Z1 considers the modelling of mechanical pressing of the kernel (Belaid et al., 2011) with module Crusher, and NRTL thermodynamic model; 90% of oil is obtained in this step. Zone Z2 includes the modelling of the pyrolysis of stem and leaves (Kan et al., 2016; Kaur et al., 2018), husk (Mohammed et al., 2014), and press cake (Santos et al., 2015) to generate bio-gases, biochar and bio-oil; these thermochemical processes were modelled with the modules Rbatch and the NRTL model. On the other hand, the lignocellulosic residues are processed in zone Z3 through acid hydrolysis plus co-fermentation (Conde-Mejía et al., 2013) and gasification (Inayat et al., 2010a), using RStoic and Rbatch modules with the NRTL model, respectively; also, in Z3 the alcohol is converted to biojet fuel through the Alcohol-to-Jet (ATJ) process based on the models reported by Ristic and Pacolli (2017), Heveling et al. (1988), Gounder and Iglesia (2011) and Tshabalala and Ojwach (2018), using RStoic modules and NRTL as thermodynamic model. In Zone Z4, the hydrotreating of the oil is described (Liu et al., 2015), using a Rstoic module and the Peng-Robinson equation. Transesterification of the oil is also modelled (Lima Da Silva et al., 2006), using a RStoic module and the UNIFAC model. Also, in Z4 the purification of the hydrocarbons produced in the ATJ and the hydrotreating processes is carried out in a distillation train, first designed with DSTW module assuming key components' recoveries of 99%, and later simulated using the Radfrac module with equilibrium stage model and BK-10 as thermodynamic model. The simulation of the

biorefinery is performed in Aspen Plus; indicators are calculated based on the results of the simulation. The economic and environmental indicators are the total annual cost (TAC) and the counting of released CO₂ emissions. The TAC involves capital cost, calculated by Aspen Economics, adding 18% and 61% due to contingencies, installation fees and equipment maintenance (Turton et al., 2012); and the operating cost, which considers utilities cost (heating and cooling), raw material cost (castor bean, hydrogen, ethanol, methanol) and additional reagents cost (glycerol, urea, H₂SO₄, etc), excluding catalyst cost and filters. The CO₂ emissions due to the production of steam and electricity are considered, and they are calculated through the methodology presented by Gutiérrez-Antonio et al. (2016). The gross profit is calculated with the product volume estimated from simulation results, and the market price of each product. Moreover, two proposed indicators are calculated: IE, energetic indicator defined as invested energy used for heating, regarding to energy delivered by the products; and IA, environmental indicator defined as CO₂ emissions regarding to total product mass obtained from the biorefinery.

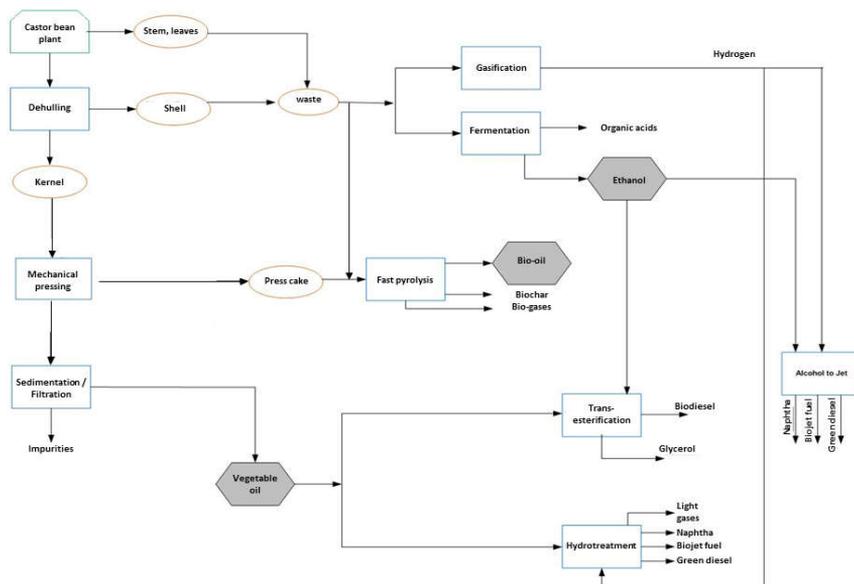

Figure 1. Block diagram of the proposed biorefinery for the conversion of castor bean plant.

3. Analysis of results

Table 1 presents the products obtained on the sections of the biorefinery and their mass flowrate. The kind of product is also indicated. RM means that the obtained product is used as raw material inside the process, while SP implies that the product is intended to be externally sold. It is observed that vegetable oil corresponds to approximately 11% of the initial biomass. From the mass of vegetable oil, approximately 50% is converted into hydrocarbons through hydrotreating, while 31% is transformed into biodiesel. It is important to notice that the hydrocarbons products from hydrotreating consists approximately on 62% of the biojet fuel fraction, which is the main product for this

biorefinery. From the gasification of biomass, an important quantity of hydrogen is obtained, which can be used to partially satisfy the H₂ requirements of the hydrotreating.

Table 1. Products obtained from the biorefining scheme.

Zone	Process	Products	kg/h	Kind of product
1	Mechanical pressing	Vegetable oil without impurities	398,320.81	RM
		Residual cake	678,428.38	RM
2	Fast pyrolysis (residue)	Bio-oil	190,461.98	SP
		Charcoal	15,665.26	SP
		Bio-gases	357,562.55	RM
	Fast pyrolysis (husk)	Bio-oil	56,843.35	SP
		Charcoal	55,991.02	SP
		Bio-gases	4971.70175	RM
	Gasification	Syngas (H ₂ , 98.75 mol%)	58,903.99	RM
	DA-AHCF	Glycerol	6,322.45	Non-recovered
		Succinic acid	7,349.43	
		Acetic acid	15,282.89	
		Furfural	114,555.53	
Ethanol		312,808.46	RM	
ATJ	Naphthas	72,119.12	SP	
	Biojet fuel	45,224.3	SP	
	Green diesel	11,149.31	SP	
3	Pyrolysis (residual cake)	Bio-oil	424,209.79	SP
		Charcoal	26,134.88	SP
		Bio-gases	240,266.56	RM
4	Hydrotreating	Naphthas	46,533.57	SP
		Biojet fuel	124,627.77	SP
		Green diesel	28,648.65	SP
	Transesterification	Biodiesel	125,457.45	SP
		Glycerol	11,839.08	RM

From the ATJ process, it can be observed that approximately 41% of the ethanol is transformed into hydrocarbons, where the biojet fuel fraction corresponds to approximately 35%.

Table 2 shows the results for the economic assessment of the biorefinery. It is observed that operational costs have the high contribution to the total annual cost, higher than 99.5%. Particularly, heating represents 48.7% of the operational costs, followed by others (which includes the cost for reactants) with 31.6%. This is a clear indicator of the need for reducing the energy requirements of the biorefinery, which could be achieved through the application of process intensification and energy integration. As reference, in January

2021 the price of fossil jet fuel was 1.51 USD/gal, while at September 2021 the price increased to 4.29 USD/gal; it is observed that the price of fossil jet fuel is increasing, so taking this aspect under consideration as well as a reduction in the processing costs could help to renewable aviation fuel to be economically competitive with its fossil counterpart.

Table 2. Results for the economic assessment of the biorefinery.

Operational cost (USDx10⁶/y)

From the environmental assessment, it has been determined that the total CO₂ emissions are 51,626.31 Mt CO₂/y. Those emissions of carbon dioxide are all associated with the production of steam for heating purposes. There is no production of CO₂ due to the generation of electricity, since the changes of pressure in the process are used to produce electricity, where this generation is even high than the electricity needs of the process. Thus, the excess electricity is sold. Then, reductions on heating requirements through advances technologies would also allow reducing the emissions of carbon dioxide.

4. Conclusions

The design and simulation of a biorefinery for the conversion of castor bean plant into biojet fuel, other biofuels and value-added products has been presented. The processing scheme considers four internal zones, where thermochemical, chemical, as well as biochemical processes are carried out. The proposed biorefinery allows obtaining biojet fuel as main product from two different routes: hydrotreating and ATJ, making use of the whole castor oil plant. It has been determined that the main contribution to the total annual cost and the environmental impact is due to the heating requirements, thus further enhancements are required to reduce those requirements and turn the production scheme economically feasible.

Abstract

Materials prepared via the polymer-derived ceramic route have been increasingly studied for protection against electromagnetic energy to mitigate electromagnetic interference. Both experimental and computational evaluations of electrospun SiCN fibers applied to electromagnetic shielding are not yet reported in the literature. This work aims to evaluate the electromagnetic properties of SiCN electrospun fibers by experiments and computational modelling and simulation. Polysilazane and polyacrylonitrile were used respectively as the ceramic precursor and spinning aid. After electrospinning, the fibers were pyrolyzed at 1000 °C. The samples were named SiCN_0, SiCN_40, and SiCN_70 respectively for 0, 40, and 70 wt.% polyacrylonitrile. The scattering parameters, impedances, and reflection losses were collected under X-band (8.2-12.4 GHz) in a vector network analyzer employing the waveguide propagation setup. The experimental scattering parameters were converted through the Nicolson-Ross-Weir method together with the shielding effectiveness and numerical electromagnetic computational studies. Simulations of scattering parameters were performed, and introductory electromagnetic scattering calculations in free space were computed including the radar cross-section (RCS) study. The relative complex electrical permittivity was approximately 3, 4.5, and 4 (real part) and 0.05, 0.22, and 0.1 (imaginary part) respectively for SiCN_0, SiCN_40, and SiCN_70. The SiCN_40 could experimentally store and lose more electromagnetic energy in the material, exhibiting a minimum reflection coefficient of -1.4 dB at 12.4 GHz. The computational simulation corroborated the better performance of SiCN_40 in reflection loss as well as in other electromagnetic spectral responses. Additionally, correlations between electromagnetic properties extracted from experiments and computational results from the RCS study were observed. The free space electromagnetic scattering of SiCN_40 showed better features when compared to the other samples. Owing to the microstructure and product design, SiCN_40 fibers demonstrated satisfying electromagnetic shielding properties in X-band. The computational experiments showed to be a new modelling and simulation approach to evaluate the electromagnetic properties of electrospun SiCN fibers. Further research will focus on material optimization and computational evaluation.

Keywords: complex electrical permittivity, polymer-derived ceramic, radar cross-section, reflection loss, shielding effectiveness.

1. Introduction

Materials prepared via the polymer-derived ceramic route have been increasingly studied for protection against electromagnetic energy to mitigate electromagnetic interference (Chen et al., 2021). The lightweight ceramic provided by these advanced materials is an important advantage over metallic alloys classically used in the military and aircraft industries (Hou et al., 2021). The protection against electromagnetic waves in X-band (8.2-12.4 GHz) is especially important since this frequency range is used for radar, satellite communication, and wireless computer networks. Recent research on electrospun preceramic fibers applied to electromagnetic shielding in X-band has been boosted with the manufacturing of SiC, SiCN, and SiBCN systems. The first work was published in 2017 reporting the electrospinning of polycarbosilane and polycaprolactone followed by crosslinking and pyrolysis at 1300 °C to produce SiC fibers with a reflection loss of -25 dB at approx. 10 GHz (thickness of 3 mm) (Hou et al., 2017).

Various methods based on modelling and simulation approaches have been addressed to investigate the shielding effectiveness of various materials (Liang et al., 2021; Ud-Din Khan et al., 2020). Despite some efforts, the manufacturing of polymer-derived ceramic fibers for high-performance in X-band electromagnetic shielding remains a daunting technical challenge. This work aims to evaluate the electromagnetic properties of SiCN electrospun fibers by experiments and computational modelling and simulation. This work contributes to studying electrospun SiCN fibers for electromagnetic shielding applications by experimental-computational technique. The results obtained here open new grounds for developing these advanced materials by computational techniques, which will be useful to assess and develop these ceramics to final applications, thus, reducing the cost of the experimental procedure. A comprehensive electromagnetic simulation is urgently needed to improve the safety and reliability of different applications in complex electromagnetic environments.

2. Material and methods

Polysilazane synthesized from crosslinked Durazane 1800 (Merck KGaA, Germany) and polyacrylonitrile 200 kDa (Polysciences, Inc., USA) were used respectively as ceramic precursor and spinning aid. The solutions were prepared using dimethylformamide 99.5% (Fisher Chemical, USA) as solvent and dicumyl peroxide 98% (Sigma-Aldrich Corporation, Germany) as crosslinker. After electrospinning, the fibers were pyrolyzed at 1000 °C in nitrogen. The samples were named SiCN_0, SiCN_40, and SiCN_70 respectively for 0, 40, and 70 wt.% of polyacrylonitrile. Five samples were prepared in silicon matrices: 5, 10, or 20 wt.% (thickness of 2.35 ± 0.32 mm). The scattering parameters, impedances, and reflection losses were collected under X-band in a vector network analyzer (VNA) N5230C-PNA-L (Agilent Technologies, USA) employing the waveguide propagation setup. The experimental parameters were converted through the Nicolson-Ross-Weir (NRW) method. The complex permittivity (ϵ) in a dispersive (frequency-dependent), homogeneous, and isotropic material medium can be expressed by **Equation (1)** (Naito and Suetake, 1971),

$$\epsilon(\omega) = \epsilon_0 \epsilon_r(\omega) = \epsilon_0 (\epsilon_r'(\omega) - j \epsilon_r''(\omega)) = \epsilon_0 \epsilon_r'(\omega) (1 - j \tan[\delta_e(\omega)]), \quad (1)$$

where ϵ_0 is the electric permittivity in vacuum, ϵ_r is the relative complex electrical permittivity, ϵ_r' and ϵ_r'' are the real and imaginary parts of the relative complex electrical permittivity, respectively. The electrical tangent loss term, $\tan[\delta_e(\omega)] = \epsilon_r''(\omega)/\epsilon_r'(\omega)$, directly relates the imaginary and real components of the permittivity and measure the inherent dissipation energy due to electrical losses. The term $\omega = 2\pi f$ is the angular

frequency ($\text{rad}\cdot\text{s}^{-1}$) with f being the frequency in Hz. The reflection loss (RL) assuming the slab considerations ended by a conduction plane in decibel units (dB) is given by **Equation (2)**,

$$RL_{dB}(\omega) = 20 \log_{10}(S_{11}(\omega)) = 20 \log_{10} \left(\frac{z_{in}(\omega) - z_0}{z_{in}(\omega) + z_0} \right), \quad (2)$$

where S_{11} is the scattering parameter obtained from VNA measurements (observed from the port 1 of the waveguide), z_{in} is the input impedance, z_0 is the reference to the impedance load. The equation for shielding effectiveness (SE) related directly to the scattering parameters in dispersive and reciprocal media is given by **Equation (3)** (Al-Saleh et al., 2013),

$$SE_{TdB}(\omega) = 10 \log_{10} \left(\frac{1}{1 - |S_{11}(\omega)|^2} \right) + 10 \log_{10} \left(\frac{1 - |S_{11}(\omega)|^2}{|S_{12}(\omega)|^2} \right) = SE_{RdB}(\omega) + SE_{AdB}(\omega), \quad (3)$$

where $SE_T(\omega)$, $SE_R(\omega)$, and $SE_A(\omega)$ represent respectively total, reflected, and absorbed shielding effectiveness and the scattering term $S_{12} = S_{21}$ in reciprocal media. The radar cross-section (RCS) is a far-field parameter employed to characterize the scattering properties of a radar target (Balanis, 2012). For three-dimensional objects, the RCS can be calculated considering the spherical coordinate system by **Equation (4)** (Balanis, 2012),

$$\sigma_{RCS}(r, \theta, \phi) = \lim_{r \rightarrow \infty} \left[4\pi r^2 \frac{\bar{S}_e(r, \theta, \phi)}{\bar{S}_i(r, \theta, \phi)} \right] = \lim_{r \rightarrow \infty} \left[4\pi r^2 \frac{|\bar{E}_e(r, \theta, \phi)|^2}{|\bar{E}_i(r, \theta, \phi)|^2} \right], \quad (4)$$

where r is the distance between the target object and the observer, $\bar{S}_e(r, \theta, \phi)$ is the scattered power spectral density, $\bar{S}_i(r, \theta, \phi)$ is the incident power spectral density (or the incident Poynting vector), $\bar{E}_e(r, \theta, \phi)$ is the scattered electric field intensity vector, and $\bar{E}_i(r, \theta, \phi)$ is the incident electric field intensity vector. The unit of $\sigma_{RCS}(r, \theta, \phi)$ is m^2 , although the RCS is also commonly presented in dBsm (decibel squared milliwatt), as expressed by **Equation (5)** (Knott et al., 2004),

$$\sigma_{RCS_{dBsm}}(r, \theta, \phi) = 10 \log_{10}[\sigma_{RCS}(r, \theta, \phi)]. \quad (5)$$

Based on the experimental electromagnetic properties, numerical electromagnetic computational studies were implemented. Simulations of reflection losses were performed in a guided electromagnetic wave study, and introductory electromagnetic scattering calculations in free space including the RCS study were computed. The computational experiments were simulated with FEKO® software (Altair, USA), which allows solving Maxwell's equations in three dimensions for solving full electromagnetic waves. The method of moments (MoM) was used by both the waveguide electromagnetic propagation with one and two ports and the free space electromagnetic propagation simulations.

3. Results and discussion

According **Equation (1)**, the relative complex electrical permittivity was approximately 3, 4.5, and 4 (real part) and 0.05, 0.22, and 0.1 (imaginary part) respectively for SiCN_0, SiCN_40, and SiCN_70 (**Figure 1**). The studies showed that 5 wt.% fibers concentration in silicone was effective on electromagnetic shielding. The SiCN_40 could experimentally store and lose more electromagnetic energy in the material, exhibiting a minimum reflection coefficient of -1.4 dB at 12.4 GHz (**Figure 2-a**). Likewise, the

computational simulation corroborated the better performance of SiCN_40 in reflection loss (**Figure 2-b**), considering the incident electric intensity field vector with unitary amplitude value, $z_0 = 377 \Omega$ (approximately the free space impedance), 2 mm of sample thickness, and WR-90 rectangular waveguide section dimensions ($a = 22.86$ mm and $b = 10.16$ mm) for all cases according to **Equation (2)**.

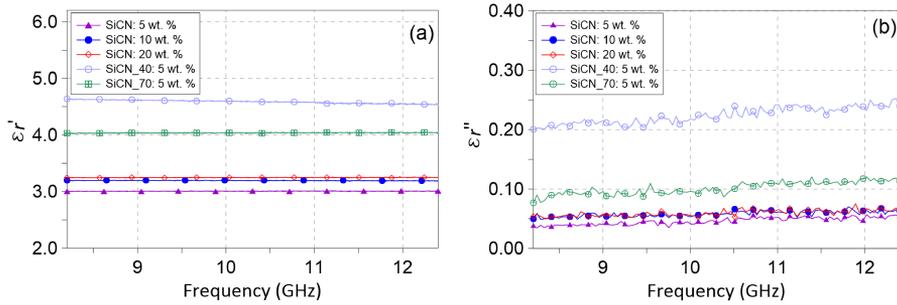

Figure 1. a) Real and b) Imaginary components of the complex relative electrical permittivity obtained experimentally by the NRW method in X-band.

There is a slight difference between experimental and computational results, which can be attributed to the alignment and agglomeration of fibers, matrix curing, and variation of sample thickness. The ability to adjust shielding properties through the addition of the carbon precursor (spinning aid), the nanostructure of SiCN, and fiber morphology opens new strategies for the development of electromagnetic shielding materials.

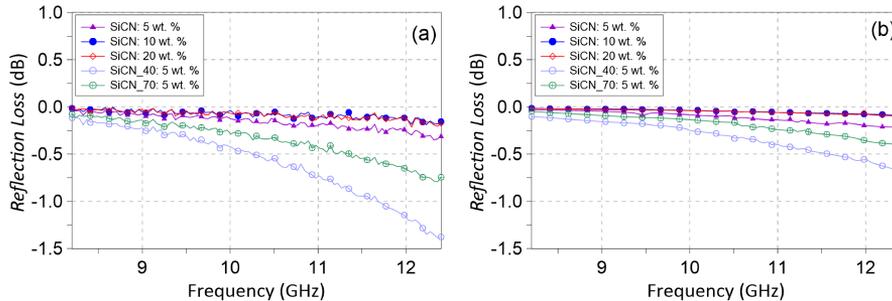

Figure 2. a) Experimental and b) Computational measurement of reflection loss in X-band.

As reported by **Equation (3)**, the total shielding effectiveness calculation in experimental electromagnetic guided conditions suggests the dominance of the waveguide experimental S_{11} scattering term contribution, i.e., the scattering reflection mechanism contribution is predominant (**Figure 3-a**). The correlations on the amplitudes are also pointed out (**Figure 3-b**).

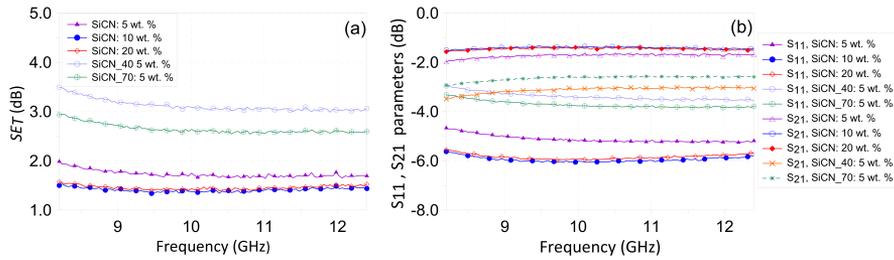

Figure 3. a) Total shielding effectiveness calculation and b) Experimental waveguide S_{11} and S_{21} scattering parameters in X-band.

The free space scattering radiation performance of an object describes how energy is scattered when an object is exposed to under a plane wave electromagnetic incident field (see the free space computational setup in **Figure 4-a**). The simulated target was defined with a thickness of 2 mm and 300 mm of side length. The blue arrow represents the direction of the electromagnetic wave propagation (i.e. the incident Poynting vector, \vec{S}_i) as normal orientation ($-z$ axis direction) assuming the x - y target plane, while the green arrow represents its polarization vector direction (i.e. the incident electric intensity field vector \vec{E}_i) defined in $-x$ axis direction, whereas its amplitude value was set as unitary (**Figure 4-a**). For clarification, the three-dimensional (3D half sphere) RCS simulated results (**Equations (4)** and **(5)**) using experimental electromagnetics properties from SiCN: 5 wt.% were calculated assuming the frequencies of $f = 8.2$ GHz (**Figure 4-b**), $f = 10.3$ GHz (**Figure 4-c**), and $f = 12.4$ GHz (**Figure 4-d**). The main RCS lobe amplitude is enhanced when the electromagnetic wave frequency increases as well the number of lateral RCS side lobes also increase due to the increments in the frequency of the wave excitation. The free space electromagnetic scattering of SiCN_40 defined with arbitrary frequency ($f = 10.3$ GHz) showed better features when compared to the other samples (**Figure 4-e**).

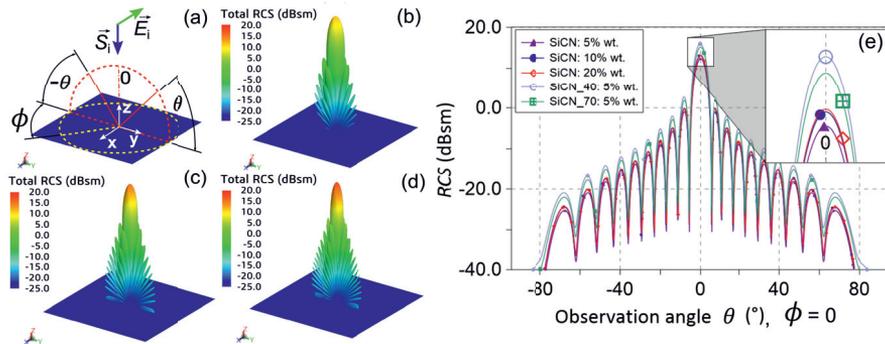

Figure 4. Computational results of RCS scattering study in free space. a) Computational setup illustration for the far-field spectral diagram of radiation scattering from SiCN: 5 wt.% at the frequency of b) 8.2 GHz, c) 10.3 GHz, and d) 12.4 GHz. e) Radiation diagram with theta, (θ), observation angle from -90° to 90° , for all sample materials at the frequency of 10.3 GHz which was chosen arbitrarily.

Direct correlations between the amplitudes from the electromagnetic properties extracted from experiments (**Figure 1**) and computational results from the amplitudes of the RCS

study were observed (**Figure 4-e**). This fact suggests the possibility of exciting opportunities owing to the advanced studies evaluations which can be performed over real and practical applications of shielding materials supported by simulation methods. Computer simulation is important for real applications that have specific targets since the RCS is a function of the effective permittivity of the material, its roughness, geometry, and angle. The simulation enables in analyzing the performance of a wide range of applications to answer RCS questions for military and aircraft industries. The simulation study showed the wave scattering in free space over the SiCN₄₀ material in electromagnetic shielding, showing that final applications can be simulated using the experimental parameters (**Figure 4**).

4. Conclusion

The experimental and computational results suggest that polymer-derived ceramics act as electromagnetic shielding materials, greatly attenuating the incoming radiation for certain frequency values. Owing to the microstructure and product design, SiCN₄₀ fibers demonstrated satisfying electromagnetic shielding properties in X-band. The computational experiments showed to be a new modelling and simulation approach to evaluate the electromagnetic shielding of electrospun SiCN fibers. The practical implications of this work are the scattering simulations with the use of the SiCN fibers for final applications including military and aircraft industries. Using electromagnetic simulations, various types of electromagnetic problems involving the use of polymer-derived ceramic fibers can be quickly and accurately solved. Further research will focus on material optimization with computational evaluation.

Abstract

This work addresses the control optimization of time-varying systems without the full discretization of the underlying high-fidelity models and derives optimal control trajectories using surrogate modeling and data-driven optimization. Time-varying systems are ubiquitous in the chemical process industry and their systematic control is essential for ensuring each system to be operated at the desired settings. To this end, we postulate nonlinear continuous-time control action trajectories using time-varying surrogate models and derive the parameters of these functional forms using data-driven optimization. Data-driven optimization allows us to collect data from the high-fidelity model without pursuing any discretization and fine-tune candidate control trajectories based on the retrieved input-output information from the nonlinear system. We test exponential and polynomial surrogate forms for the control trajectories and explore various data-driven optimization strategies (local vs. global and sample-based vs. model-based) to test the consistency of each approach for controlling dynamic systems. The applicability of our approach is demonstrated on a motivating example and a CSTR control case study with favorable results.

Keywords: Data-driven optimization, dynamic optimization, time-varying systems, optimal control, surrogate modeling.

1. Introduction

Time-varying processes are omnipresent in chemical engineering and postulating the correct optimal control laws are critical for a feasible and safe operation of any process. Commonly, such processes are studied and modeled with a set of differential or differential-algebraic equations that captures the overall dynamic balances and other algebraic relationships (e.g., rate laws) (Diangelakis et al., 2017).

A vast number of dynamic optimization techniques rely on approximations that utilize uniform and nonuniform discretization, leading to the solution of large-scale linear, nonlinear, or linearized problems (Biegler, 1984). Yet, such problems are solely addressed using calculus of variations due to the inherent complexity of the approach and its applicability is commonly limited to linear ODE systems. For highly nonlinear problems, linear control schemes are often insufficient to portray an appropriate nonlinear control strategy for a given nonlinear process. In such cases, the full discretization of the

time-varying problem is preferred to take a manipulated action at each discrete time point, which is computationally prohibitive.

Recent efforts focused on using machine learning and data-driven techniques to overcome computational challenges associated with optimizing dynamic systems. Sorek et al. (2017) used interpolation and polynomial approximations to reduce the computational burden of discretized controls for maximizing the profit in oil production optimization problems. Beykal et al. (2020) used Support Vector Machines (SVMs) to model implicit constraints and numerical infeasibilities of dynamic systems as a classification problem. The SVM model is later used within a deterministic optimization framework to find the best initial conditions of a steam cracking reactor that maximizes the profit of operation.

Although these studies have shown that data-driven modeling and optimization provides a feasible path for solving such a difficult class of optimization problems, their applications were limited to deterministic formulations and failed to address the direct derivation of optimal control trajectories within a dynamic optimization framework. In this work, our goal is to bridge this gap in dynamic optimization by avoiding the use of full discretization-based control schemes in linear and nonlinear time-varying models via surrogate modeling and data-driven optimization. To this end, we parametrize the control/input actions of a dynamic problem by postulating nonlinear surrogate models that are functions of time. The parameters of these control actions are then derived by collecting input-output information from the dynamic models and by using data-driven optimization techniques. The fine-tuned parameters are finally used to retrieve the optimal state trajectories across the time horizon. We test the applicability of our approach on a stable motivating example, as well as on a nonlinear unstable CSTR case study.

2. Continuous-Time Surrogate Models and Data-Driven Optimization

Our key idea is to represent the decision variables of a dynamic optimization problem (i.e., the control actions) with a continuous-time model rather than with discrete decisions taken at every time point. By representing the decision variables as a functional form, the decision variables of the dynamic optimization problem are parametrized and reduced to the number of parameters considered in the surrogate models. Previously, various forms of exponential and polynomial surrogate models have shown to be effective in deterministic optimization problems (Sorek et al., 2017; Beykal et al., 2018). Inspired by this, we heuristically construct one exponential (Eq. (1)) and one polynomial (Eq. (2)) continuous-time surrogate model as candidate control actions, $u(t)$.

$$u(t) = \alpha \cdot \exp(\beta t) + \gamma \quad (1)$$

$$u(t) = \alpha t^2 + \beta t + \gamma \quad (2)$$

The bounds on the unknown parameters are carefully identified by plotting these continuous actions across a wide range of parameter space. This ensures that the continuous-time action models capture all possible actions within the bounds of $u(t)$ while being flexible and generic such that they can be applied to various dynamic optimization problems.

Once the parametrization is completed and the dynamic model is constructed for a given problem, our goal is to find the optimal continuous control action that will minimize the control objective by fine-tuning the surrogate model parameters, α , β , and γ , using data-driven optimization. The data-driven optimization algorithm creates samples for the model parameters and these sampling points are used to construct $u(t)$. This continuous-

time control action is then fed to the dynamic model, which is simulated to collect the final value of the control objective as output information. If there are terminal constraints in the dynamic model, these can also be collected from the simulation and will be treated as additional output information (i.e., grey-box constraints). Using this input-output data, the solvers identify promising regions for exploration based on their specific data-driven optimization strategies and converge to a solution. We then use the fine-tuned parameters to generate the optimal state trajectories and evaluate the results. In this work, we explore two different data-driven optimization algorithms for fine-tuning: (1) ARGONAUT, a global model-based solver (Boukouvava & Floudas, 2017), and (2) NOMAD, a local sample-based algorithm (Le Digabel, 2011). The performance of these techniques is demonstrated in the following motivating example.

3. Motivating Example: A Stable Dynamic Model

We study the following dynamic formulation as our motivating example:

$$\begin{aligned} & \min_{u(t)} x^T(t_f) \cdot P \cdot x(t_f) + \int_0^{t_f} x(t)^T \cdot Q \cdot x(t) + u(t)^T \cdot R \cdot u(t) dt \\ & \text{s. t. } \frac{dx(t)}{dt} = A \cdot x(t) + B \cdot u(t), \quad x(0) = \begin{bmatrix} -0.5 \\ 0.5 \end{bmatrix} \\ & A = \begin{bmatrix} -3 & -2 \\ 1 & 0 \end{bmatrix}, B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, P = \begin{bmatrix} 0.082 & 0.082 \\ 0.082 & 1.082 \end{bmatrix}, Q = I, R = 0.01 \\ & -2 \leq u(t) \leq 2, u(t) \in \mathbb{R}, x(t) \in \mathbb{R}^2 \end{aligned} \quad (3)$$

where t_f is the final time, $u(t)$ is the control action that has the surrogate model form of either Equation 1 or 2 and is bounded between $[-2, 2]$, $x(t)$ are the two states in the problem with initial points $[-0.5, 0.5]$, and $dx(t)/dt$ is the rate of change in the states with respect to time. The unknown parameters of the surrogate control action (i.e., α , β , and γ) are the decision variables of this dynamic optimization problem and optimized using the recipe described above.

The results of the motivating example are summarized in Figures 1A and B which show that the exponential continuous-time control action can drive the states to zero and produce favorable results with a stable objective function trajectory across the time horizon. The trajectory of the optimal control action is also provided in Figure 1C. However, when polynomial continuous-time control action is employed, the states do not converge, and favorable results are not achieved (Figure 1D). This shows that not all surrogate functional forms are appropriate for pursuing data-driven dynamic optimization. Specifically for the motivating example, the exponential continuous-time surrogate model outperforms the polynomial control action by allowing states to converge at zero.

We also test the effect of changing initial conditions on the dynamic problem (Figure 2A). We observe that even with more “difficult” initial conditions, our data-driven approach will lead the states to convergence. In addition, we characterize the effect of using global versus local data-driven optimizers on the dynamic optimization performance. Over 5 random repeated runs, Figures 2A and B show that ARGONAUT, as a global solver, consistently leads to the convergence of states at zero whereas in some instances NOMAD, as a local solver, will return results that diverges the states. Hence, we observe that global optimization will consistently provide the best parameters necessary for the

control of the motivating example. Here, it is important to note that global optimality is not theoretically guaranteed due to the data-driven nature of the approach.

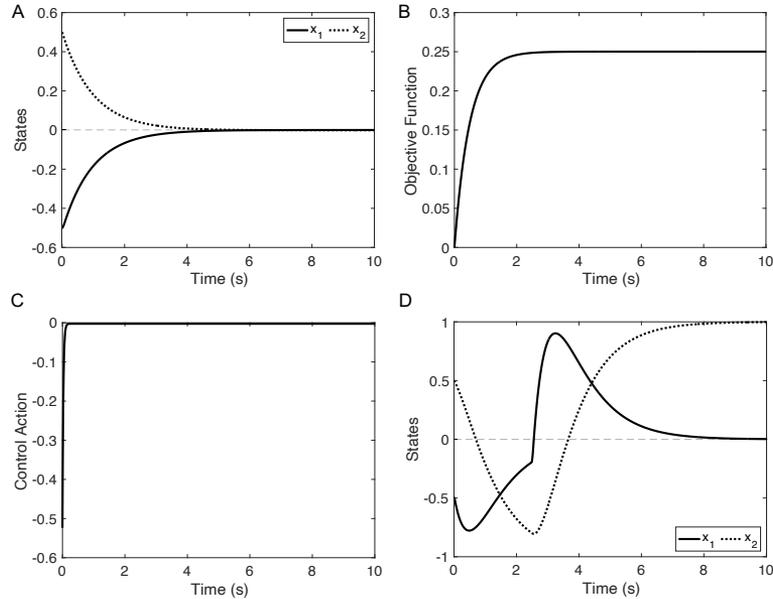

Figure 1 (A) State trajectories and (B) objective function trajectory with exponential continuous-time control action; (C) Optimal control action derived from the exponential surrogate model and data-driven optimization; (D) State trajectories with polynomial continuous-time control action.

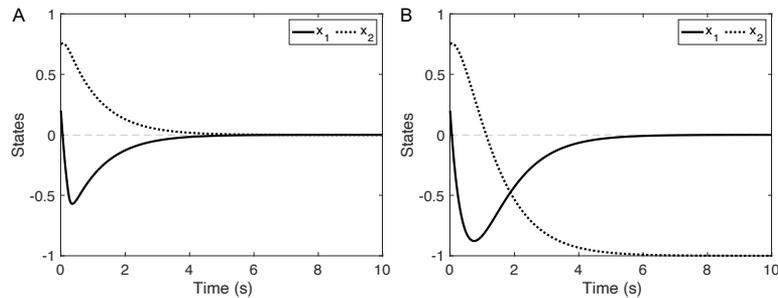

Figure 2 State trajectories for the new initial conditions, $x(0) = [0.2, 0.75]$. The parameters of the continuous-time model are fine-tuned with (A) ARGONAUT and (B) NOMAD algorithm.

We further compare the data-driven solution to the linearized Simulink solution to quantify the performance of our approach. The state profiles obtained from these two different approaches are provided in Figure 3 and the errors are quantified by calculating the area under the curve (AUC) of each state profile. The results show that the data-driven solution matches the linearized solution with high accuracy. For the case of $x(0) = [-0.5, 0.5]$ shown in Figure 3A, the relative and absolute errors between the data-driven and the linearized solution are very small (State 1: Abs. Err. = 0.0013; Rel. Err. = 0.0025; State 2: Abs. Err. = 0.0167; Rel. Err. = 0.0335). Likewise, for the case of $x(0) = [0.2, 0.75]$ shown in Figure 3B, the absolute and relative errors are very small (State 1:

Abs. Err. = 0.0005; Rel. Err. = 0.0007; State 2: Abs. Err. = 0.0070; Rel. Err. = 0.0077), which shows that continuous-time surrogate models can capture the correct dynamics and provide satisfactory results. Next, we test our approach on a nonlinear unstable system.

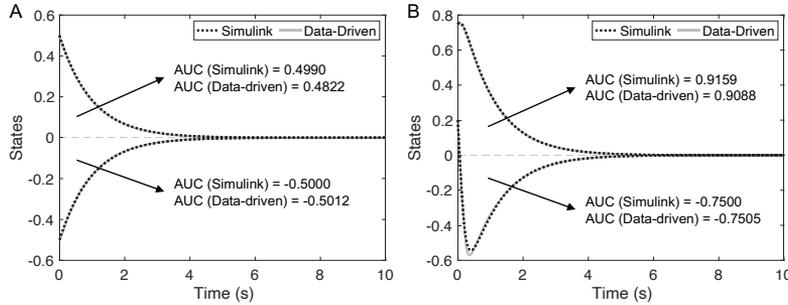

Figure 3 Comparison of state trajectories obtained from the linearized solution and the data-driven solution for: (A) $x(0) = [-0.5, 0.5]$, and (B) $x(0) = [0.2, 0.75]$.

4. Continuous-Stirred Tank Reactor Example: An Unstable Nonlinear Dynamic Model

To further test the limits of our data-driven approach, we formulate the following nonlinear setpoint tracking problem for an unstable CSTR system:

$$\begin{aligned}
 & \min_{u(t)} \int_0^{t_f} \begin{bmatrix} C_A(t) - 0.5 \\ T(t) - 400 \end{bmatrix}^T \cdot QR \cdot \begin{bmatrix} C_A(t) - 0.5 \\ T(t) - 400 \end{bmatrix} dt \\
 & \text{s. t. } \frac{dC_A}{dt} = \frac{\dot{m}}{\rho V} (C_{A0} - C_A) - k_0 C_A \exp\left(-\frac{E_a}{RT}\right) \\
 & \quad \frac{dT}{dt} = \dot{m} C_p (T_0 - T) + V \Delta H_{rxn} k_0 C_A \exp\left(-\frac{E_a}{RT}\right) + \frac{UA(T_c - T)}{V \rho C_p} \\
 & \quad QR = \begin{bmatrix} 50 & 0 \\ 0 & 1 \end{bmatrix}, C_A(0) = 9, T(0) = 400, 0 \leq \dot{m}(t) \leq 100, 10 \leq T_c(t) \leq 600
 \end{aligned} \tag{4}$$

where C_A is the concentration of reactants with the reaction mechanism $A \rightarrow B$, T is the reactor temperature, \dot{m} is the mass flowrate of the reactant into the CSTR, V is the reactor volume, T_c is the cooling jacket temperature, U is the overall heat transfer coefficient, A is the heat transfer area, C_p is the heat capacity at constant pressure, ρ is the density, ΔH_{rxn} is the heat of reaction, k_0 is the pre-exponential factor, E_a is the activation energy, and R is the gas constant. The values of the model parameters are available upon request.

As this problem is more challenging compared to the motivating example, we use the rolling horizon approach to perform data-driven dynamic optimization with continuous-time surrogate models with $t = 0.2s$ intervals. The results in Figure 4A show that the concentration of the reactants is depleting as the reaction is carried out over time. The temperature profile of the reactor presented in Figure 4B shows that the continuous-time control action can track the temperature at the required setpoint (400 K) by adjusting the cooling temperature as shown in Figure 4C. Overall, the data-driven dynamic optimization with continuous-time control actions shows favorable results in both linear stable and nonlinear unstable case studies. For a comparison with an MPC scheme based on a linearized version of the CSTR, please refer to Avraamidou and Pistikopoulos (2017).

5. Conclusions

In this work, we present a dynamic optimization strategy based on continuous-time surrogate models and data-driven optimization. By parametrizing the input control actions on the dynamic system using surrogate models that are functions of time, we avoid the full discretization of the dynamic model. The parameters of the control actions are fine-tuned by data-driven optimization which is based on collecting input-output information from the dynamic system. We explore two different continuous-time surrogate models and rigorously test the effect of initialization and type of data-driven optimizer on the control performance. Results showed that exponential continuous-time control actions lead to stable convergence for the states and perform setpoint tracking in dynamic optimization problems. Global optimization of the surrogate model parameters is also found to play an important role in achieving stable solutions. Finally, when compared to the linearized solution, our data-driven approach provides results with minimal errors and matches the linearized state profiles perfectly. This research was funded by the U.S. National Institutes of Health (NIH) grant P42 ES027704.

Abstract

Dynamic Flux Balance Analysis (dFBA) models are widely applied in the system biology field. The model connects the cellular genome information to the cell's phenotype, it can therefore be applied to predict the effect of gene deletions or the insertion of new enzymes into the metabolic network. The dFBA model consists of a system of differential equations and an optimization problem that is performed to compute the internal flux distribution. Furthermore, kinetic equations (i.e. Michaelis-Menten) are used to model the uptake of substrates. The kinetic equations have some parameters that must be estimated from batch fermentation experimental data. When the dFBA model is inserted in a parameter estimation architecture, a bi-level optimization problem arises. As is well known, bi-level optimization problems are hard to solve and suffer from convergence problems. A recent method to replace the FBA optimization with a surrogate model was developed in our research group and applied to the simulation of a model predictive control of a bioreactor. Here, that recently developed surrogate dFBA model is applied to a parameter estimation problem. The approach was tested in a case study of *Saccharomyces cerevisiae* fermentation using glucose and xylose as substrates. *S. cerevisiae* is the main microorganism for industrial alcoholic fermentation and there is research to amplify the range of substrates that can be used, such as xylose. dFBA models can be applied to link possible genetic modifications strategies with the bioreactor performance. In order to achieve this aim, the kinetic parameters in the dFBA model must be well defined. First, the surrogate model was trained using Flux Balance Analysis simulations of the Yeast 8.3 genome-scale model. After that, the kinetic parameters on the surrogate dFBA were fitted to *in silico* data. The surrogate dFBA outperformed the sequential approach where the nested LP needs to be solved many times during the estimation. Furthermore, solving the parameter estimation with the surrogate model in a simultaneous approach can considerably reduce the computational time. The results indicated that the surrogate dFBA can be an important tool for the parameter estimation and optimal design of experiments of dynamic metabolic models.

Keywords: Parameter estimation, Surrogate model, dFBA, Systems Biology, Metabolic Engineering

1. Introduction

System biology models are widely applied to characterize microorganisms and aid strain optimization (Maranas, 2016). Kinetic models of cell metabolism are a very promising category of models because of their high prediction capabilities. However, the lack of knowledge of enzymatic reactions mechanisms and the need to estimate an unbearable number of parameters makes

the application of kinetic models restricted to the description of small enzymatic pathways so far. Dynamic Flux Balance Analysis (dFBA) models appear as an alternative approach where the internal flux distribution is described by a steady-state model and the solution computed by an optimization problem. Therefore, in dFBA models, only a small number of parameters must be estimated from experimental data making the problem solvable in practice. Despite the fact that the number of parameters to be estimated is reduced, the dFBA model consists of a system of differential equations and an embedded optimization problem, making the parameter estimation problem challenging to solve.

The sequential solution of the problem consists in solving the nested LP and the ODE system inside the optimization. The lack of gradient information and the non-smoothness of dFBA makes the problem hard to solve. Leppävuori et al. (2011) developed a sequential gradient-based solution with direct sensitivities equations. They estimated 8 parameters and used a metabolic network of 1266 enzymatic reactions and 1061 metabolites. Waldherr (2016) reformulated the bi-level problem as a Mixed Integer Quadratic Program, however, due to the computational burden they used a small-scale network of 10 reactions and 12 metabolites. Raghunathan et al. (2003, 2006) reformulated the problem as a Mathematical Program with Complementary constraints (MPCC). MPCC cannot be solved by standard NLP solvers, therefore they relaxed the complementary constraints using a barrier parameter. They applied the approach to a small-scale metabolic network of 39 reactions and 43 metabolites.

Recently, our group developed a methodology to insert dFBA models in Model Predictive Control (MPC) architecture (Oliveira et al., 2021a). The methodology consists in replacing the embedded optimization problem solution by a surrogate model making the solution of FBA faster and allowing gradient computation. Here, we investigate the suitability of this methodology in order to reduce the computational load of parameter estimation problems using dFBA models. As a case study, a dFBA model is formulated to describe batch cultivation of glucose and xylose mixtures by *Saccharomyces cerevisiae*. *S. cerevisiae* is the main microorganism for industrial alcoholic fermentation; however, the spectrum of substrates is almost restricted to sugars, such as glucose and fructose. *S. cerevisiae* does not naturally consume xylose and the development of strains of *S. cerevisiae* for the conversion of xylose into ethanol by *S. cerevisiae* has been implemented (Kuyper et al., 2004). However, studies are needed in order to make the xylose fermentation by *S. cerevisiae* more efficient. Metabolic models can be very useful to achieve this aim, because they allow the understanding of xylose fermentation in a multi-scale approach, from a genome-scale level to the bioreactor operation.

2. Methodology

Flux Balance Analysis (FBA) has become one of the most popular mathematical methods for simulating metabolism using genome-scale models in the past years (Maranas, 2016), the reason for that relies on the simplicity and applicability of the method. FBA is a method based on an optimization approach using the stoichiometric matrix, by exploiting the fact that all the possible flux distributions of the cell are present in the null space of the stoichiometric matrix. FBA uses an objective function, to try to select one phenotype between the many possibilities. Mathematically, the FBA can be formulated as a Linear Programming problem as follows:

$$\begin{aligned} \max \quad & c^T v \\ \text{subject to:} \quad & S \cdot v = 0 \\ & lb \leq v \leq ub \end{aligned} \tag{1}$$

where lb and ub are lower and upper bound vectors for metabolic fluxes, respectively. The fluxes constraints are typically measured external fluxes or derived from thermodynamics data. S is the

stoichiometric matrix and c is the vector of coefficients that multiplies the flux vector in order to express the objective function. The most applied objective function on FBA is to maximize the biomass formation (Maranas, 2016), where the vector c is a vector with zeros except for the biomass reaction. Many genome-scale reconstruction models for *S. cerevisiae* have been developed so far. Among them, the consensus yeast metabolic network model is the largest network (Lu et al., 2019). Yeast 8.30 has 2666 metabolites and 3928 enzymatic reactions. The genome-scale *S. cerevisiae* model Yeast version 8.30 (Lu et al., 2019) was downloaded from the project's website: <http://sysbiochalmers.github.io/yeast-GEM/>. The uptake rates of the substrates were fixed to solve the FBA problem (note, not dFBA), the uptake rate of oxygen was set to zero, and the objective function was the maximization of biomass yield.

The dynamic version of the FBA (dFBA) model can be built by incorporating mass balance equations for the external metabolites and Michaelis–Menten kinetics equations for describing the uptake of substrates. For the anaerobic fermentation of glucose and xylose by *S. cerevisiae*, the dFBA model can be formulated as follows:

$$\begin{aligned}
 \frac{dX}{dt} &= \mu X & \frac{dG}{dt} &= v_g X \\
 \frac{dE}{dt} &= v_e X & \frac{dZ}{dt} &= v_z X \\
 v_e, \mu &= \Xi(v_g, v_z) & v_g &= v_{g,max} \frac{G}{K_g + G} \\
 X, G, Z, E &\geq 0 & v_z &= v_{z,max} \frac{Z}{K_z + Z} \frac{1}{1 + (G/K_{ig})}
 \end{aligned} \tag{2}$$

where μ , v_g , v_z , and v_e are the growth rate, and the exchange fluxes of glucose, xylose, and ethanol, respectively. X , G , Z , and E represent the biomass, glucose, xylose, and ethanol concentrations, respectively. $v_{g,max}$ and $v_{z,max}$ are the maximum uptake rate for glucose and xylose respectively. K_g and K_z are the saturation constants, and K_{ig} is the glucose inhibition constant. The exchange flux of ethanol v_e and cellular growth μ are computed by the mapping Ξ , which can be solved either by the optimization FBA problem (Equation 1) or by the surrogate approximation.

The methodology to generate the surrogate FBA model was performed as described in Oliveira et al. (2021a). First, a series of optimization problems (FBA) were solved covering the whole flux input domain (v_g and v_z). After that, a polynomial model for each output (μ and v_e) was fitted to the data by Partial Least Square (PLS) to avoid over-fitting. A parameter estimation problem for estimating the five parameters in Equation 2 was implemented. The measurements data of the extracellular metabolites were generated by *in silico* experiments using the nominal parameter values presented in Table 1. The parameter estimation was solved as a nonlinear constrained least-squares problem as follow:

$$\min_{\theta} \sum_j (y_j^c(\theta) - y_j^m)^2 \quad \text{subject to: Equation 2} \tag{3}$$

where θ is the vector of the parameter to be estimated, and y is the vector of extracellular concentrations. Indexes c and m indicates calculated and measured quantities respectively. Three different methods were applied to solve the problem in Equation 3:

1. **dFBA + lsqnonlin**: Solved as a bi-level optimization problem. The outer parameter estimation problem was solved by *lsqnonlin* routine in MATLAB with the levenberg-marquardt

method. The ODE system was solved by ODE15s with the embedded LP (FBA) solved in GUROBI. No gradient information was supplied.

2. **dfBA surrogate + *lsqnonlin***: Solved as a single-level optimization problem by *lsqnonlin* routine in MATLAB with the levenberg-marquardt method. The ODE system was solved by ODE15s with the embedded LP (FBA) replaced by the surrogate model. No gradient information was supplied.
3. **dfBA surrogate + IPOPT**: Solved as a single-level optimization problem in Julia language with the interior point NLP solver IPOPT. The ODE system was solved by orthogonal collocation with the embedded LP (FBA) replaced by the surrogate model. Automatic differentiation package was used to compute the gradient.

3. Results

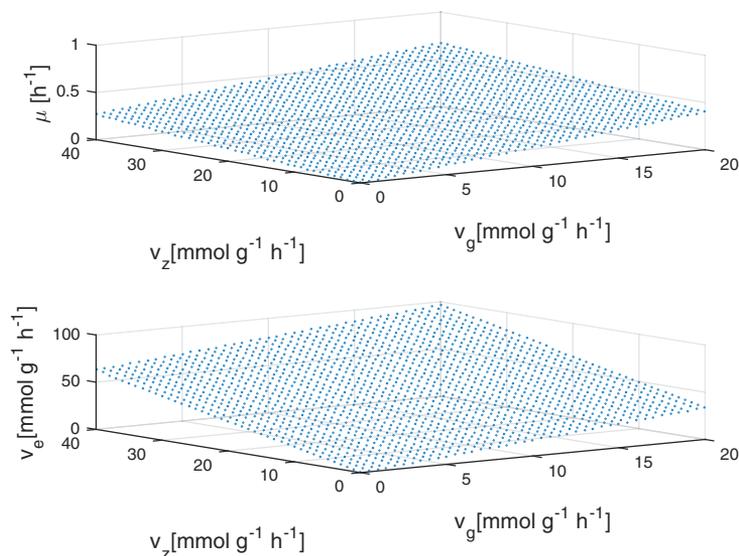

Figure 1: Profiles of the FBA (Equation 1) solutions for different values of the uptake rates of glucose v_g and xylose v_z . We solved the FBA problem for every value of the independent variables in an equidistant 40 by 40 grid.

First, the surrogate FBA model was trained using FBA simulations performed in COBRA Toolbox for MATLAB. The FBA was solved for every value of the v_g and v_z uptake fluxes in an equidistant 40 by 40 grid (Figure 1). Both response surfaces for μ and v_e are flat, which means that the amount of ethanol and biomass being produced are linearly proportional to the uptake of each substrate. Different from the non-linear response surface in Oliveira et al. (2021a) where a piecewise polynomial surrogate model was needed, here a single polynomial could fit the data. The relative Root Mean Square Error (RMSE) was $6.67e-8\%$ and $1.41e-4\%$ for μ and v_e respectively. While the relative Root Mean Square Error of Prediction (RMSEP) was $2.99e-10\%$ and $1.91e-6\%$ for μ and v_e respectively. The relative RMSE and RMSEP were computed by dividing the fluxes by the maximum value of the correspondent uptake flux.

After the FBA surrogate model was trained, the parameter estimation problem was solved using the three different methods described in the methodology section. Ten different initial guesses were supplied to solve the problem by each method and the solution with the lower objective function (OF) was selected. Figure 2 compares the predicted concentrations with the best-fitted set of parameters for each case. Visually, the methods that applied the surrogate FBA fit the *in silico* data adequately, on the other hand, the method that uses the nested LP to solve the dFBA model was unable to fit the data. In fact, all the attempts to solve the estimation problem using the nested LP resulted in a set of parameters close to the initial guess. Because of the embedded optimization problem, the *lsqnonlin* solver was not able to compute efficiently the gradient of the problem. Furthermore, the attempts of using derivative-free methods like *simplex* (i.e. *fminsearch*) have failed as well.

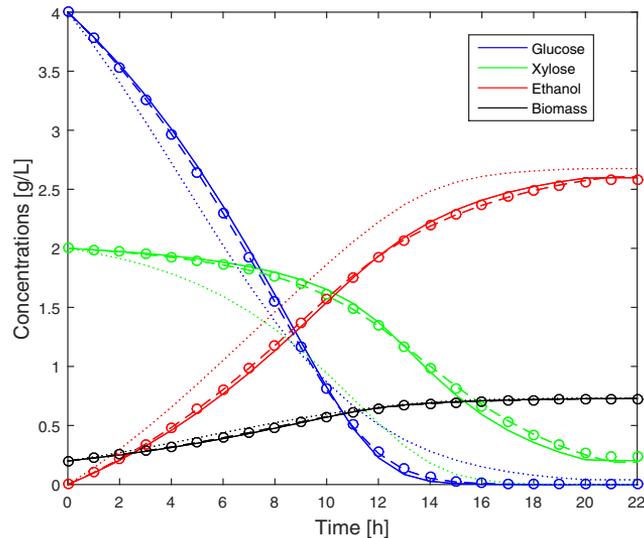

Figure 2: Simulated profiles for dFBA surrogate in Julia (solid), dFBA surrogate in MATLAB (dashed) and dFBA DA in MATLAB (dotted). *in silico* data points are presented as circles.

The performance of each method for solving the problem is presented in Table 1. The dFBA with the embedded optimization had a CPU time about 60 times higher than the methods that used the surrogate FBA. Despite the larger CPU time, the solver performed only 5 iterations and 36 function evaluations. The need of solving the nested LP at each step of the ODE solver makes this method computationally expensive and ineffective, as it can be seen by the poor fit as well (Figure 2). Comparing the methods that applied the surrogate approximation, the utilization of automatic differentiation can improve performance. However, the utilization of the surrogate FBA is enough to guarantee a good fitting. These results illustrate the advantage of the surrogate approximation FBA to solve parameter estimation problems. The time and effort to train the surrogate model must be taken into account in that analysis, but for a small number of input fluxes the task can be easily done. Moreover, Table 1 also presents the set of parameters estimated in each case, as well as the set of parameters used to generate the measurements. The set of estimated parameters was different from the one used to simulate the measurements data even when a good fit was achieved. In fact, the set of parameters in dFBA models are typically dependent and cannot be uniquely identified (Leppävuori et al., 2011). In order to make a complete analysis, the parameter uncertainty must be taken into consideration. This is a practical identifiability issue that should be discussed with more depth. A possibility is to apply a recent methodology developed in our group that used sparse Principal Component Analysis to access the identifiability of metabolic fluxes on carbon labeling experiments (Oliveira et al., 2021b).

Table 1: Comparison of the Computational Performance of each method and the parameter values used in model simulation to yield measurements.

	Model simulation	dFBA surrogate IPOPT	dFBA surrogate <i>lsqnonlin</i>	dFBA surrogate <i>lsqnonlin</i>
CPU	-	0.05 s	26.47 s	27.82 min
iterations	-	29	20	5
function evaluations	-	50	126	36
Objective function	-	0.049	0.009	7.17
v_g^{max}	7.30	6.44	7.13	30.01
K_g	1.03	0.64	0.94	12.02
v_z^{max}	32.00	26.07	4.69	7.99
K_z	14.85	10.48	1.60	0.80
K_{ie}	0.50	0.39	0.81	1.00

4. Conclusion

Dynamic metabolic models are a powerful tool that can be applied from metabolic engineering to bioprocess fields. The estimation of the model parameters poses a challenge due to the bi-level optimization architecture and the non-smooth behavior of the dFBA model. Here, the replacement of the embedded optimization problem by a surrogate model was evaluated. The results demonstrated that the surrogate model can be easily trained from FBA simulations and improve the performance of the estimation problem. In the future, the methodology should be applied to parameter estimation and uncertainty quantification problems using experimental data.

Abstract

This work presents a benchmark model of a batch process to generate data where active challenges, disturbances, and noise are fully controlled. The process is viewed at the unit level with filling, processing, draining and cleaning operations. The simulation is limited to mass balances. Chemical reactions and kinetics are omitted, as they are not relevant for the intended Machine Learning (ML) application. Several scenarios were generated where 21 disturbances of different types, causes, or fault origins are injected (isolated or combined) in the simulation to test and compare ML algorithms. The scenarios were grouped into six benchmark cycles with increasing levels of complexity in terms of intensity and duration, tackling some major challenges in ML.

Keywords: Batch Process, Machine Learning, Process Modeling, Data Generation, Hybrid Dynamic Simulation

1. Introduction

Batch processes are ubiquitous in pharmaceutical and fine-products industries (Böhner and Huusom, 2019). They are characterized by cyclic operations of one or several units whose sequence and operation parameters follow a specific recipe and a production schedule, typically based on heuristics, and regulatory constraints. Decisions in planning and scheduling are based on batch demonstrated practices (aggregate production rates) and quality constraints. Targeted tracking of batch cycle times enables improved scheduling, but this information is not always available. Time-series values of sensors and controllers are usually available in process historians, and they implicitly contain information about start, end, delays, and variability in the processes. Pre-processing, analyzing and modeling these data are of interest to the planner to support the decision-making.

The development and application of mechanistic models are often not economical in an industrial setting, especially if complex batch processes involve many units and operations. Building those models can be challenging, and extensive experiments for parameter estimation and model validation may be needed. In addition, the resulting nonlinear differential algebraic models are non-smooth, demanding specialized solvers for integration (Floudas and Lin, 2004). Due to the inherent repetitiveness of batch processes, one would expect the Machine Learning (ML) algorithms to be able to recognize patterns and generate meaningful predictions. However, their performance in practice is degraded by data noise (transient, stochastic, or discrete), scarcity of good quality training data, or disturbances in the processes. Incomplete monitoring and complex manual oper-

ations can create reasonable doubts about the quality of data acquired during production (Böhner and Huusom, 2019). Also, the time-varying and nonlinear profiles in batch systems complicate the predictions of ML algorithms. Consequently, it is hard to know which challenges constitute fundamental limitations to the performance of an ML algorithm when working with real process data. Hence, a simulated batch process with modeled data challenges that serve as a benchmark model for the development and study of data-driven techniques, in particular, ML algorithms, is valuable.

This contribution presents a benchmark model for generating simulated data that can be used to develop and test ML algorithms for batch phase-detection problems. By working with simulated data where the active challenges, disturbances, and noise are fully controlled, ML methods can be tested systematically. The dynamic simulations were conducted with a hybrid computational framework where the discrete-events are modeled as state machines in the Stateflow[®] environment, while the continuous components of the model were implemented in Simulink[®].

2. Benchmark Process Model

The benchmark process features *filling, processing, draining, and cleaning* operations on a single unit. Three liquid raw materials (Educt1, Educt2, Educt3) are valve-controlled; and solids are added through a hatch placed on top of the vessel.

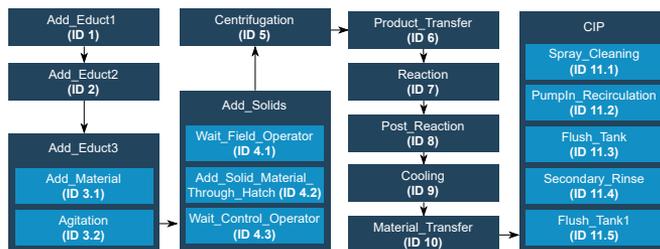

Figure 1: Benchmark Model Recipe.

Table 1: Characteristics of the simulation.

Property	Value	Unit
Vessel volume	12.5	m ³
Threshold volume †	6.25	m ³
Batch duration	19.5	h
Cleaning procedure duration	1.4	h
Simulation Time ‡	333	days
Inactivity Period † ‡	5 min-2 h	-

† The vessel is curved, and as a result, the height has a logarithmic profile until a threshold value, followed by a linear behavior. The height is given as a function of the vessel volume with the threshold mentioned above.

‡ Operation year has 333 days, already leaving a month for cleaning and maintenance.

† ‡ The inactivity period is the time between the end of a cleaning procedure and the beginning of a new batch. It is set as a random duration between 5 min and 2 h, differing on each new batch production.

Besides raw materials, it is considered that before and after the reaction, hot (steam) and cold (water) utilities are, respectively, needed to obey the process design parameters and batch recipe. Fig. 1 illustrates the path, operations (dark blue), and phases (light blue) for the reference process designed. A batch is produced from ID 1 to ID10 with filling, processing, and draining operations. The last operation (ID 11.1 to ID11.5) of each batch is the cleaning procedure.

Modeled variables are vessel contents and their sensors, valves, flows, and the hatch position. While the process just described is apparently simple, complexity is induced through mathematical expressions which emulate various disturbances. Besides linear profiles, the vessel level can

follow an exponential, step, stair function. The recipe is based on duration and volume conditions. For this purpose, the flow rate is adjusted as a degree of freedom to connect volume with time. Characteristics of the process, such as level profile and conditions, can be found in Tables 2 and 1.

Table 2: Transition trigger conditions, nominal durations, and level profiles of the benchmark process.

Event ID	Transition Trigger Condition †	Nominal Duration	Level Profile
1	L1_PV \geq 30%	3 min	Linear
2	L1_PV \geq 60%	3 min	Linear
3.1	L1_PV \geq 65% or $t >$ 5 min	5 min	Linear
3.2	L1_PV \geq 70%	5 min	Noise (\pm 5%)
4.1	$t >$ 15 min	15 min	Linear
4.2	L1_PV \geq 85%	5 min	$G = 16/(s^2 + 3.2s + 16)$
4.3	$t >$ 5 min	5 min	Linear
5	L1_PV \geq 90% Design: 5 steps	increase: 3 min inactivity: 7 min	Step
6	L1_PV \leq 60%	3 h	Linear
7	L1_PV \geq 85%	12 h	$G = 10e^{-0.05s}/(s^2 + 18s + 15)$
8	$t >$ 2 h	2 h	Linear
9	L1_PV \leq 70%	1 h	$G = 5e^{-0.05s}/(0.001s^2 + 0.2s + 3)$
10	L1_PV \leq 0%	5 min	Linear
11.1	L1_PV \geq 10%	30 min	Noise ‡
11.2	$t >$ 14 min	14 min	
11.3	L1_PV \leq 0%	5 min	
11.4	L1_PV \geq 5%	30 min	
11.5	$t >$ 2.5 min	2.5 min	

† L1_PV corresponds to filling percentage. ‡ The injected noise is part of the process nominal profile.

3. Process Model Implementation

The tank volume is calculated from a mass balance where incompressible flow and constant density at the vessel entry and exit are assumed:

$$\frac{d \text{ Volume}}{dt} = valve_{out} \cdot q_{out} - valve_{in} \cdot q_{in} \quad (1)$$

where $valve_{in}$ and $valve_{out}$ are binary variables indicating the opening of the inlet valve and the outlet valve. Changing $valve_{in}$ and $valve_{out}$ makes it possible to control the liquid flow direction. To model realistic instrumentation, the volume is transformed to a level signal representing the vessel filling level (L1_PV in Table 2). The flow rates of heating/cooling agents are assumed to increase/decrease the profile according to the transfer functions of ID7 and ID9 in Table 2. In specific states, noise is added to the level signal to obtain a specific level profile. During cleaning procedures, it is worth noting that heavy sensor noise is often masked due to the filling and draining of water, which induces agitation and oscillation behaviors.

3.1. Disturbances Mapping and Implementation

Disturbances are classified as a *step*: which mirrors time effects such as recipe changes; *seasonality*: oscillation emulating time effects such as season of the year; *stair*: for example, consecutive steps (changing supplier multiple times); and *drift*: such as a linear term overlay. Table 3 lists key disturbances scenarios studied. All disturbances are modeled stochastic wherein the user controls likelihood and severity. Twenty one simulation scenarios have been implemented in Stateflow® (ID1-ID10, ID13) or Simulink® (ID11, ID12, ID14-ID21).

4. Evaluation of ML algorithms

As a first step towards assessing how ML algorithms respond to the challenges mentioned above, Just (2021) compared the performance of Random Forests (RF) and the Hidden Markov Model (HMM). These algorithms are capable of classifying sequences in time-series data (Tsay and Chen, 2019). Several studies compare the two in terms of overall accuracy on labeling, classification speed, memory consumption, feature computation, and model complexity. A comparison between both algorithms is provided in Munther et al. (2016) regarding internet traffic data. Two criteria discussed in Just (2021) were used to evaluate the algorithms learning performance. Accuracy describes the number of correct labels divided by the total number of labels. The mean absolute error (MAE) measures the average error in identifying change points (CPs) using the distance between real (CP_{real}) and predicted change ($CP_{\text{predicted}}$) points in time units.

$$\text{MAE} = \frac{\sum_{i=1}^{\#\text{CP}} |CP_{\text{predicted}} - CP_{\text{real}}|}{\#\text{CP}} \quad (2)$$

Table 3: Disturbances mapping and description, classified by cause. ID identification for each benchmark cycle with multiple disturbances scenarios (second column).

ID	Cycles	Cause of Noise/Fault	Behavior Description
1	A-F	Delay of single-phase end	Phase end is delayed, no change in actuation occurs during the phase
2	A-F	Delay of multiple phases ends	e.g., if the yield was found to be insufficient after quality sample, an additional reaction step is provided
3	C-F	An irregular single-phase occurs	The CIP does not always occur at the batch end
4	C-F	An irregular series of phases occur	After a specific number of batches, the volume decreases between 30-70% of the batch size. Also, small variability of 2% to 5% can be added to final filling stages
5	A-F	Tank is filled to different final fill levels	End of phase 1 happens, but logged time of phase 1 is at the beginning of phase 2, the label of which is delayed
6	†	Start/End points of the label(s) are shifted	It appears wrongly labeled as phase 1 lasts for the time of the 2 phases, but the sensor measurements remain the same
7	F	Phase wrongly labeled	
8	†	Two consecutive phases have the name of the first phase	
9	A-F	A valve is opened and closed several times, and nothing happens before the material transfer starts	Instead of being opened and closed once, it happens more times. Valve starts open
10	A-B, D-F	Valve opens and closes several times, and nothing happens after material transfer ends	Instead of being opened and closed once, it happens more times. Valve starts closed
11	B-F	Phase name remains the same, but the actuation changes	A different valve is opened at several instances without that behavior having meaning to the reference process
12	A-F	A pump slowly supplies less throughput	The flow rate decreases in time. To reach the same level of liquid in the tank, a certain task takes more time to complete
13	A, D-F	The motor provides less agitation	Rotation number decreases randomly, resetting after a batch
14	C-F	Utility Flow masked with noise	Incremental changes in the flow with increasing spikes
15	C	Loss of signal	A series of data points are not written for the sensors
16	†	Value outside of sensor range	If the level measurement deviates from normal values (from 0 to 100), an error message appears
17	C, D	A sensor suffers from a gradual drift for a period of time	Drift lasting until the end of the simulation, resulting in volume shift, as much as the slope chosen
18	B, E-F	A sensor suffers from a gradual drift and is suddenly recalibrated	Similar to ID15 but the sensor has a sudden recalibration after a specific number of batches
19	B, D-F	A sensor suddenly has an offset (recalibration or fault)	At random points in time, with small durations, the sensor has offsets. The actuation remains unaltered
20	B-F	A wide variety of sensor noise	Statistical distributions: Gaussian, uniform, and waveform
21	A-F	White-Band Noise	Added to the signal introducing spikes in measurements

† Implemented but not included in the benchmark cycles reported here.

5. Results

The profile L1_PV at nominal behavior (i.e., disturbances-free) of the reference model for a single batch is represented in Fig. 2. By following a sequence with an increasing complexity level, disturbances scenarios were grouped by six benchmark cycles and listed in Table 3. Simulation

runs were conducted for the duration of a year (ca. 382 batches). Fig. 3 summarizes the accuracy and MAE obtained by RF and HMM for the benchmark cycles A-F.

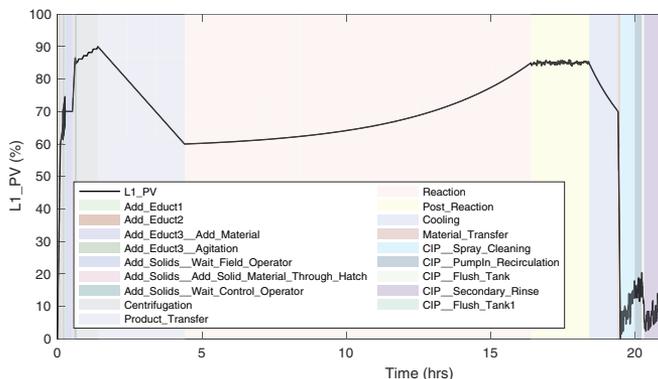

Figure 2: Nominal behavior of a batch and a cleaning procedure for the reference model with batch phase identification.

Cycles A and B yield the best results for accuracy, with the MAE decreasing slightly for the HMM on Cycle B. HMM correctly estimates in Cycle A the number of change points and the correct recipe sequence is recognized. Nonetheless, there are cases where the location of the change points is incorrectly estimated. Just (2021) show that the most problematic transitions are from *Centrifugation* to *Product_Transfer* and between all phases of the cleaning procedure. Between the HMM and RF, the latter confuses these state transitions more often than the HMM. This confusion between states might be due to heavy noise being added to the signal for the *CIP*, where the overlap of volumes for consecutive states is a limitation.

Prediction performance was worst for Cycle C, especially for the HMM. Because the implementation of ID15 is independent of the number of batches, fewer occurrences of the *CIP* affected the level profile for a longer time. While the RF can order input characteristics according to their influence on the classification decision, the HMM always outputs the same phase for these batches. The HMM could not predict Cycle F because individual observations could not be assigned to any state. By enabling a label disturbance, this algorithm failed in recognizing states.

The overall results indicate the RF to be less generalizable and tends to overfit. Also, the RF confuses more states (lower MAE), whereas the HMM can identify the correct sequences because it can learn the sequence of recipe steps. This is particularly relevant when ID4 is active for Cycles C to F. The HMM delivered accuracies above 85% in all but Cycles C and F. In these two cycles, the performance of RF was not affected, achieving accuracies of 79%–81%. The disturbances that caused the most degradation in performance were ID7 (purpose incorrectly labeled training data) and ID15 (loss of several signal points) combined with ID4 (phase occurring irregularly).

6. Conclusions

The focus of this work was to develop a benchmark model to support the testing and comparison of ML methods concerning their capability of recognizing and predicting batch recipes based on labeled time-series data. This is motivated by the fact that there are few comparable applications of ML and no formal methods for assessing the capability of the shown algorithms in the open literature. The entire process model is viewed at the unit level with filling, processing, draining,

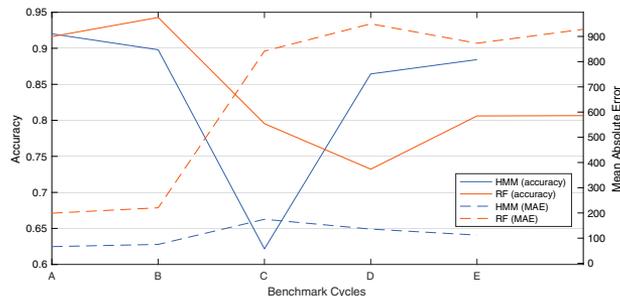

Figure 3: Evaluation of accuracy and MAE for each benchmark cycle with RF and HMM (Just, 2021).

and cleaning operations. Since active disturbances and data noise are fully controlled, the benchmark model offers capabilities that enable the user to design several simulation scenarios, building a deeper understanding of the ML algorithms.

Different scenarios were generated where up to 21 disturbances of several types, causes, or fault origins are injected into the simulated data to compare the RF and HMM algorithms. The scenarios were grouped into six benchmark cycles with increasing levels of complexity in terms of intensity, duration, and probability. The disturbances shown to be more challenging were the ones where likelihood and dependency between consecutive states are affected, which correspond to ID4, ID5, ID7, and ID11. The results show that the HMM deals with most of the implemented process disruptions and makes better predictions than the RF.

The process model here presented can be readily expanded to incorporate additional features inspired in real-life process data as those discussed in Stief et al. (2019), including: (i) valves that partially open, (ii) inclusion of equilibrium- and kinetically-controlled chemical reactions, (iii) temperature monitoring and incorporating heat transfer, and (iv) more nonlinear profiles can be considered in the batch recipe. A performant model implementation could be achieved by reducing the continuous part of the model to a simple design of experiments and emulating disturbance profiles based on process insight rather than building a detailed mechanistic model. Separating the discrete model part (Stateflow[®]) and continuous part (Simulink[®]) allowed building a modular model, facilitating its expansion and adaptation.

Abstract

The government of Chile has pledged that 100% of the city buses fleet will be powered by electricity by 2040. Since the fabrication processes of electric vehicles and electricity generation are not emissions-free, process analysis appears as a valuable tool to quantify their implications towards the optimization of the industrial processes in terms of better use of resources and recycling. This work aims to quantify the global warming potential and identify critical stages in the fabrication and use of electric and diesel city buses in Chile by process simulation of: (i) metallurgical processes (aluminum, copper and steel), (ii) thermoelectric power plants, and (iii) diesel production plants. A total of 618 kg of aluminum, 187 kg of copper and 11,538 kg of steel are required for the fabrication of an electric bus, while for a conventional bus are required 61 kg of aluminum, 10,354 kg of steel and 268 kg of cast iron. The results indicate that 12.94 tons of CO_{2,eq} per ton of aluminum, 1.22 tons of CO_{2,eq} per ton of copper and 1.38 tons of CO_{2,eq} per ton of steel are generated, with the major contribution to emissions coming from the Hall-Héroult process, the electrorefining stage and the iron blast furnace, respectively. A natural gas power plant in Chile produces 1.0 kg of CO_{2,eq} per kWh generated, which corresponds to 0.51 kg of CO_{2,eq} per km driven for electric buses. The processing of crude oil in the United States (main supplier of diesel in Chile) generates 0.61 kg of CO_{2,eq} per litre of diesel produced, corresponding to 1.38 kg of CO_{2,eq} per km driven for conventional buses. These results are in good agreement with previous reports which suggest that the positive impact of switching to electricity-powered vehicles is strongly correlated with the carbonization-level of the electricity grid related to buses fabrication and charging.

Keywords: city buses, metallurgical raw materials, electricity generation, diesel production, greenhouse gas emissions

1. Introduction

Electricity-powered vehicles do not produce greenhouse gas emissions directly during their use. However, the processes associated with their fabrication (mainly mining and metallurgical processes) and electricity generation (still strongly based on combustion of fossil fuels) are not emissions-free. Therefore, numerous life cycle assessment (LCA) studies have been issued in the past two decades aiming to quantify the real impact of switching from a transport system

powered by fossil fuels to one powered by electricity (Bouter et al., 2020; Cooney et al., 2013; Nordelöf et al., 2014; Tagliaferri et al., 2016; Xylia et al., 2019).

Nordelöf et al. reported an LCA of city buses powered by electricity, hydrogenated vegetable oil, or diesel. The dependence of the environmental impacts on the buses degree of electrification and the charging electricity generation system were studied for Sweden, the European Union and the United States of America. Their results show that the impact decrease in climate change is strongly correlated with the carbonization-level of the electricity grid related to buses fabrication and charging (Nordelöf et al., 2019c). The importance of the electric grid makeup in the life cycle inventory assessment (LCIA) of electric public transportation buses is also suggested by other authors (Cooney et al., 2013; Ercan and Tatari, 2015). Moreover, Nordelöf et al. suggested that the abiotic resource use in the fabrication of the electrical automotive traction machines, automotive power electronic inverter units, and permanent magnet electric traction motors (which includes copper, cobalt, steel, aluminum and rare earth elements such as neodymium, dysprosium and samarium) can have significant impacts in climate change (Nordelöf and Tillman, 2018; Nordelöf et al., 2018, 2019a,b).

This work aims to quantify the global warming potential (GWP) associated with the higher-impact stages in the fabrication and use of city buses powered by electricity or diesel in Santiago, Chile, pursuing the industrial processes optimization via a circular economy approach. Its novelty is centred in the methodology employed, which consist in the direct simulation of processes for key raw materials production and energy generation to determine the stages with the higher GWP associated. This method comes to complement the conventional LCA method based on the use of commercial software databases to assess the environmental impacts of production processes, which can generate data for each stage in a life cycle but cannot go into the operational details (for example, kinetics, efficiencies, stream compositions, specific energy consumptions, and their interrelations).

2. Case Study

This study is centered in two different vehicles of the bus line no. 506 in Santiago, Chile: (i) an all-electric powertrain bus, model BYD K9 (hereafter electric bus); and (ii) a diesel engine powertrain bus, model Mercedes Benz O500U (hereafter conventional bus). The latter was used as a reference for the assessment of the GWP impact associated with the fabrication and use of an electric bus. For the electric bus the analysis considered the key raw materials production processes associated with the fabrication of the lithium iron phosphate (LFP) batteries module, chassis, frame and body, and the electricity generation according with the existing energy matrix in Chile. For the conventional bus the analysis considered the key raw materials production processes associated with the fabrication of the engine, chassis, frame and body, the production of diesel, and the emissions associated with the bus operation. Data related to buses parts and operation was provided by a local bus operator stakeholder (Reborn Electric SpA¹), while information related to electricity generation and diesel production (import) was obtained from public Chilean government databases (Comisión Nacional de Energía, 2020a).

Technical information indicates that a considerable weight fraction of the LFP batteries module is represented by aluminum (33 wt.%) and copper (10 wt.%) (Golubkov et al., 2014). The fabrication of a bus chassis, frame and body requires considerable amounts of steel, while the fabrication of a conventional bus engine requires steel, cast iron and aluminum (Harr et al., 1999; BYD, 2018). Because the production of aluminum, copper, steel and cast iron is associated with difficult-to-decarbonize processes, they were considered critical stages in the fabrication of electric and conventional city buses (Davis et al., 2018). Table 1 summarizes the amounts of aluminum, copper, steel and cast iron required for the fabrication of an electric bus and a conventional bus.

¹<https://www.rebornelectric.cl/>

Regarding electricity generation in Chile, fossil fuel power plants stand for almost a 49% of the total electricity generation capacity. Of these a 16% corresponds to pulverized coal combustion, integrated gasification combined cycle and fluidized bed combustion power stations, while another 16% corresponds to gas turbine and natural gas combined cycle technologies (Comisión Nacional de Energía, 2020a; Gaete-Morales et al., 2019). Concerning diesel consumption in Chile, an 82% of the imports comes from the United States of America (Comisión Nacional de Energía, 2021).

Table 1: Weight of aluminum, copper, steel and cast iron required for the fabrication of an electric bus and a conventional bus.

<i>Electric bus</i>		
Bus part	Metal required	Weight / kg
Cathode current collector	Aluminum	618
Anode current collector	Copper	187
Chassis, body and frame	Steel	11,538
<i>Conventional bus</i>		
Bus part	Metal required	Weight / kg
	Steel	205
Engine	Cast iron	268
	Aluminum	61
Chassis, body and frame	Steel	10,149

3. Methodology

The conventional Bayer process in conjunction with the Hall-Héroult process were simulated for aluminum production from a gibbsite rich mineral (Habashi, 1998). For copper the pyrometallurgical via for the metal refining was simulated since this is the method mostly applied for processing sulfide minerals, particularly chalcopyrite, which are the mostly abundant source of copper worldwide (Schlesinger et al., 2011). Similarly, for steel and cast iron the pyrometallurgical via was simulated considering that most of its production worldwide comes from processing hematite rich minerals (Seetharaman, 2014). The computational simulations consisted of the conceptualization of the three processes flowsheets, the resolution of steady state mass and energy balances for each stage in these flowsheets, and the determination of the GWP associated with each of these stages. For this purpose, data reported in scientific publications, metallurgy books and technical reports was used to characterize the input streams flow rates and compositions, the operational parameters (e.g., solid particle sizes, temperatures, conversions) and thermodynamic values (standard enthalpies and specific heat values) associated with each process flowsheet. Suitable software for processes simulation, such as HSC Sim 10, was used.

Regarding electricity generation, pulverized coal power plants (PCPPs) and natural gas combined cycles (NGCCs) were simulated considering they are the mostly used technologies in Chile (Gaete-Morales et al., 2019). Details on the stages and data about the operational parameters associated with both processes were obtained from environmental reports published by the Servicio de Evaluación Ambiental (2015) and the information provided by the Comisión Nacional de Energía (2020b). Averages of the gross power generated in Chile by each technology were considered to facilitate the simulation of the processes.

Concerning the production of diesel, a common process for petroleum refining in the United States of America was considered since this country is the main supplier of this fossil fuel in Chile.

Details on the stages and data about the operational parameters associated with this process were obtained from (Comisión Nacional de Energía, 2020a; Liu et al., 2018).

The computational approach followed for the simulation of electricity generation and production of diesel was the same as described for the metallurgical processes.

4. Results

The results of the simulation indicate that an electrical power consumption of 984.16 MW and a heating power consumption of 6.28 GW are associated with the Bayer process in the aluminum production. These values correspond to total emissions flows of 341.97 tons of CO_{2,eq} per hour and 1,253 tons of CO_{2,eq} per hour associated with electricity generation and natural gas combustion, respectively. An electrical power consumption of 4.96 GW was determined for the Hall-Héroult process, which corresponds to a total emissions flow of 1,720 tons of CO_{2,eq} per hour. Additionally, 346.08 tons of CO_{2,eq} per hour are generated as product of the graphite anodes oxidation in the electrolysis cells. Therefore, considering a production rate of 282.91 tons of aluminum per hour (matching with the alumina production capacity of the Alcoa Pinjarra plant in Australia), a global emissions factor of 12.94 tons of CO_{2,eq} per ton of aluminum produced was determined. The process stages identified with the higher GWP are the digestion stage (Bayer process): 34.2% of the total CO_{2,eq} emissions, the calcination stage (Bayer process): 9.3% of the total CO_{2,eq} emissions, and the electrolysis stage (Hall-Héroult process): 56.4% of the total CO_{2,eq} emissions.

Regarding copper production, an electrical power consumption of 27.77 MW and a heating power consumption of 130.35 MW were determined. These values correspond to total emissions flows of 17.22 tons of CO_{2,eq} per hour and 29.52 tons of CO_{2,eq} per hour associated with electricity generation and natural gas combustion, respectively. Therefore, considering a production rate of 38.2 tons of copper per hour (matching with the copper production capacity of the “El Teniente” Codelco plant in Chile) a global emissions factor of 1.22 tons of CO_{2,eq} per ton of copper produced was determined. The process stages identified with the higher GWP are the drying stage: 18.2% of the total CO_{2,eq} emissions, the fire refining stage: 16.5% of the total CO_{2,eq} emissions, and the electrorefining stage: 58.6% of the total CO_{2,eq} emissions.

Finally, the simulation of the steel production process indicates a heating power consumption of 627 MW. This value corresponds to a total emissions flow of 126.18 tons of CO_{2,eq} per hour. Additionally, 663.8 tons of CO_{2,eq} per hour are generated as product of the reactions taking place in the iron blast furnace and the basic oxygen furnace. Considering a production rate of ca. 570.78 tons of steel per hour (matching with the steel production capacity of the Arcelor Mittal Asturias plant in Spain) a global emissions factor of 1.38 tons of CO_{2,eq} per ton of steel produced was determined. Since cast iron is an intermediate product of the steel production process an emissions factor of 1.26 tons of CO_{2,eq} per ton of iron cast produced was determined, which indicates that in this case the iron blast furnace is the stage with the higher GWP (96.7% of the total CO_{2,eq} emissions).

Concerning electricity generation, a PCPP that generates a gross power of 249.1 MW and a NGCC that generates a gross power of 390.4 MW (with 2/3 of this power generated in the gas turbine and the remaining power generated in the steam turbine) were simulated. A total emissions flow of 576.8 tons of CO_{2,eq} per hour was determined for the PCPP technology, of which a 48.7% is associated with the pulverized coal boiler operation and a 37.8% is associated with the desulfurization stage. Correspondingly, a total emissions flow of 173.2 tons of CO_{2,eq} per hour was determined for the NGCC technology associated with the combustion chamber, turbine operation, and heat recovery steam generator (HRSG) stages. Finally, considering capacity factors of 0.81 and 0.53 for the PCPP and the NGCC, respectively (Gaete-Morales et al., 2019), emission factors of 3.1 and 1.0 kg of CO_{2,eq} per kWh generated were determined. Since an electric bus consumes 1.1 kWh per km driven and assuming that the electricity matrix in Chile includes a 48.6% of natural

gas based power plants, an emissions factor of 0.51 kg of CO_{2,eq} per km driven was determined for this type of vehicle.

To conclude, the simulation of a petroleum refining plant processing 100,000 barrels of crude oil per day indicates that a total amount of 1.32 million litres of fuel per day (fuel coming from the same plant) is required to satisfy the utilities requirements of the process. This is associated with an emissions factor of 0.61 kg of CO_{2,eq} per litre of diesel produced. Therefore, since a conventional bus has a performance of 2.4 km per litre of diesel and the combustion of this fuel produces 2.69 kg of CO_{2,eq} per litre (Dirección de Transporte Público Metropolitano, 2014; US Environmental Protection Agency, 2018), the emissions factor associated with its use is 1.38 kg of CO_{2,eq} per km driven.

5. Conclusions

The results obtained indicate that the electrolysis stage (Hall-Héroult process) in the aluminum production process is related to a significant GWP due to its high electricity consumption and the generation of CO₂ as a by-product. Similarly, the electrorefining stage in the copper production process is related to the higher GWP due to its elevated electricity and heat power requirements. This represents a big challenge for the experts in electrochemical engineering to develop alternatives to these conventional processes which offer similar kinetics and the absence of undesirable by-products operating under moderate conditions. In the case of the steel production process, the CO₂ generated as by-product in the iron blast furnace is another sign of the need of developing new technologies which do not depend on the use of fossil fuels or an energy matrix with high carbonization levels. Since the fabrication of an electric bus requires a higher amount of these raw materials than the fabrication of a conventional bus (having in mind that this study does not include other materials such as lithium and rare earths also related to high environmental impacts), it is required to consider new developments and a circular economy approach for the effective implementation of these vehicles.

The resulting emissions factor associated with the use of an electric bus (0.51 kg of CO_{2,eq} per km driven) is, as expected, lower than the emissions factor associated with the use of a conventional bus (1.38 kg of CO_{2,eq} per km driven). This is a positive result considering that the electricity matrix in Chile is still highly dependent on fossil fuels. However, the fabrication impact must not be disguised by this result since it is also associated with the urgent need of recycling strategies at the end of life considering, for example, that batteries modules have an optimal lifetime of approximately six years (a half of the optimal lifetime of a conventional bus).

It is thought that the proposed methodology successfully complements the LCA studies reported in the literature since it allows to identify the processes stages with the higher GWP associated and the operational aspects that explain it, thus offering guidelines for future research and optimization in the fabrication and use of electric vehicles.

Sustainable Ammonia Production via Electrolysis and Haber-Bosch Process

Gbemisola Ojo,^aKyle Camarda^a

^a*University of Kansas, Lawrence, KS 66047, United State*

Abstract

The production of ammonia accounts for nearly 2% of global carbon emissions (Palys et al. 2018) and therefore finding ways to make ammonia using renewable energy sources is paramount. The current mechanism for NH₃ production is dominated by the Haber-Bosch process, in which the hydrogen is produced from a water-gas shift reaction (Martín, 2016). Rather than obtaining this hydrogen from fossil fuels, this project employs electrolysis, driven by a solar plant coupled with battery storage. In this work, a dynamic simulation of a chemical process plant for the synthesis of the production of ammonia electrolysis is simulated using Aspen Hysys. Since renewable sources of energy are naturally variable, the plant's dynamic performance over varying electricity availability is also investigated. Case studies are used to demonstrate the feasibility of the plant as well as to explore the maximum and minimum battery capacities required.

Results show production profiles utilizing variable energy availability while avoiding shutdowns and minimizing battery charging cycles. The results also demonstrate the feasibility of completely sustainable ammonia production. This study produced 60.25 tons/day of ammonia using 8 tons/day of hydrogen at a current density range of 43 – 90 A/cm². The minimum battery capacity required is 56.25 MW.

Keywords: Electrolysis, Ammonia, Battery, Renewable, Solar Energy.

1. Introduction

Ammonia (NH₃) is the second most produced chemical in the world. Traditionally, hydrogen is produced from methane steam reforming, while nitrogen is separated from the air. This project utilizes Aspen Hysys to simulate a dynamic model of an ammonia production plant that utilizes sustainable hydrogen production. Nitrogen is obtained from an air separation unit using a pressure swing adsorption technique. Hydrogen is produced via water electrolysis at moderate pressure and temperature conditions to ensure overall energy usage is reduced and high purity of hydrogen is obtained.

While renewable energy is crucial to handling global warming, a major challenge is intermittency. In this work, rechargeable lithium-ion batteries are implemented to allow continuous production of ammonia. The specific objectives of this study are (1) to simulate a dynamic model for hydrogen production, nitrogen separation, and ammonia synthesis (2) to integrate the process with a solar energy and battery source, (3) to test and analyze the effects of varying process parameters (4) to perform an assessment of the system to determine battery charging and discharging schedules.

2. Background

2.1. Hydrogen Production

Several production methodologies for hydrogen production can be considered in the context of ammonia production, including Alkaline Water Electrolysis (AWE), Proton Exchange Membrane Electrolysis (PEM), and Solid-Oxide Water Electrolysis (SOWE). These methods are differentiated by two major parameters: pH, and temperature. The criteria used to decide the most effective technique is based on the temperature range, the electrolytes and durability of the system. AWE was chosen because of its low capital cost, low corrosivity, high durability, and thermodynamic stability. Based on these factors, the AWE process was chosen for this project. The simulation for the proposed AWE was completed using Aspen Custom modeler.

2.2. Nitrogen Separation

A renewable-resourced ammonia production facility should obtain the required nitrogen directly from the air. Three methods of air separation were considered for this project: cryogenic distillation, pressure swing adsorption, and membrane separation. Although cryogenic distillation is the most common process employed in industry, it requires large energy input. While membranes offer a low-energy solution for air separation, the current production of membranes does not provide sufficient selectivity for practical use. PSA, on the other hand, provides a trade-off between practicality and energy consumption. Furthermore, high-quality adsorbents for oxygen already are in industrial practice. PSA was not modelled in this work, it is recommended for future work.

3. Process Description

A dynamic process is simulated which integrates a Haber-Bosch reactor with water electrolysis for hydrogen production. It utilizes a solar plant as the main source of energy with lithium-ion batteries to buffer the power availability. The process model was developed using Aspen Hysys and Aspen Custom Modeler. An overall schematic of this process is shown in Figure 1.

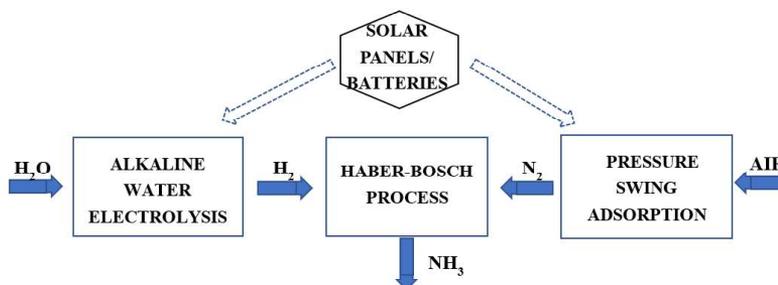

Figure 1: Overall schematic for ammonia production

3.1. Hydrogen Production Section

Alkaline water electrolysis is a process by which water is decomposed into hydrogen and oxygen in an electrolytic cell. Water is fed to the cell, which includes a porous nickel electrode and a diaphragm. Figure 2 shows the anode circulation loop,

which produces oxygen while the cathode circulation loop produces hydrogen for the Haber-Bosch process. This affects a direct separation between the hydrogen and oxygen produced. The AWE was simulated using a custom unit operation created in this work.

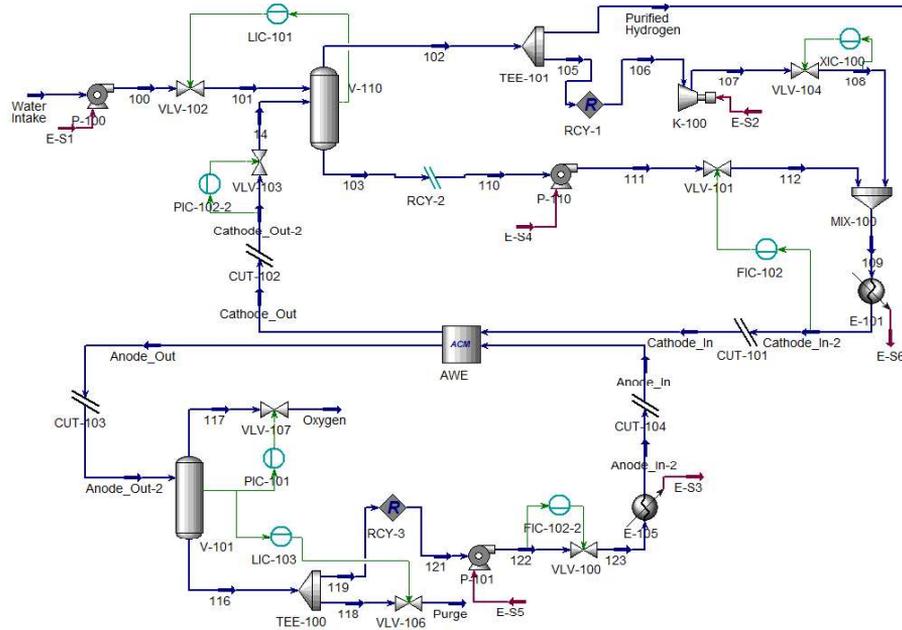

Figure 2: Alkaline Water Electrolysis showing anode and cathode circulation

3.2. Ammonia Production System

As discussed earlier, the Haber Bosch process is operated in a plug flow reactor temperature of 580 K and 150 bar. Heat integration is applied to recover excess energy from the product. Unreacted nitrogen and hydrogen are recycled to reduce energy usage.

3.3. Energy Specification

Upon the implementation of the above process model, a dynamic simulation was completed for three different case studies to demonstrate the energy requirements of the system. The objective of these case studies is to show the dynamic profile of the plant given various weather and location scenarios. The case studies are also used to understand the battery capacity required for the plant.

The storage energy system is an essential part of most off-grid renewable energy systems. Batteries are employed to store the surplus power produced from solar power allowing them to serve the load demand while balancing the hybrid system's fluctuations. The model used in this paper estimates the state of charge of the battery storage following the methods by Guezgouz et al. (2019).

4. Results and Discussions

The case studies shown describe the relationship between power availability and ammonia production level. Knowing that water electrolysis dominates the power

consumption operation of this plant, it is important to understand the power requirement of the alkaline water electrolysis based on the overall ammonia produced. The study uses a minimum and maximum current density specification to control the amount of hydrogen produced. This controls the overall ammonia production rate. The maximum and minimum current density is identified by using the specific requirements of AWE, at a limiting temperature of 90° C. Current density is directly properly proportional to temperature of the electrolytic cell. At current density ranging from 0.2 A/cm² to 0.3 A/cm², temperature ranges from 66 ° C – 90 ° C respectively.

The dynamic behavior of the integrated process was modeled using Aspen Hysys. In the system, controllers are placed in strategic places to stabilize the open loop response of the system as the current density of the process is changed. The controllers in the AWE will be tuned electrolysis to decrease the settling time and overshoot by tuning the control parameters. Dynamic studies will be continued to determine optimal operating conditions and charging/discharging schedules

For each case, the electrolyzer inlet temperature is set to 25 °C, while the inlet temperature of the for the Haber-Bosch PFR is set to 257 °C. This gives a 92% conversion rate of hydrogen to ammonia.

Case study one shows a startup for this process leading to full-capacity operation. The plant then runs at a constant density of 0.3 A/cm². Figure 3 describes the dynamic profile of the plant. It can be observed that at a constant density of 0.3 A/cm², the maximum amount of ammonia produced is 27.45 tons/day, which corresponds to a small industrial facility. The energy requirement is estimated to be 5.54e +04 kW per day. This case study serves as a base case to compare with real-word scenario.

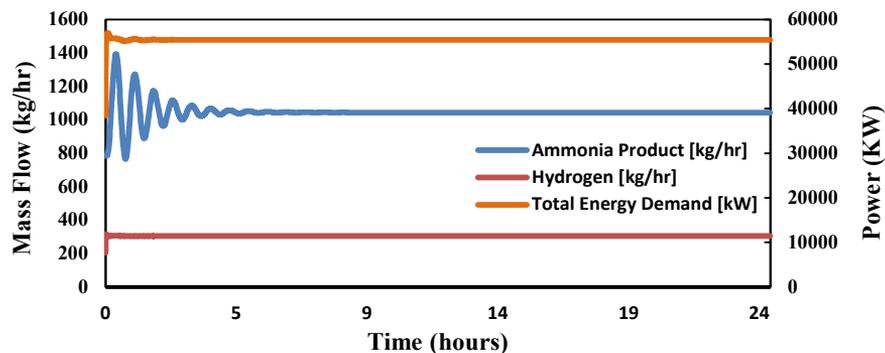

Figure 3: Ammonia production profile for case study one

Case study two assumes construction at a location closer to the equator, where there is approximately 12 hours of daylight. The current density at high solar hours is assumed to be 0.3 A/cm² which gives an ammonia production rate of 27.84 tons/day, as seen in the previous case study. This production rate decreases to 19 tons/day at a lower current density of 0.2 A/cm² when power is obtained from batteries. The excess energy produced from the solar panel at peak hours is transferred into batteries for use during the night. A total of 600 solar modules are utilized for functionality of the plant. Figure 4 shows the response to the change in current density of the overall ammonia production.

The dynamic profile also illustrates a second order response to the change in current density.

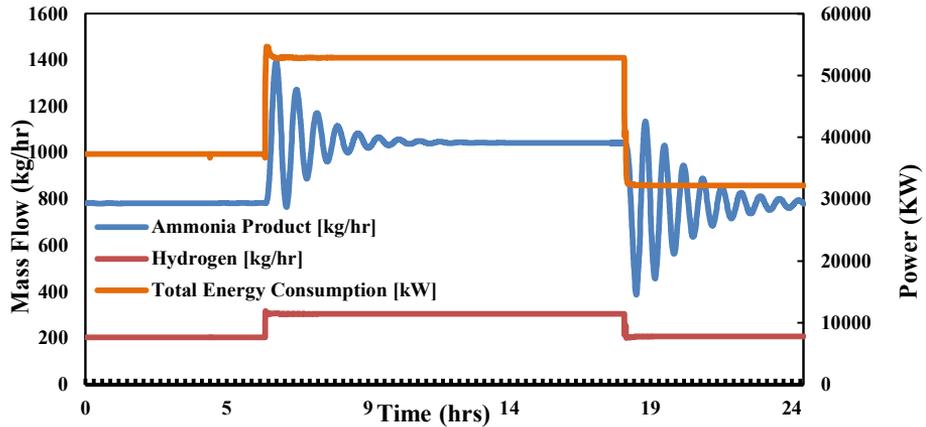

Figure 4: Ammonia production profile for case study two

Case study three involves a location further away from the equator, where there is lower amount of sunlight. The plant runs at 0.2 A/cm^2 for 16 hours at night while it runs at a higher current density 0.3 A/cm^2 for 8 hours. From the result shown in Figure 5, it can be inferred that there is an 60% increase in battery required to make the same amount of ammonia. excess energy supplied during the data is stored because it is needed to power the plant at night.

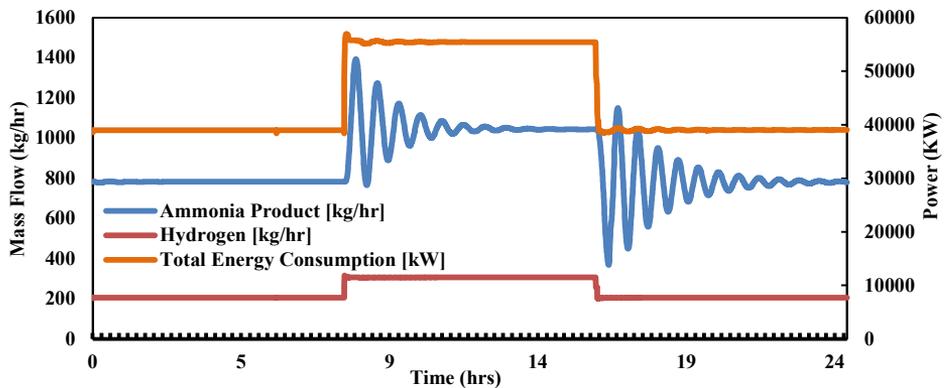

Figure 5: Ammonia production profile for case study two

5. Conclusions and Future Work

In this project, the feasibility of a 100% renewable energy chemical production plant to produce ammonia was considered. Due to the intermittency of renewable energy sources, the dynamic production profile was considered, to size the energy storage requirements. Water alkaline electrolysis and pressure swing absorption were applied to produce hydrogen and separate nitrogen respectively. The resulting profiles show the feasibility of a full-scale ammonia plant utilizing 100% renewable energy by integrating the entire Haber Bosch process with solar power. Analyzing these case studies at different current densities and time intervals gave insights on the effects of solar radiation and battery capacity on the ammonia production rate.

The battery system employed is large but not beyond currently used industrially sized systems. The key conclusion explained from the analysis shows that, the scale of the ammonia plant is necessary for the renewable energy to be economical. Several small-scale renewable plant is more cost effective than one large renewable plant. The results also show that case study 2 is more economical for the ammonia plant because it is much closer to the equator, therefore more energy can be harvested and stored in the battery for night-time. Lastly, the results also show a promising future holds for a renewable ammonia plant although this focuses on a smaller production scale. Future studies will perform MINLP optimization to minimize battery requirements and thus improve overall sustainability.

Abstract

Hydrogen, a clean multipurpose energy carrier with application in various industrial and chemical processes has been identified as a key player in meeting the global clean energy sources target. There are several ways to produce hydrogen, however, 95% commercial hydrogen is produced via steam methane reforming (SMR) which emits CO₂ as by-product making it environmentally unfriendly. Although carbon capture sequestration (CCS) can be applied, only about 90% CO₂ capture has been reported in the literature, and the burgeoning water electrolysis technology which enables zero GHG emission depending on the source of energy applied is quite expensive and limited. Hence the increasing research attention on Methane pyrolysis (MP). In this study, the different TDM technologies are explored to develop an optimization model that considers energy efficiency, CO₂ emission and water consumption in production of hydrogen at a minimum cost, selecting a sustainable MP path that is comparable to prevalent technologies– SMR with and without CCS as well as water electrolysis- for further research. An MINLP optimization model for selecting a sustainable pathway to produce hydrogen in commercial quantity is formulated using associated data from the literature with respect to the different technologies considered. Sensitivity analysis is also performed to analyze the impact of the by-products produced from each technology on the cost of production. The model is implemented in GAMS. The findings from this work selected TDM with Plasma and TDM with metal catalyst as the optimal hydrogen production pathways that can compete with prevailing technology for sustainable hydrogen production based on the process performance index considered. It also shows that the quality of carbon could greatly influence the commercialization of MP. Moreover, MP is flexible and can attain carbon-neutrality depending on the feedstock and energy source. However, the results show that this transition depends on the cost and availability of renewable energy sources. With the supposition that MP Low to zero CO₂ emission and valuable solid carbon product features makes it sustainable, TDM technology should be explored to compete with the current technology to meet hydrogen demand, and this study provides a pointer to the optimal TDM technology as well as precedes a process simulation that explores the kinetics and thermodynamics for optimization.

Keywords: Methane pyrolysis, Hydrogen production, Optimization, Carbon.

1. Introduction

There is a global burden to find sustainable ways to reduce greenhouse gases (GHG) emissions while meeting increasing energy demand. Hydrogen, a multipurpose energy carrier with application in various industrial and chemical processes has been identified as one solution to de-carbonization, given that it does not directly emit CO₂. However,

the current techniques for commercial hydrogen production to meet global demand is heavily dependent on fossil fuels (mainly Natural Gas and Coal) either directly as feedstock and fuel for the process or indirectly for electricity generation (Muradov 2017). Utilizing natural gas which is composed mainly of methane will considerably reduce CO₂ emission in comparison to its fossil fuel counterparts because it is more environmentally friendly.

Methane pyrolysis (MP) is the thermal decomposition of methane (TDM) to produce hydrogen and solid carbon. It is an endothermic reaction like the dominant SMR but it has a smaller heat of reaction as well as only one reaction step, making it much simpler than the SMR that requires the water gas shift reaction. There are several techno-economic analysis and reports on the relevance of MP towards the hydrogen economy, as well as process simulation and experiments on the different MP technologies available to push its competitive potentials. However, to the best of the authors' knowledge as of the time of this work there are quite few research works, if any, that applied modelling and optimization to decisively select an optimal pathway.

In this work, we adopt and formulate an optimization model that selects the sustainable MP technology that can be comparable to prevalent technologies— SMR with and without CCS as well as water electrolysis for commercial hydrogen production considering energy efficiency, CO₂ emission and water consumption in production of hydrogen at a minimum cost. We analyze different scenarios of energy source combination as well as the influence of the price of valuable carbon and CO₂ emission tax/credit. The work is structured as follows: section 2 describes the different hydrogen production technologies currently used or researched. Section 3 describes the process modelling. Section 4 describes the model and optimization implementation as well as discussion of results obtained. Section 5 concludes with the finding and further works considered.

2. Hydrogen Production Methodologies

There are several technologies for producing hydrogen, the hydrogen produced from these technologies are mostly identified in color codes - based on dependence of the production process on fossil fuel or clean energy sources. These mainstream technologies include:

- Grey Hydrogen (SMR, Partial Oxidation, Auto-thermal reforming, Steam-oxygen gasification of coal, flue gases) (Muradov 2017; Keipi et al. 2016; Nikolaidis and Poullikkas 2017)

- Blue hydrogen (SMR with CCS)
- Green hydrogen (Electrolysis) (Muradov 2017).

- Turquoise Hydrogen (Methane Pyrolysis, TDM) (Keipi et al. 2016).

3. Process Modeling

To select the optimal Hydrogen production route, we employ synthesis-design processing route modelling approach proposed by Bertran et al. (2017). A superstructure based optimization problem is formulated to choose among processing alternatives. The Methodology is a three-step approach design for achieving an optimal production pathway. The three stages involve synthesis (superstructure optimization process synthesis), Design (detailed design and simulation), and Innovation (optimization,

modification or improved and sustainable process integration design) with output of each stage as the input of the next (Quaglia et al. 2012). The complicated and data intensive process is decomposed into these stages to simplify the problems and finally integrate the solution obtained from each stage to form a sustainable solution. For this work, we implement the first step to choose the sustainable hydrogen processing pathway, this is a precursor to the subsequent 2 steps which would explore in detail in future works.

In modelling, a CO_2 emission target is included to assess the total CO_2 emitted from the process and energy sources of each technology, this constraint is essential for the technology selection. Figure 1 shows a representation of individual process and its components to be modelled which is repeated for the different technologies considered. Where $f_{i,k}^{IN}$, $f_{p,k}^{out}$, $f_{p,k}^{out,1}$, $f_{p,k}^{out,1}$ represents the input and output (product and by-product) variables respectively, $E_{j,k}$ are the energy consumed with respect to the source for each technology, $\text{CO}_2^{emit}_{j,k}$ accounts for the CO_2 emitted from each energy source for each technology, given that there is no direct CO_2 emission from MP and electrolysis, and $SW_{i,k}$ accounts for process waste or unconverted feedstock.

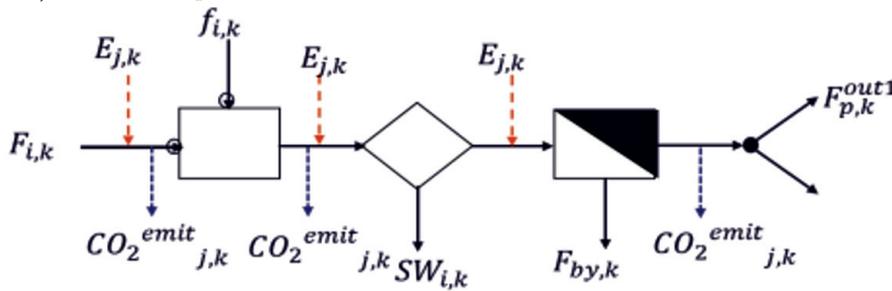

Figure 1: stages of hydrogen production process

4. Simulation, Results and Discussion

The synthesis-design processing route model as adopted from by Bertran et al. (2017) was implemented in GAMS using data from the literature on the current and competing hydrogen technologies. The objective is to select hydrogen production technology with the minimum cost given the constraints and considering the scenarios provided. The decision variables \mathbf{y}_k for the choice of technology, \mathbf{y}_a and \mathbf{y}_b for the emissions constraint. We used disjunctive programming for the modelling in GAMS and the optimization problem was solved using the BARON solver. For this work five (5) MP technologies were considered and compared to the matured technologies – SMR, SMR_CCS and Alkaline Electrolysis. The technologies considered are represented as: T1-conventional gas reactor, T2- plasma, T3-Heat exchanger reactor, T4-catalytic decomposition with metal based catalyst, T5- catalytic decomposition with carbon catalyst, T6-SMR, T7-SMR_CCS and T8-Alkaline Electrolysis. The data used for the simulation was obtained from Agency (2019); Keipi et al. (2016); Keitz (2021); Timmerberg, Kaltschmitt, and Finkbeiner (2020); Muradov 2017; Keipi, Tolvanen, and Kontinen (2018)).

4.1. Simulation

The simulation analysis was based on three (3) scenarios:

- Impact of energy sources applied: this scenario considers three sources of energy required for heating namely: Combusted natural gas (NG), electricity from the grid (EG) and renewable energy (RN) sources. A simulation for the application of

different combinations of these sources for heat as well as a single source for all technologies was carried out and the results analyzed discussed

- Impact of process by-products: considers the effect of the price of carbon on the choice MP technology to compete with prevalent technologies. Likewise, the analysis considers the influence of total CO₂ emission of each technology in the choice of technology; the carbon credit, carbon tax and carbon target were changed respectively and the effects analyzed;
- Impact of feed to product conversion ratio: this scenario considers the effect of the conversion rate of the process on the choice of technology.

4.2. Results

Table 1 shows the key variables obtained from the simulation as well as significant results obtained, the third scenario was not presented as it did not show a significant difference. The CO₂ emission constraint included in the process model is essential in the choice of technology, as it intends to meet the global emissions objective. It provides a solution space within which a decision among multiple options is made, as well as revealing parameters. It also provides a desired range with a condition for alternative decision when there is a violation, which in the case of this work influences the path selection.

The result in table 1 shows that the constraints were considered in the choice of technology for each of the scenarios assumed. It can be seen that the decision for the feed flowrate is such that it can obtain a product quantity that satisfies the CO₂ emission target, however in the case where the target is exceeded and yet a technology is selected, it points to the influence of the parameters, noting that the optimizer only tries to find the minimum. A global optimum was obtained with the given scenarios. For instance in the cases where T7- SMR with CCS is selected, the CO₂ target could be exceeded but the emission tax could easily be compensated with the cost of technology or energy cost compared to choosing electrolysis with almost zero emission but with high technology cost.

Table 1: Simulation analysis result

Scenario 1: Energy consumption

The simulation results shows, that the combination of NG and EL provided the least objective function selecting T4 i.e. the thermo-catalytic decomposition using metal catalyst using electricity from the Grid. However, the CO₂ emission was above the given emission target. This can be because of the separation requirement for the catalyst and the carbon product, given that using catalyst lowers the energy consumption thereby reducing possible emission associated with this technology. Furthermore, in the case where only electricity is applied across all the MP technologies, it is still able to select one of the MP technologies over the SMR with CCS technology. On the other hand, using the other sources of energy independently for all the technologies leads the optimizer to select the SMR process which is cheaper and has the capacity to offset for the CO₂ emission either through enough profit to pay the given tax or with the CCS technology to avoid the tax.

Scenario 2: Effects of Technology by-products

From Table 2, we observe that the byproducts of each technology significantly influence the final cost of hydrogen production. In the MP technologies there is no CO₂ produced from the process, the only emission is from the energy source giving it an advantage over the matured SMR,- given that even with CCS only about 60% have been reported practically and 90% theoretically- hence the higher chance of obtaining carbon credits than tax. Moreover, the different MP technologies produce different grades of carbon, which have different prices based on their qualities. Therefore, the price of these different types of carbon can influence the cost of production. This can be observed from the simulation result with choice T2 and T4 which have the highest prices of carbons (graphene and carbon nanotubes CNT).

The results also show that a more strict carbon emission tax leads to the selection of MP over SMR, although the increase in carbon credit had no significant effect on the selecting SMR with CCS over the MP technologies.

By using the 3-stage synthesis-design processing route approach, it gives a more structured and informed process design and optimization. In addition, the results obtained demonstrates the advantages of MP such as:

- Low CO₂ emission,
- Valuable carbon by-product
- No water required
- Ability to apply different sources of heat at different stages of the process for optimization purposes.

These attributes significantly influence the choice of the hydrogen technology.

5. Conclusion

A synthesis-design processing route approach for superstructure optimization was implemented to select the optimal hydrogen processing technology, this technique is the first of three steps which serves as a precursor to a more detailed process design, simulation and optimizations. The result of the optimization provided a direction as to the parameters that can significantly affect the optimal hydrogen production process route as well open more questions for the author to decipher in the course of the research. The result of the simulation demonstrates the advantages of Methane pyrolysis over the prevailing technologies by showing that the use of electricity from the grid as the main source of heat can lead to a more optimal MP process that can compete with the current SMR and SMR with CCS technology. The result also show that while MP has the potential to be emission free when renewable energy sources are applied, it is currently not optimal due to the maturity stage and cost of renewable energy sources.

The results obtained also showed that the quality and price of carbon product can significantly make MP a competing hydrogen production technology. Furthermore, MP technologies can enable hydrogen to have a better chance in the world energy mix with more countries adopting more strict Carbon emission regulations as the world move toward a low-zero emission. With the result of this work a detailed process simulation will be carried out with the best technology selected which in this case is between T2 (TDM with Plasma) and T4 TCDM (with metal catalyst).

The results also open room for more question for research exploration such as: The thermodynamics of the process that can lead to optimal quality carbon production, the properties of carbon produced and their modification for different applications to enable more demand, energy mix in the different process steps that can enable optimal processing. What are the main distinctions between T2 and T4, and how can they be improved to compete with the SMR technology while more research on the possibility of making MP technologies emission free is ongoing.

Abstract

Lactic acid (LA) is a raw material for poly lactic acid, which is used in food, pharmaceutical, textile, and various chemical industries. Evaporation is an essential process to produce highly pure LA after the fermentation process. Notably, the evaporation process is energy intensive, and the energy consumption corresponds to approximately 50% of the total production cost. Consequently, the energy efficiency of the LA evaporation process must be enhanced. To this end, this study was aimed at establishing a process model based on a multi-effect evaporator (MEE) and mechanical vapor recompression (MVR) system. The MEE process model involved a distillation column, virtual reboiler, and flash drum. The steam consumption was reduced by recovering the latent heat of secondary vapor. Furthermore, the steam and condensate were recovered from the final evaporator. The MVR process model involved a compressor that substituted the steam consumed in the evaporation with electricity by recompressing the vapor in the evaporator. The energy efficiency of the two processes was analyzed by comparing the steam and electricity consumption values. The steam consumption decreased from 99.381 to 37.913 ton/h with the increase in the number of effects (from one to eight), and the electricity consumption of the MVR system was 31.32 kW.

Keywords: Evaporation process, Multi-effect evaporator, Mechanical vapor recompression, Process modeling

1. Introduction

Lactic acid (LA) is an eco-friendly material produced by fermenting sugar and lignocellulosic substrates. LA is a raw material for poly LA (PLA), which is a bioplastic that can replace petrochemical polymers. Consequently, the demand for LA has increased considerably in recent years. To produce the final LA product, several purification steps must be implemented after the fermentation process, with evaporation representing the most commonly applied approach for purification. However, the evaporation process is energy intensive, with the energy consumption corresponding to approximately 50% of the total production cost. To reduce costs, the energy efficiency of the evaporation process must be enhanced. Many researchers have investigated LA purification as a potential

approach to increase the energy efficiency. Oscar et al. recommended the use of a reactive distillation column for LA purification, which could achieve 99.89% recovery of LA. Tong et al. increased the yield of LA to 82.6% through purification with paper sludge as a cellulosic feedstock by using an anion exchanger, Amberlite IRA-92. Madzingaidzo et al. demonstrated the concentration of LA through monopolar electro dialysis and obtained an average yield of more than 98% after carbon treatment.

Despite the significant efforts to increase the energy efficiency of the evaporation process, several challenges remain to be solved, specifically, the high equipment cost, reduced stability owing to the addition of chemical substances, and low economic feasibility because continuous operation cannot be realized.

To address these process, in this study, two alternative process models were designed using a multi-effect evaporator (MEE) and mechanical vapor recompression (MVR) system. The MEE can reduce the steam consumption in the evaporation process by reusing the heat of the secondary steam discharged from the evaporators arranged in series under different conditions as a heat source. In the case of MVR, the steam consumption can be reduced by replacing a part of the steam consumed during the evaporation process with electricity. The energy efficiency of these processes was analyzed by comparing the steam and electricity consumption.

2. Process description

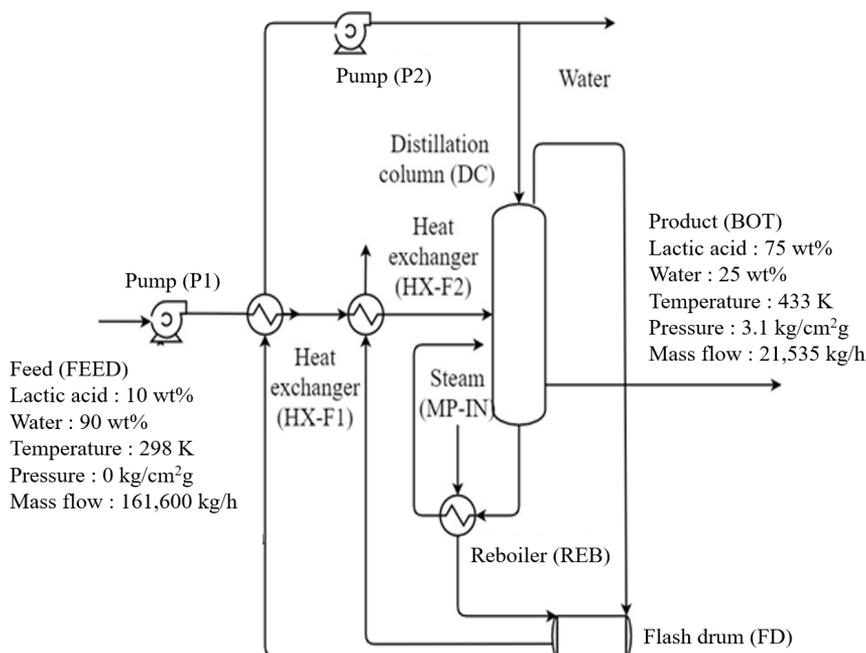

Figure 1. Process flow diagram of single-column evaporation

Among separation processes, distillation is the most effective method for evaporation in the biorefinery process. Distillation based on a single column is a conventional evaporation process for refining LA from a low concentration feed. Figure 1 shows the

process flow of single-column evaporation. After the feed is preheated through a preheater, it is supplied to the evaporator. After distillation, LA with a relatively high boiling point is discharged to the bottom of the column together with undistilled water, and water, the boiling point of which is lower than that of LA is discharged to the top of the column in the form of a gas.

3. Model development

Aspen plus V10.0 was used to simulate the process, and the considered thermodynamic equation was the UNIQUAC activity coefficient model. This equation can represent the vapor–liquid equilibrium behavior and is commonly used for simulating evaporation and condensation processes. The following assumptions were implemented.

- ✓ The feed composition is as follows: H_2O (90 wt%) and LA (10 wt%).
- ✓ The product composition is as follows: H_2O (25 wt%) and LA (75 wt%).
- ✓ Heat exchange occurs through the latent heat of steam input to the reboiler.
- ✓ The steam pressure is $9 \text{ kg/cm}^2 \cdot \text{g}$, and the temperature is $180 \text{ }^\circ\text{C}$.
- ✓ When the heat duties of the virtual reboiler and reboiler of the column are identical, the steam consumption is the optimal point.

3.1. Multiple-effect evaporation process

Multiple-effect evaporation is one of the oldest processes in desalination frameworks. In this study, the MEE process was used to increase the efficiency of the LA purification process. Figure 2 shows the process flow for a MEE.

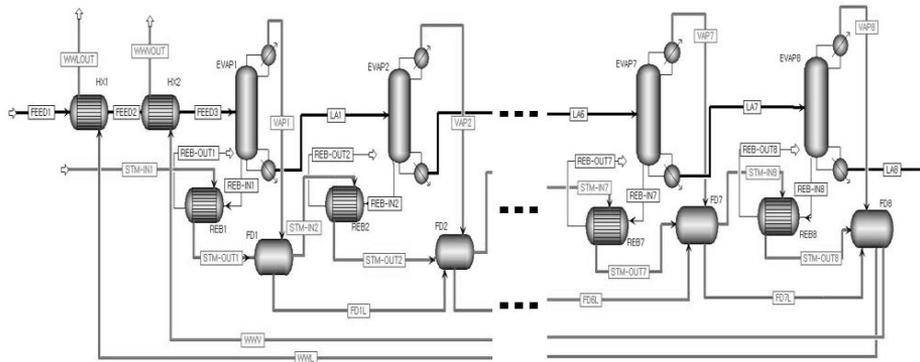

Figure 2. Schematic of multi-effect evaporator (MEE) process

The evaporator was divided into a distillation column, virtual reboiler, and flash drum in the process modeling. The virtual reboiler was used to predict the steam consumption of the distillation column. The heat calculated through the virtual reboiler and heat consumed in the distillation column were set equal to estimate the steam consumption. The impurities in the feed were ignored. The feed was preheated in the preheater and fed to the distillation column with increased pressure and temperature. The temperature and pressure of the feed and vapor continuously decreased from the first effect to the last

effect, and the least temperature and pressure corresponded to the last effect. Steam from the outside was used to evaporate the feed water in the first effect. The steam from the distillation column was used to evaporate the water/solvent in the second effect, and the steam from the second effect was used to evaporate the water/solvent in the third effect. This process was repeated until the last effect. After heat exchange at the last effect, the discharged water was separated through a flash drum and used to preheat the feed. By repeating this process until the last column, the waste heat could be effectively reused, thereby reducing the amount of steam used, which could help decrease the energy consumption. The distillation column involved 15 stages, the feed was supplied in stage 11, and the reflux stream at the top of the column was input in stage 1. The steam used as the heat source was medium-pressure steam.

3.2. MVR

MVR is a commonly used technique to recover waste heat sources as useful energy sources through mechanical compression. MVR uses only electricity as the energy source as it concentrates LA using only the secondary steam compressed through a centrifugal compressor. In general, the MVR can significantly reduce utility costs throughout the evaporation process because electricity is cheaper than steam. In the developed model, the heat of the compressed secondary vapor was set equal to the heat required by the evaporator to predict the power consumption of the centrifugal compressor.

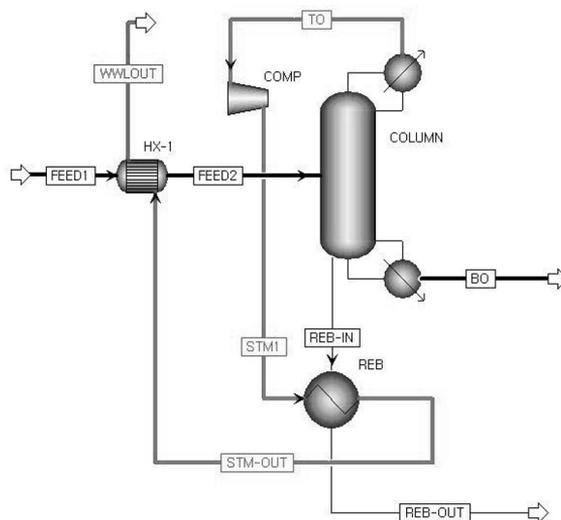

Figure 3. Schematic of mechanical vapor recompression (MVR)

Figure 3 shows the process flow for the MVR framework. In the process modeling, the evaporator was divided into a distillation column, virtual reboiler, and compressor. Furthermore, a virtual reboiler was added to predict the steam consumption of the distillation column. Feed entered the column through preheating, and the mass fraction of the product at the top and bottom of the column was the same as that for the MEE model.

4. Results

Figure 4 shows the steam consumption for each equipment in this process. The model with one effect corresponded to the conventional process. In the MEE model, the amount of steam consumption gradually decreased as the number of effects increased to eight. This phenomenon occurred because the waste heat of the steam at the top of the distillation column was reused. In particular, when eight effects were used, the steam consumption reduced from 161,656 kg/h to 37,913 kg/h. Moreover, the steam consumption for the MVR model (11,083 kg/h) was significantly smaller than that for the MEE model. This finding could be attributed to the use of electricity as the energy source in the MVR model.

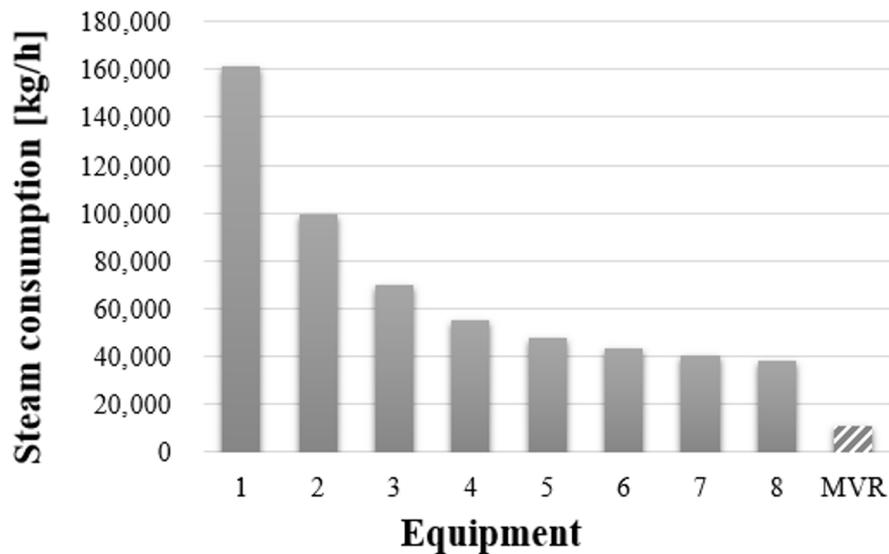

Figure 4. Steam consumption according to equipment, with the number of MEE effects ranging from 1–8

Figure 5 shows the electricity consumption for each equipment in this process. In the MEE model, the electricity consumption increased as the number of effects increased. Specifically, when eight effects were used, the electricity consumption increased from 52.88 kW to 78.899 kW. However, in the case of the MVR model, the electricity consumption reduced from 52.88 kW to 31.32 kW.

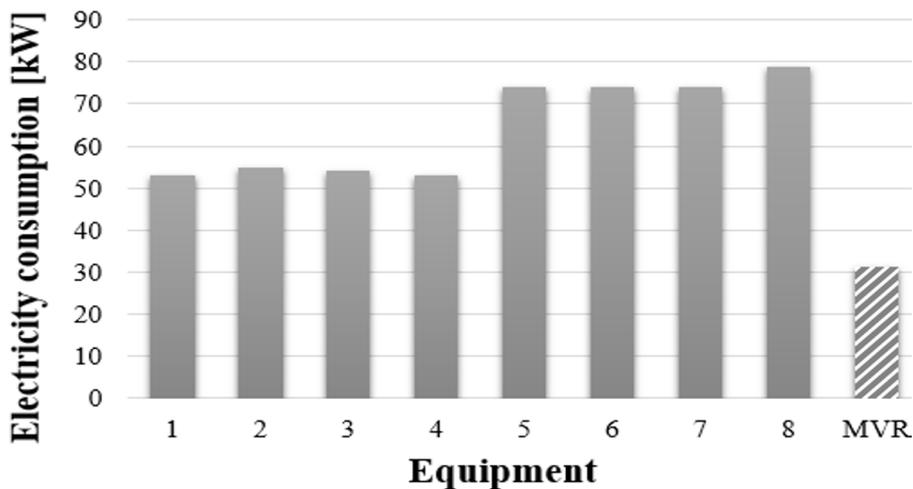

Figure 5. Electricity consumption according to equipment, with the number of MEE effects ranging from 1–8

5. Conclusions

Two process models, MEE and MVR, were established to enhance the energy efficiency of the LA evaporation process. The LA mass fractions for the feed and product were 10 wt% and 75 wt%, respectively, for both models. The energy consumption was compared by estimating the amount of steam and electricity consumed for heat exchange in each process. In the conventional process, 161,656 kg/h of steam was used. However, when eight effects were introduced, the steam consumption of the MEE model reduced by 76.55%. The MVR model, which used electricity as the main energy source, corresponded to a 93.14% smaller steam consumption. The electricity consumption of the MEE and MVR models was 49.14% higher and 40.77% lower than that of the baseline, respectively. In future work, the economic feasibility of the models can be compared by performing a techno-economic analysis considering the investment cost and operating cost.

Abstract

To understand the mechanism of a catalytic system, computational analysis is essential. Once a potential reaction mechanism has been identified, it typically involves (a) evaluating the energetics for the species and transition states using a computational chemistry method such as density functional theory (DFT), (b) relating these microscopic properties to macroscopic quantities such as reaction time. Microkinetic models may not match experimental data due to (1) inaccuracies in the energetic estimation, (2) inadequate catalyst models that are not representative of the surface environment. As a result of using experimental data, a more accurate model may be developed. If the model-experiment mismatch is resolved, a microkinetic model solution compatible with DFT assumptions may be identified. This work presents a generic optimization framework for solving parameter estimation and catalyst design problems in catalysis. Using a stochastic optimization method, Differential Evolution with Tabu List in conjunction with Aspen Plus, and considering experimental data, various activation energy and kinetic constants values were predicted. A sequential approach is a traditional approach to solving parameter estimation problems. Issues with the stiffness of the microkinetic model and the optimizer's capacity to tackle such highly nonlinear systems are common challenges. This proposal has the potential to use all the reactor models present in Aspen Plus, as well as be able to use all the kinetic models and solvers, avoiding numerical difficulty in optimization solutions. This method has several advantages, including ease of implementation, which leads to physically realizable steady-state solutions, and a reduced overall optimization problem in terms of the number of variables involved. To validate this method, a dimerization of isobutane to produce isooctane is used as base line. The data considered as base case were previously worked considering experimental and simulation work. Once the parameter estimation was performed, the error produced was almost zero, and it was possible to generate the same kinetic data, concentration profile and molar flow produced.

Keywords: optimization, kinetic data prediction, oligomerization, hydrogenation, biojet fuel.

1. Introduction

In many techniques to understand a catalytic system and for ultimate design for enhanced catalysis (Nørskov et al. 2009), computational analysis is a vital tool. Incorporating experimental data, on the other hand, enables more appropriate model construction. This activity necessitates the estimate of parameters that will allow the model-experiment

connection to be reconciled and a kinetic solution model to be identified. Nonlinear optimization challenges include parameter estimates and catalyst design. In such cases, objectives must be maximized or minimized while being constrained by the catalytic system. A traditional approach to solving the parameter estimation problem is to use a sequential approach (Biegler 2010), in which the optimizer obtains necessary information about the reaction rate, surface coverage, and gradients at each step of the optimization process, looking for a simulation of the kinetic model. The stiffness of the kinetic model and the optimizer's capacity to deal with the system's nonlinearities make this technique problematic. The equations, for example, may discover many solutions that would be undetectable under normal physical conditions. As a result, a successful solution identification may be predicated on a solver-proposed starting assumption. Furthermore, when the kinetic system exhibits a temporal variation, the NLP formulation must be modified to account for the dynamics, and orthogonal collocation methods are required. Due to the simplicity of use, access, and rigorous resolution of the models connected with each piece of equipment, computer programs to duplicate the model of diverse unit activities are currently a highly important tool. The Aspen Plus simulator was created to represent chemical processes such as non-ideal phases, processes involving recycling currents, chemical reactions, adiabatic operations, and so on. It's made to handle a wide range of operating conditions in process design. Using experimental data to construct kinetic models might be a way to improve equilibrium-based models. Kinetic models vary from equilibrium-based models in that they may depict chemical reaction conversion, which is an important stage in process design, as well as the assessment and research of the findings obtained under various operating circumstances. Because of the intricacy with which kinetic models are treated, they are more precise and comprehensive than equilibrium-based models. As a result, there is a pressing need to build kinetic rate-based simulations capable of accurately forecasting the products of numerous processes that are difficult to describe, simulate, and operate under multiple conditions. In light of the foregoing, this research proposes a generic sequential optimization framework for solving kinetic parameter estimates for the reproduction of chemical processes in the Aspen Plus process simulator. The novelty of this proposed framework is that it allows for: a) a comprehensive exploration that allows for a robust explanation of experimental observations, b) comparing and constraining solutions through automated data analysis that allows for hypothesizing competing for dominant chemistries, c) proposing objectives that maximize the expected performance of kinetic systems, and d) identifying sparse solutions that avoid overfitting by selecting the fewest number of parameters that allow for a robust explanation of experimental observations. The article begins with a description of the methodology for determining the kinetic parameters, followed by a validation example.

2. Framework description: Methodology

The models solved by the framework in this study will be described in general in this part. It will begin with the kinetic model being solved in the simulator, the goal function being solved, and the parameter estimation solution approach.

2.2 Kinetic Model

Another reason to study reaction rates is to learn more about the reaction's mechanism and fundamental stages. A kinetic of any reaction represented by a rate equation should

be thoroughly understood by studying and investigating the characteristics of a rate equation, such as the order of the reaction, rate constant, and kinetic parameters such as A (pre-exponential factor) and E. (activation energy). The rate equation is used to quantitatively characterize the rate of a reaction and to explain its functional dependence on temperature and species concentrations. In symbolic form, the rate equation is as follows:

$$r_A = r_A(T, \text{all } C_i) \quad (1)$$

The term "all Ci" is used to emphasize that the concentrations of the reactant(s), product(s), and any other compounds present, even if they do not participate in the reaction, can affect the reaction rate. The partial pressure of a material pi is another sort of rate equation, especially for gases. The coefficient k in the reaction rate equation is the rate constant (as in Eq. (2)). This rate constant is changed by temperature, but not by the concentration of the species involved in the reaction. In the rate equation, the units of k are always used as a conversion factor for the product of species concentrations and units given as a change in concentration divided by time. The temperature-dependent term, or reaction rate constant, is clearly defined by Arrhenius' law:

$$k = k_0 * \exp(-E/RT) \quad (2)$$

The frequency or pre-exponential factor and activation energy, respectively, are the two parameters of Arrhenius' law. These parameters are also known as Arrhenius parameters. These figures are obtained by plotting lnk (rate constant) against 1/T (absolute temperature) and drawing a straight line. Experiments have shown that Arrhenius' law holds across a wide temperature range.

2.3 Objective function

The fundamental problem to address is to determine which kinetic parameters E and K best characterize the empirically observed behavior. In this case, the goal of the optimization issue is to decrease the observed error between experimental data and aspen plus simulator results when different values of E and K are represented. The following is a formula for the optimization/parameter estimation issue.

$$Z_{param,est} = \min \sum_{c \in C} (y_c - \bar{y}_c)^T W (y_c - \bar{y}_c) + \delta(\pi - \pi_{nom})^T (\pi - \pi_{nom}) \quad (3)$$

Subject to

$$\frac{dx_c}{dt} = f(x_c, k_c, u_c) \quad (4)$$

$$g(x_c, k_c, u_c) = 0 \quad (5)$$

$$y_c = Bx_c(t \rightarrow \infty); x_c(0) = x_c(u_c);$$

$$u_c = \{F_{in,c}, P_{tot,c}, T_c\} \quad (6)$$

$$h(y_c, u_c, k_c) \geq 0 \quad (7)$$

$$k_c = \psi(p, \pi_c, u_c) \quad (8)$$

For each experimental condition c C, the collection of all experimental circumstances has limitations that must be met. x, y, and u are referred to as x_c, y_c, and u_c, respectively since they are dependent on the experimental circumstances c. Because the objective function can be used in a variety of contexts, the subscript c and a summation have been included. All terms in equations 3–8 are depending on the experimental circumstances. The weighted least-squares error Z_{param,est} represents the model-experiment mismatch. y c is

used to represent the experimental data. The goal to be minimized is subject to the constraints relating to the kinetic model, as well as the restrictions, where p is the collection of constraints and is the set of decision variables, and h is the set of inequalities assuring thermodynamic feasibility and the choice variable bounds. The kinetic reaction of the system (function of ψ) can be described as an Arrhenius pre-exponential constant.

2.3 Optimization Strategy

This case study was solved using Differential Evolution with Tabu List, a metaheuristic optimization approach based on natural selection theory. This evolutionary approach employs the usual Differential Evolution stages. On the other hand, the Tabu List (TL) concept improves its actions. This hybrid optimization technique was created to improve DE's computing efficiency by trying tough phase equilibrium computations followed by parameter estimation challenges in dynamic systems with numerous minimums. A modified and expanded DETL approach was then applied to handle constrained multi-objective optimization problems (Sharma and Rangaiah 2013), and the resulting algorithm was named an integrated multi-objective differential evolution algorithm. Visual Basic is used to implement the hybrid algorithm. The numerical approach generates input vectors that are evaluated using dynamic data exchange (DDE) in the process model (Aspen Plus). After that, the model evaluates the input vector before generating output vectors. After that, the hybrid approach assesses the input and output data before iterating the process depending on the evolutionary nature of the algorithm. The stochastic method's operational settings were 120 individuals, 200 generations, 50% of the number of persons as tabu list, 0.6 for the crossover, and a taboo radius of 1 1006. These values were derived from a prior calculation's tweaking procedure. The optimization approach works in such a manner that it proposes E and K values for the kinetic model in each iteration. The reactor represented in aspen will generate an output as a result of this idea.

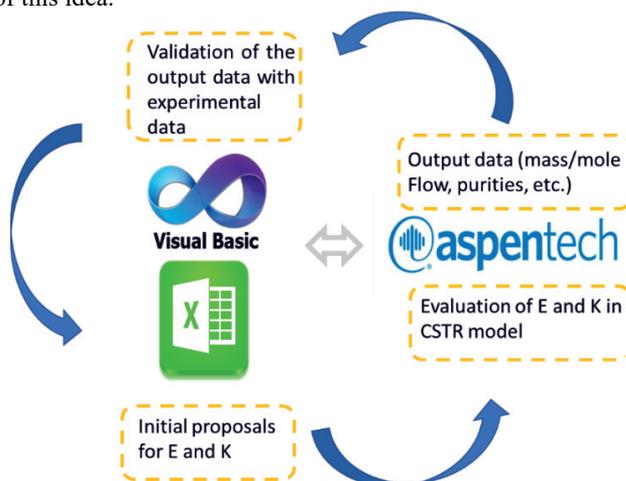

Figure 1. Determination of parameters E and K with DETL and Aspen Plus

3. Results: Isobutene dimerization.

In the 1930s, researchers looked at the dimerization of isobutylene caused by the dehydration of 2-methylpropan-2-ol. This reaction is frequently presented as an example

of alkene dimerization, and it is the subject of a laboratory experiment that allows students to check the predicted outcomes. The fact that two isomeric trimethylpentenes are created and evaluated as a mixture is a limitation of this experiment as a preparative experiment. Because of its high octane number, low vapor pressure, and lack of aromatics and sulfur, isooctane has become one of the most popular gasoline additions. Because of its high compression ratio and knock resistance, isooctane is also the principal component of aviation gasoline (Avgas). Due to the MTBE phase-out, isooctane synthesis technology allows refineries to use surplus isobutene and boost refinery earnings by converting light olefins into gasoline blends. In the not-too-distant future, isooctane use and production are predicted to skyrocket. To avoid catalyst sintering due to the highly exothermic reaction and the formation of higher oligomers that could result from the increased concentration of dimer in the reactor, most conventional isooctane production processes operate at low conversions (20-60 percent, with conversions varying depending on the catalyst and reactor design). Because of these limits, conversions of more than 60% each pass are frequently impossible and uncommon in the industry. Goortani et al. published a prior study in 2015. They propose utilizing Aspen Plus to mimic a typical commercial flowsheet that includes a dimerization reactor, distillation column, and hydrogenation reactor. They presented a concentration profile as well as kinetic data in their paper. The dimerization of isobutene to isooctane is the reaction system chosen for isooctane synthesis, as shown in the equation.

Previous experimental experiments in our laboratory (Goortani et al. 2015) employing a nickel sulfate and a Pd catalyst independently supported on Al₂O₃ were used to combine reaction kinetic data for the dimerization and hydrogenation processes in the isooctane synthesis process. These kinetic data were acquired in a 300 mL Parr autoclave reactor and pertained to liquid-phase oligomerization and hydrogenation of isobutene. The Arrhenius equation, $k = Ae^{(E/RT)}$, was used to determine the relationship between the reaction rate constant and the reaction temperature. The reaction constants k_1 for dimerization are listed below. The reaction of Dimerization:

$$r_{C_4H_8} = \frac{d[C_4H_8]}{dt} = -2k_1C_{C_4H_8} \quad (10)$$

Table 1 shows the k and E optimization limits considered for this work.

Table 1. Optimization limits

Type of Variable	Search Range	
k (mol/s/kg-cat)	Continuous	100-200
E ((kJ/kmol))	Continuous	20000-25000

Figure 2 shows the results obtained. It shows the concentration profile obtained at the reactor outlet of the reference case, and the same graph shows the concentration profile obtained by the optimization exercise proposed in this work.

Table 2. Optimization results

k (mol/s/g-cat)	E (kJ/kmol)	ISOBUT		ISOPENTA	% error	% error	% error
		(mol/s)	ISOCT (mol/hr)	(mol/hr)	isobut	isooct	isopent

4. Conclusions

In the present work, a metaheuristic optimization technique was used for the prediction of kinetic data. As a case study, the dimerization of isobutane to produce isoctane was considered. Once the adjustment/optimization tool was used, it was possible to obtain k and E data, as well as concentration profiles very close to those reported, with an error percentage of less than 0.1%. The use of this tool presents a considerable numerical advantage in the prediction of kinetics for the adequate use of simulators, based on experimental data or similar situations.

Abstract

Automatic control systems have a strong development and diversification. The research undertaken by the authors considered the development of an automatic system for optimal control of products quality from an industrial deethanizer column. The research aimed the following aspects: modelling the process using the resources of the Unisim Design simulator; process sensitivity analysis on disturbance/control agents - quality of separated products channels; identification of dynamic models associated with input-output channels; design of the dynamic simulator and controllers' tuning; design of the feedforward control system; design of the optimal control algorithm and the structure of the automatic control system; validation by simulation of the proposed control structure.

Keywords: deethanizer column, optimal control, product quality, simulation.

1. Introduction

Natural gas processing is a current global requirement. The structure of processing plants, installations components, used equipment, products and operating parameters depend on the natural gas composition and flowrate but also on the market requirements and price. One of the finished products of the natural gas processing plant is ethane.

The specialized literature dedicated for ethane product deals with three research directions. The first direction is associated with studies on natural gas processing techniques (Almeland et al., 2009, Shimekit and Mukhtar, 2012).

The second research direction is represented by the modelling and simulation of the distillation process. This category includes modelling and simulation of liquefied petroleum gas production (Elbadawy et al., 2017), studies on the modelling, simulation and optimization of an ethane and propane recovery plant (Mukherjee et al., 2013), simulation and optimization of deethanizer tower (Esfeh and Mohammadi, 2011).

The third research direction is dedicated to distillation control processes. Many papers in this category are educational or industrial manuals (Lipták and Venczel, 2016, Hughes, 2006). A small category of papers is dedicated to ethane distillation control system (Hori and Skogestad, 2007, Luyben, 2013).

Given the presented literature study, the authors researched and developed an optimal control system for products quality from a deethanizer column.

2. The Deethanizer Column

The studied deethanizer column is part of a natural gas processing plant (Halafawi et al., 2020). The deethanizer column is a classic column with partial condenser. The column feed comes from the bottom of the demethanizer column, this flow being previously

calculated by the authors (Patrascioiu et al., 2021). The quality conditions imposed for the two products are presented in Table 1. The control structure of the industrial column has as controls agents the reflux flowrate and the reboiler steam flowrate.

Table 1. Quality conditions for the deethanizer column

Product	Component	Restriction type	Value [mole %]
Distillate	C ₁	max	5.00
	C ₂	min	90.00
	C ₃₊	max	5.00
Bottom product	C ₂	max	0.25

The necessary steps to design the automatic system for optimal control of products quality are as follows:

- a) Design of steady-state simulator for the deethanizer column.
- b) Process sensitivity analysis.
- c) Basic control system.
- d) Dynamic simulation of the basic control structure for the deethanizer column.
- e) Design of the feedforward control system.
- f) Testing of the proposed feedforward control system.
- g) Design of the optimal control system.
- h) Testing of the proposed optimal control system.

3. Modelling and simulation of the deethanizer column

The first four steps listed above contain elements for modelling and simulation of the fractionation column. The Unisim Design simulator was used to perform the four stages, a simulator that contains mathematical models of various processes and allows the steady-state and dynamic simulation of the deethanizer column model. In the following will be presented the defining elements of the modelling, the results and the conclusions of these modelling stages.

3.1. Design of steady-state simulator for the deethanizer column

The Distillation Column model from Unisim Design simulator was used to simulate the deethanizer column. This model, configured for a column with partial condenser and reboiler, has three degrees of freedom and consequently three material or energy flows associated with the column must be set. Considering the structure of the column, the existing automatic system but also the requirements of the optimal control system, the authors opted for the following specifications: non-condensable gas flowrate, reflux flowrate and bottom product flowrate.

3.2. Process sensitivity analysis

The deethanizer column is characterized by the input-output variable shown in Figure 2. The sensitivity analysis aims to determine the influence of disturbances and control agents on products quality, to select control agents for products quality control. The process output variables are the concentration of ethane in the overhead product (subject to maximization), the concentration of propane in the overhead product (subject to minimization), and the concentration of ethane in the bottom stream. The most important disturbance is the feed flowrate.

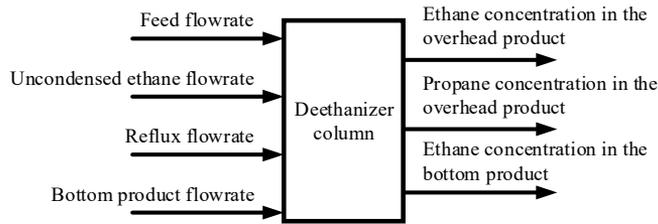

Figure 1. Block diagram of the deethanizer process

The sensitivity analysis was performed for the variation of the three control agents presented in Figure 1.

3.2.1. Process sensitivity to the variation of the non-condensable gas flowrate

From the study it was observed that a change in the non-condensable gas flowrate does not lead to significant variations in the quality of the distillate. This situation is primarily due to the high value of reflux, the usefulness of the non-condensable gas flowrate as a control agent being very low. A negative influence of the non-condensable gas flowrate is represented by the financial losses generated by the ethane lost in the non-condensable gases.

3.2.2. Process sensitivity to the variation of the reflux flowrate

The reflux flowrate is a powerful control agent for control of the separated products quality in a fractionation column. The influence of the reflux flowrate on the quality of the two separate products in the deethanizer column is as follows:

- a) The variation of the reflux flowrate changes the concentration of ethane in the distillate by 0.05% / kgmole/h, which gives importance to the reflux flowrate as control agent. At the same time, the variation of the ethane concentration in the distillate with the reflux flowrate is nonlinear, at values higher than 340 kgmole/h the variation of the ethane concentration in the distillate being small. The increase of the reflux flowrate also implies the increase of the energy consumption, both for the reboiler (steam consumption) and for the condenser (propane refrigerant consumption).
- b) For the same range of variation of the reflux flowrate, the concentration of propane in the distillate also decreases by 0.05% / kgmole/h, the nonlinear character being present in this case as well.
- c) Sensitivity analysis on the influence of reflux flowrate on the concentration of ethane in the distillate indicates the need to design an optimal system for control of the impurity concentration in the distillate (5 mole% propane) while minimizing the thermal load of the reboiler and compliance with the minimum of the quality condition for ethane (90 mole%).

3.2.3. Process sensitivity to the variation of the bottom product flowrate

The influence of the bottom product flowrate on the quality of the two separated products in the deethanizer column is as follows:

- a) The variation of the bottom product flowrate produces the change of the ethane concentration in the distillate by 0.86% / kgmole/h, 17 times higher than the gain generated by the variation of the reflux flowrate.
- b) The ethane is an impurity in the bottom product. The variation of the ethane concentration in the bottom product, depending on the bottom product flowrate, is 0.13% / kgmole/h.

The sensitivity analysis performed by the authors leads to the following conclusions:

- a) The flowrate of non-condensed ethane only influences the concentration of methane in the distillate, being a control agent only usable in the situation when the upstream column, the demethanizer column, does not work according to the specifications.
- b) To control the quality of the two separated products, two control agents are available, the reflux flowrate and the flowrate of the bottom product.
- c) The influence of the two control agents on the products quality is nonlinear.
- d) The reflux flowrate influences the energy consumption.

3.3. Dynamic simulation of the basic control structure for the deethanizer column

The development of the dynamic simulation program represented a substantial effort, being carried out according to the methodology in the literature (Patrascioiu et al., 2014). Given the lack of industrial data, the authors had to size both the flowrate measurement systems and the control valves. After the elaboration of the dynamic simulation program, the controllers were tuned, and the mathematical models associated with the input - output channels were determined. Of these models, the reflux flowrate - ethane concentration in the distillate channel and the bottom product flowrate - ethane concentration in the bottom product channel present special interest.

4. Design of the feedforward control system

The disturbances of the fractionation process are the feed flowrate and composition. Of these disturbances, the feed flowrate is the most important disturbing component, the feedforward control system being designed to reject the effect of this disturbance. The central element of the control system is the controller. Given the multivariable nature of the process (2x2), the controller will have the same characteristic, respectively 2 set-points (x_D^i and x_B^i) and two control signals ($L^i(t)$ and $B^i(t)$), Figure 2. The two controller outputs represent set-points for the reflux flowrate control system and bottom product flowrate control system respectively.

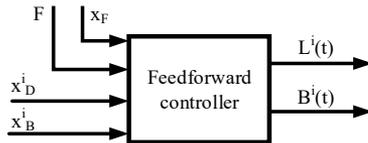

Figure 2. Block diagram of the feedforward controller

The feedforward control algorithm has two components (Marinoiu et al., 1986, Patrascioiu et al., 2015):

- a steady-state component for the calculation of the control signals values in steady-state;
- a dynamic component for the compatibility of the disturbance dynamics with that of the control signals.

4.1. The steady-state component

This component is based on the Fenske-Gilliland-Underwood model of the fractionation process and is applicable over a wide range of feed flowrate variation (the main process disturbance). The constants of the Fenske-Gilliland-Underwood model are the relative average volatility of the light component in relation to the heavy one, the number of theoretical plates. The controller has been designed with the following features:

- a) The average relative volatility α was calculated based on the equilibrium constants of ethane and propane.

- b) The feed concentration x_F was calculated considering only the ethane component.
- c) The controller set-points x_D^i and x_B^i refer only to the ethane component.

The implementation in the Unisim Design environment of the Fenske-Gilliland-Underwood relations, an extremely laborious operation, was realized using the SPRDSHT module from the environment library.

4.2. The dynamic component

The dynamic component associated with the controller outputs is materialized by 1st order transfer function for the feed flowrate - ethane concentration in the distillate channel and 2nd order transfer function for the feed flowrate - ethane concentration in the bottom product channel.

5. Optimal control system

The quality conditions of the two products (ethane and C_{3+} stream) are expressed by the restriction system

$$\begin{cases} x_{C_{2,D}} \geq 0.9 \\ x_{C_{3,D}} < 0.05 \\ x_{C_{2,B}} < 0.0025 \end{cases}$$

The performed simulations confirmed the obtaining of a $x_{C_{2,B}} < 0.0025$ ethane concentration in bottom product regardless of the set-point for ethane concentration in distillate, which validates the choice of the type and the value of the set-point x_B^i .

For the distillate quality the $x_{C_{2,D}} \geq 0.9$ condition was taken into account so the set-point for the distillate quality was considered $x_D^i = x_{C_{2,D}}$. Maximizing the ethane concentration in the distillate is achieved by increasing the set-point value.

Because the concentration of propane in the distillate must comply with the condition $x_{C_{3,D}} < 0.05$, the graph in Figure 3 shows the area where the column cannot be operated.

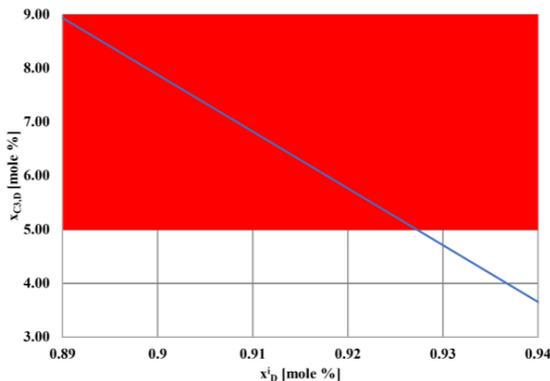

Figure 3. Variation of $x_{C_{3,D}}$ concentration depending on controller set-point x_D^i

As the energy effort of operating the column depends on the value of the ethane concentration in the distillate, it is proposed to operate the column at a minimum value of the x_D^i set-point for which the $x_{C_{2,D}} \geq 0.9$ and $x_{C_{3,D}} < 0.05$ conditions are met.

The dependency shown in Figure 3 has the equation $x_{C_{3,D}} = 103.102 - 105.8 \cdot x_D^i$.

By imposing $x_{C_{3,D}} = 0.05$, the minimum value of the controller set-point x_D^i is obtained, $x_D^i = 0.9272$. The pair of values $x_D^i = 0.9272$ and $x_B^i = 0.0025$ represent the optimal set-

point of the feedforward controller. The average deviation of the ethane concentration in the distillate in relation to the set-point is 0.85%, which validates both the calculation relations implemented in the concentration controller and the selection of the two set-points of the controller, x^i_D and x^i_B .

6. Conclusions

The research carried out by the authors led to the development of a structure for optimal control of the quality of the separated products in the deethanizer column. Steady-state and dynamic simulations validated the objective function and the proposed automation solution. The limitations of the structure developed by the authors were generated by the lack of industrial operation data and by the complexity of the industrial plant. Under these conditions, some of the elements developed in the research can only be theoretical. Future access to industrial operating data may lead to industrially applicable control structures.

Abstract

Spray drying of sensitive pharmaceuticals is challenging due to thermal and other stresses which can have large effects on product quality. In addition, the design and scale up of such processes is a difficult which oftentimes requires many experiments at different scales. By using model based design, the number of experiments can be reduced. To that end, experimental data of single droplet drying experiments is used to fit a drying model and degradation kinetics of a model heat sensitive protein. The calibrated model is used to propose large scale designs. However, it is uncommon that the literature offers such data, and such detailed experimentation requires many resources. Therefore, the large scale designs from the models calibrated using the whole data set are compared to using only inlet/outlet values, to find the importance of the intermediate data points. The results show that designing with a model fully calibrated can produce designs that consider product degradation, while using models calibrated with only start/end values poses the risk of unwanted product degradation. Consequently, full range experimental data of droplet drying is necessary to use lumped parameter drying models in process design.

Keywords: Spray drying, droplet drying, pharmaceutical design

1. Introduction

Spray drying has been a robust and widely used manufacturing process in the pharmaceutical and other industries used to produce particulate products from liquid solutions or dispersions. Pharmaceutical spray dryers are available in lab, pilot, and production scales, with capabilities for processing grams to tons per day (Poozesh and Bilgili, 2019). While the design of large production-scale spray drying processes is usually the labor-intensive experimental based result of scale up from lab or pilot scale tests, current modeling trends are trying to improve this by reducing the number of experiments required and project lead times (Dobry et al., 2009).

Protein pharmaceuticals are usually formulated in aqueous forms, however, this poses limited shelf life even under refrigerated conditions and, therefore, dry formulations can be very advantageous (Pinto et al., 2021). Although several pharmaceutical commercial protein products produced via spray drying are on the market, their drying is challenging due to the potential loss of their physicochemical properties by spray drying related stresses. Thermal stresses have been pointed out

to be the major source of protein loss of activity during spray drying of a monoclonal antibody (Schüle et al., 2007), but shear and surface effects are also present (Das et al., 2021).

Mathematical modelling can be applied to understand and predict the drying kinetics of the sprayed starting solution (droplets) and resulting particles under varying operating conditions, and relate them to product quality. Several models for the drying of droplets are available in the literature. The characteristic drying curve (CDC) concept is used here. This is a lumped parameter model that offers a good balance between complexity and prediction power when combined with parameter fitting to experimental data. Even when using simplified models, mathematical modelling of the spray drying requires fitting the predictions to experimental results. Published experimentation in spray drying is focused on proof of concept studies, process optimization studies, or model validation; however, the effect that different experimental studies would have on the fitted model are most often not the focus.

2. Mathematical model

In this study the drying of droplets into particles is considered, and other steps of a typical spray drying process such as the atomization step and the separation step are ignored. The presentation of the model used is split between the drying kinetics and the rest of the spray drying model.

2.1. Drying kinetics

Drying kinetics are at the core of the drying model for spray drying. Heat and mass transfer between the droplet and surrounding air are considered, which determines the change in droplet temperature, moisture and diameter. Analytically, the change in moisture can be expressed as in equation 1 (Parti and Palancz, 1974). The rate of evaporation \dot{m}_v is typically expressed as a mass transfer coefficient times a driving force between the bulk of the drying medium and the droplet surface, for example in terms of humidity in equation 2. Substitution of the humidity at the surface Y_s by the saturation humidity Y_{sat} would overestimate the drying rate for a dissolved product compared to a pure liquid droplet, thus in the CDC approach an empirical function f is included in equation 4 (Langrish and Kockel, 2001). f varies from 0 to 1 to account for the reduction of the drying rate when dissolved or dispersed proteins enrich the droplet surface, eventually forming a crust through which water must diffuse before it can evaporate. f is a function of a non-dimensional moisture content, typically taken as a power function as shown in equation 3.

$$\frac{dW_p}{dt} = \dot{m}_v A / m_s \quad (1) \quad f = \left(\frac{W_p - W_{p,eq}}{W_{p,crit} - W_{p,eq}} \right)^{n_{CDC}} \quad (3)$$

$$\dot{m}_v = k_Y (Y_s - Y_b) \quad (2) \quad \dot{m}_v = f k_Y (Y_{sat} - Y_b) \quad (4)$$

2.2. The drying model

The model used is a 1-dimensional plug flow for both the gas and condensed phases. The space coordinate is 0 at the tip of the atomizer and is positive in the downward direction. Equation 1 translates to equation 5 by the variable change $z = v_p t$. Particle diameter is evaluated from the balloon shrinkage assumption in equation 6, for which the density is evaluated using equation 7 (Parti and Palancz, 1974). However, equations 6-7 are only used until the moment of crust formation, which happens at moisture content $W_{p,crust}$. Further drying from this point does not change the diameter, only the density decreases with equation 8 (Cotabarren et al., 2018). Mass balance with surrounding air yields the change in air humidity shown in equation 9, heat balances yield equations 10-11 (Cotabarren et al., 2018) and momentum balance yields the particle velocity equation 12 (Truong et al., 2005). Finally, the protein residual activity ra , which varies between 1 (no degradation) and 0 (complete degradation), is calculated using eq. 13, which shows the importance of water as a stabilizer for this protein as hypothesized by Lorenzen and Lee (2012).

$$\frac{dW_p}{dz} = -\frac{\pi d_p^2 \dot{m}_v}{v_p m_s} \quad (5)$$

$$\frac{dT_p}{dz} = \frac{\pi d_p^2 [h(T_a - T_p) - \dot{m}_v \Delta_v H]}{v_p m_s (c p_s + W_p c p_w)} \quad (10)$$

$$d_p = d_{p0} \sqrt[3]{\frac{\rho_{p0} - \rho_w}{\rho_p - \rho_w}} \quad (6)$$

$$\frac{dT_a}{dz} = \frac{-N_d \pi d_p^2 (\dot{m}_v \bar{c} p_{ww} + h)(T_a - T_p) - v_p U \pi D (T_a - T_{amb})}{v_p m_a (c p_a + Y_b c p_{ww})} \quad (11)$$

$$\rho_p = \rho_s \frac{1 + W_p}{1 + \frac{\rho_s}{\rho_w} W_p} \quad (7)$$

$$\frac{dv_p}{dz} = \left(1 - \frac{\rho_a}{\rho_p}\right) \frac{g}{v_p} - \frac{3\rho_a C_d (v_p - v_a)^2}{4\rho_p d_p v_p} \quad (12)$$

$$\frac{d\rho_p}{dz} = \frac{-6\dot{m}_v}{d_p v_p} \quad (8)$$

$$\frac{dra}{dz} = \begin{cases} k_0/v_p & W_p > W_{p,r} \\ k_1 \exp\left(\frac{E_a}{RT}\right)/v_p & W_p \leq W_{p,r} \end{cases} \quad (13)$$

$$\frac{dY_b}{dz} = N_d \frac{\pi d_p^2}{v_p m_a} \dot{m}_v \quad (9)$$

3. Methods

3.1. Modelled system

The spray drying of L-glutamate dehydrogenase (GDH) in triethanolamine hydrochloride buffer is modelled. Single droplet drying experiments are reported by Lorenzen and Lee (2012). GDH was chosen as model system due to its high heat sensitivity, in addition to practical requirements such as high enzymatic activity and high water solubility. Lorenzen and Lee (2012) continuously measured droplet surface temperature and droplet radius for several minutes while the droplets dried in an acoustic droplet levitator. In addition, they measured the protein's residual activity at several time points in order to follow degradation kinetics.

3.2. Model calibration

The results of Lorenzen and Lee (2012) are used to fit the model parameters in two ways.

First, the totality of the data is considered and unknown parameters are fitted: $W_{p,crit}$, $W_{p,crust}$, $W_{p,r}$, n_{CDC} , k_0 , k_1 , E_a , SEF . These parameters are as defined in section 2., in addition we define the SEF parameter empirically as follows. First the Nusselt number is evaluated from the Ranz and Marshall correlation for drying droplets (Ranz, 1952), from which the heat transfer coefficient can be obtained. Then, the SEF factor is used to account for the elevated temperatures seen in the acoustic droplet levitator in the form $Nu_{AL} = SEF \times Nu$. Note that this parameter is only required to reproduce the experimental results in the acoustic droplet levitator and that it is removed when using the model to produce actual spray drying results. Equilibrium moisture is included in the form of the GAB desorption isotherm of skim milk taken from Lin et al. (2005) for the GDH system since they have similarities, and the data captured by single droplet drying experiments is not enough to improve on this. Further parameters and boundary conditions applied to equations 5-13 are taken from the experimental conditions of Lorenzen and Lee (2012), $W_{p0} = 33\text{kg/kg}$, $V_{drop} = 2\mu\text{L}$, $T_{a0} = T_{p0} = 35\text{-}60\text{ }^\circ\text{C}$, $RH_0 = 10\text{-}50\%$, $ra_0 = 1$. U is assumed 0 in the acoustic levitator. The fitting method is based on minimization of the sum of absolute errors computed for temperature, droplet diameter and protein residual activity at 1s intervals, for the 6 experimental runs of Lorenzen and Lee (2012), implemented in python.

Second, only starting and ending points are considered. Typically, spray dryers used in laboratories or pilot facilities have temperature sensors for the air before entering the drying chamber and in the collection pipe after the drying chamber, and similarly, droplet and particle sizes can be measured at the atomizer and after the product is collected. Therefore, it is common to see reported in literature the initial and final values of these variables for a multitude of spray drying equipment and (pharmaceutical) products, e.g. Jiang et al. (2021), and this second model tries to mimic this.

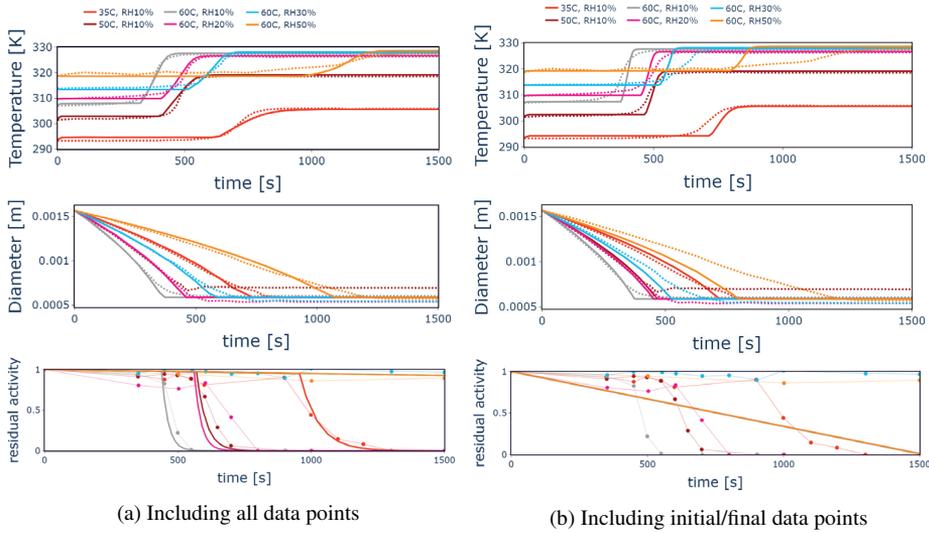

Figure 1: Parameter fit results at different temperatures ($^{\circ}\text{C}$) and relative moisture (RH%). Lines indicate model prediction, broken lines and dots indicate experimental values.

Parameters and boundary conditions used are the same as in the previous case. $W_{p,crust}$ and SEF are fitted by minimizing the error of both temperature and droplet diameter at time point 0 and end time, while n_{CDC} is assumed to be 1. The linear assumption of the characteristic drying curve is relatively common, used by Langrish and Kockel (2001) and later for example by Truong et al. (2005). In turn, $W_{p,crit}$ is taken to be equal to $W_{p,crust}$, and only the parameter k_0 is fitted in the residual activity equation 13 due to the lack of data, achieved in the model by setting $W_{p,r}$ to 0.

3.3. Methods for comparison of the fitted models in a design operation

A spray dryer design is given for a hypothetical GDH production facility. In this case the parameters and initial values are as follows. The production rate is fixed at 300L/h of liquid and the initial droplet size is fixed at 70 micron, values common in the industry. For simplicity all droplets are kept at the same size. The fitted model parameters from each of the calibrated models are used, namely $W_{p,crit}$, $W_{p,crust}$, $W_{p,r}$, n_{CDC} , k_0 , k_1 , and E_a . Inlet air humidity RH_0 is set to 0 and the assumed coefficient for heat loss to ambient $U = 5\text{W/m}^2\text{K}$. The remaining parameters are taken as the design variables, namely the chamber diameter D , inlet air temperature T_{a0} and air flow rate m_{a0} .

The design approach used here is similar to the thermodynamic design space (Dobry et al., 2009), which is based on drawing acceptable limits of variables calculated from a thermodynamic model on a flow-temperature diagram. By drawing boundaries it is easy to visualize which conditions remain inside all boundaries, which leads to an easy design process.

4. Results

4.1. Model calibration results

Figure 1 shows the predicted temperature and diameter profiles together with the experimental data. The parameters fitting with complete data are $W_{p,crit} = 2.8$, $W_{p,crust} = 1.1$, $n_{CDC} = 1.5$, $SEF = (3.2, 3.2, 3.2, 3, 2.7, 2.1)$, $W_{p,r} = 8\text{e-}2$, $k_0 = 5.0\text{e-}5$, $k_1 = 8.0\text{e}4$, $E_a = 4.0\text{e}4\text{ J/mol}$. The parameters

Table 1: Criteria used to define boundaries in figure 2

Parameter	Limit	Color (fig 2)	Reasoning
Residual moisture	5%	Red if > 5%	Product shelf life
Protein residual activity	95%	Pink if < 95%	Product quality
Outlet air humidity	0.2	Black if < 0.2	Economic optimization

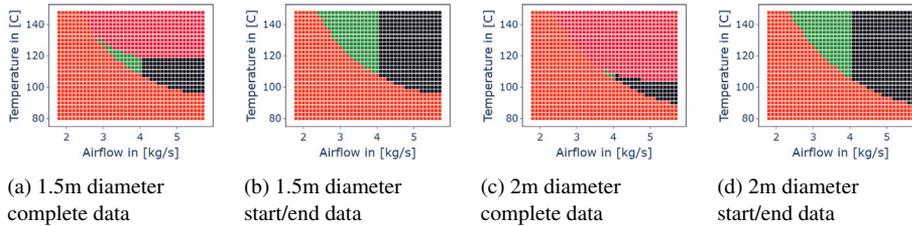

Figure 2: Design spaces predicted for different diameter dryers with both calibrated models

fitting with starting/final values are $W_{p,crust} = 1.1$, $SEF = (3, 3, 3, 3, 3, 3)$, $W_{p,r} = 0$, $k_0 = 6.6e-4$. Experimental data and predictions agree in the case when all data points are included in the calibration. However, in the case of only using starting and final values, differences are notable. This is specially true in the case of the protein residual activity, in view that the only logical assumption is to set $W_{p,r} = 0$ (equation 13).

4.2. Comparison of spray drying design space using the fitted models

Figure 2 shows the predicted design spaces for a 1.5 m diameter and 3 m length dryer, as well as for an increased diameter of 2 m. The boundaries have been defined based on the criteria of table 1. The points remaining in green after all other colors removed are all valid choices according to the defined criteria. However, it becomes apparent that the windows predicted from the different models are different: while the predicted boundary of maximum residual moisture is not largely different, the model without the intermediate data fails to predict that GDH will degrade at higher temperatures. In addition, while from an economic standpoint it would be advantageous to operate the dryer at lower air flows, the model with intermediate data points suggests using higher flows and lower temperatures. More importantly, when the diameter is increased the model without intermediate data suggests positive outcomes on a large window (figure 2d), the model calibrated with intermediate data predicts protein degradation due to particles having too long residence time (figure 2c). This comparison showcases the importance of having good lab scale experimentation before attempting to scale up the process. Protein degradation is one of the major sources of restrictions when scaling up, but data is not easily obtained, and this comparison shows that measurement of only spray dryer outputs might not be enough to predict it.

5. Conclusions

Experimental data for drying of acoustically levitated single droplets has been used to calibrate the drying model in two ways; using the full data set to try to provide the best reproduction of reality, and using only starting and ending values, to try to reproduce the steps that might be used when trying to fit the model to lab or pilot scale process data. The calibration of both models reproduces reasonably well the complete experimental data. However, both models perform very differently in terms of protein degradation.

The models have then been used to calculate design spaces for a commercial scale spray dryer. The acceptable ranges are defined by 3 criteria: product sufficiently dry, product not degraded, and air moisture in the outlet above a minimum value to justify operating costs. As expected both give similar results in terms of residual moisture and dryer performance. However, they differ when predicting protein degradation. Therefore single droplet drying experimental data is crucial when using lumped parameter models for the design of spray drying of heat sensitive products.

Process modelling of Direct Air Capture (DAC) of CO₂ using solid amine sorbents

So-mang Kim^a, Grégoire Léonard^a

^a*Chemical Engineering, University of Liège, Belgium*

Abstract

This paper presents a fixed bed reactor system to capture CO₂ from ambient air via Temperature Vacuum Swing Adsorption (TVSA) cycles employing Lewatit® VP OC 1065 amine-functionalized adsorbents. Firstly, a model describing CO₂ mixture flow, mass, and heat transfer with adsorption isotherm model is developed in Aspen Adsorption environment to study the performance of DAC processes with TVSA. Then, a single adsorption column is simulated to study both adsorption and breakthrough curves, and the model is validated with literature results. Secondly, a full DAC model with TVSA cycle is developed and the results are compared to TVSA cycle with a steam purge in literature to validate the reliability and simulation capabilities of the software tool. Lastly, a model of a process capturing 1.1 kilograms of CO₂ per day is developed as a base case, and studies on the energy requirements, capital, and operating costs of the DAC system are conducted. In addition, sensitivity studies on the model parameters are carried out. This work stands as one of the first identified modelling studies of TVSA-based Direct Air Capture and serves as a basis to analyze the feasibility of DAC system deployment and its relevance in comparison to CO₂ capture from point sources.

Keywords: Direct air capture, Carbon capture, TVSA, Adsorption, Process modelling

1. Introduction

The idea of CO₂ capture from ambient air, also referred to as Direct Air Capture (DAC), was first suggested by Lackner and coauthors in 1999 to mitigate climate change. CO₂ adsorption processes are often considered as the most suitable option for DAC and many laboratory and pilot scaled units have been developed over the last decade. In particular, there are 15 operational DAC plants globally capturing more than 9000 tCO₂/year (IEA, 2020). Some of the industrial pioneers are Climeworks (Switzerland) and Global Thermostat (USA) where solid sorbents are used to capture CO₂ while Carbon Engineering (Canada) has developed a liquid solvent-based DAC system. Also, some examples of active academia are Twente University and ETH Zurich where DAC systems with amine solid sorbents are studied while Arizona State University is developing Moisture Swing Adsorption (MSA). However, there is currently a scarcity of literature on simulation studies of adsorption processes in the DAC context. To address this gap, the present work studied a TVSA DAC process in an attempt to bring a new light on process system design and DAC performances under cyclic operation.

2. Modelling and validations

In this paper, a one-dimensional model for gas adsorption in a fixed bed is developed in Aspen Adsorption. The adsorption isotherm and model assumptions are described below.

2.1. 2 Adsorption Isotherms

Toth Isotherm parameters described in Bos et al. (2019a) are used to describe an amine-based solid sorbent, Lewatit® VP OC 1065 that numerous authors including Veneman et al. (2012), Bos et al. (2019a&b), Young et al. (2021) have studied extensively. The Toth isotherm is presented in Equation 1 and the fitting parameters can be found in the work of Bos et al. (2019a).

$$q_e = \frac{q_s b P_{CO_2}}{(1 + (b P_{CO_2})^t)^{\frac{1}{t}}} \quad (1)$$

The parameters q_s , b and t in the Toth isotherm described in Equation 1 are the saturation loading, the affinity of the sorbent to CO_2 and the heterogeneity respectively and each parameter is a function of temperature. These parameters can be used to calculate CO_2 equilibrium loading (q_e) at various CO_2 partial pressures (P_{CO_2}) and operating temperatures. More details of the parameters and related equations can be found in the work of Bos et al. (2019a).

2.2. Fixed bed model validation

2.2.1. Model Assumptions

The model consists of mass, momentum, and energy balances of the gas and the adsorbent phases. The balance equations form a set of partial differential equations (PDEs) that are solved using a software package, achieving a cyclic steady state in Aspen Adsorption. The process model is based on the following assumptions:

- The gaseous mixture obeys the ideal gas law.
- Only carbon dioxide is adsorbed.
- The resistance of mass transfer in the gas phase is negligible; the kinetics of mass transfer within a particle is approximated by the linear driving force (LDF) model.
- A constant heat of adsorption is used.
- The adsorbent is considered as a homogenous phase and its physical properties are assumed to be constant.

The first-order upwind differencing scheme (UDS1) spatial discretization method was selected for its comparatively higher stability. A default number of nodes (20) was used and the system is assumed to be isothermal for the model validation steps in section 2.2.2.

2.2.2. Breakthrough curve

The experimental breakthrough curves of Yu et al. (2017) at air inlet conditions of 25 °C, at atmospheric pressure, and 400 ppm on a clean adsorption bed are compared with the results from the Aspen Adsorption fixed bed model in Figure 1. Table 2 presents modelling parameters and operating conditions used in the fixed column model.

Table 1. Parameters and operating conditions for breakthrough modelling

Parameter	Description	Value	Unit	Source
V_g	Superficial velocity	0.14 and 0.27	m s^{-1}	Yu et al. (2017)
$C_{p,s}$	Sorbent heat capacity	1580	$\text{J. mol}^{-1}\text{K}^{-1}$	Veneman et al., (2012)
R_p	Particle diameter	0.26	mm	Bos et al., (2019b)
ρ_p	Particle density	1580	kg m^{-3}	Bos et al., (2019b)
ϵ	Particle voidage	0.23	$\text{m}^3 \text{m}^{-3}$	Lanxess
MTC	Mass transfer coefficient	3.26×10^{-4}	s^{-1}	Yu et al. (2017)
L	Column height	0.5	m	Yu et al. (2017)
D	Column diameter	0.016	m	Yu et al. (2017)

Figure 1 shows the model results (solid lines) obtained at the operation conditions presented in Table 2 and experimental breakthrough curves (dotted lines) from Yu et al. (2017) at 0.14 m/s and 0.27 m/s superficial velocities of inlet feed. The model lines show a slightly steeper increase at the beginning of the breakthrough curve which may be due to the existence of dead spaces in the actual experimental column.

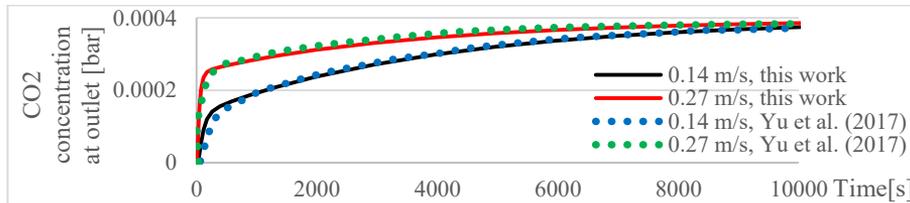

Figure 1. Fixed bed operations breakthrough curves at the superficial velocity of 0.14 m/s and 0.27 m/s with 1 g of Lewatit® VP OC 106 solid sorbent at 25 °C.

Yu et al. (2017) also computed adsorption half-time ($t_{1/2}$), which is the time required to adsorb 50% of the maximum adsorption capacity, at different V_g . In this study, $t_{1/2}$ were simulated and the model and literature values are compared in Table 3.

Table 2. Adsorption half-time comparison between this work and the results of Yu et al. (2017).

V_g [m/s]	$t_{1/2,model}$ [min]	$t_{1/2,Yu\ et\ al.,(2017)}$ [min]	Difference [%]
0.05	54.5	55	0.92
0.1	42.83	43	0.39
0.2	38.6	38	1.55
0.3	37.5	37	1.33

The results were found to be consistent with the experimental works of Yu. Also, an equilibrium loading of 1.06 mol/kg of CO₂ was obtained from the fully saturated model at the feed CO₂ concentration of 400 ppm as calculated using the Toth isotherm presented in Equation 1, and this simulation value agrees with Bos et al. (2019a) and Yu et al. (2017).

2.2.3. Temperature Vacuum Swing Adsorption (TVSA) cycle

In order to further validate the reliability and simulation capabilities of the software tool, a full TVSA cycle using a different adsorbent, an amine nanofiber, was simulated using Aspen Adsorption based on the work of Stampi-Bombelli et al. (2020). The change of materials is due to insufficient cycling results identified in the literature for Lewatit. The Toth isotherm equations, parameters, and operating conditions can be found in the aforementioned literature. Note that the value of one parameter (\mathbf{b}_0) needed to be retrieved from Gebald et al. (2014) which is one of the preceding studies on the nanofiber adsorbent, as the value reported by Stampi-Bombelli et al. (2020) for this parameter led to aberrant results. The cycle validation is presented in Figure 2.

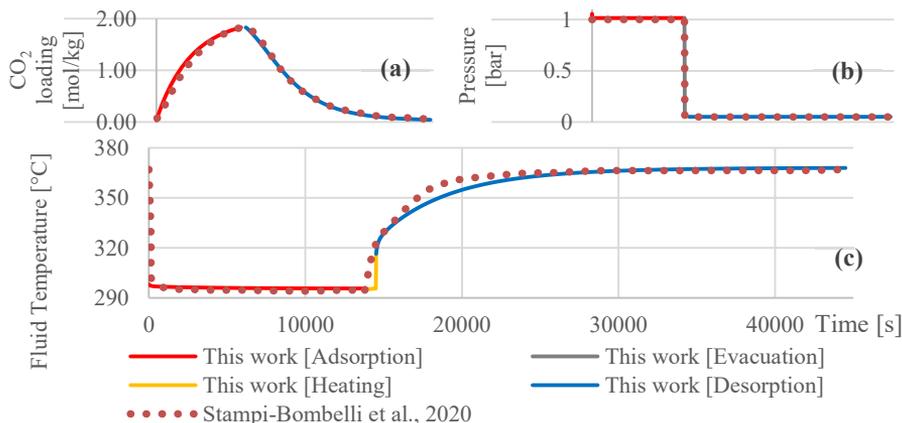

Figure 2. Cyclic profiles (solid lines) from Aspen Adsorption during the adsorption (red), evacuation (grey), heating (yellow), and desorption (blue) steps. The dotted lines show the cyclic profiles reported in Stampi-Bombelli et al. (2020). (a) CO₂ loading profile, (b) pressure profile and (c) temperature profile.

The TVSA cycle (Stampi-Bombelli et al., 2020) consists of four steps which are adsorption (20 °C, 1bar, 13772 s), evacuation (0.05 bar, 30 s), heating (via heating jacket, 704 s), and desorption (95 °C) with purge steam. The difference observed in the temperature profile could be due to the absence of a wall energy balance and the usage of the overall heat transfer coefficient in Aspen Adsorption. In general, the results from the simulation showed the same trends as reported in the literature. The next section will present a kilogram scaled DAC model as a basis to study the operating and economic performances.

3. DAC model of 1.1 kg/day results and discussion

3.1. DAC model CO₂ capture rate, purity and recovery

In the recent paper of Schellevis et al. (2021), a complete kilogram scale TVSA fixed bed model utilizing Lewatit® VP OC 1065 was presented based on experimental results collected on a small-scale DAC pilot. In the present paper, an Aspen Adsorption model is developed to study a similar process with a steam purge. Details of the bed geometry and operating conditions were retrieved from Schellevis et al. (2021). The cycle involves four steps which are the adsorption, evacuation, desorption, and cooling, and in this study, the step time of 3200 s, 30 s, 4700 s, and 2300 s were assumed respectively since these parameters were not reported in the literature. Figure 3 presents a cyclic CO₂ loading at the end of the adsorption bed over a period of 24 hours.

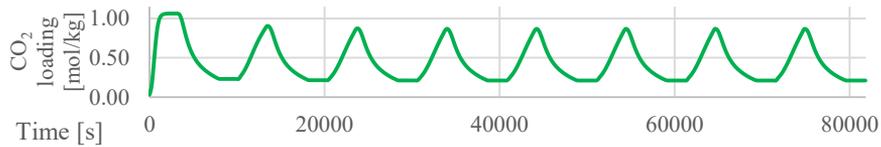

Figure 3. Cyclic CO₂ loading results at the end of column obtained from Aspen Adsorption

Based on our simulation results, 0.0339 kg_{CO₂}/cycle could be obtained, leading to 0.2712 kg_{CO₂}/day. Indeed, as can be seen in Figure 3, a total of 8 cycles could be achieved within a day. To achieve 1.1 kg CO₂ capture per day, Schellevis et al. (2021) proposed a DAC process with several parallel fixed bed reactors. In our case, four parallel reactors are needed to capture 1.1 kg of CO₂ per day. Finally, assuming all the purge steam will be condensed out of the CO₂ product stream, purity of 99.98% was achieved while a recovery of 71.70% was obtained.

3.2. Economic performances of the 1.1 kg/day DAC process

The feasibility of the DAC system was studied where such system consists of thermal and electrical energy requirements. Main thermal energy uses arise from the reaction and sensible heats of CO₂, H₂O, and steam while pumps and compressors contribute to the electrical energies. The distribution of exergy assuming an ideal heat transfer is presented in Figure 4 and the magnitude of distributions calculated in the current study are in the same magnitude as reported in Schellevis et al., (2021).

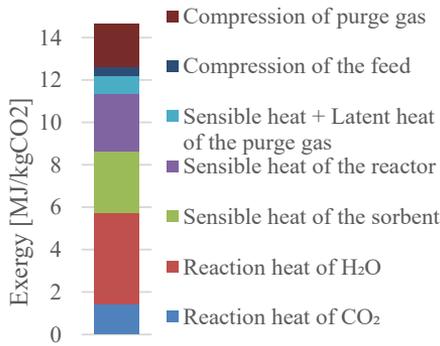

Figure 4. Distribution of exergy use

Table 3 Capital and operating expenditures

CAPEX	Value [€/yr]
Contactors	21
Fan	26
Vacuum pumps	72
OPEX	Value [€/yr]
Sorbents	0.77
Electricity	114.7
Steam	11.0
Maintenance	7.9
Labor	2.3

Annualized capital and operating expenditures are summarized in Table 4 where contactors, fans, and vacuum pumps are considered for CAPEX in this study. The costs of equipment are obtained from the per-unit costs from the manufacturers and annualized assuming a lifetime of 10 years. Since the unit size is smaller ($D = 0.4$ m, $L = 0.024$ m) than the usual industrial size, the price of each unit could be more expensive to manufacture. In the case of operating costs, sorbents are expected to have a lifespan of 2.6 years (NASEM, 2019), and electricity and steam costs are included while maintenance and labor are assumed to be 3% of total capital requirement and 30% of maintenance cost respectively. Based on the aforementioned information, a preliminary capture cost of 942 €/tonne of CO₂ was obtained for this non-optimized process, which is slightly higher than the figure reported by IEA (2020).

3.3. A preliminary sensitivity analysis

The effects of adsorption time on recovery and CO₂ capture rate per day are examined under the same operating conditions. It was observed that as the adsorption time increases, recovery decreases. This is due to the adsorption bed being fully saturated and CO₂ is being lost in the outlet stream. In the case of capture rate, by varying the adsorption time, the total number of cycles per day changes. For example, when the adsorption time is 1200 s instead of 3200 s, it is possible to achieve 10 cycles per day. However, the CO₂ capture rate per cycle (0.0163 kg_{CO₂}/cycle) is very low and requires more DAC units to achieve the same output per day when compared to the adsorption time of 3200 s which involves 8 cycles with 0.0339 kg_{CO₂}/cycle output. Therefore, there is a tradeoff between the adsorption time, recovery, and the capture rate. From the sensitivity analysis, it was found that the optimal capture rate can be achieved at the adsorption time of 3200 s as presented in Figure 5

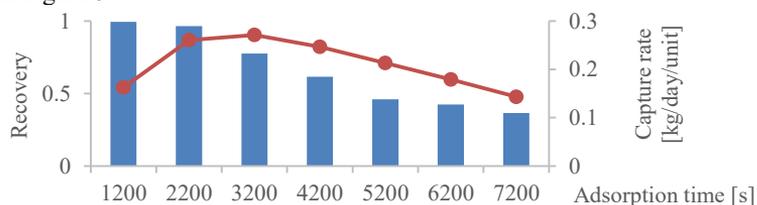

Figure 5. CO₂ recovery (bars) and CO₂ capture rate per day (line) for different adsorption times.

4. Conclusion and future work

This study has developed a fixed-bed DAC process model and presented validation for adsorption and breakthrough curves of Lewatit® VP OC 1065 amine-functionalized solid sorbents under DAC conditions with the literature. Also, a full TVSA model for DAC is developed to analyze cyclic operations as well as feasibility and economic performances. Further work needs to be done to include co-adsorption of H₂O and CO₂ on solid sorbents to better understand the influence of humidity on the adsorption stability which requires more work for accurately assessing the impact of operating conditions on sorbent performances and lifetime. Finally, these elements will lead to a more detailed techno-economic analysis and provide more insights into the relevance and possible deployment of DAC in comparison to CO₂ capture from point sources.

Abstract

This contribution introduces a data acquisition and modelling framework for the prediction of banana pests' incidence. An IoT sensors-based system collects weather and micro-climate variables, such as temperature, relative humidity, and wind speed, which are uploaded in real time to a cloud storage space. The incidence of the red rust thrips (*Chaetanaphothrips signipennis*) is collected "manually" by periodic inspection. The mathematical model is adapted from population growth functions and a model of insect species development and allows predictions to be made at various time intervals with an accuracy greater than 80%, improving decision-making capacity for agro-producers and enabling the improvement of pest management actions.

Keywords: Mechanistic modelling; IoT sensors; Precision agriculture; Organic banana; Red rust thrips.

1. Introduction

Peru, with an extension of organic agriculture of 197,837 ha (Sánchez Castañeda, 2017), is one of the main suppliers of organic banana to the American market (Machovina and Feeley, 2013), representing approximately 3% of the world production. However, like other crops produced in this country and worldwide, the presence of pests and diseases, influenced by climate change, is one of the main problems that afflict farmers (Dadrasnia et al., 2020; Gaitán, 2020), directly affecting the productivity and quality of the product.

Mathematical representation of the phenomena taking place on the farm (*e.g.*, plant growth, pest incidence and its impact on the plant development, etc.) are of paramount importance for improving the knowledge and decision-making for banana production. The data available shows that, in the case of the banana pests incidence, an exponential growth can be observed. Moreover, pest control measures have an effect of reducing the insect number in a similar way that antibiotics reduce bacterial populations. Various mathematical representations have been developed to describe the behaviour of bacterial population growth, which consider the effect of antibiotics on the development (Romero Leiton et al., 2011).

The problem of inefficient pest management affects small and medium agro-producers in the Piura region, impacting on the quantity and quality of their produce, and preventing them from competing on the international market. Thus, the development of a tool that improves the pest management will bring along benefits. However, to achieve this, improved representation of the pest

behaviour is required. Therefore, in the following sections, a mathematical model for predicting the level of pest incidence in banana crops is proposed, based on first principles of population growth in insect species, with roots in bacterial population growth models. The objective is to develop a tool to facilitate decision-making for organic banana agro-producers worldwide, enabling the adjustment of the model parameters to account for environments where the atmospheric and microclimate conditions differ from those studied in the current work.

2. Methodology

2.1. Data acquisition

A network of IoT sensors, Figure 1, is used to measure the weather, micro-climate and soil variables listed in Table 1.

Table 1: Features of the IoT sensors

	Level	Sensor	Variables	Manufacturer
Weather station	Climate	Vantage Pro 2	- Temperature - Relative humidity - Atmospheric pressure - Wind speed - Rainfall rate	Davis Instruments
Node 1 and Node 2	Micro-climate	Davis Instruments 6830	- Temperature - Relative humidity	Davis Instruments
	Soil	GS3 decagon	- Water content - Bulk electrical conductivity - Temperature	Decagon Devices

The data acquisition system measures these variables every minutes, while its gateway device stores it at 15 minutes intervals and uploads it to a web server. For this duration, the average, the maximum and minimum value, and variables that are not directly measured (*e.g.*, dew point, evapotranspiration, heat index, etc.) are calculated automatically. Thus, a total of 96 items are stored in the database every day. Finally, the data acquisition interface takes these values and calculates a daily average for each of the variables stored.

Based on previous studies (Elbehri et al., 2015), (Zhang et al., 2019), the variables with the highest impact on the efficiency of the process are the temperature, the relative humidity, the rainfall rate, and the wind speed. In the following, the average daily atmospheric temperature will be used, since it was found that a correlation exists between this and the growth rate of the pests.

2.2. Pest incidence

To assess the level of infection in the banana crop, the pest incidence will be used. The pest incidence is a statistical metric resulting from the inspection of the crop and is calculated by randomly choosing a defined number of plants per hectare and examining each of them for the presence of

Figure 1: Nodes and weather station distribution, dimensions in meters.

the respective pest in the stem and leaves. The following equation is used for determining the pest incidence (α) (Pasapera Cordova, 2013):

$$\alpha = \frac{\text{Total insects}}{\text{Total of plants inspected}} \quad (1)$$

Table 2: Thrips incidence level classification

Criterion	Incidence level	Control action	Cost
$0 < \alpha \leq 0.5$	Low	Leaf fumigation	18.64 USD/ha
$0.5 < \alpha \leq 1$	Medium	Stem fumigation	35.13 USD/ha
$1 < \alpha$	High	Stem fumigation and cleaning	54.04 USD/ha

Based on this measure, the corresponding control action is decided according to the criteria illustrated in Table 2.

2.3. Mathematical Modelling

Figure 2 shows the data of the incidence of red rust thrips (*Chaetanaphothrips signipennis*) from December 2019 to April 2021. During the summer (January, February and March), there is an accelerated growth of the thrips incidence, which confirms the information collected from the farmers on the field on the seasonal behaviour of the pests.

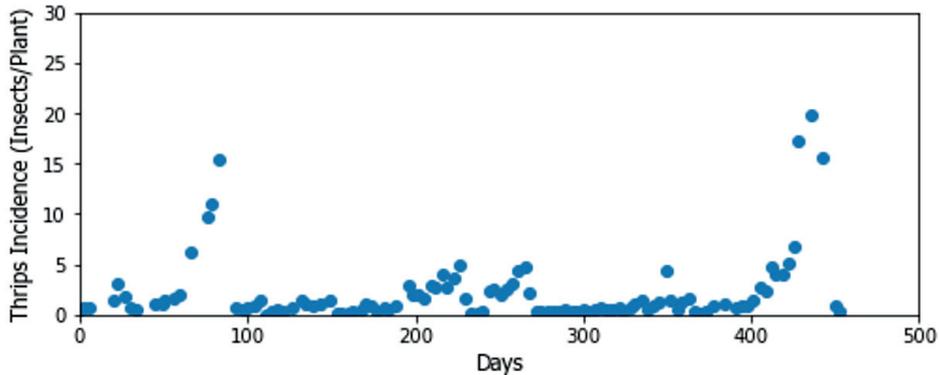

Figure 2: Thrips incidence over time.

As the behaviour in Figure 2 resembles an exponential function, a relationship can be written for the incidence of the thrips in differential form as:

$$\frac{dI_T(t)}{dt} = r \cdot I_T(t) \quad (2)$$

$$r = \beta - \mu - \alpha_1 F_1 - \alpha_2 F_2 - \gamma C \quad (3)$$

Where t is the time (day), r is the effective growth rate (1/day), and $I_T(t)$ is the incidence of Thrips as a function of time (insects/plant). The growth rate is a function of: the natural population growth rate, β (1/day), the mortality rate by natural causes, μ (1/day), the mortality rate by fumigation of thrips, α_1 (1/day), and by fumigation of other pests, α_2 (1/day), the mortality rate by cleaning γ (1/day), the concentration of the fumigation chemical for thrips, F_1 , and for other pests, F_2 , and the theoretical concentration of the plot cleaning, C .

For the modelling of the thrips development, a relationship based on temperature, following the Sharpe Schoolfield Ikemoto (SSI) function is used (Prasad et al., 2021):

$$\beta = \frac{T - T_{min}}{k} \quad (4)$$

Where T is the average daily temperature ($^{\circ}\text{C}$), T_{min} is the minimum temperature at which the species develops ($^{\circ}\text{C}$), and k is the thermal constant in degree days ($^{\circ}\text{C day}$).

To calculate the concentration of the fumigation chemicals F_i and the theoretical cleanup C a modification of the equation used to calculate the antibiotic concentration in (Esteva et al., 2011) is used, which after integration results in:

$$F_i = \int_{t_1}^{t_2} -\Phi_{F_i} F_i dt = e^{-\Phi_{F_i}(t_2-t_1)} \quad (5)$$

$$C = \int_{t_{1c}}^{t_{2c}} -\Phi_C C dt = e^{-\Phi_C(t_{2c}-t_{1c})} \quad (6)$$

Where Φ_{F_i} is the degradation rate corresponding to the fumigation chemical i , Φ_C is the degradation rate of the cleaning, t_1 is the date of the last fumigation, t_2 is the date pest incidence is evaluated after the fumigation, and $(t_2 - t_1)$ is represented in days.

2.4. Training and testing algorithm

The model is implemented as a multi-period integration, so that the next value of the thrips incidence can be predicted from the previous one. The experimental data is split into training and test sets, and the Group Shuffled Split (GSS) method of the Sci-kit learn Python library (Ojala and Garriga, 2010) is used to perform cross validation. The metrics used for the analysis of the model performance are the coefficient of determination (R^2) and the root mean square error (RMSE), calculated for each set generated with the GSS algorithm. The process is detailed in Figure 3.

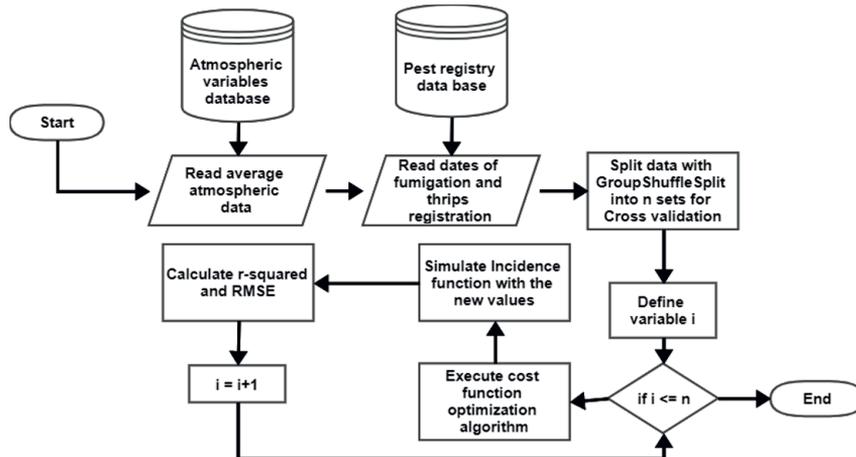

Figure 3: Flow diagram for training and testing algorithm.

3. Results

A total of 500 sets are used in the cross validation to obtain the histograms shown in Figure 4. Analysis shows that using a higher number of sets does not have a significant impact on the

results. In the training data sets, 1.56 and 0.77 are obtained as average values of RMSE and R^2 , respectively, while for the test sets the values of 1.60 and 0.68 are obtained.

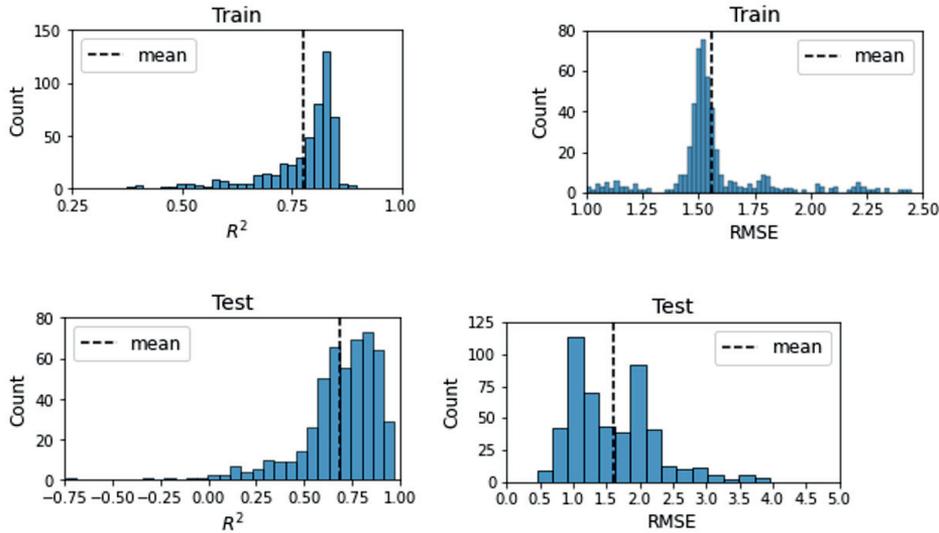

Figure 4: R^2 and RMSE histogram for training and testing sets

Table 3: Estimated parameters

Variable	Name	Value
μ	Mortality rate by natural causes	0.150195
α_1	Mortality rate by fumigation of thrips	0.529771
α_2	Mortality rate by fumigation of other pests	0.05
γ	Mortality rate by cleaning	0.0
Φ_{F_1}	Degradation rate corresponding to the thrips fumigation chemical	0.045171
Φ_{F_2}	Degradation rate corresponding to the other pests fumigation chemical	0.598177
Φ_C	Degradation rate corresponding to the cleaning	0.0496006
T_{min}	Minimum temperature at which the species develops	10.98
k	Thermal constant in degree days	0.012956

Furthermore, looking into more detail at the data set for which the best results are obtained during training and testing, the prediction of the total number of points collected is performed. The Figure 5 shows a good accuracy of the model for the prediction of the low and medium values of thrips incidence, while for large values there is a greater margin of error. This may be caused by the fact that the SSI model is linear and fails to mimic the real behaviour of population growth. However, the selected model achieves a coefficient of determination of 0.83 and an RMSE of 1.46.

4. Conclusions

This work is a starting point for the development of new techniques and models that promote artisanal agriculture, and can compete with the industrialized agricultural sector. Based on growth models with roots in bacterial population growth, a mathematical model for predicting the level

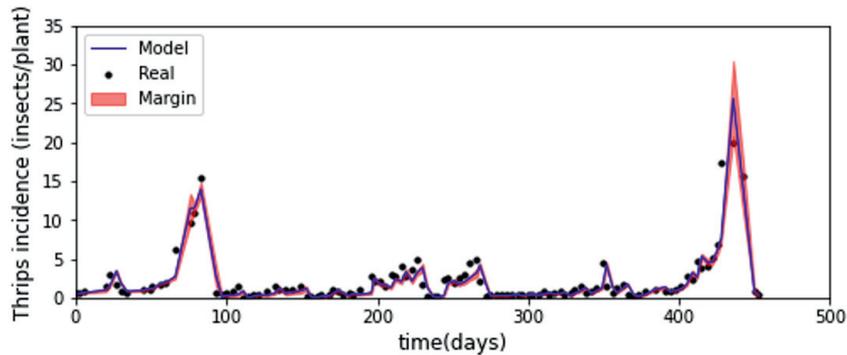

Figure 5: Comparison of model prediction and experimental data

of pest incidence in an organic banana crop is obtained. The results show that the implementation of a linear relationship based on temperature does not correctly describe the pest behaviour across the whole range of temperatures.

Future work will focus on considering more realistic, nonlinear representations of the growth rate, in order to improve the accuracy of the results. However, it should be emphasised that the current linear model gives a real physical meaning to the considered variables and offers sufficient understanding of the abiotic components and spread of the pests. Thus, it can prove a sufficiently accurate solution for implementation of fumigation or cleaning schedules, that may require iterative computations of the pest incidence model.

This will enable the farmers to improve their performance in pest control, increasing the quality of the organic product and reducing costs of spraying and maintenance of the plot.

A novel approach to modelling trickle bed reactors

Bogdan Dorneanu, Norbert Heinzelmann, Klaus Schnitzlein, Harvey Arellano-Garcia

LS- Prozess- und Anlagentechnik, Brandenburgische Technische Universität Cottbus-Senftenberg, Cottbus D-03044, Germany

Abstract

In this contribution, the development of a toolbox for the simulation of trickle bed reactors based on a model able to account for the local properties of the liquid and gas flow in a packed bed at particle scale is introduced. The implementation uses a modular and flexible setup, with local liquid distribution considered as a function of the operating conditions and the physical properties of the three phases. Moreover, the impact of the local incomplete wetting on the conversion, as well as the mass transport and kinetics at both particle and reactor scale are accounted for. Furthermore, different particle geometries are considered, and the model is able to reliably predict the performance of the catalytic trickle bed reactors.

Keywords: Trickle bed reactors; Multiphase reactors; Modelling; Multiscale analysis.

1. Introduction

The trickle bed reactors (TBRs) are a frequently used solution for industrial multiphase exothermic catalytic reactions between gaseous and liquid components (e.g., hydrogenation, oxidation), in which the gas and the liquid flow downward through packed beds and undergo chemical reactions (Guo et al., 2008). The feedstock, in liquid phase forms a film around the solid catalyst, while the reactant, in a continuous gaseous phase, fills the remaining space of the catalyst bed, flowing separately (Fan et al., 2020). TBRs provide simple and safer operation at high temperature and pressure, higher conversion and selectivity due to the low axial dispersion, high interfacial area, less catalyst cost per operation run, and often lower energy consumption compared to other reactor types (Degirmenci & Rebrov, 2016; Markthaler et al., 2020; Zhao et al., 2020). On the other hand, the TBR's behavior is very complex and depends on mass and heat transfer, as well as on hydrodynamics (Qi et al., 2020). Its performance largely depends on the complex wetting morphology, which consists of film flow, rivulet flow, liquid pendulum and liquid pocket (Tang et al., 2022), with the hydrodynamic parameters (e.g., liquid holdup, gas holdup, liquid distribution, catalyst particle size, particle porosity, bed porosity) having a significant impact (Azarpour et al., 2021). However, TBRs show unacceptable levels of performance when moving from laboratory to pilot or commercial scale due to the maldistribution of the gas/liquid flow and the difficult control of the temperature (Muharam et al., 2020). Thus, the proper understanding of the TBRs remains a challenge, since numerous transport and reaction phenomena occur simultaneously inside the reactor, with uncertainties in the catalyst heterogeneity, packing, fluid flow, and transport parameters elevating the complexity (Azarpour et al. 2021). In this sense, different approaches have been developed over time to deal with their highly coupled multiphysics and multiscale nature, ranging from experimental techniques that enable global characterization of hydrodynamic behavior and reaction characteristics, to modelling and

simulation studies, with different levels of description, developed depending on the objective to satisfy, and the phenomena of interest (Qi et al., 2020). As a result, varied assumptions accompany these models, such as considering constant velocity profiles and no pressure drop for multiphase plug flow reactor (PFR) models, neglecting mass and energy radial gradients, which often result in reduced accuracy of the predictions (Uribe et al., 2019). More rigorous, computational fluid dynamics (CFD) models to simulate the multiphase flow inside the TBRs are often computationally expensive and do not always capture the wetting characteristics of the gas-liquid interface (Deng et al., 2020). Furthermore, they are not always capable of handling the multiscale coupling and the establishment of two-way communication schemes between the different scales (Uribe et al., 2019).

The focus of the paper is the improvement of a novel and intuitive tool for the design and analysis of trickle bed reactors operating in the low-interaction-regime, based on the work in Schwidder & Schnitzlein (2012). In that case, the modelling of the liquid distribution, the two-phase flow, and the reaction are modelled using an Euler-Lagrange approach. Furthermore, due to the complexity of the phenomena taking place inside the TBR, only isothermal processes are considered. To enable the extension of the tool to any type of particle geometry (*e.g.*, cylinders, Raschig rings, Pall rings, etc.), not possible using the previous model version, a new description of the surface is proposed.

2. BasMo – A simulation toolbox for trickle bed reactors

2.1. An interactive toolbox for the simulation of trickle bed reactors

The toolbox, *BasMo* (Basis Model), an interactive solution for the simulation of TBR, is implemented in C++ using a modular setup, mirroring the multiscale structure of the TBR, from reactor level to particle and fluid film levels, including reaction kinetics information, as illustrated in Figure 1.

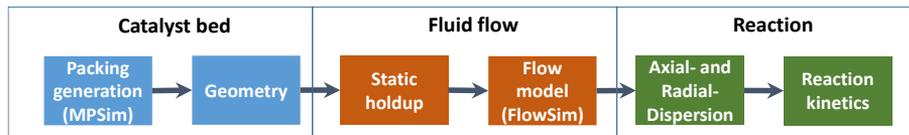

Figure 1: *BasMo* modular structure (adapted from Schwidder, 2012)

The starting point for the model development is the generation of random-loose catalyst packing bed. A layer of particles is placed at the bottom of the reactor and every particle is assumed to move with small increments in every direction. In the resulting Monte Carlos simulation, should the movement of a particle come in conflict with another, its movement will be skipped. To achieve a close packing, a “raining” mechanism is added, which assumes that a particle drops inside the vessel until it is fixed, together with a compressing algorithm based on simulated annealing, and a shacking procedure for the packing, to ensure a particle is fixed inside the bed (Schnitzlein, 2001). The resulting packing can be used directly, or saved for later simulations. During the following stage, the packing model is used to extract all the necessary global and local geometric information, to be used for the further steps, *e.g.*, the determination of system-relevant contact points, and the volume of every single bond existing at this points of contact (Schwidder & Schnitzlein, 2010). A distinction is made for the cases in which the contact point is between two packing particles or between the particle and the wall, due to the difference in wettability and curvature of the bulk or wall materials.

In the second step, using this geometric information (particle distribution, number of active and inactive particles, bed diameter and height, position of a single particle, etc.), the physical parameters and the static holdup can be predicted, as described in Schwidder & Schnitzlein (2012).

Subsequently, during the third step, based on the specified operating parameters, the liquid flow is determined. This can be used to predict the axial and radial dispersion. Furthermore, with the addition of the kinetic model for the specific heterogeneous catalytic system under consideration, other measures such as the conversion inside the reactor, or the residence time distribution can be predicted.

The modular structure of the simulation toolbox offers flexibility in adding new modules for improved representation of the internal geometries as well as of the different phenomena (e.g., holdup, fluid flow, kinetics, etc.) taking place inside the TBR, as well as expansion to energy and momentum balance.

2.2. Graph network model

The toolbox utilizes the approach introduced by Schwidder & Schnitzlein (2012) for the

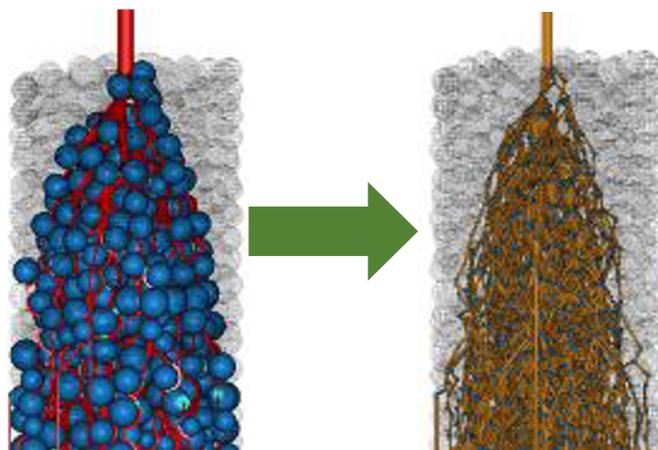

Figure 2: Three-dimensional graph network representation (right) based on the fluid distribution through the packing (left)

representation of the movement of the fluid through the bed, which is considered as a combination of two effects: the complete mixing in the cavities between the packing elements, and the displacement in the channels that connect these cavities.

A three-dimensional network (Figure 2) of edges and nodes (vertices) is created based on the knowledge on the local distribution of

the static and dynamic holdups. Furthermore, a steady-state approach is used to model the liquid distribution, while the dispersion and the reaction are modelled dynamically.

It is considered that the liquid flows in the form of rivulets on the particle surface. These rivulets are mapped by *Edges*, while the liquid within the inter-particle spaces is mapped by *Vertices*. Furthermore, an ideal PFR is used to model the rivulets, while the inter-particle liquid is modelled as a continuous-stirred tank reactor (CSTR), as

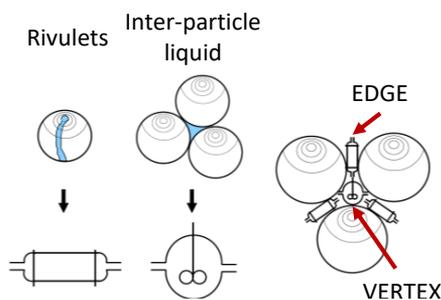

Figure 3: Representation of the liquid flow through the packing (adapted from Schwidder, 2012)

illustrated in Figure 3. Dynamic mass balances are used to describe the concentration of the two phases, accounting for both gas-solid and liquid-solid mass transfer. By connecting the two reactor types, the behavior of the liquid inside the reactor can be modelled, with experimental measurements used to account for the characteristic parameters of the reactors, mass transport, etc. As such, by using this simplified representation of the liquid as a set of PFRs and CSTRs, the computational time is significantly reduced compared to a full CFD simulation.

2.3. Extension of the particle representation inside the packed bed

An important disadvantage of the current implementation of the particle representation inside the packed bed is the fact that only simple spherical shapes can be used, which limits the applicability of the toolbox to more complex particle geometries. The geometry is accounted based on the symmetry properties of the spherical shape. To enable the use in the investigation of more realistic scenarios, methods such as the Lattice

Boltzmann (LB) or the volume of fluid (VOF) methods can be applied (Rong et al. 2020; Tang et al. 2022). However, the main drawback would be the fact that the accurate modelling of a realistic TBR implies simulation of several thousands of particles, which leads to high computational times. Furthermore, the discrete element method (DEM) has been investigated, and deemed inappropriate for the calculation of the contact points. For the improvement of the toolbox towards applicability to any arbitrary particle geometries, a new approach is considered for the representation of the surface, which will be called

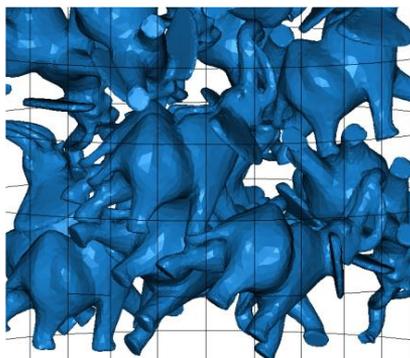

Figure 5: Representation of complex geometries

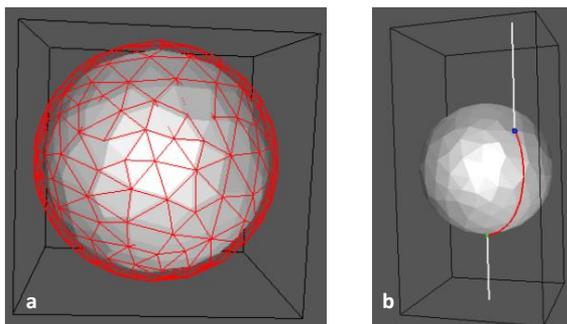

Figure 4: a) Particle surface mesh and b) liquid path flow representation using the LET method

further the *liquid element tracking* (LET) method. In the LET method, the particle surface is discretized over a finite number of triangles (Figure 4a). The path of the liquid flow (for example a rivulet) on the particle surface is then described as a pointwise sequence of motion of the fluid over individual partial surfaces, based on the applied forces. Thus, the position of impact on the particle surface can be determined (Figure 4b). The resolution of the discretization can be changed depending on the desired accuracy, although fine meshing will increase the model complexity, and lead to higher CPU times. Thus, complex particles can be represented, for example (although not a realistic catalyst shape) elephants (Figure 5).

2.4. Validation of the LET surface mesh representation

Since the spherical particle representation existing in the previous version of BasMo has been validated experimentally in the precedent work (Schwidder & Schnitzlein, 2010; 2012), in the following, the results based on the LET-approach will be validated against its predictions for spherical particle shapes.

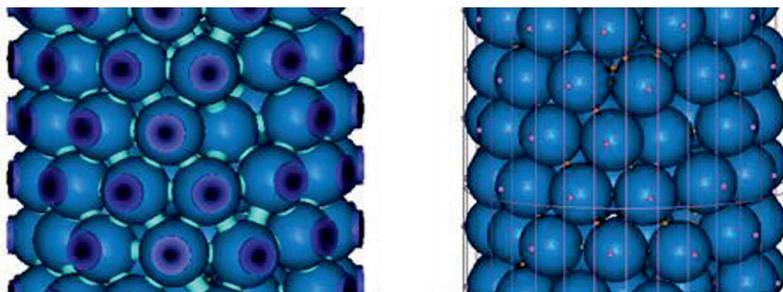

Figure 6: Prediction of static holdup based on BasMo v1 (left) and v2 (right) particle representation

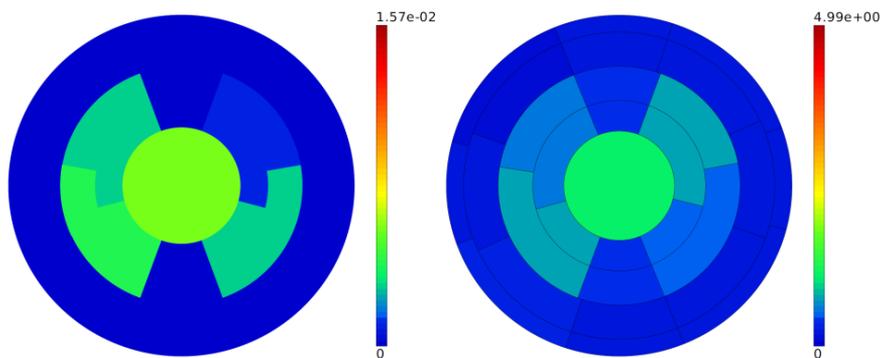

Figure 7: Prediction of the radial flow distribution

Once the information on the geometry is available, the static holdup can be calculated, with acceptable accuracy (Figure 6). The static holdup is determined from the volume of every single bond existing at a contact point, as described in Schwidder & Schnitzlein (2010). Finally, the radial flow distribution can be predicted, as shown in Figure 7, using the models developed in Schwidder & Schnitzlein (2012).

3. Conclusions

This contribution introduces improvements done in the implementation of a modular toolbox for the simulation of trickle bed reactors. The implementation of BasisModel (BasMo) in C++ mirrors the multiscale nature of the phenomena taking place in the reactor, moving from the large scale of the reactor to the medium and low scale of the particle bed, fluid flow, as well as the fluid-solid and fluid-fluid interactions, including the chemical reactions. The toolbox allows for the implementation of complex geometries for the catalyst particles, enabled by the new representation of the surface mesh. A graph network model representation is used for the liquid flow, which enables the calculation of the properties based only on the local geometry, reducing significantly the

computational effort, without hindering the accuracy. Although the new implementation of the surface mesh shows in general good agreement with the previous version of the toolbox, validated experimentally in the previous work, significant experimental work is still ongoing to validate the models for complex, non-spherical geometries, for which new models for the static holdup or the radial dispersion may need to be derived.

The knowledge gathered from the modelling of the liquid phase, and the liquid-solid interactions, as well as improvements on the particle surface representation enable new features to be displayed on the simulation toolbox in order to represent accurately the TBR under real operating conditions. Further improvements are envisaged which include the addition of enhanced modules for the continuous gas flow, liquid-gas interactions, as well as momentum balances, to improve the representation of the fluid pathways inside the bed.

Alkaline Water Electrolysis Model to Purify GMP grade NaOH Solutions for Biopharmaceutical Manufacturing Processes

^aYeonghyun Kim, ^aYoungjin Kim, ^aJae Hyun Cho, ^aIl Moon

^aYonsei University 50 Yonsei-ro Seodaemun-gu, Seoul, 03722, Republic of Korea

Abstract

It is essential that the Cl⁻ ions purity contained in NaOH solutions for the use of the biopharmaceutical production processes would be below 30 ppm to meet Good Manufacturing Practice (GMP) guidelines (Gilleskie, G. et al.). The development of a commercially efficient process for purifying NaOH 50% aqueous solution of such purity is of interest in the related industry. This study describes a lab-scale electrochemical mathematical model for producing GMP grade NaOH aqueous solutions and a design of electrochemically efficient lab-scale production configuration. The model validation is carried out with experimental data for a different set of membrane configurations (Marangio, F. et al.). The model calculates the theoretical open-circuit voltage via a thermodynamic analysis of the electrochemical purifying process and then outputs the expected voltage during operation by applying the Butler-Volmer equation (Jang, D et al.). A set of physical properties of the solution are obtained from well-known theoretical equations: concentrations from Henry's law and membrane diffusivity, permeability, and ionic conductivity from the Arrhenius equation, respectively. An experimental data fitting makes it possible to obtain estimated values of critical process parameters and their data tendency at different temperatures. The proposed model shows about 90% accuracy at an electrochemical lab-scale, to produce GMP grade (Cl⁻ ions below 30 ppm) 50% NaOH aqueous solution, and an appropriate cation exchange membrane-based experimental configuration turns out to be of electrochemically high efficiency. Future work is to enhance the experimental scale model to scale up to a commercial scale, with an emphasis on the optimization of electrochemical reaction time, power and voltages.

Keywords: Alkaline Water Electrolysis (AWE), prediction model, NaOH purification.

1. Introduction

With the ongoing globally pandemic COVID-19, the production of biopharmaceuticals is getting more attention as vaccines are highly demanded worldwide. In particular, efficient purification of NaOH up to GMP grade NaOH solutions becomes vital in biopharmaceutical manufacturing processes as it effectively removes proteins and nucleic acids and inactivates most viruses, bacteria, yeasts, fungi, and endotoxins (Giro, P et al.). As such, it is essential to produce GMP-grade NaOH of high purity. In this study, Alkaline Water Electrolysis (AWE) is proposed as an experimental configuration for purifying a 50% aqueous NaOH solution at GMP grade, specifically targeting below 30 ppm of Cl⁻ ion in 50% NaOH solution, and its electrochemical model is developed and verified with experimental data.

2. Experiment

The proposed experimental framework comprises two electrodes immersed in a liquid alkaline electrolyte (See Fig. 1), and its specifications are given in Table 1 (Zeng, K et al.). As the NaOH solution in an ionic state undergoes electrolysis, the electrochemical reactions described in Eqs. 1 and 2 take place where hydroxide ions react to produce oxygen and water at the anode, and hydroxide and hydrogen are generated at the cathode. The characteristic of the membrane, which selectively allows Na^+ ions passing through from the anolyte to the catholyte, leads Cl^- ions to get diluted in the catholyte. As the reaction time goes by running the experiment, the concentration of the Cl^- ion-free catholyte increases, and that of the anolyte decreases. It takes around 200 hours to reach 19M of catholyte.

Table 1. Operating conditions of AWE

Parameters	Unit	Value

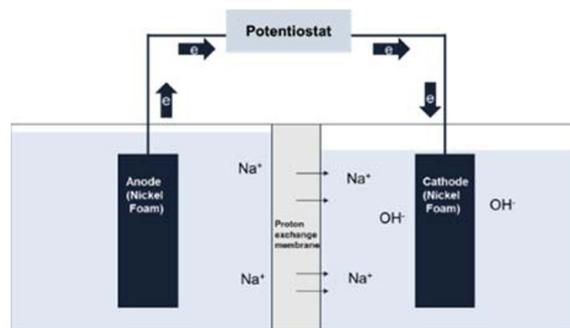

Fig. 1. Reaction mechanism of Alkaline Water Electrolysis (AWE)

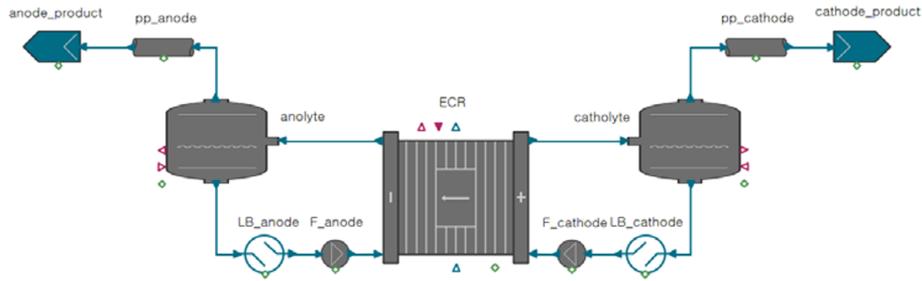

Fig. 2. Conceptual framework of the AWE model

3. Model and its Verification

3.1. Alkaline Water Electrolysis (AWE) Model

An AWE model is developed to derive the dynamics of the AWE based on gPROMS PROCESS™, which is operated in batch mode (See Fig. 2.) The initial amounts of anolyte and catholyte in the tanks are 200 mL of anolyte, 150 mL of catholyte, respectively. It is assumed that the fluids are circulated between the tanks (anolyte and catholyte) and the Electrochemical Cell Reactor (ECR) in Fig. 2 simply as a way to make sure the fluid in the tanks interacts with the membrane and electrodes in order to represent batch operation in reality. 0.5A of current is kept constant in the entire experiment time. g-SAFT (gPROMS physical property package) is selected as its physical property model for materials involved in the experiment. The operating temperature of the current reactor is 40°C, and the temperature change was found to be less than 1°C. Therefore, the reaction is assumed to be isothermal. Since there is no change in pressure as operated in the atmosphere, the reaction is isobaric. The AWE model shows the trends of electrolytic cell voltage as well as the catholyte concentration. The total voltage of the electrolysis is determined by summing up the open-circuit voltage, the activation and ohmic over-voltages as Eq. 3 below (Han, B et al.):

$$V = E_{oc} + \eta_{act} + \eta_{ohm} \quad (3)$$

The open-circuit voltage is calculated based on the Nernst equation.

$$E_{oc} = E_o + \frac{RT}{zF} \ln\left(\frac{p_{H_2} p_{O_2}^{0.5}}{p_{H_2O}}\right) \quad (4)$$

where R, T, p, and F are the universal gas constant, operating temperature, partial pressure, and Faraday constant, respectively; p_{H_2} & p_{O_2} i the partial pressure of hydrogen and oxygen gases near the electrode under Henry's law. E_o , the standard electrode potential is calculated by the Eq. 5 (Han, B et al. & Prentice, G.):

$$E_o = 1.229 + 0.9 \times 10^{-3}(T - 298.15) \quad (5)$$

The activation over-voltage is the consumed voltage caused by the electrochemical reaction (Jang, D et al.). It occurs at both electrodes, and the over-voltage on the anode appears larger than the cathode in most cases (Hammoudi, M et al.). The activation over-voltages can be determined by the Butler-Volmer equation (Prentice, G):

$$\eta_{act} = \frac{RT}{\alpha_{an}F} \sinh\left(\frac{i}{2i_{o,an}}\right) + \frac{RT}{\alpha_{ca}F} \sinh\left(\frac{i}{2i_{o,ca}}\right) \quad (6)$$

where α_{an} and α_{ca} represent the charge transfer coefficients of anode and cathode, respectively. The exchange current densities of anode and cathode are expressed as $i_{o,an}$ and $i_{o,ca}$, respectively. The exchange current density has a significant influence on the activation over-voltage (Zhang, Z. et al.). The exchange current density coefficients of the Ni electrodes used for the anode and cathode are calculated, using Eqs. 7 and 8, with data provided in (Henao Diaz, C).

$$i_{o,ca} = 1.5 \times 10^{-4} \left(\frac{P}{P_{ref}} \right)^{0.1} \exp \left[-\frac{23000}{RT} \right] \left(1 - \frac{T}{T_{ref}} \right) \quad (7)$$

$$i_{o,an} = 0.9 \times 10^{-4} \left(\frac{P}{P_{ref}} \right)^{0.1} \exp \left[-\frac{42000}{RT} \right] \left(1 - \frac{T}{T_{ref}} \right) \quad (8)$$

The charge transfer coefficients are calculated using Eqs. 9 and 10 with data provided in Ref. [9].

$$\alpha_{an} = 0.07835 + 0.0017T \quad (9)$$

$$\alpha_{ca} = 0.1175 + 0.00095T \quad (10)$$

In general, the transfer of ions or electrons causes an ohmic over-voltage which is present at electrodes, electrolytes, and membranes, comprised of the electrolysis cell. The ohmic over-voltage is generated by the resistance encountered by the ions to the flow through the membrane (Marangio, F et al.). The obstruction to the flow of ions could be due to the ionic conductivity of the membrane and gas bubble coverage of the active area (Jang, D et al.). Choi et al. express this mechanism as below:

$$\eta_{ohm} = \delta_m \frac{i}{\sigma_m} \quad (11)$$

The conductivity, σ_m in Eq. 11, is calculated by Springer et al., which also considers the membrane hydration.

$$\sigma_m = (0.005139\lambda - 0.00326) \exp \left(1268 \left(\frac{1}{303} - \frac{1}{T} \right) \right) \quad (12)$$

Membrane diffusivity, permeability and ionic conductivity are calculated based on the Arrhenius equations, respectively.

$$k_i^{diff} = k_{i,ref}^{diff} \exp \left(-E_i^{diff} \left(\frac{1}{T} - \frac{1}{T_{ref}} \right) \right) \quad (13)$$

$$k_i^p = k_{i,ref}^p \exp \left(-E_a^p \left(\frac{1}{T} - \frac{1}{T_{ref}} \right) \right) \quad (14)$$

$$\sigma_i = \sigma_{i,ref} \exp \left(-k_{\sigma_i} \left(\frac{1}{T} - \frac{1}{T_{ref}} \right) \right) \quad (15)$$

where *diff*, *p*, *ref*, *E*, σ_i and *T* indicate the diffusivity coefficient, permeability coefficient, reference, activation energy, ionic conductivity and temperature.

3.2. Na⁺ ions mass balance

The mass balance of Na⁺ represents the dynamic of Na⁺ at the anode, which includes its migration to the cathode through the membrane. Eq. 16 illustrates the molar flow rate of Na⁺ corresponds to that of OH⁻ at the anode and cathode. The molar flow rate of Na⁺ by diffusion ($\dot{N}_{Na^+,d}$) and electroosmotic drag ($\dot{N}_{Na^+,eo}$) account for that of Na⁺ via the membrane in Eq. 17. The flux of water accompanied by the flow of Na⁺ is characterized by the electroosmotic drag coefficient (n_d), which is an inherent property of the membrane. Eq. 19 describes the Na⁺ concentration gradient present in the NaOH solution across the membrane according to Fick's law of diffusion, where A, D_w and C are membrane area, diffusion coefficient and concentration. The following equations apply:

$$\dot{N}_{Na^+,m} = \dot{N}_{OH^-,an} = -\dot{N}_{OH^-,cat} \quad (16)$$

$$\dot{N}_{Na^+,m} = \dot{N}_{Na^+,d} + \dot{N}_{Na^+,eo} \quad (17)$$

$$\dot{N}_{Na^+,eo} = \frac{n_d i}{F} \quad (18)$$

$$\dot{N}_{Na^+,d} = \frac{AD_w}{\partial m} (C_{Na^+,cat} - C_{Na^+,an}) \quad (19)$$

3.3. Model Verification

Fig. 3 shows the transient variation of NaOH concentration in the catholyte to verify the proposed model as compared to the experimental data. In the case of the Nafion 117, the experimental data show 240 hours of the reaction time at the cathode to reach 19M, and the reaction time calculated by the model is approximately 235 hours. This yields 5.69 of a root mean square deviation. In the case of the thinner Nafion 212, the reaction times of the experiment and models are 171 and 165 hours, respectively, showing 6.15 of the root mean square deviation. The proposed model shows good agreement with the experimental data at our laboratory scale.

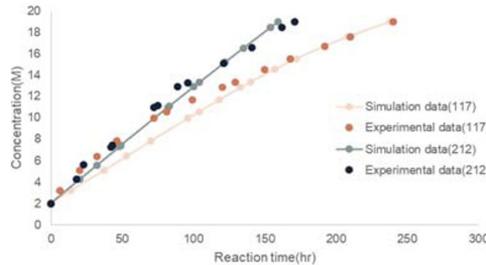

Fig. 3. Transient variation of NaOH concentration in the catholyte

4. Conclusion and Future Work

In this paper, the cation membraned-based Alkaline Water Electrolysis (AWE) model to purify GMP grade NaOH solutions (below 30 ppm Cl⁻ contained in 50% NaOH solutions)

is proposed, using gPROMS PROCESSTM and verified with experimental data, showing 90% accuracy. As future work, the proposed model at a laboratory scale will be developed further for commercial biopharmaceutical manufacturing processes.

Abstract

In the pharmaceutical industry, the flow of fine powders between different manufacturing steps can be challenging due to both the solid and liquid-like behavior of bulk solids. To better understand flow behavior, the use of predictive models, such as the discrete element method (DEM) has increased in recent years. However, a general model for fine bulk solids is not yet available. This is mainly due to the long computational time requirements and the complexity of the flow, as the discharge of fine particles is influenced both by cohesive forces and interaction with the surrounding air.

In this study, a DEM model was used to predict the flow dynamics of a free-flowing powder SuperTab[®] 11SD and to determine the extent to which the model can predict the discharge behavior of fine particles from a silo. Flow behavior was comprehensively characterized in terms of flow profile development over time, mass flow index, and residence time distribution. Furthermore, mass flow rate predictions were verified considering experimental data of a laboratory-scale cylindrical silo for different aperture sizes. Lastly, in order to obtain an accurate DEM prediction, a leaner approach was implemented by introducing a relation that takes into account the aerodynamic drag effect on the system.

Keywords: Fine particles, Discrete Element Model, Computational Fluid Dynamics

1. Introduction

In continuous manufacturing of solid dosage pharmaceuticals, powder flow in silos or bins is critical to the process performance and end-product quality. The flow properties of powders vary with each material's chemical and physical characteristics, which include particle size and shape, bulk density, compressibility, cohesive strength, moisture, and the material's behaviour under vacuum, atmospheric, and loading conditions. Often, due to cohesive and poorly flowing powders, it can be challenging to accurately feed, blend, and transfer between different manufacturing steps, despite using tooling such as agitators and rotating bridge breakers to obtain uniform flow. Moreover, in pharmaceutical applications where fine particles are commonly handled, in addition to the relevant effect of the cohesive forces that affect flow behavior, the interaction between interstitial air and particles also plays an important role, since the backflow of air can cause inconsistent discharge rate.

Owing to the degree of challenge and despite the increasing research in particle technologies for pharmaceutical applications, a general model to predict such powder flow behavior is still missing and the development of first-principles models to obtain mechanistic insights is limited. This is often attributed to the exhibition of both solid and liquid-like behavior of the bulk solids. Commonly used models are based on empirical approximations for cohesionless coarse particles that are not influenced by aerodynamic drag (e.g. Beverloo, Rose and Tanaka) Gu (1991), multivariate predictions that require collection of a large amount of experimental data to generate a model, and more recently, computational models that use fundamental first principles to capture the underlying physical phenomena and predict the overall bulk behaviour, such as finite element method (FEM), computational fluid dynamics (CFD), and Discrete Element Method (DEM). There is a growing interest within the pharmaceutical industry to develop predictive models for fine powder discharge to avoid non-uniform flows and discharge rate variations, which can further affect downstream operations. While DEM has been extensively used to predict powder discharge, it remains underutilized in the pharmaceutical industry due to the required computational time to simulate particle dynamics in the micron size range, stringent process constraints, the wide variability of powder and bulk properties, and the failure to capture the interstitial air effect on fine particles. This last aspect is mostly resolved by the computationally intensive DEM-CFD coupling approach (Hesse et al., 2020). In this study, a leaner approach is proposed by using scaled-up particles and introducing a relation that can be directly applied to the DEM results to obtain an accurate prediction of discharge rates in silos when handling fine particles. Therefore, a preliminary basis for the application of DEM models to study discharge dynamics in a silo is provided for a free-flowing powder (SuperTab[®] 11SD spray-dried lactose monohydrate) and determine to what extent the model can predict the discharge behavior of fine particles.

2. Methodology and implementation

The DEM methodology is exemplified by an application case of discharge dynamics in a laboratory silo for a free-flowing powder (SuperTab 11SD[®]). The implementation stages included bulk calibration of DEM input parameters for the scaled particles. Subsequently, a qualitative comparison of powder flow patterns in two different silos (flat bottom and converging wall), determination of flow uniformity, and quantitative comparison between the residence time of the particles located in the upper layer of the powder bed. Then, a verification of the model results was performed by comparing the experimental and numerical discharge rate values of a cylindrical laboratory-scale silo for a set of aperture sizes was performed. Lastly, a relation was implemented to include the effect of interstitial air and rectify the mismatch between the discharge rate prediction by DEM and experimental values.

2.1. Numerical method

This contribution focuses on one of the most commonly used mechanistic models for granular flow, DEM. In this numerical method, the macroscopic material behavior is predicted based on the mechanical dynamics of discrete particles. Each particle is treated as a discrete element with a specific position and velocity which is estimated for each time step based on the tangential and normal contact forces exerted on the particles and Newton's second law. This process is repeated iteratively to track the dynamic motion of particles at any time. The rotational and translational motion are calculated based on the following Eq. 1 and Eq. 2 respectively. Where I , ω , M_p , t , v , m , F_g , F_c , F_{nc} , and F_f respectively correspond to moment of inertia, angular velocity, contact torque, time, translational velocity, mass of the particle, gravitational force, contact forces (e.g. elastic, plastic), non contact forces (e.g., Van der Waals, electrostatic) and particle–fluid interaction forces (e.g. pressure gradient, drag).

$$I \frac{d\omega}{dt} = M_p \quad (1) \quad m \frac{dv}{dt} = F_g + F_c + F_{nc} + F_f \quad (2)$$

This approach has been implemented in various pharmaceutical manufacturing processes such as blending, coating, and tableting, and it has proven to be an effective tool to improve the understanding of the underlying interaction of material properties, process settings, and equipment design Yeom et al. (2019). Despite its benefits, DEM application in the pharmaceutical industry is still limited as it can be significantly computationally intensive to simulate particle dynamics in the micron size range.

2.1.1. Contact model

The commonly used soft-sphere discrete simulation approach is considered in this study. In this method, discrete particles are allowed to overlap to represent the deformation that occurs during collisions. The contact models use the amount of overlap between particles to calculate the magnitude of forces acting on normal and tangential directions. In pharmaceutical application, the selection of a contact model that considers the elastic and plastic properties for non-cohesive and cohesive materials is highly relevant to adequately represent the interaction phenomena and overall bulk behavior. In this study, the commonly used Hertz-Mindlin contact model with JKR (HM + JKR) is implemented. This is a non-linear elastic model that takes into account cohesion, allowing the representation of materials as dry powders. This model has been applied in several pharmaceutical manufacturing applications such as blending and granulation Yeom et al. (2019). A detailed description of the model and governing equations can be found in Johnson et al. (1971).

2.2. Model parameter determination

The model parameters used in this study are subdivided into two types, intrinsic parameters and contact parameters. The intrinsic parameters that depend on the material properties such as density, shear modulus and Poisson's ratio are fixed from literature values. The contact parameters, such as surface energy and the coefficients of static and rolling friction, are not established directly from experimental or literature values but are calibrated with virtual experiments.

Therefore, the calibration procedure is thus performed to gain confidence in the modeling results, by linking the material properties to the actual bulk behavior. The calibration methodology used in this study consists of the comparison between experimental tests carried out with the real material and the virtually replicated test. The DEM input parameters are adjusted to match the experimental bulk response with the prediction from the experiments.

The calibration test is selected to replicate the stress state and flow regimes expected of the real application case. Therefore, as low stresses and quasi-static regime flow are expected in the selected silo, the most suitable calibration test is considered to be the ring shear cell. The calibrated factors include rolling friction (particle-particle, particle boundary), static friction (particle-particle, particle boundary), and JKR surface energy, and results between the experimental bulk response and the virtual experiment prediction are compared in terms of apparent cohesion, yield locus slope, and pre-shear point. Detailed information regarding the set of experiments and its results is considered out of the scope for this study.

The DEM input parameters, including the calibrated values for SuperTab[®] 11SD, are shown in Table. 1. Since the selected set of parameters achieves a satisfactory representation of the behavior of the powder in the ring shear cell, these are later used in the silo discharge model.

2.3. Silo model setup

The discrete element method (DEM) is applied to model silo discharge flow of a free-flowing powder (SuperTab[®] 11SD spray-dried lactose monohydrate), using the software package EDEM[®],

Table 1: DEM input parameters

Parameter	Value
Particle density [kg/m^3]	1530
Particle coefficient of restitution	0.5
Shear modulus [Pa]	5×10^6
Poisson's ratio	0.25
Static friction particle-particle	0.6
Rolling friction particle-particle	0.1

considering gravity as an external force and Hertz-Mindlin with JKR as contact model. The computational domain consists of a quasi-three dimensional silo with parallel periodic boundary conditions. Particles are represented by scaled monodisperse bi-spheres. The general computational procedure for each run consist of three steps. First, based on the set of calibrated parameters particles are created, inserted into the closed silo, and allowed to settle under gravity into a static state. Second, the silo outlet is open and particles are allowed to discharge by gravity. Lastly, the simulation continued until all the particles exit the silo. The developed DEM silo model is used to qualitatively compare the changes in flow profile development (e.g., mass flow, funnel flow) depending on the silo geometry (e.g., flat bottom, converging walls) for a specific material.

In addition to the visualization of the flow patterns, the mass flow index (MFI) and the residence time distribution (RTD) are estimated using Eq. 3 and Eq. 4. The MFI is applied to more accurately classify the developed flow profile between mass flow and funnel flow, where MFI values lower than 0.3 correspond to funnel flow. The MFI estimation relates the particle average velocities near the wall (v_{wall}) and at the center of the silo ($v_{centerline}$), providing an estimation of flow uniformity within the hopper Ketterhagen et al. (2009). The RTD was used to analyze the flow behavior in an arbitrary spatial region in the silo, where $F(t)$ represents the fraction of particles that leave the silo that have spent a time t or less. In this study, the particles located in the top layer of the powder bed are tracked to verify the flow sequence.

$$\frac{v_{wall}}{v_{centerline}} = MFI \quad (3) \quad \int_0^t E(t)dt = F(t) \quad (4)$$

2.4. Model verification

As previously mentioned, during silo discharge of fine powder the air effect is highly relevant as it can be an impediment to the gravitational powder flow and consequently reduce the discharge rates. Since in the proposed DEM model no CFD coupling was involved, an overprediction of the discharge rates could be expected. Therefore, to verify the suitability of the DEM model for the prediction of discharge rates, an instrument to measure the flow rate of powders passing through apertures of various diameters (24mm, 28 mm, and 32mm) is used and the discharge rate values from the DEM model and the experiments for SuperTab[®] 11SD are compared.

The computational domain consists of a laboratory-scale cylindrical silo where the calibrated particles are allowed to be discharged by gravity. Throughout the discharge process, the mass flow rate is monitored to verify the changes over time and the average value is estimated. The verification model allows a quantitative comparison between the discharge rates obtained with the DEM model and the experimental values for different aperture sizes. Based on this comparison, the need to include a relation that account for air impediments in the system is highlighted. The relation proposed by Wikström et al. (2021) is implemented in Eq. 5, where g , ε , D_p , D , μ_A , and M respectively correspond to gravity constant, voidage, particle diameter, outlet diameter, air viscosity, and mass flow rate. The equation considers a balance between the gravitational effect and the aerodynamic resistance, neglecting the inertial effects of fine particles.

$$\frac{\pi g \varepsilon^2 \rho^2 D_p D^2}{720 \mu_A} = M \quad (5)$$

3. Results and discussion

Based on the selected set of calibrated parameters, shown in Table. 1 and the simplified silo geometry the silo application case is implemented. The results in terms of developed flow profiles in time, flow uniformity (MFI), and residence time distribution for particles located in the top layer of the powder bed are shown in Fig. 1.

The results shown in Fig. 1 indicate that the flow profile developed depends on the silo geometry. This finding is in agreement with the observations of Ketterhagen et al. (2009) for granular flow and Jenike's design methodology studies (Mehos, 2018). Jenike's required silo angle to prevent funnel flow is 30° , which matches the predicted flow pattern for the converging wall silo (angle 35°). In general, as the flow progresses in time the flat bottom silo develops a central channel with the formation of stagnant areas, while in the case of the silo with converging walls a uniform mass flow develops. These results are corroborated by the values of mass flow index, which indicate a uniform flow for the silo with converging walls, with a MFI higher than 0.3. The results regarding RTD also corroborate our earlier observations regarding the flow profile development in the silos. The RTD values showed that particles located in the top layer of the powder bed have smaller residence time values for the flat bottom silo compared to the silo with converging walls, with mean residence time values of 0.08 s and 0.17 s respectively. These findings further support the idea that funnel flow results in a first-in-last-out flow sequence, often leading to particle segregation. Moreover, this indicates potential challenge in setting-up material traceability in silos with flat bottom and their application in continuous pharmaceutical manufacturing where material traceability is a regulatory requirement (ICH Expert Working Group, 2018).

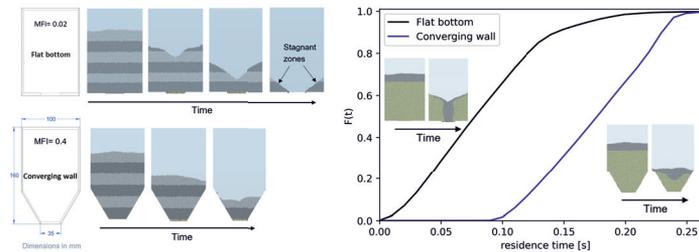

Figure 1: (A) Flow profile evolution snapshots and (B) residence time distribution of gray-colored particles, for two silo geometries

Next, experimental and numerical mass flow rates were compared for validation model as shown in Fig. 2. It is observed that the DEM model gives an overestimation of the discharge rate values for all aperture sizes considered. This result can be explained by the fact that the DEM model developed does not consider the critical air impediment effect during the fine particles discharge process. This finding, while preliminary, suggests that a relation needs to be considered to account and correct for air interaction in DEM discharge rate predictions for fine particles. The study by Wikström et al. (2021) showed that for fine particles, a model that considers the effect of the aerodynamic resistance and gravitational forces, neglecting the inertial effects, can adequately predict the discharge rate of commonly used excipients in intermediate size silos (20 L IBC). Since the assumptions in terms of the importance of forces such as drag in the discharge rate calculation are still considered valid for the current case study, the relationship implemented by

Wikström et al. (2021) is used to correct the predicted DEM discharge rates for a laboratory-scale silo. The relation proved to adequately correct the DEM results for different aperture sizes, with an average relative error of 10% with respect to the experimental values. However, the general applicability of this model for different powders and silo shapes remains to be verified. Furthermore, the assumptions in terms of the selected particle representation (size, shape) need to be further reviewed.

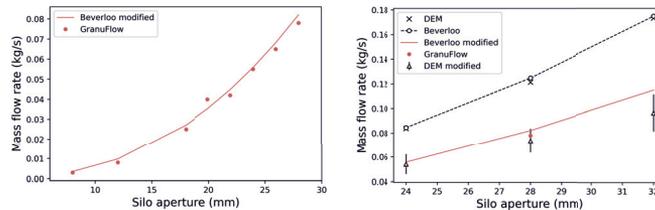

Figure 2: Comparison of numerical and experimental mass flow rate values depending on orifice size

4. Conclusions and outlook

A predictive model for powder discharge in a silo has been developed. The implemented model served as a preliminary basis in identifying the DEM's capabilities to predict flow profiles and discharge rate of fine powders. In addition, it highlighted the influence of the interaction between air and particles when discharging fine particles.

The first part of this study allowed a qualitative comparison of the flow profiles developed in two silo geometries. The results in terms of flow patterns, flow uniformity, and residence times indicated an association between silo geometry and flow profile, matching the findings of earlier studies Mehos (2018). The second part of the study showed a comparison of discharge rates for different silo apertures. The results indicated an overprediction of the DEM model in all cases, these findings may be explained by the effect of air impediment. Additionally, a relation was applied to the DEM results to accurately predict discharge rates.

The DEM model developed included assumptions in terms of the selected particle representation (size, shape, size distribution) that need to be further revised for the selected application. Moreover, additional verification is ongoing to include discharge rate comparisons for smaller silo openings.

Abstract

Today, the design of biorefineries is following the traditional chemical process design, thereby reflecting that biorefining-specific models are not established. This issue is one of the predominant reasons why most biorefinery concepts still remain limited in their commercial as well as sustainable capabilities. This situation most likely originated from the very heterogeneous, multi-scale as well as multi-disciplinary nature of biorefineries - a circumstance that often turns model design into an expensive and elaborate task. However, models are essential for understanding integrated biorefining and how feedstock and operating conditions affect performance. Correspondingly, the absence of reliable predictive models causes uncertainties, which put investors off and generate significant development bottlenecks in design, optimisation and control.

The aim of this contribution is to outline the current state of biorefinery modelling, derive the presumed root causes, and expose the preferred characteristics of the models required for condign biorefinery research.

Keywords: modelling, simulation, process control, optimisation, process design.

1. Motivation

The social support for a more sustainable process industry has never been this high yet, although the considered processes are leaping behind considerably. Most biorefinery concepts are still in the experimental design phase, thus remaining limited and far off the expected industrial standard in their commercial and sustainable capabilities. This is partly governed by the lack of proper design methods for plants and supply networks, as reported by Bauer et al. (2017), Dragone et al. (2020), Temmes & Peck (2020), and Ubando et al. (2020). Their further development and commercial implementation are hampered by high investment costs and risks, and little trust in its novel technologies, expected yields, and operating reliability.

Although many biorefinery concepts are technically feasible and can have positive environmental impacts, the costs and sustainability are determined by the effectiveness of each process step and the utilisation of the different platform products (Corona et al., 2018). Therefore, a successful design requires intensive research and development activities, and one requires rigorous models to achieve a high-quality, reliable, and optimal design (Tey et al., 2021). Experimental studies may be the conventional alternative but they are expensive, time-consuming and often not viable in all operational areas or even reliable for the exploration and testing of differing process scales. Numerical simulations are done in computers and as such not limited by physical constraints. They thus allow for the exploration of physical regions that are commonly

not accessible by experimental work. The fast development of computing in recent decades rapidly increased the capabilities of process simulation, thereby enabling the simulation of more and more complex models. However, as we will discuss in this study, large parts of biorefinery research and development do not seem to follow this trend, thereby failing to provide robust models.

Without rigorous holistic models, parameter estimates and process designs are speculative, and reliable identification of the dynamics is improbable. Correspondingly, Alzate et al. (2018) and Solarte-Toro et al. (2021) conclude that the absence of reliable predictive models causes uncertainties, which put investors off and generate significant development bottlenecks in design, optimisation, control, and implementation.

Therefore, we reason that the hampered implementation of biorefinery processes is the result of a lacklustre state of modelling in this domain. To discuss this hypothesis within the scope of this short contribution, we shall first outline the present state of biorefinery modelling. Next, we uncover the primary challenges in biorefinery design, which will indicate the presumed root causes for the lack of modelling. To conclude, we expose the preferred characteristics of mechanistic models required for biorefinery concepts and their potential benefits for research, development and process integration.

2. Outlining the current state of biorefinery modelling

Scopus[®] (Elsevier B.V., 2021) shows that less than 17 % of biorefinery-related publications in the last 20 years dealt with topics of modelling, while the overall share in chemical engineering publications is almost 24 %. This lack of modelling activities in the biorefinery community is significant and raises concerns. It implies that today biorefineries are designed on the backbone of industrial chemistry and not based on process systems engineering concepts.

Although several biorefinery-specific conversion processes have been studied, the understanding of the dynamic nature of most of these reactions remains incomplete and limited. The lack of comprehensive mechanistic knowledge combines with a lack of experimental data: Since bioconversion platform processes are in most cases still confined to pilot-scale set-ups, De Buck et al. (2020) found that many related models are highly assumption-based, and often rely on ideal kinetics. These models are only valid for the narrow processing conditions and feedstocks for which they were created and extrapolation does not produce reliable results.

Most of the published biorefinery designs follow a top-down approach, only demonstrating kinetic process models for one particular process part at a time (De Buck et al., 2020). Detailed and replicable process designs, especially ones designed for flexible operational conditions, are few, as observed by Chaturvedi et al. (2020).

Without reliable modelling, assessment studies remain speculative. Although various decision support systems have been developed, strategic, tactical and operational decision tasks are not considered together in most of these studies, even though studies like Geraili et al. (2014) attest significant interdependence between them. Aristizábal-Marulanda et al. (2020) conclude that, until now, knowledge on the best configurations remains limited, and only few studies have looked at the environmental sustainability and socio-economic impacts of specific biorefinery routes. To the best of our knowledge, none has focused on finding the most-sustainable biorefinery cascade. Most life-cycle assessment (LCA) studies on biorefineries compare feedstocks between each other and to fossil references. Some compare the impacts of different processing routes, however, Julio et al. (2017) found these evaluations to concern already designed processes, thereby considering only unique operations in the assessments. Since even

small changes in operating parameters can notably modify environmental impacts, the reliability of those studies is questionable.

Problems are best solved by attempting to correct or eliminate the root causes instead of merely addressing the immediately obvious symptoms of the current state. Therefore, we will discuss in the following section the presumed root causes for the lacklustre development of biorefinery modelling before we will list the characteristics of the models required for overcoming the present period of stagnation in the field.

3. The challenges facing biorefinery modelling

Modelling chemical and biological processes is intrinsically a multi-scale and multi-disciplinary problem that requires expert knowledge from different scientific domains. This diversity is even more obvious in biorefinery concepts, which predominantly process aqueous solutions of manifold substances. Since many of the processed chemical compounds have not notably been encountered in traditional chemistry, their thermodynamic data and reaction kinetics are widely missing today (Corazza & Trancoso, 2021). Furthermore, the widespread utilisation of solids in biorefining increases the need for robust particle and surface reaction simulations, which has not been accomplished satisfactorily so far due to the computational complexity inherent. These circumstances often turn model design into a time-consuming and elaborate task.

With models being at the top end of the overall assessment process, the correctness and completeness of the model equations are of the highest priority in modelling. Since the processes we observe are intrinsically an ensemble of various sub-processes on different time and spatial scales, the model design has to incorporate this behaviour consistently, including linking multiple scales for accuracy and integrity. Multi-scale models pose notoriously difficult theoretical and computational problems, but the knowledge and abilities in mathematics, physics, biology, chemistry, process control, and engineering are proliferating. In biorefinery processes, the multi-scale issue is amplified by these systems being critically dependent on interactions often coupled through multiple spatial and temporal domains without clear, discrete differences between scales. Consistent and reliable mathematical relations of the behaviour and interactions of the various scales are required to obtain robust and predictive models. Modern biorefinery concepts have to utilise a vast amount of scientific disciplines for reliable design and optimisation (Punnathanam & Shastri, 2020), effective process control implementations (Petre et al., 2020), and accurate assessment (Julio et al., 2017) to get the most out of any feedstock in competitive pricing ranges. One modeller cannot be an expert in all of the topics encompassed, and, more often than not, communication between experts of different scientific fields appears to be cumbersome.

Biorefinery processes' modelling, assessment, and control is challenging due to the complexity and non-linearity, uncertain kinetics, different scales of process and logistics, the heterogeneous and seasonally fluctuant solid biomass feedstocks, and high uncertainty in bioprocess kinetics (Ifrim et al. (2015); Nguyen et al. (2015)). Latter implies that understanding and modelling those processes requires taking several dynamic factors into account. However, dynamic models are often restricted to one dimension as otherwise, the computational cost would be tremendous. Nevertheless, they are critical for optimising start-up and shut-down procedures, HAZOP studies, and investigating the plant transient operation under high load change rates. Additionally, plant control systems, have to be trained on dynamic models. The cost or even lack of adequate sensors further hampers the design of reliable control structures (Petre et al., 2020).

Conversion models require fairly detailed feedstock composition, while supply network models are often limited to only predicting the expected amounts of the available feedstock during a specific time period. Additionally, conversion and logistics models are usually built on significantly different time scales (Baldea & Harjunkoski, 2014). Since many conversion processes in biorefinery concepts, like fermentation, are batch processes, it is very important to define the optimum conditions for both, logistics and operation, to achieve feasibility. Due to this and the small profit margins to be expected, the assessment of biorefineries must be accurate, utilise all biomass fractions, and encompass economic, environmental and social aspects as well as the erratic supply and pricing of feedstocks. The sustainability and economic feasibility of the required feedstock's supply to the plant is crucial when designing and operating a biorefinery (De Buck et al., 2020). The time perspective in these assessments is particularly relevant for biorefineries due to the feedstock's highly seasonal cultivation characteristics.

4. A wish list for biorefinery modelling

To address the myriad of challenges to biorefinery modelling, adequate efforts have to encompass a multitude of characteristics that can probably only be achieved by extensive interdisciplinary liaisons. In the following, some of these characteristics will be discussed. Most of the flowsheeting packages commercially available are probably not suitable for the complex needs in biorefinery modelling and not flexible enough for custom-modelling efforts. Since these packages have been developed for and traditionally been used by the petrochemical industries, their libraries lack unit operations as well as many chemical properties specific for biomass processing. Furthermore, most of these packages are designed to solve steady-state mass and energy balances on a plant-wide scale only. Quite obviously, this is rather not sufficient for the design of the dynamic, multi-scale models required for biorefineries. Fortunately, many of those issues have been addressed in non-commercial modelling suites like, for example, ModKit (Bogusch et al., 2001) and ProMo (Preisig, 2021).

Since strategic, tactical and operational decision tasks have to be considered together in the design and operation of biorefineries, jack-of-all-trades modelling efforts are a necessity, targeting not only commercial feasibility and operational safety but also social and environmental sustainability (Sikdar, 2003). This high degree of interconnectivity is further reflected by the study of Corona et al. (2018), in which maximising product yields proved to be the most important environmental optimisation parameter for green biorefineries, even more important than reducing energy consumption. The secret to sustainability hides, after all, in the optimisation of processes. Hence, LCA studies cannot rely on black-box models but must be coupled to detailed process simulation. Suggested by Julio et al. (2017), those simulations should be built on multi-objective optimisation algorithms that establish iterative corrections between operational condition changes and the effects on life-cycle aspects.

Although empirical models can offer some understanding of the processes, in-depth process understanding and predictive modelling are the only reliable prerequisites for decision-making tools and to achieve a cost-effective design of biorefineries. This emphasizes the importance of multi-scale modelling approaches from the plant scale down to the molecular level. Holistic models require a more in-depth understanding of the processes, however, once developed, these models can be used for a wide range of processing conditions. Consequently, they enable efficient process optimisation and reliable up-scaling studies.

True process parameter estimates are crucial for the development of robust models. Therefore, non-linear process dynamics that are inherent in complex bioprocesses cannot be circumvented when modelling the plant. While steady-state models can provide accurate results regarding the plant operation on specific loads and are very useful in investigating the sustainable minimum load limit, only dynamic models are reliable sources to evaluate the plant performance, optimizing its operation, and improve its efficiency under the flexible operations inherent to most biorefinery concepts.

A time scale is particularly relevant for biorefineries due to erratic feedstocks and the interdependence of processing and logistics. The feedstock fluctuations must be taken into account in the models, whilst also considering the multitude of possible feedstocks. Early considerations of fluctuant as well as substitutable feedstocks can eventually speed up the design and implementation of economically viable biorefineries.

In conversion processes, kinetic modelling constitutes a critical step. Like any chemical plant, a biorefinery consists of multiple, interconnected equipment units. Thus, any unit's performance is strongly affected by the operation of the others. This underlines the need for the implementation of proper plant-wide control concepts in such complex plants as biorefineries to ensure optimal productivity with the desired specifications. Furthermore, operational issues caused by a lack in adequate instrumentation can often be circumvented by utilising robust predicting models that estimate unavailable process variables.

The complex exigencies on biorefinery models place a high demand on the modellers. This induces an increasing interest in more effective model generation processes that incorporate the various expert's knowledge, which can additionally open up new prospects for many projects and may have the effect of building bridges between different disciplines and people (Preisig et al., 2019).

5. Conclusion

When aiming for condign biorefinery research and development efforts, modelling is not only an option but a necessity. However, the abundance of obstacles to biorefinery modelling led to a research community struggling to implement robust, holistic approaches but relying on empirical models if at all. The pulp and paper domain demonstrated the issue before: Although the significance of models in this field were identified early (Pilati & Rosen, 1978), a lack of model utilisation and a thereby caused stagnation have been reported even decades later by studies like Blanco et al. (2009). Similarly, if the biorefinery community's current state is not abandoned but prolonged into the next scientific generations, biorefinery research will be hampered for decades to come, thus failing to comply with the urgency of attaining sustainable industries.

Simulation of a Fischer-Tropsch reactor for jet fuel production using Aspen Custom Modeler

Alejandro Morales^a, Gregoire Leonard^a

^a*Chemical Engineering, University of Liège, Belgium.*

Abstract

The reduction of CO₂ emissions is a key aspect to the world energy transition. Fischer-Tropsch (FT) technologies can contribute to lower our CO₂ emissions to the environment by transforming captured CO₂ into a wide array of hydrocarbon chains. Under optimized conditions, the reaction yields a high concentration of long carbon chains; which in turn, can be further upgraded into jet fuel. Thus, difficult to electrify sectors of the economy such as the aviation sector could have a defossilized supply of fuel; provided that the feedstock required for the reaction originates from low-carbon energy. In this context, the objective of the present research is to design, install, operate and optimize a FT reactor to serve as core of a future Power-to-Jet Fuel pilot-scale implementation at the University of Liège (ULiège). The first step was to select from the literature the stoichiometry and the kinetics that accurately depict the FT reaction. In this study, the kinetics reported by Iglesia et al. (1993) and the stoichiometry proposed by Hillestad et al. (2014) were selected and implemented in a simulation model developed using Aspen Custom Modeler (ACM). This model was then validated by simulating a computational FT implementation reported in the literature by Tomte (2013). Once validated, the parameters are used to simulate a FT pilot reactor having an inlet of 62 mol H₂/h and 29.5 mol CO/h, in compliance to the electrolysis capacity available at the ULiège. The results portray a production of 0.3 mol/h C₁₂₋₂₀ chains that could be further upgraded to jet fuel and a conversion of almost 50% of CO towards the FT reaction. In future work, the ACM model of the FT reactor will serve as input for a more complex process model of the Power-to-Jet Fuel production chain, further improving conversion efficiency.

Keywords: Fischer-Tropsch, Jet Fuel, Aspen Custom Modeler, Simulation.

1. Introduction

The European Commission aims to lower CO₂ emissions by 55 % compared to 1990 by 2030. In 2016, the aviation sector accounted for 3.6% of overall emissions and 13.4% of transport emissions in the EU (EASA et al., 2019). The sector also has the lowest share of renewables, with only 6% (European Commission, 2020). Thus, innovative alternatives such as using green hydrogen as fuel or producing jet fuel in sustainable ways are considered to defossilize this means of transportation. Sustainable jet fuel could become an adequate substitute of its traditional counterpart by providing at least 70% life-cycle carbon reductions (Sustainable Aviation, 2019).

The present study is carried out in the framework of further improving the Power-to-Jet Fuel value chain. By utilising hydrogen and carbon monoxide as feedstock, a FT reactor synthesizes jet fuel as liquid energy vector. This chemical pathway is rendered more sustainable when the hydrogen is produced from renewable energy sources via water

electrolysis; and the carbon monoxide is obtained from the Reverse Water Gas Shift (RWGS) of said hydrogen and captured carbon dioxide.

Although the production of sustainable FT fuels has already been studied (e.g. Loewert et al., 2019; U. Pandey et al., 2021), most of these studies do not focus on the maximization of jet fuel production. Moreover, previous studies mostly focus on reaction modelling, and less work has been carried out regarding process study. To do so, the present work uses ACM. First, it allows to make use of the vast properties database that AspenTech provides and second, it allows a detailed modelling of the reactor with complex kinetics associated to different catalysts and reactor configurations. In further work, the reactor model will then be included into a complete process model developed in Aspen Plus. Thus, it will be easier to understand the challenging interactions between the synthesis section and other process steps (RWGS, product upgrade, recycling loop...).

In this paper, the main properties of the reaction and modelling assumptions are first portrayed. Then, the simulation is validated by comparison with a model developed by Tomte at the Norwegian University of Science and Technology (NTNU). Finally, the FT reactor model is scaled down in compliance to the electrolysis capacity available at the ULiège, corresponding to a pilot-scale reactor.

2. Model description

The FT reaction results in a wide array of hydrocarbon products. Jet fuel, the main focus product of this present study, has a desirable composition of 75-85 vol% consisting of paraffins, iso-paraffins and cycloparaffins and the remaining 15-25% of olefins and aromatics. Jet fuel also encompasses hydrocarbon chains of 12 to 20 carbon atoms (Doliente et al., 2020). There are many technological configurations that enable the FT reaction but to maximize the production of C₁₂₋₂₀ chains the use of low temperatures (200-230°C) as well as cobalt as catalyst is preferred (Dieterich et al., 2020).

The developed reactor model uses kinetics from Iglesia et al. (1993) further adapted by Panahi et al. (2012); and the stoichiometry proposed by Hillestad et al. (2014) based on the Anderson-Schulz-Flory (ASF) distribution. The ASF model proposes a statistical distribution of FT products based on the chain growth probability (α). The Hillestad stoichiometry makes some simplifications. It only considers the methanation reaction in parallel to the FT reaction and the production of linear paraffins by the FT reaction (Table 1). Likewise, it models all products with carbon atom number below 21 as individual units. On the other hand, components with carbon atom number from 21-30 were put together in a component designated C₂₁₊. The lumped component C₂₁₊ is modelled as C₃₀H₆₂ due to similar properties.

For low-temperature cobalt FT, a constant α value of 0.9 is assumed, as done by Hillestad. Based on Eq. 1, this leads to a H₂/CO ratio (Z) of 2.1. By using Eq. 2 and Eq. 3, the ASF coefficients for every single potential hydrocarbon that can be produced via FT are estimated. These coefficients are then used in Eq. 4 to provide the full stoichiometry of the FT reaction. Additionally, Eq. 5 provides the stoichiometry for the methanation reaction.

$$Z = \frac{H_2}{CO} = 3 - \alpha \quad (1)$$

$$ASF \text{ coefficient}_i = (1 - \alpha)^2 * \alpha^{i-1} \quad \text{for } C_i, i = 1, 2, 3 \dots 20 \quad (2)$$

$$ASF \text{ coefficient}_{21+} = (1 - \alpha) * \alpha^{20} \quad \text{for } C_{21 \rightarrow 30} \quad (3)$$

Table 1. Reactions in parallel in the FT reactor.

FT reaction:	$CO + Z H_2 \rightarrow \sum_{i=1}^{20} (ASF \text{ coefficient})_i C_i H_{2i+2} + (ASF \text{ coefficient})_{21+} C_{30} H_{62} + H_2 O \quad (4)$
Methanation reaction:	$CO + 3 H_2 \rightarrow CH_4 + H_2 O \quad (5)$

The Iglesia kinetics modified by Panahi, portrayed by Eq. 6 and Eq. 7, provide reaction rates in $\text{kmol/m}^3 \cdot \text{s}$ for the methanation (r_{CH_4}) and FT (r_{FT}) reactions respectively. With k_i being kinetic constants reported by Panahi and P_{H_2} & P_{CO} being the partial pressure for hydrogen and carbon monoxide. The kinetics are valid for a range of temperature between 200 and 210 °C, 100 to 3000 kPa and a $Z = H_2/CO = 1$ to 10.

$$r_{CH_4} = \frac{k_1 P_{H_2} P_{CO}^{0.05}}{1 + k_3 P_{CO}} \quad (6)$$

$$r_{FT} = \frac{k_2 P_{H_2}^{0.6} P_{CO}^{0.05}}{1 + k_3 P_{CO}} \quad (7)$$

For all models the reactor length is discretized in 5 sections and mass and heat balances are evaluated for each one of them.

3. Validation model

The Tomte study performed at NTNU (Tomte, 2013) is taken as main reference for the validation of the simulation. It simulated a Gas-to-Liquid (GTL) plant capable of achieving a similar production capacity to that of the Bintulu GTL plant, 14700 bbl/day. In the present study, only the FT reactor of the plant will be analyzed and simulated. Similar inlet conditions as in the reference model were chosen (Table 2). The Tomte study does not report the molar fractions of each of the components at the inlet flow of the reactor but the molar flow of groups of hydrocarbon chains (C_{1-2} , C_{3-4} , C_{5-11} , C_{12-20} , C_{30}); thus, an estimate was calculated for each one of them. It is important to highlight that there is presence of products in the inlet flow of the reactor as a recycle is used to further improve the conversion of the reactor.

Due to the highly exothermic nature of the FT reaction and to keep the reaction as close to isothermal as possible, the Tomte study used pressurized liquid water at 220°C to exchange heat with the reactor. A very large but not specified molar flow was used to keep the cooling water at a constant temperature. As no additional information is

provided, for the present study an overall heat value coefficient of $400 \text{ W/m}^2\cdot\text{K}$ was chosen for the heat balance of the system (M. Boda et al., 2017).

The Tomte study implemented a 1000 m^3 multitubular fixed bed reactor but does not provide additional information; thus, the dimensions of the reactor had to be estimated as well. A patent for a gas phase reaction multitubular fixed bed reactor (G. Olbert et al., 2007) states that these reactors have in between 10000 to 30000 catalytic tubes. These tubes have an internal diameter between 20 mm and 35 mm and a length of 1.5 to 7 m. By following these design parameters and keeping the same reaction volume as the Tomte study, a train of 16 reactors in parallel with 28500 catalytic tubes each is chosen. The catalytic tubes have an internal diameter of 20 mm and a length of 7 m each. Due to the low pressure drop reported by Tomte, these reactors are assumed isobaric. The chosen configuration achieves a similar outlet temperature and molar product flows from the reactor as the Tomte study (Table 2). It is worth highlighting that a similar configuration is used in the Pearl GTL plant in Qatar. This plant has 24 reactors, each containing 29000 catalytic tubes, and achieves a production of 140000 bbl/day (Shell, n.d).

Table 2. Inlet and outlet conditions of the validation model and comparison with the Tomte study.

Variable	Units	Inlet stream	Outlet, this work	Outlet, Tomte (2013)	Relative difference (%)
Total molar flow	kmol/h	46563.2	34895.6	34228.03	1.95
Molar flow CO		12183.5	6349.68	6015.95	5.55
Molar flow H ₂		25595.8	13073.9	12354.56	5.82
Molar flow C ₁₋₂		3472.67	3882.25	3908.84	0.68
Molar flow C ₃₋₄		132.19	215.18	223.78	3.84
Molar flow C ₅₋₁₁		195.56	383.68	385.27	0.41
Molar flow C ₁₂₋₂₀		0	110.65	112.55	1.69
Molar flow C ₃₀		0	66.39	71.07	6.59
Molar flow H ₂ O		4988.41	10822	11156.01	2.99
Temperature		°C	210	221.4	221.8
Pressure	Bar	20	20	19.4	3.09

Due to the close proximity of the results (less than 7% deviation for partial flowrates), it was possible to confirm that the simulation was validated. The slight differences between the results could be attributed to the fact that the Tomte study does not report the exact compositions of each of the components at the inlet flow of the reactor, as previously

stated. It can also be attributed to neglecting pressure drops in the reactors. Likewise, the temperature profile of the Tomte reactor is not presented in the study.

4. Case study - ULiège model

Once the FT kinetics and stoichiometry have been validated in the previous section, the model is scaled down to integrate the operating conditions of a pilot-scale project at ULiège. The feed of the ULiège model is composed only of hydrogen and carbon monoxide; although, it is planned that future work will explore the influence of a recycle into the reactor. The hydrogen feed is based on the total hydrogen production capacity of the 3 electrolyzers at ULiège, 62 mol H₂/h. Based on the Z ratio used so far, a molar flow of 29.5 mol CO/h is required. As previously mentioned, the Iglesia kinetics work better in a range of 200 - 210 °C; therefore, a fixed bed reactor with a cooling jacket having a high inlet flow of water at 210°C is chosen (instead of 220°C as implemented in the validation model). The same overall heat coefficient, inlet temperature and inlet pressure are used as in the validation model. No pressure drops are considered in this model either.

A reactor volume of 2.5 L (having an internal diameter of 0.05 m and a length of 1.275 m) is chosen. This volume yields a 49.01% conversion of the inlet CO through the FT reaction and 2.57% through methanation. The rest remains unreacted, 13.95 mol/h. These conversion values are similar to the ones reported by Tomte and the validation model. Figure 1 displays the production of FT products inside the reactor. A molar flow of 0.3 mol/h of C₁₂₋₂₀ chains that could be further upgraded to jet fuel is achieved. Figure 2 displays the temperature profile, the temperature is kept close to 210°C as intended.

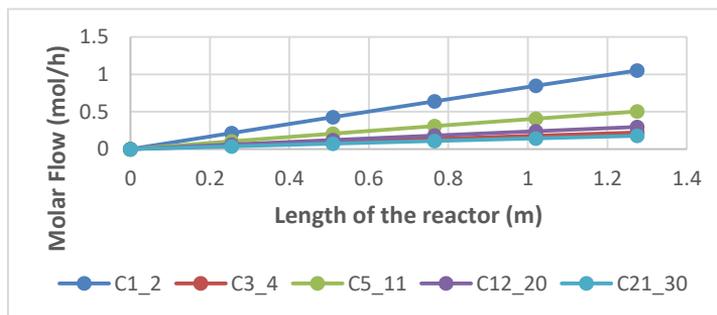

Figure 1. Molar flow of FT products of the ULiège model.

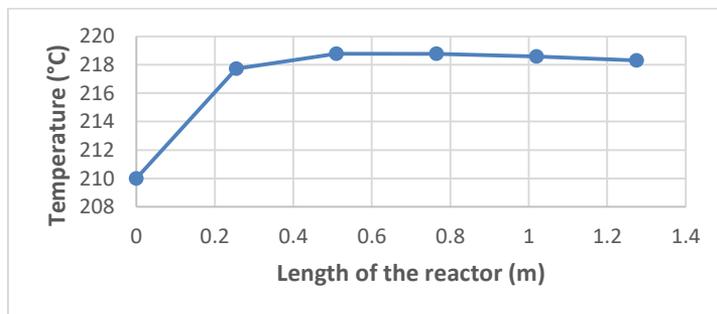

Figure 2. Temperature profile of the ULiège model.

5. Conclusions

The kinetic model of Iglesia (Iglesia et al., 1993) and the stoichiometry proposed by Hillestad (Hillestad, 2014) for the FT reaction were validated using ACM by obtaining the same results as the Tomte study (Tomte, 2013), which in turn modelled a GTL plant with a capacity of 14700 bbl/day. The hydrogen production capacity available at ULiège was then used as guideline for a scaled-down design of a FT pilot reactor.

Future work will focus on further improving the accuracy and the performance of the simulation for jet fuel production maximization. A sensibility analysis will be performed on multiple process variables to determine their influence on jet fuel production. Some of the variables to consider are: the temperature, volume and pressure of the reactor; the cooling medium and its temperature; the catalyst and its configuration; and the recycle ratio of the outlet flow of the reactor. In parallel, new models will be developed using more detailed kinetics. For example, they will comprise other products other than paraffins (e.g. olefins) and will evaluate α as a function of the temperature of the reactor and other operation conditions. Later phases will focus on improving the integration of the carbon capture, electrolysis, RWGS, recycle and post-treatment sub-processes to the reactor.

Abstract

Biodiesel and bioethanol play an important role as renewable liquid fuels. The production of these biofuels generates low-value by-products, such as sugarcane bagasse (usually used for heat generation). This bagasse can be processed to produce a sugarcane bagasse hemicellulose hydrolysate (SCBH) that contains fermentable sugars, mainly xylose. Oleaginous yeasts (eg., *Rhodotorula toruloides*) can grow in this SCBH producing microbial oil (MO) which can be used as raw material for biodiesel production. This strategy arises as a promising approach to exploit a synergy between bioethanol and biodiesel production processes within a biorefinery. Since techno-economic-environmental analysis (TEEA) can identify bottlenecks, providing insights concerning feasibility and sustainability of processes, in this work TEEA was applied to a study case consisting of a MO production from SCBH integrated into a first-generation (1G) bioethanol plant. The 1G section of the plant – processing 4×10^6 t of sugarcane per season (240 days) - produces bioethanol and bioelectricity generating a surplus bagasse, which is sent to the MO production. Net present value and internal rate of return were chosen as the economic metrics and global warming potential as environmental one for evaluating the process options simulations. The main result of this study had the plant producing 74.8 m³/h of bioethanol, 2.8 t/h of MO, and 89.3 MW of bioelectricity. The integrated process exhibited a positive economic performance (net present value equals to US\$ 34.5×10^6 and internal rate of return of 12.4%) indicating that the microbial oil production from sugarcane is feasible. From the environmental perspective, a decrease of 13% in GHG emissions was obtained.

Keywords: microbial oil, biorefinery, techno-economic analysis, modelling and simulation.

1. Introduction

The diversification of energy matrices is of vital importance in slowing down climate change effects caused by use of fossil fuels. In order to simultaneously mitigate climate change in transport and chemical sectors and reduce the dependence on oil, alternative

production chains are necessary. Biomass is considered as the primary emerging option to replace the fossil fuel resources, since it can deliver energy and multiple products through of the biorefineries. These facilities are integral to supporting a knowledge-driven and environmentally robust circular bio-economy (Awasthi et al. 2020).

The established sugarcane mills in Brazil are biorefineries, since they produce bioethanol, sugar, power, fusel oil, yeast biomass, and other products. However, there still a potential for improvement of this process. One example is the integrated production of bioethanol and biodiesel, since these biofuels play an important role as renewable sources of energy for transport and they are an attractive solution for reducing global warming (GWP), energy crisis, and fossil fuel depletion (Souza and Seabra 2014). Sugarcane bagasse, a by-product of the sucrose and ethanol production, can be processed to generate a sugarcane bagasse hemicellulose hydrolysate (SCBH) that contains fermentable sugars, mainly xylose. Oleaginous yeasts (eg., *Rhodotorula toruloides*) can grow in this SCBH producing microbial oil (MO) which can be used as raw material for biodiesel production. Therefore, such MO production does not compete with food supply and arable land is not required (Bonturi et al. 2017).

The integration of MO production into a first-generation (1G) bioethanol production plant could decrease this lipid cost due to the easier availability of raw material, utilities (steam and electricity), effluent treatment, and disposal and logistic distribution. Therefore, the objective of this study was to applied the techno-economic-environmental analysis (TEEA) to a study case consisting of a MO production from SCBH integrated into a first-generation (1G) bioethanol plant in order to evaluate the feasibility of MO production from byproducts generated in the bioethanol process.

2. Methods

2.1. Process modelling and simulation

EMSO (Environment for Modelling, Simulation and Optimization, Soares and Secchi (2003)), an equation-oriented simulator, was used to carry out the simulations. The TEEA was performed considering the implementation of the MO production process integrated into a 1G bioethanol plant. The modelled biorefinery (Figure 1) can produce 1G bioethanol from sugarcane juice, MO from bagasse, and electricity from bagasse and residues in an integrated process.

The process data used in the 1G simulation were based on Elias et al. (2021). The bagasse obtained after milling is diverted into two fractions. The first one is fed in the boiler (Elias et al. 2021) and the second one is used for MO production. The bagasse diverted to MO production undergoes a diluted acid pretreatment to solubilize the hemicellulose fraction. This is carried out at solid to liquid ratio 1:10 (10% w/v of bagasse in 1.5% (w/v) H_2SO_4) for 60 min at 121 °C. The pretreated mixture cooled to 80 °C is filtered. The solid fraction is sent to the combined heat and power sector and the liquid fraction is concentrated to 55 g/L of xylose in an evaporator at 80 °C. The obtained SCBH is directed to the MO production by the oleaginous yeast *R. toruloides* in a bioreactor for 120 h at 30 °C with the operating conditions described in Lopes et al. (2021).

Yeast suspension from the bioreactor is concentrated through centrifuge operations. The moisture content of the microbial cells is reduced to 1% using a spray dryer. The dried cells are mixed in a tank with hexane (25% w/w) and directed to the high-pressure homogenizer in order to disrupt cells and release the intracellular lipids (Koutinas et al. 2014). The homogenate is then suspended in hexane and sent to a decanter, where the

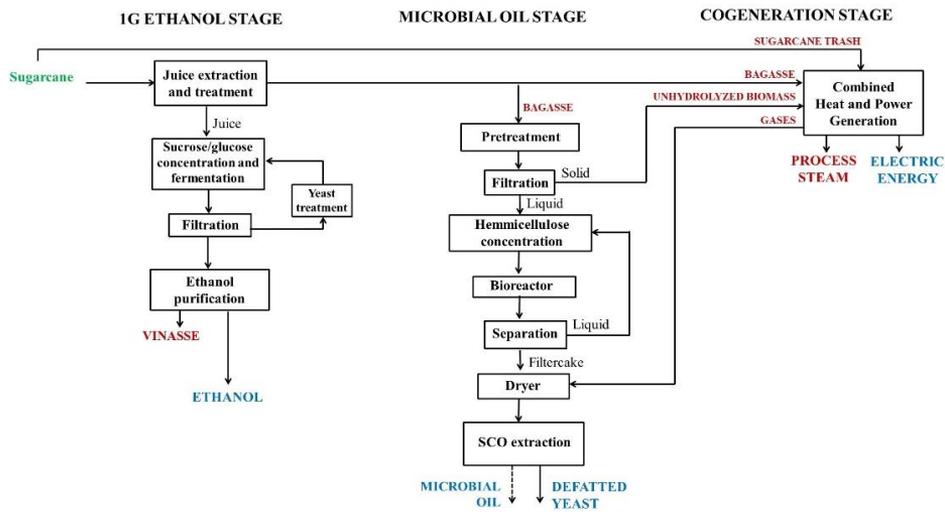

Figure 1. Simplified process diagram of the integrated bioethanol-bioelectricity-MO sugarcane biorefinery

defatted biomass is separated from the MO containing hexane. The MO is recovered from the organic solvent in an evaporator (Vieira et al. 2016) and the hexane is recycled.

2.2. Environmental analysis

The life cycle assessment (LCA) implemented in EMSO considered the climate change impact category using the GWP under a horizon of 100 years – GWP100. This metric is indicated in Renovabio, a Brazilian federal biofuels policy (Grassi and Pereira 2019). It was performed an inventory of inputs, outputs and emissions based on process simulation (item 2.1), agricultural data (Potrich et al. 2020), transporting and burning steps under a cradle to grave scope. The functional unit was defined as 1 MJ of bioethanol and impacts are allocated based on energy. SimaPro 8.4 software and Ecoinvent database 3.0 (Wernet et al. 2016) were used to for raw materials inputs. The average logistical distance of transport in the road modal was considered to be 700 km for bioethanol resulting in transport emissions of 0.80 CO_{2eq}/MJ. The emissions of 0.44 CO_{2eq}/MJ were considered for the biofuel burning step (Matsuura et al., 2018).

2.3. Economic analysis

The economic analysis was also implemented in EMSO coupled to the process model. The integrated plant processes 4 million tons of sugarcane per year operating 5040 h per year (Elias et al. 2021). Capital Expenditure (capex) were estimated from industrial information (personal communication) and data reported in the literature (Koutinas et al. 2014; Vieira et al. 2016) adjusted for inflation (Peters, Timmerhaus, and West 2002). The final investment included the costs of equipment and their installation, civil construction, electricity installation, instrumentation, land, and engineering. The price of the MO is US\$ 1.077/kg (Vieira et al. 2016). Other relevant costs were US\$ 0.535/L of ethanol, US\$ 68.758/MWh of electricity, US\$ 0.352/kg of defatted biomass, US\$ 17.853 US\$/t of sugarcane, US\$ 7.712/t of sugarcane straw. The CO_{2eq} saved, the carbon credit, was estimated. The price of US\$ 5.203 US\$ per t of CO_{2eq} saved was assumed (B3, 2021). Brazilian foreign trade statistics platform (ComexStat 2020) was used for others inputs

and outputs costs and Oliveira et al. (2018) was used for utilities price. Results of the economic analysis were reported in terms of net present value (NPV) and internal rate of return (IRR) (Peters, Timmerhaus, and West 2002). The economic evaluation is based on the following hypothesis: construction and startup period of 24 months; project lifetime of 25 years; discount rate of 11%; 100% of outlay of investment in the first year; linear depreciation over 10 years; no salvage value of direct fixed capital; maintenance of 3.0% of capex per year; tax rate of 34%; working capital of 10% of capex, and values at an exchange rate from Brazilian currency real to US dollar of 3.89 R\$/USD (BCB, 2020).

3. Results and discussion

The integrated plant produces 74.8 m³/h of bioethanol (333.1 million of L/year of bioethanol), 89.3 MW of electric energy and 2.8 t/h of MO (13,001 t/year of MO). Considering that about 1 t of biodiesel is produced from 1 t of lipid (Pimentel and Patzek 2008), this amount of MO has the potential to generate 13,001 t of biodiesel. This biofuel can be used to substitute the diesel in the agricultural operations without engine modification integrating and connecting the agricultural and industrial fields (Ogunkunle and Ahmed 2019). Considering an average specific consumption of 4 L of diesel per ton of sugarcane (Seabra et al. 2011), the biodiesel from MO could replace about 80% of the total diesel consumption in the sugarcane plant.

The total emissions of 23.38 g CO_{2eq}/MJ of ethanol were obtained from biorefinery assessed. This represent a decrease of 6.6% in GHG emissions when comparing with the emissions from traditional 1G bioethanol process estimated by Junqueira et al. (2017) (25.03 g CO_{2eq}/MJ of ethanol considering the cradle-to-grave analysis of the 1G-base scenario). When compared with the emission of the gasoline process (emissions of 87.4 g CO_{2eq}/MJ of gasoline) (Grassi and Pereira 2019) this value represented a reduction by over 73% , saving about 540 · 10³ t of CO_{2eq} per year. The reduction in the emissions is observed because the integrated plants present higher energy yields (higher energy production per unit of biomass). The decrease in climate change impacts when MO is produced integrated into a 1G plant indicated that energy efficiency improvements in the industrial process are imperative for the improvement in the sustainability of sugarcane biorefineries in Brazil.

The economic assessment (Table 1) was performed in order to evaluate the feasibility of the integrated bioethanol-bioelectricity-MO production from sugarcane. It can be realized that the process is economically feasible, since the NPV is positive and the IRR is higher than the discount rate applied (11%). However, the feasibility of the integrated bioethanol-bioelectricity-MO production is achieved mainly because 1G bioethanol process is a traditional, established, and highly profitable industry. It should be highlighted the importance of the carbon credits representing 1.02% of the annual sales of the plant, and indicating that the environmental performance have a direct impact on the economic profitability of the biorefinery. As MO production systems from *R. toruloides* are still at an early stage of development, the TEEA results can be further improved with the development of each step of the process. Therefore, further improvement of the MO process performance could enforce the potential for the MO use as a sustainable resource for biodiesel production.

Table 1. Economic assessment of the integrated biorefinery

Parameter	Value
Capex	
Total (US\$ · 10 ⁶)	318
Sugarcane reception, juice extraction, and evaporation (%) ^a	14.4
Combined heat and power (steam and electricity) (%) ^a	32.3
Ethanol production (fermentation, distillation/dehydration) (%) ^a	18.2
Pretreatment, hemicellulose separation and concentration (%) ^a	3.01
MO production (bioreaction and separation) (%) ^a	20.03
MO extraction and purification (%) ^a	0.52
Others costs (%) ^a	11.45
Annual operating costs (US\$ * 10 ⁶ /year)	198
Annual sales	
Total (US\$ · 10 ⁶)	274
Bioethanol (%) ^b	73.7
Bioelectricity (%) ^b	11.3
MO (%) ^b	5.57
Defatted yeast (%) ^b	8.41
Carbon credit (%) ^b	1.02
NPV (US\$ * 10 ⁶ /year)	34.5
IRR (%)	12.4

^a Percentage of the total industrial investment; ^b Percentage of the annual sales.

4. Conclusions

A techno-economic and environmental assessment was performed considering the implementation of the MO production process integrated to a 1G bioethanol plant. The integrated plant was able to produce 74.8 m³/h of bioethanol, 2.8 t/h of MO, and 89.3 MW of bioelectricity. The integrated process exhibited a positive economic performance (NPV equals to US\$ 34.5x10⁶ and IRR of 12.4%) indicating that the microbial oil production from sugarcane is feasible. From the environmental perspective, the decrease in GHG emissions was 13%.

Abstract

Reactive distillation (RD) is the integration of reaction and thermal separation in one piece of equipment. Structured catalytic packings have been developed for this application, but their simulation and design are often limited to manufacturer software. Studies in the literature that rely on process simulation using Aspen Plus typically assume that the RD equipment has trays partially filled with catalyst, and do not take into consideration the pressure drop across the column. This simplification, in turn, affects the temperature profile and the reaction kinetics of the column, which might lead to simulation results that would be unfeasible, due to catalyst degradation. In this work, a custom model was developed for hydrodynamic modeling of the Katapak-S packing in Aspen Plus. The model was validated using literature data on pressure drop and holdup for the water-air system and the esterification of lactic acid with ethanol over Amberlyst-15, showing a good fit between the literature data and the model results. Therefore, the model offers a more representative description of RD columns and serves as a tool for the holdup, pressure drop, and diameter sizing in Aspen Plus simulations.

Keywords: Aspen Plus, Structured packing, Katapak, Reactive distillation

1. Introduction

Reactive distillation (RD) is a successful application of process intensification concepts, in which catalyzed reactions and distillation take place in a single equipment. Such a combination may be beneficial to overcome equilibrium limitations of reactions, and separate azeotropes based on the differences between the reaction rates of the substances forming the azeotrope with another reaction (Kiss et al., 2019). RD can be held in structured catalytic packings, which are modular hybrid structures composed of separation and reaction elements assembled in an alternate sequence. The commercial Katapak-S packing, commonly used in RD, is characterized by separation elements made of corrugated sheets of distillation layers, and reaction elements consisting of catalytic baskets filled with catalyst particles (Viva et al., 2011).

The hybrid structure of the catalytic packing influences the flow development in the packed bed, as well as the reactive and separation performances of the RD column. Parameters such as the holdup inside the catalytic baskets and corrugated sheets and the pressure drop across the column (Viva et al., 2011) must be monitored and represented via process simulation, but several works in the literature adopt simplifications that affect the temperature profiles and reaction kinetics of the column, leading to unfeasible simulation results. For example, Gudena et al. (2013) used the Mellapak-250Y properties in Aspen Plus to calculate column pressure drop and holdup using the

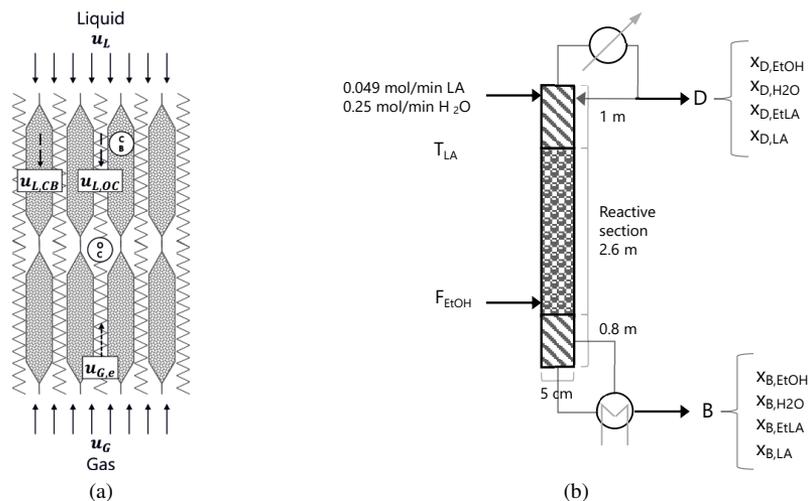

Figure 1: (a) Packing representation. Adapted from Hoffmann et al. (2004); (b) Pilot-scale RD column configuration. Experimental setup from Asthana et al. (2005)

Stichlmair method to simulate a hybrid reactive stripper-membrane process for methyl lactate hydrolysis, which has resulted in the overestimation of pressure drop (Ratheesh and Kannan, 2004). Su et al. (2013) performed simulation on lactic acid esterification in Aspen Plus assuming that the column trays are partially filled with catalyst, but they do not provide enough information regarding reaction holdup in their simulations. Therefore, the development of more rigorous models for RD simulation is required.

This work developed a custom model in Aspen Plus for the rigorous hydrodynamic simulation of the Katapak-S packing in an RD column, which was further validated against experimental data. Model validation was conducted with literature data on pressure drop and holdup for the water-air system and the esterification of lactic acid with ethanol over Amberlyst-15. The good fit between the literature data and the model results demonstrate that the custom model developed in this work offers a more representative description of RD columns and serves as a tool for RD column sizing and performance evaluation in the Aspen Plus platform.

2. Methods

To estimate the liquid holdup, pressure drop, and column diameter, the Katapak SP-12 packing characteristics were applied in a user model subroutine in the rigorous distillation model Radfrac in Aspen Plus v10. Table 1 and Table 2 show the equations and packing parameters used in the Aspen Plus packing user model, respectively. The modelling is based on the work of Ratheesh and Kannan (2004), who obtained the experimental correlations to determine the loading point and the pressure drop profile for liquid velocities in the range between 0.001 and 0.008 m/s. Figure 1a shows a representation of the catalytic packing, where CB represents the catalyst bags and, OC, the open channels.

The gas is assumed to flow only in the open channels, while the liquid flow is distributed in the open channels and the catalyst bags. An important variable in the design of packed columns is the gas loading velocity ($u_{G,LP}$, Equation 11), i.e., the gas flow rate that causes the holdup to increase from a constant value at a given liquid flow rate. The loading point distinguishes two different flow regimes, that are treated separately. Below the loading point, the liquid holdup (h_{LP} , Equation 13)

Table 1: Equations used in the Aspen Plus packing user model

Parameter Ref.	Definition	
Effective gas velocity ^a	$u_{G,e} = \frac{u_G}{\epsilon_{OC} \sin \alpha}$	(1)
Liquid load; Liquid superficial velocity ^b	$u_L = u_{L,CB} \phi + u_{L,OC} \epsilon_{OC}$	(2)

	$f = \frac{0.628}{Re_g^{0.131}}, \text{ for } Re_g > 1500$	(19)
Gas phase Reynolds number ^c	$Re_g = \frac{d_H u_{G,e} \rho_g}{\mu_g}$	(20)
Irrigated pressure drop below the loading point ^c	$\left(\frac{\Delta P}{\Delta Z} \right)_{irr} = 1.941 (h_{LP})^{0.446} \left(\frac{\Delta P}{\Delta Z} \right)_0^{1.12}$	(21)
Irrigated pressure drop above the loading point ^c	$\left(\frac{\Delta P}{\Delta Z} \right)_{irr} = 0.6208 \rho_L g u_L^{0.815} (u_g \sqrt{\rho_g})^{4.183}$	(22)

^a Ellenberger and Krishna (1999) ^b Moritz and Hasse (1999) ^c Ratheesh and Kannan (2004) ^d Hoffmann et al. (2004)

is independent of the gas velocity and pressure drop, and it has two contributions: one in the open channels ($h_{L,OC}$) and another in the catalyst bags ($h_{L,CB}$). Due to difficulties in reproducing the equations reported by Ratheesh and Kannan (2004) for the liquid holdup, Equations 14 and 15 were based on the work of Hoffmann et al. (2004) for MULTIPAK packing. The pressure drop is calculated in terms of gas and liquid flow contributions, where the irrigated packing pressure drop is determined as an enhancement of the dry gas pressure drop $\left(\frac{\Delta P}{\Delta Z} \right)_0$, which is measured when only air flows upwards in the packing (Ratheesh and Kannan, 2004).

Above the loading point, the pressure drop is correlated in terms of liquid and gas superficial velocities (Equation 22) and the liquid holdup (h_L , Equation 16) is calculated as a function of the pre-loading holdup (h_{LP}) and the pressure drop. For design and rating purposes, the maximum capacity is defined as the operating point at which a pressure drop of 1200 Pa/m of packing is obtained. So, the approach to the maximum capacity is defined as the ratio between the superficial gas velocity and the velocity that would result in the 1200 Pa/m pressure drop. Also, an iterative procedure is used in the *Design Spec* tool of Aspen Plus. The reaction holdup in the reactive stages is recalculated based on the holdup in the catalyst bags determined from the hydrodynamic model ($h_{L,CB}$) and the calculated diameter to satisfy the approach to maximum capacity.

The lactic acid esterification (Equation 23) in an RD column (Figure 1b) was simulated using the pseudo-homogeneous kinetic model (Equation 24) for the liquid-phase reaction using the Amberlyst-15 ion-exchange resin (Delgado et al., 2007) for an assumed catalyst bag void fraction (ϵ_{CB}) of 0.35 and an Amberlyst-15 density of 608 kg/m³ (Yu et al., 2004). The temperature dependence of the kinetic constant k_e was determined in the range from 328 to 360 K (Equation 25), and the activity-based equilibrium constant K_{eq} estimated by Pereira et al. (2008) (Equation 26) was used. To model the vapor-liquid equilibrium, the non-random two-liquid (NRTL) activity coefficient model was used for the liquid phase and the Hayden-O'Connell equation of state was used for the vapor phase, using the parameters from Marchesan et al. (2021).

$$r = k_e \left(a_{LA} a_{EtOH} - \frac{a_{EtLA} a_{H_2O}}{K_{eq}} \right) \quad (24)$$

$$k_e = 1.88 \times 10^8 \left[\frac{\text{kmol}}{\text{s} \cdot \text{m}^3 \text{holdup}} \right] \exp \left(- \frac{58.47 \left[\frac{\text{kJ}}{\text{mol}} \right]}{RT} \right) \quad (25)$$

$$K_{eq} = \exp \left(2.9625 - \frac{515.13}{T} \right) \quad (26)$$

3. Results and Discussion

The validation of the model was performed with the comparison with experimental data for two RD systems, showing good agreement between experimental and simulated results. Figure 2 shows the comparison for air-water systems reported by Ratheesh and Kannan (2004); Götze et al. (2001) as a function of the gas load (expressed in terms of the F-factor, Equation 12). The results show that the model offers a reasonable estimate of the hydrodynamic behavior of the packing, namely the holdup and pressure drop across the column for varying liquid and gas loads. Despite its limitations, it offers a more suitable approximation of industrial applications compared to other models based on tray columns with an estimate of the volume occupied by the catalyst in each tray (Su et al., 2013; Dai et al., 2019; Mo et al., 2011).

 Figure 2: Holdup (a-b) and pressure drop (c-d) at various liquid loads (m³/(m² h)) in comparison with experimental results from (a, c) Ratheesh and Kannan (2004) and (b, d) Götze et al. (2001).

A further validation of the custom model was performed with experimental data of the esterification of lactic acid with ethanol over Amberlyst-15 in the RD column depicted in Figure 1b for three scenarios under varying operational conditions (ethanol molar flow rate, lactic acid feed temperature, and distillate molar flow rate), based on the results reported by Asthana et al. (2005). Table 3 shows that, except for the overrepresentation of the water mole fraction in the bottom stream, the mole fraction estimations produced by the custom model are in accordance with the experimental results. Also, the temperature of the reboiler (close to 80 °C) and the calculated conversions (around 80%) in the three scenarios obtained via simulation were close to the values reported

experimentally. The differences in the composition of the bottom streams can be explained by the formation of lactic acid oligomers in small amounts for the chosen scenarios, which were not included in this study for simplification. Furthermore, Asthana et al. (2005) reported material balances closure of $\pm 7\%$.

4. Conclusion

This work developed a rigorous custom model in Aspen Plus for the hydrodynamic modeling of the Katapak-S packing in reactive distillation columns, considering the effect of performance parameters such as the holdup and the pressure drop. The model was validated with experimental datasets of two different applications (water-air system and esterification of lactic acid with ethanol). This showed that it successfully represents the performance of RD columns with Katapak-S packings for varying applications and process conditions. Therefore, the custom model serves as a reliable tool for future studies on the sizing and performance evaluation of RD columns in Aspen Plus.

Abstract

Computational fluid dynamics (CFD) provides the detailed information about flow and pressure distributions in microdevices, whose importance in the chemical process industry has increased in recent years. However, since CFD requires a considerable computational time, the use of a simple model different from CFD would be desirable to efficiently investigate the influence of design parameters on the flow and pressure distributions in microdevices. In this study, the previously proposed simple model, which is based on the predictive equation for the pressure loss due to viscous forces, is extended by taking into account inertial forces. A case study on plate-fin microdevices shows that the extended simple model can predict the flow distribution among microchannels with almost the same accuracy as CFD not only under low flow rates but also under high flow rates. In addition, another case study demonstrates that the optimal shape of manifolds of stacked/unstacked plate-fin microdevices with uniform flow distribution is efficiently derived using the extended simple model.

Keywords: Shape design, Microdevices, Simple model, CFD model.

1. Introduction

Microdevices, which are composed of channels on the order of micrometers or millimeters, have large specific surface area and short diffusion distance. Therefore, microdevices are characterized by high-efficiency heat exchange and rapid mixing. There are many reports that these characteristics have improved the reaction performance of organic synthesis, polymerization, particle synthesis, and so on. While expectations are growing that microdevices are used for mass production of chemical materials, it is necessary to develop models for analyzing flow and transport phenomena, optimal design and control methodologies, and sensing and monitoring technologies. The throughput of microdevices is increased by numbering-up, that is, parallelization of channels. At this time, if the flow distribution among the channels is not uniform, the product quality may deteriorate (Delsman et al., 2005). Since the channels are small, it is not realistic to install sensors and actuators in all the channels. Therefore, it is important to appropriately design a flow distributor that bundles the parallelized channels. So far, bifurcation-type (Amador et al., 2004), manifold-type (Commenge et al., 2002), and split-and-recombine-type (Tanaka et al., 2011) flow distributors have been reported. Computational fluid dynamics (CFD) model is often used to predict the flow patterns in the flow distributors and derive optimal design conditions (Tonomura et al., 2004). By comparison with experiments, it has been reported that CFD achieves high prediction accuracy of flow and transport phenomena in microdevices. (Bothe et al., 2006; Zhendong et al., 2012).

The use of CFD model enables rigorous flow simulation, but enormous time and effort is associated with geometric model creation, mesh generation, and calculations. Therefore, an optimal design method based solely on the CFD model may not be realistic. So far, a simple model has been proposed in place of the CFD model (Commengé et al., 2002). This simple model, which is called the conventional simple model in this paper, is based on the formula for estimating the pressure loss of laminar flow in a pipe from the average flow velocity and the pipe size. The pressure and flow velocity distributions over the device are approximated by connecting the compartments to which the conventional simple model is applied. However, since the conventional simple model does not consider the influence of fluid inertia forces, there is a problem that the prediction accuracy decreases for high Re (Reynolds) flow. In this study, the conventional simple model is extended by taking into account inertial forces. The usefulness of the extended simple model is verified through case studies on plate-fin microdevices.

2. Simple Model Development

A schematic diagram of the plate-fin microdevice is shown in Fig. 1. A reactant is fed to the inlet manifold, distributed to the parallelized microchannels, and rejoined at the outlet manifold. The model described in this chapter is used to efficiently design the shape of the device so that the flow distribution among the parallelized microchannels is uniform.

As shown in Fig. 2, the plate-fin microdevice is divided by compartments. Each of microchannels is considered as one compartment, and the inlet and outlet manifolds are divided into as many compartments as the number of microchannels (N [-]). The compartments assigned to the inlet manifold, outlet manifold, and microchannels are called the distribution, junction, and channel compartments, respectively, which are numbered in order from the upstream side. In the distribution compartments, the flow velocity and pressure at the inlet of the i -th compartment are expressed as U_1^i and P_1^i ,

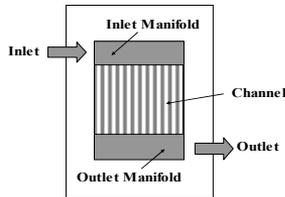

Fig. 1 Plate-fin microdevice.

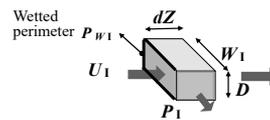

Fig.3 Small volume element for a compartment.

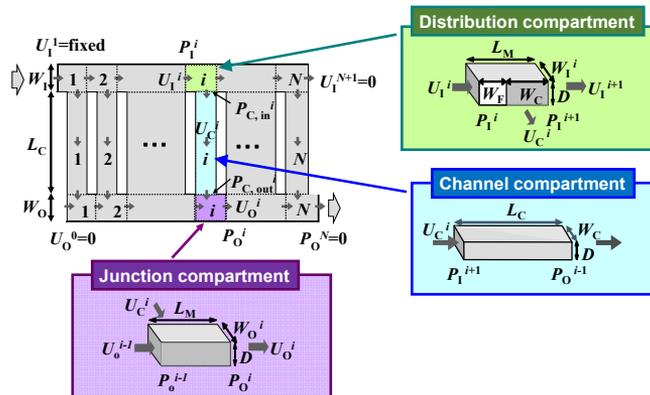

Fig. 2 Compartment-based simple model for plate-fin microdevice.

respectively. In the junction compartments, the flow velocity and pressure at the outlet (after mixing) of the i -th compartment are expressed as U_o^i and P_o^i , respectively. In the channel compartments, the flow velocity, inlet pressure, and outlet pressure of the i -th compartment are expressed as U_c^i , $P_{c, in}^i$, and $P_{c, out}^i$, respectively. Each compartment is assumed to be a rectangular channel having length L [m], width W [m], and height D [m]. The subscript C for each variable is the microchannel, I is the inlet manifold, O is the outlet manifold, and M is both manifolds. W_F [m] is the distance between parallel channels, that is, the fin width. In this study, D is fixed to be constant in all compartments and the z axis is defined in the direction of flow at the inlet. The flow velocity and pressure distributions over the device are predicted on the basis of the mass balance and pressure balance equations among the compartments. The mass balance is expressed by

$$W_1^i U_1^{i+1} - W_1^i U_1^i = -W_c U_c^i \quad 1 \leq i \leq N, \quad (1)$$

$$W_o^i U_o^i - W_o^{i-1} U_o^{i-1} = W_c U_c^i \quad 1 \leq i \leq N. \quad (2)$$

The pressure balance among adjacent compartments is expressed by

$$\Delta P_c^i + \Delta P_o^i = \Delta P_1^{i+1} + \Delta P_c^{i+1} \quad 1 \leq i \leq N - 1. \quad (3)$$

ΔP_c^i is given by the following equation that estimates the pressure drop of a fully developed laminar flow in a rectangular channel.

$$\Delta P_c^i = P_{c, in}^i - P_{c, out}^i = \frac{32\lambda_c \mu L_c}{D_{Hc}^2} U_c^i \quad 1 \leq i \leq N \quad (4)$$

Here, λ_c is the correction coefficient for the cross-sectional shape of the channel, μ is the fluid viscosity [Pa·s], and D_H is the hydraulic equivalent diameter [m]. ΔP_1^i and ΔP_o^i are given by the following equations:

$$\Delta P_1^i = P_1^i - P_1^{i+1} = 8\lambda_1 \frac{(D + 2W_1^i)W_c^i + 2(D + W_1^i)W_F}{DW_1^i D_{H1}^i} \mu U_1^i + 2\rho U_1^i (U_1^{i+1} - U_1^i) \quad (5)$$

$$\Delta P_o^i = P_o^{i-1} - P_o^i = 8\lambda_o \frac{(D + 2W_o^i)W_c^i + 2(D + W_o^i)W_F}{DW_o^i D_{Ho}^i} \mu U_o^i + 2\rho U_o^i (U_o^i - U_o^{i-1}) \quad (6)$$

These equations were derived by formulating the momentum change in the z -axis direction due to pressure loss and shear stress for a small volume element as shown in Fig. 3. On the right-hand side of each equation, the first and second terms represent the viscous and inertia terms, respectively. The feature of this study is that the pressure loss and pressure balance equations are established in consideration of both viscous and inertia terms. The conventional simple model ignores the inertia term, and its application will be limited to low flow rates. When the dimensions of all compartments and the following

are given to the mass balance and pressure balance equations, the number of unknown variables and the number of independent equations are equal to $4N$, that is, the degrees of freedom are 0, and as a result, U_i^i , U_c^i , and U_0^i can be derived.

3. Evaluation of Prediction Accuracy of the Developed Model

A case study on the plate-fin microdevice is conducted to compare the prediction accuracy of the conventional simple model, the developed simple model, and the CFD model. Table 1 shows the design conditions and fluid physical properties. The width of all compartments, W_i^i and W_0^i , is set to be constant at W_M . The remaining design conditions are as follows: $(L_c, W_c) = (20 \text{ mm}, 300 \mu\text{m})$ and $(20 \text{ mm}, 1000 \mu\text{m})$. Under these conditions, flow simulation based on each model is performed for $U_1^1 = 0.001$ m/s, 0.01 m/s, 0.1 m/s, and 0.5 m/s. Ansys Fluent® and gPROMS® are used for calculations based on the CFD model and the simple models, respectively. Comparing the calculation times, the CFD model took tens of minutes to several hours, but the conventional and developed simple models took only 1 to 2 seconds. The flow velocity of each microchannel normalized by flow velocity averaged by all microchannels ($U_{c, \text{ave}}$) is plotted in Fig. 4, where +, □, and ● represents the results of conventional, developed, and CFD models, respectively. The results of CFD model show that as the inlet flow velocity increases, more fluid flows into the microchannels far from the inlet due to the influence of flow inertia. The results of the conventional simple model differ from those of the CFD model, especially when the flow velocity is high. On the other hand, the results of the developed simple model are close to those of the CFD model under any flow velocity condition.

4. Design of Plate-fin Microdevice

The shape design of manifolds of a plate-fin microdevice is carried out. The design conditions are shown in Table 2. The design objective is to minimize the manifold volumes. The manifold shape is optimized under the following constraints: 1) in each microchannel, the relative deviation of the flow velocity from the value under uniform flow distribution is 0.25% or less, 2) the upper limit of the pressure loss of the entire

device is 500 Pa, and 3) the upper and lower limits of the width of the manifolds are 2 mm and 0.2 mm, respectively. The shape of the inlet and outlet manifolds is represented by a piecewise linear function. The design procedure is as follows. First, assuming that the device has a point-symmetrical shape, optimization is performed with the number of sections of the piecewise linear function in both manifolds being 1. If no solution is obtained, the device is considered to have a non-point symmetric shape and optimization is performed. If no solution is still obtained, the design optimization is repeated while increasing the number of sections by 1. As a result of this optimization, the manifold shapes shown in Fig. 5 were derived. Table 3 shows the flow velocity distribution among the microchannels by the simple models and the CFD model. The conventional simple model predicts the achievement of the uniform flow distribution, but this prediction result is not achieved when CFD is executed for the manifold shape derived by the conventional simple model. On the other hand, it is shown that there is almost no difference between the results of the developed simple model and the CFD model.

5. Design of Stacked Plate-fin Microdevices

In addition to parallelizing the channels in one device, it is possible to increase the production amount by stacking the device. In this chapter, the microdevice designed in the previous chapter is stacked. A schematic diagram of the entire apparatus when the number of stacked devices is 10 is shown in Fig. 6. The purpose of this chapter is to design the inlet and outlet headers that realize equal fluid distribution to the stacked devices. The design conditions are as follows: 1) the shape and dimensions of the channels and manifolds of each plate-fin microdevice are equal to the design result in the previous chapter, 2) the thickness of each plate-fin microdevice is 1 mm, 3) the header is a circular tube with a constant diameter, 4) the header and each microdevice are connected by a rectangular duct with depth of 500 μm , width of 2 mm and length of 4 mm, 5) the number of stacked microdevices is 10, 6) total flow rate is 0.5 cm^3/s , 7) assuming that the pressure loss of each microdevice are proportional to flow rate, and 8) the fluid is water (298K). The design objective is to minimize the header volumes. The diameters of inlet and outlet headers are optimized under the following constraints: 1) in each microdevice, the relative deviation of the flow rate from the value under uniform flow distribution is 0.25% or less, and 2) the upper and lower limits of the header diameter are 10 mm and 2 mm, respectively. This optimum design problem is solved using the developed simple model. That is, the stacked microdevices and the headers are regarded as the parallelized microchannels and the manifolds in the developed simple model, respectively, as shown in Fig. 6. As a result of optimization, D_{IN} and D_{OUT} were determined to be 5.24 mm and 5.96 mm, respectively. To verify this design result, CFD simulation was performed. Table

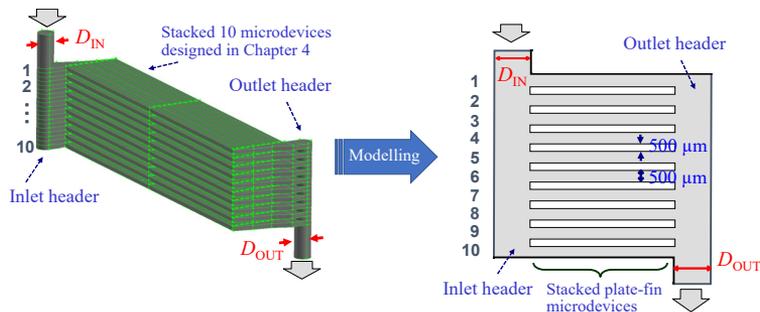

Fig. 6 Stacked plate-fin microdevice (left) and application of the developed model to it (right).

4 shows the flow rate of each microdevice. It was shown that a more uniform flow distribution was achieved after optimization, compared to before optimization ($D_{IN} = D_{OUT} = 2$ mm), and that the predicted flow rates after optimization of the developed simple model and the CFD model were almost the same. Therefore, it was confirmed that the developed simple model is useful not only for the optimal design of the plate-fin microdevice itself but also for the optimal design when it is stacked.

6. Conclusions

The application of microdevices in the chemical process industry has gained significant importance in recent years. The production capacity of microdevices can be increased by numbering-up. Such microdevices often have manifolds that help to guide the fluid into many microchannels. The flow uniformity depends on pressure and flow distributions inherent to the design of manifolds and others. In this study, the compartment-based simple model was developed to realize efficient design. The developed model is composed of mass balance and pressure balance equations among compartments. When establishing pressure balance equation, both viscous and inertia terms were considered in the developed model. The conventional model ignored the inertia term, and as a result, its application was limited to low flow rates. The usefulness of the developed simple model was verified through case studies on plate-fin microdevices at high flow rates.

Abstract

The fixed bed reactor design is traditionally based on a model that assumes a piston flow and regards the fixed bed as homogeneous porosity. This kind of model is often unsuitable for designing fixed bed compact reactors in which wall and local phenomena dominate. In this work, three-dimensional steady-state computational fluid dynamics (CFD) simulation was performed to analyze how the geometric structured packing with spherical particles, reactor diameters, and particle sizes, which are important design variables, influence the conversion and selectivity of a model reaction. The simulation results show that the generation of flow perpendicular to the axis of the reactor leads to the improvement of the reactor performance. In addition, it was suggested that the honeycomb type fixed bed compact reactor is superior to the packing type one in realizing a uniform reaction temperature field and reducing the pressure loss.

Keywords: CFD simulation, Compact reactor, Fixed bed, Fluid dynamics, Heat transfer.

1. Introduction

The market for functional chemicals, including pharmaceutical intermediates, is growing. Currently, functional chemicals are manufactured exclusively by the batch method, and a large amount of waste containing organic solvents is discharged, and energy is consumed to dispose of the waste. In recent years, it has been reported that functional chemicals are synthesized by a flow method utilizing an immobilized catalyst having high selectivity (Tsubogo et al., 2015). It is expected that the use of such a flow method will increase in the future in place of the batch method. In a reaction process with an immobilized catalyst, compact reactors such as microreactors, which are expected to enable rapid mass and heat transfer due to the large specific surface area between different phases, are often used. However, research on fixed bed compact reactors is not sufficient compared to conventional reactors, and their design methods have not been established. Although catalyst development is being actively carried out, the performance of the developed catalyst will not be fully exhibited without consideration of appropriate reactor design. It is important to rationally solve the engineering problems of the fixed bed compact reactors such as temperature control and pressure loss reduction, based on the models, which can quantitatively express mass and heat transfer as well as fluid dynamics.

When analyzing the flow and transport in a conventional reactor, a model that assumes a piston flow and regards the fixed bed as homogeneous porosity is often used. On the other hand, in the case of a fixed bed compact reactor, which is often used for reaction processes involving a large amount of heat of reaction, a model with high prediction accuracy of heat transfer is required to realize strict reaction control. Considering that heat transfer

depends on flow, a model that can analyze local flow and transport is required. Therefore, it is useful to analyze the fixed bed compact reactor based on CFD simulation, which can express the discrete porosity distribution in consideration of an individual shape of catalyst carriers. In CFD simulations of fixed bed conventional reactors, CFD has been considered to be a powerful tool for predicting the hydrodynamics and mass transfer from microscale perspectives (Haroun et al., 2012; Hamidipour et al., 2013; Bouras et al., 2021). CFD simulation will also be useful for fixed bed compact reactors. In this study, the flow and transport characteristics of a fixed bed compact reactor were analyzed by CFD simulation. How the packing methods of spherical catalyst carriers, reactor diameters, and catalyst carrier sizes, which are important design variables, affect the conversion and selectivity of a model reaction was investigated.

2. Simulation settings

This chapter describes the settings for CFD simulation of the reactor.

2.1. Reaction system

A reaction system, its rate equation, and the physical properties of fluid and catalyst were given with reference to the reaction examples dealt with in NEDO project (see Ref.). The parallel reaction was assumed to proceed on the surface of the catalyst particles. A is the raw material, B is the main product, and C is the by-product. The temperature dependence of each reaction rate follows the Arrhenius equation. The reaction parameters including standard reaction enthalpy ($\Delta_r H_i^\circ$) are shown in Table 1. The higher the reaction temperature, the more by-product is produced. The physical properties of the reaction fluid and catalyst are shown in Table 2. They were all assumed to be constant.

2.2. Design and operation conditions

Figure 1 shows an example of packing type fixed bed compact reactors used in this study. Assuming that spherical particles are regularly packed as a carrier, two typical of packing methods were examined as shown in Fig. 1. Packing method 1 (PM1) has a fundamental structure where one particle is placed between adjacent particles located below it. Packing method 2 (PM2) has a fundamental structure where one particle is placed directly above another particle located below it. Assuming that the shape of the reactor is tubular, the inner diameter of the reactor (d_r) was set to 10 mm and 40 mm, and the ratio of the inner diameter of the reactor to the carrier particle size (N) was set to 10 and 4, referring to the reactors developed in the NEDO project. The reaction fluid was supplied from the reactor inlet at a temperature of 300 K, a linear velocity of 0.08 m/s, and a raw material concentration of 1 kmol/m³. The outlet pressure of the reactor was assumed to be equal to atmospheric pressure. The reactor wall temperature was constant at 300 K.

Table 3 Simulation conditions and results in each case

Case	α	d_r	N	PM	X_r	X_s
1	0.95	10	10	1	1.000	0.812
2				0.997	0.810	
3			4	1	0.986	0.833
4				2	0.915	0.834
5		40	10	1	0.963	0.781
6				2	0.905	0.781
7			4	1	0.851	0.799
8				2	0.712	0.806

In a preliminary study to evaluate the flow velocity distribution over the packed bed while changing the number of layers from 3 to 10, the result was that there was almost no effect of the number of layers on the flow velocity distribution. Therefore, in consideration of the computational load, the number of layers was fixed at 3. In addition, regarding mesh generation by CFD, the mesh quality deteriorates near the contact points between particles and the contact points between particles and reactor wall, and as a result, mesh generation cannot be performed. To avoid this problem, the particle volume change coefficient α was introduced and set to 0.95 (Bai et al., 2009). This means that each particle is slightly shrunk in size but its position remains unchanged. It was examined in advance that the relationship between the reaction results and the particle shrinkage or expansion is as shown in Fig. 2. In this figure, it was judged that α does not have a large effect on the reaction results.

3. Simulation results and discussion

CFD simulation was performed using Ansys Fluent[®] software to investigate how the packing methods (PMs), reactor diameters (d_r), and catalyst carrier sizes ($d_p = d_r/N$), which are important design variables, affect the reaction conversion and selectivity, which are represented by X_r and X_s , respectively. The simulation results of eight cases, where the diffusion coefficient D was set to 1.0×10^{-5} m²/s and the catalyst area in the reactor was constant, are summarized in Table 3. In addition, the cross section of the packed bed (Planes 1-3) and the cross section along the axis were analyzed to evaluate the distributions of velocity, concentration, and temperature. The following sections show and discuss the obtained CFD simulation results in detail.

3.1. Packing methods: PM1 vs. PM2

Focusing on Cases 7 and 8, the effect of the PMs on the reaction results is discussed. The X_r of PM1 was 0.139 higher than that of PM2. The tendency of this result was also

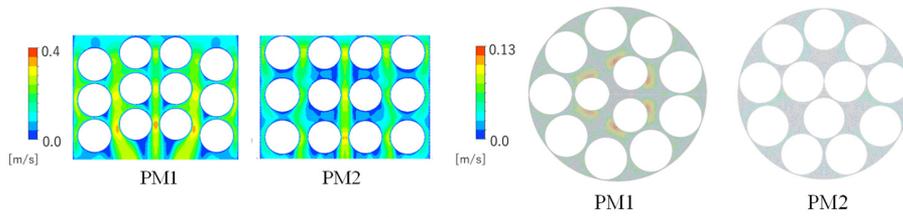

Fig. 3 Flow velocity distribution on the axis plane.

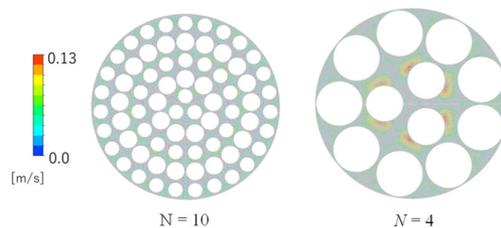

Fig. 4 Radial flow velocity distribution on plane 3.

observed in other similar cases. It was also shown that the difference in X_r was larger when N was smaller and when d_r was larger. As shown in Fig. 3, PM2 has more regions where the velocity is 0 above and below each catalyst particle, that is, stagnant portions, compared to PM1, and as a result, the raw material is not efficiently supplied to the particle surface. On the other hand, in the case of PM1, it can be seen that radial flows occur as shown in Fig. 4. The maximum radial flow velocity corresponds to 0.63 times the axial flow velocity in the bed. It can be estimated from the CFD analysis results that the effective area of the catalyst particles used for the reaction is about 1.3 times larger in Case 7 than in Case 8, and it was reflected in the reaction results.

3.2. Reactor diameter and catalyst carrier size

The effect of $N (=d_r/d_p)$ on the reaction results is discussed. Focusing on Cases 5 and 7, it was shown that X_r was 0.112 higher and X_s was 0.018 lower for $N = 10$ than for $N = 4$. X_r became higher for $N = 10$ than for $N = 4$, regardless of cases. The increase in X_r may be due to the fact that the catalyst surface area per unit volume of $N = 10$ is 2.5 times that of $N = 4$. However, if the heat of reaction is not removed efficiently, it is expected that the catalyst surface temperature will rise, resulting in a decrease in X_s . This expected result was actually seen in Cases 5 and 7. When PM1 is adopted as the catalyst packing method, the efficient heat removal by convective heat transfer of radial flow may be achieved. As shown in Fig. 5, the radial flow was observed in both Cases 5 and 7. However, it can be seen that the maximum velocity of the radial flow in the case of $N = 10$ is about half that in the case of $N = 4$. Therefore, it was difficult to expect a great heat removal effect by the radial flow in the case of $N = 10$.

The effect of d_r on the reaction results is discussed. Focusing on Cases 3 and 7, it was shown that when d_r was changed from 40 mm to 10 mm, the reaction rate increased by 0.135 and the selectivity increased by 0.034. This is because as d_r becomes smaller, mixing by diffusion is promoted, resulting in a more uniform concentration field, as shown in Fig. 6, and in addition, the efficiency in heat removal through the reactor wall is improved, resulting in a more uniform temperature field.

Fig. 5 Radial flow velocity distribution on plane 3 ($N=4, 10$).

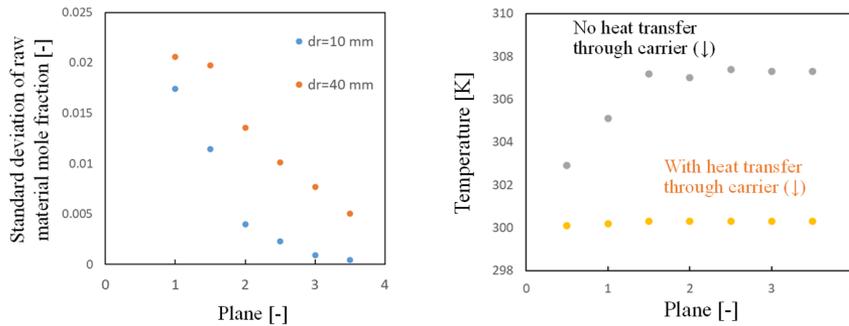

Fig. 6 Raw material dispersion on planes. Fig. 7 Average cross-sectional temperature in the reactor.

3.3. Heat transfer through catalyst carriers

The effect of heat transfer through catalyst carriers on the reaction results is discussed. CFD simulation was performed for case 7 under the condition of $\alpha = 1.05$. This value of α means that the size of each particle was increased by 5% but its position has not changed. As a result of CFD simulation, it is shown that X_r increased by 0.004 very slightly but X_s increased by 0.109. The large increase in X_s is largely due to the improvement in the ability to remove reaction heat by conduction heat transfer through the catalyst carriers, which partially overlap each other. Figure 7 shows average fluid temperatures on cross sections in the reactor with/without heat transfer through catalyst carriers. It can be seen that an isothermal reaction field was realized in the reactor with heat transfer through catalyst carriers, and as a result, X_s was improved.

3.4. Honeycomb type catalytic reactor

The result in the previous section suggests that promotion of conduction heat transfer through the catalyst carriers achieves a more uniform temperature field. However, in an actual particle-packing type fixed bed compact reactors, it may be difficult to realize the structure that connects particles by planes instead of points. Therefore, the usefulness of a honeycomb type compact reactor was examined by CFD. Figure 8 shows the honeycomb type compact reactor designed in this study. The cross section of the reactor and the cross section of each channel were assumed to be square, and the wall thickness and the channel width were set to 1.1 mm and 1.3 mm, respectively. This channel width was determined by dividing the channel volume by the catalyst surface area. Since 14 channels were arranged in both the vertical and horizontal directions, the total number of channels was 196. The CFD simulation results for packing type and honeycomb type

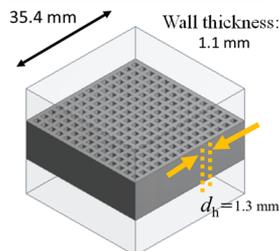

Table 4 CFD-based evaluation of honeycomb type fixed bed compact reactor.

	X_r [-]	X_s [-]	ΔP [Pa]
Packing type	0.979	0.879	101
Honeycomb type	0.989	0.901	60

Fig. 8 Honeycomb type fixed bed compact reactor.

fixed bed compact reactors are summarized in Table 4. It can be seen that the honeycomb type can achieve the same reaction result as the packing type shown in the previous section. Furthermore, it can be seen that the pressure loss of the honeycomb type was reduced by about 40% compared to the packing type.

4. Conclusions

In this study, CFD simulation was used to analyze the flow and transport phenomena of the packing type fixed bed compact reactors, which are currently used for synthesizing functional chemicals, and to evaluate the reaction results. The simulation results showed that the generation of flow perpendicular to the axis of the reactor leads to the improvement of the reaction results because the surface area of each catalyst can be effectively used. In addition, it was suggested that the honeycomb type is superior to the packing type in controlling the reaction time, realizing a uniform reaction temperature field, and reducing the pressure loss.

Abstract

Volatile organic compounds (VOC) use is ubiquitous in the pharma industry, posing great risks as potential organic gas releases are harmful to both environment and human health. Fixed-bed columns containing activated carbon or other adsorbents selectively remove VOCs from gas effluent streams. Nevertheless, they can be quickly and/or irregularly saturated, due to a great, simultaneous variation of flowrates and mixture compositions. This paper presents the development and implementation of a dynamic, non-isothermal adsorption model (under both adiabatic as well as non-adiabatic conditions) for the study of multicomponent alkane adsorption. A scenario-based investigation of binary mixture (heptane-decane) behaviour examines the effect of key parameter changes and reveals the preferential adsorption of decane on beaded activated carbon (BAC) under different flowrate, mixture composition and column length. Modeling of heat transfer boundary conditions (BC) combined with critical parameter variations improves our operational understanding, towards comprehensive technoeconomic VOC abatement optimisation.

Keywords: Volatile Organic Compound (VOC), dynamic simulation, adsorption.

1. Introduction

The fragile interconnected relationship between human health and physical environment is increasingly highlighted, with air pollution heavily affecting both (Dobre, 2014). Volatile organic compounds (VOC) represent a class of solvents commonly employed for industrial process use, contributing to ca. 40% of VOC emissions in the EU for 2017 (EEA, 2019). In an effort to mitigate climate impact, pharma industries turned to VOC abatement and its process optimisation. Adsorption, as less capital- and energy-intensive vs. other technological options, is established practice. Nevertheless, quick and irregular bed saturation due to feed variability impedes process efficiency and increases costs.

This work presents the development and application of a dynamic, nonisothermal, VOC adsorption model under both adiabatic and non-adiabatic conditions. Recent literature studies (Fournel et al., 2010; Tefera et al., 2013 & 2014; Knox, 2016) forego the detailed investigation of heat balance boundary conditions. Our aim here is to highlight the effect of key operating parameter changes (flowrate, composition, column length) under varying heat transfer scenarios, to establish a framework for industrial column usage optimisation.

2. Dynamic Model Development: Assumptions and Structure

The mathematical model used in the present study relies on the following assumptions:

1. The temperature difference between particles and the gas phase as well as carrier gas adsorption are considered negligible, while the ideal gas law also applies (Suzuki, 1990).
2. Equilibrium obeys the Extended Langmuir model/binary mixtures (Tefera et al., 2014).
3. Mass transfer in the solid phase is approximated by the LDF model, Eq. (Sircar, 2000).
4. Adiabatic conditions modelled by eliminating last term in Eq. (22) (Ruthven, 1984).

The model equations are derived from these sources, with Eqs. (17-21) from Knox (2016). The Bosanquet formula, Eq. (12) thus Eq. (5), is verified (Krishna & van Baten, 2012).

A short model description follows (i: component): in Eq. (1), C , $D_{z,i}$, u , ε_b , R and q are the gas phase VOC concentration (mol m^{-3}), the axial dispersion coefficient ($\text{m}^2 \text{s}^{-1}$), the interstitial velocity (m s^{-1}), the bulk bed porosity, the column inner radius (m) and the adsorbed phase VOC concentration (mol m^{-3}), respectively. Eq. (2) further introduces Sc_i , Re_p , $D_{AB,i}$, and α_0 as the Schmidt number of i, the Reynolds number (adsorbent particle), the molecular diffusivity ($\text{m}^2 \text{s}^{-1}$) and the empirical mass diffusion correction factor (20) respectively. In Eq. (3), Σv is the atomic diffusion volume (A: VOC, B: carrier), T is temperature (K), P is pressure (atm) and M is molecular weight (g mol^{-1}). On Eq. (4), ρ_p , $k_{LDF,i}$ are the particle density (kg m^{-3}) and LDF mass transfer coefficient (s^{-1}) respectively and $q_{e,i}$ is the inlet PT adsorbent equilibrium capacity (mol kg^{-1}). In Eq. (5), ε_p is the particle porosity, $C_{0,i}$ is the inlet concentration of i (mol m^{-3}), $D_{eff,i}$ is the effective diffusivity of i ($\text{m}^2 \text{s}^{-1}$), τ_p is particle tortuosity, $C_{s0,i}$ is the adsorbed phase concentration at equilibrium with $C_{0,i}$ (mol m^{-3}) and d_p the particle diameter (0.75 mm). Eqs. (6)-(13) present ρ_b , D , V_{pore} , $D_{k,i}$, r_p as bed density (kg m^{-3}), bed inner diameter (m), adsorbent pore volume ($5.7 \cdot 10^{-4} \text{ m}^3 \text{ kg}^{-1}$), Knudsen diffusivity ($\text{m}^2 \text{s}^{-1}$) and pore radius ($1.1 \cdot 10^{-9} \text{ m}$). Eqs. (14)-(15) introduce $q_{e,i}$, $q_{m,i}$, b_i , $b_{o,i}$ and $\Delta H_{ad,i}$ as the equilibrium and maximum adsorption capacity of i (mol kg^{-1}), the Langmuir affinity coefficient ($\text{m}^3 \text{ mol}^{-1}$), the pre-exponential constant ($\text{m}^3 \text{ mol}^{-1}$) and the heat of adsorption (J mol^{-1}), respectively. Then, Eq. (16) presents α_i , $\Delta H_{vap,i}$, IP_i , γ_i and w_{mic} as polarizability (10^{-24} cm^3), heat of vaporization (kJ mol^{-1}), ionization potential (eV), VOC surface tension (mN m^{-1}) and average micropore width (nm), respectively. Eqs. (17)-(22) introduce T_w , ρ_g , C_{pg} , C_{pp} , k_{ez} , k_{eff} , k_g , k_p , h_o , h_i , k_{ew} , k_w , x , d_{lm} as the wall temperature (K), gas density (kg m^{-3}), specific heat capacity of gas/particle ($\text{J kg}^{-1} \text{ K}^{-1}$), effective axial thermal conductivity/effective /gas/particle thermal conductivity ($\text{W m}^{-1} \text{ K}^{-1}$), overall/internal heat transfer coefficient ($\text{W m}^{-2} \text{ K}^{-1}$), effective wall/wall thermal conductivity ($\text{W m}^{-1} \text{ K}^{-1}$), column wall thickness (m), mean logarithmic column diameter, respectively. Finally, μ is gas viscosity (Pa s^{-1}), Pr is the Prandtl number, Q the volumetric flowrate ($\text{m}^3 \text{ s}^{-1}$), and A the bed area (m^2).

3. Dynamic Model Parameters for Adsorption Systems

The adsorption of a binary (heptane–decane) mixture, with air as the carrier, has been examined on BAC (Tefera et al., 2014) under both isothermal and adiabatic BC (CS0), different flowrate, composition, bed length (CS 1–3). The set of PDEs is solved using orthogonal collocation on finite elements using the gPROMS[®] Process 2.0 software suite. Viscosities are computed from Wilke’s equation and densities through pure component data via mixing rules ($T=300 \text{ K}$, $P=1 \text{ atm}$) (NIST, 2021). Air is assumed a binary mixture ($\text{N}_2:\text{O}_2=79:21 \text{ \% v/v}$). Tables 1, 2 and 3 present key parameter values for the simulations.

Table 1: Parameters for heptane-decane scenarios and axial dispersion coefficient calculation.

4. Results and Discussion

Breakthrough curves, temperature and pressure variations of the examined systems are shown in Fig. 1. Our model is successfully validated, Fig. 1 (a), vs. published experimental breakthrough curves which dictated our inputs (CS0) in Fig. 1 (a)-(d) (Tefera et al., 2014). Fig. 1 (a) shows a breakthrough duration predicted with minimal error for decane, but a mismatch for heptane, particularly during the transient high-C phase of the latter. Discrepancies could be attributed to the limitations of our 1-D nonisothermal model, but we remark this mismatch is very similar to that in the published plot (Tefera et al., 2014).

We consider three case studies (CS 1-3) of different flowrate (CS1), composition (CS2) and bed length (CS3), depicted in Fig. 1 (e)-(h). Adiabatic BCs of the base case, Fig. 1 (d), clearly induce a heat buildup within the bed, compared to the isothermal BCs of Fig. 1 (c). A linear ΔP profile is seen in Fig. 1(b), consistent with reported trends (Tefera et al., 2013).

Fig. (e) presents the heptane-decane binary mixture behaviour at a flowrate 50% smaller than the base case (CS1). The order of affinity strength remains (decane > heptane), but the onset of breakthrough occurs later and the duration is longer compared to the base case. The lower flowrate is directly associated with a 56% pressure drop reduction presented in Fig. 1 (f), i.e. roughly half the pressure drop observed in Fig. 1 (b) for CS0.

Fig. 1(g) illustrates the effect of mixture composition variation: $C_{decane} = 3 \cdot C_{heptane}$ (CS2). Though gradual displacement of heptane persists, the plot indicates that the concentration change induces a earlier breakthrough onset for decane as well as a later one for heptane, combined with a clearly shorter duration for both VOCs compared to the base case (CS0).

Finally, Fig. 1(h) presents the effect of key design variable changes, considering a design variation of 50% increased bed length (CS3), and its effect on breakthrough behaviour. Once again, decane is adsorbed much later with the same trend of heptane displacement, but the onset of breakthrough for both occurs later in time, due to the increased bed size.

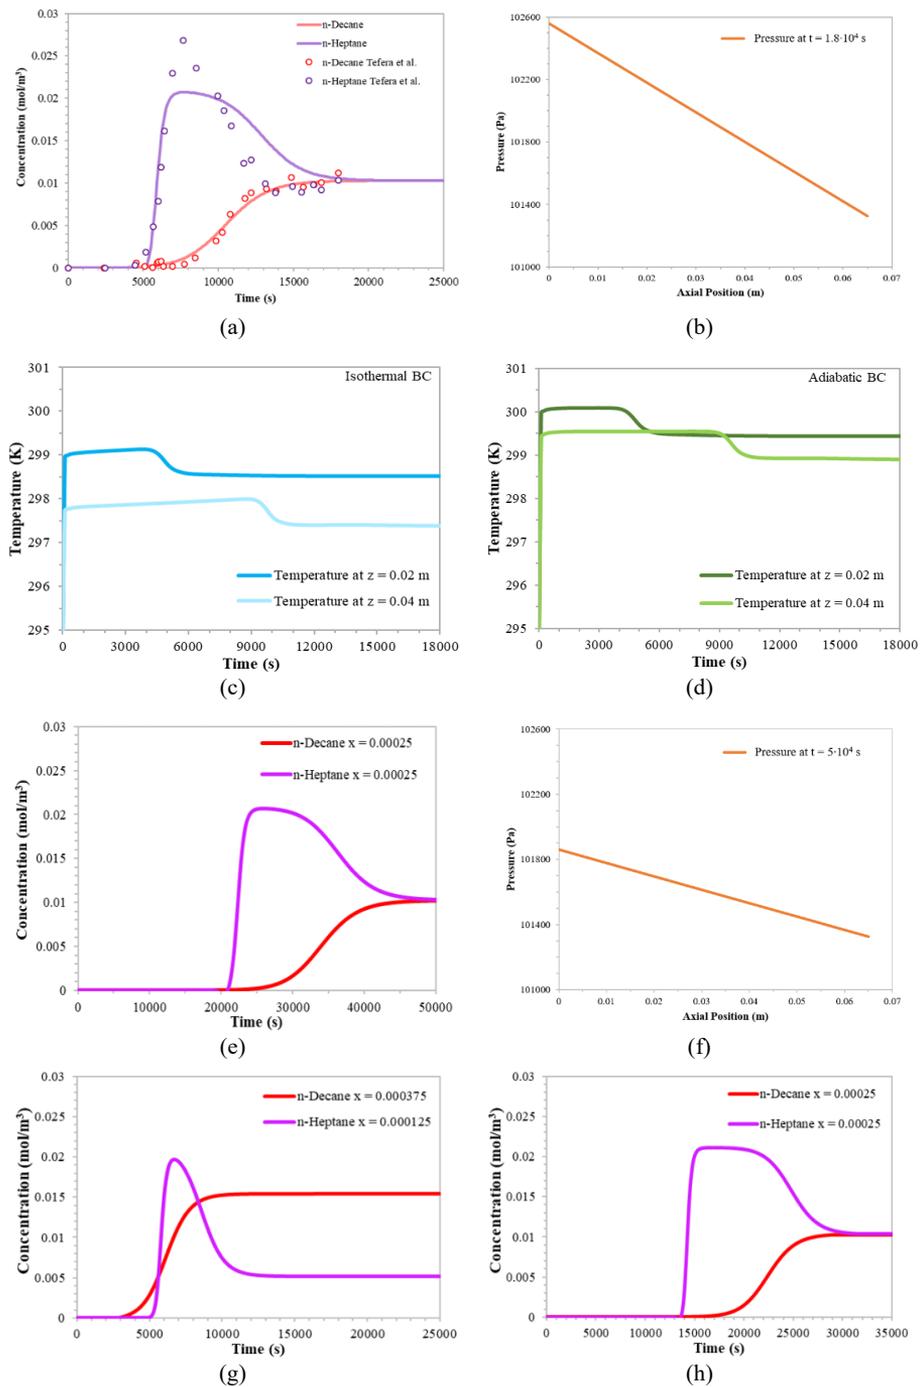

Figure 1: Model validation (a) (Tefera et al., 2014); operat. profiles (b)-(d); case studies (e)-(h).

5. Conclusions

Active Pharmaceutical Ingredient (API) manufacturing relies on the use of vast amounts of solvents, thus increasing risks on environment and public health due to VOC emissions. Cognizant of the growing environmental concern, pharma companies are shifting their focus towards drastic climate impact minimisation through process optimisation in an effort to mitigate air pollution caused by VOC emissions. Adsorption is often adopted as an industrial VOC abatement method, yet not without operational efficiency challenges. Although adsorption modelling is extensively studied in the literature, comprehensive studies examining the effect of operational decisions on VOC removal efficiency towards technoeconomic process optimisation still remain elusive (Tzanakopoulou et al., 2021).

This paper demonstrates the development and application of a one-dimensional in space, multicomponent, nonisothermal adsorption model to highlight the complex phenomena taking place inside pharma VOC adsorption columns, considering axial dispersion in the gas phase and the Linear Driving Force model for solid phase mass transport. Differences between isothermal and adiabatic BC are critical considering the exothermic nature of the process. Our simulations revealed quicker uptake of heptane under varying flowrate, composition and bed length, with decane is adsorbed later in all four cases we considered. A decrease in the flowrate resulted in a later onset, a larger duration of breakthrough and a reduction of pressure drop compared to the base case, thus implying inefficient practice. In view of industrial applications, a larger (thus costlier) bed length investigation resulted in a later onset and longer breakthrough duration. Reliable modelling of multicomponent, nonisothermal VOC adsorption paves the way for technoeconomic optimisation efforts.

Abstract

According to the International Energy Agency, hydrogen is one of the pillars to reach Net Zero CO₂ emissions by 2050. Forecasts indicate a market size of 200 Mton in 2030, of which 35% will be blue hydrogen (IEA, 2021). This work approaches the separation of hydrogen from carbon dioxide, by integrating the Python software environment with Aspen Plus software. Compression and cooling of the feed components to the hydrate formation conditions upstream the NetMIX is modelled in Aspen Plus. In the Python interface, the heat and mass balances associated with the NetMIX are performed, including the Gibbs Energy Minimization algorithm, developed by Ballard (Ballard, 2002) for the prediction of hydrate/liquid/vapor equilibrium. The model developed was applied to a case study, which considers a gas stream of 3300 m³_{PTN}·h⁻¹, containing 60 % of hydrogen and 40 % of carbon dioxide (molar percentages). The results show an improvement in the purity of H₂ in the gaseous stream of nearly 25 %, reaching a value of 84 %, while also a recovery near 62% of CO₂ via the hydrate phase is obtained, with 30 MJ_e · m³_{PTN}⁻¹ of electrical demand and 210 MJ_t · m³_{PTN}⁻¹ of cooling demand.

Key Words: **Hydrogen separation; NetMIX technology; Hydrates.**

1. Contextualization

1.1. CO₂ concerns

In 2015 in Paris, during the United Nations Framework Convention on Climate Change, the Paris Agreement was signed, where 195 nations agreed that changes were required to combat climate change and mitigate its impacts. In 2021, at the COP26 UN Climate Conference, 190 countries reinforced the targets set by the Paris Agreement to limit global warming to below 2 degrees Celsius, and as close as possible to 1.5 degrees Celsius. This objective can be achieved through the reduction of the emissions of greenhouse gases, such as carbon dioxide (CO₂) and methane (CH₄). The CO₂ concentration has increased around 40 times since preindustrial times, mainly due to its emissions by the burning process of fossil fuels. A solution to reduce these emissions urges and one possibility consists of finding fuel alternatives to fossil fuels, such as hydrogen.

1.2. H_2 as a source of energy

Hydrogen has an energy density of $120 \text{ MJ}\cdot\text{kg}^{-1}$, which is more than two times larger than methane. In the context of reaching net zero emissions by 2050, hydrogen needs to be produced from electrolysis with renewable electricity, i.e., green hydrogen, or steam methane reforming with CO_2 capture, i.e., blue hydrogen. Hydrogen can then be used as an energy source, either by producing energy in turbines or by its use in fuel cells, after going through the required purification steps.

1.3. Hydrates

Hydrates are non-stoichiometric crystalline structures, composed of hosts, typically water molecules, that are connected to each other by hydrogen bonds. These hosts create cavities, where guests, small gas molecules, are constrained. For hydrates to form, low temperatures and high pressures are required and the amount of gas in contact with the liquid must surpass the solubility limit of the gas on water. The hydrate formation conditions are specific to the gas molecule being hosted, thus providing a way for separating different gases in a gas mixture, such as flue gas (CO_2 and N_2) or mixtures for a reformer outlet (CO_2 and H_2), while allowing the storage of gases in solid form.

For hydrates to keep their stability, the necessary temperature and pressure conditions must be maintained. This is very challenging for a continuous production scenario since the hydrate formation process is highly exothermic.

A solution proposed to this challenge is the use of NetMIX technology, which consists of a network of mixing chambers, interconnected by transport channels, which enable better control of the mixing process, and result in outstanding heat transfer capabilities (Costa et. al., 2015), providing an efficient heat removal that keeps hydrates stable.

The aim of this work is to develop a framework simulation for modelling the formation of hydrates in NetMIX device (Lopes et al., 2019), as a method to separate hydrogen from a mixture with carbon dioxide, to investigate the potential of this solution.

2. Materials and Methods

2.1. Process modelling

The software used for creating the simulation model was Aspen Plus. The designed flowsheet is shown in Figure 1.

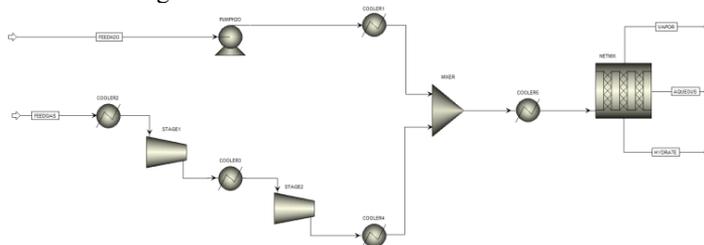

Figure 1 - Designed flowsheet for the hydrogen separation via hydrate.

The flowsheet consists of two feed streams: one for water, the other for the gas mixture. The water feed is sent to a pump, to increase the pressure to 125 bar, and through a cooler, to decrease the temperature to $0.5 \text{ }^\circ\text{C}$, the conditions for hydrate formation. The gas feed first goes through a cooler, to decrease the temperature, due to the high temperatures of the reforming stage. Then it goes through a two-stage compressor, with a cooler in between, to control the temperature increase due to the compression. The gas stream, at the operating pressure, then goes through a cooler, to decrease the temperature. The streams are then mixed, and to prevent temperature increase due to the mixing process, a

cooler is added after the mixer. This stream is then fed to the NetMIX device, where the separation occurs.

Aspen Plus does not contain a model of the NetMIX device, nor can it predict the formation of hydrates. For these purposes, a Python code was implemented. This code, named *HydrateFlash.py* (Darnell et. al., 2017) is the Python translation of another software application, named CSMGem. This software was developed by Adam Ballard (Ballard, 2002) and predicts the formation of hydrates, based on the Minimization of the Gibbs Energy. It contains a set of components in its database, but not hydrogen. Thus, the properties of hydrogen were added to the *HydrateFlash.py* code database.

2.2. The *HydrateFlash.py* simulator

The *HydrateFlash.py* simulator minimizes the Gibbs Energy, coupling with the thermodynamic equilibrium conditions, where temperature, pressure, and fugacity are equal for all phases. The objective function uses the concept of K-values. These values represent the repartition coefficient between two phases, one of those being the reference phase.

Assuming that the equilibrium of a mixture of carbon dioxide, hydrogen, and water, under certain conditions, can be restrained to a three-phase distribution, those being vapor, liquid and hydrate phases, two sets of K-values must be given. Assuming that the vapor phase is the reference one, then the simplified Raoult's law can be used to express the liquid/vapor equilibrium, while a thirteen-parameter equation, described in Ballard's work is used to express the equilibrium between the vapor and the hydrate phase.

3. Results and Discussion

3.1 Validation of *HydrateFlash.py* results

The results of *HydrateFlash.py* for predicting the thermodynamic equilibrium between the vapor-liquid-hydrate phases were validated with the results obtained with CSMGem for different scenarios for vapor-liquid-hydrate equilibrium. When possible, these results were checked with results published in the literature.

Figure 2 shows the results obtained by CSMGem and *HydrateFlash.py* for a mixture of CH₄/CO₂, since these components are present in both softwares. The objective was to compare the equilibrium line, i.e., the conditions at which hydrate is formed, for a temperature, in the range of 0.5 to 8.5 °C.

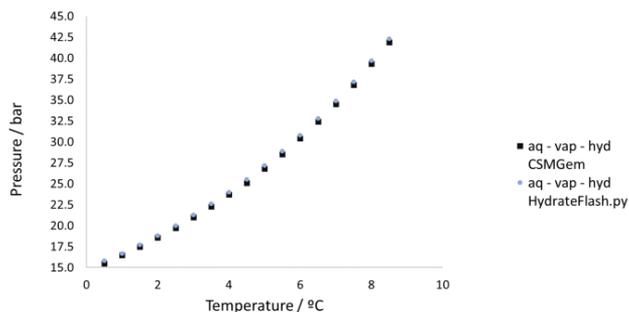

Figure 2 - Equilibrium lines for the H₂O, CH₄ and CO₂ mixture

As seen from Figure 2, the results present slight deviations of about 0.3 bar, on average. This behavior can be justified by the fact that CSMGem, at a certain range of pressures (very near the transition zone of vapor-liquid equilibrium to vapor-liquid-hydrate equilibrium), does not produce results, due to convergence problems. However,

HydrateFlash.py presented no convergence problems in these zones. Thus, the *HydrateFlash.py* code can be considered as a valid approach to simulate the equilibrium of formation of hydrates.

3.2 Vapor-Liquid equilibrium

The values obtained with *HydrateFlash.py* code for vapor-liquid equilibrium between hydrogen and carbon dioxide were validated against Aspen Plus predictions for the PSRK thermodynamic model with H₂ as a Henry component, since H₂ is at the supercritical region (Skogestad, 2009), and has a solubility in water less than 0.005 (mol:mol) at the target conditions (Rahbari et. al, 2019). The phase fraction, as well as the phase composition are shown in Figure 3 (a) and (b), respectively.

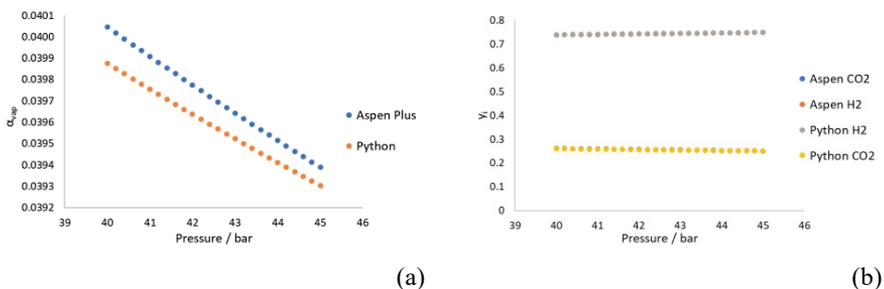

Figure 3 – (a) Vapor fraction evolution at 0.5 °C and, (b) Molar fraction on the vapor phase for CO₂ and H₂ at 0.5 °C.

The results are matching with a deviation of 0.36 % for the H₂ vapor phase composition, while the average error for the phase fraction was 0.32 %.

3.3 Validation of Vapor-Liquid-Hydrate equilibrium

The results presented in the work of Kumar et. al (2006) were compared with the equilibrium pressure of a mixture of water/hydrogen/carbon dioxide, predicted by the *HydrateFlash.py* software, for different H₂ fractions. As an example, Figure 4 shows the results concerning pressure vs. temperature for an H₂ fraction of 0.608 and 0.579.

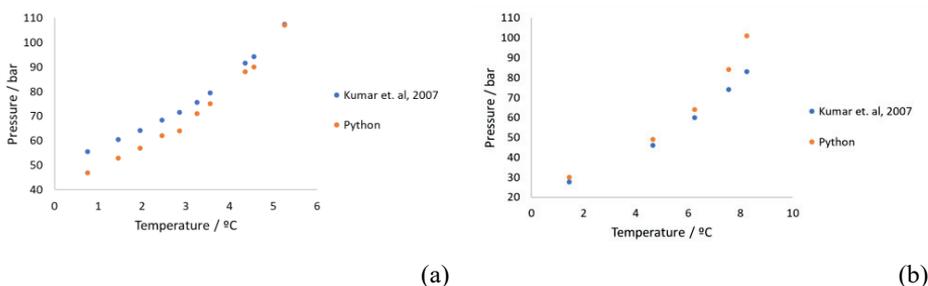

Figure 4 – Equilibrium pressure variation for $y_{H_2} = 0.608$ (a) and $y_{H_2} = 0.421$ (b).

The highest relative deviation between the published work and the model prediction was 11.3 %, obtained for the H₂ molar fraction of 0.579 (Figure 4b), being so these results were considered acceptable.

3.4 Influence of Pressure and Temperature for H₂/CO₂ hydrates formation

Figure 5 (a) shows the pressure influence on the hydrate fraction, at 0.5 °C, while Figure 5 (b) shows the temperature influence on the equilibrium pressure. For the pressure, up to the equilibrium pressure of 51.6 bar, obtained via the equilibrium model of the *HydrateFlash.py* code, no hydrates are formed. After reaching this value, an increase of pressure leads to an increase in the hydrate phase fraction. For the temperature, it was noted that the increase in temperature increases the equilibrium pressure.

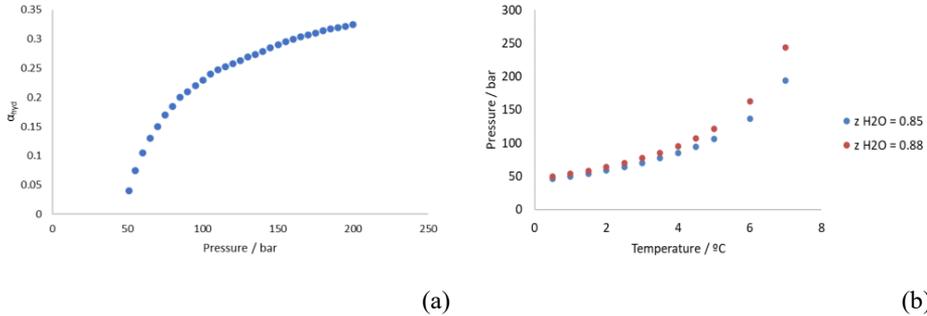

Figure 5 – (a) Pressure influence on the hydrate fraction and, (b) temperature influence on the equilibrium pressure.

3.5 Case study

The flowrate assumed for this simulation was 3300 m³_{PTN}·h⁻¹, which was composed of 60 % carbon dioxide, and 40 % hydrogen (molar percentages). For this flowrate, it would be required to feed 1000 ton·h⁻¹ of water to the reactor.

The conditions of the gas stream were a temperature of 200 °C, and a pressure of 30 bar (Iulianelli et al., 2015). For the water stream, it was considered to be at ambient conditions, those being 20 °C, and at 1 bar.

The process was then set so that the operating conditions are 0.5 °C and 125 bar, being these conditions defined to obtain a hydrate phase fraction larger than 30%. For the gas side, it was required to specify the conditions of the multi-stage compressor. For that, a compression ratio of 2.04 was used, and the outlet cooler temperature was 35 °C.

The results of the simulation indicate a gaseous stream with a molar H₂ fraction of 84 %, while the remaining 16 % is CO₂. The hydrate phase is mainly composed of water, representing 87 %, while 12.5 % is CO₂. The phase distribution obtained was 50 % aqueous phase, 37 % hydrate phase and 13 % vapor phase.

The results show an increase of nearly 25 % in the purity of the gas stream, regarding hydrogen. Additionally, 62 % of the carbon dioxide at the NetMIX inlet is recovered from the hydrate outlet stream. A separation factor, defined in equation (1), of 90 was obtained. This means that CO₂ tends to be kept in the hydrate phase more than H₂, while this last tends to remain in the vapor phase.

$$SF = \frac{n_{CO_2,hyd}/n_{CO_2,vap}}{n_{H_2,hyd}/n_{H_2,vap}} \quad (1)$$

Additionally, the energy consumption was calculated. A value of 30 MJ_e · m³_{PTN}⁻¹ was obtained, considering the pump and the compression system, while it would be required 210 MJ_t · m³_{PTN}⁻¹ for cooling, considering heat removal on the heat exchangers, the

intercooler, and the NetMIX device. Reducing the energy requirements of the process may be achieved through heat integration and the use of promoters which will be covered in a future work.

Conclusions

This work approached the production of blue hydrogen, via continuous hydrate production. The results obtained show that the gas stream enriches in H₂, reaching a purity of 84 % (mol:mol), while the hydrate produced is mainly composed of CO₂. A separation factor of 90 was achieved between the vapor and hydrate phases, translating to a preference of H₂ to be kept in the vapor phase, while CO₂ tends to go to the hydrate phase. Due to the early stage in knowledge regarding this mixture behavior under hydrate formation conditions, these results can be further improved under different circumstances, such as different operating conditions, which will be approached in a future work.

Abstract

This work combines a particle model and experimental data as an alternative to improve the agreement between predicted and experimental results in pyrolysis. A mechanistic model, implemented and solved in gPROMS, is used to describe biomass pyrolysis in a shrinking particle. The content of cellulose, hemicellulose and lignin in palm kernel shells (PKS) is determined with high performance liquid chromatography (HPLC) and UV-Visible spectrophotometry. A synthetic sample of cellulose, hemicellulose and lignin is prepared to resemble PKS composition. Pyrolysis of both PKS and the synthetic sample is evaluated using thermogravimetric analysis (TGA). The results highlight the complexity of pyrolysis and the importance of supporting modelling with experimental data. TGA results show the effect of biomass components interactions in pyrolysis. A 20% difference in pyrolysis mass conversion was found between PKS and the mixture. The agreement between predicted and experimental results improves when the model is modified considering PKS pyrolysis information. This work represents a step forward for understanding the role of combined modelling and experimental strategies in describing complex processes like pyrolysis.

Keywords: biomass pyrolysis, mechanistic model, TGA, palm kernel shells

1. Introduction

The production of fuels and platform chemicals from renewable sources can contribute to generate a shift from our current oil-driven economy towards more environmental-friendly alternatives. Biomass is an abundant resource that could facilitate such a shift. Pyrolysis is a key technology for transforming biomass into both fuels and platform chemicals, which could support the transformation of agro-industries into biorefineries. However, the integration of pyrolysis into biorefineries requires a better understanding of the complex interactions between biomass components. This is particularly critical for the development of reliable models for pyrolysis process design (Bridgwater, 2018). Previous pyrolysis models consider biomass as a cellulose, hemicellulose and lignin mixture (Ranzi et al., 2017; Di Blasi, 1994). However, biomass components interactions are not fully understood and they are difficult to quantify (Wu et al., 2016); thus leading to poor agreement between predicted and experimental results. There are previous experimental works that

have identified interactions between biomass components (Hosoya et al., 2007; Wu et al., 2016). However, this is not the case for modelling approaches, where there is little information regarding the effect of such interactions over pyrolysis modelling outcomes. Moreover, information is still scarce regarding the effect of such interactions in residues with a complex morphology like PKS.

2. Biomass pyrolysis and modelling strategies

Lignocellulosic biomass is an abundant resource that contains cellulose, hemicellulose, lignin, water, inorganic components and extractives. Cellulose, hemicellulose and lignin represent more than 90 wt.% of biomass constituents. The thermochemical decomposition of biomass in pyrolysis involves a complex system of primary and secondary chemical reactions. Hence, the determination of biomass pyrolysis reaction mechanisms and their associated kinetic parameters is a difficult task. This is particularly challenging for lignin because of the different composition and structures that lignin could present (Debiagi et al., 2015). Previous models have addressed pyrolysis complexity by considering biomass as a cellulose, hemicellulose and lignin only mixture (Anca-Couce and Zobel, 2012; Di Blasi, 1994). Other modelling approaches have included extractives by using additional lumped pyrolysis reactions (Debiagi et al., 2015; Ranzi et al., 2017). Inorganic components are not usually included in pyrolysis models; however, they could catalyze secondary reactions (Ranzi et al., 2017). Existing interactions between cellulose, hemicellulose and lignin have been identified in pyrolysis (Wu et al., 2016; Hosoya et al., 2007); however the effect of such interactions over pyrolysis kinetics is not fully understood. Further work is needed to incorporate such interactions into biomass pyrolysis models, for improving the agreement between predicted and experimental results (Wu et al., 2016). The combination of modelling and experimental approaches in complex thermochemical processes like pyrolysis, stands out as an opportunity to develop reliable models for future process design and optimization. This work aims to combine modelling and experimental strategies as an alternative for improving predictions in pyrolysis.

3. Experimental approach and particle model for biomass pyrolysis

3.1. Materials and experimental methods

This work considers PKS and a synthetic mixture of cellulose, hemicellulose and lignin, as materials. PKS from the *Elaeis guineensis* Jacq. variety were collected from a palm oil extracting company in Ecuador. The synthetic mixture combined cellulose (Alpha Chemika), low sulfonate lignin (Sigma-Aldrich) and D-xylose (LobaChemie) to resemble PKS composition. The characterization of the PKS includes moisture and ash content analysis, and cellulose, hemicellulose, lignin and extractives determination. Moisture and ash contents are determined by gravimetry in accordance with BS EN 18134-1:2015 and BS EN 18122:2015 standards, correspondingly. Extractives were separated from PKS with solid-liquid extraction using ethanol USP grade and water. The content of cellulose, hemicellulose and lignin is determined using high performance liquid chromatography (HPLC) and UV-Visible spectrophotometry. For this purpose, samples are prepared and hydrolyzed in accordance with the NREL/TP-510-42618 laboratory analytical procedure (Sluiter et al., 2004). Cellulose and hemicellulose contents are determined using an Agilent 1260 Infinity HPLC equipment with a refraction index detector. The acid soluble lignin is determined with a Hach DR6000 UV-Visible spectrophotometer and the acid insoluble lignin is determined by gravimetry. PKS and the synthetic mixture's pyrolysis is studied with a Shimadzu TGA-5 thermogravimetric analyzer. TGA experiments are performed by duplicate using a 50 mL min⁻¹ of nitrogen, a maximum temperature of 800 °C and a 50° C min⁻¹ heating rate.

3.2. Particle model for biomass pyrolysis

A particle model for describing PKS pyrolysis is developed using mass, energy and momentum conservation. Similar approaches exist to describe cellulose pyrolysis (Di Blasi, 1994; Chico-

Proano et al., 2021); however, they do not analyze differences between pyrolysis of ideal and real samples. For addressing this, a shrinking particle is modelled considering isometric behaviour and including only radial variation of properties. Only gases move across the particle and they follow an ideal behaviour. Moreover, gas/solid local thermal equilibrium is considered (Ranzi et al., 2017). The model includes a combination of lumped kinetic models for cellulose, hemicellulose and lignin pyrolysis from literature (Di Blasi, 1994; Miller and Bellan, 1997). Products are grouped under three categories, solids (char), condensables (tar) and gases as shown in Figure 1.

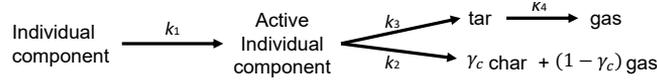

Figure 1: Scheme of the kinetic model considered for pyrolysis.

The changes in the particle's porosity, ϕ , are calculated using bulk, $\bar{\rho}$, and initial, ρ , densities. The mass balance for the solid phase, S , and for each individual solid component, S_i , includes net formation rates for the solid phase Γ_S and for individual species $\Gamma_{S,i}$ as shown in Eqs. (1) to (6).

$$\partial_t [\rho_S (1 - \phi)] = \Gamma_S \quad (1)$$

$$\partial_t [\rho_{S,i} (1 - \phi)] = \Gamma_{S,i} \quad (2)$$

$$\phi = \frac{(\bar{\rho}_{\text{char}} + \bar{\rho}_{\text{biomass}})^2}{(\rho_{\text{char}} \bar{\rho}_{\text{char}} + \rho_{\text{biomass}} \bar{\rho}_{\text{biomass}})} \quad (3)$$

$$\Gamma_S = \sum_{i=1}^{n_c} \Gamma_{S,i} \quad (4)$$

$$\Gamma_{S,i} = \sum_{j=1}^{n_r} \gamma_{i,j} r_j \quad (5)$$

$$r_j = A_j e^{-\left(\frac{E_{a,j}}{R_{\text{ideal}} T}\right)} C_{i,j} \quad (6)$$

In the previous equations, reaction rates, r_j , are determined using the stoichiometric coefficients, γ_i , of each i component in a j reaction. The Arrhenius equation is applied, using the concentration of a specie, $C_{i,j}$, the pre-exponential factors A_j and the activation energy $E_{a,j}$ from literature (Miller and Bellan, 1997). For the gas phase, G , and its individual components, G_i , the mass balance is described in terms of the velocity of the gaseous phase, \mathbf{u} , and its density, ρ_G , the net formation of the gaseous phase, Γ_G , and of individual components, $\Gamma_{G,i}$, and mass fractions $w_{G,i}$ as follows:

$$\partial_t (\rho_G \phi) = -\nabla \cdot (\rho_G \phi \mathbf{u}) + \Gamma_G \quad (7)$$

$$\partial_t (\rho_G \phi w_{G,i}) = -\nabla \cdot (\rho_{G,i} \phi w_{G,i} \mathbf{u}) - \nabla \cdot \mathbf{j}_{G,i} + \Gamma_{G,i} \quad (8)$$

The Darcy equation, Eq. (10), describes the movement of the gaseous phase, and the individual gas flux through the porous particle is calculated with the diffusive term $\nabla \cdot \mathbf{j}_{G,i}$, the effective diffusivity, $D_{\text{effective}}$, the gas phase viscosity, μ_G , the permeability of the solid phase, K_S and the pressure P .

$$\mathbf{j}_{G,i} = -D_{\text{effective}} \nabla \rho_G \phi w_{G,i} \quad (9)$$

$$\mathbf{u} = -\frac{K_S}{\phi \mu_G} \nabla P \quad (10)$$

The energy balance in Eq. (11) includes averaged specific heats for the solid, \hat{C}_{pS} , and gaseous phases, \hat{C}_{pG} . Similarly, the \mathbf{q} term includes the heat of reaction and the thermal conductivities.

$$(\rho_S \phi \hat{C}_{pS} + \rho_G (1 - \phi) \hat{C}_{pG}) \frac{DT}{Dt} = -\nabla \cdot \mathbf{q} - \left(\frac{\partial \ln \rho_G}{\ln T} \right)_P \frac{DP}{Dt} \quad (11)$$

Table 1: Properties of substances and initial conditions used in the model.

Property	Value	Units	Reference
r_0	$138 \cdot 10^{-6}$	m	Experiments

ρ_{lignin}	1600.00	kg m^{-3}	(Gorensek et al., 2019)
ρ_{char}	1540.00	kg m^{-3}	(Anca-Couce and Zobel, 2012)
μ_G	$3.0 \cdot 10^{-5}$	$\text{kg m}^{-1} \text{s}^{-1}$	(Di Blasi, 1994)
P_0	101325	Pa	-
T_0	373	K	-

Table 2: Palm kernel shell characterization.

Property	Value
Moisture content (wt.%)	10.62 ± 0.07
Extractives (wt.%)	5.78 ± 0.18
Cellulose (wt.%)	14.25 ± 1.89
Hemicellulose (wt.%)	21.44 ± 0.23
Lignin (wt.%)	45.65 ± 0.97
Ashes (wt. %)	1.93 ± 0.14

The particle's initial temperature, T_0 , radius, r_0 and pressure, P_0 , and the used properties are defined in Table 1. The particle's boundary is at temperature T_R following a $50^\circ\text{C min}^{-1}$ heating rate, like the experiments. The model is implemented and solved in gPROMS ModelBuilder® 7.0.

4. Results and Discussion

Table 2 shows that lignin is the main component of PKS, followed by hemicellulose and cellulose. Consequently, cellulose/lignin and hemicellulose/lignin interactions would be expected in pyrolysis (Hosoya et al., 2007). PKS also show a relatively low content of extractives and ashes. Regarding the pyrolysis experiments, Figure 2 a) shows that the synthetic mixture decomposes differently than the PKS during pyrolysis. Whereas PKS mainly decompose between $250 - 400^\circ\text{C}$, the synthetic mixture decomposes between $200 - 800^\circ\text{C}$. Thus, the remaining mass after pyrolysis reaches 18% for PKS and 34% for the mixture. This represents a biomass-to-gas mass conversion of 82% for the PKS and of 66% for the mixture. Such behaviour could be due to the different morphology that PKS and the mixture present. Moreover, lignin/cellulose and lignin/hemicellulose interactions would be expected for PKS, which could affect pyrolysis conversion (Hosoya et al., 2007). Figure 2 b) shows that the synthetic mixture's pyrolysis resembles that of pure lignin. On the contrary, in PKS, lignin seem to form a stable structure, which is more difficult to be pyrolyzed.

Figure 3 a) shows that the developed model reproduces cellulose pyrolysis from experiments. For both the model and the experiments, cellulose pyrolysis occurs between 300 and 400°C , and the remaining mass at 800°C is 3.3% for the experiment and 0.43% for the model. Discrepancies are found between modelled and experimental results for hemicellulose and lignin, which is evidenced in Figure 3 b). Indeed, for hemicellulose, experiments show pyrolysis occurring between $200 - 500^\circ\text{C}$, whereas the model predicts pyrolysis between $300 - 400^\circ\text{C}$. A similar behaviour was observed for lignin. Although for hemicellulose, there is a good agreement between modelled (3.1%) and experimental (5.9%) remaining mass at 800°C ; a poor agreement was found for lignin between predicted (3.0%) and experimental (43.1%) pyrolysis remaining mass. This behaviour could be explained when considering that unlike cellulose, hemicellulose and lignin are not formed by homogeneous building blocks. Whereas hemicellulose is a mixture

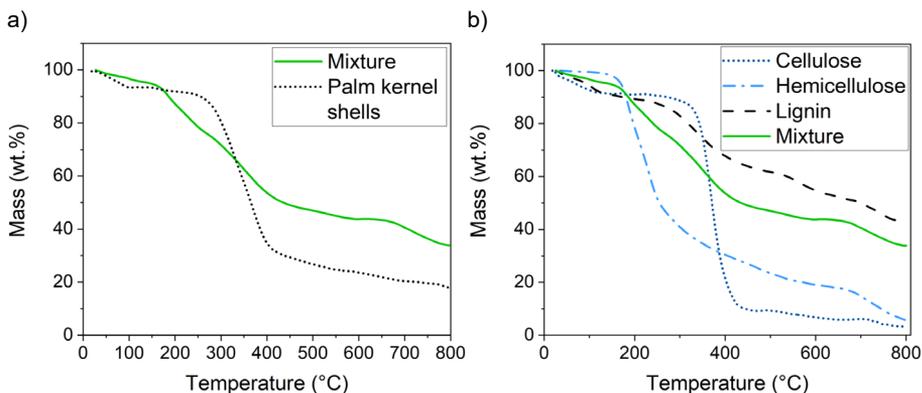

Figure 2: Comparison of the remaining mass in TGA with $50\text{ }^{\circ}\text{Cmin}^{-1}$ for pyrolysis of the synthetic mixture and PKS a), and for the synthetic mixture and its individual components b).

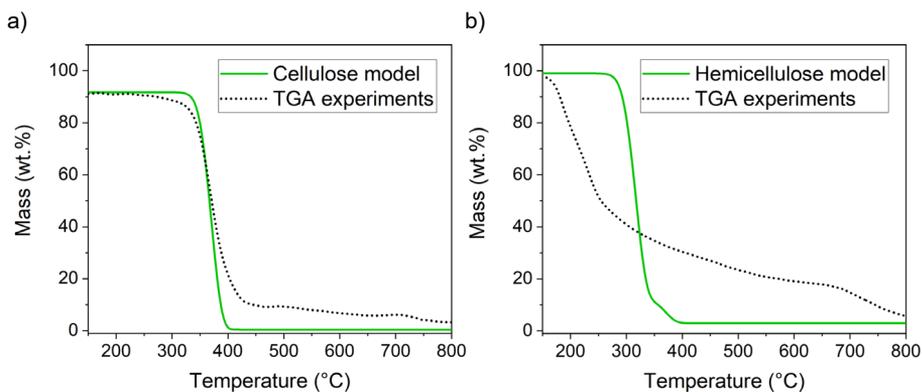

Figure 3: Comparison of experimental and modelled remaining mass for cellulose a) and hemicellulose b) pyrolysis, with a heating rate of $50\text{ }^{\circ}\text{Cmin}^{-1}$.

of pentoses, hexoses and hexuronic acids; lignin contains a variety of aromatic monomers (Debiagi et al., 2015), which are not included in the model. Consequently, modelling PKS pyrolysis as a mixture of individual components, overestimates PKS pyrolysis conversion. This is shown in Figure 4 as a lower remaining mass in the model (2.3%), compared to the experimental results (17.9%). Modified models that included additional forms of hemicellulose, and a 2-stage lignin pyrolysis model (Wang et al., 2016) were also included in the analysis. Although such modifications improve the model's prediction, there is still a discrepancy in the lignin pyrolysis region ($> 400\text{ }^{\circ}\text{C}$). Considering the temperature ranges for cellulose, hemicellulose and lignin pyrolysis, and the poor agreement between modelled and experimental results after $350\text{ }^{\circ}\text{C}$; discrepancies could be attributed to lignin/hemicellulose and lignin/cellulose interactions. Moreover, the used kinetic models consider types of hemicellulose and lignin that might not represent the PKS. Using a detailed kinetic model for PKS, considering the effect of components interactions to adjust the model, and including experimental kinetic parameters for PKS, could improve the model's predictions. The internal structure of the biomass could be also playing a role in PKS pyrolysis, and further work should be performed to understand the way morphology affects pyrolysis kinetics.

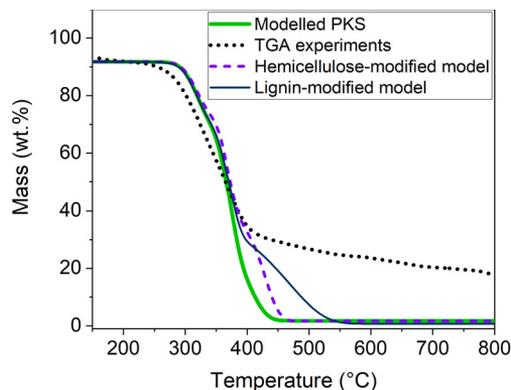

Figure 4: Comparison between experimental and modelled PKS pyrolysis at 50 C min^{-1} . Modelled PKS consider a mixture of cellulose, hemicellulose and lignin. The modified PKS models consider different kinetics for hemicellulose and lignin from Wang et al. (2016).

5. Conclusions

The studied PKS decompose in the $250 - 400 \text{ }^\circ\text{C}$ range throughout pyrolysis. The developed mechanistic model describes cellulose pyrolysis better than hemicellulose and lignin pyrolysis. The agreement between experimental and modelled results for PKS is improved by modifying the model in accordance with the experimental TGA results.

Abstract

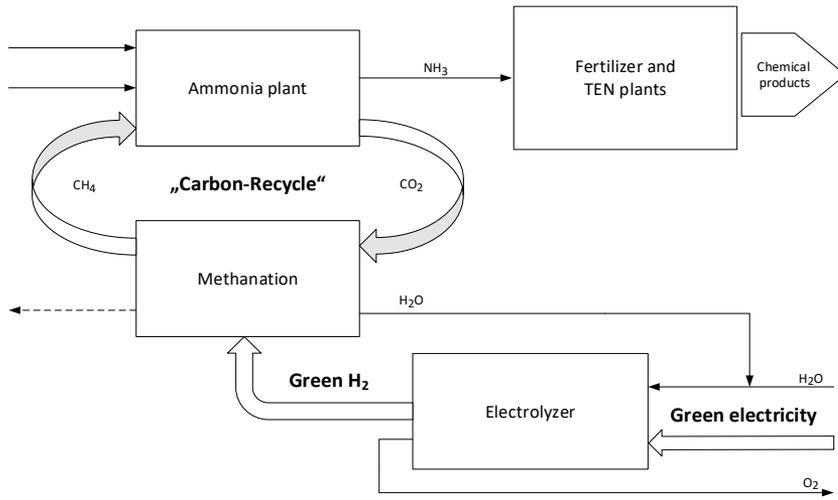

Methanation with regard to the symbiosis of the Borealis and voestalpine industries operating in the chemical park in Linz (Austria) is studied using the commercial software Aspen Plus. The methanation of carbon dioxide with hydrogen allows a reduction of carbon dioxide emissions, especially by considering green energy for electrolysis. The reaction dynamics of carbon dioxide methanation is studied to obtain a suitable range of operating parameters, and a general flow diagram is proposed. Flow schemes and process parameters are proposed based on thermodynamic equilibrium and kinetic reaction models. The effects of using coke oven gas in an ammonia synthesis-methanation complex are presented.

Keywords: CO₂ methanation, Haber-Bosch-process methanation coupling, process model design, kinetic model process simulation

1. Introduction

Borealis operates two ammonia plants at the chemical park in Linz, Austria. An integrated Haber-Bosch process is operated, which uses natural gas as feedstock for the ammonia synthesis. Ammonia is then used as feedstock for downstream fertilizer and melamine plants. Located adjacent to the chemical park are the voestalpine steelworks, a fully integrated steel mill. Coal is processed in coke ovens to produce coke as a carbon source for the blast furnace. This process emits off gas rich in hydrogen, also containing nitrogen, called coke oven gas. Coke oven gas is currently used thermally. A direct chemical utilization as hydrogen source in the methanation reaction would reduce emissions and increase the value chain. These local practicalities enable a methanation unit to run highly efficient. Abundant CO₂ sources are available as concentrated streams along with off gases, and green hydrogen can be synthesized by electrolysis with green energy sourced locally. Carbon emissions could be reduced substantially with the additional benefit of producing a valuable feedstock extensively used by local companies. The implementation enables the formation of a continuous “carbon recycle” across multiple facilities, contributing economic and environmental benefits.

Due to this favorable industrial site set up, the operation of a methanation unit coupled with the Haber-Bosch process and supported by coke oven gas input is simulated to estimate the benefits of its implementation.

Graphical abstract: Ammonia plant methanation coupling

2. Methods

In this work process simulations were performed with Aspen Plus Version 10 (36.0.1.249). Physical properties of the components involved were provided directly by the software from following databanks: APV, APESV (Aspen Plus exclusive) and NISTV (Linstrom and Mallard). Thermodynamic models used are Redlich-Kwong-Soave and Peng-Robinson equations of state. A second order rate expression kinetic model by Lunde (1973), modified and reported by Falbo et al. (2018) was used. The kinetic is:

$$r_{CO_2} = \frac{k}{1+\alpha p_{H_2O}} \left\{ [p_{CO_2}]^n [p_{H_2}]^{4n} - \frac{[p_{CH_4}]^n [p_{H_2O}]^{2n}}{(K_{eq}(T))^n} \right\} \quad (1)$$

$$K_{eq}(T) = \text{EXP} \left[\left(\frac{1}{1.987} \right) * \left(\frac{56000}{T^2} + \frac{56000}{T} - 16.4 \ln T + 0.00557T \right) + 33.165 \right] \quad (2)$$

$$k = k_0 \exp \left(-\frac{E_A}{RT} \right) \quad (3)$$

The following kinetic parameters, provided by Falbo et al. (2018), are used:

$$k_0 = 95.43 \frac{\text{mol}}{\text{s g}_{\text{cat}} \text{ata}^{5n}}$$

$$E_A = 75.3 \frac{\text{kJ}}{\text{mol}}$$

$$n = 0.152 \frac{\text{kJ}}{\text{mol}}$$

$$\alpha = 0.91 \frac{1}{\text{ata}}$$

3. Thermodynamic and kinetic baseline simulations

Several reaction simulations were performed to establish a scientific basis, concerning temperature and pressure dependence of the methanation reaction. The influence of reaction temperature at 1 bar is shown in Figure 1.

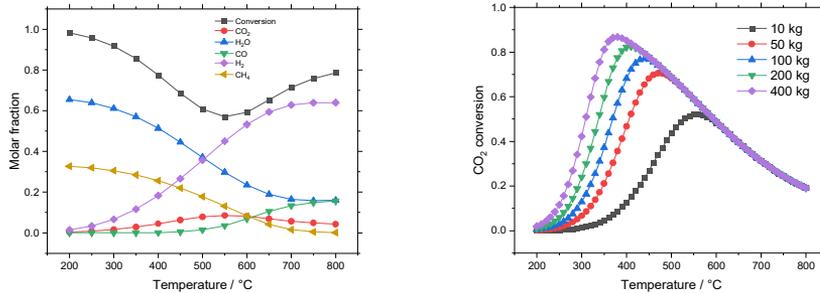

Figure 1: Influence of temperature on product composition and CO₂ conversion in methanation at 1 bar and thermodynamic equilibrium (left). Influence of temperature on CO₂ conversion in methanation at 1 bar and different catalyst loads (kinetic model) (right).

Product gas composition is highly dependent on reaction temperature and in accordance with the observed changes in the conversion of CO₂. Increasing temperature shifts the thermodynamic equilibrium of the methanation reaction to the educt side. An increase in reaction temperature dramatically boosts catalyst activity up to a maximum between 340 and 500 °C after which conversion is reduced again due to the thermodynamic limits on reaction temperature. The methanation reaction responds strongly to an increase in pressure (figures not included). Under increasing pressure higher conversions can be achieved, and higher temperatures can be employed.

4. Process model

The full plant model used is shown in Figure 2. A two-reactor setup was chosen to compensate for thermodynamic and kinetic differences concerning the influence of the reaction temperature.

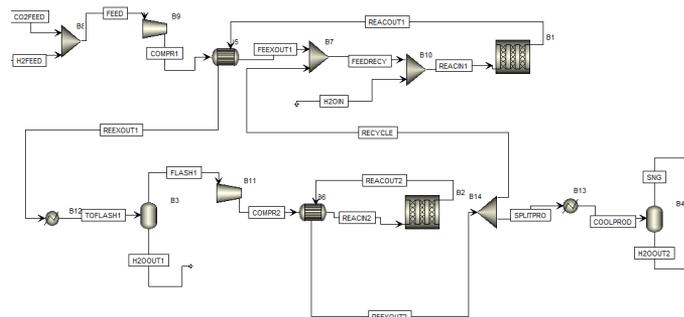

Figure 2: Full kinetic plant model as Aspen Plus flowsheet.

Reactor cooling was simulated with cooling fluid at constant temperature. The volume of reactor one and two are 2 m³ and 3 m³, respectively. For reactor 1 cooling fluid at 500 °C was chosen to simulate molten salt. The second reactor was used to perform with cooling medium at 350 °C resembling steam. The compressors are set to 10 bar for reactor 1 and 30 bar for reactor 2. The split fraction is set to 0.5. All simulations are performed with 1000 kg/h CO₂ and 181 kg/h H₂ input. Steam addition before reactor 1 is set to achieve 10 mol % of water at the reactor inlet by implementation of a design specification. Performance curves are shown in Figures 3 and 4.

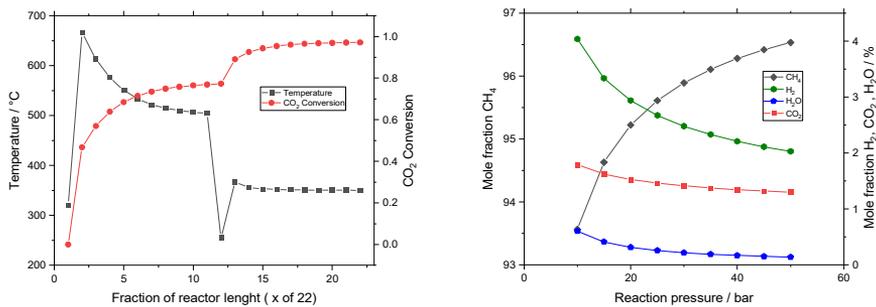

Figure 3: Reactor temperature and CO₂ conversion of both reactor B1 (1-11) and reactor B2 (12-22) (left). Product composition at changing reaction pressure in reactor B2 at 0.5 product recycle fraction (right).

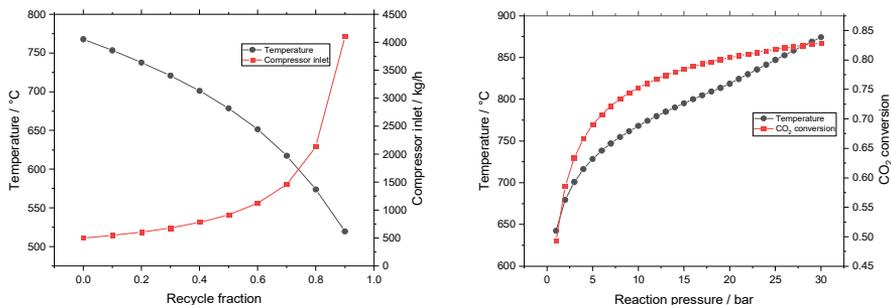

Figure 4: Change in maximum reactor temperature of B1 and compressor B1 inlet at increasing recycle fraction (left). Change in maximum reactor temperature and CO₂ conversion in reactor B1 at increasing reaction pressure and 0.5 product recycle fraction (right).

Characteristic for the methanation reaction is the severe temperature spike at the reactor inlet. This temperature spike could be successfully reduced by 150 to 200 °C if a product recycle and limitation of the reaction pressure in B1 is employed. These methods show disadvantages of higher compression work and lower conversion, respectively. It can be seen in Figure 3 that a product composition in agreement with Austrian natural gas grid quality guidelines according to ÖVGW G. 31 (2001) can be achieved if reaction pressure in B2 is set accordingly.

5. Coke oven gas utilization

Coke oven gas generally contains sizeable amounts of nitrogen. Due to the large amounts of water formed and separated in the methanation reaction the nitrogen content is further increased in the finished product. Natural gas containing nitrogen is problematic for grid injection and may also lead to difficulties in further industrial use. It would be beneficial if the nitrogen content of the synthetic natural gas does not need to be removed before injection into the steam reformer in the Haber-Bosch process. The influence of increasing nitrogen load in the reformer natural gas feed, as commercial natural gas is exchanged, is therefore studied. This was done by manual configuration of the internal Aspen Plus simulation model for the ammonia 2 plant operated by Borealis in Linz. Four Simulations were performed. The observed parameters are reaction pressure (1), feed flow (2), process air flow (3), purge gas flow (4), product flow (5) and product quality (6). Table 1 and 2 show parameter allocation and overall results and Figure 5 examples of recorded performance indicators.

Table 1: Fixed and variable parameter allocation for simulations performed.

Simulation	Fixed parameters	Variable parameters
1	(1), (2), (3), (4)	(5), (6)
2	(3), (5)	(1),(2),(4),(6)
2.5	(3), (6)	(1),(2),(4),(5)
3	(4), (6)	(1),(2),(3),(5)
4	(5), (6)	(1),(2),(3),(4)

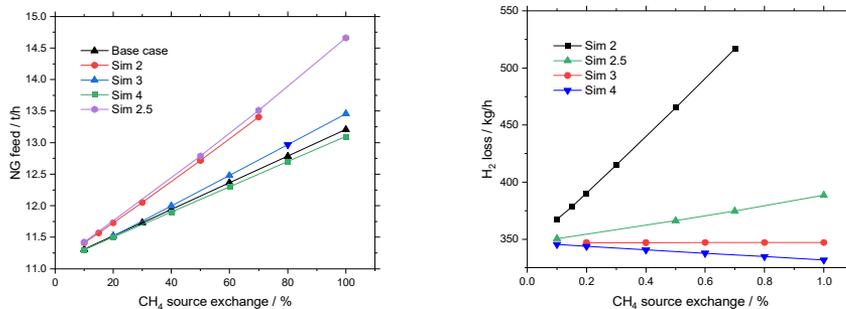

Figure 5: Comparison of NG feed flows and H₂ losses according to CH₄ source exchange at static CH₄ amount

Table 2: Comparison of synthesis gas, reaction pressure, H₂ loss, CH₄ input and NH₃ output changes of different simulations with the base case

Simulation	Change in % vs base case at maximum exchange				
	Synthesis gas	Reaction pressure	H ₂ Loss	CH ₄ Input	NH ₃ Output
1	+101.34	0.00	+0.04	-5.39	+1.27
2	+20.45	-41.67	+48.98	+6.61	+0.00
2,5	+14.25	-1.09	+12.03	+11.00	+10.43
3	+3.44	-3.70	+0.06	+1.90	+2.32
4	-0.46	-0.60	-4.33	-0.83	0.00

Simulations 1 to 3 show large changes in the observed process parameters and therefore bring large overall economic advantages and disadvantages. The setup in simulation 4 shows only direct advantages, but the magnitudes are generally smaller.

6. Conclusion

Insight into CO₂ methanation reaction characteristics is gained by detailed temperature and conversion curves at 1 bar. At thermodynamic equilibrium methanation is most effective at temperatures below 500 °C and high pressure. The kinetic model shows increasing conversion with temperature (maxima between 340 and 500 °C), due to rising catalyst activity. At temperatures exceeding 500 °C the conversion then starts to decline again as a result of the thermodynamic limitations.

A full flow sheet simulation model able to convert 1 t/h of CO₂ to SNG at high conversion and selectivity is designed and optimization paths based on temperature control and product quality are outlined. The model contains 2 cooled methanation reactors and a product recycle. A performance curve is recorded, showing 97 % CO₂ conversion under temperature requirements imposed by catalyst stability.

It is concluded that a complete exchange of external natural gas with natural gas from methanation with coke oven gas as hydrogen source is not only tolerable, but has considerable advantages concerning feed requirements, as H₂ loss, recycle gas volume and reaction pressure. Five different plant operation setups are simulated and able to reduce synthesis loop volume by 0.5 %, reaction pressure by 42 %, H₂ loss by 49 %, CH₄ input by 11 % and increase product output by 10 %. One setup showed purely positive effects of N₂ input concerning the observed parameters. Recycle volume is reduced by 0.46 %, reaction pressure by 0.6 % H₂ loss by 4 % and CH₄ input by 0.83 % at the same product output.

Abstract

Process simulations must involve evaluating output variables by specifying input variables and process parameters. However, in a real process, input data and parameters contain uncertainties, which requires a more realistic analysis, using for example, a stochastic simulation procedure. This technique is based on a large set of simulations using random data according to a suitable probability density function. The aim of this work is to analyze the propagation of uncertainties on the calculation of an equilibrium quantity in a distillation column through a stochastic simulation approach, a very useful tool in process system engineering. In this way, the result is not one exact value for the parameters, but a range of probable values. This method proved to be promising and means more accurate process calculations, generating energy savings in industrial units. A debutanizer column was specified based on FUG algorithm, and Monte Carlo (MC) approach has been used to quantify and calculate the uncertainty propagation on parameters. The feed vapor fraction, distillate (D), and bottom (B) temperatures and compositions were evaluated. The results demonstrate a smooth propagation and a large range in D and B temperatures.

Keywords: Uncertainty analysis, Monte Carlo method, Distillation Column calculation.

1. Introduction

Process simulations must involve evaluating output variables by specifying input variables and process parameters. However, in a real process, input data and parameters contain uncertainties, which can limit the use of simulation results to predict plant behavior. Engineers must therefore know the importance of reliability in the property data of pure substances and mixtures, and understand how small uncertainties in this information can significantly affect the technical and economic performance of an industrial plant. (Santana, 2021^a)

A common mistake made in process calculations is to treat problems using a set of parameters and input data and not as a range. literature presents works using stochastic methods to quantify and measure the propagation of uncertainties along real chemical processes. (Santana, 2021^b)

The quantification of uncertainties, in general, consists basically of three steps: (1) representing the uncertainties in the input parameters of the system; (2) propagation of uncertainty throughout the process, and (3) estimating the stochastic effect on the calculations. (Ramos, 2014) These uncertainties can be introduced mainly in two ways: the first is associated with the method used and depends, for example, on the thermodynamic model, or on the numerical method, and the second way, the error presented in the input data propagates in the result. thus, the better the quality of the data

provided and the accuracy of the prediction methods, the better the estimate of the desired property will be. (Vasquez & Whiting, 2004)

To obtain a more realistic analysis, a stochastic simulation procedure can be performed using the Monte Carlo method, the most widely used stochastic method for calculating uncertainties. This technique is based on a large set of simulations using random data according to a suitable probability density function to estimate the chance of a future event happening. Thus, several simulations are performed to calculate the probabilities of hit or miss the generation of random numbers must follow a probability density function and respect a certain range. (Ramos, 2014.)

This work presents an application of stochastic simulation procedures in the chemical process industry. The method was applied to the calculation of a distillation column (a debutanizer), under uncertainty in the Antoine parameters. The objective of this paper is to analyze the propagation of uncertainties on the calculation of an equilibrium quantity through a distillation column (i.e., debutanizer).

2. Methodology

The specifications for the debutanizer such as column operating pressure, reflux ratio, number of stages, and feed location were obtained and then the distillation column were obtained in the literature (Seader, et al., 2011.) through the FUG algorithm for multicomponent distillation on a debutanizer distillation column. And the component properties were obtained in the DIPPR data bank. (DIPPR801, 2021) and all these data were used to simulate the distillation column on Aspen Plus v12.

Microsoft excel was used to compare pseudo-experimental data for vapor pressure from the DIPPR® data bank with the calculated vapor pressure from Antoine's equation. and the least-squares method was employed using MS excel solver to minimize the uncertainty between the calculated values and the experimental ones. Thus, new parameters were defined (if necessary) and optimized for the estimated temperature range (simulated temperature $\pm 10\%$).

Using the uncertainty from Vapor pressure comparison, the MC approach was applied to quantify and determinate how these uncertainties impact the operation. The column feed, which was flashed at column pressure using the adiabatic flash procedure (Eq. 1). was simulated under uncertainty in the vapor pressure using the generation of 10000 random numbers for P^{sat} defined by Eq. 4 and Eq. 5, of each component. The K-values for vapor-liquid equilibrium were given by Raoult law (Eq. 2) once the pressure system is near to ambient pressure. The stochastic approach generates a range of values for the vapor fraction in the feed stage. Using the boxplot chart, the outliers were removed and a vapor fraction range was found.

Furthermore, simulations were performed on Aspen Plus using different vapor fractions in the feed stage. Different results were obtained on the top and bottom of the column, and MC procedure was used to estimate the probable range of temperature in the bottom and top based on the results of the under-uncertainty simulations.

These different feed conditions generate a range of different product compositions at the bottom and in the top of the column. As the outputs are in a liquid state it must be calculated the bubble point temperature (Eq. 3), using the MC approach, with uncertainty in the P^{sat} , like the feed calculations, and in the component's composition (from feed uncertainty).

The bubble temperature was calculated using 1000 MC simulations. Through the boxplot plot, the outliers were removed and a bubble temperature range was found.

$$\sum_i \frac{z_i K_i}{1 + v(K_i - 1)} = 1 \tag{Eq. 1}$$

Where z_i is the molar fraction composition of the feed, K_i is the partition coefficient defined by the K-values equations, in this case the equation chosen was Raoult Law (Eq. 2.) and v is the vapor fraction of the feed

$$K_i = \frac{P^{sat}}{P} \tag{Eq. 2}$$

For bubble point calculations it is defined that the vapor fraction of the mixture is equal to zero ($v=0$), and the composition is defined as $z_i=x_i$, so that Equation 1 is simplified in the form of Equation 3, below.

$$\sum_i K_i x_i = 1 \tag{Eq.3}$$

The K_i values estimated from Raoult's Law can be defined by $K_i = P^{sat} / P$, where P^{sat} can be calculated using the Antoine equation defined in the Equations 4 and 5 (with 5 and 3 parameters respectively). The Antoine parameters are found in Table 1.

$$P^{sat}(Pa) = e^{A+B/T(K)+C \ln T(K)+DT(K)^E} \tag{Eq. 4}$$

$$P^{sat}(Pa) = 10^{\left(A - \frac{B}{T(K)+C}\right)} * 1000 \tag{Eq. 5}$$

As can be seen, the variables temperature and vapor fraction can be easily found using numerical calculations. Microsoft Excel's VBA programming language was used to solve the equations using interactive methods through Solver and to generate the random numbers from Monte Carlo simulations.

Table 1. Antoine equation parameters (DIPPR801, 2021; L. Santana, 2021^b)

Comp	A	B	C	D	E	Eq
iC4	108.4300	-5039.9000	-15.0120	0.0227	1	4
nC4	66	-4363.2	-7	9.45E-06	2	4
iC5	3.89559	999.99096	-44,1236	N/A	N/A	5
nC5	79	-5420.3	-9	9.62E-06	2	4
C6	104.65	-6995.5	-13	1.24E-05	2	4
C7	88	-6996.4	-10	7.21E-06	2	4
C8	96	-7900.2	-11	7.18E-06	2	4
C9	109.35	-9030.4	-13	7.85E-06	2	4

3. Results

A preview of the debutanizer can be seen on the Figure 1 and the column specifications in the table 2. These results are based on FUG calculation procedure from Seader, et al., 2011. The information from figure 2 and table 2 was used in the Aspen Plus v.12 where temperature, molar fraction, and other results have been obtained.

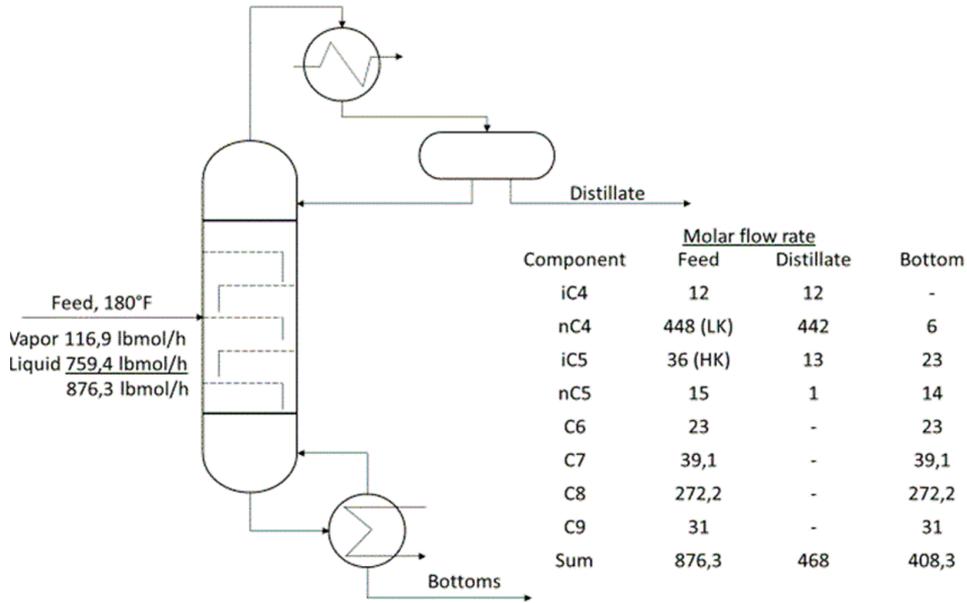

Figure 1: Debutanizer specifications

Table 2: Column specifications (J. Seader, et al., 2011.)

Number of stages	18
Reflux ratio	0.8
Drop pressure	5 Psia
Feed location	Above stage 6

Table 3 shows the first simulating results resume. Used as base case for the MC procedures.

Table 3: initial simulating results.

	Feed	Distillate	Bottom
Molar vapor fraction	0.133	0	0
Temperature	355.372	328.231	447.582
Pressure (Pa)	497565.306	558475.340	592949.127

The Antoine's parameters shown to be very accurate for the range of initial feed temperature $\pm 10\%$, then wasn't necessary to optimize the parameters values. The parameters uncertainties after this analysis can be found in Table 4 and the confident interval is based on this data. All uncertainties used in the calculations are presented in Table 4, and in Table 5 it can be seen the results of uncertainty analysis.

Table 4: Uncertainty (%) based

Component	In P^{sat} (from Literature data) (DIPPR801, 2021)	In P^{sat} (after analysis)	In distillate composition (after simulations)	In bottom composition (after simulations)

Ic4	3.00000	0.09736	0.048625	44.74108
Nc4	3.00000	0.12408	0.745863	42.80125
Ic5	3.00000	0.12408	19.81697	10.06561
Nc5	3.00000	0.12408	24.47607	7.398475
C6	3.00000	0.36381	44.33357	0.146274
C7	3.00000	0.12517	47.55897	3.09486E-03
C8	3.00000	0.19169	51.43366	3.52628E-05
C9	3.00000	0.20361	53.90483	5.45788E-07

Based on the results from Figure 3 we can conclude that the uncertainty remains smooths in the process after the outliers have been excluded, the data from table 5 shows that the results respect an almost ideal normal distribution with a very low asymmetry coefficient. With a smooth platykurtic format curve, that is a distribution with a larger standard deviation than the mesokurtic curve, and so the curve is less peaked.

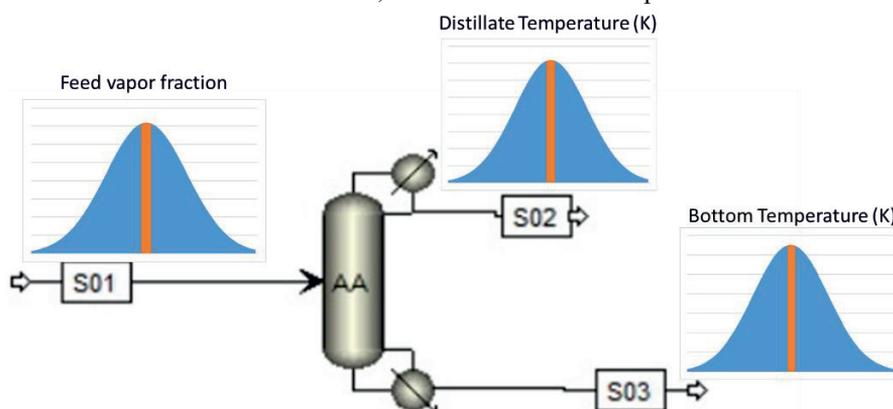

Figure 3: Monte Carlo simulation result

Table 5: Evaluated uncertainties results

	Feed (v)	Distillate (T [K])	Bottom (T [K])
Mean \pm Std. dev.	0.13256 \pm 0.02664	326.6694 \pm 1.1097	435.9215 \pm 3.0647
Uncertainty (In vapor pressure)	3%	3%	3%
Confidence interval	12%	14%	13%
Kurtosis coefficient	0.26687 (platykurtic)	0.29101 (platykurtic)	0.28090 (Platykurtic)
Asymmetry coefficient	-0.05281	-0.01199	0.03687

4. Conclusion

The stochastic approach is a good way to simulate and predict most of the feasible scenarios in an industrial plant, being an alternative to overcome the problems caused by the lack of reliability in the data for process calculations. Uncertainties are intrinsic to any process, so the approach to real physical problems must be seen as a range of probable values and not as a set of result. Therefore, it is essential that chemical engineers know the characteristics of this category of approach and know the fundamental steps to quantify process uncertainties. In this work, the method was applied to the calculation of chemical processes, the calculation of a debutanizer, the results show that a minimal

uncertainty in only one temperature-dependent property can produce larger output uncertainty.

Abstract

The projected increase in the market share of renewable energy sources such as wind and solar power will demand a similar increase in the global energy storage capacity. Batteries represent one of the most flexible solutions to cope with this demand because of their easy installation and high energy density when compared to other large-scale energy storage systems. In this context, one of the most promising technologies is Li-O₂, whose energy density can exceed 1000 Wh kg⁻¹. However, many challenges need to be addressed for this battery technology before it can become available to the market. For instance, the O₂ transport inside the battery limits the power density. One of the strategies to improve the supply of O₂ to the battery is the so-called wet electrode approach, in which parts of the O₂ electrode are filled with gas instead of electrolyte, thus serving as a means to deliver O₂ to the interior of the electrode. Bearing all this in mind, this study presents the simulation of two battery models working under different current densities to demonstrate the impact of electrode geometry on the performance of the battery. The models, developed on COMSOL Multiphysics 5.6, consist of two Li-O₂ batteries with either a simple flooded O₂ electrode or a wet O₂ electrode with gas diffusion channels, with both electrodes based on properties of carbon nanotubes. According to the results, although the gas diffusion channels take space inside the battery and decrease the surface area for deposition of discharge product, this electrode design strategy increased the accessibility of O₂ throughout the length of the electrode. The increased transport capacity was fundamental to increasing the energy density of the battery. The results also indicate that this design approach was fundamental to enable increased power demand for Li-O₂ batteries without compromising their energy density because of the possibility to deliver O₂ more easily to the whole electrode. Based on this design, it is important to optimize the density of these gas diffusion channels to increase the available surface area of the O₂ electrode without compromising the transport of O₂ to the interior of the electrode. Moreover, the optimization of this design should also consider limitations related to surface properties of electrode materials such as hydrophobicity and hydrophilicity to ensure that the gas diffusion channels stay available for O₂ transport.

1. Introduction

Solar and wind power have become the source of electricity with the lowest cost on a global average (Lazard, 2020). This achievement will enable the wide adoption of renewable electricity sources in the near future. However, these renewable electricity sources are intermittent, and their wide adoption will represent a challenge for grid

operators unless energy storage becomes widely available. To accomplish this, energy storage costs must decrease, and new capacity needs to be installed across the whole grid (Jülch, 2016). One technology option to meet these requirements is the Li-O₂ battery. Batteries can be installed everywhere, independent of suitable geography. Moreover, this battery has a specific energy potential above 1000 Wh kg⁻¹, higher than that of lithium-ion, and this factor has an important contribution to device cost (Tan et al., 2017).

However, the full potential of Li-O₂ batteries is still hindered by many factors, such as instability of battery components, high resistivity of the discharge product, irreversibility of discharge product, mass transport of O₂, among others (Wang et al., 2020). Sluggish O₂ transport represents a large burden because the battery reaches the cut-off potential much sooner when more O₂ transport is demanded at an increased discharge rate.

As the diffusion of O₂ is faster in gas than in liquid, one of the solutions to improve the transport of O₂ is to only partially fill the electrode with electrolyte — the wet electrode approach (Gwak & Ju, 2016). Bearing all this in mind, this work shows the simulation of Li-O₂ batteries operating with a flooded or a wet electrode. The performance of the two cases was compared in different current densities. Results demonstrate the potential of gas diffusion channels in improving the performance of Li-O₂ batteries for increased power output without compromising the energy density of the device.

2. Method

Figure 1 illustrates a Li-O₂ battery and the two approaches considered in this model: flooded electrode and wet electrode with gas diffusion channels. Both models were built on COMSOL Multiphysics® 5.6 (COMSOL AB, 2020). In both electrodes, the regions with carbon nanotubes were modeled using the Newman approach. In the wet model, gas diffusion channels with diameters of 3–9 μm were built to simulate the presence of macropores free of electrolyte inside the O₂ electrode. The models represent a slice of the O₂ electrode to account for the variability of pore shape, whose geometry was based on images of pores from other works (Su et al., 2020). The battery operates at 25 °C.

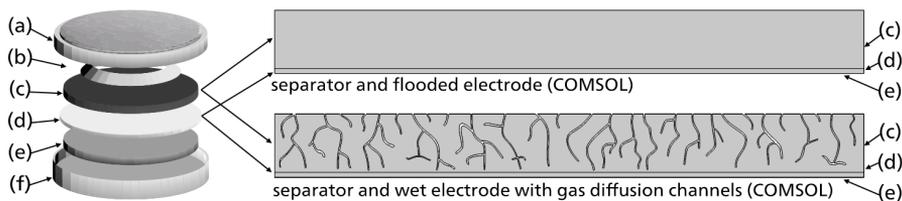

Figure 1. Exploded-view drawing of a Li-O₂ coin cell (not to scale) showing: a) perforated top cover, b) spring, c) O₂ electrode, d) separator membrane, e) Li electrode, f) bottom casing. At the right side, the equivalent 2D model on COMSOL Multiphysics® for the flooded and wet electrodes, showing the c) O₂ electrode (top domain), d) separator membrane (bottom domain), and the Li electrode (bottom boundary). O₂ is fed at the boundary at the top of the O₂ electrode.

In this battery, the reactions described in Eq. (1) and (2) take place during discharge. Li⁺ is dissolved in the electrolyte (LiClO₄ in dimethyl sulfoxide) at a concentration of 1 mol L⁻¹, which is a range suitable for the application of the concentrated solution theory (Tan et al., 2017). The concentration of a species *i* is expressed based on the Nernst-Planck equation as a function of the volume fraction of electrolyte (ε_l), concentration (C_i), molar flux (N_i), and a source or sink term (r_i), as shown in Eq. (3). The volume fraction of electrolyte is related to the electrode volume fraction (ε_s) and the volume fraction of Li₂O₂ (ε_p , the discharge product), as shown in Eq. (4). The molar flux of Li⁺ and O₂, considering

that no convection is present, is a function of the effective diffusion ($D_{Li^+}^{eff}$ or $D_{O_2}^{eff}$), concentration (C_{Li^+} or C_{O_2}), current density in the electrolyte (i_l), transference number (t_+), and the Faraday constant (F), as shown in Eq. (5) and (6).

$$Li \rightarrow Li^+ + e^- \quad (E^0 = 0.00 \text{ V}) \quad (1)$$

$$2 Li^+ + O_2 + 2e^- \rightarrow Li_2O_2 \quad (E^0 = 2.96 \text{ V}) \quad (2)$$

$$d(\varepsilon_i C_i)/dt + \nabla \cdot \mathbf{N}_i = r_i \quad (3)$$

$$1 = \varepsilon_s + \varepsilon_l(t) + \varepsilon_p(t) \quad (4)$$

$$\mathbf{N}_{Li^+} = -D_{Li^+}^{eff} \nabla C_{Li^+} + \mathbf{i}_l t_+ / F \quad (5)$$

$$\mathbf{N}_{O_2} = -D_{O_2}^{eff} \nabla C_{O_2} \quad (6)$$

Considering a binary Li⁺ electrolyte, the current density in the liquid solution is a function of the effective ionic conductivity of the electrolyte (κ_{eff}), electrolyte potential (φ_l), universal gas constant (R), temperature (T), and activity coefficient of Li⁺ (f_{\pm}), as shown in Eq. (7). The derivative of f_{\pm} is given by Eq. (8) in the range of $0.2 < C_{Li^+} < 2 \text{ mol L}^{-1}$ (Nyman et al., 2008). Transport of charges in the O₂ electrode follows Ohm's law, and it is a function of the effective electronic conductivity of the O₂ electrode (σ_{eff}) and the potential of the electrode (φ_s), as shown in Eq. (9). Because of the porous structure of the O₂ electrode, effective parameters are estimated based on the volume fraction and the tortuosity of the porous medium. According to the Bruggeman model (Tjaden et al., 2016), in the case of carbon nanotubes, the tortuosity can be estimated as the reciprocal of the porosity, thus leading to Eq. (10)–(13) to estimate the effective parameters. In this model, O₂ is fed to the battery by means of a boundary condition, as a function of the partial pressure of O₂ (p_{O_2}) and the O₂ solubility in the electrolyte (H), as seen in Eq. (14).

$$\mathbf{i}_l = -\kappa_{eff} \nabla \varphi_l - 2RT \kappa_{eff} / F (-1 + t_+) (1 + \partial \ln(f_{\pm}) / \partial \ln C_{Li^+}) \nabla \ln(C_{Li^+}) \quad (7)$$

$$\frac{\partial \ln(f_{\pm})}{\partial \ln C_{Li^+}} = \frac{(0.28687C_{Li^+}^2 - 0.74678C_{Li^+} + 0.44103)}{0.1287C_{Li^+}^3 - 0.4106C_{Li^+}^2 + 0.4717C_{Li^+} + 0.5508} - 1 \quad (8)$$

$$\mathbf{i}_s = -\sigma_{eff} \nabla \varphi_s \quad (9)$$

$$D_{Li^+,eff} = \varepsilon_l^2 D_{Li^+} \quad (10)$$

$$D_{O_2,eff} = \varepsilon_l^2 D_{O_2} \quad (11)$$

$$\kappa_{eff} = \varepsilon_l^2 \kappa \quad (12)$$

$$\sigma_{eff} = \varepsilon_s^2 \sigma \quad (13)$$

$$C_{O_2,e}^{sat} = H p_{O_2} / RT \quad (14)$$

Conservation of charges is described by Eq. (15). Transference of charge between phases is a function of available surface area (a) and local transfer current density (j), as shown in Eq. (16). Based on these parameters, the source term is calculated via Eq. (17).

$$\nabla \cdot \mathbf{i}_l + \nabla \cdot \mathbf{i}_s = 0 \quad (15)$$

$$\nabla \cdot \mathbf{i}_l = aj \quad (16)$$

$$r_i = -aj / F \quad (17)$$

The rate expression for the electrochemical reaction at the O₂ electrode can be described by the Butler-Volmer kinetics, shown in Eq. (18), which is a function of the anodic and cathodic rate constants (k_a and k_c) and the activated overpotential (η_c), described in Eq. (19). The activated overpotential is a function of the potential drop over the electrolyte, the electrode, and the film of Li₂O₂ ($\Delta\varphi_{film}$), and the equilibrium potential of the reaction (E_c°). The potential drop in the film of discharge product is a function of its thickness (Δs)

and conductivity (σ_p), as shown in Eq. (20). The volume fraction of discharge product deposited onto the O₂ electrode ($\varepsilon_{Li_2O_2}$), given by Eq. (21), is a function of its concentration ($C_{Li_2O_2}$), molar mass ($M_{Li_2O_2}$), and density ($\rho_{Li_2O_2}$). This volume fraction is used to estimate the surface coverage (θ) with Eq. (22), the available surface area with Eq. (23), and the thickness of the film with Eq. (24).

$$j/nF = k_a C_{LiO_2} \exp(F\eta_c/RT) - k_c C_{Li^+}^2 C_{O_2} \exp(-F\eta_c/RT) \quad (18)$$

$$\eta_c = \varphi_s - \varphi_l - \Delta\varphi_{film} - E_c^\circ \quad (19)$$

$$\Delta\varphi_{film} = j\Delta s/\sigma_p \quad (20)$$

$$\varepsilon_{Li_2O_2} = C_{Li_2O_2} M_{Li_2O_2}/\rho_{Li_2O_2} \quad (21)$$

$$\theta = (\varepsilon_{Li_2O_2}/\varepsilon_{l,0})^Y \quad (22)$$

$$a = a_0(1 - \theta), \quad a_0 = 2\varepsilon_s/r_0 \quad (23)$$

$$\Delta s = (\sqrt[3]{(\varepsilon_{Li_2O_2}\theta + \varepsilon_s)/\varepsilon_s} - 1)r_0 \quad (24)$$

The membrane and electrode thicknesses were set to 25 μm and 500 μm , and the slice of O₂ electrode had 3 mm. The conductivity of the O₂ electrode was 300 S m⁻¹ between planes and 5000 S m⁻¹ in-plane (Matsumoto et al., 2021). Other parameters were based on previous literature (Sahapatsombut et al., 2013). A mesh refinement study was performed to decide upon the number of mesh elements and solver tolerance. The simulations were run on an Intel Core i5 9600KF (overclocked to 4.7 GHz and with 32 GB RAM). The batteries were discharged at current densities of 0.5, 2.0, 3.5, and 5.0 A m⁻² till the stop condition of deep discharge (cut-off potential of 2.5 V) was reached.

3. Results and discussion

Figure 2 presents the results of the mesh refinement study. In the case of the flooded electrode, the mesh with 336 elements was selected because increasing the number of elements to 760 leads to a variation of 0.1% in the specific capacity with an increase of 80% in solver time. For the wet electrode, the mesh with 5135 elements was selected because increasing the number of mesh elements to 8389 leads to a change of 0.02% in the specific capacity with an increase of 82% in solver time. Relative tolerance of 10⁻³ was selected because tightening the relative tolerance from 10⁻³ to 10⁻⁴ leads to a change in the specific capacity of 0.006% in the flooded electrode and 0.004% in the wet electrode, with an increase in the solver time of 60% and 130%, respectively.

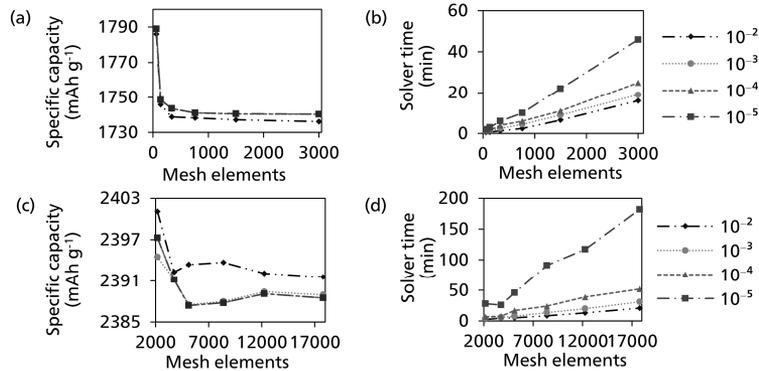

Figure 2. Mesh refinement study for the flooded (a, b) and wet (c, d) electrodes showing the specific capacity (a, c) and solver time (b, d) for different relative tolerances (10⁻²–10⁻⁵).

Figure 3 shows the specific capacity of the Li-O₂ battery for different current densities (0.5–5.0 A m⁻²) in both flooded and wet electrodes, and Figure 4 shows the distribution of Li₂O₂ after discharge at 0.5 and 5.0 A m⁻² and the concentration of O₂ after discharge at 5.0 A m⁻². Comparing graphs (a) and (b) of Figure 3, it is possible to see that, despite presenting 6.85% less area for discharge than the flooded electrode, the wet electrode reaches a specific capacity 15% larger at 0.5 A m⁻² and almost three times larger at a current density of 5 A m⁻². Also, a tenfold increase in the current density leads to a loss of capacity 21% lower in the wet electrode when compared to the flooded electrode.

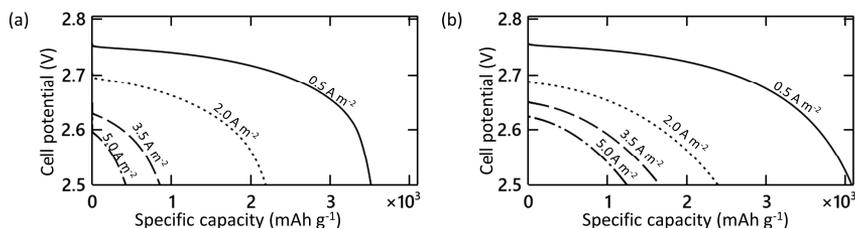

Figure 3. Specific capacity of the Li-O₂ battery for different discharge current densities (0.5–5.0 A m⁻²) for the a) flooded and b) wet electrodes.

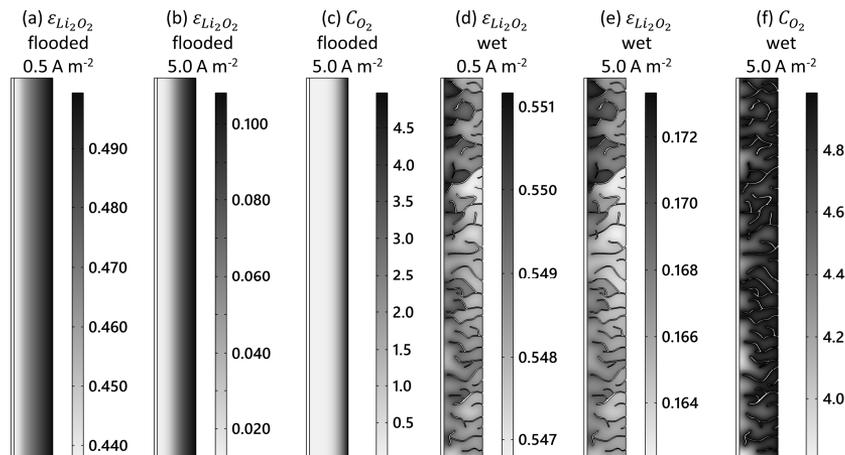

Figure 4. Distribution of discharge product represented as the volume fraction of Li₂O₂ ($\epsilon_{Li_2O_2}$ in a, b, d, e) for current densities of 0.5 (a, d) and 5.0 (b, e) A m⁻² and concentration of O₂ (C_{O_2} in c, f) at a current density of 5.0 A m⁻² for flooded (a–c) and wet (d–f) electrodes.

The decreased performance of the battery in the case of the flooded electrode is explained by the poor distribution of discharge product in the O₂ electrode, as seen in Figure 4. Observing graph (a) of Figure 4, it is possible to see a large gradient of discharge product distribution, with a significant product buildup near the O₂ feed side of the O₂ electrode. In this case, the volume fraction of discharge product in the O₂ electrode varies from 0.438 to 0.499, a range of 0.061. On the other hand, in the wet electrode, it varies from 0.547 to 0.551, a range of only 0.004. Because of the large range in the case of the flooded electrode, the effective diffusion of O₂ near the O₂ feed side decreases faster as discharge takes place because of the increased volume of solids in this region, according to Eq. (11). This problem is circumvented in the case of the wet electrode.

The challenge of delivering O₂ to the flooded electrode is better demonstrated at a current density of 5.0 A m⁻². In this case, the final volume fraction of Li₂O₂ in the flooded electrode varies from 0.012 to 0.108, a range of 0.096. In the wet electrode, the final volume fraction of Li₂O₂ varies from 0.162 to 0.173, a range of only 0.011. The O₂ diffusion bottleneck is clear in the comparison of graphs (c) and (f) of Figure 4. At the end of the discharge, O₂ concentration is below 10% of the saturated concentration in 59% of the flooded electrode, and below 1% of the saturated concentration in 41% of the flooded electrode, making it underused. However, the lowest O₂ concentration in the wet electrode is 76% of the saturated concentration, showing that the presence of gas diffusion channels greatly increases the capacity of supplying O₂ to the cell during discharge.

4. Conclusions

Past works have demonstrated that one of the main problems of Li-O₂ batteries is the transport of O₂ inside the battery. This work compared two electrodes: the flooded electrode and the wet electrode with gas diffusion channels. The results show that mass transport of O₂ is greatly assisted by the presence of gas diffusion channels despite the small space occupied by them inside the electrode (6.85%), and they allow a loss of capacity 21% lower for a tenfold increase in discharge current. The great improvement also indicates that the geometry of these gas diffusion channels can be further analyzed to find a balance between their size and performance improvement taking into consideration the limitations of materials for the manufacture of O₂ electrodes.

Abstract

Natural gas liquefaction has been deployed in different countries to produce liquefied natural gas (LNG) for the economic transportation to distant markets. However, when assessing a natural gas monetisation technology, the profitability of the project is evaluated using the economic performance indicator, net present value (NPV), under deterministic conditions. This does not reflect the real-life scenario since the risks associated with exogenous uncertainties arising from emergence of new suppliers, and changes in contractual structures are not captured under deterministic analysis. Consequently, risks associated with investing in a mega LNG plant shall be considered in the design stages to decide on an optimal strategy for dealing with possible uncertainties throughout the lifetime of the project. In this study, a techno-economic analysis is conducted for the flexible AP-X LNG production technology licensed by Air Products. A three-steps methodology is considered to assess the AP-X technology: (1) technical assessment; (2) economic evaluation; and (3) techno-economic risk assessment and management. In the technical assessment, an LNG production plant model is developed and simulated using the Aspen HYSYS software, and evaluated under deterministic conditions using the NPV. The process is then evaluated under stochastic conditions using Monte Carlo Simulation to understand the impact of different uncertainties on the profitability of the plant. A proactive mode of response strategy to deal with risks is tested to increase the responsiveness of the project to exogenous changes through embedding flexibility in production in the early design stages of the project. The results indicate that a flexible system demonstrates a better economic performance than a rigid system.

Keywords: liquefied natural gas, flexibility, uncertainty, stochastic analysis

1. Introduction

In the past few years, natural gas has been the fastest growing fossil-based fuel due to its environmental and economic characteristics. This is especially true after the Paris Agreement in 2015, where different countries shifted to cleaner energy resources such as natural gas and renewables. Natural gas can be physically or chemically monetized to increase its economic attractiveness. Amongst the different monetization options, liquefied natural gas (LNG) has been adopted by different projects worldwide for economic transportation of natural gas to distant markets. However, the deployment of LNG infrastructures is capital intensive and require signing long-term purchase agreements with consumers in the pre-final investment decision phase of the project (Pre-FID) to guarantee sales, and minimize risks associated with investment both suppliers and

consumers have been tied together with long-term contracts. However, different factors have influenced the LNG business in the last few years, such as the emergence of new suppliers, competitiveness with renewable resources and natural gas supply disruptions due to unexpected shocks, such as the latest unprecedented COVID-19 pandemic that disrupted global energy demand and halted the financing of several LNG projects worldwide due to associated investment risks.

In addition to the latest changes in the LNG business, the liquidity of the US and European natural gas markets also contributed to reshaping the contractual structures, where spot selling and short/mid-term contracts have been favored by consumers to avoid long-term sales and purchase agreements under demand and prices uncertainties. This resulted in an increase of un-contracted LNG volumes, oversupply, and prices fluctuations. Consequently, investigating uncertainties prior to starting new LNG projects is crucial to understanding future possible market trends and behavior in terms of demand and prices. This investigation is essential for investors for financing such capital-intensive projects, for decision-makers to decide on production and selling strategies, and for policymakers for policies developments.

After studying uncertainties involved in final markets, different passive and active mode of responses can be considered to deal with uncertainties. Amongst the different tools, the concept of flexibility arising from financial engineering has been trending for designing flexible engineering systems with certain characteristics and design to allow for changing the system when needed (Cardin et al., 2015; Saleh et al., 2009). Designing a flexible LNG production system provides the producer the right, but not the obligation, to adjust the production capacity based on market demand and prices to capture high demand opportunities or avoid possible losses from selling LNG at lower prices. This study evaluates the flexibility of an AP-X LNG production system under final markets prices uncertainties.

2. Methodology and Data

Natural gas liquefaction is the core of an LNG project and the most capital-intensive part of the project. After treating natural gas, the stream undergoes fractionation for removing heavy hydrocarbons (C3+) wherein by-products such as liquefied petroleum gases (LPG) and natural gas liquids (NGL) are produced. The natural gas stream then undergoes for liquefaction by cooling it down to -164 °C using the AP-X technology licensed by air products. The AP-X technology consists of three main cooling sections: pre-cooling in propane multistage coolers, main cooling in the main cryogenic heat exchanger using mixed refrigerants, and final sub-cooling in the nitrogen expander.

2.1. Process Simulation

Initially, the AP-X LNG production system is simulated using the commercial software Aspen HYSYS V.11 for producing 7.5 MTPA of LNG with methane purity of 90mol%. The economic profitability of the AP-X technology is then evaluated using the economic performance indicator, net present value (NPV), at deterministic demand and forecasted Henry Hub natural gas price in international markets. A flexible design is then proposed to allow for changing the production capacity based on the market needs. Finally, the flexible AP-X system is evaluated under stochastic natural gas prices to evaluate the economic performance of the proposed design.

2.2. Deterministic and Stochastic Economic Analysis

The economic performance indicator, net present value (NPV), is used to evaluate the profitability of the project under deterministic LNG sales price. Subsequently, the project value is evaluated using stochastic modelling under fixed capital and operational costs. Mean reverting jump diffusion Geometric Brownian Motion (GBM) (Poisson distribution) model is considered to describe the stochastic behavior of Henry Hub natural gas prices. Python programming language in Visual Studio Code enabled by Anaconda software is used to create a large sample size of 10,000 using Monte Carlo Simulation (MCS). The stochastic analysis results are essential to understand risks arising from uncertainties. This is also known as Jensen’s Law:

$$f(E[x]) \neq E[f(x)] \tag{1}$$

Where the NPV under average prices and/or demand $f(E[x])$ does not equal the expected NPV under a distribution of prices and/or demand $E[f(x)]$ (Cardin et al., 2015). Hence, time series modelling for natural gas prices is crucial to calculate the expected NPV under different price and/or demand scenarios. The mean-reverting jump diffusion GBM model was given by (Lucheroni & Mari, 2018):

$$d\log(P_t) = (\theta^{gas} - \alpha^{gas} \log(P_t))dt + \sigma^{gas} dW + JdN \tag{2}$$

Where P_t is the natural gas Henry Hub spot price at time t ; θ^{gas} and α^{gas} are the mean-reversion parameters; σ^{gas} is the volatility of gas prices; W is the standard Brownian motion Wiener Process, with zero mean and a standard deviation of 1; and N is the jump-diffusion process, Poisson process, with a jump amplitude of J and intensity λ^{Jump} . The jump-diffusion process is normally distributed with a mean of zero a standard deviation σ^{Jump} . Moreover, the jump diffusion process (N) and the standard Brownian motion Wiener Process are independent process.

Table 1: Geometric Brownian motion and jump diffusion process model parameters (Lucheroni & Mari, 2015).

Parameter	Notation	Value
Mean-Reversion parameters	θ^{gas}	0.0432
	α^{gas}	0.0292
Jumps intensity	λ^{Jump}	0.2542
Standard deviation for Poisson process	σ^{jump}	0.1258
Volatility of gas prices	σ^{gas}	0.0737
Mean for Poisson process	μ^{Jump}	0.01

The estimated natural gas Henry Hub spot prices (P_t) are then used to calculate 10,000 NPV to analyze the NPV distribution, possible risks and opportunities associated with investing under market uncertainties. The capital and operating costs for a brownfield AP-X technology with 7.5 MTPA production capacity are \$5.53 billion (year 2021) and \$1.39 billion (year 2026), respectively (Steuer, 2019). A project’s lifetime of 25 years, with 5 years of construction and 20 years of operation is considered. Revenues from NGL and LPG sales are assumed for evaluating the profitability of the fractionation section of the LNG plant. Hence, only revenues from LNG sales to Asia-Pacific markets under

different pricing/contractual systems were assumed for estimating the NPV and ENPV of the AP-X liquefaction process. LNG can be sold under long-term contracts (LTCs) at a fixed price of \$8.76/MMBTU (year 2025), or under mid-term contracts (MTCs) and/or on spot based on forecasted Henry Hub natural gas prices. Different combinations of selling strategies influence the NPV and ENPV of the project. Consequently, scenarios based on different selling strategies are investigated based. Henry Hub natural gas prices are forecasted using mean-reversion GBM jump diffusion model utilizing parameters obtained from literature based on historical data from 1990 to 2013 (Lucheroni & Mari, 2015):

2.3. Flexibility Analysis

Understanding the potential of embedding flexibility with an industrial system is essential to be evaluated in the early design stages of the project. After evaluating the baseline production system technically and economically under both deterministic and stochastic conditions. The flexibility of the AP-X technology is investigated technically and economically. The stochastic ENPV is used to evaluate the economic performance of the flexible production system under different selling strategies.

3. Results and Discussion

Investing in mega-projects is capital intensive where different entities are involved in project financing. Moreover, with the changes in the LNG business due to emergence of new suppliers, changes in contractual structures and demand disruptions due to COVID-19 pandemic, proactive risk management is required prior to starting new LNG projects. Flexibility implementation is one of the promising proactive modes of responses to be implemented in the AP-X technology. The AP-X natural gas liquefaction technology is simulated using Aspen HYSYS software as illustrated in Figure 1. After liquefying natural gas, nitrogen is removed in a nitrogen distillation column (T-300) and compressed in a series of compressors, whilst the bottom stream (S-301) is LNG produced at $-164\text{ }^{\circ}\text{C}$ and pumped to storage before prior to shipping to final markets.

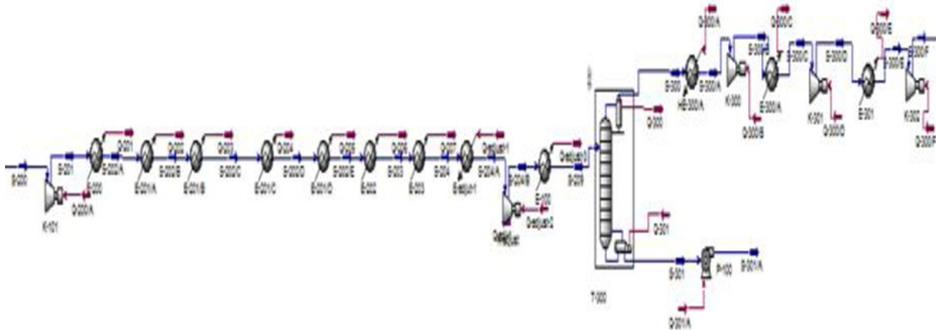

Figure 1: AP-X natural gas liquefaction process simulated using Aspen HYSYS.

The technology is further assessed under deterministic fixed capital and operating costs, and fixed selling price to Asia Pacific markets under LTCs, which results in an NPV of \$5.86. billion. However, in real-life scenarios, it is challenging to secure 100% of production capacity for a single market under LTCs. This is due to the flexibility needed by consumers in diversifying their import portfolios to minimize risks. Consequently, the AP-X technology is further assessed through dedicating the full capacity to spot selling.

The stochastic simulation of the mean-reversion jump-diffusion GBM with an initial Henry Hub natural gas price of 3.06 \$/MMBTU resulted in an ENPV of \$ -3.57 billion and an NPV distribution illustrated in Figure 2. This proves that dedicating the full capacity of a mega LNG production process to spot markets is risky and would potentially involve economic losses. Hence, a diversified selling strategy is needed to hedge against market risks. Moreover, flexibility in production can be implemented though shutting down the third cooling unit (the nitrogen expander) in the AP-X technology. This would result in reducing the production capacity from 7.8 MTPA to 5 MTPA without technical limitations (Roberts et al., 2002).

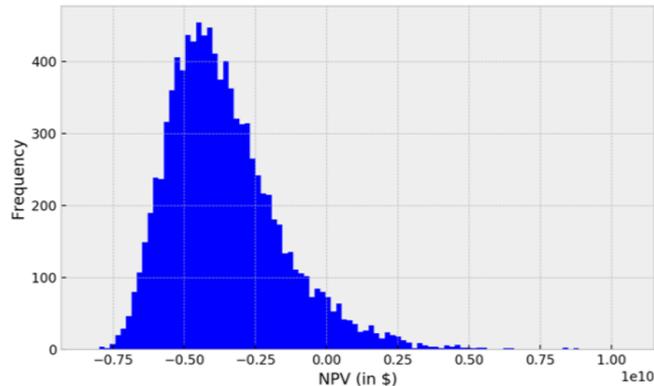

Figure 2: NPV distribution of AP-X's technology with LNG sold based on forecasted stochastic Henry Hub natural gas prices.

An investor might decide on investing on a full capacity (7.8 MTPA) in the early years of the project or start with a production capacity of 5 MTPA and introduce the nitrogen expander during the project's lifetime to increase the production capacity to 7.8 MTPA. Consequently, time-series market analysis is crucial in evaluating the optimal time to expand the production capacity. In this work, it is assumed that a full capacity AP-X technology is deployed in the early years of the project to capture any market opportunities. This is especially important due to the fact that LNG is a transitional fuel, where the market demand for fossil-based fuels is anticipated to gradually decrease with shifts to renewable resources.

When considering a flexible production, this allows the producer to increase the capacity up to 7.8 MTPA when the market conditions are favorable, or to operate at 5 MTPA when the market conditions are low. A producer might consider dedicating 5 MTPA to LTCs and selling the remaining capacity on spot based on market conditions. A case-study of multi-demand level was analyzed to evaluate the influence on considering production flexibility and selling strategies diversification on the ENPV of the project. The multi-demand scenario assumes that the process will only operate at 5 MTPA in the first 5 years of production, then the demand increases where the producers can expand the production capacity up to 7.8 MTPA and sell the remaining in the spot market. In this scenario, the Henry Hub natural gas spot prices mainly influence the returns from LNG sales in spot market and result in NPV distribution illustrated in Figure 3. When following this selling and operating strategy, an ENPV of \$2.72 billion is resulted, which indicates the profitability of considering the presented strategy over dedicating the full capacity to spot selling. A flexible LNG production system will give the producer the right to increase

the production capacity when the market is favorable, or to reduce the capacity subject to unfavorable market conditions.

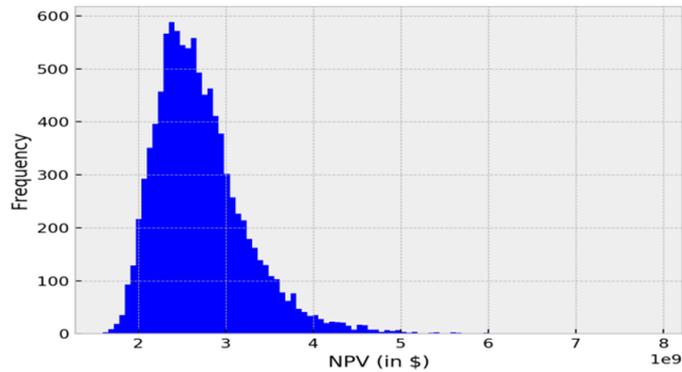

Figure 3: NPV distribution of flexible AP-X's with diversified selling strategy.

4. Conclusion

The last changes in the energy markets due to unexpected shocks, emergence of new suppliers and competitiveness with other renewable resources have influenced the natural gas and LNG markets. Moving from the pre-FID to the FID investment decision change has been challenging in new LNG projects. Consequently, this study proposes embedding flexibility in production with selling strategies diversification as a proactive mode of response to uncertainties. In fact, different combinations of selling strategies influence the ENPV of the project. Multiple demand and selling strategies scenarios can be studied in the early design stages of a mega project to understand possible future market behavior. Moreover, the concept of flexibility can be extended to multi-product value chains that consists of different products. For example, in a natural gas to multi-product value chain, the flexibility in producing different products, i.e., CNG, LNG, methanol, and hydrogen, could contribute to capturing market opportunities and/or avoiding risks based on the market performance.

Modelling and Parameter Fitting of the Dosage of Hydrogen Peroxide in a Photo-Fenton Process

Kourosh Nasr Esfahani, Montserrat Pérez-Moya, Moisès Graells*

*Chemical Engineering Department, Universitat Politècnica de Catalunya, Av. Eduard Maristany, 16, 08019 Barcelona, Spain.
moises.graells@upc.edu*

Abstract

This study addresses the modelling of the photo-Fenton processes, sensitivity analysis, and parameter fitting, focusing on the supply of hydrogen peroxide (H_2O_2) and aiming at the future exploitation in model-based optimization. A flexible H_2O_2 inlet flow (fed-batch) reported in the literature (Audino et al. 2019) was adopted and computational experiments were performed to examine the behaviour of the model and to investigate the opportunities for reducing its complexity. The fitting of the kinetic and stoichiometric parameters was first undertaken using simulated data and focusing on the experimentally available information: H_2O_2 , Total Organic Carbon (TOC), and dissolved oxygen (O_2). Hence, sensitivity analysis was conducted to assess the influence of the parameters of the model and the exclusion of those that do not contribute to explaining the process. Finally, the modified model was shown to fit to experimental data. These results provide valuable insight into the planning of the subsequent experimental phase of this research aimed at providing a reliable model of the flexible dosage of H_2O_2 in photo-Fenton processes.

Keywords: Photo-Fenton, H_2O_2 Dosage, Parameter Estimation, Sensitivity Analysis.

1. Introduction

Toxic and low biodegradable organic pollutants in wastewaters can be hardly removed through conventional biotreatment methods. An alternative to cope with such persistent contaminants is advanced oxidation processes (AOPs), based on the generation of highly oxidant hydroxyl radicals ($\cdot OH$) which could easily degrade recalcitrant compounds. In particular, the photo-Fenton process is a photocatalytic process in which UV irradiation, Fe(II) salt, and H_2O_2 generate such hydroxyl radicals. However, it is well known that an excess of H_2O_2 in the photo Fenton process can lead to unproductive reactions that reduce process performance. Although the use of H_2O_2 is essential, oversupply can be counterproductive, which causes the need to model the flexible dosage of H_2O_2 and the challenge of optimizing its supply (Ortega-Gómez et al., 2012). Several studies have experimentally addressed the improvement of the photo-Fenton process performance by proposing a reasonable hydrogen peroxide supply (Yu et al., 2020, Zazo et al., 2009), but solutions are still incomplete and far from model-based approaches. Hence, this study is limited to the development of a flexible dosage model capable to be fit to experimental data that could be later used for model-based optimization purposes.

2. Methodology

The work addresses the simulation of the operation of the photo-Fenton reactor, its parameter estimation and sensitivity analysis, and the fitting to experimental data.

2.1. Mathematical Modelling

The study adopts the kinetic model (Fig.1) first proposed by Cabrera Reina et al. (2012).

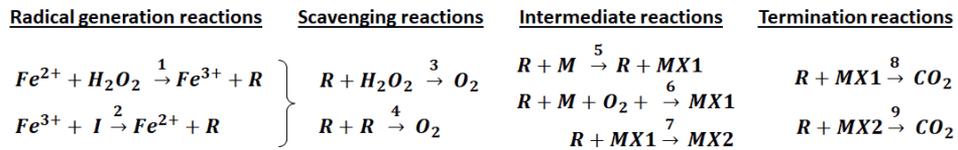

Figure 1. Kinetic model of the photo-Fenton process (Cabrera Reina et al., 2012).

The model takes into account the continuous production of hydroxyl radicals (R) from H_2O_2 , iron and irradiation (I); the consumption of radicals in scavenging reactions; and the reduction of organic matter (M) to CO_2 through some partially oxidized intermediates (MX_1 and MX_2), all of them leading to the lumped parameter measured ($TOC = M + MX_1 + MX_2$). This model gives the set of ODEs listed in Table 1.

Table 1. Equations of the mathematical model of the dosage of the photo-Fenton process.

Reaction type	Reaction rates	Kinetic constants	Eq.
Efficient reactions (Production of radicals)	$r_1 = k_1[Fe^{2+}][H_2O_2]$ $r_2 = k_2[Fe^{3+}][I]$	k_1 k_2	(1) (2)
Inefficient reactions (Decomposition of radicals)	$r_3 = k_3[R][H_2O_2]$ $r_4 = k_4[R][R]$	k_3 k_4	(3) (4)
Degradation of parent compound and intermediates	$r_5 = k_5[M][R][O_2]$ $r_6 = k_6[M][R]$ $r_7 = k_7[MX_1][R]$ $r_8 = k_8[MX_1][R]$ $r_9 = k_9[MX_2][R]$	k_5 k_6 k_7 k_8 k_9	(5) (6) (7) (8) (9)
Material balances:			
	$d[H_2O_2]/dt = (F/V) \cdot ([H_2O_2]_{in} - [H_2O_2]) - r_1 - r_3$		(10)
	$d[O_2]/dt = (F/V)([O_2]_{in} - [O_2]) + g_1r_3 + g_2r_4 - c_1r_5 + K_L a([O_2]^* - [O_2])$		(11)
	$d[TOC]/dt = d[M]/dt + d[MX_1]/dt + d[MX_2]/dt$		(12)
being:			
	$d[M]/dt = (F/V) \cdot ([M]_{in} - [M]) - r_5 - r_6$		(13)
	$d[MX_1]/dt = (F/V) \cdot ([MX_1]_{in} - [MX_1]) + r_5 + r_6 - r_7 - r_8$		(14)
	$d[MX_2]/dt = (F/V) \cdot ([MX_2]_{in} - [MX_2]) + r_7 - r_9$		(15)

The model includes the overall gas-liquid mass transfer coefficient for O_2 ($K_L a$) and three stoichiometric coefficients describing the oxygen balance (c_1 , g_1 , and g_2). Finally, the fed-batch model by Audino et al. (2019) extends the kinetic model by including an inlet flow (F) allowing the flexible supply of hydrogen peroxide ($[H_2O_2]_{in}$).

2.2. Model fitting and parameter estimation

The model has been implemented in Simulink[®]. The photo-Fenton process has been simulated and the estimation of the set of kinetic and stoichiometric parameters has been first studied through the fitting of the model to perfect data obtained by simulation for H_2O_2 , TOC, and O_2 profiles (the common experimentally measured information) using the parameter values reported by Cabrera Reina et al. (2012). This allows testing the

potential of the fitting procedure and provides a quantitative reference, given by the sum of the squared errors to be minimized (eq.1), and the root mean square error (RMSE), the normalized root-mean-square deviation (NRMSE), and the coefficient of variation of the RMSE, CV(RMSE) to quantify the goodness of fit.

$$\min Z = \sum_i([\widehat{TOC}]_i - [TOC]_i)^2 + \sum_j([\widehat{H_2O_2}]_j - [H_2O_2]_j)^2 + \sum_k([\widehat{O_2}]_k - [O_2]_k)^2 \quad (16)$$

$$RMSE = \sqrt{(\sum_{n=1}^N (\hat{y}_n - y_i)^2 / N)} \quad (17)$$

$$NRMSE = RMSE / (\hat{y}_{max} - \hat{y}_{min}) \quad (18)$$

$$CV(RMSE) = RMSE / \hat{y}_{mean} \quad (19)$$

2.3. Sensitivity analysis

Sensitivity analysis has been performed based on variances-based sensitivity analysis of model output using Simulink Design Optimization software. Sensitivity analysis was conducted to assess to which extent variations of the model parameters can affect each measured response (TOC, H₂O₂, and O₂). Hence the model is discussed regarding its hypothesis and chances for reducing complexity. The Rank Partial Correlation method was used to analyze to which extent each model parameter affects the function output. The correlation coefficients vary from -1 to 1, and a zero value means no correlation at all. The correlation coefficient between two sets of variables X and Y, R_{XY}, is given by:

$$R_{XY} = C_{XY} / \sqrt{C_{XX}C_{YY}} \quad \text{being} \quad C_{XY} = cov(X, Y) = E[(X - \mu_X)(Y - \mu_Y)] \quad (20)$$

One approach to sensitivity analysis is local sensitivity analysis, which is derivative-based (one-at-a-time technique). The term local refers to the fact that all derivatives are taken at a single point. However, this approach can be infeasible for complex models, where formulating the cost function (or the partial derivatives) is nontrivial. Also, they do not provide insight into how the interactions between parameters influence the cost function. Another approach to sensitivity analysis is global sensitivity analysis, often implemented using Monte Carlo techniques. This approach uses a representative (global) set of samples to explore the design space.

Mathematically, the sensitivity of the cost function with respect to certain parameters is equal to the partial derivative of the cost function concerning those parameters. Accordingly, A sensitivity function was defined as the partial derivatives of Eq.16 with respect to each parameter. This function implies the matching of output signals (TOC, H₂O₂, and O₂) to measured (perfect) data as the requirement.

2.4. Fitting to experimental data

The experimental data is from the work by Yu et al. (2020) that measured different hydrogen peroxide dosage profiles for Fenton and photo-Fenton processes. The parameter estimation procedure will be tested by fitting the model to some of the assays reported.

3. Result and discussion

3.1. Fitting of the photo Fenton model to No dosage & Dosage cases

First, perfect data was obtained through the simulation of the model using the parameter values reported by Cabrera Reina et al. (2012). Figure 2 shows the profiles obtained for TOC, H₂O₂, and O₂ during a 4h reaction time. Simulations with (b) and without (a) dosage are also shown. The H₂O₂ dosage profile (Fig. 2b) is given by an on-off profile set to be on from 0 to 15 min and from 45 to 60 min.

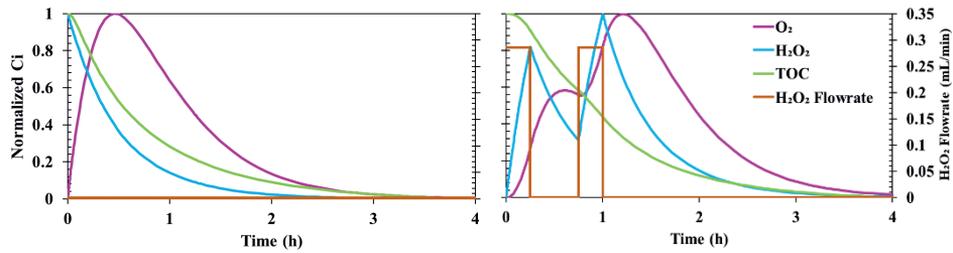

Figure 2. Profile of TOC, H_2O_2 , and O_2 : (left) No dosage, (right) Flexible dosage profile

The fitting of these simulated data using the parameter estimator tool in Simulink[®] was checked setting different sets of initial kinetic parameter values obtained randomly in the range of $\pm 50\%$ of the true values. Results (Fig.3) showed a good agreement between perfect data and predicted data in no dosage mode with the lowest values of C.V.(RMSE) resulted in 0.52%, 0.61%, and 1.04% for TOC, H_2O_2 , and O_2 , respectively. Similarly, the parameter search resulted in good agreement of the fitted data after parameter estimation with the lowest values of C.V.(RMSE) of 0.52%, 1.83%, and 1.01% for TOC, H_2O_2 , and O_2 , respectively. The C.V.(RMSE) results, as represent the simulation errors, below than the detection limits of the measurements corresponding to the capability of the given model to “fit” the datasets. This provides a reliable model of the flexible dosage of H_2O_2 in photo-Fenton processes for further experimental studies.

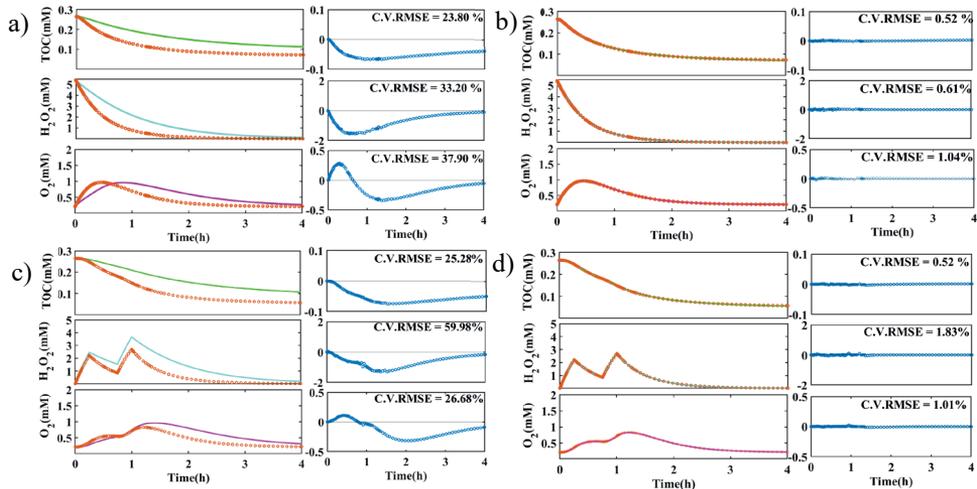

Figure 3. Fitting to simulated data and residuals: No dosage (a, b); Dosage (c, d)

3.2. Sensitivity analysis on the photo Fenton model

Global sensitivity analysis was performed to explore which model parameters (assumed independent) most influence the goodness of fit. A set of 100 parameter samples was generated randomly by varying the value of each parameter for both no dosage and dosage cases. The corresponding correlation coefficients R_{XY} are plotted in Figure 4 in order of influence on the signal matching of the simulated data to the perfect data for TOC, H_2O_2 , and O_2 in the role of the sensitivity function.

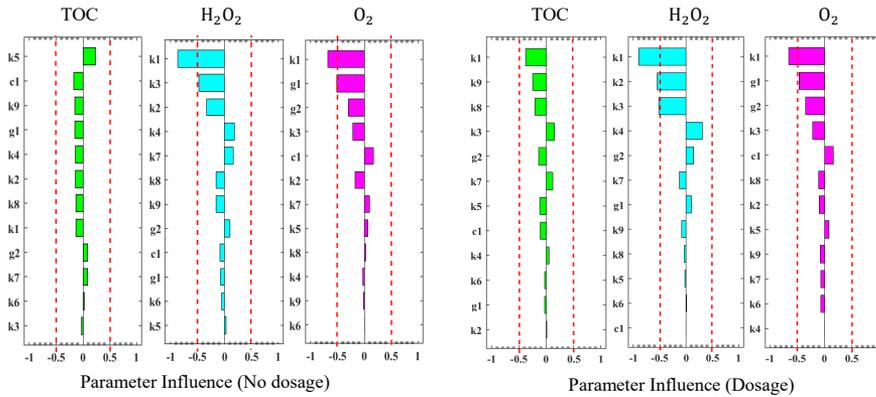

Figure 4. Ranked influence of model parameters on the signal matching with respect to TOC, H_2O_2 , and O_2 : Case without dosage (Left), Case with flexible dosage (Right).

The different ranked series of kinetic parameters were obtained for the measured variables TOC, H_2O_2 , and O_2 considering no dosage and dosage cases. For a better interpretation of the sensitivity analysis plots, a threshold line (red dash line) was defined at $R=\pm 0.5$. k_1 with respect to the criterion $|R|\geq 0.5$ indicated the most significant parameter in the ranking plots to H_2O_2 , and O_2 . In the case of TOC, the order of parameters showed an almost similar magnitude of $|R|$ value lower than 0.5, but again k_1 was in the place of a significant parameter.

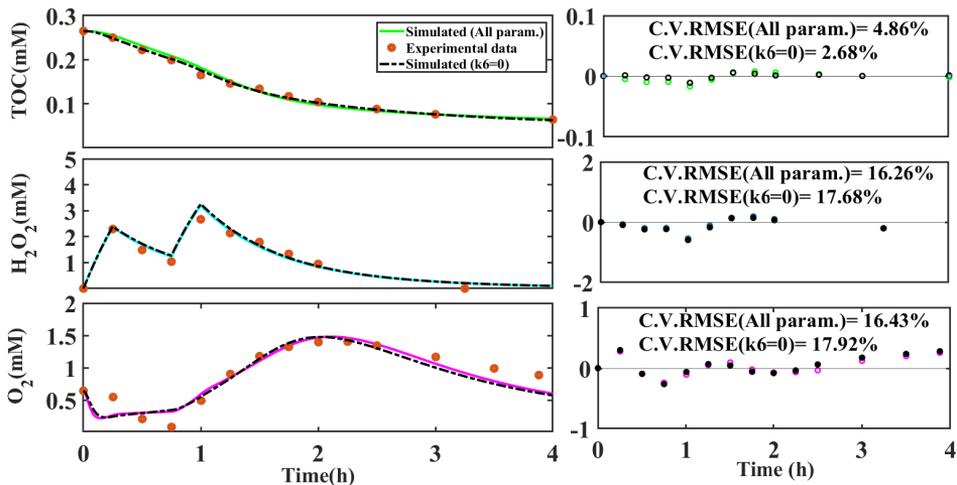

Figure 5. Experimental data and simulated profiles in dosage mode: Considering all parameters for the estimation (solid line); excluding k_6 from model ($k_6 = 0$) (dash line)

Figure 5 shows the model profiles fitting the experimental data with and without considering k_6 . Likewise, similar fitting results were obtained with and without considering k_6 through parameter estimation of experimental data by very close ($\pm 2\%$) C.V.(RMSE) values for TOC, H_2O_2 and O_2 . Whilst this real experimental insight adequately represented the unimportant effect of k_6 on the model fitting, further studies using diverse H_2O_2 dosage profiles would be required to validate the efficient fitting of the model for flexible H_2O_2 profile.

4. Conclusions

This work has developed a kinetic model for the dosage of hydrogen peroxide in photo-Fenton processes to be fit to experimental data obtained from different dosage profiles. The model focuses on the process variables to be easily measured (TOC, H_2O_2 , and O_2). After verifying the model with the adjustment to simulated data a sensitivity analysis of the model fitting has been performed, which provided a valuable insight into the nature of the model. One of the reactions proposed in the literature has been found to have a scarce influence on the fitting of the model, for which it has been excluded. After checking the insignificant effect of this reaction on the fitting, the model has been shown to be able to adjust to a series of experimental data (C.V.(RMSE) of 2.68%, 17.68%, and 17.92% for TOC, H_2O_2 , and O_2 , respectively). Therefore, the model is ready to address further experimental data (dosage profiles) and hence attempt the model-based optimization of the dosage profile.

Acknowledgments

Financial support was received from the Spanish "Ministerio de Ciencia e Innovación" and the European Regional Development Fund, both funding the research Project CEPI (PID2020-116051RB-I00) and also the Secretariat of Universities and Research of the Department of Business and Knowledge of the Generalitat de Catalunya through the program FI SDUR (Grant ref. BDNS 481561) are fully acknowledged.

Abstract

Today, Liquefied Petroleum Gas, Natural Gas Liquids Recovery, and Condensate Stabilisation have gained significant interest, given their increased selling prices and market demands. Nevertheless, many operational units do not meet the desired profits and lack proper optimisation initiatives. In this study, a case study from the operating condensate stabilisation unit within the liquefied natural gas process is considered, where a sensitivity analysis of key process operating parameters is applied to investigate process performance. The process is optimised to achieve the highest efficient performance, maximum productivity rate, and minimum energy consumption. Based on the available production data and operating conditions, an existing condensate stabilisation unit is simulated using the Aspen HYSYS V10 simulator, which is based on the Peng-Robinson equation of state. The most significant process variables and constraints that directly affect the performance, and production of condensation stabilisation units are highlighted to demonstrate the connection among process operating conditions and the influence on process objectives. The optimal process operating conditions are determined to achieve a stable column operation. The most effective process variables based on the sensitivity analysis are stabiliser column pressure, stabiliser feed temperature, the outlet temperature of process gas from the wellhead, and stabiliser bottom temperature. After collecting process data from the sensitivity analysis, MATLAB has been used to formulate and solve the multi-objective optimisation problem. Beginning with a natural gas feed flow of 554 MMSCFD, a condensate with 956.9 barrel/day standard liquid volume flow and a reboiler load of 0.86MW have been achieved. After performing the singular optimisation problem in MATLAB, the condensate standard liquid volume flow is increased to 1273 barrels/day, and the reboiler load has decreased to 0.79MW.

Keywords: Condensate stabilisation, optimisation, sensitivity analysis, LNG, simulation.

1. Introduction

Natural gas (NG) is one of the world's most common, promising and affordable fuels, with a wide range of uses. However, in the gaseous state, transportation presents a number of challenges. As a result, the method of transforming NG into intermediate liquid streams has been recommended and used for years to alleviate the difficulties posed by its gaseous composition (Bahmani et al., 2017). Liquefied petroleum gas (LPG) and natural gas liquids (NGLs) are the two main products sourced from all commercial gas refineries' NG stabilisation systems. Natural gas products to be fed into the pipeline for the gas distribution system or to be liquefied must meet the applicable minimum requirement for the pipeline's network or liquefaction unit to work effectively. As a result, natural gas extracted at the wellhead should be refined before it can be liquefied and securely

transported to the long-distance, high-pressure pipelines that transport the fuel to the consumer, as it mainly consists of contamination (non-hydrocarbon gases) and natural gas liquids. Gas condensate is a valuable liquid hydrocarbon mixture that is generated while delivery in raw gas collecting pipelines or naturally from a gas well, can be used as a dilution in oil products or turned to various oil products such as diesel and aviation fuel, amongst others (Uwitonze et al., 2017). To meet the appropriate requirements for transportation and storage, the raw condensate must be reduced in water, salt, and acid content (i.e., H_2S , CO_2 , mercaptans, etc.) (Moradi Kazerooni et al., 2015). The aim of this condensate treatment process is to remove lighter hydrocarbons (methane, ethane, propane, etc.), including acidic components from liquid hydrocarbons in order to make them commercially viable (Zhu et al., 2016). Whereas distillation is the primary method that is widely applied to separate a mixture of components based on their boiling points by boiling the more volatile components out of the mixture preferentially. The degree of separation of a multi-component system depends on the properties of the feed mixture, operating conditions, and other process-imposed restriction. The aim of the unit is to reduce liquid condensate vapor pressure. In order to avoid vapor phase generation while flashes to the storage tank. This method, is structured to distinguish very light hydrocarbon gases, such as methane and ethane, from heavier hydrocarbon components (Adib et al., 2015). Light ends are processed for more commercialisation purposes such as liquefied natural gas (LNG) processing and natural gas liquid extraction while stable condensate is stored (Uwitonze et al., 2017). In the field of condensate stabilisation for natural gas, significant research has been conducted, and numerous papers have been developed. Tavan et al. (2019) investigated the energy and exergy of the condensate stabilisation system and discovered the best location for the water withdraw tray within the condensate stabiliser column. Furthermore, Moghadam et al. (2012) optimised the condensate stabilisation unit's process design and suggested that the design with the minimum operating pressure had the lowest fixed capital cost, and also required the least power due to the high separation performance and low energy demand. In this study, an LNG operating condensate stabilisation is has been selected, where sensitivity analyses are carried out by Aspen HYSYS for the key process parameters to determine their effect on the condensate product and stabiliser energy consumption. After which, the optimal process parameters are determined using the MATLAB software by solving the singular and multi objectives optimisation problems related to the minimisation of stabiliser reboiler duty and the maximisation of condensate flow.

2. Methodology

The sequential structure of methodology adapted in this study is depicted in Figure 1. Firstly, the condensate stabilisation process is developed in the steady-state mode using Aspen HYSYS V10. Subsequently, sensitivity analyses are carried for the key process parameters to allocate their effect on stabiliser reboiler duty and condensate flow. In this, one parameter is subjected to change at a time, while the others are kept constant in the simulation model so that it should not deviate from the actual operating situation. Eventually, these process parameters are optimised using MATLAB to maximise condensate production and minimise the sabiliser energy consumption.

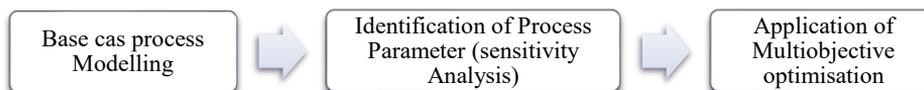

Figure 1: Schematic of methodological steps undertaken in this study.

3. Condensate stabilisation process

The pre-separation units consists of three units, which are a three-phase separation, dehydration unit, and condensate stabilisation unit (Bahmani et al., 2017). Natural gas from different wells is gathered and enters the three-phase separator at nearly 80 bar pressure. In the three-phase separator condensate, water and gases are separated. After the three-phase separation process, the outlet condensate is sent to the condensate stabilisation facility, and water is sent for additional processing and gas as one mainstream sent to the gas dehydration. Raw condensate from the reservoirs has light hydrocarbons, which flash at high temperature and low pressure causing loss of valuable products and environmental pollution (Rahmanian et al., 2016). The separated natural gas condensate requires reduction in acid, water, and salt contents to meet expected standards. Subsequently, it is transformed into a transportable and distributable format that is commercially acceptable (Moradi Kazerooni et al., 2015). While the extracted condensate can be transported without further refining, it must be stabilised often in order to be blended into the crude oil. The aim of the condensate stabilisation process is to lower the vapor pressure of the condensate liquids such that no vapor phase is created when the liquid is flashed to atmospheric storage tanks (Uwitonze et al., 2017). It entails the number of intermediates (C_3 to C_5) and (C_{6+}) components in condensate, while removing light hydrocarbons from liquid hydrocarbon. There are no precise product standards other than meeting process criteria or particular product specifications (Zhu et al., 2016). The primary objective towards stabilising natural gas condensate is to extract as much liquids condensate as possible while maintaining its Reid vapor pressure (RVP) within 10.5 psia. The condensate leaves the three-phase separator V101 where its pressure is dropped by a control valve at 27.5 bar, and the gases are recovered in a flash drum and sent for recompression. The condensate pressure is further dropped by vale V102 at 10 bar. Subsequently, the condensate is sent to the stripper where it is heated, and the light gases are recovered and sent for the recompression and recycle. The stabilised condensate which is obtained from the bottom of stripper is cooled down and sent to the storage tank. The process flow diagram is illustrated in Figure 2.

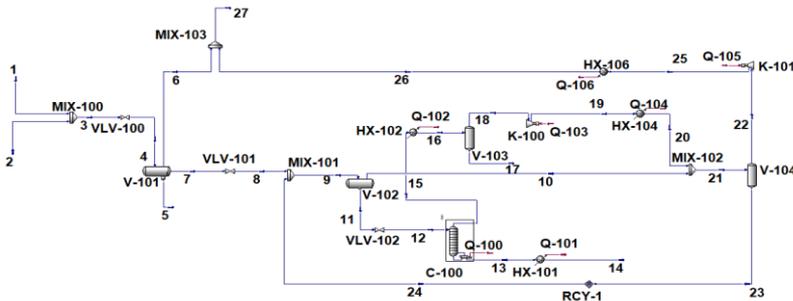

Figure 2: Process Flow Diagram of Condensate stabilisation process.

4. Sensitivity analyses

The most critical process variables and constraints that directly affect the production and the performance of the plant are discussed in the following sections.

4.1 Relationship of feed gas flow rate and stabiliser duty

The feed gas flow rate that is used in this study is 554 MMSCFD, while the feed gas composition is illustrated in Table 1.

Table 1. Feed gas composition.

Name	Mole fraction %
N ₂	0.0500
H ₂ S	0.0150
CO ₂	0.0280
C ₁	0.8093
C ₂	0.0425
C ₃	0.0179
n-C ₄	0.0103
n-C ₅	0.0257
M-Mercaptan	0.0002
Benzene	0.0005
Toluene	0.004
P-Xylene	0.0004
Temperature	27 C
Pressure	80 bar
Mass flow Rate	554 MMSCFD

The sensitivity analysis is carried out while RVP is kept constant. Figure 3a demonstrates the effect of gas flow rate change on the stabiliser duty. As the gas flowrate increases, the duty of the stabiliser increases steadily due to the increase energy requirement to remove light gases from the condensate.

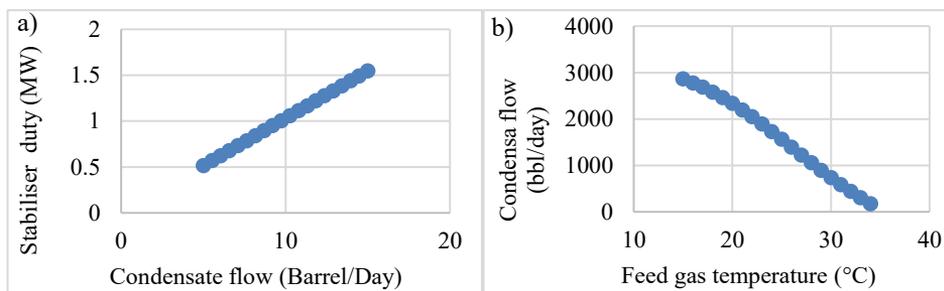

Figure 3: Trends of condensate flow and (a) stabiliser duty and (b) feed gas temperature.

4.2 Relationship of feed gas temperature and condensate flow

The normal temperature of the feed gas is 27 °C. This temperature is varied between 15 and 35 °C while maintain the RVP constant. As illustrated in Figure 3b, condensate production gradually reduced from 2865 bbl/day to 176.1 bbl/day as the temperature of the feed gas increased. It implies that at low condensate temperature at the inlet of the stabiliser plant more condensate is produced. By increasing the temperature, light gases are flashed off which reduces condensate production.

4.3 Relationship of feed gas temperature and energy consumption in the reboiler

As illustrated in Figure 4a, as the temperature of feed gas decreases in the outlet of the wellhead, stabiliser duty increases because condensate productivity rate increase as a result of heavier hydrocarbon condensation. In addition, the total consumed energy increases considerably as a result of increasing reboiler heating duty.

4.4 Relationship of stabiliser pressure and reboiler duty

The condensate stabiliser column pressure is directly controlled by the overhead column vapours. Figure 4b illustrates the relation between condensate stabiliser column pressure and the stabiliser duty. As the pressure of the column increases, the duty of the stabiliser also increases. Hence, the stabiliser feed pressure is directly proportional to the total energy consumed in the stabilisation column.

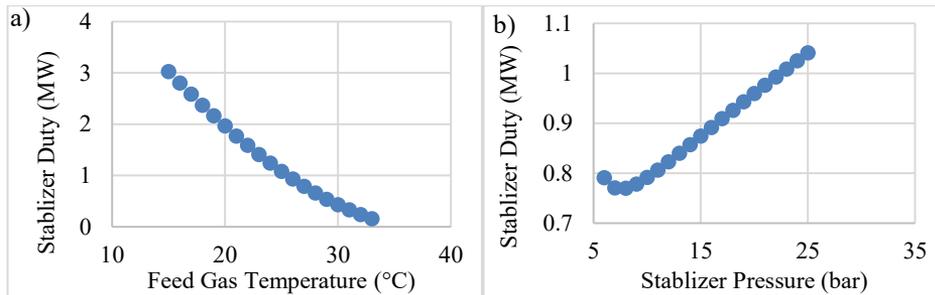

Figure 4. Trends of stabiliser duty and (a) feed gas temperature and (b) stabiliser pressure.

5. Optimisation problem

The optimisation problem is considered for singular and multi objectives, where condensate flow is maximised and energy consumption in the stabiliser is minimised. For optimisation formulation, MATLAB’s genetic algorithm is used as it works for discrete as well as continuous functions. Base case and optimised case results for the singular optimisation problems are given in Table 2 and Table 3, while Figure 5 demonstrates the Pareto front of condensate flow and the stabiliser duty for the multi objective problem.

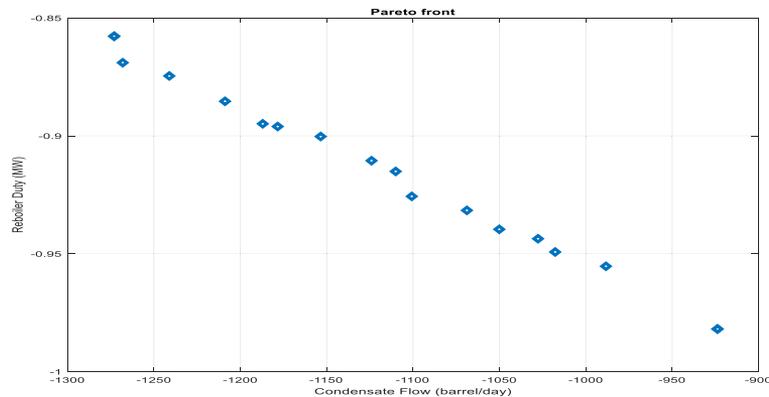

Figure 5. Pareto front of condensate flow and stabiliser Duty.

Table 2: Base case and optimised case results for first objective function.

Optimisation problem \ Cases	Base case	Optimised case
Objective function: Maximisation of condensate flow (bbl/day)	957	1273
Function constrains: RVP (psia)	9.4	10.15
Function Primary variables:		
Stabiliser column pressure bar	10	10
Feed gas Temperature °C	27	25
Stabiliser bottom temperature °C	137.4	133.1

Table 3: Base case and Optimized case results for second objective function.

Optimisation problem \ Cases	Base case	Optimised case
Objective Function: Minimisation of stabilizer column energy (MW)	0.86	0.799
Function constrains: RVP (psai)	9.4	10
Function primary variables:		
Stabiliser column pressure bar	10	10
Feed gas Temperature °C	27	27
Stabiliser bottom temperature °C	137.4	133.1

6. Conclusion

This study has provided a framework for investigating and improving the performance of an existing condensate stabilisation unit recovery plant. The condensate recovery plants in operation require continuous innovation and selection of suitable operating conditions such that it can increase their returns. The outcomes of this study demonstrate the importance of the optimal process operating variables as an essential role in improving condensate production, power consumption, and separation performance of the condensate column. This is demonstrated through the increase in the objective function of condensate production by 33% (316 bbl/d) from the original case with 4.78% increase in pentanes plus mole fraction in the condensate product. Moreover, regarding the second objective for the reduction of reboiler duty in the stabiliser column, the respective energy consumption is reduced by 6.1% (0.061 MW).

Abstract

Online and offline optimization of dynamic operation trajectories applied to real processes remains a challenging task when models are hard to evaluate, or when their plant-model-mismatch is unsatisfactory. These issues can be tackled by training data-driven models when sufficient measurement data is available. Time dependencies in operation trajectories can be exploited by recurrent neuronal networks (RNN). In this contribution, RNNs with LSTM cells without and with series-parallel (*teacher forcing*) output regressor configurations were trained for their use as surrogate models of an example first-principles batch distillation model simulated from start-up to shutdown. For the offline optimization of a reference batch trajectory, a parallel configuration with predicted output feedback is discussed as a better performing alternative to the classical simulation approach. The prediction accuracies achieved by these configurations is compared and their applicability to optimization of chemical processes is discussed.

Keywords: dynamic data-driven model, recurrent neuronal network, batch distillation

1. Introduction

In the context of process optimization for the reduction of costs and environmental impact in the chemical industry, prediction of the process behaviour under different operating conditions is required. Specifically, online and offline optimization of dynamic operation trajectories applied to real processes remains a challenging task when models are hard to evaluate, or when their plant-model-mismatch is unsatisfactory. These issues can be tackled by training data-driven models when sufficient information through measurement data is available.

Processes with complex dynamics such as discrete changes in the manipulated variables and vanishing phases are no exception, rendering batch distillation a good example. There, simplifications such as neglecting the filling, preheating and shutdown batch phases are often made to obtain simple, first-principles models (Wang et al. (2003)). The flexibility achieved by machine learning models opened new possibilities to avoid such simplifications (Venkatasubramanian (2019)). Furthermore, time dependencies in operation trajectories can be exploited by recurrent neuronal networks (RNN), with long short-term memory (LSTM) cells to tackle long-term dependencies (Hochreiter and Schmidhuber (1997)). Successfully applied to fields such as natural language processing and time series forecasting, these models seem promising for predicting operation trajectories of complex chemical processes (Esche et al. (2022)).

RNNs with LSTM cells may be trained as surrogate models in three different configurations presented in section 2. When the goal of the trained models is to be used for offline optimization (as in

the optimization of a reference batch trajectory to be tracked online), only the manipulated variables are known *a priori*. Typically, a configuration with only control regressors is used for this purpose. Series-parallel configurations trained with *teacher forcing* (Williams and Zipser (1989)), where past measurements are known, have the ability to model the prediction error while advancing in a moving horizon, but cannot be used in offline optimization tasks. A parallel configuration might tackle both restrictions while sacrificing computation time.

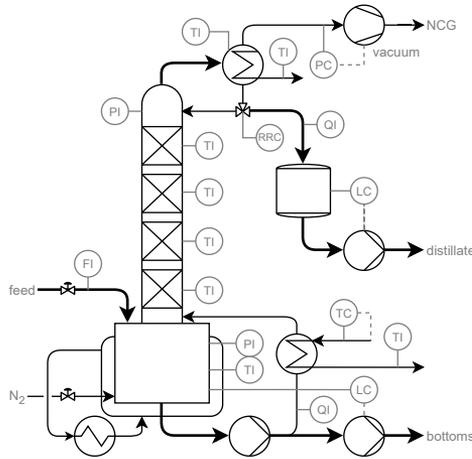

Figure 1: Flowsheet of the case study process: a batch distillation column and its instrumentation

As an example for a chemical process with complex dynamics, the proposed configurations are applied to an example batch distillation column for the separation of water-methanol mixtures shown in Fig. 1, simulated based on a pressure-driven model in Aspen Plus Dynamics (see Brand-Rihm et al. (2021)) with the scope of validation through real plant experiments.

Complexities include vanishing phases and discrete changes in some of the 12 manipulated variables detailed in Tab. 1. As outputs, any variable can be chosen from the flowsheet simulator. Here, $n_y = 26$ outputs are chosen as realistic online measurements, including temperature profiles, pressures, liquid levels, mass flows, and mass fractions. For better visibility, only the 15 main outputs are listed in Tab. 1.

Table 1: Plant controls and main outputs

control	description	output	description
x_{VN_2}	nitrogen valve position	$T_{med,out}^{Cond}$	cooling medium outlet temperature
PC^{SP}	pressure controller setpoint	T_1	temperature at the column top
x_{VF}	feed valve position	T_{10}	temperature at the bottom vessel
RRC^{SP}	reflux ratio controller setpoint	$T_{med,out}^{Reb}$	heating medium outlet temperature
$T_{Reb}^{med,in}$	heating medium inlet temperature	\dot{m}_D	distillate mass flow
LC_D^{MODE}	level controller mode*	\dot{m}_B	bottoms mass flow
LC_D^{SP}	condenser level controller setpoint	\dot{m}_{NCG}	gas flow of non-condensable gases
LC_D^{OP}	condenser level controller output	w_D^{MeOH}	methanol mass fraction in distillate
PC^{MODE}	pressure controller mode*	w_D^W	water mass fraction in distillate
PC^{OP}	pressure controller output	$w_D^{N_2}$	nitrogen mass fraction in distillate
LC_B^{MODE}	sump level controller mode*	p_D	condenser pressure
LC_B^{OP}	sump level controller output	p_B	bottom vessel pressure
		\dot{Q}^{Cond}	condenser cooling duty
		\dot{Q}^{Reb}	reboiler heat duty
		L_B	liquid level in bottom vessel

* (\cdot)^{MODE} $\in \{0 = auto, 1 = manual\}$

The achieved prediction accuracies of the proposed models are discussed in section 3.

2. Methods

2.1. Prediction, simulation, and forecasting

Different definitions exist for prediction and forecasting. Nonetheless, their differences seem to be clear in the field of data science when time plays a decisive role. Since this contribution considers datasets provided by dynamic multiple input-multiple output (MIMO) processes in the form of time series, the specific task of predicting future states is called forecasting.

In the field of system identification, a difference is made between a task focus where regressors are constructed only for the controls \mathbf{x}_k at a discrete timestep k (*simulation*) in contrast to configurations that also include an autoregressive part with output regressors \mathbf{y}_k , called *predictions*.

Following notation can be used for regressor sets, where l and m are the past horizons for controls and outputs, respectively: $x_k^{(l)} = (x_{k-l}, x_{k-l+1}, \dots, x_k)$, $y_k^{(m)} = (y_{k-m}, y_{k-m+1}, \dots, y_k)$.

When the goal is offline optimization based on data-driven models, an alternative to the *simulation* configuration (Fig. 2 a) **Sim** based on a *series-parallel* architecture trained with teacher forcing (Fig. 2 b) **S-P** can be used, which exploits the modelling of prediction errors while maintaining a simulation focus due to its parallel predicted output regressor loop (Fig. 2 c) **Par**.

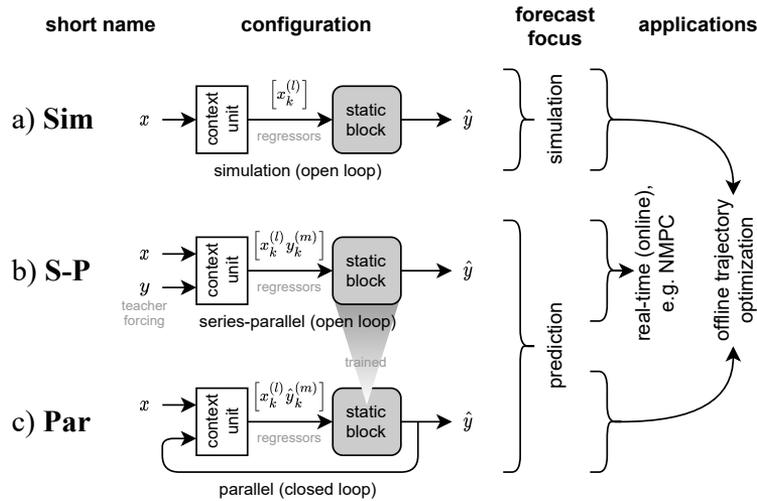

Figure 2: Configurations adopted in this contribution

The **Par** configuration predicts future states using the trained **S-P** model. Since here the regressor set includes predicted outputs instead of real measured outputs, an accumulating prediction deviation is expected. The prediction accuracy of **Par** might be less than in the **S-P** configuration, but only controls are needed.

2.2. Sampling for simulated dataset generation

A simulated dataset consisting of batch runs sampled over an operation recipe to enhance the feasibility ratio of the simulations was generated to train and test different data-driven models according to Brand-Rihm et al. (2021). Here, $n_s = 645$ of 1000 samples converged. A train/test ratio of 3/4 is chosen, leaving $n_s^{est} = 162$ samples for testing. The generated dataset consists of an array with size (samples n_s , timesteps n_t , channels $n_x + n_y$) = (645, 401, 12 + 26).

3. Results and discussion

The prediction accuracies can be analysed comparing the mean squared errors (MSE) between min-max scaled testing (y_{stc}^{test}) and predicted (\hat{y}_{stc}) data for each sample s separately (MSE_s) and for each model (MSE), according to:

$$MSE_s = (n_t \cdot n_y)^{-1} \sum_{t=1}^{n_t} \sum_{c=1}^{n_y} (y_{stc}^{test} - \hat{y}_{stc})^2 \quad MSE = (n_s^{test})^{-1} \sum_{s=1}^{n_s^{test}} MSE_s$$

Since only configurations **Sim** and **Par** support offline optimization, their predictions can be compared qualitatively. Fig. 3 shows the worst test trajectories (highest MSE_s) predicted by **Sim** (top) and **Par** (bottom). It is shown that even in the worst **Par** prediction the test trajectories show correct trends. On the contrary, the worst **Sim** prediction misses the trends while the parallel configuration performs to a satisfactory degree.

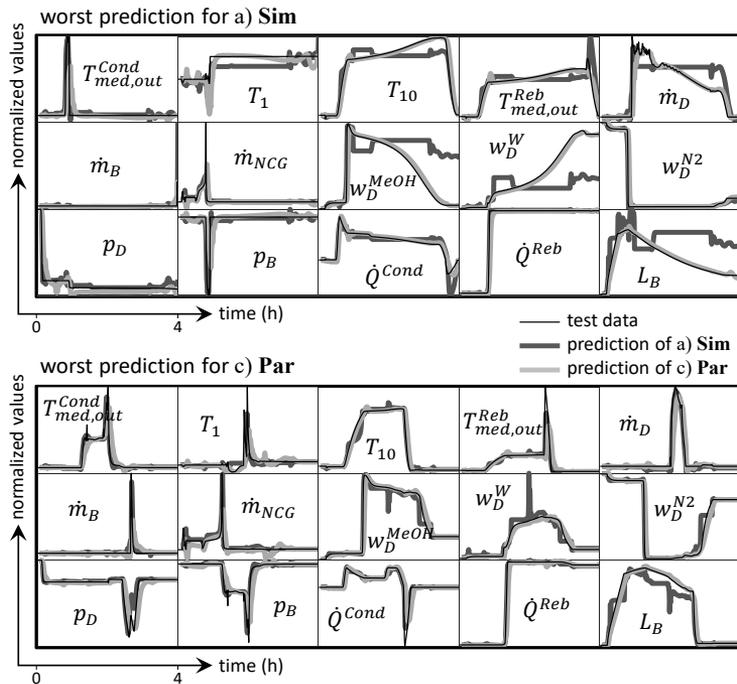

Figure 3: Worst predicted samples (in terms of MSE) for configurations a) **Sim** and c) **Par**

Table 2: Statistics of prediction accuracies for the three configurations

configuration	$MSE \cdot 10^3$				elapsed times (s)	
	mean	P_{25}	P_{50}	P_{75}	training	prediction
a) Sim	4.06	1.91	3.01	5.12	$1.47 \cdot 10^3$	5.14
b) S-P	1.66	1.43	1.67	1.86	$1.54 \cdot 10^3$	6.02
c) Par	3.46	2.70	3.64	4.04	$1.54 \cdot 10^3$	$2.26 \cdot 10^3$

The prediction accuracies in terms of overall MSE among all samples, as well as elapsed training and prediction times are shown in Tab. 2. The prediction error distributions with their mean, median (P_{50}), 25% and 75% percentiles (P_{25} and P_{75}) are presented in Fig 4.

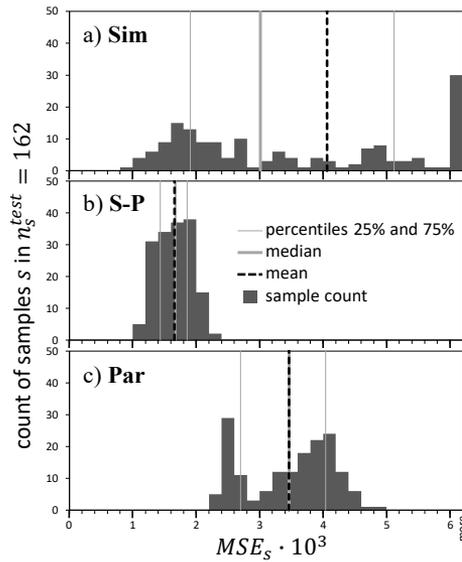

Figure 4: Sample prediction error distributions of the presented methods

It is shown that for the performed sampling and its test data, among the configurations capable of predicting operation trajectories based solely on given controls (**Sim** and **Par**), the parallel architecture outperforms qualitatively and quantitatively (in terms of prediction error) the simulation architecture, although the computation time of the prediction is larger by three orders of magnitude. This might be enhanced by optimizing the code for the feedback loop. The percentile statistics show a lower median (P_{50}) for **Sim**, but having a stronger variance with many test samples with insufficient prediction accuracy. Therefore, the **Par** configuration might be more robust.

Absolute prediction errors for the samples with the best prediction accuracies are shown in Fig. 5. Although no clear advantage is visible for the **Par** over the **Sim** configuration during the first half of the time period, in almost all cases **Par** outperforms **Sim** in the second half.

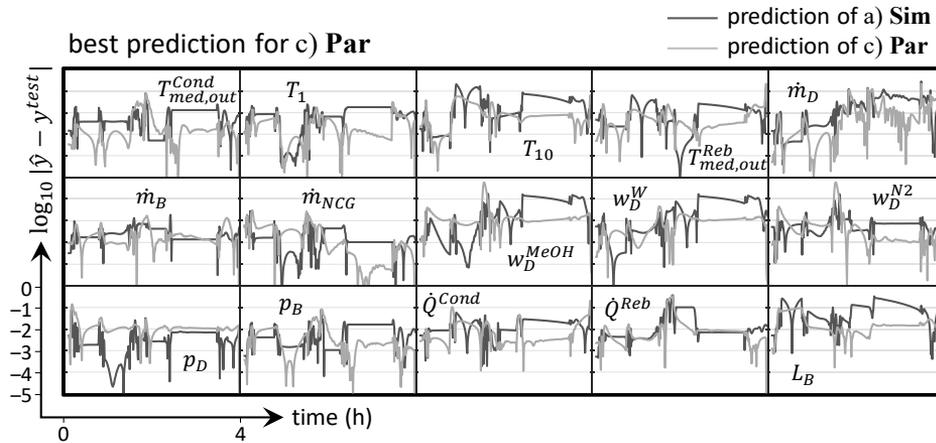

Figure 5: Errors of best predicted samples (in terms of MSE) for configuration c) **Par**

In the context of batch distillation, the second half of the predicted time period is often described by distillate depletion, inertization and shutdown. The conditions in the column states that must be met to proceed with inertization and shutdown strongly depend on the actions taken from the beginning of the operation. These actions in the manipulated variables are bound to past measurements according to an operation recipe. The **Par** configuration can be trained on those conditions using past states, explaining its advantages over **Sim**.

4. Conclusions

For the presented use case, RNN configurations with and without external output feedback loops were tested. A proposed parallel configuration based on a model trained in series-parallel form (*teacher forcing*) showed better overall prediction accuracy and lower variance in the mean squared errors than a simulation configuration with only control regressors. This is due to the modelling of the prediction error considering past testing timesteps. The qualitative behaviour of predicted trends supports the choice of this architecture, although the computation time of the prediction is three orders of magnitude higher. Training of the presented RNNs on large simulated datasets provides data-driven models for trajectory optimization in chemical processes with complex dynamics. The trained models will be used for the optimization of batch distillation cycles in a real batch distillation column.

Abstract

In the pathway toward decarbonization, hydrogen is presented as a great option as it can be produced from a wide variety of feedstock using multiple production, storage and transportation options for diverse applications. Although H_2 could provide flexibility and sector coupling to energy systems, the design and management of the hydrogen supply chain (HSC) is also identified as a challenging task. Until now, most of the HSC designs are treated as problems with single or multiple objectives without any hierarchical conflict. This paper proposes a mixed-integer bi-level programming (MIBLP) approach as a mathematical model of the Stackelberg game. The solution strategy considers the MIBLP as a multi-parametric problem: if the feasible set of the lower level optimization problem (LLP) of the bi-level programming problem (BLPP) is parametric in terms of the optimization variables of the upper level problem (ULP), each level can be solved with a different approach. Consequently, to handle continuous and discrete variables at both levels, we propose a hybrid method involving Differential Evolution (DE) for the ULP and an Integer Linear Programming Solver (ILPS) for the LLP. The developed hybrid evolutionary-deterministic strategy evaluates the performance of two HSC study cases combining Steam Methane Reforming and Electrolysis processes for H_2 production: a classical Stackelberg game design vs. a Stackelberg one leader - multi followers under Cournot competition. In both scenarios, the ULP objective is to minimize the distribution cost while the LLP objective tries to minimize the production cost of a given producer. The experimental results obtained show that the solution method is efficient and promising for dealing with one-leader multi-objective / multi-follower single objective optimization cases.

Keywords: bi-level programming, hydrogen supply chain, Stackelberg Games, Cournot Equilibrium, MIBLPP.

1. Introduction

Hydrogen (H_2) can be obtained from a wide variety of renewable and non-renewable sources with many different production, storage and transport modes, so that the development of an optimal Hydrogen Supply Chain (HSC) arises as a complex task. With the objective of a low or zero carbon energy future, and with the faster growing research interest in this topic, as proposed in Lindorfer et al. (2019); Borschette (2019), hydrogen can offer new pathways for the energy transition. Until now, most of the HSC designs are treated as single level programming problems (SLPP) with

single or multiple objectives without any hierarchical conflict. SLPPs can be seen as centralized decision-making systems, where the highest level in the hierarchy has enough power to dictate the decisions and have them executed by the lower levels without any chance of opinion. However, a more realistic formulation would recognize the role of the lower levels as part of the decision process. Therefore, the optimization of non-cooperative supply chains using bi-level programming models has received increased scientific attention due to the natural representation of this kind of hierarchical situations.

Bi-level programming problems (BLPP) constitute a class of nested optimization problems where an optimization problem contains another optimization problem as part of the constraint definition. Main approaches used to tackle BLPP are commonly divided into two classes: deterministic / classical approaches and evolutionary approaches, for further detail refer to Sinha *et al.* (2018). Mostly of the classical optimization literature is related with simple, single-objective problems with linear constraints when it is possible to replace the lower level optimization problem with its Karush-Kuhn-Tucker (KKT) conditions. Existing models usually can only handle linear or quadratic problems in the follower level using classical approaches, like the transformation of the bi-level problem into a single level problem using the KKT conditions, e.g. Dempe and Franke (2019); Li *et al.* (2016); Yue and You (2014). On the evolutionary approach branch, studies on computational techniques like evolutionary algorithms had proved the efficiency solving from small to big size problem instances, e.g. Sinha *et al.* (2017); Bylling (2018).

This work attempts to solve a non-cooperative HSC in the presence of multiple followers (producers) that compete in a shared market. In a previous work, we proposed a more realistic HSC formulation that recognize the role and influence of each stakeholder as part of the whole decision process, based on Flores-Perez *et al.* (2020) and represented as a non-cooperative supply chain in the form of a single leader - single follower BLPP.

In Game Theory, the Cournot Competition Game is an economic model to describe how n rival companies compete when they offer the same product in the same market and collusion is not possible or is forbidden. Ledvina and Sircar (2012) define that the Cournot Oligopoly Model occurs when more than two firms (players) choose their individual production level q_i and the market price is determined by the total sum of outputs while each firm wants to maximize their profit. Recent studies, e.g. Lu *et al.* (2021); Zhang *et al.* (2020), demonstrate the usefulness of this approach applied to energy markets, where the authors use a Cournot Game to model the interactions and competition among strategic generators.

In this paper, we formulate the HSC as a BLPP where the leader is a monopolistic distribution company and the Cournot Oligopoly Game model is adopted to formulate production competition between different producers (followers). The rest of this paper is organized as follows. Section 2 defines the HSC model represented as a Mixed Integer Bi-level Programming Problem (MIBLPP), including the shared market competition. Section 3 explains the functionality of the hybrid algorithm to solve MIBLPP, the Cournot model definition and the expected interaction between levels. Section 4 and 5 highlight the results obtained and conclusions, respectively.

2. Problem Definition

Due to the complex and non-general structure of the HSC, and to test the viability of the developed algorithm, we propose a modified numerical example of a Production-Distribution problem adapted from literature, see Avraamidou and Pistikopoulos (2019). There are two main ways to produce hydrogen. Today, around 99% of hydrogen comes from fossil fuels, primarily by reforming natural gas into hydrogen and CO_2 . This hydrogen is often referred to as "grey hydrogen" if greenhouse gases are emitted into the atmosphere. The "green" alternative refers to hydrogen gas that is generated via electrolysis powered by renewable energy such as hydro, solar or wind energy.

The resulting HSC planning activity can be modeled as MIBLPP with continuous and discrete variables at both levels to represent production and distribution activities of a HSC, with the par-

Sets and index		Parameters			
P, p	Set of H_2 producing plants, plant index		$p = 1$	$p = 2$	
S, s	Set of storage units, unit index		13,500	10,000	
R, r	Set of refueling stations, station index		$r = 1$	$r = 2$	$r = 3$
Constants					
$PCap_p$	Max production capacity of plant p (kg)				
$TCap^{prod}$	Connection capacity at production level (kg)				
$TCap^{dist}$	Connection capacity at distribution level(kg)				
CC_{sr}^{trans}	Transmission cost from storage s to station r (\$/kg)	$s = 1$	1	1	1
CC_{ps}^{conv}	Conversion cost at plant p for storage s (\$/kg)	$s = 2$	2	2	2
UTC_{ps}	Transp. cost from plant p to storage s (\$/kg)		$s = 1$	$s = 2$	
UPC_{ps}	Prod. cost of H_2 at plant p for storage s (\$/kg)	$p = 1$	0.7	0.7	
D_r	Demand for refueling station r (kg)	$p = 2$	1	1	
c_p	Marginal production cost for producer p (\$/kg)		$s = 1$	$s = 2$	
a, b_p	Coefficients for the inverse demand function	$p = 1$	2.3	2.3	
		$p = 2$	1.6	1.6	
			$s = 1$	$s = 2$	
		$p = 1$	2.3	2.3	
		$p = 2$	1.6	1.6	
			$r = 1$	$r = 2$	$r = 3$
			5,500	6,500	1,500
Decision variables					
Q_{sr}	H_2 sent from storage s to station r (kg)				
y_{sr}	Existence of route connecting storage s to station r		$p = 1$	$p = 2$	
Q_{ps}	H_2 produced in plant p for storage s (kg)		$1.21e^{-4}$	$3.2e^{-4}$	
x_{ps}	Existence of route connecting plant p to storage s	$p = 1$			
q_t^*	Optimal quantity produced by producer t (kg)	$p = 2$	2.3	1.6	
Π_t^*	Total profit for producer t (\$)	$r = 1$			
Q^*	Optimal quantity produced (kg)	$r = 2$			
P^*	Market price (\$/kg)	$r = 3$			

Table 1: Sets, index and parameters for HSC case study

ticularity of multiple followers competing for the production market. For the case study considered here (see Figure 1), the HSC for mobility application is operated by two different companies, production and distribution, described as follows:

The upper level problem (ULP) represents the distribution company, the objective function consists in minimizing the costs that arise of getting the hydrogen from plants and then to distribute it to the refueling stations, including the cost associated to hydrogen storage in the dedicated facilities. The lower level problem (LLP) represents the decisions of the multiple production companies, which have the interest in minimizing the total operating cost associated to production activities while maximizing their individual profit via a Cournot model, more detail in Osborne (2002). The fixed cost related to the decision of establishing a connection between a production plant and storage units corresponds to the cost of compression/liquefaction.

The resulting mathematical model is presented by equations (1-17) using the nomenclature and parameters of Table 1. The parameters associated with production, storage, distribution

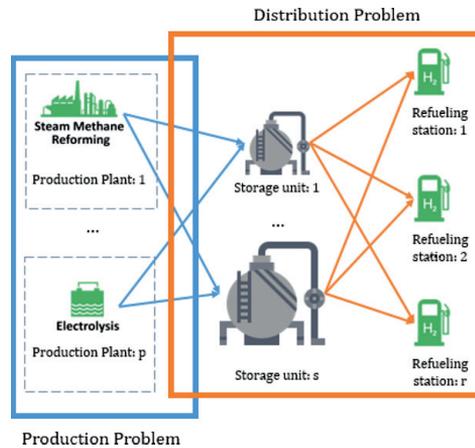

Figure 1: Non-cooperative Hydrogen Supply Chain.

and conversion/transmission for the H_2 supply chain are taken from Hydrogen Council and McKinsey & Company (2021).

3. Hybrid MIBLPP Algorithm. The multi-follower case

The solution algorithm consists of two sections: the Upper Level (UL) problem and the Lower Level (LL) problem. The UL problem solved by a Differential Algorithm approach describes the general properties of the leader problem, including the Upper Level Variables (ULV), each iteration includes a call to the LL problem to optimize the LL objective function, more detail of the algorithm can be found in Flores-Perez et al. (2020). In other words, for each UL population member with no constraint violation, the © IBM CPLEX Solver evaluates the LL problem taking into account the production levels proposed by the general Cournot model. The result of the evaluation returns to the UL as fixed values (parameters) so the algorithm can evaluate the UL objective function. Each UL iteration ends up with the Differential Evolution engine executed. It is possible to define two tolerances for the stopping criteria: the number of generations or a predefined feasible solution; a tolerance is a threshold which if crossed stops the iterations of a solver.

$$\begin{aligned} \min_{y_{sr}, Q_{ps}} \sum_{s \in S} \sum_{r \in R} CC_{sr}^{trans} y_{sr} + \sum_{s \in S} \sum_{r \in R} UTC_{ps} Q_{ps} \quad (1) \\ \sum_{s \in S} Q_{sr} \geq D_r, \quad \forall r \in R \quad (2) \\ Q_{sr} \leq TC_{ap}^{dist} y_{sr}, \quad \forall s \in S, \forall r \in R \quad (3) \\ Q_{sr} \geq 0, \quad \forall s \in S, \forall r \in R \quad (4) \\ C = \sum_{p \in P} c_p \quad (5) \\ q_p = \frac{1}{b_p} \left(\frac{a+C}{n+1} - c_p \right) \quad (6) \\ Q^* = \frac{1}{b_p} \left(\frac{an-C}{n+1} \right) \quad (7) \\ P^* = \frac{a+C}{n+1} \quad (8) \end{aligned}$$

$$\begin{aligned} \Pi_p^* = \frac{1}{b_p} \left(\frac{a+C}{n+1} - c_p \right)^2 \quad (9) \\ \min_{x_{ps}, Q_{ps}} \sum_{p \in P} \sum_{s \in S} UPC_{ps} Q_{ps} + CC_{ps}^{conv} x_{ps} \quad (10) \\ s.t. \quad \sum_{s \in S} Q_{ps} \leq PCap_p, \quad \forall p \in P \quad (11) \\ \sum_{p \in P} Q_{ps} \geq \sum_{r \in R} Q_{sr}, \quad \forall s \in S \quad (12) \\ \sum_{s \in S} Q_{ps} = q_p, \quad \forall p \in P \quad (13) \\ Q_{ps} \leq TC_{ap}^{prod} x_{ps}, \quad \forall p \in P, \forall s \in S \quad (14) \\ Q_{ps} \geq 0, \quad \forall p \in P, \forall s \in S \quad (15) \\ Q_{sr} \in \mathbb{R}, y_{sr} \in 0, 1 \quad (16) \\ Q_{ps} \in \mathbb{R}, x_{ps} \in 0, 1 \quad (17) \end{aligned}$$

The aforementioned Cournot model is a general static linear oligopoly with multiple producers with asymmetric production cost. Market price (Eq. 8) is the same for everyone in the market. We assume there are n groups of H_2 producers grouped by production technology p ($1, 2, \dots, n$), each one with profit function (Eq. 9) where the total production (Eq. 7) is obtained from the optimal individual production quantities (Eq. 6). Equations (5-9) are obtained via the diagonalization solution method, for details see Ioan and Ioan (2015). For this specific example, arbitrary values are assigned to a , that represents the intercept for the price equals to 0, and b , the slope of demand curve, in order to obtain a similar demand as defined in the problem definition (13,500 kg). The total marginal cost C correspond to the summation of unit production cost c_p established for each hydrogen producer as parameters (see Table 1).

4. Results

This section compares the results obtained via our classical MIBLPP approach and the proposed MIBLPP+Cournot Algorithm. Identical algorithmic parameters were chosen for both examples, e.g. a population of 400 individuals and 2,500 generations.

In the classical version, the algorithm converges to a unique solution (see Figure 2) where the leveled cost of H_2 (do not confuse with market price from Cournot Model) is 4.21 USD/kg, there is no overproduction but also there is no shared market since the production is managed entirely by a unique company (monopoly) (see Table 2). Not surprisingly, the production company decides to produce the entire demand in the SMR plant since it implies the lowest connection cost (1 USD/kg) and thus a lower total cost.

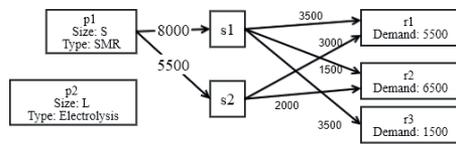

Figure 2: Classic MIBLPP Solution

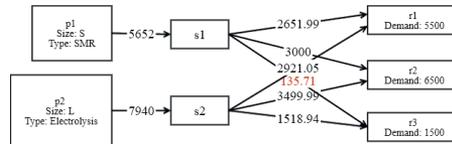

Figure 3: MIBLPP + Cournot Solution

In the case of MIBLPP+Cournot, two different companies in competition, each one with different production technologies and therefore different production costs, must supply the total production of H_2 . In this case, there is a wide variety of feasible solutions, the solution with the lowest total cost of H_2 (Solution 1) is 4.091 USD/kg but with a large overproduction of 2,532 kg of H_2 . As shown in Table 2, a better feasible solution is obtained corresponding to a total cost of 4.30 USD/kg with a low surplus of 135.71 kg of H_2 (Solution 2). The higher total cost, compared with the classical approach, is the result of producing a large amount of H_2 using a large size production plant driven by Electrolysis even if that represents a higher connection cost (2 USD/kg), see Figure 3.

The result obtained using the hybrid algorithm with producers under competition demonstrates the impact of production levels for each producer in order to maximize the individual profit. The results for the Cournot Model are: $q_1 = 8,264.46$ kg, $q_2 = 5,312.50$ kg, $Q = 13,576$ kg, $P = 3.3$ USD, $\pi_1 = 8,264.46$ USD, $\pi_2 = 9,031.25$ USD*

It must be emphasized that even if the cost data used exhibit the order of magnitude observed in the hydrogen roadmaps, the values obtained do not represent a real profit value.

Finally, Table 3 presents both optimal solutions found for comparison purpose between the classical MILPP and the MILPP + Cournot approach.

Approach	Production cost (USD/kg)	Distribution cost (USD/kg)	Total cost (USD/kg)	H_2 produced (kg)	H_2 distributed (kg)	Overproduction (kg)	UL objective function (USD)	LL objective function (USD)
Classic MIBLPP	2.0148	2.1926	4.2074	13,500	13,500.00	0.00	29,600.00	27,200.20
MIBLPP + Cournot (Sol. 1)	1.8911	2.1996	4.0907	13,592	16,123.99	2,531.99	25,703.80	35,466.06
MIBLPP + Cournot (Sol. 2)	1.8911	2.4086	4.2997	13,592	13,727.71	135.71	25,703.80	33,064.12

5. Conclusions

This paper proposes a Cournot Oligopoly Model in the new hydrogen energy market to formulate the competition among non-cooperative suppliers using SMR or electrolysis for hydrogen production. A hybrid strategy to solve mixed-integer BLPP models including multiple players in

Approach	Q_{ps}				Y_{ps}				Q_{sr}			x_{sr}								
	p1		p2		p1		p2		s1	Q_{sr}		s2	r3	s1	x_{sr}		s2	r3		
	s1	s2	s1	s2	s1	s2	s1	s2	r1	r2	r3	r1	r2	r3	r1	r2	r3	r1	r2	r3
Classic MIBLPP	8,000	5,500	0.00	0.00	1	1	0	0	3,500	3,000	1,500	2,000	3,500	1,186.61	1	1	1	1	1	0
MIBLPP+Cournot (Sol. 2)	5,652	0.00	0.00	7,940	1	0	0	1	2,652	3,000	135.71	2,921.06	3,500	1,518.94	1	1	1	1	1	1

Table 3: Optimal solution comparison

competition for the lower level problem is developed for the optimal management of a hydrogen supply chain. This approach has the advantage to couple engineering and economic approaches. The resulting algorithm was tested with a small HSC instance. Further work will now be devoted to a robustness analysis with larger size instances and with the consideration of price elasticity of demand.

Abstract

The improvement of water and energy use in the industrial sector is an important concern for decarbonisation of industries, as well as to improve the overall techno-economic performance of single plants. The improvement of water efficiency, in particular, is a potential approach in the context of its interdependencies to energy use, comprehended by the *water-energy nexus*. A practical application corresponds to the use of heat-driven water treatment units such as multi-effect distillation (MED). Such technology is commonly used for the desalination of seawater, as well as industrial waste saline water streams. This work presents a customised model for an industrial MED unit, namely its assembling using the object-oriented Modelica language, and also a brief economic assessment for the viability of such unit for industrial application. The model was validated with literature data by comparing the theoretical temperature profiles with the simulation results. A payback time of 7.1 years was estimated by excluding negligible parcels of operating expenses (OPEX) for the MED project, which may be considered reasonable in terms of economic feasibility.

Keywords: water and energy integration; Multi-effect distillation; waste heat recovery; water efficiency; Modelica.

1. Introduction

Water and energy integration involve a set of methods, measures and practices to improve their usage in industry (Alnouri et al., 2014), corresponding to two of the most extensively used resources in an industrial plant. The interdependencies of water and energy resources, namely the understanding of the improvement of water use through the understanding of the use of energy, are studied in the scope of the *water-energy nexus* (Oliveira et al., 2019). Moreover, practices of *Combined Water and Energy Integration* corresponds to the simultaneous application of water recirculation and heat recovery principles. In practice, these may be implemented through the use of a water stream as a waste heat stream (Savulescu and Alva-Argaez, 2013). An alternative approach which makes use of the principle of heat recovery, relies on the waste heat potential from a waste stream to set the operation of a water treatment and recirculation system.

In the alignment of the latter approach, this work studies a Multi-Effect Distillation (MED) technology, which may be used (among other applications) for industrial wastewater treatment, namely to desalinate saline water streams (Rahimi and Chua,

2017). This technology makes part of a set of heat-driven water treatment technologies, with the operation of such system needing the supply of a sensible heat source. The approach considered in this work, explores the MED technology, namely the development and validation of a numerical model using the Modelica language, followed by the analysis of its performance and a brief economic assessment in an industrial plant.

2. Modelling of a Multi-Effect Distillation (MED) Unit

The modelling and simulation procedure have been performed using the Modelica object-oriented modelling language, namely using the open-source software OpenModelica 1.18.1. The models for each one of the operational units as well as the whole model have been developed through the use and adaptation of the existing code presented in the ThermoPower Modelica Library (Politecnico di Milano, 2021).

2.1. Theoretical Model

The study performed by Rahimi and Chua (Rahimi and Chua, 2017) presents an overall model that describes the physical phenomena occurring in a MED unit. Following this work, a conventional MED configuration model is presented. The assembling of the MED model considered 3 main components: i) first effect, ii) second-to-last effects and iii) condenser sections. The physical phenomena model described by Rahimi and Chua (2017) is based on mass and energy balances, including an analysis of the heat transfer and fluid phenomena. The model enables a division of the temperature profiles of the effects by zones, which divide specific different sections with different trends for the respective temperature profiles of the hot and cold streams. The mass and energy balance equations for each section are presented in Table 1, while the temperature profiles for each section are represented in Fig. 1.

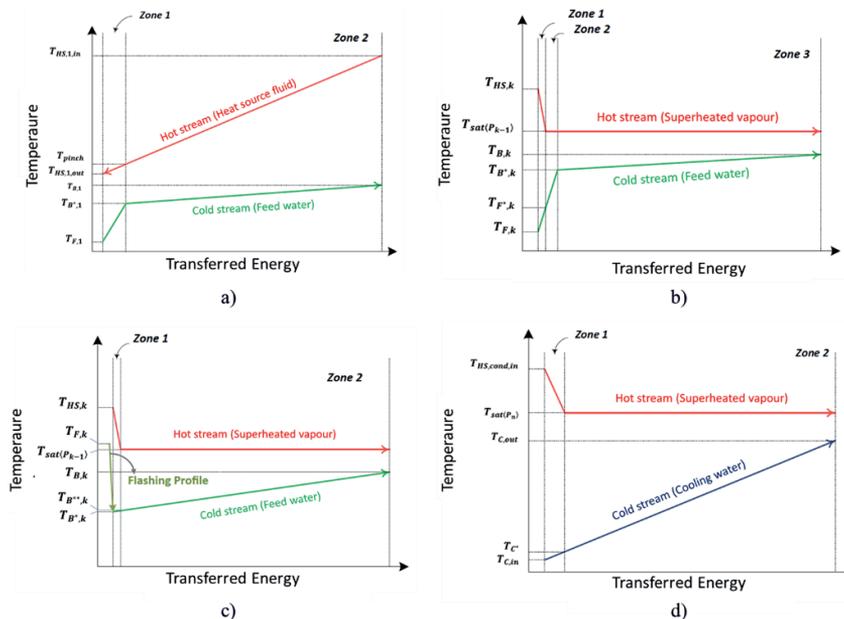

Fig. 1. Temperature profiles for a) first effect section, b) second-to-last effects section without flashed feed stream, c) second to last effect section with flashed feed stream and d) condenser section (adapted from (Rahimi and Chua, 2017))

Table 1. Mass and Energy balances for a conventional MED system

Balance	Zone	Equation
Mass Balance	First effect	$M_{F,1} = M_{B,1} + M_{V,1}$ (1)
		$M_{F,1} \cdot X_{F,1} = M_{B,1} \cdot X_{B,1}$ (2)
	Second-to-last effects	$M_{F,k} = M_{B,k} + M_{V,k}$ (3)
		$M_{HS,k} = M_{V,k-1}$ (4)
		$M_{F,k} \cdot X_{F,k} = M_{B,k} \cdot X_{B,k}$ (5)
	Condenser	$M_{HS,cond} = M_{V,n}$ (6)
Enthalpy Balance	First effect	$M_{F,1} \cdot h_{F,1} + M_{HS,1} \cdot h_{HS,1,in} = M_{B,1} \cdot h_{B,1} + M_{V,1} \cdot h_{V,1} + M_{HS,1} \cdot h_{HS,1,out}$ (7)
	Second-to-last effects	$M_{F,k} \cdot h_{F,k} + M_{HS,k} \cdot h_{HS,k,in} = M_{B,k} \cdot h_{B,k} + M_{V,k} \cdot h_{V,k} + M_{HS,k} \cdot h_{HS,k,out}$ (8)
		$h_{HS,k,out} = h_{f,sat}(P_k)$ (9)
		$M_{HS,cond} \cdot h_{HS,cond,in} + M_C \cdot h_{C,in} = M_{HS,cond} \cdot h_{HS,cond,out} + M_C \cdot h_{C,out}$ (10)
	Condenser	$h_{HS,cond,in} = h_{v,nn}$ (11)
		$h_{HS,cond,out} = h_{f,sat}(P_n)$ (12)

2.2. Development of a MED Unit model in Modelica

The procedure of this work involved the development of a model for each component of a MED unit: i) First effect, ii) Second-to-last effects and iii) Condenser. Each one of these models was assembled considering the mass and energy balances and the heat transfer along the effects and condenser. In order to build the computational models, it was necessary to adapt such equations, in order to simplify and enable the convergence of the simulation. For instance, the heat transfer equations were discretized using the finite volume method (FVM). The assembled model (considering a total of four MED effects) is represented in Fig. 2 (in which Effects 3 and 4 are omitted). The equations used to describe the heat transfer phenomena in a MED unit are presented in Table 2 and Table 3. It is to note that, in the sets of equations, i designates a node of the control volume of an effect or the condenser.

	$q(i) = U_{1,1} \cdot (A(i+1) - A(i)) \cdot dT(i)$ (16)	
	Zone 2	$q(i) = M_{HS,1} \cdot C_{P,HS,1} \cdot (T_{HS,1}(i) - T_{HS,1}(i+1))$ (17)
	$dT(i) = ((T_{HS,1}(i) - T_{F,1,sat}) + (T_{HS,1}(i+1) - T_{F,1,sat})) \cdot 0.5$ (18)	
	$q(i) = U_{1,2} \cdot (A(i+1) - A(i)) \cdot dT$ (19)	

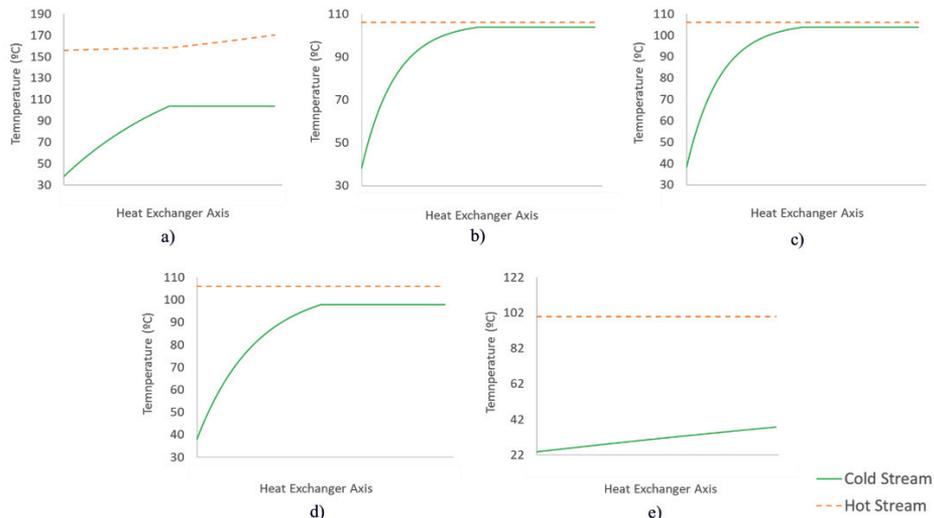

Table 3. Model equations for heat transfer associated to Effect k, Condenser and its respective zones

Section	Zone	Heat Transfer Equations	Section
Effect k	Zone 2	$q(i) = M_{HS,k} \cdot (h_{HS,k}(i) - h_{HS,k}(i+1))$	(20)
		$q(i) = M_{F,k} \cdot C_{P_w} \cdot (T_{F,k}(i) - T_{F,k}(i+1))$	(21)
		$dT(i) = \left((T_{HS,k_{sat}} - T_{F,k}(i)) + (T_{HS,k_{sat}} - T_{F,k}(i+1)) \right) \cdot 0.5$	(22)
	Zone 3	$q(i) = U_{k,2} \cdot (A(i+1) - A(i)) \cdot dT(i)$	(23)
		$q(i) = M_{HS,k} \cdot (h_{HS,k}(i) - h_{HS,k}(i+1))$	(24)
		$dT(i) = \left((T_{HS,k_{sat}} - T_{F,k_{sat}}) + (T_{HS,k_{sat}} - T_{F,k_{sat}}) \right) \cdot 0.5$	(25)
Condenser	Zone 2	$q(i) = U_{k,3} \cdot (A(i+1) - A(i)) \cdot dT(i)$	(26)
		$q = M_{F,cond} \cdot C_{P_w} \cdot (T_{F,cond}(i) - T_{F,cond}(i+1))$	(27)
		$dT(i) = \left((T_{HS,n_{sat}} - T_{F,cond}(i)) + (T_{HS,n_{sat}} - T_{F,cond}(i+1)) \right) \cdot 0.5$	(28)
		$q(i) = U_{cond,2} \cdot (A(i+1) - A(i)) \cdot dT(i)$	(29)

The following modelling assumptions have been considered: steady-state simulation; constant and equal recovery ratio of the primary MED effects; negligible heat losses and pressure losses; constant temperature and salinity of the inlet feed water stream; null salinity of the outlet treated water stream; a temperature difference of 2.5 °C between the condensed vapour and the outlet concentrate streams for primary MED effects. The heat source stream, which is the hot stream in Effect 1, is a liquid with a specific heat capacity of 6643 J/(°C.kg), entering in Effect 1 at a temperature of 170.0 °C and at pressure of 1.5 bar.

2.3. Simulation Results and Model Validation

The model validation has been performed in order to assess its reliability and accuracy in comparison with the theoretical data (Rahimi and Chua, 2017). In this work, model validation has been performed by comparing the heat transfer phenomena occurring in each one of the sections, namely the temperature profiles. The temperature profiles achieved by the simulation of the model for each one of the components of the MED unit are represented in Fig. 3.

**Fig. 3.** Obtained temperature profiles for a) Effect 1, b) Effect 2, c) Effect 3, d) Effect 4, e) Condenser

By comparing the theoretical temperature profiles reported in the literature with the simulated ones (respectively Fig. 1 and 3), it is observed that the simulated temperature profiles are overall consistent with the theoretical ones. The temperature profile of the cold fluid for the zone 2 of effects 2, 3 and 4 (second-to-last effects) presents a sharper variation compared to the linear variation shown in Fig. 1(c), which may be attributed to the use of FVM method for the computation of mean temperature difference, which produces relatively more accurate results. Considering these aspects, it is possible to conclude that the developed model is overall consistent on the prospect of the performed simulation being able to reproduce the real phenomena.

3. Economic Assessment

In addition to the development of a model for a MED unit, Rahimi and Chua (2017) expanded their analysis to a generalized method for the economic assessment of such desalination installations. The simplistic economic model included the capital cost and payback period associated to a MED project, as detailed in Table 4, while the economic savings and payback period estimations considering the water savings results obtained by the simulation are presented in Table 5. A water price of 1.1952 €/m³ was considered for the conversion of water production (assumed to be equal to potential freshwater savings) related to the economic savings.

Table 4. Capital costs and associated payback period determination for a MED unit (Rahimi and Chua, 2017)

Capital Cost	$TCC_{MED} = 2535 \cdot D_t^{0.9751}$	(30)
Payback Period	$PB = TCC_{MED}/(Sav - AEC)$	(31)

Table 5. Determination of water production, economic savings and payback period

Water Production (D_t) (m³/day)	843.28
Water Production (D_t) (dam³/year)	292.41
Investment costs (TCC_{MED}) (k€)	1807.57
Electricity costs (AEC) (k€/year)	95.21
Economic savings (Sav) (k€/year)	349.49
Payback Period (PB) (years)	7.1

Considering the parameters listed in Table 5 and applying equations (30) and (31), a payback period of about 7.1 is obtained. Note that this analysis has not considered certain parcels of the OPEX, for instance, costs associated to chemicals (which includes the costs associated to the acquisition and use of the heat source stream), maintenance, spares, incomes and labour. These are assumed to be common to both MED and conventional wastewater treatment. In this case, these parcels are considered to have already been taken into account in the project of the industrial site in which the MED unit is installed. The payback lies within the acceptable economic viability interval 4 – 16 years of payback time (Baniasad Askari and Ameri, 2021), and therefore it is possible to say that this project is economically feasible. However, considering different studies for the techno-economic assessment of thermal vapour compression MED units, in which payback times correspond to less than 5 years, it is concluded that the MED unit project considered in this work still requires further analysis in terms of potential improvements.

4. Conclusions

This work presents the study of a heat-driven water treatment system, in particular through the exploitation of the multi-effect distillation (MED) technology. This has been achieved by the development and assembling of numerical models describing a conventional MED unit, using the Modelica language. Literature data has been

considered as case-study enabling the modelling of MED unit. The modelling results were validated by comparing the temperature profiles with the theoretical ones. The simulated temperature profiles were, in general, consistent with the theoretical ones, thus ensuring the validity of the model for the simulation of the real occurring phenomena. Furthermore, a brief economic assessment was performed to assess the viability of the MED plant project in an industrial plant. A payback period of 7.1 years was determined, suggesting that the desalination project may be considered economically viable (considering a reasonable payback time of 4 – 16 years), although this is still high when compared to payback periods of other MED unit projects. Further improvement measures (for instance, improved configurations of multi-effect distillation such as preheated MED, boosted MED and flash boosted MED units) will be analysed in the following studies.

Nomenclature

<i>A</i>	Heat Transfer Area (m ²)	Subscripts	
<i>AEC</i>	Cost of electricity (€/year)	<i>B</i>	Concentrate/ Brine Stream
<i>D_t</i>	Daily quantity of water production (m ³ /day)	<i>C</i>	Cooling Water Stream
<i>h</i>	Specific Enthalpy (J/kg)	<i>Cold</i>	Cold Stream
<i>M</i>	Mass flow rate (kg/s)	<i>cond</i>	Condenser
<i>P</i>	Pressure (Pa)	<i>F</i>	Feed Water Stream
<i>PB</i>	Payback Period (years)	<i>Hot</i>	Hot stream
<i>TCC</i>	Capital Cost (€)	<i>HS</i>	Heat Source Stream
<i>Sav</i>	Economic Savings (€/year)	<i>in</i>	Inlet
<i>U</i>	Overall Heat Transfer Coefficient (W/(m ² .°C))	<i>k</i>	Effect number designation
<i>X</i>	Salt concentration (ppm)	<i>MED</i>	MED unit
		<i>n</i>	Total number of effects in a MED unit
		<i>out</i>	Outlet
		<i>total</i>	Total
		<i>sat</i>	Saturation

Continuous operation of a solar photobioreactor with linearizing control – A simulation study

Joris Sébile-Meilleroux^a, Mariana Titica^a, Jérémy Pruvost^a

^a *Nantes Université, Oniris, CNRS, GEPEA, UMR 6144, F-44600 Saint-Nazaire, France*

Abstract

This paper focuses on continuous operation of a closed solar photobioreactor using a feedback linearizing control strategy, maximizing productivity, by acting on dilution rate. Lumostatic and turbidostatic operations were investigated in simulation, using a dynamic model from the literature. This model couples a radiative model describing light gradient into the culture bulk and a kinetic growth model for *Chlorella vulgaris* strain. Results on performances and system operation under different solar light profiles have been discussed in a comparative study considering practical implementation. The result is that the use of solar irradiance prediction led to significant productivity improvement over a year scenario, under turbidostatic operation.

Keywords: Linearizing control, turbidostat, solar photobioreactor, microalgae, biomass production.

1. Introduction

Seeking an economic sustainability and reducing carbon emissions are two of the main current scientific challenges. Use of microalgae (unicellular photosynthetic microorganisms, living in saline or freshwater environments), can be an answer to both these challenges. Indeed, by performing a photosynthetic activity, these organisms convert CO₂ into O₂ when exposed to light. The resulting microalgae biomass represent a source of renewable biofuels (hydrogen, biodiesel, bioethanol). Their operating at optimum productivity, in solar conditions (the sine qua non condition to make them profitable), is a real challenge, which process automation can meet. This is the subject of the work presented here, which aims to implement a feedback control strategy keeping biomass concentration into the culture medium at a predefined set point by acting on the dilution rate, in such a way to reject main disturbances in solar conditions, i.e. uncontrolled various light conditions. Linearizing control has been already studied on microalgae cultures under controlled lighted conditions (Tebbani et al., 2016). In this study, main idea is to go a step further investigating continuous operation with linearizing controller under solar conditions; constant and varying set points, optimizing growth have been investigated. The paper is organized as follows: process description, together with modelling and control problem, is presented in Section 2. The results of the simulation study, investigating control performances under various set points are presented in Section 3. Determination of set points on a daily or annual basis, with different optimization criteria, is discussed and the resulting dilution rates and resulting productivities are compared over a “virtual plant” application. Conclusions and Perspectives are presented in last section.

2. Process description and modelling

2.1. Growth modelling

A flat panel photobioreactor, exposed to solar light has been considered. The reactor is operated in continuous mode, the dilution rate being the manipulated variable. Algal concentration within the culture system, called X ($g_X \cdot L^{-1}$), has been controlled with a feedback linearizing controller. Its temporal evolution, in a homogenous culture medium, in a bioreactor operated at constant volume, is given by mass balance equation (Pruvost et al., 2011):

$$\frac{dX(t)}{dt} = \langle r_X \rangle - D(t) \cdot X(t) \quad (1)$$

$\langle r_X \rangle$ represents the biomass growth rate at volume scale and $D(t) \cdot X(t)$ term represents the biomass flowrate removed from the reactor. This term defines system productivity ($g_X \cdot L^{-1} \cdot s^{-1}$). $D(t)$, the dilution rate (s^{-1}), represents the ratio of feeding flowrate over reactor volume, which effects culture density. Microalgal concentration can then be controlled by dilution, thanks to a pumping system.

In this study, non-limiting growth conditions except light have been considered. In these conditions, biomass growth rate depends on available light into the culture bulk. By coupling a radiative model to a photosynthetic growth model for eukaryotic microalgae, the kinetic model links solar radiation to biomass population expansion inside PBR. The model used in this study has been extensively presented (Sebile-Meilleroux et al., 2020) for *Chlorella vulgaris* strain.

Under high lights conditions, biological phenomena leading to decreasing of biomass growth rate were considered by coupling a mathematical penalty to the kinetic model. Based on experimental results (Artu, 2016), $\langle r_X \rangle$ decreases from a MRPA (Mean Rate of Photonic Absorption) value of $30 \text{ mmol}_{hv} \cdot kg^{-1} \cdot s^{-1}$, until reaching a null value above $40 \text{ mmol}_{hv} \cdot kg^{-1} \cdot s^{-1}$.

2.2. Simulated light profiles

In this study, solar radiation has been described as the total flux density q_0 ($\mu\text{mol}_{hv} \cdot m^{-2} \cdot s^{-1}$) with collimated and diffuse components q_{col} and q_{dif} :

$$q_0 = q_{col} + q_{dif} \quad (2)$$

Four light flux density typical profiles have been defined in order to evaluate the impact of sky coverage (cloudy and sunny situations) and season (winter and summer) on the system productivity. For each profile, three parameters have been considered: maximum total flux density $q_{0,max}$, sky coverage q_{col}/q_{dif} , and sunshine duration t_{day} (h). Parameters values, synthetized in Table I, were taken from meteorological data of Nantes city, France, on the whole year of 2015, given by Meteonorm measurements. With ideal simulated light profiles, parameters were kept constant for a given situation, leading to a sinusoidal light profile.

Table I: Parameters of simulated light profiles

Day	Cloudy winter	Sunny winter	Cloudy summer	Sunny summer
$q_{0,max}$ ($\mu\text{mol}_{\text{hv}}\text{m}^{-2}\text{s}^{-1}$)	150	450	450	1350
$q_{\text{col}}/q_{\text{dif}}$	0.1	1.4	0.1	1.4
$t_{\text{day}}(h)$	10	10	15	15

2.3. Control strategy

A feedback linearizing control law has been implemented to control the biomass concentration at a set point maximizing productivity. This supposes the biomass concentration can be measured online. In these conditions, the control law calculates the dilution (at each control step of 10 minutes), in such a way to keep biomass concentration as close as possible to the set point. In the case of linearizing controller, the control law is defined as follows (Tebbani et al., 2016)

$$D(t) = \frac{1}{X(t)} \cdot \langle r_X \rangle - \frac{\lambda}{X(t)} \cdot [X_{sp} - X(t)] \quad (3)$$

where λ is a constant positive tuning parameter and X_{sp} ($g_X \cdot L^{-1}$) is the biomass concentration set point. In this study λ was set at $6.0 h^{-1}$ thanks to preliminary studies which looked for a successful set point tracking at different constant biomass concentration values, with *Chlorella vulgaris* and *Chlamydomonas reinhardtii* strains.

3. Results

Simulations have been performed using the dynamic model presented in Section 2 as a virtual plant, under simulated and real light profiles, in open and closed loop. The linearizing controller has been used for tracking constant and various set points, chosen with purpose to increase system productivity. Simulations were achieved on Matlab software (R2021a). Typical light profiles were repeated every 24 hours until the appearance of a steady-state on culture behaviour, defined by biomass concentration evolution.

3.1. Study on typical daily light profiles

3.1.1. Lumostatic operation

A way for optimizing process operation is to impose light gradient into the bulk, to ensure optimization of light energy absorption. For microalgae, the maximum volumetric productivity was obtained when full-light attenuation occurs without a dark zone, meaning PBR illuminated fraction equals 1 (Takache et al., 2009). This condition defines the lumostatic mode, in which light absorption is maximized. To do so, optimal concentration X_{sp} has been updated every 10 minutes based on incident irradiance measurements, in such a way to keep lumostatic operating conditions

Applying the linearizing controller (equation 3) to track this variable set point leads however to culture wash-out. This phenomenon was due to low incident lights occurring at the start and the end of the day, to which corresponds low optimal biomass concentration. Indeed, to reach such low concentrations, high dilution rates have to be applied. Then, due to low growth kinetics of microalgae species when compared with the incident irradiance increase over the day, it is not possible to reach next values of biomass concentration set point. In other words, the imposed set point is not achievable. Indeed, further investigations on several lumostatic regimes have shown that microalgae growth

kinetics should be increased by a factor of 20 to be able to track biomass concentration set points ensuring full-light attenuation without a dark zone. So, following a biomass concentration related to lumostatic mode in solar conditions was not realistic; this set point tracking strategy has been consequently rejected.

3.1.2. Turbidostatic operation

In the following, biomass concentration set point has been determined in such a way to optimize productivity on a daily or season basis. Constant biomass concentration set point maximizing daily productivity, for each light scenario (as reported in Table I), has been considered. To do so, 100 values between 0 and $2 \text{ g}_X \cdot \text{L}^{-1}$ for X_{sp} were simulated.

Unlike setting an instantaneous light-dependent concentration set point, setting a constant value over the day is efficient to keep a stable culture, without any wash-out (Figure 1). As it can be seen, the control law applied dilution rates in such a way to track the defined set point. Indeed, due to lack of light during night, biomass concentration decreases even when no dilution is applied. The major effect is the absence of dilution operation in the morning, in order to allow biomass concentration increase. Thanks to photosynthesis achieved under light conditions of first hours of the day, culture densified until reaching the defined set point. Once set point attained, dilution rate given by linearizing controller followed a bell shape (with a flattened part around midday). This shape is similar to the light profile, in order to continuously keep the biomass concentration as long as received light amount is sufficient. In the following, a constant set point giving the highest daily productivity have been selected. Optimal set points and associated productivities applied on repeated daily light profiles were summarized in Table II. Optimal set point values appear to vary with light scenarios, meaning that they are highly light-dependent.

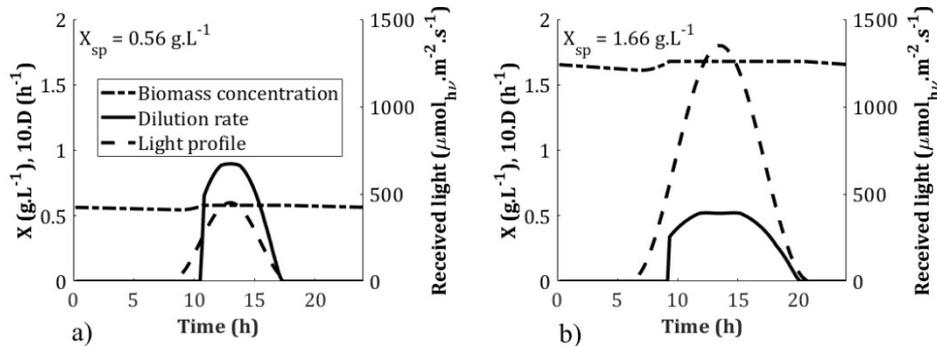

Figure 1: Turbidostatic operation over 24 hours on a) sunny winter and b) sunny summer light

Table II: Daily optimal set points and productivities

Day	Cloudy winter	Sunny winter	Cloudy summer	Sunny summer
Solar flux ($\text{mol}_{hv} \cdot \text{m}^{-2} \cdot \text{day}^{-1}$)	2.70	8.10	12.2	36.4
$X_{sp,opt}$ ($\text{g}_X \cdot \text{L}^{-1}$)	0.26	0.56	0.58	1.66
Productivity ($\text{g}_X \cdot \text{m}^{-2} \cdot \text{day}^{-1}$)	2.22	6.02	8.47	17.6

3.2. Study on year scenario

3.2.1. Closed-loop operation at constant set point over the year

In the following, constant biomass concentration over a year, maximizing annual productivity has been investigated. In order to simulate light decrease from an unperfect light transmission of cover and presence of biofilm on irradiated surface, received light by microalgae was considered half of solar irradiance. A reference scenario has been used to define the constant set point, maximizing the overall productivity. This typical scenario profile represented the yearly light evolution averaged from 10 consecutive years of real data (2005 to 2014), for a given location. Maximal production on this typical profile is attained for X_{sp} at $0.50 \text{ g}_X \cdot \text{L}^{-1}$ for Nantes, France. When applying this set point on year 2015 scenario for the same location, associated productivity hits $5.67 \text{ g}_X \cdot \text{m}^{-2} \cdot \text{day}^{-1}$. For a large-scale “virtual plant”, associated biomass production is $20.7 \text{ t}_X \cdot \text{ha}^{-1}$, meaning turbidostatic operation in solar conditions can satisfy industrial production expectations.

3.2.2. Closed-loop operation at constant set point over the day

As illustrated in previous sub-section, set point value on biomass concentration is highly light-dependent. In the following, a strategy where daily set point value has been adapted to daily light amount, has been investigated. This strategy requires perfect weather predictions over 24 hours to determine the next day total light amount $q_{0,tot}$ ($\text{mol}_{hv} \cdot \text{m}^{-2}$). Thanks to results on typical daily light profiles from Table II, daily optimal set point value appears to follow equation 4 (linear regression: $R^2 = 0.99$).

$$X_{sp} = 0.042 \cdot q_{0,tot} + 0.16 \quad (4)$$

The linearizing controller performed satisfactorily for tracking the biomass concentration set point given by equation 4, as illustrated in Figure 2. Figure 2(a) represents biomass concentration evolution and Figure 2(b) represents the applied dilution rates, over the second week of July of 2015. Adapted set point kept constant over each day (“daily set point” strategy), and set point kept constant over the year (“yearly set point” strategy) were studied. When applying “daily set point strategy”, associated productivity goes up to $6.58 \text{ g}_X \cdot \text{m}^{-2} \cdot \text{day}^{-1}$, meaning a total biomass production of $24.0 \text{ t}_X \cdot \text{ha}^{-1}$. Consequently, daily adaptation of biomass concentration set point improves production by 16 % when compared to an optimal set point kept constant over the year.

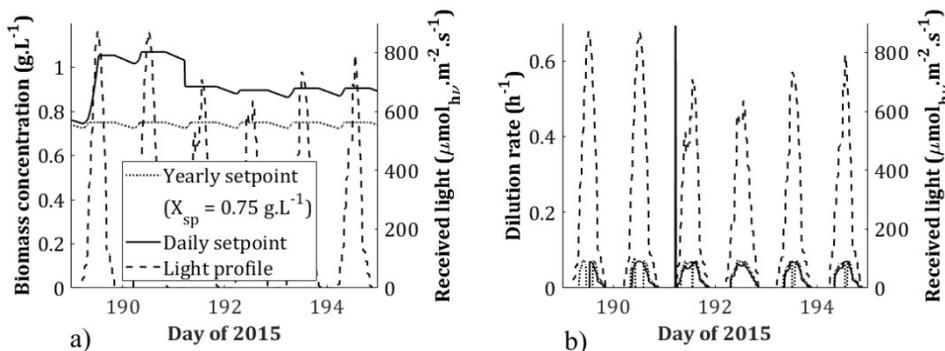

Figure 2 : Daily and yearly strategies effects on a) biomass concentration and b) command law

It can be noticed the efficiency of turbidostat operation using a linearizing control strategy in non-ideal solar conditions, either with a daily or a yearly set point strategy. Nonetheless, using a daily optimal set point can induce a sharp dilution peak, as seen on third day in Figure 2(b). Indeed, if daily set point value drops from previous day

(passing from a high to a lower sunny day), short dilution appears at the beginning of the day in order to quickly attain the new set point value. When diluting a real solar photobioreactor with this daily optimal strategy, this could cause issues with expected productivity, due to pumping limitations. Regarding yearly set point, it has been observed that dilution can be stopped around midday, contrary to daily set point which diluted continuously enduring the sunny hours of the day. Therefore, such a strategy working with a set point optimized at year-scale is not well-suited for high light summer light profiles, because it can induce light stress with negative impact on the productivity. These issues are under study in our ongoing research considering uncertainties on model parameters and saturation on applied dilution rates.

4. Conclusions

When cultivating microalgae in solar conditions, a way to optimize system productivity is to operate in closed-loop continuous mode, at predefined set point for biomass concentration control. The issue in solar condition is to choose a feasible set point, in such a way to optimize system productivity under uncontrolled, varying incident light conditions. In this study, different set point trajectories have been investigated in simulation, using a linearizing controller applied to a “virtual plant”. Working with such strategies requires a dynamic model describing main phenomena related to light influences on the microalgae growth. It has been noticed that the optimum set point ensuring lumostatic conditions wasn’t achievable, as demonstrated in simulation with the linearizing controller applied every 10 minutes. The feedback linearizing controller was able to maintain the biomass concentration at desired set point (constant over the year and piecewise constant over the day), determined in such a way to maximize productivity (turbidostatic operation). Optimizing biomass concentration set point on a daily basis, thanks to global solar irradiance perfect prediction over 24 hours, led to a 16 % improvement of microalgae yearly production, when compared to an optimal set point predefined on a yearly basis. More realistic simulations in the presence of uncertainties in the weather data are currently being studied. On the other hand, practical implementation is envisaged on a solar-scale experimental pilot.

Abstract

Inherently safer design (ISD), which focuses on reducing the inherent hazards of a design before applying any safety controls, is one of the most effective and reliable tools for improving the safety of a process. However, while an intensified process may be inherently less hazardous, if the design restricts the controllability of the process, then the design may have a higher risk and be less safe overall. Therefore, considering both the inherent hazard contained within the process and the ease by which these hazards can be controlled is necessary for a more complete evaluation of the inherent safety of a system.

The objective of this research is to implement a strategy to simultaneously design and control an inherently safer distillation column. The PARAmetric Optimization and Control (PAROC) framework is used as a basis for the simultaneous design and control of a distillation column. The Safety WEighted Hazard Index (SWEHI) is incorporated into the PAROC framework, and the distillation column is optimised for cost, while receding control horizon policies are implemented to ensure that the column is capable of controlling disturbances. The dynamic effects of different operating variables on safety are analysed and discussed. The integration of ISD with simultaneous design and control allows for a greater understanding of inherent safety during process design and substantially reduces operability issues that result from an uncontrollable process design and allow for greater tolerance and ease of control.

Keywords: Dynamic Optimization, Distillation Column Design, Inherently Safer Design, Design and Control Integration.

1. Introduction

The design of industrial processes requires the consideration of a number of different characteristics, including profitability, safety, and sustainability. Traditionally, the focus of both academia and industry has been to optimize the early design of process systems primarily for profitability. Other considerations, such as safety and sustainability, are postponed until later stages of engineering design. In such an approach, the process of risk management typically only involves implementing prevention, mitigation, and response methods after the design is nearly finalized. However, such approaches are typically inefficient and result in unsafe designs [1]. Therefore, there has been a movement towards the use of inherent safety principles to improve the safety and profitability of industrial process designs [2].

1.1. Inherently Safer Design

Inherently Safer Design (ISD) is one of the most effective methods for assessing safety in the early stages of design [3]. Inherent Safety uses four main principles to determine the safety of a process.

Intensification (or Minimization) involves reducing hazardous inventories in both process equipment and storage. Substitution means replacing hazardous chemicals with less hazardous chemicals. Attenuation (or Moderation) is using hazardous chemicals in conditions that would make them less hazardous (i.e. reducing the pressure or temperature). Limitation of Effects is to reduce consequences by using designs or reaction conditions rather than by adding protective equipment that may fail or be neglected

Using these principles, inherent safety addresses potential hazards and risks that can potentially lead to the need for costly add-on safety later in the process lifecycle. Therefore, the earlier in the design that inherent safety is considered, the more opportunities there are for the application of inherently safety in the design [4]. One of the limitations of current inherent safety metrics is that they are typically do not consider dynamic disturbances that may impact the safety of the process. During start-up, shutdown, and even during regular operations, the safety of the process will fluctuate with changes in process parameters and variables. However, the fluctuation of safety is not accounted for in the early stages of design by current inherent safety metrics.

It is difficult to determine the dynamics of a system in the early stages of design because most process systems are quite complex. The design of an industrial process influences the ability of its control systems to reject disturbances [5]. Due to the complexity of these processes, the control response is difficult to assess without designing the controller, a development that typically occurs at a later phase. However, without knowing the control response the dynamic inherent safety cannot be assessed.

Recently, the PARAmetric Optimization and Control (PAROC) framework was proposed at a method to allow for the representation, modelling, and solution of simultaneous design and control problems [6]. PAROC allows for the simultaneous simulation of design and operating variables in the early design phase under optimal multi-parametric Model Predictive Control (mp-MPC). This allows for the measurement of the dynamic behavior of industrial processes in the early design phase. Thus, the incorporation of PAROC with inherent safety allows for a dynamic understanding of the interaction between safety and operability in the early stages of design.

The aim of the present work is to demonstrate how PAROC can be used to dynamically measure and optimize the design of an industrial process with respect to its profitability, safety, and controllability. A distillation column is used as a case study. The Safety Weighted Hazard Index (SWeHI) is input as an extra variable into the high-fidelity model to quantify the inherent safety of the distillation column [7]. Disturbances are introduced into the process, and the dynamic change in the safety index is compared to the steady-state index. Finally, the safety index is added as a constraint to the dynamic optimization of the process, allowing for a process that is optimized for cost, operability, and safety.

2. Case Study – Binary Distillation

2.1. Benzene-Toluene-Xylene Production

In 2018, the US produced 11.3 billion lbs of benzene, 6.1 billion lbs of toluene, and 10.0 billion lbs of mixed xylenes [1-3]. Benzene is used to make nylon, styrene, polycarbonate, and epoxy resins [4]. Toluene and xylene are used as solvents in paints, thinners, glues, and other household items [5]. Approximately 45% of the United States' benzene is

produced by conversion of naphtha to benzene, toluene, and xylene via catalytic reforming and separations [6].

The Benzene-Toluene-Xylene (BTX) production process converts naphtha to benzene, toluene, and xylene by catalytically cracking naphtha and then using a series of separations processes to separate BTX from the resulting pyrolysis gas. The benzene-toluene distillation unit of the BTX production process will be optimized in this work.

2.2. Dynamic Challenges in Inherent Safety

Luyben and Hendershot examined the BTX aromatics fractionation process from a control and safety perspective. In this study, they examined the control effects of decreasing molar holdups in the reboilers and the reflux drums and found that making the process inherently safer via intensification may make the column less operable, and thus dynamically less safe [8]. However, no attempt at optimizing the process was performed, and so the problem of determining an inherently safer, controllable, and cost-optimal design remains unsolved.

3. Methodology

3.1. Incorporating safety into the PAROC framework

The basic principles of the PAROC framework in the context of simultaneous design, control, and safety optimisation are presented in Figure 1.

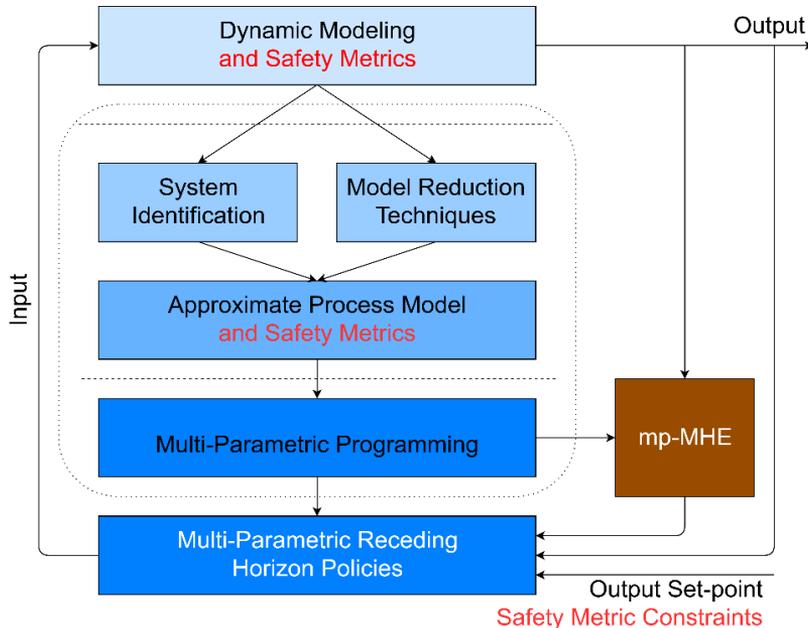

Figure 1. The PAROC framework for simultaneous design, control, and safety.

The first step of the PAROC framework is to create a “high fidelity” model to capture the dynamic behavior of the process, based on first principles modelling and data driven approaches. This includes mass/energy balances, driving force constraints, thermodynamic relations, sizing constraints, and numerous other empirical correlations. The primary basis of the model was that of Bansal et al [9]. The modelling was performed in gPROMS® and steady state accuracy was confirmed in ASPEN Plus [10, 11]. Since

safety may depend on the states, controlled variables, and design variables, the overall safety of the system is defined as a separate variable that is a function of each of these process variables.

The next step is model approximation. While the high-fidelity model presents a highly accurate representation of the process, designing a controller for such a complex system is a difficult task. The MATLAB® System Identification toolbox was used to derive a set of linear state-space models that include design variables in the model expressions.

Multiparametric programming is then performed using the Parametric Optimisation (POP) toolbox to define a set of critical regions where a multiparametric controller can act in order to keep the process within acceptable control limits [12].

Next, the developed receding horizon control policy is tested against the high-fidelity model in-silico. Since the controller was created via a model approximation, this step is necessary to ensure the applicability of the controller to the original high-fidelity system.

Finally, the controller is placed into the original model, and the entire model is dynamically optimised using gPROMS Modelbuilder as a Mixed Integer Dynamic Optimization (MIDO) problem to solve for the design variables.

Continuous design variables that were considered were tray volume and reboiler and reflux drum size. Mixed integer design variables considered were number of trays, feed tray location. Safety was assessed via the Safety Weighted Hazard Index. SWeHI examines material properties such as flammability, reactivity, toxicity, and vapor pressure, as well as operating properties such as operating pressure, tray temperature, and molar flowrate. Molar composition of the distillate and the bottoms is controlled by changing the steam flowrate in the reboiler, and the reflux flowrate into the condenser.

4. Results and Discussion

A 10% sinusoidal disturbance was introduced into the feed composition with a period of 80 seconds. A high-fidelity model and mpMPC was developed and optimized. The high-fidelity model contained 1948 algebraic equations, 81 differential equations, and 2029 unknown variables.

Steam flowrate varied sinusoidally between 6.0 and 7.3 kmol/min, and reflux flowrate varied between 3.5 and 5.0 kmol/min. Figure 2 shows the corresponding output purity. The control response is within acceptable limits, and the output purity is constrained within the bounds.

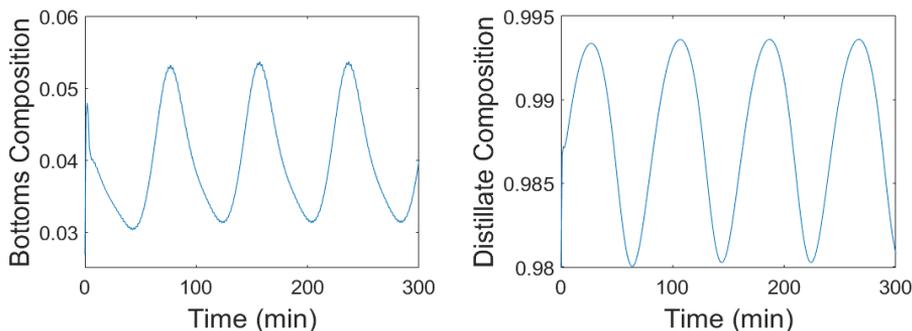

Figure 2. The output purity of the bottoms (left) and distillate (right) streams are constrained above 0.98 and below 0.06 respectively.

Table 1 compares the dynamic optimization performed in this study to the previous dynamically optimized model in literature. The previous model considered a feed flow disturbance that was not examined in this work, which is why its cost is higher.

Table 1. A comparison of the current model optimization with optimized models in literature

	Current Approach	Bansal et al.[9]
Condenser Area (m ²)	121	83.33
Reboiler Area (m ²)	63.3	131.6
Diameter of Column (m)	2.11	1.91
# Trays	22	23
Feed Tray	10	12
Total Cost (\$1k)	7.494	7.908

A dynamic safety assessment was performed. Figure 3 shows the overall safety rating of the column. The total steady state value of the column is 1900. This rating varies from 1888 to 1909, a negligible (1%) difference compared to the steady state value.

Figure 4 shows the safety rating of the reboiler and the reflux drum, which varies from 100 to 110 in the reboiler, and from 50.2 to 51 in the reflux drum. This equates to a 5 % difference in the reboiler, and a 1 % difference in the reflux drum. One important observation to note is that the oscillation in the SWeHI hazard rating in the lower trays and the reboiler are 180 degrees out of phase with those of the upper trays and the reflux drum. This produces destructive interference that muffles the overall change in safety index throughout the column. This oscillation also indicates a dynamic vertical transfer of hazard from one side of the column to the other as a response to a sinusoidal feed composition change. Although the distillation tower as a whole remains at a near constant hazard, the inherent hazard is being transferred up and down the column periodically with the disturbance.

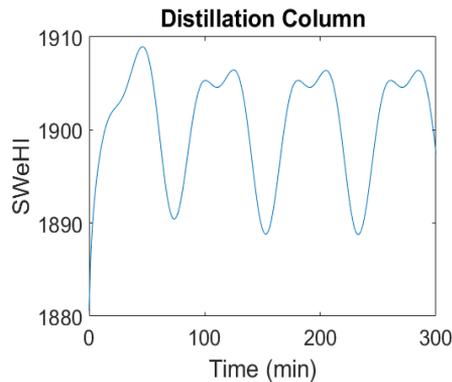

Figure 3: Dynamic SWeHI hazard rating of the overall column.

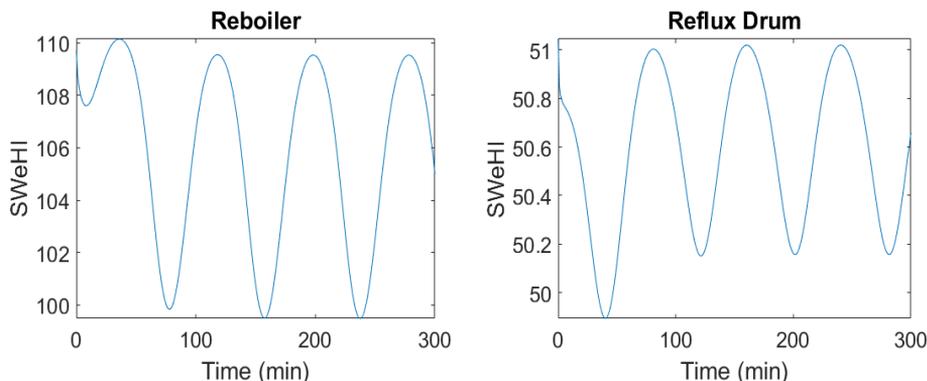

Figure 4: The SWeHI hazard ranking of the reboiler (left) and condenser (right).

5. Conclusions

A methodology for the dynamic optimization of design and safety with guaranteed control was presented. The methodology was applied to a distillation column case study. A dynamic safety assessment was conducted on the distillation column.

An overall 1% difference between steady-state and maximum dynamic damage radius was observed within the process as a result of feed composition disturbance. A 5% difference was observed within the reboiler and a 1% difference was observed in the reflux drum, along with oscillations in safety along vertical sections of the column. A similar assessment and optimization could be performed on any process unit.

Abstract

The main objective of this work is to develop a one dimensional model to simulate the flow of Non-Newtonian fluids under Modelica software. We built a new library of components that provide the simulation of Newtonian and Non-Newtonian fluids flows. Within the pipe model, a new first order scheme of finite volume method to resolve Navier-Stokes equations for incompressible fluids with varying density is implemented. To introduce pressure drops, a Bingham plastic model is considered to represent the rheological behavior of the Non-Newtonian fluids. With the new library components, we perform a first numerical simulations of water flow in a pipe network of extended length. The computational cost of the performed simulation with the the Modelica Standard Library components reduced by a significant orders of magnitude compared to the previous implementation, while the dynamic results are not affected. Then we simulate the flow of the phosphate slurry through the real Pipeline network design and compare the results with industrial data.

Keywords: Modelica, Bingham, finite volume, Non-Newtonian

1. Introduction

OCP Group a worldwide leader operating in the mining and marketing of the phosphate ore and its derivatives. The industrial process involves transporting the ore from the deposits to the processing plants. Since 2014, as part of the optimization strategy, it was decided to replace the rail transport mode between the city of Khouribga and the Jorf Lasfar plant by a flow of phosphate slurry through a network of pipes (Rusconi et al., 2016). the pipeline extends over 187 km of terrain with varied topographies. However, the control parameters available for this system are the density of the slurry, the prescribed inlet flow rate and the pressure at the network's downstream. Therefore, flow models are required to predict system behavior and ensure optimal control by avoiding ore deposition, pressure drops, and the damages that can result from such events. Fully three-dimensional flow models with water-particles fluid models are too complex to build and are CPU time consuming to be exploitable in any real process control, optimization or design (Ghodke and Apte, 2016). Alternatively, one may consider an averaged rheology for the mixture and in this case the slurry can be characterized by a Non-Newtonian rheology. Given the complexity of the non-Newtonian rheological behavior of the phosphates slurry, besides the length of the network, a phenomenological model to simulate this flow is requested (Lima, 2020).

In the present work we developed a new fluid library under Modelica software, to simulate flows through pipelines for both Newtonian and Non-Newtonian fluids. Indeed, we have developed

a new numerical scheme to solve the Navier-stokes equations for incompressible fluids drained into a circular pipe in one dimension. The new scheme is implemented within the pipe model. Then, we integrated the frictional pressure drop calculation models for both types of fluid. For the Non-Newtonian fluid, we adopt the Bingham model as it give a fair description of the rheological behavior (Maazioui et al., 2021). To validate the new scheme model, we perform numerical simulations through different sizes of pipeline network (10, 100, and 200 pipes) using the new fluid library and the Modelica Standard Library (MSL) components. We compare their results and the computation time. Moreover, we simulate the flow of the phosphate slurry through the first part of the pipeline network formed by 1293 pipes, and we compare the results with industrial data.

2. Methodology

The purpose of this work is to develop a one-dimensional model to simulate the flow of Non-Newtonian fluids withing a pipe of length L , a circular section of diameter D , and inclined to the horizontal by the angle θ . We define T the internal volume of the pipe and C its contour, S_{in} and S_{out} are respectively the inlet and outlet sections of the pipe.

2.1. Mathematical model

Consider the conservation of mass and momentum equations for incompressible flow with suitable boundary conditions

$$\begin{cases} \frac{\partial \rho}{\partial t} + \text{div}(\rho \mathbf{u}) = 0, \\ \frac{\partial (\rho \mathbf{u})}{\partial t} + \text{div}(\rho \mathbf{u} \otimes \mathbf{u}) + \nabla P = \rho \mathbf{g} + \mu \Delta \mathbf{u} \end{cases}, \quad (1)$$

where ρ is the density, \mathbf{u} the velocity vector, P the pressure, \mathbf{g} the gravity acceleration vector, and μ the fluid dynamic viscosity. The hypothesis of flow incompressibility rewrites the continuity equation as

$$\text{div}(\mathbf{u}) = 0. \quad (2)$$

The boundary conditions are specified for the present model as follows. For the inlet, we consider that the average density of the fluid and the mass flow through the inlet section ($\mathcal{A} = L_y L_z$ and $d\sigma = dydz$) are given in input following

$$\begin{cases} \rho_{in}(t) = \frac{1}{\mathcal{A}} \int_{S_{in}} \rho(0, \sigma, t) d\sigma, \\ q_{in}(t) = \int_{S_{in}} \rho(0, \sigma, t) \mathbf{u}(0, \sigma, t) \cdot \mathbf{e}_x d\sigma. \end{cases} \quad (3)$$

Then, we define the average input velocity

$$v_{in}(t) = q_{in}(t) / \mathcal{A} \rho_{in}(t) \quad (4)$$

At the pipe outlet, the pressure P_{out} is determined as $\frac{1}{\mathcal{A}} \int_{S_{out}} P(L_x, \sigma, t) d\sigma = P_{out}(t)$. The boundary condition at the wall is specified according to the no-slip conditions as $u = 0$ By integrating $\text{div}(\mathbf{u})$ we get

$$\int_{S_{in}} (\mathbf{u} \cdot \mathbf{e}_x)(0, y, z, t) dydz = \int_{S_{out}} (\mathbf{u} \cdot \mathbf{e}_x)(L_x, y, z, t) dydz \quad (5)$$

2.2. Finite volume discretization

We discretize the pipe into N segments of equal length L_x/N where $x_i = \frac{iL_x}{N}$, where $i = 0, \dots, N$. Integrating the mass conservation constraint in Eq. (2) over the volume of control $V_{i+\frac{1}{2}}$ to get

$$\begin{cases} m_{i+1/2} \equiv \int_{V_{i+1/2}} \rho d\tau, 0 \leq i \leq N-1, \\ \varphi_{m_i} \equiv \int_{S_i} \rho v d\sigma, 0 \leq i \leq N \end{cases} \quad (6)$$

The equation of mass conservation is therefore expressed as follows

$$\frac{dm_{i+1/2}}{dt} = \varphi_{m_i} - \varphi_{m_{i+1}}, \quad 0 \leq i \leq N-1, \quad (7)$$

Similarly, integrating Eq. (4) over a control volume $V_{i+1/2}$ we find that

$$(\rho v)_{S_i} \simeq \rho_{S_i} v_{in} \quad (8)$$

A first order approximation is hereafter retained, which allowed to obtain

$$m_{j+1/2} = A\Delta x \rho_{j+1/2} \quad (9)$$

from which, at first order, we get

$$\varphi_{m_i}^{(1)} = \frac{m_{i-1/2}}{A\Delta x}, \quad 1 \leq i \leq N \quad (10)$$

then, Eq. (7) is expressed as follows

$$\frac{dm_{i+1/2}}{dt} = \frac{v_{in}}{\Delta x} (m_{i-1/2} - m_{i+1/2}), \quad 0 \leq i \leq N-1, \quad \text{with } m_{-1/2} = A\Delta x \rho_{in} \quad (11)$$

2.2.1. Momentum conservation integration

We integrate (4) over $V_{i+\frac{1}{2}}$. First, we define $I_{i+1/2} \equiv \int_{V_{i+1/2}} \rho v d\tau$, we obtain

$$\frac{dI_{i+1/2}}{dt} = \varphi I_i - \varphi I_{i+1} + A(\Pi_i - \Pi_{i+1}) + \int_{V_{i+1/2}} \rho \mathbf{g} \cdot \mathbf{e}_x d\tau + \int_{V_{i+1/2}} \mu \Delta v d\tau, \quad (12)$$

where

$$\varphi I_i \equiv \int_{S_i} \rho v^2 d\sigma, \quad 0 \leq i \leq N, \quad \Pi_i \equiv \frac{1}{\mathcal{A}} \int_{S_i} P d\sigma, \quad 0 \leq i \leq N. \quad (13)$$

We note $(\Delta P)_{i+1/2}$ the pressure loss due to friction over the control volume $V_{i+\frac{1}{2}}$, therefore

$$(\Delta P)_{i+1/2} = \frac{1}{\mathcal{A}} \int_{V_{i+1/2}} \mu \Delta v d\tau, \quad 0 \leq i \leq N-1 \quad (14)$$

Besides, since $\mathbf{g} \cdot \mathbf{e}_x$ is constant (equal to $-|g| \sin(\theta)$)

$$\int_{V_{i+1/2}} \rho \mathbf{g} \cdot \mathbf{e}_x d\tau = (\mathbf{g} \cdot \mathbf{e}_x) m_{i+1/2} \quad (15)$$

From (8) we get

$$I_{i+1/2} \equiv \int_{V_{i+1/2}} \rho v d\tau = \bar{v}_{V_{i+1/2}} m_{i+1/2} \quad (16)$$

where $\bar{v}_{V_{i+1/2}}$ is the density weighted average velocity over the volume $V_{i+1/2}$. Thus, we replace $\bar{v}_{V_{i+1/2}}$ with v_{in} in (16) to get

$$I_{i+1/2} = m_{i+1/2} v_{in} \quad \text{and} \quad \varphi I_i = v_{in} \varphi m_i, \quad (17)$$

and eventually returning to (12) we get

$$(\Pi_i - \Pi_{i+1}) = \frac{1}{\mathcal{A}} \left(\frac{dv_{in}}{dt} + |g| \sin(\theta) \right) m_{i+1/2} - (\Delta P)_{i+1/2}, \quad 1 \leq i \leq N-1, \quad (18)$$

where $\Pi_N = P_{out}$

2.3. Pressure Loss determination

The general Darcy-Weisbach equation expresses the pressure loss for an incompressible fluid, due to friction along a given length of pipe at the average velocity of the fluid flow

$$\Delta P = \frac{\rho L v^2 f_D}{2D}, \quad (19)$$

where f_D is the Darcy friction factor, which is a dimensionless quantity given for each fluid behavior and flow regime (laminar/turbulent) by specific formulas.

2.3.1. Darcy friction factor for Newtonian fluids

For a **laminar** flow, the friction factor value is given by Poiseuille's law related to the Reynolds number Re by $f_D = 64/Re$, where $Re = \frac{\rho v D}{\mu}$. In the **turbulent** regime ($Re > 4000$), the friction factor is not only dependent on Reynolds number, but also on the relative roughness of the pipe wall k/D . Haaland (1983) expressed this coefficient explicitly as

$$\frac{1}{\sqrt{f_D}} = -1.8 \log \left[\frac{6.9}{Re} + \left(\frac{k}{3.7D} \right)^{1.11} \right] \quad (20)$$

in transient regime, the friction factor is expressed by linear interpolation between the limit values of the two regimes.

2.3.2. Darcy friction factor for Non-Newtonian fluids

Hedstrom (1952) introduces the following dimensionless numbers, to express the friction factor for the **laminar** region for Bingham flows $Re_B = \frac{DV\rho}{\mu_B}$, with $He = \frac{\tau_0 D^2 \rho}{\mu_B^2}$ where Re_B the Bingham Reynolds number, and He the Hedstrom number. The laminar Darcy friction factor for Non-Newtonian fluids was first published by Buckingham-Reiner in an implicit formulation. Later this formula was approached by the explicit equation of Swamee and Aggarwal (2011)

$$f_L = \frac{64}{Re_B} + \frac{64}{Re_B} \left(\frac{He}{6.2218 \times Re_B} \right)^{0.958} \quad (21)$$

Darby et al. (1992) proposed the semi-empirical equation presented above to give a friction factor for turbulent flow $f_T = 10^a Re_B^b$, where $a = -1.47(1 + 0.146 \times e^{-2.9 \times 10^{-5} He})$ and $b = -0.193$. Since the transition from laminar to turbulent is not sudden for Bingham slurries. Darby et al. (1992) reviewed the previous work and proposed to combine the laminar and turbulent Darcy friction factors into the following equation, which is valid for all flow regimes

$$f_D = (f_L^m + f_T^m)^{1/m}, \quad (22)$$

where $m = 1.7 + 40000/Re_B$. Within the pipe model, we integrate the friction calculation equations for Newtonian and non-Newtonian fluids into a package called `Wallfriction`. We extend them into the flow model based on the equations Eq. (11) and Eq. (18). The choice of the friction model used is set according to the value of a Boolean parameter set by the user.

3. Results and Discussions

3.1. Comparison with Modelica Dynamic Pipe

In this section, we will compare the results of our model implemented on Modelica, to the classical pipe model available in the Fluid library of the MSL (`Modelica.Fluid.Pipes.DynamicPipe`),

we compare therefore the computation time between both models. Beside the pipe model, we have also developed two models for pressure and mass flow sources. We attached all these components to the FluidPort connector that we developed in this way, to ensure the connections. We gather them all in one new library.

Network description: To validate our model of dynamic pipe flow, we create a network consisting of an upstream mass flow source (1106.5 kg/s), a pipe series, and a downstream pressure source (10 bar) from the two libraries. We take the pipe geometry data from the OCP pipeline design data. We use the Newtonian fluid model considering the carried fluid is water of density $\rho = 995.5 \text{ Kg/m}^3$ and dynamic viscosity of $\mu = 10^{-3} \text{ Pa}\cdot\text{s}$. The models predict the pressure drops and then the pressure at the inlet of the pipe. We calculate and plot the resulting piezometric lines from each case to compare their values.

Results and discussion:

As shown in Fig. 1 and the RMSE column of Table 1, the results given by the new model fit quite closely to those given by the components provided in the Fluid library of the Modelica MSL.

Moreover, by increasing the number of pipes, we notice that the difference between the number of solved equations and the simulation time becomes more significant. With a network of two hundred pipes, the new model is 7 times faster than the MSL model. Which is more favorable in our case of study where we will use a network containing more than 5000 pipes. It is noteworthy to mention that increasing further the maximum number of pipes by two leads to an RMSE almost constant, which indicates that the solution achieves solution convergence.

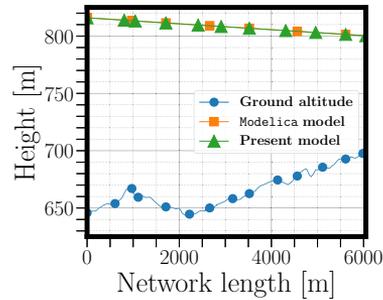

Figure 1: Piezometric lines versus Network length

Pipes Number	Number of equations		Simulation time [s]		RMSE
	MSL Library	New Library	MSL Library	New Library	
10	1277	276	0.0909168	0.0213864	0.0054
100	12437	2706	1.12199	0.083706	0.038
200	24837	5406	2.27997	0.30165	0.082

Table 1: comparison of simulation time and piezometric results between MSL model and the New model

3.2. Simulation of the Non-Newtonian slurry flow

As industrial data, we dispose of the phosphate slurry flow data during a period of 20 minutes along the pipeline. The inlet flow rate as well as the outlet pressure are set by the operator. The fluid density $\rho = 1680.0 \text{ kg/m}^3$. Besides the upstream and the downstream of the network, pressures are captured at 5 points distributed along the pipeline: PMS₁, Valve Station, PMS₂, PMS₃, and PMS₄. We calculate the friction pressure losses from the industrial data set and fit these values in terms of the input velocities to determine the Bingham rheological parameters (μ_B & τ_0) of the transported fluid. We use the `scipy.optimize.curve_fit` function included in the Scipy python library to fit the function ΔP , given by Eq. (19) where we replace the Darcy friction factor f_D by Eq. (22) into industrial data. We obtain a plastic viscosity $\mu_B = 0.012 \text{ Pa}\cdot\text{s}$, and a yield stress of $\tau_0 = 6.1 \text{ Pa}$. Exploiting the fitting parameters, we implement the slurry network between the inlet and PSM₁ with its real geometry, the network consists of 1293 pipes of internal diameter 0.85 m, its longitudinal profile is presented in Fig. 2a. We perform numerical simulations using the inlet

mass flow rates and the PMS_1 pressures from the industrial data set of OCP Slurry Pipeline. We compare the inlet pressures obtained from these simulations with the measured values; see Fig. 2b. The plot of the inlet pressures estimated by our model almost matches the curve of the pressures measured in reality. The mean square error is 218.4, corresponding to a relative mean error of 6%. This error can occur due to different phenomena. The fluid characteristics can be changed during the flow through a long distance. Indeed, it is often noticed at the OCP that the density downstream of the network varies from that of entry. Also, the deposition of the slurry sediment on the inner wall of the pipe can affect the flow. Further, the parameters of Bingham's law that we have used are not derived from a rheological study applied on the slurry mixture conveyed by the pipeline. The total computation time is 3.6 minutes, which is quite satisfying considering the network size considering the network size of 46.43 Km.

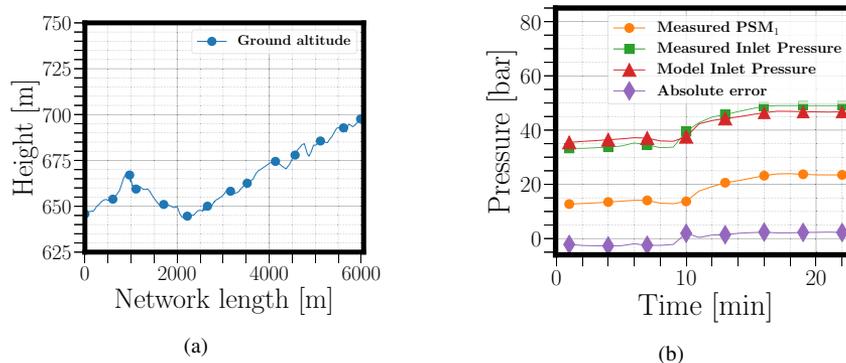

Figure 2: (a) Network altitude versus length and (b) Inlet pressure Comparison

4. Conclusion

The objective of the present work is to build a model able to simulate the flow of phosphate slurry through a pipeline of significant length. The model that has been developed presents a significant gain in computational time compared to the model already available under the Modelica Standard Library, while the flow results are not affected. Using the Bingham parameters from the industrial data fitting, we obtained estimated pipe inlet pressures close to the real values, although a mean relative error of 6% remains. This ongoing work intends to overcome this limitation by taking into account the variation of the fluid characteristics along the network and using more accurate rheology parameters to be obtained from lab measurement.

Acknowledgement: This work was supported by a research fund from OCP group.

Abstract

The need of hydrogen as a clean fuel has grabbed a lot of global attention. Therefore, various processes have been developed for hydrogen production. Conversion of plastic wastes is one of the attractive option to produce H₂ because of its hydrocarbon structure, higher heating value and availability. Polyethylene (PE) and polypropylene (PP) are considered in this study because of their massive worldwide availability in the category of waste plastics. In this study, the simulation of conversion of plastic wastes (PE and PP) to hydrogen fuel via steam gasification process is developed to perform the techno economic analysis. The composition of produced syngas from steam gasification unit was validated with the literature results followed by sensitivity studies to see the impact of various process parameters on the syngas composition. The syngas produced in the steam gasification unit is then treated in the water gas shift units followed by acid gas (H₂S and CO₂) removal to produce pure H₂. To enhance the hydrogen production capacity and overall process efficiency, plastic gasification is further integrated with the steam methane reforming coincided with gasification to utilize the energy from the gasifier to provide heat to the natural gas reformer. It has been seen from results that the new integrated design containing both gasifier and reformer enhances the hydrogen mass production rate per mass feed rate by 5.6%. Furthermore, the process performance analysis showed that the efficiency of the new process is increased up to 1.82%, where the hydrogen production cost showed the reduction of 29% compared to the standalone gasification cases. In terms of carbon dioxide specific emission, the new design showed the reduction in CO₂ emissions by 4.0%. Overall, the technical and economic analysis favored the new design over the standalone plastic gasification case.

Keywords: Gasification; Reforming; Waste Plastic; H₂ production; GHG Emissions.

1. Introduction

Globally from 1950-2018, 6.3 billion tons of plastics produced; only 9% had been recycled, where 12% had been burnt (Okunola A et al., 2019). Incinerating the plastics produces sever harmful pollutants, such as Dioxins, Furans, and Mercury, which are highly hazardous that negatively impact the creatures health, and cause climate changes . An essential, clean fuel can be produced from plastic wastes (i.e. hydrogen fuel) via gasification process. Hydrogen is more efficient than traditional fuel, because it burns easily with zero carbon emissions. Hence, a strategic way to produce hydrogen from non-considered feedstock is to convert biomass, and plastic wastes into hydrogen. A study conducted by (AlNouss et al., 2020), on techno economic evaluation of biomass into

hydrogen. They used the thermal approach in converting the biomass to hydrogen, investigating the effect of the type of feedstock and the gasifier agent. The study demonstrated the dominance of pure steam as a gasification agent than other agent. A study performed by (Chai et al., 2020), on the production of hydrogen from plastic wastes using co-pyrolysis/gasification process. They tested Ni-CaO-C as a novel catalyst to facilitate H₂ production. Their results revealed a high hydrogen production with a composition of 87.7 mole% with a minimal CO₂ production. Therefore, the conversion of plastics into hydrogen is a feasible process proved experimentally and theoretically. Although, the catalytic gasification process is energetically preferable, however, it is more complex and needs more development. Hence, we will perform our work on purely thermal gasification using steam as a gasification agent as it was recommended by (Namioka et al., 2011).

Our constituted objectives are to produce hydrogen with high purity from polyethylene and polypropylene via steam gasification controlling the greenhouse gases. We will design an alternative model that is anticipated to reduce the energy consumption and production cost. Hence, we will execute energy and economic analysis for the two models likewise to precisely compare the two models.

2. Modelling and Simulation

Aspen Plus (V11) had been used to develop the simulation models to produce hydrogen. The Peng Robinson was used as the effective thermodynamic package, where, polyethylene and polypropylene were defined based on proximate and ultimate analysis. To keep the consistent analysis, the RYield, RGibbs and REquil reactor models are used to match the results with the literature and to achieve the required compositions. Table 1 demonstrates the process conditions of the main units. The steam gasification process conditions were according to (Saebea et al., 2020)(Ahmed, 2021)(Khalafalla et al., 2020).

Table 1: Design Assumptions taken for case 1 and case 2

Equipment	Aspen Model	Assumption
Plastic flowrate	RYield	Plastics = 100 kg/h H ₂ O: Plastic = 1.25
Gasifier	RYield, RGibbs reactors	Entrained flow gasifier; temperature = 650 °C and 900 °C respectively; P = 1 atm
Pre-reformer	RStoic (Reactor)	Heavier hydrocarbon hydrocracking
Reformer	RGibbs (Reactor)	Temperature = 894.3 °C, pressure = 1 bar, H ₂ O: NG = 1.6; nickel-based catalyst
Water Gas Shift (WGS)	REquil (Reactor)	Two Equil reactors H ₂ O: Syngas = 1.09 and 0.73 respectively
Acid Gas Removal (AGR)	RadFrac and flash drums	Rectisol process; temperature = - 30 °C, P = 1 bar CO ₂ Removal = 99%; Remaining H ₂ S = 10 ppm

3. Process Description

Two cases had been designed in Aspen Plus (V11). Figure 1 shows the case 1(i.e. base case design), where, plastics were used to produce synthesis gas, and then WGS was modeled to maximize the hydrogen production. Finally, we removed the acid gases (i.e. H₂S and CO₂) in acid gas removal unit (AGR).

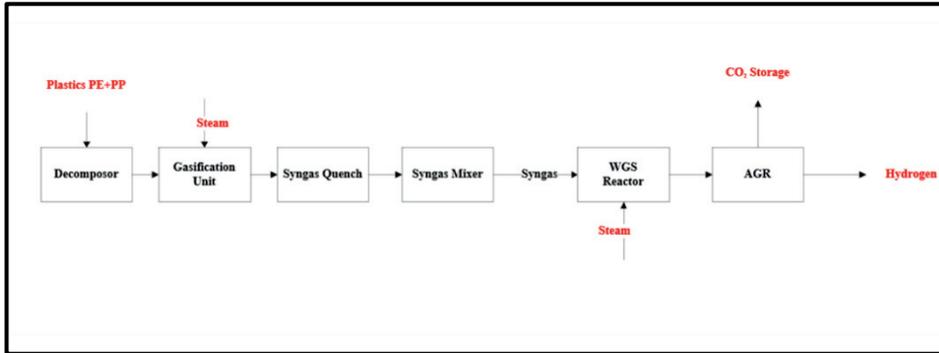

Figure 1: Production of hydrogen from PE and PP through conventional process: Case 1

Case 2 (the integrated design) is given in Figure 2. The SMR produced additional syngas with more hydrogen rich than the plastic gasification. The mixing of syngas from gasification and reforming units will yield higher hydrogen to CO ratio that can enhance the normalized hydrogen production.

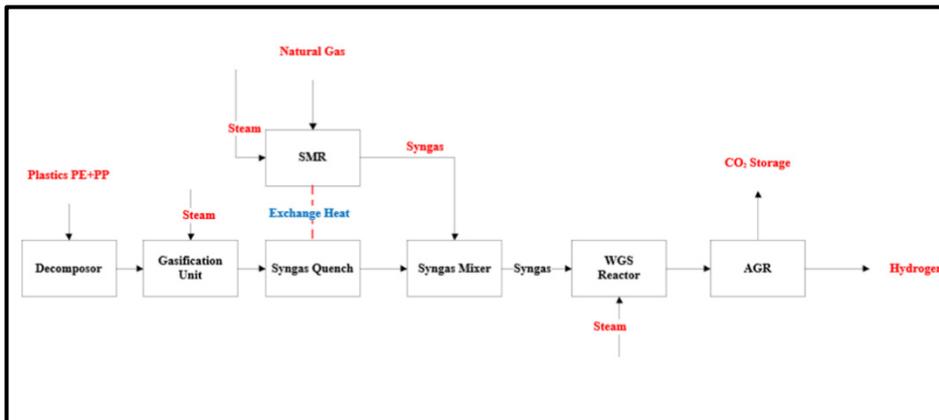

Figure 2: Production of H₂ from PE and PP via an integrated process: Case 2

4. Results and Discussion

The steam gasification results in producing syngas from polyethylene and polypropylene was validated with experimental results (Wu & Williams, 2009) (Erkiaga et al., 2013). Additionally, the SMR syngas composition was validated with (Ghoneim et al., 2016). Our results and the referenced data for syngas composition were in good agreement.

4.1 Syngas Composition at the Outlet of WGS and Overall Production Rates

Case 1 and case 2 results were analyzed in terms of synthesis gas production, heating value, CO₂ specific emissions, energy and economic analysis. The results revealed that, case 2 is superior to case 1 in production syngas with higher heating value. The LHV for case 1 and case 2 were 23.55 and 24.73 MJ/Kg, respectively. On the other hand, the synthesis gas HHV were 26.18 and 27.67 MJ/kg for the two cases correspondingly, which was higher in case 2 compared to case 1 by 5.7%. Additionally, the normalized hydrogen production per feed stock in mass basis was calculated as 50% and 52.8% for case 1 and

case 2, respectively. The integrated case showed higher production rate than the base case by 2.8%.

4.2 Process performance analysis

The overall process efficiency for both cases is calculated using the equation (Eq 1).

$$\text{Process Efficiency} = \frac{\text{H}_2 \text{ thermal energy [MWth]}}{\text{Feed stock thermal energy [MWth] + Energy consumed [MWth]}} \times 100\% \quad (1)$$

The feed stock energy for case 1 included only waste plastics (i.e. PE and PP), however, for case 2 it was combined feed of natural gas and plastics. The feedstock thermal energy for the two cases were 1198.61, and 1757.07 kW respectively. The total consumed energy in the whole design was calculated and deduced to be 3162.28 and 4641.99 kW respectively. Hence, the process efficiency was found to be 31.32% and 31.90% respectively. Figure 3 represents the overall process efficiency and hydrogen to carbon monoxide ratio. It was found that, the H₂/CO ratio was 1.86 and 2.2 for case 1 and case 2 respectively. Those results revealed the superiority of the integrated case than the base case. We also considered the CO₂ specific emissions for the two models which were 0.26 and 0.257. Hence, the carbon dioxide emissions was reduced in case 2 by 1.2%.

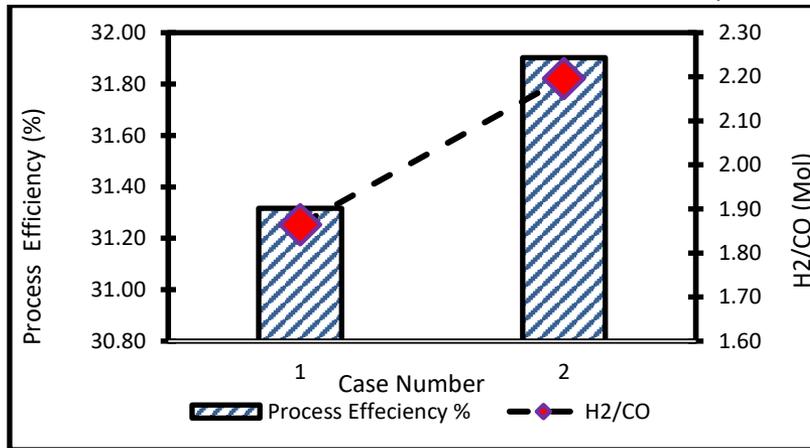

Figure 3: Process efficiency and H₂/CO ratio for case 1 and case 2

5. Economic Analysis and Project Feasibility

The economic analysis was performed for the two cases evaluating the capital expenditures and operating expenditures. The CAPEX mainly encompasses the equipment cost, piping and installation costs, civil work, instrumentation etc. On the other hand, the operating expenditures includes the utilities, maintenance, catalyst replacement, administration, and labor costs. The calculation for CAPEX was based on process costs from previous studies considering the capacity and CEPCI index. The value of x is taken as 0.6 in the Equation 2, where the current CEPCI is taken as 620.

$$\text{Cost}_{\text{New}} = \text{Cost}_{\text{Old}} \times \left(\frac{\text{Capacity}_{\text{New}}}{\text{Capacity}_{\text{Old}}} \right)^x \times \frac{\text{CEPCI}_{\text{New}}}{\text{CEPCI}_{\text{Old}}} \quad (2)$$

For the comparative analysis, the equation 2 is well used in the literature as it can predict the class 3-4 type economic analysis. The economic analysis results revealed that, the total investment cost for case 1 and case 2 in terms M€ were 3.795 and 4.457 respectively. Case 2 required higher investment cost because it involved the SMR process. However,

the total investment cost per hydrogen production in tons (TIC) were 76.53 and 59.25 M€/ton correspondingly. Case 2 reduced the TIC with respect to case 1 by 22.6%. We additionally, calculated the total OPEX per year, and found that, case 2 consumed higher operating expenditures than case 1 by 79.3 in €(10³) / year. However, the operating expenditures per hydrogen production rate for case was lower than case 1 by 32.35%. The normalized hydrogen production rate; which represents the conversion of feed stocks to produce H₂, was higher in case 1 which is attributed in reducing the total OPEX per hydrogen ton. Table 2 displays the main cost analysis parameters for case 1 and case 2.

Table 2: Economic Analysis

	Units	Case 1	Case2
Total Investment Cost	€(10 ³)	3795	4457
TIC per ton of H₂	M€/ton	76.53	59.25
Total OPEX/Year	€(10 ³) / Year	1390.0	1469.3
Total OPEX/ton H₂	€(10 ³) / ton	3.4	2.3
Revenue	M€/year	4.804	7.289
Hydrogen Cost	€/kg	3.675	2.585

The two cases were also evaluated in terms of cash flow diagram. The cash flow revealed that, case 2 is superior to case 1 and the profit is higher. The cash flow return on investment was higher in the integrated case than the conventional case by 52%. Additionally, NPV (the net present value) was larger than the base case by 78%, where PVR (the present value ratio) was higher by 45% compared to the base design. Therefore, the economic analysis proved that, case 2 is much feasible than case 1. It reduced the production cost and it is a promising design to produce hydrogen fuel from waste plastics.

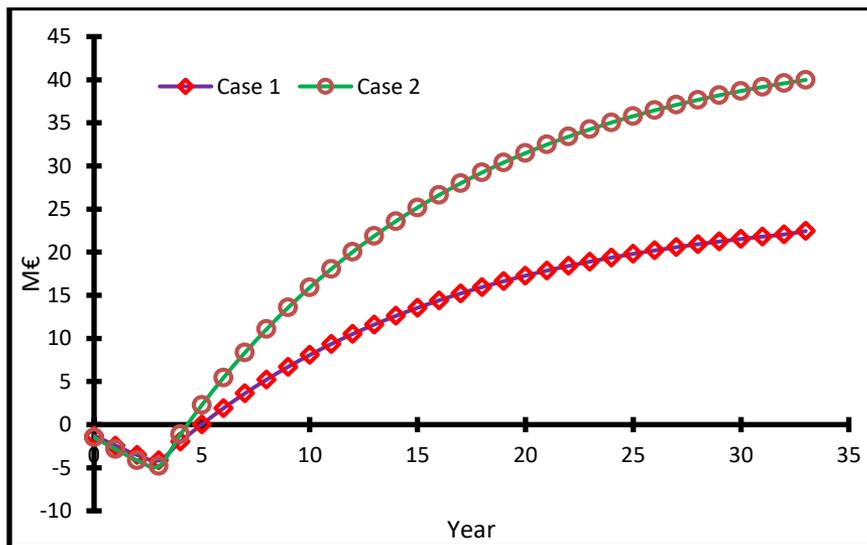

Figure 4: The cash flow diagram for case 1 and case 2

Conclusions

The modeling of production of H₂ from plastic wastes (polyethylene and polypropylene) has been done by developing two models. The energy and economic analysis for the two models conducted. The normalized hydrogen production per feedstock for case 2 was higher than case 1 by 5.6%. Additionally, the heating value, process efficiency, and H₂/CO ratio at the inlet of WGS reactors were estimated. It has been analyzed that case 2 outperformed the case 1 in all the technical and economic evaluations. Moreover, the comparison in terms of CO₂ specific emissions has been conducted, and the results revealed an emission reduction by 1.0%. Additionally economic analysis revealed that the alternative case (2) has lower TIC and fuel production cost per kg of H₂ produced compared to the case 1 by 23%, and 30% respectively. Overall, case 2 showed more promising results than case 1, and it may be experimentally tested in future.

Evaluating the flexible operation of vacuum-pressure swing adsorption for CO₂ capture from modern gas turbines

Mathew Dennis Wilkes ^a, Solomon Brown ^{a*}.

^a*Department of Chemical and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, United Kingdom, s.f.brown@sheffield.ac.uk*

Abstract

Flexible post-combustion capture (PCC) of CO₂ is crucial for reaching net-zero emissions targets. Within this paper, a process model for CO₂ capture via vacuum-pressure swing adsorption (VPSA) is developed, validated, and scaled to process flue gas from a small-scale modern gas turbine. The realistic load-following ‘Flexible’ scenario shows small differences in CO₂ recovery rate, purity, and specific energy demand, compared to the ‘Baseline’ scenario. This highlights VPSA is a suitable technology for Flexible- PCC.

Keywords: CO₂ Adsorption, VPSA, PCC, Flexible Operation, Dynamic Modelling

1. Introduction

Electricity systems require balancing capacity to ensure security of supply and counter-act imbalances due to intermittent renewables and inflexible nuclear (Rai, et al., 2022). Open-cycle gas turbines (OCGT) are quick-response dispatchable generators, that are expected to increase in capacity between 2020-2050 (Heuberger & Mac Dowell, 2018). Therefore, OCGTs that incorporate Carbon Capture, Utilization, and Storage (CCUS) may play a vital role in achieving net-zero by 2050.

Dispatchable power generation by nature is highly transient, and any post-combustion capture (PCC) technology will also need to operate flexibly. The majority of Flexible-PCC revolves around the benchmark MEA CO₂ capture (Wilkes, et al., 2021a). However, adsorption technologies are attractive due to high CO₂ recovery rates and purity, as well as lower specific energy demands compared to MEA (Ben-Mansour, et al., 2016).

1.1. Aims and Objectives

In this study we show how CO₂ can be captured through vacuum-pressure swing adsorption (VPSA) in order to clean highly transient gas turbine exhaust. This study does not investigate the optimized design of the VPSA CO₂ capture system. The aim of this paper is, instead, to highlight the effects transient flue gas production has on the process’s key performance indicators. The OCGT assumed flue gas flowrate is based on our previous paper (Wilkes, et al., 2021a). Hence, within this flexible-VPSA study:

- A process model for VPSA is developed in gPROMS Process.
- Model validation is carried out against pilot-scale data.
- The process model scaled to handle exhaust flow from a small OCGT.
- Baseline and Flexible results are shown for a typical 5-hour OCGT operation.

This study only considers the operation of the capture plant, and not the design of the gas turbine or the CO₂ conditioning system. For information on the effect of transient operation on the conditioning system see (Wilkes, et al., 2021b).

2. Adsorption modelling

Carbon capture by adsorption (CCA) is an inherently dynamic process considered as being in cyclic steady state. Each adsorption column requires a set of partial differential and algebraic equations (PDAEs) to calculate the quantity of CO₂ adsorbed, whilst considering the conservation of mass, energy, and momentum (Kikkinides, et al., 2010). Li et al. (2018) provides an extensive review of CCA modelling. Within this study the following assumptions are made to model Flexible-VPSA:

- One-dimensional axially dispersed plug flow regime.
- No radial variation in temperature, pressure, or concentration.
- Mass transfer described through the linear driving force model.
- Adsorption amount described through the dual-site Langmuir isotherm model.
- Pressure drop along the column is calculated through the Ergun equation.
- Thermal-equilibrium heat transfer model.
- Power demand for the pumps is described in (Nikolaidis, et al., 2017).

As there are multiple CO₂ capture technologies and various sorbents for CCA, it is important to quantify certain key performance indicators (KPI) to enable comparison to alternative processes. Important KPI's for CCA technologies that are commonly used in the literature include CO₂ recovery rate (η), specific energy demand (E_T), and productivity (P_r), calculated using Equation 1, 2, and 3, respectively.

$$\eta [\%] = \frac{M_{CO_2}^{in} - M_{CO_2}^{out}}{M_{CO_2}^{in}} \times 100 \quad 1$$

$$E_T [kWh/tCO_2] = \frac{\text{Total Energy Demand [kWh]}}{M_{CO_2}^{in} - M_{CO_2}^{out} [\text{ton}]} \quad 2$$

$$P_r [tCO_2/m^3 \text{ Adsorbent/day}] = \frac{M_{CO_2}^{in} - M_{CO_2}^{out} [\text{ton}]}{V_A [m^3] \times t_c [s] \times 3600} \quad 3$$

Where M_{CO_2} is the mass of CO₂ either entering (superscript 'in') or exiting (superscript 'out') the process. The total energy demand is the sum of the power supplied to each of the blowers and vacuum pumps divided by the total amount of CO₂ captured. The productivity is the quantity of CO₂ captured by the adsorbent during a given time frame, where V_A is the volume of adsorbent and t_c is the total cycle operating time.

2.1. Model validation

Pilot-scale results from Krishnamurthy et al. (2014) are used to highlight the fidelity of the VPSA process model. The pilot experiment investigated CO₂/N₂ VPSA using Zeolite 13X in a single adsorption column. The Skarstrom style four-step cycle includes: pressurization using the flue gas feed, adsorption of CO₂ onto Zeolite 13x, forward blowdown to de-pressurize the column, and reverse evacuation to desorb and recover CO₂. The step timings and pressure levels are highlighted in Figure 1. The inlet feed flowrate was 1000 SLPM and contained 85 mol.% N₂ and 15 mol.% CO₂. The column geometries, particle characteristics, isotherm data and heat transfer parameters can be found in (Krishnamurthy, et al., 2014) and (Haghpahan, et al., 2013).

The KPI's for the pilot experiment and simulation results are shown in Table 1. The simulation showed almost identical column pressure increase and flowrate profiles (not shown in this paper) compared to the pilot results. As the model is pressure driven, the

accuracy of the pressure profile is important in calculating the quantity of CO₂ adsorbed. The simulation's recovery rate (84.30%) is within the error of the pilot results (85.40% ± 4.52). The purity (89.56%) is lower than expected (94.70% ± 1.05). It can be manipulated by the evacuation valve flow coefficient, but this is a set input parameter that cannot be altered specifically during the evacuation step. The lower purity also leads to an increased specific energy demand, as less CO₂ is captured during the operation. Overall, the model is in good agreement with pilot results and the isotherm model accurately predicted the amount of CO₂ adsorbed onto the zeolite surface.

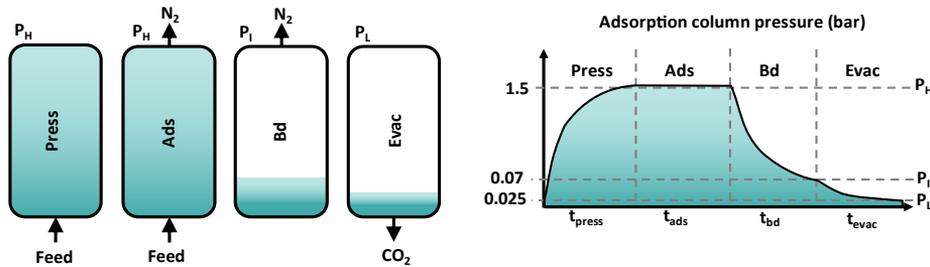

Figure 1: Single column VPSA operation, step notation: "Press" is pressurization to 1.5 bar, "Ads" is adsorption at 1.5 bar, "Bd" is blowdown to 0.07 bar, and "Evac" is evacuation to 0.025 bar (Krishnamurthy, et al., 2014).

Table 1: Key performance indicators for the single column VPSA model and pilot experiment

KPI	Pilot	Simulation	Deviation (%)
η (%)	85.40 ± 4.52	84.30	- 1.29
Purity (%)	94.70 ± 1.05	89.56	- 5.14
E_T (kWh/tCO ₂)	510.50 ± 25.5	569.68	+ 11.70
P_r (tCO ₂ /m ³ ads/day)	1.40 ± 0.07	1.18	- 15.00

2.2. Scaled-VPSA design

The single column model is scaled up to handle the flue gas flow from a small 10.4 MWe open-cycle gas turbine (OCGT). The flexible OCGT operation is described and analyzed in our previous study (Wilkes, et al., 2021a). The scaled system design is based on (Luberti, et al., 2017), where the flue gas source (FGS) is split (FGS1 and FGS2) and processed in two parallel VPSA units, to handle the large flue gas flowrate. The model assumes the flue gas is cooled and treated prior to CO₂ capture. Each VPSA unit consists of two beds operating simultaneously for continuous flue gas processing. Table 2 shows the adsorption steps and timings used in the scaled-VPSA process model.

Table 2: Scaled-VPSA adsorption steps and timings

Step	Time (Sec)	Pressure (bar)
Pressurization	80	1.5
Adsorption	220	1.5
Blowdown	80	0.07
Evacuation	220	0.025

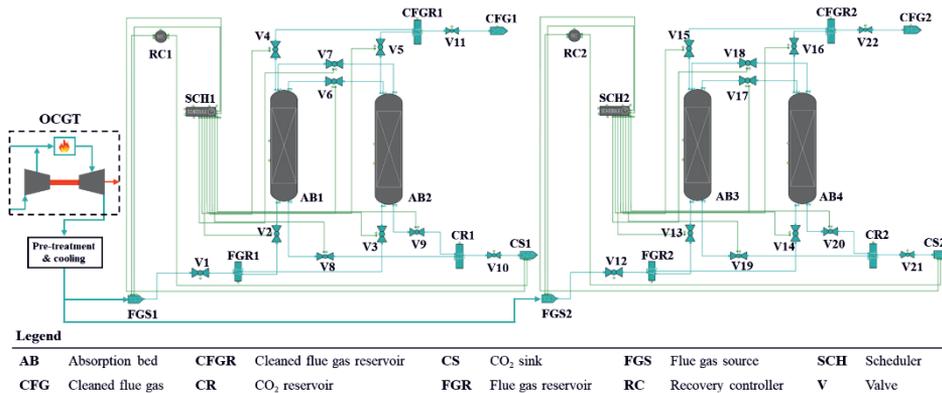

Figure 2: Scaled-VPSA model topology and legend, including cycle steps and durations.

3. Results and discussion

For the Baseline and Flexible scenarios, the flue gas input (FGS1 and FGS2) into each identical VPSA unit is 16.9 kg/s, shown in Figure 3A and Figure 3B. As the total cycle time is 600 seconds and the total operating period is 5 hours (18,000 seconds), the operation requires 30 complete cycles. During the Flexible scenario the start-up and shutdown operations are included, extending the operating period from 18,000 to 18,480 seconds. Also included in the Flexible scenario is ramping to different OCGT power outputs. At 3,600 seconds the flue gas ramps to 70% load. At 10,800 seconds the flue gas ramps to 50% load. This assumes the flue gas and power output are directly proportional. The flowrate profiles for the CFG and CS streams are similar to the pilot results shown in (Krishnamurthy, et al., 2014), where there is an initial spike in flowrate due to the pressure draw, which then equalizes during each operating step. When one bed is pressurizing and adsorbing, the other bed is evacuating N₂ and CO₂ to allow for continuous operation. Due to computational limitations the simulations cannot calculate adsorption characteristics with zero flow. Therefore, during the start-up operation in the Flexible scenario the FGS1 and FGS2 flowrates ramp from 0.9 to 16.9 kg/s in 8 minutes (480 seconds), the inverse occurs during the shutdown operation.

The adsorption bed pressure profiles (see Figure 4A and Figure 4B) also exhibit similar results as the pilot study. During the low-load points in the Flexible scenario, as less flow enters the columns, the bed pressure does not increase to the level shown in the Baseline scenario. As the process is pressure driven, the lower bed pressure should affect the quantity of CO₂ adsorbed. However, the decrease in recovery rate between the Flexible and Baseline scenario (see Table 3) is only 0.04%. It is worth noting that, the scaled-VPSA Baseline recovery rate is 97.07% and 13.66% higher than the pilot study. This increase in efficiency is related to the adsorption step timings, column sizing, valve operation and parameter scaling. This study does not focus on optimized process scaling, the aim is to assess the performance under transient flue gas conditions.

At low load periods (70% and 50%) the blower and vacuum pumps require less energy (processing less fluid), however, the quantity of CO₂ captured is smaller. Therefore, during the Flexible scenario the specific energy demand is 1274.04 kWh/tCO₂, 6.91% higher than the Baseline scenario at 1191.72 kWh/tCO₂. A possible solution is modifying the adsorption step timings and pressure levels specifically during low load operation, to minimize fluctuations in specific energy demand.

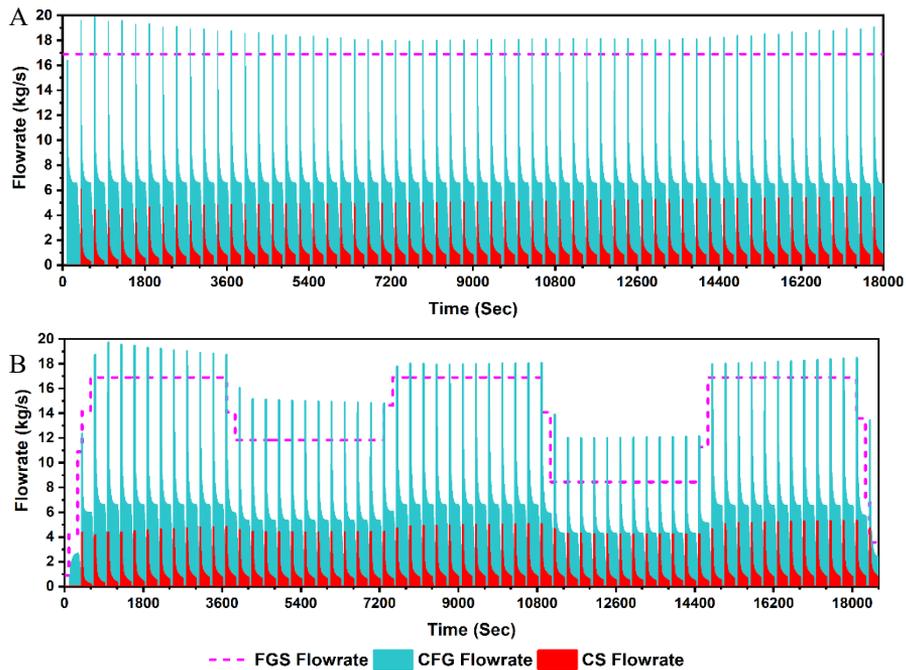

Figure 3: Flue gas source (FGS), cleaned flue gas (CFG) and CO₂ sink (CS) flowrate profiles during the Baseline (A) and Flexible (B) scenarios. for one of the parallel VPSA units.

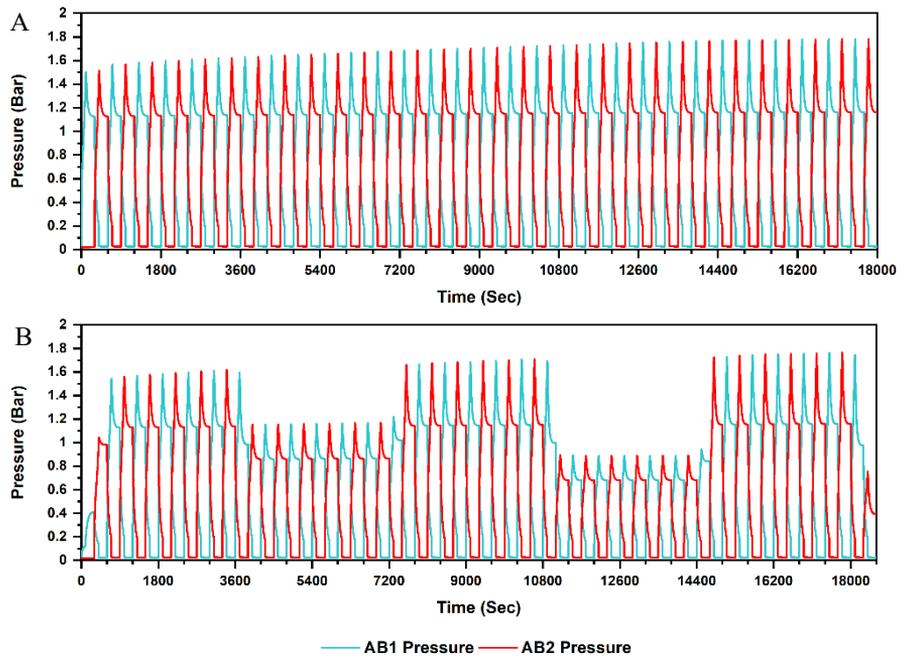

Figure 4: Column pressure for AB1 and AB2 during the Baseline (A) and Flexible (B) scenarios.

Table 3: Scaled-VPSA key performance indicators

KPI	Baseline	Deviation ^a (%)	Flexible	Deviation ^b (%)
η (%)	97.07	+13.66	97.03	-0.04
Purity (%)	80.74	-14.74	79.54	-1.49
E_T (kWh/tCO ₂)	1191.72	+133.67	1274.04	+6.91
P_r (tCO ₂ /m ³ ads/day)	1.28	-9.02	1.07	-15.85

^a deviation between the baseline and pilot results, ^b deviation between Baseline and Flexible scaled-VPSA scenarios

4. Conclusion

To attain net-zero by 2050, small-scale dispatchable gas power generation will require CCUS. Current research in Flexible-PCC revolves around amine-based CO₂ capture. This study considered VPSA as an alternative CO₂ capture technology for modern and highly transient OCGT's. The process model is found to have a high fidelity, with the validation study showing the predicted capture rate is within the error bounds stated in the pilot results. During Flexible-VPSA, the recovery rate and purity deviate <2% compared to the Baseline (no change in flue gas) scenario. The specific energy demand increased during periods at 70% and 50% load (+6.91% overall), as less CO₂ is captured during the total operation. This is lower than Flexible-PCC using MEA (+18.53%) shown in our previous work (Wilkes, et al., 2021a), highlighting VPSA is a viable alternative technology for Flexible-PCC.

Abstract

In our preliminary study (Sidek and Othman, 2020), vapour recompression (VRC) proved to have a promising energy performance in the case of palm kernel oil (PKO) fatty acid fractionation. This paper extends the research by applying an exergy analysis as well as incorporating four vacuum fractionation columns to represent a real industry application. The study also included a two-step optimization approach based on response surface methodology. All configurations were evaluated for their exergetic and economic performances. Due to the high costs and low efficiency, the optimised VRC-assisted columns are not in favour of this study. The standard VRC-assisted columns, though exhibit a higher CAPEX than the conventional columns, are more thermodynamically efficient and demonstrate a substantial reduction of 84-88% in OPEX. A thorough optimisation study is needed for future works.

Keywords: vapour recompression, fatty acid fractionation, optimization, exergy.

1. Introduction

Since the pandemic, the oleochemical industry has witnessed greater product demand due to increased hygiene needs. Specific measures must be implemented to ensure a continuous supply of oleochemical products to consumers. The industry's primary separation units are distillation columns, which are used to separate oleochemical cuts. In practice, distillation columns are well-known as major energy consumers. In recent years, research on heat pump-assisted distillation has recently piqued the interest of many academics to reduce the associated energy consumption. However, no research has been devoted to heat pumping in oleochemical distillation. Besides, the majority of established oleochemical refineries in Malaysia still employ mature distillation technologies. In light of these circumstances, oleochemical distillation appears to be a prime focus for improvement. In a prior study, we discovered that vapour recompression (VRC), a popular heat pump scheme, showed promising energy performance in the case of palm kernel oil (PKO) fatty acid fractionation (Sidek and Othman, 2020). The research, although attempting to move towards a more sustainable approach, is still preliminary. The reason is that to facilitate convergence, only one fractionation column was considered to evaluate the feasibility of VRC. In an industrial operation, the PKO fatty acid fractionation involves four operational columns, which include a pre-fractionator for recovering C8-C10 products, a light-cut column for recovering C12, a middle-cut column

for separating C14 as a top product, and a still column for heavy-cut separation (C16-C18) (Othman and Rangaiah, 2020). Another aspect that is yet unknown from the study is the effect of thermodynamic conditions on the simulated VRC-assisted column. Using an exergy analysis, Mangili (2020) presented that a VRC-assisted pressure swing column for di-*n*-propyl-ether and *n*-propanol processes has outperformed another direct heat-integrated column in terms of exergetic efficiency. Intriguingly, a comprehensive study of a VRC-assisted vacuum membrane distillation for sulfuric acid waste treatment by Si et al. (2020) has shown a very low exergetic efficiency of only about 4%. Since the thermodynamic performance of each VRC-assisted column varies depending on the process and operating conditions, a thermodynamic analysis is, therefore, essential to evaluate how much of recovered heat is transformed into useable work. In this paper, the study continues to analyse all operational columns, exactly replicating the industrial operation, from the standpoints of exergetic and economic performance. All process simulations were carried out in Aspen PLUS V12.0 using UNIQUAC thermodynamic model, as recommended by Sidek and Othman (2019) for PKO fatty acid. In Design Expert, the simulated columns were optimised using the response surface methodology.

2. Methodology

2.1. Process Simulation

The PKO fatty acid compositions were adopted from a Malaysian industrial oleochemical refinery, as shown in Othman and Rangaiah (2020). Unlike our previous studies (Sidek and Othman, 2020), this one utilised four (4) major units of fractionation column at a high vacuum pressure to represent the actual process. A process with a crude PKO fatty acid feed flow rate of 9167 kg/h was operated at 80 mbar in a pre-fractionator (V5001), 25 mbar in a light-cut column (V5002), 13 mbar in a middle-cut column (V5003), and 10 mbar in a heavy-cut column (V5004). To avoid chemical degradation, the vacuum application helped to regulate vapour pressure and ensure the working temperature was between 180 and 250 °C. To ensure a fair comparison, a VRC-assisted column configuration was simulated based on the same column conditions and desired product specifications as the CCs. The VRC-assisted column works by compressing the top vapour stream to make it hotter than the reboiler. The elevated vapour temperature allows the utilisation of recovered latent heat for bottom liquid reboiling (Parhi et al., 2019). To achieve that, the vapour stream was first superheated before being introduced into a compressor to avoid partial condensation. A maximum practical compression ratio was taken to be 3.0. The compressed vapour will heat exchange with the bottom liquid stream through a heat exchanger. A minimum temperature approach was kept between 5-10 °C.

2.2. Process Optimisation

In this study, the experimental design based on response surface methodology (RSM) was carried out, which included two-level factorial analysis (TLFA) and central composite design (CCD). RSM develops both statistical and mathematical models to provide adequate predictions of a defined response. Prior to running the TLFA, the variables were first obtained from a sensitivity analysis in Aspen PLUS. For the optimisation part, CCD was primarily chosen to allow the estimation of all regression variables that were required to fit a second-order model to the response. An adequacy test for the developed model was observed in the analysis of variance (ANOVA), whereby the *p*-value must be less than 0.05 and the adequate precision value must be larger than 4. Meanwhile, for chemical processes, the *R*² value must be larger than 0.9. The soundness of the model was determined through a surface contour plot. The optimal conditions must be validated in Aspen Plus to assure convergence.

2.3. Exergy Analysis

Exergy analysis measures how much valuable energy is being neglected in a certain system. A more detailed explanation of exergy computation in the distillation column has been demonstrated by Nguyen and Demirel (2010). According to them, the exergy difference between the product and the feed stream indicates the minimum isothermal separation work which corresponds to Eq. (1).

$$\dot{E}_{x,min} = \sum_{out} \dot{n}e_x - \sum_{in} \dot{n}e_x \quad Eq. (1)$$

where \dot{n} is the mole flow and e_x is the specific exergy of the streams. An exergy loss, $\dot{E}_{x,loss}$, or irreversibility can be computed from Eq. (2).

$$\dot{E}_{x,loss} = \sum_{in} \left(\dot{n}S + \frac{Q_{sink}}{T_{sink}} \right) - \sum_{out} \left(\dot{n}S + \frac{Q_{source}}{T_{source}} \right) \quad Eq. (2)$$

Here, S represents the entropy of a stream and Q is the heat involved with the process. Meanwhile, the conversion of the supplied heat into separation work can be calculated by a thermodynamic efficiency, η using Eq. (3).

$$\eta = \frac{E_{x,min}}{E_{x,loss} + E_{x,min}} \quad Eq. (3)$$

2.4. Economic evaluation

The economic performance of the VRC-assisted columns was evaluated using capital expenses (CAPEX) and operational expenses (OPEX). The plant was assumed to be in operation for approximately 10 years, with 8,000 hours of operation per year. The electricity tariff for the industry was \$0.084/kWh, high-pressure (HP) steam was \$17/t and cooling water was \$0.06/t (Parhi et al., 2019).

3. Results and Discussions

3.1. VRC-assisted fractionation columns

A schematic representation of the proposed VRC-assisted fractionation process for PKO fatty acid is depicted in Fig. 1. In the studied configuration, two columns namely V5002 and V5003 were determined to be the ideal candidates for integration with the VRC system. The V5001 and V5004 were unable to deliver at least 10% of heat duty for the evaporation of the bottom liquid streams even when a maximum practicable compression ratio (CR) of 3.0 was used in a two-stage compression. The proposed VRC system for both V5002 and V5003 exhibits two compression stages to a) comply with the maximum CR, b) fulfil the reboiler's entire heat requirement and c) ensure the outlet temperature is

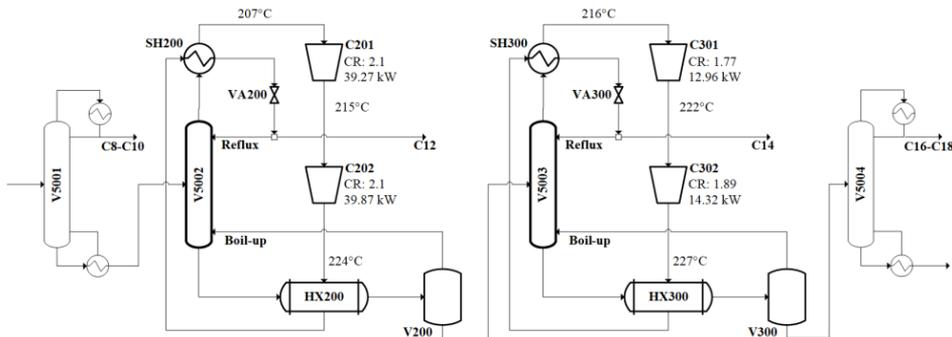

Fig. 1. VRC-assisted fractionation process for PKO fatty acid

sufficiently high for heat exchange. The overhead vapour stream of V5002 was superheated prior to being fed into the first compressor, C201. This procedure is crucial not only for preventing liquid rupture in the compressors but also for avoiding the use of higher CRs. Condensation of the C202 outlet vapour stream was accomplished by transferring heat to the heat exchanger, HX200. In contrast to our earlier work, the compressed vapour of the V5002 column effectively delivered the necessary heat to evaporate the bottom liquid stream, obviating the need for a trim reboiler. Furthermore, the resulting condensate from HX200 was used to superheat the overhead vapour in the SH200, thus, no auxiliary heating was required in this column. Following that, the stream was pressure reduced by the throttle valve, VA200, to the column operating pressure and separated into reflux and distillate sections. Meanwhile, the bottom liquid was routed to the flash drum, V200, whereby the vapour was returned to the column as a boil-up and the liquid was introduced to the V5003. The identical VRC configuration was simulated in the V5003, except that the two compressors, C301 and C302, had lower CRs and hence performed less mechanical work.

3.2. Optimisation using sensitivity analysis and RSM

Although the compressed overhead vapour could satisfy the heating requirements of the V5002 and V5003, there were some deviations in the heat exchanger's minimum temperature approach, ΔT_{\min} . Technically, a small ΔT_{\min} requires a larger heat exchanger to transfer heat. In the sensitivity analysis, the superheated temperature, CR, and exchanger duty were identified as the key factors in the VRC performance. These factors were then investigated as independent variables for their impacts on the ΔT_{\min} in RSM optimisation alongside mechanical compression work. A 2^4 fractional factorial design with 16 runs was used to analyse all variables. However, only 12 of the 16 proposed runs showed convergence in the simulation. This resulted in a slight effect in the interaction prediction between the variables. The results for the V5002 and V5003 optimisations agree with all of the TLFA outputs necessary to demonstrate that the models were a good fit and significant. One solution for optimal conditions from the TLFA was selected for the centre points in the CCD. The two most contributing factors, namely superheated temperature and second stage CR, were used, while other variables were held fixed. Fig. 2a and Fig. 2b illustrate the 3D surface contour plots for the V5002 and V5003.

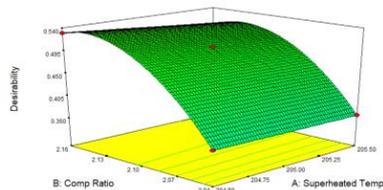

Fig. 2a. 3D surface plot for V5002

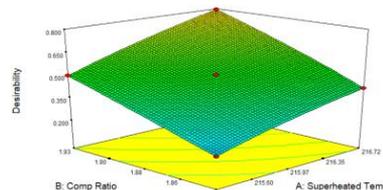

Fig. 2b. 3D surface plot for V5003

The form of the plot for V5002 shows some curvature, suggesting that the factors had a quadratic effect on the ΔT_{\min} , thus the optimum conditions could be determined from the model. The V5003 plot has a relatively flat surface but is still acceptable. For the V5002, the proposed optimal points are the superheated temperature of 204.5 °C, first stage CR of 2.29, second stage CR of 2.14 and exchanger duty of 690 kW. Whereas, the proposed optimal points for the V5003 are the superheated temperature of 216.72 °C, first stage CR of 2.10, second stage CR of 1.93 and exchanger duty of 340 kW.

3.3. Energy and exergy performances

The V5002 and V5003 utility requirements, as well as the findings of the exergy analysis of conventional columns, VRC-assisted columns, and optimised VRC-assisted columns,

are summarised in Table 1. The table clearly indicates that the CC's energy requirements were excessive in contrast to the VRC-assisted columns.

Table 1. Summary of utility requirements and exergy analysis.

Configuration	CC		VRC		Optimised-VRC	
	V5002	V5003	V5002	V5003	V5002	V5003
Cold utility (kW)	924.87	413.53				
Hot utility (kW)	766.58	378.31			76.58	38.31
Mech. work (kW)			79.14	27.27	84.20	31.66
Total (kW)	1691.45	791.84	79.14	27.27	160.78	69.97
Compression ratio 1			2.10	1.89	2.29	2.10
Compression ratio 2			2.10	1.77	2.14	1.93
Thermodynamic efficiency (%)	78.55	97.66	93.93	98.34	92.90	97.01

The VRC needed no cooling since the vapour condensed during heat exchange with the bottom liquid and in the superheater. Moreover, the compressed vapour successfully fulfilled the reboiler's total heating requirement. Because the optimized-VRC assisted columns were largely focused on the heat exchanger's ΔT_{\min} , nearly 10% of external heating was necessary. The exchanger sizes were reduced at the expense of the overall energy required. This is also seen by the higher compression ratios of the optimised VRC columns. As mentioned before, only 12 TLFA proposed runs were converged, which consequently affected the optimisation results. In view of this, the variables selection, defined ranges and response objectives should be comprehensively reassessed in order to generate more sensible findings. Meanwhile, the exergy analysis shows that the VRC-assisted V5002 and V5003 columns were more thermodynamically efficient. Remarkably, the VRC-assisted V5002 column outperforms the CC by around 20%. This indicates that more heat was converted into usable work. On the other hand, the optimised-VRC columns were somewhat less effective than the original VRC columns for V5002, and surprisingly, the optimised-VRC V5003 column has an even lower thermodynamic efficiency than the CC.

3.4. Economic evaluations

Table 2 summarises the economic evaluation results for conventional columns, VRC-assisted columns, and optimized VRC-assisted columns. The Aspen Process Economic Analyzer was used to compute the CAPEX and OPEX. As opposed to the CC, both the VRC and optimized-VRC systems show greater CAPEX. This is to be anticipated since the VRC system for the studied process needs two stages of compression, despite the removal of the CC's condenser and reboiler. However, as the data shows, the optimised VRC columns exhibit a higher CAPEX than the ordinary VRC-assisted columns. While the cost of the exchanger has been greatly lowered, the V5002's first compressor cost has risen by 11% after the optimisation. Meanwhile, the average 15% increment of compressor costs was seen in V5003. The additional trim reboilers has also impacted the overall CAPEX for the optimised-VRC columns. Attention must be paid to the VRC's excellent performance in OPEX, whereby the only source of energy needed is electricity to drive the compressors. As can be seen in the table, approximately 84% and 88% of energy savings can be achieved by integrating the V5002 and V5003 columns, respectively, with the VRC system. Taking a wider perspective, there is a good chance that over the course of ten years of the VRC-assisted column operation for the fractionation of PKO fatty acid, plant revenues may be boosted by the amount saved on utility usage.

Table 2. Summary of CAPEX and OPEX.

Configuration	CC		VRC		Optimised-VRC	
	V5002	V5003	V5002	V5003	V5002	V5003
CAPEX (x10⁵ \$)						
Column tower	2.616	2.367	2.616	2.367	2.616	2.367
Column condenser	0.113	0.096				
Column reboiler	0.397	0.255				
Superheater			0.107	0.111	0.096	0.106
Heat exchanger			0.313	0.300	0.236	0.179
Compressor 1			0.523	0.191	0.581	0.221
Compressor 2			0.530	0.172	0.539	0.199
Flash drum			0.334	0.324	0.334	0.324
Trim reboiler					0.097	0.094
Total	3.126	2.718	4.423	3.465	4.500	3.491
OPEX (x10⁵ \$/y)						
Electricity			0.583	0.200	0.620	0.233
High-pressure steam	2.637	1.301			0.263	0.132
Cooling water	0.924	0.413				
Total	3.561	1.714	0.583	0.200	0.883	0.365

4. Conclusions

The present study was designed to investigate the exergetic performance of the VRC-assisted columns to fractionate out PKO fatty acid cuts in four operating columns. The optimized version of the VRC configurations showed a less promising performance than the ordinary one. Without a doubt, despite increased CAPEX at the start of the business, a considerable rise in profitability might be realised in the coming years. Although, a comprehensive optimisation is to be done for future works for more sensible data. Despite the PKO fatty acid feed's limited flexibility and familiarity, the positive results from this research serve as a baseline for future environmentally friendly and cost-effective oleochemical separation processes.

Abstract

Shallow bubble column reactors are gas-liquid reactors which are intensively used in chemical industries because of their simple design and efficiency. They are characterized by a low height-to-diameter ratio when compared to traditional columns. In such equipment, the bubble size distribution is an important design parameter that defines the interfacial area which plays an important role in designing and scaling-up these reactors. In this contribution a new reduced population balance model is developed based on OPOSPM (One Primary One Secondary Particle Method) framework to predict the coupled bubble hydrodynamics and mass transfer in shallow bubble column reactors. The model is composed of four transport equations where two of which are used to describe the total number and volume bubble concentrations and the other two transport equations are devoted for chemical species balances. Other consecutive equations are used to model the bubble relative velocity, breakage, coalescence, interphase mass transfer, and reconstruction of bubble probability density. The model capability to predict the experimental data for the coupled hydrodynamics and mass transfer in the shallow bubble column reactor of Lau et al. (2012) is successfully demonstrated. In conclusion, the model is simple and still efficient for modelling such reactors with the essential phenomena from the detailed population balance equation (PBE) is captured.

Keywords: OPOSPM, Population balance, Bubble columns, Mass transfer.

1. Introduction

Bubble column reactors are widely used in the chemical, petrochemical and biochemical industries (Jakobsen, 2008). The design of these columns is characterized by a high L/D (height-to-diameter) ratio which is required to allow the bubble hydrodynamics to approach a fully developed state. On the contrary, shallow bubble columns are characterized by a low L/D ratio to make use of the high gas holdup due to small size population of bubbles produced above the distributor. This is required to estimate the specific interfacial area to provide a closure for the momentum and mass transport equations which are solved for each phase (Jakobsen, 2008). However, with limited available experimental studies on shallow bubble columns (Lau et al., 2012), the design and scale up of this equipment is still dependent on pilot scale experiments. As an approach for modelling of the bubble column reactors, the mixture model does not take into account the instantaneous discrete events of bubble breakup and coalescence. On the

other hand, multi-fluid models which include bubble-bubble interactions are expensive from computational point of view if detailed column geometry is needed. Along these lines, the emergence of the reduced population balance models as fast solvers of the PBE have gained considerable interest in reflecting the discrete flow and accommodate particle-particle interactions (Wu et al., 1998, Drumm et al., 2010, Shonibare and Wardle, 2015, Attarakih and Bart, 2020, Santis et al., 2021). In this regard, Wu et al. (1998) derived the interfacial area transport equation from the particle number density transport equation followed by the derivation of bubble breakage and coalescence kernels which were improved by Ishii and Hibiki (2011). Drumm et al. (2010) introduced the coupled OPOSPM-CFD as a reduced population balance model, which is derived from the discrete PBE based on the Sectional Quadrature Method Of Moments (SQMOM) (Attarakih et al., 2009). Shonibare and Wardle (2015) used OPOSPM for the numerical investigation of vertical plunging jet using a hybrid multifluid CFD Solver which is implemented in OpenFoam version 2.2.1. Santis et al. (2021) used OPOSPM in the GEneralized Multifluid Modelling Approach (GEMMA) which is used by the well-known open-source CFD code OpenFOAM version 7.0. This modelling technique based on reduced population balances presents a valuable tool for understanding the hydrodynamics of annular centrifugal contactors. Motivated by these findings, we used the OPOSPM framework to model the coupled hydrodynamics and mass transfer of the bubbly flow in shallow bubble column reactors as a building block for detailed CFD models.

2. Coupled bubble hydrodynamics and mass transfer using OPOSPM

The model for the coupled bubble hydrodynamics and mass transfer is derived from the PBE. This equation transports the number concentration function in space-time coordinates and the particle property space through the number concentration function $f(z,d,t)$ where z is the special domain, d and t are bubble size and time respectively. This function is assumed continuous, satisfies regulatory conditions and describes the number concentration of bubbles. In this work we used the reduced population balance model based on the OPOSPM framework to describes the coupled hydrodynamics and mass transfer which is given by:

$$\frac{\partial(N)}{\partial t} + \nabla \cdot (N \langle \langle v_g \rangle \rangle) = S_B - S_C + N^{in} \delta(z - z^{in}) \quad (1)$$

where N is the total bubble concentration, $\langle \langle v_g \rangle \rangle$ is the mean bubble velocity, S_B and S_C are the instantaneous rate of change of bubble number concentration due to bubble breakup and coalescence respectively which are described by the consecutive equations of Hibiki and Ishii (2000) in terms of mean bubble diameter (d).

$$S_B = C_b \frac{\varepsilon^{1/3} (1 - \alpha)}{d^{2/3} (\alpha_{max} - \alpha)} \exp \left(-K_b \frac{\sigma}{\rho_f d^{5/3} \varepsilon^{2/3}} \right) N \quad (2)$$

$$S_C = \frac{C_2 d^{7/3} \varepsilon^{1/3}}{(\alpha_{max} - \alpha)} \exp \left(-K \sqrt[6]{\frac{d^5 \rho_L^3 \varepsilon^2}{\sigma^3}} \right) N^2 \quad (3)$$

The values of the constants in Eqs. (2) and (3) have the same values that were given by Hibiki and Ishi (2000): $C_b = 0.0037$, $C_2 = 0.0014$, $K_b = 1.37$, $K = 1.29$ and $\alpha_{max} = 0.52$.

The source terms are function of the physiochemical properties, gas phase holdup, mean bubble diameter and energy dissipation. The transport of the gas phase holdup (α_G) presents the second OPOSPM transport equation which is given by:

$$\frac{\partial(\alpha_G \rho_G)}{\partial t} + \frac{\partial(\alpha_G \rho_G \langle \langle v_g \rangle \rangle)}{\partial z} = -k_L a \left(\frac{C_G}{H} - C_L \right) M_G + \rho_G^{in} U_G^{in} \delta(z - z^{in}) \quad (4)$$

where C refers to oxygen concentration, H is the dimensionless Henry's constant, $k_L a$ is the volumetric liquid phase mass transfer coefficient and M_G is the solute (oxygen) molecular weight. The energy dissipation ε (m^2/s^3) is calculated using the correlations given by WU et al. (1998). Similarly, the solute transport equation in the gas phase reads

$$\frac{\partial(C_G \alpha_G)}{\partial t} + \frac{\partial(C_G \alpha_G \langle \langle v_g \rangle \rangle)}{\partial z} = -k_L a \left(\frac{C_G}{H} - C_L \right) + C_G^{in} U_G^{in} \delta(z - z^{in}) \quad (5)$$

while the solute transport equation in the liquid phase is given by:

$$\frac{\partial(C_L \alpha_L)}{\partial t} + \frac{\partial(C_L \alpha_L \langle v_L \rangle)}{\partial z} = +k_L a \left(\frac{C_G}{H} - C_L \right) + C_L^{in} U_L^{in} \delta(z - z^{in}) \quad (6)$$

where the subscript L refers to the liquid phase and the mean gas velocity is given by:

$$\langle \langle v_g \rangle \rangle = \langle v_L \rangle / (1 - \alpha_G) + v_{gr} \quad (7)$$

In the above equation the relative bubble velocity is calculated from the equation:

$$v_{gr} = \sqrt{g d_{30} \Delta \rho / (3 C_D \rho_L)} \quad (8)$$

where C_D is the drag coefficient which is function of the mixture Reynolds number (Wu et al., 1998) and d_{30} is the bubble mean volume diameter which couples the bubble number and volume concentrations:

$$d_{30} = \sqrt[3]{\frac{6 \alpha_G}{\pi N}} \quad (9)$$

In the OPOSPM framework, two low-order moments are conserved (α_G, N), and the secondary particle position (d_{30}) represents a Lagrangian fluid particle carrying information about the mean bubble size of the whole population through its low-order moments. On the other hand, the interfacial area concentration is calculated from an algebraic model based on the ratio between gas holdup and the bubble Sauter mean diameter:

$$a = \frac{6 \alpha_G}{d_{32}} \quad (10)$$

The Sauter mean diameter is related to the mean volume diameter (d_{30}) by the empirical relation $d_{30} = (0.75 - 0.80) d_{32}$ as recommended by Shonibare and Wardle (2015) and Santis et al. (2021). As the full bubble size distribution is concerned, the OPOSPM-Weibull distribution, as a least biased probability number density estimator, can be used as derived and explained in our previous work (Attarakih and Bart, 2020).

3. Numerical solution

The model equations (1-9) represent a set of hyperbolic conservation laws which requires special attention during space-time discretization phase (Attarakih et al., 2013). This

system can be casted for a given spatial cell of index j and width Δz using the first order upwind scheme as follows:

$$\left(\frac{dU}{dt}\right)_j + \frac{1}{\Delta z}(F_j - F_{j-1}) = S_j, \quad j = 1, 2, 3 \dots n \quad (11)$$

where $U = [N \ \alpha_G \rho_G \ C_G \alpha_G \ C_L \alpha_L]^T$, $F = U \bullet [\langle v_g \rangle \ \langle v_g \rangle \ \langle v_g \rangle \ \langle v_L \rangle]^T$ are the conserved variables and numerical flux vectors respectively and S is the source term of Eqs. (1-6). For the time discretization, the MATLAB ODE23 solver is used with the built-in default settings. The relative velocity which is given by Eq.(8) is solved iteratively and found to converge with 5 to 10 iterations. By assuming the liquid phase is stagnant and perfectly mixed and there are negligible changes in the oxygen concentration in the rising bubbles, Eq.(6) simplifies into an ODE which has an analytical solution (Lau et al., 2012).

4. Results and discussion

In this section, the numerical results from solving the semi-discrete OPOSPM model (Eqs.11) are compared to the experimental data of Lau's et al. (2012) measured in a pilot scale shallow bubble column reactor of 14 cm diameter.

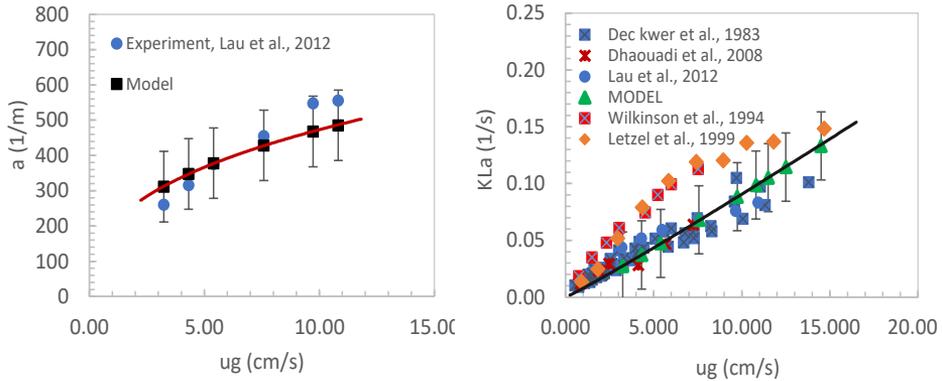

Figure (1): Predicted steady state mean interfacial area concentration and volumetric mass transfer coefficient as compared to published experimental data at $L/D = 7.2$.

The column is equipped with a perforated plate distributor having 211 orifices that are 3 mm in diameter and configured in triangular pitch. Tap water is used as a stagnant phase, while air is used at 1.0 bar and 25 °C as the gas phase and the gas velocity is varied from 3.2 to 10.8 cm/s. The number of spatial cells (n) is set to 25 with further increase is found to have no effect on the numerical results. The initial conditions for the gas phase are set to small positive numbers close to the square root of the machine epsilon since the stagnant water phase is purged by nitrogen before presetting the air flow. In Lau's et al. (2012) experiment, the steady state gas holdup and the interfacial area were measured, while in the mass transfer experiments, the dynamic oxygen concentration at $L/D = 7.2$ of the column height is measured using an optical fiber oxygen probe. In addition to this, the mass volumetric mass transfer coefficient is calculated from the measured data. In our present model, the inlet mean bubble diameter (d_{32}) is calculated using Wilkinson et al. (1994) correlation based on perforated gas distributor and corrected such that $d_{30} = (0.8)d_{32}$ as recommended by Shonibare and Wardle (2015) and Santis et al. (2021). The inlet area concentration is calculated from Hikita correlation, while the liquid side mass

transfer coefficient is calculated by the correlation of Akita and Yoshida which are reported in Shah et al. (1982). Note that the liquid side mass transfer coefficient is independent of the (u_g) which is consistent with the experiments of Lau et al. (2012).

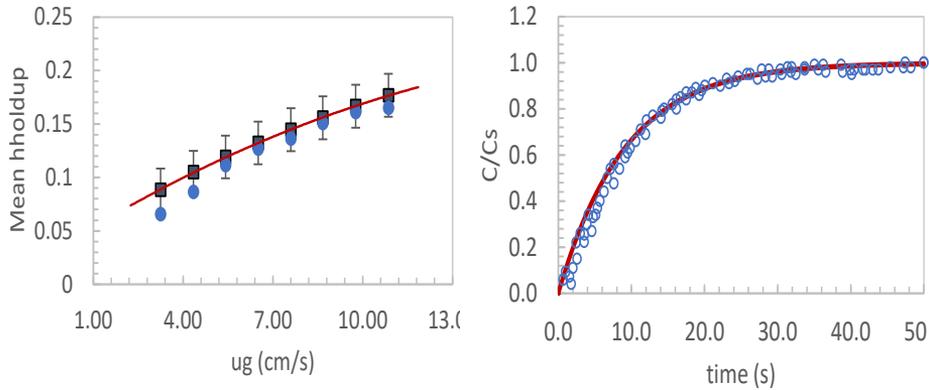

Figure (2): Steady state mean gas holdup at $L/D = 7.2$ and the dynamic evolution of the oxygen concentration in a stagnant tap water column with filled and open circles are the Lau's et al. (2012) experimental data.

The bubble column hydrodynamics coupled with mass transfer is simulated using the present OPOSPM model. A sample of results is shown in Fig.(1) which compares the predicted mean interfacial area concentration as function of the superficial gas velocity (u_g) to the experimental data of Lau et al. (2012) in a shallow bubble column. The model equations were integrated with respect to time until steady state is achieved at 50 s. As can be noticed, the interfacial area concentration increases due to the shear-induced bubble breakup at the nozzle as u_g increases. We used ± 100 (m^{-1}) as fixed bandwidth for the error bar which covers the experimental fluctuations around the predicted values, where rigorous parameter estimation with confidence intervals is beyond the scope of this work. On the right hand side of Fig.(1) is the predicted liquid side volumetric mass transfer coefficient as compared to the published experimental data including those of Lau et al. (2012) with error bandwidth ± 0.03 (s^{-1}). According to Lau et al. (2012), the large dispersion in the measured data is due to different designs of gas distributors, presence of impurities and the sensitivity of mass transfer to system temperature. Nonetheless, the model predicts most of the experimental data except those of Letzel et al. (1999) where slight under predictions is present in the gas velocity middle range (5 - 13 cm/s). On the left hand side of Fig.(2) is the predicted mean gas holdup (filled square) as compared to the experimental data of Lau et al. (2012) with error bandwidth equals to ± 0.02 . Compared to the interfacial area predictions (Fig.(1), Left), the error bandwidth is narrower which may be attributed to the higher measurement accuracy of the gas holdup compared to the interfacial area. By assuming that the liquid phase is perfectly mixed, Eq.(6) can be reduced to a first-order ODE and is solved at $L/D = 7.2$, while the gas phase is modelled as plug flow from the gas distributor. In Fig.(2, right), the dynamic evolution of oxygen absorption in the stagnant water phase is compared to model prediction. It is obvious that the most accurate result of the model is that of mass transfer profile despite the complex coupling with the uncertainties induced by the bubble hydrodynamics. While bubble breakup and coalescence are calibrated based on the work of Hibiki and Ishii (2000), we did not adjust any model or correlation parameters to improve the model prediction. Therefore, we believe that building a database on experimental data and

calibrating individual population balance sub-models, will certainly improve and widen the window of model predictions.

5. Summary and conclusions

In this work, we used the OPOSPM framework as a reduced population balance model to derive the transport equations of coupled hydrodynamics and mass transfer in shallow bubble columns. The model consists of four transport equations with sub-population balance models and consecutive relations. No further sub-model calibration is used other than that in the published literature for those of breakup and coalescence for bubbly flow in vertical tubes. The predicted results by the present model are compared to the published experimental data with good and high accuracy for bubble hydrodynamics and mass transfer respectively. The 1D semidiscrete hyperbolic system is solved using MATLAB ODE23 solver with CPU time as fraction of second. We believe that the relative simplicity of the model offers the bubble column designers one-, two- and three-dimensional models that can be implemented in complex CFD codes.

Abstract

The present paper deals with the development of a model of gypsum crystallization during the production of phosphoric acid. The objective is to predict the kinetics of formation of products and consumption of reagents, as well as the time-varying crystal size distribution. The population balance model involving primary and secondary nucleation and crystal growth rates is thus investigated using the method of moments, along with the Pitzer thermodynamic model. Both models involve unknown parameters to be identified from experimental data. Two databases are therefore used, (i) the first one which consists of equilibrium measurements is used to identify the unknown parameters of the Pitzer model, (ii) and the second one which contains temporal profiles of supersaturation ratio, is used to determine the nucleation and growth unknown parameters. The identified parameters are then used to compare the predictions of the developed models with the experimental measurements. The results are very promising, and the models can be used in the design and optimization of gypsum crystallization processes.

Keywords: Crystallization, Population balance model, Pitzer model, Method of the moments.

1. Introduction

In the phosphate industry, phosphoric acid is a major component in the manufacture of fertilizers. It is mainly produced by the digestion of phosphate ore by a concentrated sulfuric acid solution. The products are phosphoric acid and solid gypsum, which are separated in a vacuum filtration unit downstream of the digestion tank (Becker, 1983). The optimization of the process performance is very challenging and aims mainly to: (i) extract the maximum amount of phosphate from the ore during the digestion, (ii) crystallize gypsum with optimum filterability and washing characteristics, (iii) and produce the most concentrated and purest phosphoric acid possible, at a lower cost and with little impact on the environment. In this work, we focus mainly on the modeling of the crystallization of gypsum which strongly influences the quality of the produced phosphoric acid, and the performance of the units downstream of the process, namely, the filtration units.

The objective of this paper is to develop a crystallization model based on the population balance equations (PBEs) along with the Pitzer thermodynamic model (Pitzer, 2018). The latter enables to predict the supersaturation ratio which is involved in the driving force of the crystallization process.

The Pitzer model is first calibrated using equilibrium measurements, and the unknown parameters of the PBEs are identified from the kinetic measurements. The PBEs are then solved using the method of moments.

2. Modeling framework

2.1. Population balance model

For a population of crystals whose size distribution evolves over time, the population balance allows to express its number density function (n) as a function of time (t) and of a characteristic size (x). Assuming that the crystallization is carried out in an isothermal perfectly mixed batch reactor with a volume of 50 cm^3 , and that the growth rate of crystals is size independent, the PBE writes (Hanhoun et al., 2013):

$$\frac{\partial n(t, x)}{\partial t} = -G(t) \frac{\partial n(t, x)}{\partial x} + R_N(t) \delta(x - x_0) \quad (1)$$

where R_N is the sum of primary and secondary nucleation rates, G is the crystal growth rate, and δ is the Dirac function. The nucleation and crystal growth rates are defined by (Hanhoun et al., 2013; Zhu et al. 2016):

$$R_N(t) = A \times \exp\left(\frac{-B}{\ln S(t)^2}\right) + k_s \times [\ln S(t)]^s \times \mu_3(t) \quad (2)$$

$$G(t) = k_g [\ln S(t)]^g \quad (3)$$

where A, B, k_s, s, k_g and g are unknown parameters to be identified from experiments, S is the supersaturation ratio which depends mainly on the speciation of the reacting medium, and μ_3 is the third order moment of the number density function (n).

2.2. Method of moments

The method of moments is a model reduction technique used mainly to solve the population balance equation. It transforms the partial differential equation (1) into a dynamic system of ordinary differential equations (ODEs) with unknowns independent of the spatial variable (x). It is based on the calculation of the k^{th} -order moment μ_k which is defined as follows:

$$\mu_k(t) = \int_0^{\infty} x^k n(t, x) dx \quad (4)$$

Multiplying Eq. (1) by x^k and integrating from zero to infinity, the following system of ODEs is obtained:

$$\frac{d\mu_0(t)}{dt} = R_N(t) \quad (5)$$

$$\frac{d\mu_k(t)}{dt} = k G(t) \mu_{k-1}(t), \quad k \geq 1 \quad (6)$$

$$\mu_k(0) = \int_0^{\infty} x^k n_0(x) dx \quad (7)$$

where n_0 is the crystal size distribution (CSD) at $t=0$.

2.3. Mass balance equations and supersaturation ratio

In this work, we assume that gypsum crystals are formed as a result of direct attack of pure tricalcium phosphate with a concentrated sulfuric acid solution according to the following reaction:

The use of the third moment of the CSD allows to calculate the amount of gypsum produced as follows (Hanhoun et al., 2013; Zhu et al., 2016):

$$C_{\Delta\text{gyp}}(t) = \frac{k_v \rho_s}{M_c} (\mu_3(t) - \mu_3(0)) \quad (9)$$

where k_v is a volume shape factor, ρ_s is the density and M_c is the molecular weight of the formed crystals, respectively. The material balance in the batch reactor can be written as:

$$C_i(t) = C_i^0 + v_i C_{\Delta\text{gyp}}(t) \quad (10)$$

where C_i^0 and v_i are the initial concentration and the stoichiometry coefficient of the component i involved in the reaction (8), respectively. The resolution of the material balance allows then to calculate the supersaturation ratio expressed as:

$$S = \left(\frac{a_c a^2 + a_{\text{SO}_4^2} - a_w^2}{K_{sp}} \right); a_i = m_i \cdot \gamma_i \quad (11)$$

where a_i, γ_i, m_i denote the activity, the activity coefficient, and the molality of the component i , respectively, K_{sp} is the solubility product of gypsum. The activity coefficients are predicted using the following Pitzer model:

$$\ln(\gamma_i) = \frac{z_i^2}{2} f + 2 \sum_j m_j \lambda_{i,j}(I) + z_i^2 \sum_j m_j m_k \lambda'_{j,k}(I) + 3 \sum_{j,k} m_i m_j m_k \psi_{i,j,k} \quad (12)$$

where z_i are the charges of component i , f is the Debye-Huckel function, I is the ionic strength, $\lambda_{i,j}$ and $\psi_{i,j,k}$ represent the short-distance binary and ternary interaction parameters, respectively. Their values are to be identified from experimental equilibrium measurements.

The resulting crystallization model equations (2-3, 5-7, 9-12) are implemented and solved within MATLAB environment.

3. Experimental measurements

Several experimental measurements are carried out in our laboratory. They mainly consist of equilibrium measurements, namely the speciation of sulfuric and phosphoric acids, for a wide range of temperature and concentration conditions. In addition, measurement data of gypsum solubility and water activity are collected from the literature (Bouchkira et al. 2021d). They are used for the identification of the unknown parameters of the Pitzer model. Moreover, experimental measurements of the kinetics of gypsum crystallization during the production of phosphoric acid are taken from the literature (Zhu et al., 2015). They consist of supersaturation ratio of gypsum and are used to identify the kinetic parameters of the PBE.

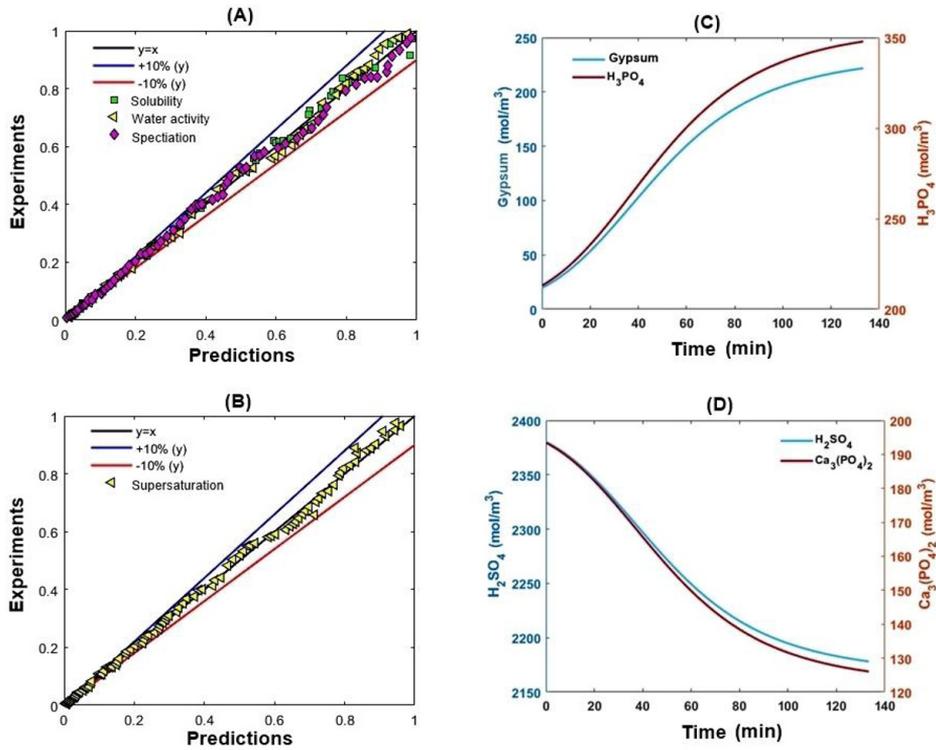

Figure 1: Modeling results. (A): Parity diagram for the identification of the Pitzer unknown parameters. (B): Parity diagram for the identification of the PBE unknown parameters from the supersaturation data. (C): Gypsum and phosphoric acid production profiles. (D): Tricalcium phosphate and sulfuric acid consumption profiles.

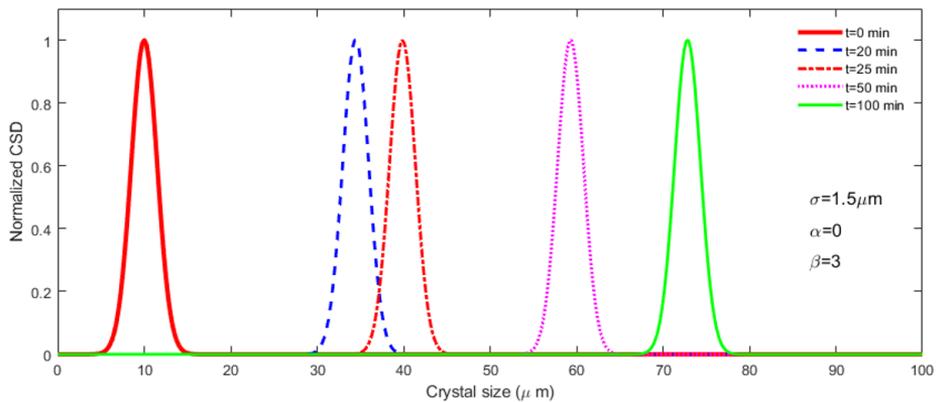

Figure 2: Normalized CSD at different times.

Table 1: Variations of the average size of gypsum crystals with time.

Time (min)	0	20	25	50	100
\bar{x} (μm)	10	34.46	39.87	59.31	72.84

4. Results and discussions

Equilibrium measurements (i.e., gypsum solubility, water activity and speciation) are used to determine the optimal values of the unknown parameters of the Pitzer model, i.e., $\lambda_{i,j}$ and $\psi_{i,j,k}$. Indeed, the optimization of these parameters has been widely investigated in our recent works (Bouchkira et al., 2021a, b, c, d, e). The comparison of the predictions of the identified Pitzer model with the experimental measurements (Fig.1(A)) shows a very good agreement. On the other hand, the data on supersaturation ratio are used to determine the unknown parameters of the PBE, i.e., A, B, k_s, s, K_g and g . The optimal values of these parameters are then used to compare the model predictions with the experiments. It can be seen that the model predictions are very accurate. It is noteworthy that the estimability of the unknown parameters from the available data was carried out using an estimability analysis method based on global sensitivities (Bouchkira et al., 2021c). The most estimable thermodynamic parameters were identified by means of a branch-and-bound method (Sahinidis, 1996) using the Neos server (Czyzyk et al., 1998) hosted by machines at Arizona State University, whereas the kinetic parameters were identified based on a derivative-free method using a Dell Precision T7810 Bi-Xeon 12x Core 64 GB workstation.

Fig.1(C) shows the predictions of phosphoric acid and gypsum production, and Fig.1(D) presents those of sulfuric acid and tricalcium phosphate consumption. The results are coherent since the amounts of phosphoric acid and gypsum increase over time as the reaction proceeds, while those of sulfuric acid and tricalcium phosphate decrease. Furthermore, as expected, Table 1 shows that the average size of gypsum crystals increases with time, meaning that the growth of the particles formed by nucleation takes place uniformly in the reactor. On the other hand, the parameters of the CSDs are computed using different centred moments of order k ($\mu_k^*(t) = \mu_k(t) - \mu_k(0)$) at different crystallization times. Thus, the standard deviation is deduced from the centred moment of order 2 as $\sigma = \sqrt{\mu_2^*} = 1.5 \mu\text{m}$, the skewness is computed using the centred moment of order 3 as $\alpha = \mu_3^*/\mu_2^{3/2*} = 0$, and the kurtosis is calculated from the centred moment of order 4 as $\beta = \mu_4^*/\mu_2^{2*} = 3$. It is worth noticing that the values of these parameters do not change over time and the last two values are typical of a normal distribution. Moreover, since the initial CSD is assumed to be normal, and only nucleation and growth kinetics are involved in the reactor, the parameters σ, α and β remain unchanged as illustrated in Fig.2.

The developed model shows that it is able to predict relevant variables to the design, optimization and control of gypsum crystallization processes. Moreover, it can be used to determine the optimal operating conditions that allow to extract the maximum amount of phosphate from the ore, and to better monetize the gypsum.

5. Conclusions

In this work, we considered the modeling of gypsum crystallization that occurs during the production of phosphoric acid. A PBE is developed and solved by means of the method of moments. The required gypsum supersaturation ratio and the activity coefficients of the components involved in the process are estimated by means of the Pitzer model. Although the results obtained are interesting and promising, the crystallization model developed is a one-dimensional model and does not allow to account for the influence of impurities present in the phosphate ore. It is a very important issue since the impurities have a strong influence on the type and shape of gypsum crystals and therefore on the performance of the digestion tank and of the units downstream. Further work will deal with a multi-dimensional PBE in order to quantify the effects of impurities on gypsum crystal growth.

Abstract

Whole-body physiologically-based pharmacokinetic (PBPK) models are complex mathematical models that consist of a large number of compartments and describe the anatomical structure of the organism. We present the development of a whole-body PBPK model for high-dose methotrexate by expanding a previously developed minimal PBPK model. We increase the number of body compartments described and introduce an *a priori* description of the fluid volumes, blood flows, and capillary exchanges in each tissue and organ, which do not increase the complexity and dimensionality of the identification procedure. The model is identified and validated with an experimental dataset and produces detailed simulations of concentration within the plasma, ISF, and ICF of each modeled tissue and organ. The original modeling approach demonstrated can be a reference for the development of other whole-body PBPK models.

Keywords: Pharmacokinetics, PBPK, Whole-body, Methotrexate, HDMTX.

1. Introduction

Pharmacokinetic (PK) models describe the relationship between the dose administered to an individual and the resulting concentrations inside various body compartments. Several forms of PK models have been described, with profound differences in terms of structure, complexity, and effort required for the model development and application. PK models usually employ compartments (*i.e.* a defined volume within which concentration is assumed to be homogeneous) as their building blocks. Physiologically-based pharmacokinetic (PBPK) models are a class of compartmental PK models whose compartments are based on the anatomical structure of the organism (Nestorov, 2003).

Whole-body PBPK models generally consist of a large number of compartments, representing the fluid volumes within several organs and tissues, and emulate the actual human anatomy and physiology. Each compartment is usually described by a differential equation representing the drug material balance. The equations feature drug-specific parameters that characterize the interactions and the physicochemical properties of the specific compound and system-specific parameters that describe physiological processes and human anatomy. While many parameters can be estimated and assigned *a priori* (*e.g.*, drug-specific parameters that have been experimentally measured, or physiological

parameters that have been estimated in previous studies), there is usually a significant number of parameters that cannot be assigned *a priori*.

These adaptive parameters are fitted through a nonlinear regression procedure by minimizing the distance (described by a suitable objective function) between model simulations and experimental concentration-time profiles. This approach may lead to numerical and identifiability issues. In this context, minimal PBPK models lump together similar compartments, thus reducing the complexity of the model and the identification procedure, while retaining their physiological foundations (Cao & Jusko, 2012).

We present the development of a whole-body PBPK model for high-dose methotrexate (HDMTX, an intravenously administered antitumor drug), that expands a previously developed minimal PBPK model (Pesenti et al., 2021a) by increasing the number of described body compartments representing different organs and tissues. The additional parameters introduced to expand the previous model are assigned *a priori*, by combining a detailed characterization of anatomical fluid volumes, physiological blood flows, and a comprehensive description of the capillary exchange in each tissue.

2. Methods

The structure of the whole-body PBPK model is shown in Figure 1. The model describes 14 tissues and organs and employs for each one a dedicated compartment for the plasma, interstitial fluid (ISF), and intracellular fluid (ICF). Four additional plasma compartments (*i.e.* large veins, large arteries, left and right heart chambers) represent the general blood circulation that connects all the plasma compartments.

For each i -th tissue and organ, we estimate the weight using a recently developed repository of equations (Stader et al., 2019), and compute the overall volume (V_{tot}) with the specific tissue density (Valentin, 2002). The ISF and ICF volumes (V_{ISF} and V_{ICF}) are evaluated as fractions of V_{tot} (Schmitt, 2008), whereas the estimation of plasma volumes (V_p) follows the approach presented in Pesenti et al. (2021b), based on the blood amount within each tissue (Valentin, 2002) and the patient's hematocrit.

Mathematically, the whole-body PBPK model describes each compartment with an ordinary differential equation, representing the drug material balance. While each material balance depends on the specific flows and connections that involve a compartment, consistently with Fig. 1, the following equations present the formulation of these balances in plasma, ISF, and ICF, for a representative tissue (*e.g.*, adipose tissue, brain, muscle).

$$V_{p,i} \frac{dc_{p,i}}{dt} = Q_{p,i} c_{p,large\ arteries} - Q_{p,i} c_{p,i} - k_{p \rightarrow ISF} A_{cap,i} c_{p,i}^u + k_{ISF \rightarrow p} A_{cap,i} c_{ISF,i}^u \quad (1)$$

$$V_{ISF,i} \frac{dc_{ISF,i}}{dt} = k_{p \rightarrow ISF} A_{cap,i} c_{p,i}^u - k_{ISF \rightarrow p} A_{cap,i} c_{ISF,i}^u + \\ - k_{ISF \rightarrow ICF} K_{50}^u \frac{c_{ISF,i}^u}{K_{50}^u + c_{ISF,i}^u} V_{ICF,i} + k_{ICF \rightarrow ISF} K_{50}^u \frac{c_{ICF,i}^u}{K_{50}^u + c_{ICF,i}^u} V_{ICF,i} \quad (2)$$

$$V_{ICF,i} \frac{dc_{ICF,i}}{dt} = k_{ISF \rightarrow ICF} K_{50}^u \frac{c_{ISF,i}^u}{K_{50}^u + c_{ISF,i}^u} V_{ICF,i} - k_{ICF \rightarrow ISF} K_{50}^u \frac{c_{ICF,i}^u}{K_{50}^u + c_{ICF,i}^u} V_{ICF,i} \quad (3)$$

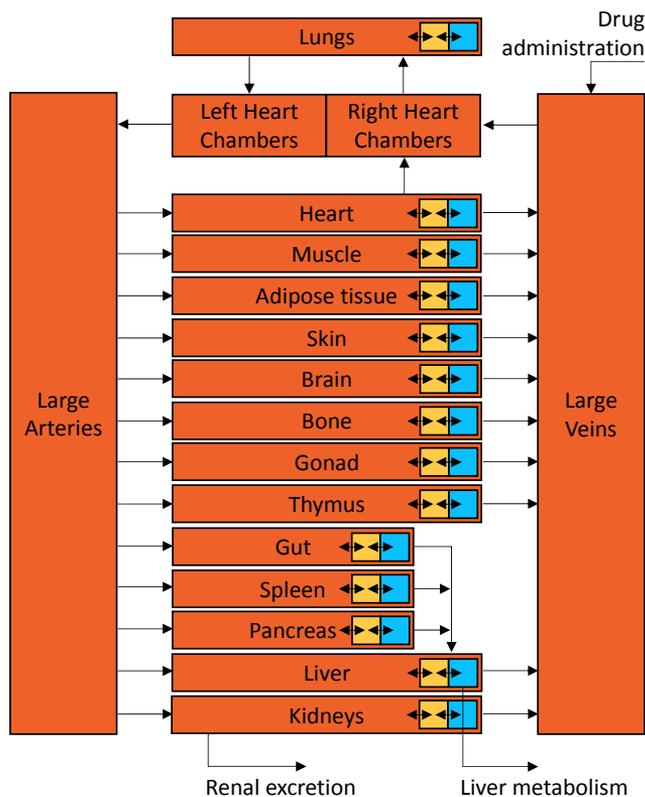

Figure 1 – Structure of the whole-body PBPK model. The rectangles represent the compartments of plasma (dark orange), ISF (mustard), and ICF (cyan) volumes. Black arrows are the drug flows, *i.e.* administration, blood circulation, capillary and cellular exchanges, metabolism, and excretion.

The drug is administered intravenously and enters the large veins plasma compartment, where it reversibly binds to plasma proteins. Plasma compartments are subject to the exchanges due to blood circulation, represented by the plasma flows Q_p , which are estimated as described in Stader et al. (2019). Renal excretion is the main elimination pathway for HDMTX and is estimated as a function of the patient's body weight, height, gender, age, and serum creatinine, as previously described in Pesenti et al. (2021a). Drug clearance due to hepatic metabolism is estimated as approximately 4% of renal excretion. The cellular exchanges, which affect the ISF and ICF compartments, are described with Michaelis-Menten kinetics (Pesenti et al. (2021a)).

The capillary exchange takes place between plasma and ISF of tissues and organs, allowing the unbound drug fraction (denoted by superscript u) to be exchanged with ISF through the gaps and openings of the capillary wall. We compile information from the literature describing capillary density n_{cap} (Freitas, 1999) and the type of capillary in each tissue and organ, as reported in Table 1. For the geometrical modeling of capillaries, we assume average values of capillary length (0.75 mm) and diameter (6 μm) (Freitas, 1999), attaining a geometrical surface a_{cap} of about 0.014 mm^2 . For each capillary type, we obtain rough estimates of the average surface fraction f_{open} that is open to capillary

exchange according to available data (Bundgaard, 1988; Levick, 2004). Eq. 4 estimates the capillary surface A_{cap} that is available for capillary exchange in each tissue.

$$A_{cap,i} = V_{tot,i} n_{cap,i} a_{cap} f_{open,i} \quad (4)$$

Table 1 – Characteristics of the capillaries in each tissue and organ described.

Organ/tissue	Capillary density $n_{cap,i}$ (mm ⁻³)	Capillary type	Open surface fraction $f_{open,i}$ (-)
Muscle	300	Continuous	0.0005
Adipose	100	Continuous	0.0005
Skin	68	Continuous	0.0005
Brain	2750	Continuous (tight junctions)	0 - 0.0005*
Bone	100	Continuous	0.0005
Gonad	300	Fenestrated	0.0062
Thymus	300	Fenestrated	0.0062
Heart	2750	Continuous	0.0005
Lungs	2750	Continuous	0.0005
Gut	300	Fenestrated	0.0062
Spleen	2750	Discontinuous	0.07
Pancreas	300	Fenestrated	0.0062
Liver	2750	Discontinuous	0.07
Kidneys	2750	Fenestrated	0.019

The number of unassigned remaining parameters is four, *i.e.* the same as the minimal PBPK model. These four parameters, describing capillary exchange ($k_{p \rightarrow ISF}$ and $k_{ISF \rightarrow p}$ in cm/min) and cellular exchange ($k_{ISF \rightarrow ICF}$ and $k_{ICF \rightarrow ISF}$ in min⁻¹), are identified with a nonlinear regression using the `fminsearch` routine in MATLAB R2020b (The MathWorks, Natick, MA, US). The regression minimizes the objective function, defined as the mean squared logarithmic error, using an experimental dataset of 84 patients and 657 methotrexate plasma concentrations (Pesenti et al., 2021a).

3. Results and discussion

The model is successfully identified and validated with two different subsets of the experimental dataset, which is split randomly, comprising respectively 56 and 28 patients. The objective function obtained with the identification procedure is 0.9831, which is comparable to the value obtained with the original minimal PBPK model (0.8568) (Pesenti et al., 2021a). Consistently, plasma predictions show a satisfactory agreement with experimental data and are similar to the results of the minimal PBPK model. Figure 2 shows the simulated predictions of the whole-body PBPK model for a patient whose objective function (0.8190) represents the median value of the validation dataset. The investigated time frame covers the administration of three consecutive HDMTX infusions (Fig. 2a). Panel 2c presents the generally good agreement between experimental and predicted plasma concentrations (representing large veins, where experimental

* While the brain features continuous capillaries with tight junctions, in the treatment of brain tumor the blood-brain barrier is usually disrupted, and f_{open} is tentatively assumed equal that of continuous capillaries with loose junctions.

concentrations are measured), and includes the average predicted ISF and ICF concentrations.

Panels 2c-f represent the phenomena of accumulation and exchange described by Eqs. 1-3 in different organs and tissues. For the sake of space and clarity, we present the results for only a few relevant tissues and organs: muscle, adipose tissue, kidneys, skin, and brain. As expected, our results show that predicted plasma concentrations in different compartments are comparable, due to the rapid drug distribution determined by the systemic blood circulation.

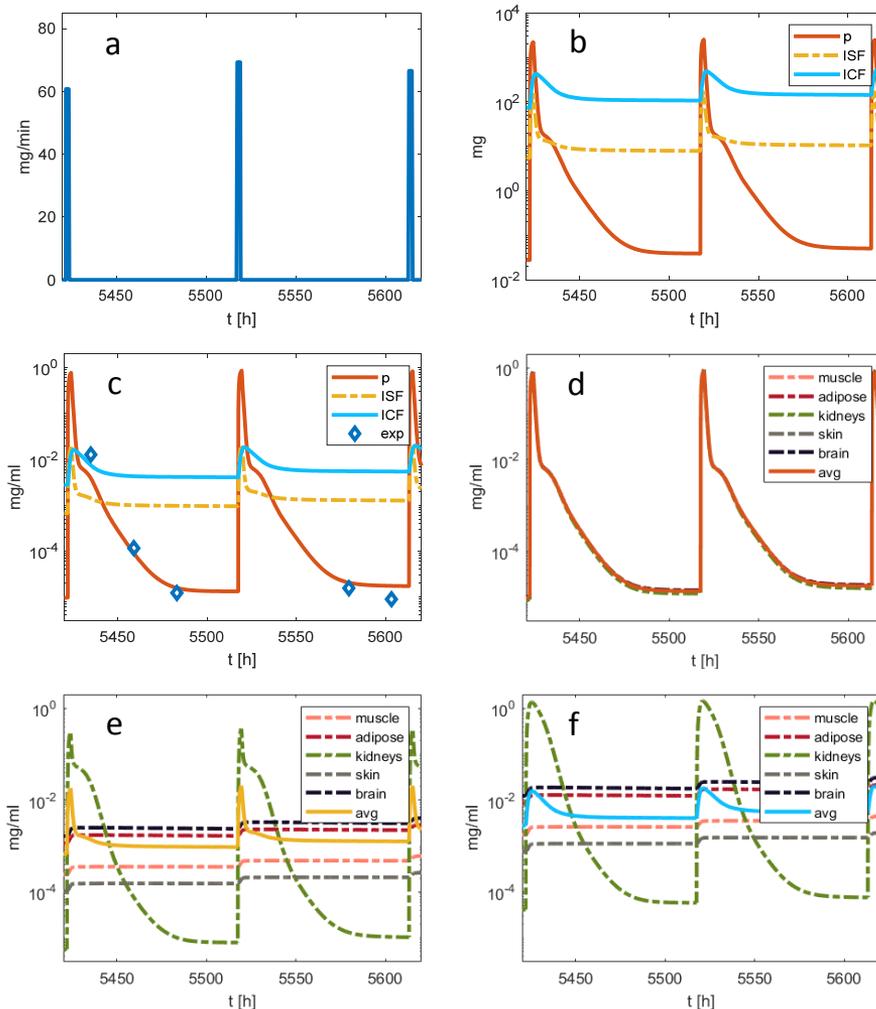

Figure 2 – Simulated curves for “630.3” patient: a) infusion rate, b) drug amounts in plasma, ISF, ICF, c) simulated and experimental concentrations in plasma, compared with the average ISF and ICF concentrations. Panels d-f compare the average concentration with the trends in a few tissues and organs (muscle, adipose tissue, kidneys, skin, and brain) related to d) plasma, e) ISF, f) ICF.

Conversely, the predicted concentrations in ISF and ICF differ significantly from tissue to tissue, consistently with the wide range of capillary exchange features (Table 1). For example, the predicted ISF concentration in kidneys (Fig. 2e) closely resembles the

predicted plasma concentration, thanks to both high capillary density and large open fraction of fenestrated capillaries. On the contrary, muscle and skin reach lower ISF concentration values due to slower capillary exchanges. Interestingly, the predicted ISF concentrations of adipose tissue are slightly higher than the average, despite the capillary features similar to those of the skin (low capillary density and permeability), likely due to the significantly smaller ISF and ICF volumes. The paramount effect of capillary exchange on predicted concentrations is also reflected by ICF concentrations, which present trends that are analogous to those described in ISF.

4. Conclusions

We presented a whole-body PBPK model for HDMTX featuring 46 body compartments, which was successfully identified and validated with an experimental dataset of 657 plasma concentrations. Plasma predictions showed a satisfactory agreement with experimental data and were comparable to the results of the minimal PBPK model. The detailed simulations of concentration within the plasma, ISF, and ICF of each modeled tissue and organ allowed straightforward physiological interpretations and better insights. The results allowed carrying out comprehensive analyses and defining improved therapeutical targets.

This work demonstrates an original approach to the development of a whole-body PBPK based on the extension of a minimal PBPK model. By introducing an *a priori* description of the 46 fluid volumes, 16 blood flows, and 14 capillary exchanges in each tissue and organ, the resulting whole-body PBPK model increased the level of detail of the minimal PBPK model while maintaining equivalent predictive capabilities, without amplifying the complexity and dimensionality of the identification procedure. The proposed modeling approach can serve as a reference for the development of other whole-body PBPK models that can retain their strong physiological consistency while minimizing the number of adaptive parameters, which facilitates the development process.

Abstract

In this study, two one-dimensional first-principles models are developed to simulate an isothermal process where ammonia is adsorbed on a doped activated carbon. A single-scale LDF model and a multi-scale Fickian model. Both models are described by mass balance equations along with thermodynamic and kinetic relations. The modeling methodology is based on experimental measurements of ammonia adsorption isotherms and breakthrough fronts combined with a parameter estimability analysis and an identification method. The models are implemented and solved within COMSOL Multiphysics[®]. The Kolmogorov-Smirnov non-parametric test is used to statistically validate the predictions of the models. The results of the identified and validated multi-scale model using the fitted parameters show very good agreement with the experimental measurements. This is confirmed by the performance indices such as the Pearson correlation coefficient, the mean-square error, the (modified) index of agreement and the chi-square error.

Keywords: Air purification boxes, Ammonia adsorption, Doped activated carbon, Experimental measurements, Model validation.

1. Introduction

In chemical hazards, ammonia is a component that deserves careful study to protect the health of exposed people. Indeed, when used in large quantities, for example in agro-chemistry, in building and civil engineering, or in waste treatment and recycling, ammonia can be dangerous to the respiratory tract. Its concentration in the air should therefore be minimized and controlled. One of the most used processes to reduce the ammonia concentration in the air is adsorption.

In this work, an industrial ammonia adsorption process used in air purification, where ammonia is adsorbed on a doped activated carbon, is considered. The activated carbon is stacked in a parallelepipedic bed and placed in the centre of a box equipped with a feed and an outlet. The box is designed so that air highly concentrated in ammonia is sucked through the fixed-bed of activated carbon, and the purified air is recovered at the outlet. The fixed-bed is replaced once the ammonia starts to breakthrough, and naturally, the idea is to reduce the frequency of the renewal of activated carbon. To this end, different adsorption models are developed ranging from a simple single-scale LDF (linear driving force) model to a complex multi-scale model (Cardenas, 2021; Cardenas et al., 2021). All these models are identified and then tested with additional breakthrough front measurements performed at three gas flow rates and two concentrations, different from those used for parameter identification.

In the present paper, the objective is to statistically validate these models and use them in order to optimize the design and operation of air purification boxes. Many statistical tests are used to validate the predictions of the models. They include the Student t -test, the Fisher-Snedecor F -test, the chi-square test, etc. However, the use of these parametric statistical tests requires the distributions of the model predictions and measurements to be normal which is very often not the case. To overcome this problem, the Kolmogorov-Smirnov non-parametric test is used. In addition, the performance of the models is evaluated using different criteria such as the Pearson correlation coefficient, the root mean-squares error, the (modified) index of agreement, and the chi-square error.

2. Ammonia adsorption process modeling

Different models are developed to describe the behavior of dynamic adsorption of ammonia on doped activated carbon. They range from a single-scale model to more complex models involving multi-scales (Cardenas, 2021). The modeling is based on mass balance, momentum balance, thermodynamic, hydrodynamic, and kinetic equations. These balances are established at both the adsorption box scale and at the particle scale, and are based on the following assumptions: (i) the gas mixture obeys the ideal gas law, (ii) the pressure drop in the box is neglected, (iii) ammonia is the only adsorbed molecule, (iv) the resistance to the mass transfer through the boundary layer surrounding the solid particles is characterized by a mass transfer coefficient, (v) the intra-particle mass transport is due to the Fickian diffusion and is characterized by an effective diffusion coefficient in the macropores, (vi) the mass transport of ammonia in the crystal micropores is due to intracrystalline diffusion, (vii) the Toth equation describes the equilibrium isotherm of the gas phase with the adsorbent, (viii) the adsorbent particles are assumed to be spherical and homogeneous in size and density, (ix) the temperature of the box and the physical properties of the adsorbent are assumed to be constant, (x) only the axial dimension of the box is considered (mono-dimensional model). On the other hand, for the lack of space reasons, only two models will be presented below: the single-scale LDF model and the multi-scale model.

2.1. Single-scale LDF model

In this model, the mass balance of the gas phase ammonia in the box is described by a dynamic equation involving diffusion, convection, and adsorption, given as:

$$\frac{\partial c}{\partial t} - D_{ax} \frac{\partial^2 c}{\partial z^2} + \frac{\partial (vc)}{\partial z} = - \frac{1 - \varepsilon_b}{\varepsilon_b} \frac{\partial \bar{q}}{\partial t} \quad (1)$$

where c and \bar{q} (mol.m^{-3}) are the ammonia concentrations in the gas phase and in the adsorbed phase respectively, v (m.s^{-1}) is the interstitial velocity, D_{ax} ($\text{m}^2.\text{s}^{-1}$) is the axial dispersion coefficient, and ε_b is the bed void fraction.

The kinetics of mass transfer is approximated by means of the LDF equation as:

$$\frac{\partial \bar{q}}{\partial t} = k_{LDF} (q_e^* - \bar{q}) \quad (2)$$

where q_e^* (mol.m^{-3}) is the concentration of ammonia in the solid phase at equilibrium, and k_{LDF} (s^{-1}) is the overall mass transfer coefficient which accounts for the contributions of gas/solid mass transfer, and macropore and intracrystalline diffusion.

The initial conditions of the variables are given as follows:

- For $0 \leq z \leq L$, at $t = 0$: $c = 0$, $\bar{q} = 0$,

and the boundary conditions are expressed as:

- For $t > 0$, at $z = 0$: $-D_{ax} \frac{\partial c}{\partial z} = v(c_0 - c)$, $\bar{q} = 0$ and at $z = L$: $\partial c / \partial z = 0$, where c_0 (mol.m^{-3}) is the concentration of ammonia at the box inlet.

2.2. Multi-scale model

This model takes into account the following three spatial scales: the bed, the particle, and the crystal scales. The particle is divided into two phases: a solid phase for the crystal (micropores) and a gas phase (macropores) and are coupled by continuity at outer surface of the crystal. The model equations are detailed below.

(i) In the box, the ammonia mass balance equation in the gas phase is expressed as follows:

$$\frac{\partial c}{\partial t} - D_{ax} \frac{\partial^2 c}{\partial z^2} + \frac{\partial(vc)}{\partial z} = - \frac{1 - \epsilon_b}{\epsilon_b} \frac{3}{r_{pe}} k_f (c - c_{pe}|_{r_p=r_{pe}}) \quad (3)$$

(ii) In the particle, assuming the absence of lateral and azimuthal variations of the concentration, the mass balance in the radial direction can be written as:

$$\epsilon_{pe} \frac{\partial c_{pe}}{\partial t} + (1 - \epsilon_{pe}) \frac{\partial \bar{q}}{\partial t} = \frac{D_e}{r_p^2} \frac{\partial}{\partial r_p} \left(r_p^2 \frac{\partial c_{pe}}{\partial r_p} \right) \quad (4)$$

(iii) In the crystal, the ammonia mass balance equation is given as:

$$\frac{\partial \bar{q}}{\partial t} = \frac{15D_\mu}{r_c^2} (q_e^* - \bar{q}) = k_1 (q_e^* - \bar{q}) \quad (5)$$

where $c(z, t)$ and $c_{pe}(z, r_p, t)$ (mol.m^{-3}) are the concentrations of ammonia in the gas phase of the box and in the particle respectively, r_{pe} and r_c (m) are the radii of the particle and the crystal respectively, k_f (m.s^{-1}) is the external film mass transfer coefficient, $c_{pe}|_{r_p=r_{pe}}$ (mol.m^{-3}) is the ammonia concentration at the surface of the particle, \bar{q} (mol.m^{-3}) is the average amount of ammonia adsorbed on the crystal, D_e and D_μ ($\text{m}^2.\text{s}^{-1}$) are the effective and intracrystalline diffusion coefficients respectively, and k_1 (s^{-1}) is the internal mass transfer coefficient.

The initial conditions of the variables are given as:

- For $0 \leq z \leq L$, at $t = 0$: $c = 0$, $c_{pe} = 0$, $\bar{q} = 0$,

and the boundary conditions are expressed as:

- For t and $r_p > 0$, at $z = 0$: $-D_{ax} \frac{\partial c}{\partial z} = v(c_0 - c)$, $\bar{q} = 0$ and at $z = L$: $\partial c / \partial z = 0$;

- For t and $z > 0$, at $r_p = 0$: $\frac{\partial c_{pe}}{\partial r_p} = 0$ and at $r_p = r_{pe}$: $-D_e \frac{\partial c_{pe}}{\partial r_p} = k_f (c - c_{pe}|_{r_p=r_{pe}})$

2.3. Implementation and simulation of the models

The external mass transfer coefficient is calculated using the following Wakao and Funazkri (1978) correlation:

$$k_f = \frac{D_m Sh}{2r_{pe}} \quad \text{with} \quad Sh = c_{m1} + c_{m2} Re_p^{0.6} Sc^{1/3} \quad \text{and} \quad c_{m1} = 2 \quad (6)$$

where Sh , Re_p and Sc are the dimensionless Sherwood, Reynolds and Schmidt numbers respectively, D_m ($\text{m}^2.\text{s}^{-1}$) is the molecular diffusion coefficient. For the axial dispersion coefficient, the correlation of Rastegar and Gu (2017) is used:

$$D_{ax} = \frac{2r_{pe}v}{Pe'} \quad \text{with} \quad \frac{1}{Pe'} = \frac{0.7D_m}{2r_{pe}v} + \frac{\epsilon_b}{c_{m3} + c_{m4} (Re_p)^{0.59}} \quad (7)$$

where Pe' is the dimensionless Peclet number. The effective diffusion coefficient is linked to the mixture diffusion by means of the following relation: $D_e = \varepsilon_{pe}^{4/3} D_M$. It is important to point out that D_{ax} and k_f increase with increasing gas flow rate. To keep this property, c_{m2} , c_{m3} and c_{m4} are also considered as unknown parameters to be identified from the measurements. Hence, in the LDF model three unknown parameters are to be estimated, i.e., k_{LDF} , c_{m3} and c_{m4} , whereas in the multi-scale model, five unknown parameters are to be determined, i.e., k_1 , D_M , c_{m2} , c_{m3} and c_{m4} . Comsol Multiphysics[®] version 5.5 is used to implement and solve the set of partial differential equations of the two models.

2.4. Parameter estimability analysis and identification

A preliminary step in the development of a reliable mathematical model, before the problem of parameter identification, is to evaluate the structural identifiability and estimability of the model parameters. The objective is to determine the most estimable parameters from the available measurements. The estimability algorithm used in this work is the same as the one developed by Yao et al. (2003) and used in Cardenas et al. (2020). Moreover, the choice of the estimability threshold value which defines the limit between estimable and non-estimable parameters, is still arbitrary and depends on the studied process. In this work, it is set equal to 0.04 as in Yao et al. (2003) and gives a good idea about the actual sensitivity of the adsorption models to the unknown parameters. However, it should be noted that there are more advanced and sophisticated methods in the literature (Bouchkira et al., 2021).

2.4.1. Parameter estimability analysis results

The estimability analysis algorithm using the orthogonalization algorithm described by Yao et al. (2003) is applied to the ammonia adsorption process models and leads to the following estimability order: $k_{LDF} > c_{m3} > c_{m4}$ for the LDF model, and $k_1 > D_M > c_{m2} > c_{m3} > c_{m4}$ for the multi-scale model. It should be noted that all parameters are estimable on the basis of available experimental measurements.

2.4.2. Parameter identification

The experimental data used consist of breakthrough front measurements carried out at four different concentrations of ammonia (0.066, 0.054, 0.041 and 0.029 mol.m⁻³) and three different gas flow rates (13.8, 9.0 and 4.4 L.min⁻¹), for a total of 12 experiments to identify the parameters, using the Toth isotherm model. The results obtained show that the LDF model fits the adsorption process well with identified parameter values close to those in the literature (see figure 1). However, this model does not allow to understand all the different mechanisms involved in the adsorption box since all the mass transport resistances are lumped into a single global coefficient. The multi-scale model which shows very good agreement between measurements and predictions allows a better understanding the adsorption phenomena by considering the three scales: gas phase in the box, gas phase and solid phase in the particle.

2.4.3. Model prediction performance

The prediction performance of the model is quantitatively assessed by means of criteria which compares model predictions with the experimental measurements. In this study, it is evaluated according to two different criteria: The root mean-square error function (*RMSE*) and the Pearson correlation coefficient (*r*).

3. Model validation

The identified models are then validated with five additional breakthrough front measurements performed at three gas flow rates 17, 15 and 7 L.min⁻¹ with an ammonia concentration of 0.041 mol.m⁻³; and at a gas flow rate of 13.8 L.min⁻¹ with two ammonia concentrations of 0.021 and 0.012 mol.m⁻³, different from those are used for parameter identification. The optimized values of the parameters previously estimated are used to simulate these fronts (Cardenas, 2021). Figure 1 shows the comparison between the time-varying predicted and measured fronts at different gas flow rates and different ammonia concentrations.

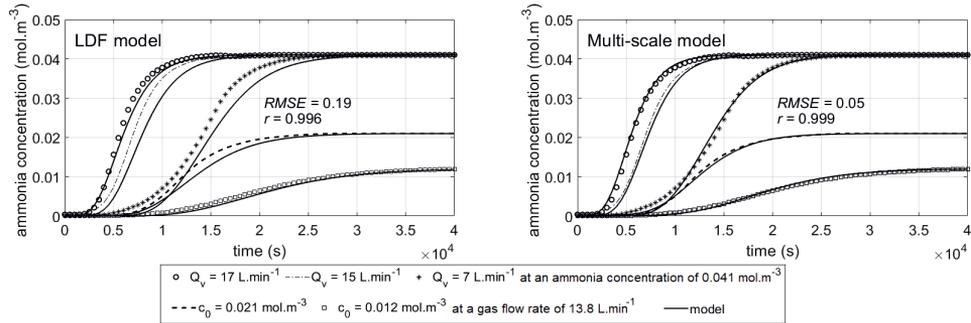

Figure 1: Comparison between predicted and measured breakthrough fronts at three gas flow rates 17, 15 and 7 L.min⁻¹ with an ammonia concentration of 0.041 mol.m⁻³; and at a gas flow rate of 13.8 L.min⁻¹ with two ammonia concentrations of 0.021 and 0.012 mol.m⁻³

The high values obtained for the Pearson coefficient (close to unity, $r \geq 0.996$) and low $RMSE$ values (at most 0.19) show excellent prediction performance of the developed models. Furthermore, to validate these models, many statistical tests may be considered and can be parametric or non-parametric. Parametric tests are based on assumed statistical distributions in the data. Therefore, certain validity conditions must be verified for their results to be reliable. For example, the Student t -test for independent samples is only reliable if the data associated with each sample follow a normal distribution and if the variances of the samples are homogeneous. However, since the validity conditions are not always met, which is the case in our data, the parametric tests can no longer be used. Non-parametric tests which are not based on statistical distributions can therefore be considered. More specifically, the Kolmogorov-Smirnov test is used and is based on the calculation of the divergence (D_n) between two distributions. It is expressed as the maximum value between the predicted (c) and measured (c^{mes}) ammonia concentration values at each instant t , i.e.:

$$D_n = \max_t |c(t) - c^{mes}(t)| \quad (8)$$

The null hypothesis (H0) is defined as: the predicted and measured breakthrough fronts have the same distribution with the probability of 95%. Therefore, the alternative hypothesis (H1) is that the predicted and measured breakthrough fronts do not have the same distribution with the probability of 95%. On the other hand, the critical value of the divergence (D_n^*) corresponding to the number of experimental measurements minus one, and to the significance level of the test (5%) is expressed by $(D_n^* = \frac{1.36}{\sqrt{n}})$ and is equal to 0.06. To pass the validity test, the divergence D_n must be less or equal to the critical value D_n^* . In table 1, bold values correspond to the calculated divergence which is less than the critical value, meaning that the null hypothesis (H0) cannot be rejected. We can therefore affirm that the predicted and measured breakthrough fronts have the same distribution with a probability of 95%. In addition, the performance of the model is evaluated by means of different criteria, i.e., the index of agreement (IA), the modified index of agreement

(IAM), and the nonlinear chi-square error (χ^2). These performance criteria are calculated and their values are reported in table 1. It can be seen that the indices *IA* and *IAM* are close to unity and the low values of chi-square confirm the excellent agreement between the model predictions and measurements. The multi-scale model is therefore the most performing prediction model, as it has successfully passed all the tests. On the other hand, despite the good performance indices of the LDF model, its validation at the 5% significance level is not guaranteed.

Table 1: Performance criteria for adsorption models

	LDF model					Multi-scale model				
Q_v L.min ⁻¹	17	15	7	13.8		17	15	7	13.8	
c_0 mol.m ⁻³	0.041			0.021	0.012	0.041			0.021	0.012
D_n	0.076	0.149	0.128	0.127	0.076	0.048	0.052	0.047	0.038	0.040
χ^2	0.001	0.032	0.009	0.004	0.007	0.001	0.020	0.003	0.002	0.002
<i>IA</i>	0.996	0.995	0.996	0.996	0.998	0.999	0.999	0.999	0.999	0.999
<i>IAM</i>	0.979	0.954	0.955	0.961	0.961	0.986	0.982	0.988	0.991	0.978

4. Conclusions

Among the developed models, the multi-scale model is the most effective since it exhibits higher performance indices and successfully passes the validation tests considered. This model can now be used as a tool to predict the breakthrough time in an ammonia adsorption box with doped activated carbon to protect operators working in an ammonia-contaminated environment. It can also be used to study the effect of different operating conditions such as temperature, concentration, flow rate, bed geometry, porosity, etc., and more generally in optimal design and operation of such adsorption processes.

Abstract

Due to increased ammonia emissions, there has been a growing interest in developing ammonia removal technologies. Adsorption is one of the most widely used separation techniques to reduce the concentration of ammonia in the air. This study aims to use CFD-based modeling to investigate ammonia adsorption on a doped activated carbon in an industrial air purification box. An experimental study is first carried out, then followed by detailed modeling of the processes that occur in the box. The hydrodynamic and adsorption models are implemented and solved using COMSOL Multiphysics[®] software in the 5.6 version. Adsorption is modeled by means of a multi-scale Fickian model, which demonstrated to be very efficient to predict the experimental data. The performance of the predictions of the model is assessed using several statistical criteria such as the mean-square error and the Pearson correlation coefficient.

Keywords: Air purification boxes, Ammonia adsorption, Doped activated carbon, Experimental measurements, Modeling and simulation

1. Introduction

Ammonia is one of the most toxic pollutants, it causes massive burning by inducing an exothermic reaction in the respiratory system. Despite its harmful effects on humans, it is one of the most widely used gases in the manufacture of fertilizer, polymers, and resins. Controlling pollutant emissions at the source is the most effective way to reduce total air pollution and protect human health. However, if this is not possible, pollutant concentrations should be targeted, with preventative and abatement measures. Among different air purification techniques, adsorption of pollutants on activated carbon is one of the most effective. Air purifiers are becoming increasingly popular as a means of removing contaminants from ambient air. CFD is a powerful tool for modeling and investigating mass transfer and diffusion mechanisms in fixed-bed adsorption boxes in less time and at a lower cost than experiments, thereby improving the design and optimization of processing equipment. This paper deals with a CFD modeling and simulation of an industrial fixed-bed adsorption box where ammonia is removed from the air using a doped activated carbon. The model predictions are compared to experimental measurements of breakthrough fronts carried out at different gas flowrates.

2. Mathematical modeling

The air purification box used for the flow modeling is the Honeywell SP Défence Filagric K100. Depending on the manufacturer, the air flowrate supplied can range from 40 to 100 m³.h⁻¹. Thus,

the modeling and simulation of the phenomena will concern the two extreme values of the flow range.

2.1. Hydrodynamic model

The hydrodynamic model developed is based on the following assumptions: (i) negligible gravity force, (ii) the flow is considered as incompressible, (iii) the gas properties are those of air, (iv) the temperature of the box and the physical properties of the adsorbent are constant, (v) the average properties of the porous medium are isotropic. On the other hand, particular attention to the flow regime is required for proper modeling of the problem. As shown in figure 1, the purification box does not have a constant section. Hence, the Reynolds number is calculated in inlet, outlet and bed sections. The values are all exceeding the critical Reynolds number found in the literature (Reynolds, 1883; Hanks and Ruo, 1966), showing that the purification box operates in a turbulent flow regime.

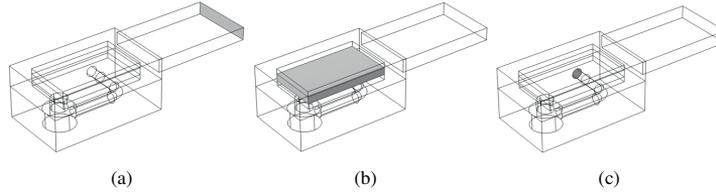

Figure 1: (a) Inlet section (b) Fixed bed section (c) Outlet section

The flow model is then described by the continuity and the Navier-Stokes equations along with the Brinkman-Forchheimer equation for the porous medium domain. The continuity equation is expressed as:

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

where \mathbf{u} ($\text{m}\cdot\text{s}^{-1}$) is the average velocity vector. The momentum balance is given by Reynolds averaged Navier-Stokes (RANS) equations as:

$$\rho_f \nabla \cdot \mathbf{u} + \nabla \cdot \overline{\rho_f (\mathbf{u}' \times \mathbf{u}')} = -\nabla p + \nabla \cdot (\mu_f (\nabla \mathbf{u} + (\nabla \mathbf{u})^T)) + \mathbf{F} \quad (2)$$

where p (Pa) is the average pressure, ρ_f ($\text{kg}\cdot\text{m}^{-3}$) is the fluid density, μ_f (Pa.s) is the fluid dynamic viscosity and \mathbf{F} (N) is the vector representing all the external forces applied to the fluid. However, because the activated carbon filter is a porous medium, the RANS alone cannot describe the fluid flow inside the process. The following Brinkman equations are therefore used:

$$\frac{1}{\varepsilon_b} \rho_f \mathbf{u} \cdot \nabla \frac{1}{\varepsilon_b} = -\nabla p + \nabla \cdot \left(\frac{\mu_f}{\varepsilon_b} (\nabla \mathbf{u} + (\nabla \mathbf{u})^T) \right) - \left(\mu \kappa^{-1} + \beta \rho_f |\mathbf{u}| + \frac{Q_m}{\varepsilon_b^2} \right) \mathbf{u} + \mathbf{F} \quad (3)$$

where ε_b ($\text{m}^3\cdot\text{m}_{\text{box}}^{-3}$) is the porosity of the bed, κ (m^2) is the permeability, \mathbf{u} ($\text{m}\cdot\text{s}^{-1}$) is the fluid average velocity over the porous medium, which is related to the interstitial velocity v ($\text{m}\cdot\text{s}^{-1}$). The Brinkman-Forchheimer drag term β (m^{-1}) and the permeability κ (m^2) are modeled using Ergun equation. The corresponding boundary conditions are given as follows. At the inlet, the velocity is determined by the volumetric flow rate Q_v ($\text{m}^3\cdot\text{s}^{-1}$) and the inlet section Ω_m (m^2) as: $\mathbf{u} = -U_0 \mathbf{n}$ and $U_0 = \frac{Q_v}{\Omega_m}$, where \mathbf{n} represents the boundary outward pointing normal. At the outlet, the following pressure condition is defined: $(-p \mathbf{I} + (\mu + \mu_T) (\nabla \mathbf{u} + (\nabla \mathbf{u})^T)) \mathbf{n} = -p_0 \mathbf{n}$, where p_0 (Pa) is the gauge pressure, set equal to 0 kPa, and \mathbf{I} is the identity matrix. A crucial point

is the correct modeling of the fluid flow in the vicinity of the wall, given the formation of a viscous sub-layer and a buffer region. The behavior of the flow near the walls is therefore approximated, since the RANS model is not suitable anymore to properly describe this area at low Reynolds numbers. A non-slip condition is then considered on every wall, and this is written as: $\mathbf{u} = 0$. There is no need for an additional boundary condition since the turbulence model we used is algebraic.

2.2. Adsorption model

The adsorption model developed takes into account three scales: the fixed-bed scale, the intra-particle scale and the crystal scale. It is based on the following assumptions: (i) the gas mixture obeys the ideal gas law, (ii) only ammonia is adsorbed, (iii) resistance to mass transfer across the boundary layer surrounding the solid particles is characterised by an external film mass transfer coefficient, (iv) intra-particle mass transport is due to Fickian diffusion, (v) intra-crystalline mass transport of ammonia in the crystal micropores is due to the intra-crystalline diffusion, (vi) the adsorbent particles are assumed to be spherical and homogeneous in size and density, (vii) only the axial dispersion in the bed is taken into account (one-dimensional model). The amount of ammonia adsorbed on the doped activated carbon is described by the Toth adsorption isotherm, better detailed by Cardenas (2021). The model equations are given below.

(i) The ammonia mass balance in the bed domain is expressed as:

$$\frac{\partial c}{\partial t} + \nabla \cdot (-D_{ax} \nabla c) + v \cdot \nabla c = -\frac{(1 - \varepsilon_b)}{\varepsilon_b} \frac{3}{r_{pe}} k_f (c - c_{pe}|_{r_p=r_{pe}}) \quad (4)$$

where c and $c_{pe}|_{r_p=r_{pe}}$ (mol.m^{-3}) are the concentrations of ammonia in the gas phase and on the particle surface respectively, k_f (m.s^{-1}) is the external mass transfer coefficient, D_{ax} ($\text{m}^2.\text{s}^{-1}$) is the axial dispersion coefficient, and r_{pe} (m) is the mean radius of the particle.

(ii) The intra-particle mass balance in the radial direction can be written as:

$$\varepsilon_{pe} \frac{\partial c_{pe}}{\partial t} + (1 - \varepsilon_{pe}) \frac{\partial q}{\partial t} = \frac{D_e}{r_p^2} \frac{\partial}{\partial r_p} \left(r_p^2 \frac{\partial c_{pe}}{\partial r_p} \right) \quad (5)$$

where ε_{pe} ($\text{m}_g^3.\text{m}_{pe}^{-3}$) is the porosity of the particle, q (mol.m^{-3}) is the amount of ammonia adsorbed on the solid and D_e ($\text{m}^2.\text{s}^{-1}$) is the effective diffusion coefficient. The associated initial and boundary conditions of equations (4-5) are:

— for $t = 0$: $c = 0$, $c_{pe} = 0, \forall r_p$ and z ; — for $z = 0$: $\frac{\partial c}{\partial z} = \frac{v}{D_{ax}} (c - c_0), \forall r_p$ and z

— for $z = H$: $\frac{\partial c}{\partial z} = 0, \forall r_p$ and t ; — for $r_p = 0$: $\left. \frac{\partial c_{pe}}{\partial r_p} \right|_{r_p=0} = 0, \forall z$ and t

— for $r_p = r_{pe}$: $-D_e \frac{\partial c_{pe}}{\partial r_p} = k_f (c - c_{pe}|_{r_p=r_{pe}}), \forall z$ and t

where c_0 (mol.m^{-3}) is the concentration of ammonia at the box inlet.

(iii) The ammonia mass balance in the crystal is given as:

$$\frac{\partial \bar{q}}{\partial t} = k_1 (q_e^* - \bar{q}) \quad (6)$$

where \bar{q} (mol.m^{-3}) is the average amount of ammonia adsorbed on the crystal, q_e^* (mol.m^{-3}) is the amount of ammonia adsorbed at equilibrium, and k_1 (s^{-1}) is the internal mass transfer coefficient in the crystal. The associated initial condition is given as: for $t = 0$: $c = 0, c_{pe} = 0, \bar{q} = 0, \forall r_p$ and z .

3. Results and discussion

It is important to notice that since the geometry shown in figure 1 leads us to very high computational times, we decided to change the ventilator shape in order to take advantage of symmetry

and therefore only implement one half of the domain.

3.1. Mesh quality

Accurate solution of CFD models requires mesh refinement to achieve a grid-independent solution. The first mesh used for the discretization of the domain is a fine physics controlled mesh, and its convergence is evaluated with respect to a user-controlled one. The first has 2.08×10^6 elements and an average quality of 0.7, while the latter has a number of elements of 3.82×10^6 and a mean quality of 0.74. Both meshes predicted the same velocity and pressure profiles; we concluded then that our solution is grid independent.

3.2. Pressure and velocity fields

Figure 2 (a) shows the pressure profile in the activated carbon bed for an inlet flowrate of $100 \text{ m}^3 \cdot \text{h}^{-1}$. The pressure drop computed is about 113 Pa. It decreases to 38 Pa when the overall inlet flowrate decreases to $40 \text{ m}^3 \cdot \text{h}^{-1}$. Figure 2 (b) shows a heterogeneous velocity distribution throughout the bed with an average velocity of about $0.22 \text{ m} \cdot \text{s}^{-1}$. However, this is true only in the gas inlet section. In fact, as soon as the flow encounters the activated carbon particles the velocity distribution becomes more homogeneous.

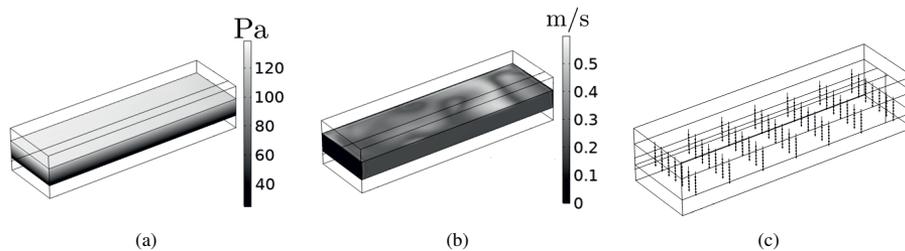

Figure 2: Fixed bed hydrodynamics: (a) Pressure drop (b) Velocity distribution (c) Arrow plot

Figure 2 (c) shows that the velocity field in the fixed bed domain is homogeneous. It is therefore clear that the z component is the only significant one, but in order to prove it, a volume average evaluation group is used to determine the values of the three components of the velocity. The evaluation showed us that the absolute value of the z component is very close to the velocity magnitude in the fixed bed domain, while the x and y components have a magnitude of $10^{-6} \text{ m} \cdot \text{s}^{-1}$.

3.3. Residence time distribution

Numerical residence time distributions (RTDs) are computed in order to determine the time available for adsorption. Figure 3 shows a normalized RTD and the resulting mean residence time. The corresponding space-time is equal to 3.2 s. It can be seen that, the average residence time is higher than the space-time, meaning that the molecules of ammonia remain on average longer than would remain if the velocity distribution was homogeneous.

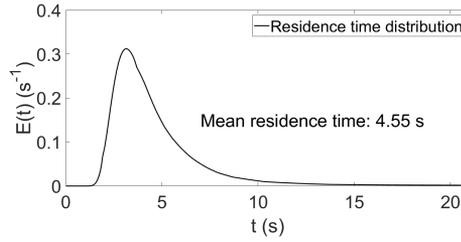

Figure 3: Residence time distribution in the purification box

On the other hand, the RTD curve exhibits a long tail indicating the presence of dead zones which degrade the air purification box performance.

3.4. Adsorption results

In order to solve the model equations, it is necessary to determine the unknown parameters such as the internal mass transfer coefficient (k_1), the axial dispersion coefficient (D_{ax}), the effective diffusion coefficient (D_e), and the external mass transfer coefficient (k_f). The latter is calculated by means of the Wakao and Funazkri (1978) correlation as:

$$k_f = \frac{D_m Sh}{2r_{pe}} \quad \text{with} \quad Sh = c_{m1} + c_{m2} Re_p^{0.6} Sc^{1/3} \quad \text{and} \quad c_{m1} = 2 \quad (7)$$

where D_m ($\text{m}^2 \cdot \text{s}^{-1}$) is the molecular diffusion coefficient. The axial dispersion coefficient is evaluated using the Rastegar and Gu (2017) correlation as:

$$D_{ax} = \frac{2r_{pe} v}{Pe'} \quad \text{with} \quad \frac{1}{Pe'} = \frac{0.7 D_m}{2r_{pe} v} + \frac{\epsilon_b}{c_{m3} + c_{m4} (Re_p)^{0.59}} \quad (8)$$

The effective diffusion coefficient is linked to the mixture diffusivity by means of the following relation : $D_e = \epsilon_{pe}^{4/3} D_M$. It is noteworthy that D_{ax} and k_f increase with increasing gas flowrate. To keep this property, c_{m2} , c_{m3} and c_{m4} are also considered as unknown parameters to be identified from the experimental data. The most estimable parameters are determined from experimental measurements of the breakthrough fronts at different gas flowrates and the non-estimable parameters have their values fixed from the literature or from previous studies (see Cardenas et al. (2021)). A total number of five estimable parameters is therefore identified, i.e. k_1 , D_M , c_{m2} , c_{m3} and c_{m4} .

3.4.1. Parameter estimation

The COMSOL optimization module is used to estimate the optimal values for the model parameters. More specifically, the Monte Carlo solver is employed. Table 1 shows the values as well as their 95% confidence intervals (CI).

Table 1: Identified values of the Fickian Multi-scale model parameters.

Parameter	Value	CI (95 %)
k_1 (s^{-1})	5.79×10^{-4}	$\pm 1.26 \times 10^{-5}$
c_{m2}	0.10	$\pm 6.52 \times 10^{-3}$
c_{m3}	2.18×10^{-2}	$\pm 4.97 \times 10^{-3}$
c_{m4}	7.75×10^{-3}	$\pm 1.82 \times 10^{-3}$
D_M ($\text{m}^2 \cdot \text{s}^{-1}$)	6.53×10^{-5}	$\pm 2.54 \times 10^{-5}$

As the *CI* values are lower than the parameter values, we can conclude that the parameters are determined with good precision. The optimal values of the parameters are then used to simulate ammonia breakthrough fronts at different gas flowrates and at a concentration of 0.041 mol.m^{-3} , shown in figure 4. It can be seen that the breakthrough occurs more rapidly as the flow rate increases. A higher flowrate leads to a faster movement of the mass transfer zone. On the other hand, a lower flowrate results in slower transport of ammonia molecules, which increases the breakthrough time.

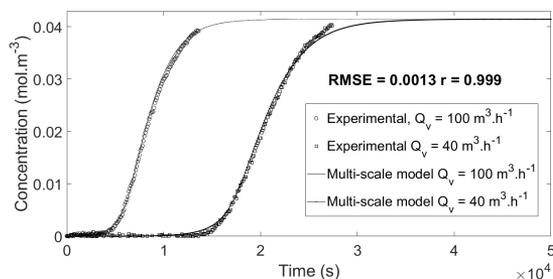

Figure 4: Comparison between predicted and measured breakthrough fronts

It should be noted that, based on the overall calculated *RMSE* (0.0013), the multi-scale model fits the adsorption process very well. Moreover, the Pearson coefficient value (very close to 1) shows that the model predictions are in excellent agreement with the experimental measurements.

4. Conclusions

After performing a hydrodynamic analysis of the air purification box, the CFD model was expanded to include the ammonia adsorption breakthrough profile on the activated carbon filter. Then, the COMSOL optimization tool allowed to determine the optimal values of the estimable parameters and their confidence intervals. For various inlet gas flowrates, the Fickian multi-scale model has proven to be the best suitable fit with experimental breakthrough profiles. However, by modeling adsorption in 3D, there is still the possibility for model improvement. Furthermore, the performance of the model predictions could be improved by working with different flowrates and inlet ammonia concentrations. Despite this, the numerical model developed could be used to further analyze and optimize the design and operation of industrial air purification boxes.

Abstract

Changes in the generation of crop residues are expected due to the introduction of cultivars adapted to climate change, and there is a need to promote polygeneration of crop-derived production processes in order to effectively utilize crop residues for sustainable development. A process flow model of a Japanese sugar mill was developed and was incorporated into the integrated modeling of agricultural-industrial process. A boiler designed to maximize the power sold after 10 years from now cannot be operated in its current state because the heat transfer area of the bagasse boiler is too large to maintain the temperature of the final flue gas. A boiler designed to produce only the steam needed for sugar production after 10 years from now can make effective use of excess bagasse and can still be operated today.

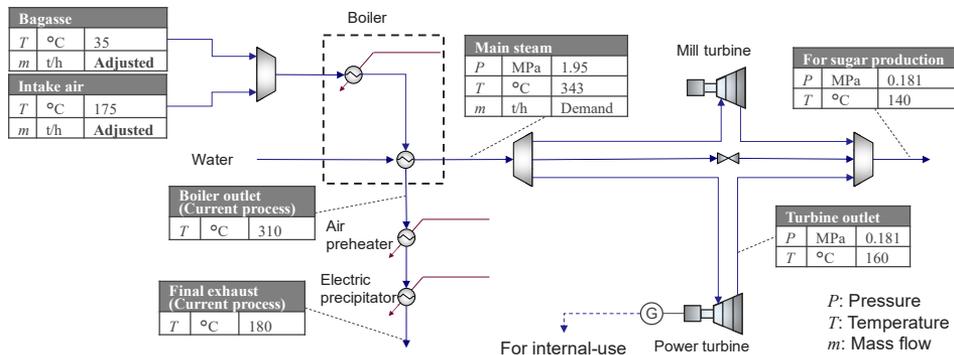

Keywords: Sugarcane bagasse, Bagasse boiler, Process modeling, Integrated modeling

1. Introduction

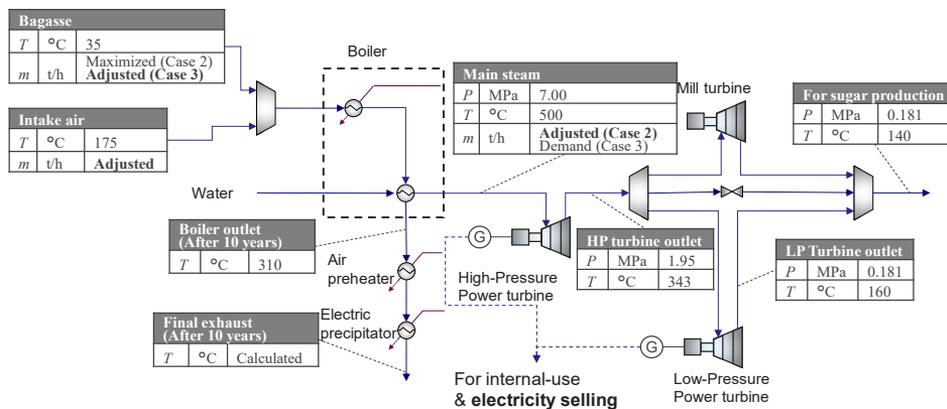

In the context of sustainable developments, polygeneration of crop-derived production processes will have a significant role. For many crops, agricultural operations are followed by industrial processing, and the residues may be used as fuel for operations. Currently, as the polygeneration of sugarcane industry, technological options for energy systems such as selling surplus electricity (Palacio et al., 2018; Birru et al., 2019), producing ethanol (Ohara et al., 2019) and producing unused heat to vicinal area (Kikuchi et al., 2016; Fujii et al., 2019) are being explored to effectively use the residue, bagasse. However, many crops need to be adapted to local environmental changes (Ma et al., 2017), and as new cultivars such as high-yielding cultivars, are introduced and gradually diffused, the balance between product and residue yields will change dynamically. Therefore, factories that are considering expanding their functions hereafter need to plan their facilities replacements carefully, taking into account the balance between maintaining production yield and efficient production of by-products. This study focuses on polygeneration in the sugarcane industry and aims to support the planning of equipment replacement to functionalize new high-yielding cultivars and excess thermal energy using computer-aided process engineering.

2. Material and methodology

Figure 1(a) shows a schematic of a conventional sugar mill that is not connected to the regional power grid. As an example, the flow of a sugar mill in Japan (Kikuchi et al., 2016) is shown. Sugarcane is supplied to the mill turbine first, then bagasse is transported to the bagasse boiler to be burned as fuel. Steam is generated by bagasse combustion, and 1.95 MPa of steam is split to the mill and power turbine, respectively, then depressurized steam is provided to evaporating and crystalizing process of sugar. Thus, typical sugar mills can provide its own steam and electricity demand utilizing bagasse. A process flow model was developed to simulate the mass and heat balance around a bagasse boiler in the sugar mill. This process flow model was incorporated into the already developed integrated modeling of agricultural and industrial processes for sugarcane-derived products (Ouchida et al., 2017). The expected increase of sucrose and fiber calculated by the expected composition of the cultivars for the next decade are shown in Figure 2. The cultivars considered were NiF8, NiTn18, Ni22, and a new cultivar (KY10-1380) with high-yielding and high percentage of fiber content (Hattori et al., 2019). The introduction

(a) Current process

(b) Selling surplus electricity

Figure 1 Schematic of sugar mill around bagasse boiler

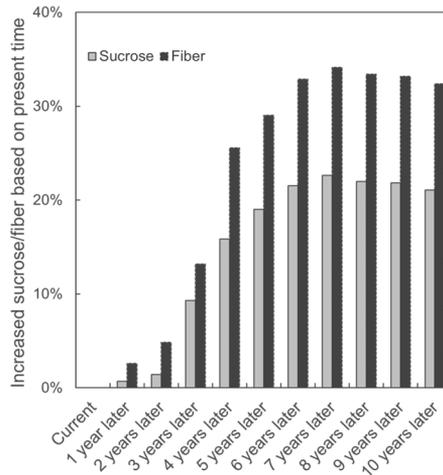

Figure 2 Increased sucrose and fiber in sugarcane based on present time

and expansion of new cultivar with high fiber content leads to further increase bagasse as biomass energy in the future. In order to make effective use of these surplus resources, this study examines the functionalization of new cultivars, using electricity sales as a case study.

The mass and heat balance of the plant for each year were calculated for the three cases. Case 1 is the case where the existing boiler is used without replacement. In the current energy flow of the sugar mill, the flow rates of bagasse and intake air are unknown. The UA value of the existing bagasse boiler was calculated by adjusting these unquantified parameters until the target values of 310 °C for the boiler outlet temperature and 10% for the oxygen concentration in the final exhaust flue gas were reached. The energy balance in the heat exchanger was divided into the phase change part of the steam and the other part, and the phase change part was divided into 10 intervals, and UA was calculated in each interval by the logarithmic mean temperature difference method, and the UA value of the entire heat exchanger was calculated by summing these values according to the temperature and flow rate of each fluid. The mass flow rate of bagasse supplied to the bagasse boiler in each year was adjusted to maintain this quantified UA value. In the cases where surplus electricity is sold to the local power grid (Cases 2 and 3), as shown in Figure 1(b), the bagasse boiler generates steam at 7 MPa, a high-pressure power turbine is installed, and exhaust steam from the high-pressure power turbine is introduced into the mill turbine and the low-pressure power turbine. In Case 2, the UA value of the bagasse boiler was designed to maximize the amount of electricity sold to the local power grid after 10 years from now by consuming excess bagasse as much as possible, except for exporting excess bagasse as bedding for livestock. The mass flow rate of the generated steam in each year was adjusted to maintain the UA value. In Case 3, the UA value of the bagasse boiler was designed to generate high-pressure steam required only for sugar production after 10 years from now. The generated steam is assumed to be introduced into a high-pressure power turbine to generate surplus electricity that is sold. The UA value was maintained by adjusting the mass flow rate of bagasse in each year.

3. Result and discussion

3.1. Amount of excess bagasse after 10 years with the current boiler (Case 1)

The UA value of the existing bagasse boiler was calculated by adjusting the volumetric flow of intake air and bagasse input to match the current operating data (temperature of the boiler outlet and oxygen concentration of the final exhaust flue gas). The UA value of the boiler was maintained by adjusting the amount of bagasse input to the bagasse boiler in each year, assuming that the existing boiler would not be replaced when a new high-yielding cultivar was introduced. Figure 3 shows the results of the bagasse production estimated by the integrated modeling of agricultural and industrial processes for sugarcane derived products, which incorporates the heat exchange process around the bagasse boiler in the sugar mill, and the change in bagasse input to the boiler adjusted by the energy flow model. About three years after the introduction of the new high-yielding cultivar, total sugar production increases with the spread of the new cultivar, and bagasse input to the bagasse boiler and required steam flow also increase. The new cultivar (KY10-1380) has a higher stem height and higher yield than other typical cultivar, but because of the high proportion of fibrous material within the cane, the amount of bagasse generated per unit of sugar produced increases as the new cultivar spreads, and the excess amount of bagasse increases. The current excess bagasse is exported as much as possible as bedding for livestock, but with the increase in bagasse production, it was expected that 7500 tons/year of excess bagasse would be generated which would be difficult to store as shown in Figure 3. Since this excess bagasse could be used to supply additional biomass energy to the surrounding area, the introduction of the electricity selling process is discussed in the next section.

3.2. Selling surplus electricity (Case 2 and 3)

The process selling surplus electricity by increasing the main steam pressure of the bagasse boiler and by utilizing excess bagasse that is expected to increase with the introduction of new high-yielding cultivar was simulated. The results of the ratio of electricity sold to the local power grid and self-consumption in the sugar mill are shown in Figure 4(a) when the UA of the bagasse boiler is designed to maximize the amount of electricity sold after 10 years. The UA value of the bagasse boiler in this case was 1.3 times higher than the current process. Although the internal power consumption of the sugar mill increases in accordance with the increase in total sugar production due to the spread of new high-yielding cultivar, the results show that 9.8 GWh of surplus power can be sold to the local power grid, mainly due to the increase in total power generation by the introduction of the high-pressure steam turbine. Figure 4(a) shows the temperature change of the final exhaust flue gas. Since the heat transfer area of the bagasse boiler designed to maximize the amount of electricity sold after 10 years is too large for the total heating value of bagasse that can be supplied to the bagasse boiler at present, the temperature of the final exhaust flue gas in this case at the present stage is below 140 °C, as shown in Figure 4(a). In order to avoid the temperature of the final flue gas falling below the acid dew point, sugar mills empirically maintain the temperature above 150 °C. Therefore, in this case, the current process should be maintained until enough excess bagasse is generated to introduce the process of selling surplus electricity, and the boiler should be replaced after 3 to 4 years when sufficient bagasse amount is obtained and the final exhaust gas temperature exceeds 150 °C.

Next, the case where the bagasse boiler generates only the steam required for sugar production in each year at high pressure was considered. The mass flow rate of bagasse was adjusted to generate the mass flow rate of steam required for sugar production after

10 years, and the UA value of bagasse was quantified. The quantified UA value was fixed, and the bagasse mass flow rate was adjusted annually to meet the sugar production demand. The results of the simulation of the ratio of electricity sold to the local power grid and self-consumption at the sugar mill and the temperature change of the final exhaust flue gas are shown in Figure 4(b). In this case, the UA value of the bagasse boiler was 1.2 times higher than that of the current process. The total amount of electricity sold after 10 years resulted in 8.0 GWh, which was about 20% lower than Case 2, but the temperature of the final exhaust flue gas was found to be able to be maintained at around 180 °C, the same level as the current process, because the mass flow rate of bagasse was optimized in each year to generate only the steam required for sugar production. Although not all of the bagasse generated in this case can be effectively used after 10 years, the excess amount can be reduced to less than half of that in Case 1, and furthermore, it is found that operation is possible even if the boiler is currently replaced.

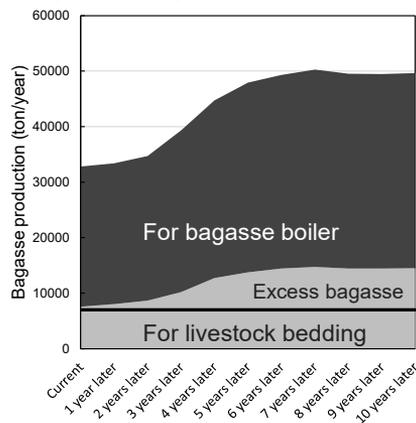

Figure 3 Change in bagasse amount in 10 years

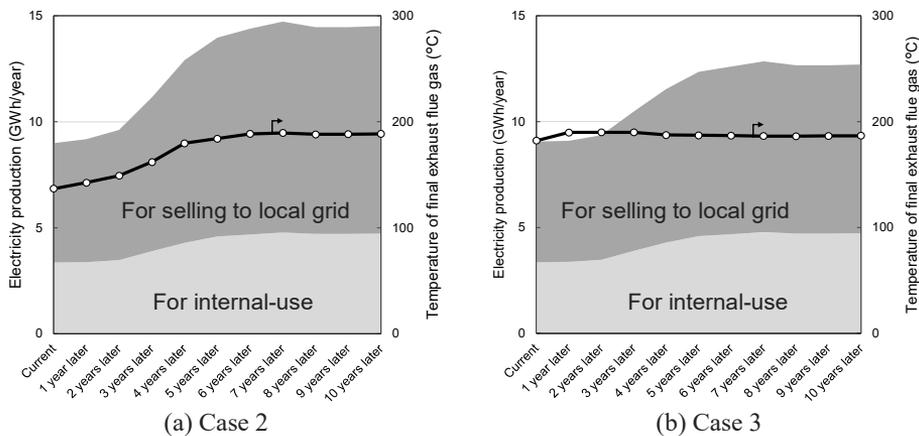

Figure 4 Change in balance between internal-use and selling electricity

4. Conclusion

In this study, a process flow model of a sugar mill was incorporated into an integrating model of agricultural-industrial process, and an electricity selling process using the excess thermal energy of sugarcane bagasse combustion associated with the introduction and diffusion of a new high-yielding cultivar was investigated. It was found that the bagasse, which is estimated to be unprocessable with the current facilities after 10 years from now, can be effectively utilized by introducing a high-pressure steam turbine and a process for selling electricity to the local community. In addition, by constructing a process flow model that takes into account the size of the heat transfer area of the boiler, it is possible to construct a strategy for the timing and scale of the replacement of the bagasse boiler based on the constraints of the flue gas temperature.

Abstract

Solar cell manufacturing is based on solar grade silicon which can be obtained using Silane as precursor instead of Trichlorosilane in the well-known Siemen's process. The silane production can be done in a reactive distillation (RD) column in which reaction and separation take place simultaneously. The typical RD column has one reactive section, but in a recent work (Zang et al., 2017) it has been shown that an RD column with multiple reactive sections can enhance the internal mass integration and/or energy interaction between the reactions and the separation of Silane. Therefore, this work aims to optimize an RD column for silane production with up to three reaction sections. The number and location of the reactive sections are found after solving a proposed global stochastic optimization framework based on a modified Simulated Annealing Algorithm. The results show that the increase in the number of reactive sections does not necessarily mean and reduction in the cost of the process.

Keywords: Silane, Global stochastic optimization, Reactive Distillation, Process Intensification

1. Introduction

Silane is produced by three simultaneous disproportionation reactions of Trichlorosilane (SiHCl_3). These reactions have a rather unfavorable reaction kinetics and a thermodynamic conversion close to zero. Therefore, this process can be intensified by means of a reactive distillation (RD) column where the reactions and the separation of Silane are carried out simultaneously.

The most important process to obtain Solar-grade Silicon (SoG-Si) is the Siemens process, accounting for approximately 90% of worldwide polysilicon production (Bye and Ceccaroli, 2014) while the second most widely used commercial process, accounting for almost all non-Siemens technology-based production, utilizes the thermal decomposition of Silane (SiH_4) through a pyrolysis reaction in fluidized bed reactors (FBR) (Yadav et al., 2017).

The FBR method has the following advantages: 1) low production cost, 2) low energy consumption, and 3) high productivity. This method can reduce the energy consumption per unit mass of Silicon from the 40–60 kW h/kg (Mongstad et al., 2016) of the Siemens

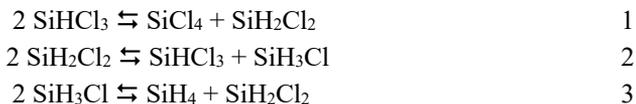

process to 5–8 kW h/kg (Tejero-Ezpeleta et al., 2004) for the silane pyrolysis step. Thus, the energy-saving and pollutants discharge reduction may generate a tremendous social and economic benefit (Zhang et al., 2018).

RD can overcome the chemical equilibrium limitation and separate Silane continuously. Thus, RD and intensified process for Silane production. The typical RD column feeds SiHCl_3 as raw material and generates Silane as the top product and Tetrachlorosilane (SiCl_4) as the bottom byproduct (Huang et al., 2013). However, Zang et al. (2017) studied an RD column with multiple reaction sections. Their results showed that three reaction sections attained higher condenser and reboiler duty savings. Thus, they claimed that the use of multiple reaction sections is a better intensification alternative for the RD column. This work proposes a rigorous global stochastic optimization framework that uses a modified Simulated Annealing Algorithm (m-SAA) in which integer optimization variables (e.g., number of stages, number and location of reactive stages) are treated more effectively to avoid unnecessary continuous relaxations of variables. Moreover, the proposed framework can find the number and locations of reactive sections without any prespecified structural constraint.

2. Methodology

2.1. Case study

An RD column for the production of Silane and Tetrachlorosilane from a feed containing Trichlorosilane was studied as shown in Figure 1a. Intermediate components are Monochlorosilane (SiH_3Cl) a Dichlorosilane (SiH_2Cl_2) respectively. The feed and product specifications are shown in Table 1. The kinetic parameters to model the disproportionation reactions in Eqs. 1 to 3 were taken from Huang et al. (2013). Also, the Peng Robinson model was used to estimate the vapor-liquid equilibrium relationships. The simulations were done in the Aspen Plus V11.0 simulation software, and the built-in block RADFRAC was used. Finally, the number of reactive sections ranges between one and three as previously considered by Zang et al. (2017) for the sake of comparison.

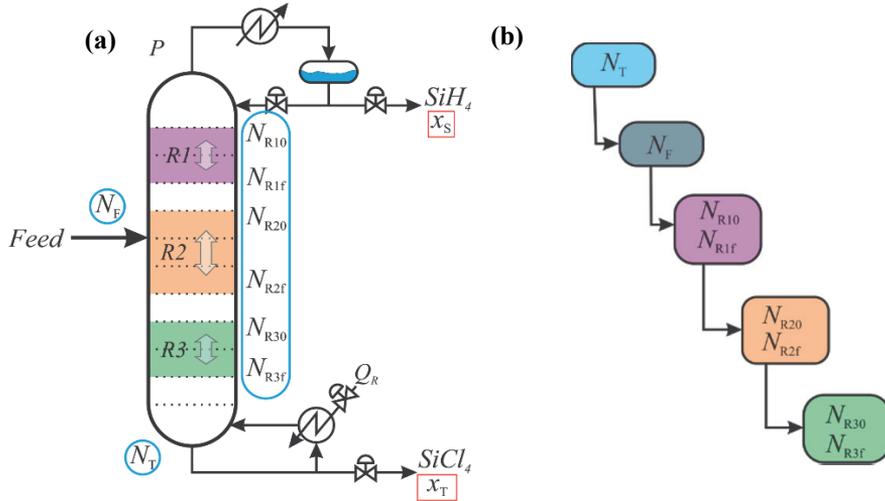

Figure 1. Reactive distillation column: (a) design variables, (b) sequential evaluations

N_T and N_F are the number of total stages and feed stage, respectively. N_{R10} , N_{R20} , and N_{R30} are the top stages for the first, second, and third reactive section, while N_{R1f} , N_{R2f} , and N_{R3f} are those for the bottom stages, respectively. x_S and x_T are the SiH_4 and SiCl_4 purities at the RD column top and bottom, respectively.

Table 1. Feed and product specifications for the RD column

Variable	Value
SiHCl_3 feed flow rate (kmol/h)	10
Pressure (atm)	5.0
Pressure drop (kPa)	0.5
SiH_4 purity (%mol)	99.3
SiCl_4 purity (% mol)	99.0

2.2. Mathematical treatment

The minimization of the total annual cost (TAC) was performed. The optimization variables are those related to N_T and the locations of N_F , N_{R10} , N_{R20} , N_{R30} , N_{R1f} , N_{R2f} , and N_{R3f} as shown in Eq.4. It is worth to mention that the operating variables such as reflux and reboiler duty were calculated by the build-in *design specification* and *vary* features of the module RADFRAC. Therefore, the optimization was solely done in terms of structural, integer variables.

$$\min(TAC) = f(N_T, N_F, N_{R10}, N_{R1f}, N_{R20}, N_{R2f}, N_{R30}, N_{R3f}) \quad 4$$

subject to Eq. 5

$$\vec{y}_i \geq \vec{x}_i \quad 5$$

where \vec{y}_i is the vector for the calculated purities for each component i and \vec{x}_i is the purity assigned target.

The optimization was carried out by a modified Simulated Annealing Algorithm (m-SAA) capable of handling integer variables in a more effective way than their typical continuous relaxation (Cabrera-Ruiz et al., 2021). The m-SAA was programmed in the Spyder platform (Spyder, 2021), which is a free and open-source scientific environment written in Python, mainly because it is free access and open-source software that has been gaining great interest by scientists and engineers in recent years. Also, it offers direct connectivity with the simulation software Aspen Plus. Thus, the optimization-simulation interface was done as shown in Figure 2.

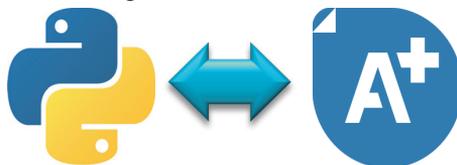

Figure 2. Optimization-simulation software interface

This work considers that the bounds of optimization variables change dynamically as the problem is being solved to handle the number of reactive sections and their locations. Thus, the variable bounds are expressed in terms of optimization variables as shown in Table 2. It was possible to assign these bounds on the random variables in the m-SAA by performing a normalization of variables between 0 and 1 as shown in Eq. 6. The generated values by the m-SAA take a normalized value (\bar{x}_i) and the actual value can then be calculated since the upper bounds (UL_i) and lower bounds (LL_i) are known despite they change dynamically. Furthermore, the values of those bounds depend sequentially on the result of the previous variable as shown in Fig. 1b. This strategy also offers the advantage of avoiding the generation of infeasible design points and the redundancy in terms of iterations for the calculation of new points due to design constraints (Cabrera-Ruiz et al., 2021).

Table 2. Optimization variables

Variable	Optimization bounds
N_T	[20,50]
N_F	[2, $N_T - 1$]
N_{R10}	[2, $N_T - 3$]
N_{R1f}	[N_{R10} , $N_T - 3$]
N_{R20}	[$N_{R1f} + 1$, $N_T - 2$]
N_{R2f}	[N_{R20} , $N_T - 2$]
N_{R30}	[$N_{R2f} + 1$, $N_T - 1$]
N_{R3f}	[N_{R30} , $N_T - 1$]

The solution procedure to find RD columns with multiple reaction sections is shown in Fig. 4a.

$$\bar{x}_i = \frac{UL_i - x_i}{UL_i - LL_i} \quad 6$$

The TAC was calculated using the Guthrie method (Turton et al., 2018) with a payback time of 5 years using the CEPCI value corresponding to the one for 2019. The cost of utilities was taken from Seider et al. (2009).

3. Results and Discussion

The solution of the m-SAA showed short computation time and few iterations compared to a traditional stochastic optimization in a software interface, proving that the normalization of variables offered an advantage not only in computational terms but also in the handling of dynamic bounds on optimization variables.

Figure 4b shows the optimization results of several solutions. Different designs are shown because their TAC values are very similar. Equation 7 shows the TAC average value and its standard deviation. It becomes clear that it is possible to obtain different designs with a similar cost.

$$\overline{TAC} = \$144,481.56 \pm 150.32 \quad 7$$

It also can be observed that in terms of TAC, there is not a significant improvement towards the selection of three reactive zones because the second solution from left to right in Fig. 4b has only one reactive zone, the one in the middle has two reactive zones, while the rest have three reactive sections. Nevertheless, the solutions with three reactive sections have one or two stages between them. Therefore, it is not completely clear if the increase of reactive sections attains better solutions. The existence of one equilibrium stage between reactive sections can be due in part to the rounding of the continuous variables that is used in all stochastic algorithms (Cabrera-Ruiz et al., 2021). In general, the variables that remain almost the same in all solutions are N_T and N_{R10} while N_F tends to be located near the top of the column.

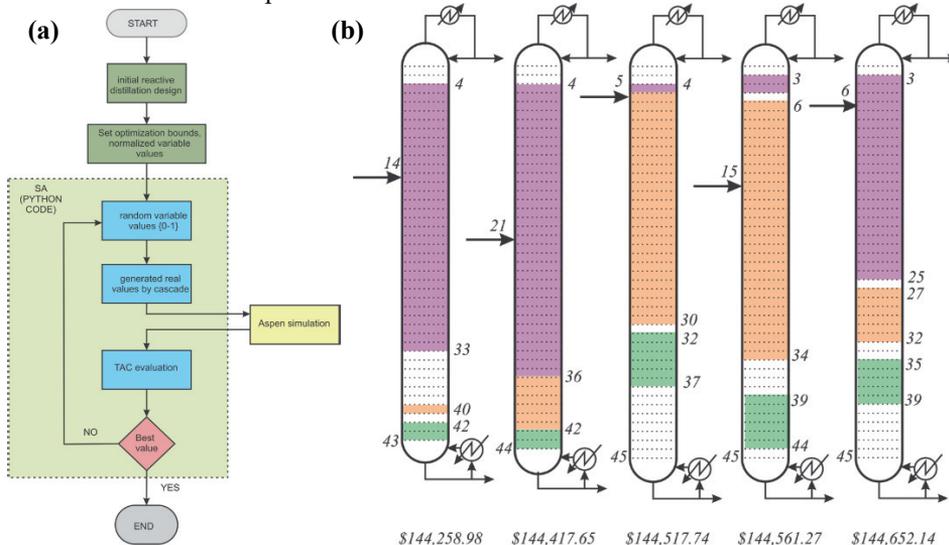

Figure 4. (a) Solution procedure for a general RD column, (b) optimization results

4. Conclusions

In this work, a global stochastic optimization framework was proposed for the economic minimization of an RD column with the possibility of having up to three reactive sections. The selection of lower and upper bounds for the reactive sections was done dynamically through a normalization of the optimization variables. The proposed m-SAA performed satisfactorily showing great flexibility and capability for handling integer variables

dynamically. The results showed that there are multiple solutions with similar cost despite the number of reactive sections. It was observed that one to two reactive zones are favored sometimes. Therefore, the selection of three reactive sections was not remarkably superior. Therefore, it is imperative to perform further optimizations considering alternative objective functions.

Abstract

This paper proposes a nonlinear multiscale mathematical model for age-structured proliferating and quiescent cell populations (PDEs) coupled with cell cycle protein dynamics (ODEs). The model assumes a bidirectional transition between the proliferating and quiescent subpopulations. The coupling between the two scales is introduced based on biological findings inherited from the literature. Numerical simulations are performed using the finite volume method to examine the impact of parameters on the nonlinear dynamics of the model. The main focus of this paper is to investigate the balance between proliferating and quiescent cell populations, which play a crucial role in maintaining homeostasis in a cell population.

Keywords: Multiscale model, Tumor growth, Population dynamics

1. Introduction

The cells subject to division can be categorized into two compartments, i.e., proliferating and quiescent cells. Proliferating cells undergo division by passing through various stages of cell division cycle (G_1, S, G_2, M). However, quiescent cells neither grow nor divide but either transit to the proliferative compartment or stay in the G_0 phase until differentiation or death. The switching of the cells between proliferating and quiescent phases thus plays a crucial role in maintaining tissue homeostasis. In fact, any disturbance in the transitional balance between proliferating and quiescent phases results in an unconditional growth in tumoral tissue, van Velthoven and Rando (2019). The switching mechanism, however, depends on cell signaling molecules representing growth or anti-growth factors, Heldt et al. (2018). In this paper, we focus on modeling and analyzing the dynamics of cell population distributed in proliferating and quiescent phases coupled with cell cycle protein dynamics. The motivation stems from recent experimental outcomes, see Hartwell and Kastan (1994), which state that the cyclins are the most determinant control molecules in cell cycle phase transitions. Therefore, we couple the cell cycle protein dynamics to predict the transitional balance between proliferating and quiescent populations at macroscale, which is critical to homeostasis. At microscale, various proteins are expressed but for the sake of simplicity, we consider only four proteins (Cyclin D/CDK 4-6, E2F, p21 and Rb) which are mainly contributing in G_1 to S phase transition. We further assume at microscale that the molecular interactions are happening in a fast renewing cell population and not in an individual cell. Therefore, the molecular concentrations of these proteins act only as averaged concentrations in a subpopulation without accounting for cell-cell variability. The overall aim of this paper is to analyse the role of Cyclin D/CDK 4-6 complex in the deregulation of transitional balance between proliferative and quiescent cell compartments, which can eventually lead to an unlimited tumor growth.

2. Mathematical model

We consider two predominant scales comprising of cell populations and subcellular protein dynamics. The macroscale is characterised by age-structured partial differential equations to model cell population in quiescent and proliferating phases. Whereas, sub-cellular protein interactions involved in cell cycle dynamics are modeled using ordinary differential equations. Here age refers to biological clock of the cell in the cell cycle phases. The two scales are coupled via feedback in both directions. The schematics of the model is shown in Figure 1.

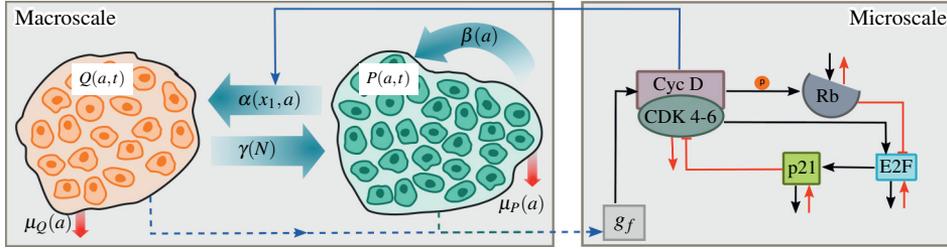

Figure 1: Schematics of the model.

2.1. Physiologically structured model

The macroscale level comprising of quiescent $Q(a,t)$ and proliferating $P(a,t)$ cell populations is described by transport type nonlinear hyperbolic partial differential equations (PDEs) which describe the number densities of the cells with respect to their physiological age a and time t :

$$\begin{cases} \frac{\partial}{\partial t} Q(a,t) = \alpha(x_1,a)P(a,t) - (\gamma(N) + \mu_Q(a))Q(a,t), \\ \frac{\partial}{\partial t} P(a,t) + \frac{\partial}{\partial a} (g(a)P(a,t)) = \gamma(N)Q(a,t) - (\beta(a) + \alpha(x_1,a) + \mu_P(a))P(a,t). \end{cases} \quad (1)$$

The first term on the right side of Eq. (1)a is the influx from the proliferative compartment by the rate function $\alpha(x_1,a)$ which is regulated by a microscale state, i.e., Cyclin D/CDK 4-6 complex x_1 . The second term describes the decrement in cell density due to either transitioning back to proliferating phase with the recruitment function $\gamma(N)$ or by cell death due to the apoptosis (or necrosis) with death rate $\mu_Q(a)$. In Eq. (1)b, $g(a)$ denotes the evolution speed of age a with respect to time t . The first term on the right side is the influx from the quiescent phase. The second term represents the number of cells completing the cell division with rate function $\beta(a)$, whereas the cells transitioning from the proliferating phase to quiescent phase without undergoing division are denoted by the third term. Finally, the death rate $\mu_P(a)$ represents the loss of cells in proliferating phase. The function $N(t)$, represents the total cell number in proliferating and quiescent phases, is defined as $N(t) = \int_0^{a^*} (P(a,t) + Q(a,t)) da$, where a^* represents the maximum age of cells.

To complete the model, we define the initial conditions at $t = 0$ as $Q(a,0) = Q_0(a)$, $P(a,0) = P_0(a)$, $\forall a \geq 0$. The boundary condition for $t > 0$ takes the form: $g(0)P(0,t) = 2 \int_0^{a^*} \beta(a)P(a,t) da$, where the number 2 represents two newborn cells which start with age 0 in the proliferating phase. The recruitment function $\gamma(N)$ is described using a Hill function $\gamma(N) = \frac{\nu \theta^\kappa}{\theta^\kappa + N^\kappa}$, where κ is the Hill coefficient, ν is the maximum transition rate and θ defines the total cell population achieving the half maximum of the transition rate ν . The rate function $\beta(a)$ is given as $\beta(a) = \rho_1 a^{\gamma_1} / (\rho_2^{\gamma_1} + a^{\gamma_1})$, where, ρ_1 represents the maximum proliferation rate, ρ_2 is the value of age achieving the half maximum effect and γ_1 is the Hill coefficient. Finally, the rate function α given as $\alpha(x_1,a) = \sigma_1 \cdot \sigma_2^{\gamma_2} / (\sigma_2^{\gamma_2} + x_1^{\gamma_2}) \cdot \sigma_3^{\gamma_3} / (\sigma_3^{\gamma_3} + a^{\gamma_3})$, determines the number of cells which cannot undergo division due to anti-growth factors. Here, γ_2 and γ_3 are Hill coefficients, σ_2 and σ_3 are the switching values of Cyclin D/CDK 4-6 complex and age a beyond which the rate function α becomes effectively

zero, preventing escape to quiescence. This implies that at age equals to σ_3 , the cell population is irreversibly committed to proceed into the proliferative phase. The value of σ_2 is the threshold of Cyclin D/CDK 4-6 complex determining the restriction point R. In the signaling mechanism among the cells, the growth response is modulated by the cytokine proteins, the details are given in Batool and Bajcinca (2021b,a). Thereby, the growth factors are defined as $g_f = 1/(1 + k_f N)$.

2.2. Cell cycle model

We employ Michaelis-Menten kinetics to explain the series of enzymatic reactions in the form of ODEs. The list of selected proteins and their description is given in the Table 1. Given the evolution speed of age a with respect to time t as $g := da/dt$, the dynamics of the cell cycle with respect to age a is then described by the following system, Gérard and Goldbeter (2012):

$$\begin{cases} \frac{dx_1}{da} = \frac{1}{g(a)} \left(k_{1s} \left(\frac{g_f}{k_{gf} + g_f} \right) - k_{14} x_4 x_1 - k_{1d} \left(\frac{x_1}{k_1 + x_1} \right) \right), \\ \frac{dx_2}{da} = \frac{1}{g(a)} \left(k_{21} \left(\frac{x_{2t} - x_2}{k_2 + (x_{2t} - x_2)} \right) x_1 - k_{32} x_2 x_3 - k_{2d} x_2 \right), \\ \frac{dx_3}{da} = \frac{1}{g(a)} \left(k_{3s} - k_{32} x_2 x_3 - k_{31} \left(\frac{x_3}{k_3 + x_3} \right) x_1 - k_{3d} x_3 \right), \\ \frac{dx_4}{da} = \frac{1}{g(a)} \left(k_{4s} + k_{42} \left(\frac{k_{34}}{k_{34} + x_3} \right) x_2 - k_{41} \left(\frac{x_4}{k_4 + x_4} \right) x_1 - k_{4d} x_4 \right). \end{cases} \quad (2)$$

Description	State
Cyclin D/CDK 4-6	x_1
E2F	x_2
Rb	x_3
p21	x_4

Table 1: Cell cycle states at microscale.

Param.	Description	Value	Unit
k_{1s}	Rate constant for synthesis of x_1 induced by growth factors g_f	0.175	h^{-1}
k_{gf}	Michaelis constant for synthesis of the x_1 induced by g_f	0.1	μM
k_{14}	Bimolecular rate constant for binding of cyclin D/CDK4-6 to p21	0.15	$\mu M^{-1} h^{-1}$
k_{1d}	Maximum degradation rate of cyclin D/CDK4-6	0.245	$\mu M h^{-1}$
k_1	Michaelis constant for the degradation of Cyclin D/CDK4-6	0.1	μM
k_{21}	Rate constant for activation of E2F by cyclin D/CDK4-6	0.805	h^{-1}
k_2	Michaelis constant for E2F activation by cyclin D/CDK4-6	0.01	μM
x_{2t}	Total concentration of the transcription factor E2F	2	μM
k_{32}	Bimolecular rate constant for binding of Rb to E2F	0.01	$\mu M^{-1} h^{-1}$
k_{2d}	Apparent first-order rate constant for non-specific E2F degradation	0.02	h^{-1}
k_{3s}	Basal rate of synthesis of Rb	0.8	h^{-1}
k_{31}	Rate constant for phosphorylation of Rb by cyclin D/CDK4-6	2.2	h^{-1}
k_3	Michaelis constant for Rb phosphorylation by cyclin D/CDK4-6	0.1	μM
k_{3d}	Apparent first-order rate constant for Rb degradation	0.01	h^{-1}
k_{4s}	Basal, E2F-independent rate of synthesis of p21	0.8	$\mu M h^{-1}$
k_{42}	Rate constant for synthesis of p21 induced by E2F	0.1	h^{-1}
k_{34}	Constant of inhibition by Rb of p21 synthesis	0.1	μM
k_{41}	Rate constant for inactivation of p21 through phosphorylation by x_1	50	h^{-1}
k_4	Michaelis constant for p21 phosphorylation by Cyclin D/CDK 4-6	0.5	μM
k_{4d}	Apparent first-order rate constant for non-specific p21 degradation	0.06	h^{-1}

Table 2: Parameters of cell cycle model.

In Eq. (2)a, the first term on right hand side describes the synthesis of Cyclin D/CDK 4-6 complex (x_1) induced by the growth factors g_f . The last two terms describe the binding of x_1 with tumor suppressor protein p21 and the degradation rate induced by other cell cycle proteins. In Eq. (2)b, first term on right side describes the synthesis of transcription factors E2F (x_2) induced by x_1 . The

second term denotes the decrement of x_2 due to inhibition by retinoblastoma protein Rb, while the last term depicts a constant inactivation rate of x_2 . In Eq. (2)c, the first term on right side represents the synthesis of free un-phosphorylated retinoblastoma protein Rb (x_3). The second term denotes the decline in Rb by making a complex with x_2 to inhibit it. The third term refers to deactivation of Rb by phosphorylation from x_1 and the last one to the degradation of Rb. In Eq. (2)d, the first and second term represent the synthesis of p21 (x_4) by ATM/ATR, TGF β pathways and by x_2 , respectively. The third and fourth term represent the decrement in p21 due to inhibition of x_1 and the degradation of p21. The description of the involved parameters is given in Table 2.

3. Numerical solution

In this section, we present the numerical method used to solve the system (1)-(2) in MATLAB. Finite volume method (FVM) is implemented using central upwind discretization scheme, Kuzmin (2010). Hereby, we introduce the following notations: Δa is mesh size and Δt is the time step, $\Delta a = a^*/N_a$, where N_a is a maximum number of age nodes given by $a_i = i\Delta a$, $0 \leq i \leq N_a$ and time is discretized into N_t steps with equidistant interval $\Delta t = t^{k+1} - t^k$. The computational mesh is shown in the Figure 2, where the domain is divided into many control volumes (for instance, the one highlighted in green) and we approximate the integral conservation law on each control volume. The red arrows are pointing the flux through the boundary of the control volume where the flux \mathcal{F} is computed at each grid point using central upwind scheme as schematically depicted with yellow boxes for $k = 2$ at $i = 2, 3$ with the green arrows. In the sequel, we describe the discretized model and fluxes. The discretized cell densities of quiescent cells associated with the i^{th} spatial interval at time k reads

$$P_i^k = \frac{1}{\Delta a} \int_{a_{i-\frac{1}{2}}}^{a_{i+\frac{1}{2}}} P(a, t^k) da, \quad Q_i^k = \frac{1}{\Delta a} \int_{a_{i-\frac{1}{2}}}^{a_{i+\frac{1}{2}}} Q(a, t^k) da.$$

The necessary Courant-Friedrichs-Lewy (CFL) condition for convergence of the solution requires

$$\left. \begin{aligned} & \Delta t [\gamma^k + \max(\mu_Q(a_i))] \\ & \Delta t \left[\frac{\max(g(a_i))}{\Delta a} + \max(\alpha(x_{1,i}^k, a_i) + \beta(a_i)) \right] \end{aligned} \right\} \leq 1.$$

The initial conditions for Q_i^0 and P_i^0 are defined below

$$Q_i^0 = \frac{1}{\Delta a} \int_{a_{i-\frac{1}{2}}}^{a_{i+\frac{1}{2}}} (a, t^0) da, \quad P_i^0 = \frac{1}{\Delta a} \int_{a_{i-\frac{1}{2}}}^{a_{i+\frac{1}{2}}} P(a, t^0) da.$$

Next, the discretized form of the PDEs (1) are given as

$$\begin{aligned} Q_i^{k+1} - Q_i^k &= \Delta t \alpha(x_{1,i}^k, a_i) P_i^k - \Delta t (\gamma^k + \mu_Q(a_i)) Q_i^k, \\ P_i^{k+1} - P_i^k - \frac{\Delta t}{\Delta a} (\mathcal{F}_{i+1/2}^k - \mathcal{F}_{i-1/2}^k) &= \Delta t \gamma^k Q_i^k \\ &\quad - \Delta t (\alpha(x_{1,i}^k, a_i) + \beta(a_i) + \mu_P(a_i)), \end{aligned}$$

```

where $\gamma^k = \gamma(N^k)$ and $N^k = \Delta a \sum_i [Q_i^k + P_i^k]$. The fluxes represented by \mathcal{F} are defined using central upwind scheme as $\mathcal{F}_{i+1/2}^k = g(a_{i+1/2})P_{i-1}^k$. The cell division boundary condition at age $a = 0$ reads $g(a_0)P_0^{k+1} = 2\Delta a \sum_{i=1}^{a^*} \beta(a_i)P_i^k$. Then, we define the growth factors as $g_f = 1/(1 + k_f N^k)$. We have used ode45 function of MATLAB to solve cell cycle model at each time step k . The resulting outcome of Cyclin D/CDK 4-6 complex $x_{1,i}^k$ is then used in the macroscale model.

4. Results and discussion

In this section, we present the numerical results of the model proposed in Section 2. The initial states and the used parameters are given in Table 2 and 3. In all the simulations, we used the spatial step size $\Delta a = 0.5$ with a maximum age of cells $a^* = 50$ and the time step $\Delta t = 0.02$. In the sequel, we will discuss two case studies. First, we investigate the stability of the non-trivial steady-state solutions. Figure 3(a) and (b) represent the cell density distribution of proliferating $P(a,t)$ and quiescent $Q(a,t)$ cells, respectively. Both subpopulations show the trends of achieving a steady-state with time. The growth factors influence the behavior of Cyclin D/CDK 4-6 complex as depicted in Figure 3(c). The total cell count is initially low (see Figure 4(a)) while the growth factors are at their maximum (see Figure 4(b)), which results in the proper activation and degradation of cyclin D/CDK 4-6 complex along with the age of the cell. The latter depicts a complete cell cycle or successful division of cells on average. However, as the growth factors decline to a point where no (or fewer) new cells are required, the average behavior of Cyclin D/CDK 4-6 complex in proliferating cells also exhibit non-oscillatory dynamics, and it remains at lower concentration throughout, which is a depiction of no cell divisions, see Figure 4(c). In Figure 4(a), we plot the total cell population $N(t)$ comprised of proliferating, and quiescent phases exhibit an exponential increase in cell number and ultimately achieve a steady-state. On the other hand, Figure 4(b) shows the growth factors influenced by total cell population are maximum initially due to low cell count and gradually start declining until achieving an equilibrium. The transition rate $\gamma(N)$ from quiescent to proliferating phase is depicted in Figure 4(c). The increase in the total cell population invokes a decrement in the transition from quiescent to proliferating phase.

Param.	Value
ν	0.6 day^{-1}
θ	0.095×10^6
κ	1
ρ_1	0.7
ρ_2	0.35
γ_1	5
σ_1	0.01
σ_2	0.35
σ_3	14 h
γ_2	7
γ_3	7
k_f	1.80×10^{-9}

Table 3: Parameters used in the simulations.

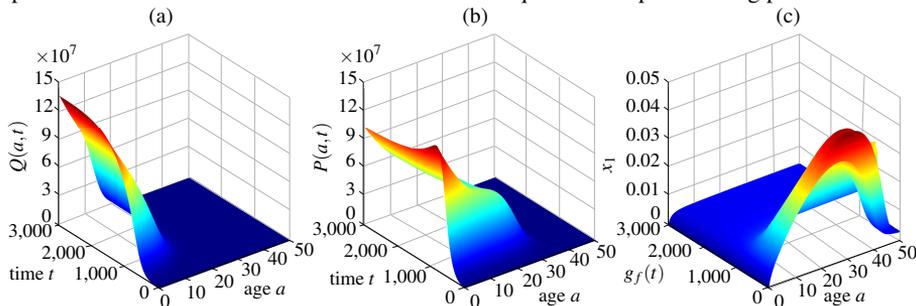

Figure 3: Density distribution of (a) proliferating cell population and (b) quiescent cell population with respect to age a and time t . (c) Concentration of Cyclin D/CDK 4-6 complex x_1 .

Next, we investigate the instability of the solution in Figure 5. The dynamics of the proposed model is very robust in general due to the feedback loops. However, the transition function $\alpha(a, x_1)$ is sensitive concerning noise in the cell cycle states. Here, to analyze a situation in which the cell cycle behaves abnormally, we changed a parameter value, i.e., $k_{gf} = 0.0001$, which depicts that the influence of the growth factors on the production of Cyclin D/CDK 4-6 complex is somehow compromised, or in other words, we are inducing delays in completing a Cyclin D/CDK 4-6

complex oscillation. Resultantly, the cell number grows exponentially due to more cells in proliferative compartment as compared to quiescent phase. All other parameters used in this case study are similar to the first case of non-trivial steady-states. The total cell number is plotted in Figure 5 (a). It grows exponentially in the presence of a larger amount of growth factors, see Figure 5 (b).

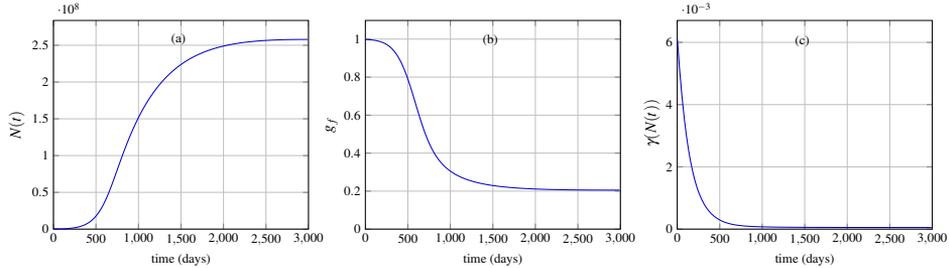

Figure 4: Steady state. (a) Total cell population $N(t)$. (b) Growth factors g_f . (c) Gamma function γ representing the rate at which the cells move back to proliferation phase from quiescent phase.

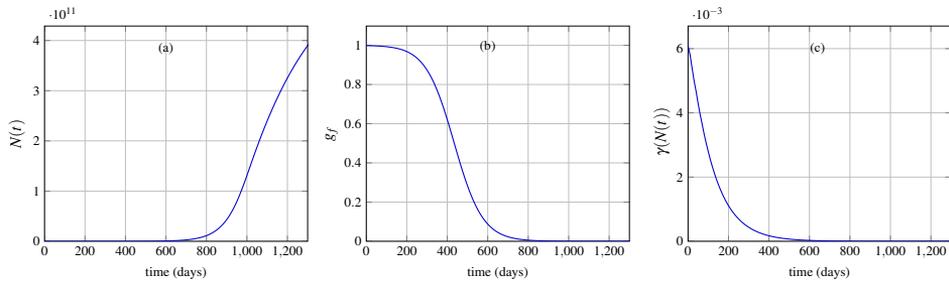

Figure 5: Exponential growth. (a) Total cell population. (b) Growth factors. (c) Gamma function.

5. Conclusion

This paper proposes a nonlinear, multiscale model of an age-structured population of proliferating and quiescent cells coupled with an averaged cell cycle dynamics which plays a crucial role in the cell's commitment for irreversible cell division. There exists a bi-directional transition between the two populations. The closed feedback loop couples the two scales and further aids in keeping the overall growth of the cells in homeostasis. We investigated the role of the complex formed by Cyclin D with its inhibitor CDK 4-6 in the bi-directional transition, and we concluded that an imbalance in this transition could result in tumor initiation and progression.

Abstract

An optimization model for the food supply chain is presented. This model is formulated as a Mixed Integer Linear Programming (MILP) problem and optimizes the land distribution, the amount and types of food produced, imported and exported, the number of livestock, the greenhouse gas emissions, the nitrogen uptake, the amount of food waste, etc. The production technologies considered are conventional, organic, conservation agriculture and food production in greenhouses. The requirements of the European Green Agreement and the Farm-to-Fork Strategy are considered. The model was applied to optimize different scenarios in the food chain in Slovenia, such as population growth and changing dietary habits, and to optimize different objectives, such as food self-sufficiency, greenhouse gas emissions, nitrogen balance, economic efficiency and a multicriteria objective. The results show that food supply could be improved through optimization even with the expected population growth. Greenhouse gas emissions and synthetic fertilizer use could be reduced. The results of the model can provide a guide for the development of agricultural policies for sustainable supply of locally produced food.

Keywords: food chain, locally produced food, optimization, MILP, multi-objective.

1. Introduction

The food supply chain is a complex system that includes the production of agricultural crops and animals, their processing into food, the distribution and consumption of food, and the collection and processing of waste. The agricultural sector is one of the main sources of environmental impacts and is accompanied by a number of uncertainties (Zirngast et al., 2019). In rapidly developing countries, the negative impact of agriculture on the environment increases as the food security of the population improves (Qi et al., 2018). The objectives of reducing greenhouse gas emissions, the use of artificial fertilizers, nitrogen inputs, the preservation of biodiversity, etc. must be taken into account (European Commission, 2019). Therefore, systematic methods need to be applied to optimize the efficient use of available agricultural land, as demonstrated in the case of Estonia (Põldaru et al., 2018) and in the case of the Milan metropolitan region, where changes in land use and dietary habits were assessed through linear programming (Sali et al., 2016). Optimization has also been applied to accurately determine nutritionally adequate meals, considering environmental impacts and economic aspects (Benvenuti et al., 2021).

This paper presents a MILP model for optimizing food production of plant and animal origin on available arable land in Slovenia. The novelty of the model is that it considers

a balance between production, consumption, import and export of food, considers different technologies of food production and incorporates the requirements of European and national directives. The optimization is performed for several single objectives and as a multi-objective problem by combining the most important indicators.

2. Mathematical model for food supply optimization

The cultivation land for distribution is constrained by Eq. (1):

$$\sum_i \sum_k A_{i,k} \leq A_{TOT} \quad (1)$$

where i is a set of food and feed of plant origin, k set of cultivation technologies (e.g. conventional, organic, conservation, greenhouses), A area (ha), A_{TOT} total available arable land (ha). Production of food and feed of plant origin is defined as:

$$mpp_{i,k} = A_{i,k} \cdot yha_{i,k} \quad (2)$$

where mpp is a mass of plant food produced (t/y), yha hectare yield (t/(ha·y)). Balance for food and feed of plant origin is as follows:

$$\sum_k mpp_{i,k} + mpi_i = mpc_i + mpe_i + \sum_k mpl_{i,k} \quad (3)$$

where mpi and mpe are masses of imported and exported plant food (t/y), mpc consumed plant food (t/y), mpl lost plant food (t/y). According to the statistical definition, the domestic production of food of animal origin is defined as:

$$map_j = NZS_j \cdot mcrcS_j + NZE_j \cdot mcrcE_j - NZI_j \cdot mcrcI_j \quad (4)$$

where j is a set of food of animal origin (e.g. beef, pork, poultry, milk, eggs), map a mass of domestically produced food of animal origin (t/y), NZS , NZE and NZI are numbers of livestock slaughtered domestically, exported or imported (y^{-1}), $mcrcS$, $mcrcE$, $mcrcI$ are carcass masses per slaughtered, exported and imported animal (t). For milk and eggs, NZS represents the number of dairy cows or laying hens, and $mcrcS$ represents yearly milk or egg production per animal. For milk and eggs, $mcrcE$ and $mcrcI$ are equal to 0.

Balance of food of animal origin is given by Eq. (5):

$$mac_j + mae_j + mal_j = \sum_j NZS_j \cdot mcrcS_j + mai_j \quad (5)$$

where mac is a total mass of consumed food of animal origin (t/y), mai , mae and mal imported, exported and lost food products of animal origin (t/y), respectively.

Consumption of plant fodder for animals:

$$mpc_{ia} = \sum_j map_j \cdot fconv_{ia,j} \quad (6)$$

where ia is a subset of plants used for animal fodder, $fconv$ is a specific mass of consumed plant fodder in tons of plant fed per ton of carcass. Greenhouse gas emission is estimated as follows:

$$mghg = \sum_i \sum_k mpp_{i,k} \cdot fghg_{i,k} + \sum_j map_j \cdot fghg_j \quad (7)$$

where $mghg$ mass of greenhouse gas emission (t CO_{2eq}/y), $fghg$ specific emission per mass of food (t CO_{2eq} per ton of food). The amount of mineral fertilizers used is calculated:

$$mmf = \sum_i \sum_k A_{i,k} \cdot mfer_{i,k} \quad (8)$$

where mmf is total mass of mineral fertilizers used (t/y) and $mfer$ mass of mineral fertilizers used (t/(ha·y)). Nitrogen balance is presented in Eq. 9:

$$mnit = \sum_j map_j \cdot fnit_j + mmf \cdot wnit - \sum_i \sum_k A_{i,k} \cdot mnup_{i,k} \quad (9)$$

where $mnit$ is a mass of nitrogen (t N/y), $fnit$ specific nitrogen emission from livestock manure (t of N per ton of carcass), $wnit$ mass fraction of nitrogen in synthetic fertilizers, $mnup$ nitrogen uptake by plants (t N/(ha·y)). Economic added value (€/y) is defined as:

$$\begin{aligned} value = & \sum_i mpc_i \cdot ppd_i - \sum_i \sum_k mpp_{i,k} \cdot cpd_{i,k} + \sum_j mac_j \cdot pad_j - \sum_j map_j \cdot cad_j + \\ & \sum_i mpe_i \cdot ppe_i + \sum_j (NZE_j \cdot mcrcE_j + mae_j) \cdot pae_j - \sum_i mpi_i \cdot ppi_i - \\ & \sum_j (NZI_j \cdot mcrcI_j + mai_j) \cdot pai_j \end{aligned} \quad (10)$$

where ppd and pad are prices of food of plant and animal origin at domestic market (€/t), ppe and pae prices of exported food (€/t), ppi and pai prices of imported food (€/t), cpd production cost of plant food/feed (€/t), cad production cost of food of animal origin (€/t). Self-sufficiency for food for human is calculated by Eq. (11):

$$SS_{hum} = \left(\sum_{ih} \sum_k mpp_{ih,k} + \sum_j map_j \right) / \left(\sum_{ih} mpc_{ih} + \sum_j mac_j \right) \quad (11)$$

where ih is a subset of plants used for human food. A set of logical relations is used for the exclusive choice between food import and export:

$$\begin{aligned} ypi_i + ype_i &\leq 1 & mpi_i &\leq MB \cdot ypi_i & mae_j &\leq MB \cdot yae_j \\ yai_j + yae_j &\leq 1 & mpe_i &\leq MB \cdot ype_i & NZI_j &\leq MB \cdot yNZI_j \\ yNZI_j + yNZE_j &\leq 1 & mai_j &\leq MB \cdot yai_j & NZE_j &\leq MB \cdot yNZE_j \end{aligned} \quad (12)$$

where ypi and ype are binary variables for imported and exported plant food/feed, yai and yae binary variables for imported and exported food of animal origin, $yNZI$ and $yNZE$ for imported and exported livestock. MB is a large positive constant.

The basic objective function is formulated as the total mass of food and fodder produced:

$$Z = \max \left(\sum_i \sum_k mpp_{i,k} + \sum_j map_j \right) \quad (13)$$

where Z (t/y) represents a domestic production of food of plant and animal origin. In addition, other objective functions can be optimized, namely maximizing economic value, minimizing greenhouse gas emissions, and minimizing excess nitrogen from mineral and organic fertilizers. A normalized multi-objective function was also formulated to account for multiple conflicting criteria.

$$Z_{multi} = \max \left(\frac{value}{value^0} + \frac{SS_{hum}}{SS_{hum}^0} - \frac{mghg}{mghg^0} - \frac{mmf}{mmf^0} \right) \quad (14)$$

where subscript 0 represents the current value of specific variable. The list of variables in the model is as follows:

$$A_{i,k}, mpp_{i,k}, mpc_i, mpi_i, mpe_i, mpl_{i,k}, NZD_j, NZI_j, NZE_j, map_j, mac_j, mai_j, mae_j, mal_j, mghg, mnit, SS_{hum}, value \geq 0; \quad ypi_i, ype_i, yai_j, yae_j, yNZI_j, yNZE_j \in \{0,1\}$$

3. Slovenian case study

The developed model was used to optimize the distribution of arable land in the Republic of Slovenia, which has about 2 million inhabitants and 460,000 ha at its disposal.

3.1. Scenarios of various changes in food supply chain

The first part of the experiments dealt with scenarios that considered projected population growth, legal directives, and health recommendations.

Scenario 1. Population growth. It was estimated (Drofenik et al., 2021) that the population could increase by 9 % by 2050, which will affect food demand, so all further scenarios were also optimized for this forecast.

Scenario 2. Reduction of fertilizer use. The European Farm-to-Fork Strategy foresees a reduction in fertilizer use of at least 20 % by 2030. Therefore, the upper limit for fertilizer use has been set at 80 % of current levels.

Scenario 3. Proportion of land devoted to organic farming. The 2030 Agenda for Sustainable Development envisages an increase in the share of agricultural land used for organic farming to 25 %. In Slovenia, this share is currently 7.7 %. Therefore, the requirement to increase this share was included in the model.

Scenario 4: Healthier diet. Per capita consumption of red meat in Slovenia is significantly higher than the European average. The consumption of red meat should be reduced. In this scenario it was assumed that the per capita consumption of beef and pork would decrease by 30 %.

3.2. Optimization of the various objectives

In the second part, optimizations of various single objective functions and a composite criterion for multi-objective optimization were performed.

Scenario 5. Greenhouse Gas Emissions. Agriculture is an important source of GHG emissions. Therefore, the criterion in Eq. (7) was minimized to estimate the target potential for reducing emissions from the agricultural sector.

Scenario 6. Surplus in the nitrogen balance. Nitrogen input from animal manure and synthetic fertilizers often exceeds the nitrogen uptake that plants take from the soil for growth, which is an environmental problem. Therefore, the criterion $mnit$ defined in Eq. (9) was minimized to balance out the surplus of nitrogen.

Scenario 7. Added economic value. Although the main objective is to ensure an adequate supply of quality food, the food supply chain is also an economically important system. The economic value defined in Eq. (10) has therefore been maximized.

Scenario 8. Self-sufficiency. Maximizing food self-sufficiency as defined in Eq. (11) is the most important criterion for formulating national food policy.

Scenario 9. Multi-objective optimization. Many important factors for the agricultural sector have conflicting effects on food supply chain optimization. Therefore, a multi-objective optimization of the composite objective function of the four most important criteria defined in Eq. (14) was performed.

4. Results

The results of the first set of optimizations are shown in Table 1. All values of Z_{multi} are positive, indicating an improvement over the current situation. In scenario 1, self-sufficiency increases despite a projected increase in population. This is the effect of an optimized distribution of land and food produced compared to the current situation, which is not optimized. The area devoted to human food production increases significantly. Vegetable production in greenhouses increases and is even exported.

Table 1: Results of scenarios

	Unit	Current	Scenario 1	Scenario 2	Scenario 3	Scenario 4
Added value	M€/y	443.7	499.8	496.8	451.8	482.6
GHG emission	kt/y	1,464	1,493	1,456	1,180	1,342
Nitrogen balance	t/y	1,565	11,866	11,855	6,159	2,510
Synthetic fertilizers	t/y	87,613	107,349	70,091	67,359	98,570
Total self-sufficiency	%	86.1	101.9	99.8	96.7	103.1
Self-sufficiency human	%	80.9	102.9	96.6	94.8	111.4
Area for human food	ha	60,129	101,116	93,726	90,584	105,516
Area for animal feed	ha	402,877	361,890	369,280	372,422	357,490
Area (conventional)	ha	427,155	456,592	263,681	340,841	456,592
Area (organic)	ha	35,651	0	0	115,752	0
Area (conservation)	ha	0	0	192,911	0	0
Area (greenhouses)	ha	200	6,414	6,414	6,414	6,414
Z _{multi}	%	0.0	15.3	51.8	61.4	42.2

A requirement for a 20 % reduction in fertilizer use (scenario 2) leads to the introduction of conservation agriculture with lower fertilizer use but almost the same yields per hectare as conventional production. The requirement of 25 % of the land dedicated to organic production (scenario 3) leads to a significant reduction in the economic criterion. The level of self-sufficiency decreases compared to the previous scenarios. Imports of plant and animal foods increase. A 30 % reduction in red meat consumption (scenario 4) would have several positive impacts, increasing self-sufficiency while decreasing emissions and excess nitrogen inputs. The production of plant foods for human consumption would increase significantly. Necessary imports of animals and meat products would decrease, and value added would increase.

The results of the optimizations for different objectives are shown in Table 2. Minimizing GHG emissions (scenario 5) provides a solution in which GHG emissions are 33 % lower than at present, but the economy and self-sufficiency deteriorate. The lower emissions are achieved by switching a significant part of production from conventional to organic and conservation agriculture with lower fertilizer use.

Table 2: Results of various objective functions

	Unit	Scenario 5	Scenario 6	Scenario 7	Scenario 8	Scenario 9
Added value	M€/y	431.2	448.1	511.4	472.5	451.4
GHG emission	kt/y	1,085	1,187	1,495	1,221	1,143
Nitrogen balance	t/y	5,163	0	17,832	6,894	6,587
Synthetic fertilizers	t/y	44,626	92,826	110,155	109,166	46,309
Total self-sufficiency	%	82.6	93.6	90.3	96.8	92.9
Self-sufficiency human	%	81.3	85.8	100.1	120.1	108.7
Area for human food	ha	125,727	88,277	90,584	144,954	131,840
Area for animal feed	ha	337,279	374,729	372,422	318,052	331,166
Area (conventional)	ha	179,285	459,265	456,592	456,003	179,285
Area (organic)	ha	129,942	0	0	0	76,593
Area (conservation)	ha	153,779	0	0	590	200,714
Area (greenhouses)	ha	0	3,741	6,414	6,414	6,414
Z _{multi}	%	72.7	18.9	11.1	46.9	105.2

Minimizing nitrogen surplus (scenario 6) offers a solution with an ideal balance between nitrogen supply and uptake, but also lower economic value added. A solution with maximum economic value (scenario 7) has high self-sufficiency, but also higher GHG emissions and excess nitrogen. Many animals and vegetables are produced, which are also exported. Maximizing self-sufficiency (scenario 8) achieves 120 % food self-sufficiency for people, and excess food could be exported. Optimization with a composite objective function (scenario 9) yields a compromise solution in which 21 % of the land is devoted to organic agriculture. GHG emissions would be 25 % lower and fertilizer use 53 % lower than at present, while food self-sufficiency would be over 100 %.

5. Conclusions

A MILP food supply chain optimization model was developed. The model determines the optimal distribution of arable land, crops, livestock and meat production. Besides, it considers the requirements of various European and national directives regarding the environmental and social impacts of agriculture, while the main motivation is to increase the food security through stable production of safe, quality and accessible food, and to shorten the supply chain taking into consideration CO₂ emissions that could be avoided. The results point out the need to promote a shift from intensive meat production, especially cattle, to grass-based production, and to change people's diets from meat and meat products to a greater proportion of vegetables. Promoting organic farming and other unconventional forms of agriculture is another driver for reducing the environmental impact of agricultural production. The consideration of multiple criteria in the optimization suggests a favorable trade-off solution, confirming the need for multi-objective decision-making in guiding national agricultural policy. The assumptions set in the strategies can have a strong impact on the results in the different scenarios. The sensitivity of these assumptions will be explored in future work, which will include options for food waste reduction and processing, and nutritional information about foods.

Abstract

Carbon capture and storage (CCS) is one of the most efficient techniques for reducing carbon dioxide (CO₂) emissions into the atmosphere. Combining CCS with enhanced oil recovery (EOR) processes is a very attractive method for carbon capture and utilisation (CCU). These operations enable CO₂ emissions to be reduced through geological sequestration, whilst generating additional revenue from enhanced oil production due to CO₂ re-injection via EOR. In practice, mass balance and temporal features of a given location are considered when planning EOR operations. When numerous oil reservoirs are involved, it is vital to allocate available CO₂ supplies and schedule EOR operations for these reservoirs at suitable timings. As a result, CO₂ allocation and scheduling are crucial for maximising the economic benefits of EOR operations. As such, this study introduces a resource trade scheme for CO₂ integration and utilisation within the state Qatar, where a mixed integer linear programming (MILP) model is developed to address CO₂ allocation and scheduling based on environmental and economic objectives. The model considers a single CO₂ source (Qatar Gas) within an multi sink scenario which includes several sinks within an industrial setting (QAFCO, QAFAC, PEARL GTL, ORYX GTL, Dukhan Field Well (EOR)). Two scenarios are considered to allocate CO₂ to different sinks (including EOR) to obtain the optimal solution for each scenario. The outcome of scenario 1 demonstrates that the optimal solution is to utilize 13.5Mt/y of carbon dioxide, which results in an annual profit varying from 14.3 to 42.8 billion US dollars. The maximum CO₂ utilisation occurs at Dukhan Field Well (EOR), which utilises up to 67%. Scenario 2 is implemented based on scenario 1 to further improve the model; where the profit increased annually, and the model became more sustainable.

Keywords: Sustainability, CO₂ utilisation, carbon capture and storage, EOR

1. Introduction

The allocation of carbon dioxide (CO₂) emissions is critical in defining reduction responsibilities at the national level or emission permits at the company level. Different techniques for calculating CO₂ emissions have been developed and applied throughout the last few decades. Various approaches could be used in order to reduce carbon dioxide emissions, among the most notable examples are increased energy efficiency by system integration, the adoption of energy saving technologies, carbon storage and sequestration, as well as fuel switching and renewable energy sources. Many studies have focused on the use of renewable and clean energy sources, carbon capture and storage (CCS), and

energy efficiency, yet minimal research has been published on methods for systematically investigating carbon utilisation approaches. Carbon dioxide can be converted chemically or biologically into fuel, food supplements, polymers, or other value-added products. (Mikkelsen *et al.*, 2010). Furthermore, in the case of enhanced oil recovery (EOR), storing CO₂ underground may provide financial incentives to reduce emissions (Hasan *et al.*, 2014). Injecting CO₂ into reservoirs for EOR is the only commercially recognized carbon usage method that allows permanent large-scale storage for captured CO₂ (Núñez-López *et al.*; Moskal *et al.* 2019). This study aims to design a framework allocation model between a single CO₂ source and several sinks based in the State of Qatar and evaluating a network design for carbon capture, storage, utilisation and transportation. A multi-period mathematical optimization is used that considers varying marketing prices of value-added products to determine the optimal solution in the model's revenue and utilisation target.

2. Literature Review

In the context of increased oil recovery and storage sinks, steps and mechanisms related to the allocation of carbon have been previously investigated. Turk *et al.* (1987) was able to provide a framework of sources particularly improved oil recovery sites, power plants and sinks, while taking into account the injection and transportation costs by the use of a nonlinear mathematical model. In addition, Middleton and Bielicki (2009) studied the supply and allocation of carbon dioxide. The study used the MILP spatial model, which addresses carbon capture and storage facilities. Weihs and Wiley (2012) also investigated the cost-optimal for CO₂. The transport of carbon dioxide in various phases was studied by Knoope *et al.* (2013), while He *et al.* and Tan *et al.* (2013) investigated the storage of multiphase carbon. Tan *et al.* (2013) used the source and sink approach for carbon capture and storage, capacity and injection. He *et al.* (2013) used the addressed the uncertainties of source-to-sink matching, where elements of physical and time limitations were integrated in a MILP to address the allocation of CO₂. The formulation focused mainly on the geological storage of sinks and attempted to optimise CO₂ storage by one source connected to a sink, relying on the flow and storage capacity. Hasan *et al.* (2014) analysed the matching of enhanced oil recovery sinks at a national level considering a wide network of CO₂ supply chains that selected the appropriate capture technology for various CO₂ sources and used geographical sites and transportation of pipelines. Alhajaj *et al.* (2013) applied the same approach at a regional level in the UAE.

3. Model Design and Optimisation

3.1. Available data and assumptions

The framework structure in this study consists of a single CO₂ source, Qatar gas (QG), since it is the world's largest LNG producer, with an annual CO₂ emissions of 35.8 Mt/year approximately (Mohammed, 2016), and six application sinks: (a) Qatar Fertiliser Company (QAFCO) and Qatar Fuel Additives Company (QAFAC) located south of Qatar in Mesaieed industrial zone (approximately 100 km from QG), (b) Dukhan Field Well (EOR) located west of Qatar in Dukhan City (approximately 100 km from QG); and

(c) Pearl GTL and Oryx GTL plants located north of Qatar in the Ras Laffan industrial zone (approximately 5 km and 3 km from QG) (Al-Yaeshi et al., 2020).

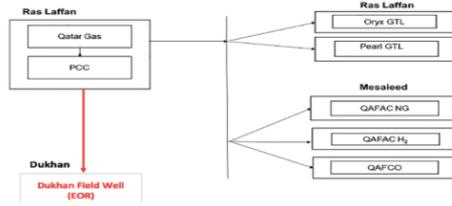

Figure 1: Framework design for CO₂ allocation.

Table 1 presents the products of each sink with their production rates when utilising 1 tonne of CO₂. Chemical absorption with amine solvents was anticipated to capture CO₂ at 100% efficiency, with an OPEX of \$ 40/t CO₂ (Al-Yaeshi et al., 2020), while maintaining its stability as a CO₂ source. In this model, a set amount of 15 Mt CO₂/year is assumed to be captured and sent to sinks reliably. The CCU is estimated to invest \$169 million on CAPEX. Post combustion carbon capture technology (PCC) is utilised due to its high level of commercial availability and technology development. Therefore, in the case of Qatar, PCC technology is considered to be extremely viable for absorbing CO₂ from power plants and other industrial operations. It provides a highly reliable CO₂ source, despite its higher cost compared to alternative capture technologies. Furthermore, the CO₂ composition of flue gas available in Qatar is less than 5%, which meets PCC technology standards (Herzog and Golomb, 2004). In this model, the PCC unit is placed in Qatar Gas LNG plant since it has the highest CO₂ emissions in Qatar (35.8Mt/y) compared to other plants (Mohammed, 2016).

Table 1: Production Rate of each sink for one tonne of CO₂.

Sink	Product	Production rate (tonne of product/tonne of CO ₂)	Reference
QAFAC CH ₄	Methanol	3	(Al-Yaeshi et al., 2020)
QAFAC O	Urea	1.35	(Al-Yaeshi et al., 2020)
QAFAC H ₂	Methanol	5.9	(Al-Yaeshi et al., 2020)
ORYX GTL	Wax, Diesel, and Gasoline	0.884	(Al-Yaeshi et al., 2020)
Pearl GTL	Wax, Diesel, and Gasoline	0.884	(Al-Yaeshi et al., 2020)
EOR	Oil	0.2	(Li and Abushaikha, 2021)

3.2. Model Formulation

The mixed integer linear programming (MILP) model is developed to address the optimal CO₂ allocation from Qatar gas to QAFAC, Pearl GTL, ORYX GTL, QAFAC with H₂, QAFAC with natural gas, and Dukhan Field Well for EOR. This model determines the allocation of CO₂ as a function of commodity price variability which essentially directs the optimal CO₂ allocation from the source to the sinks. The data is collected over a period of 15-year (Al-Yaeshi et al., 2020). This time period is chosen since it is frequently symbolic of the life planning/cycle phase of a CO₂ utilisation project, for which the model tries to identify allocations that optimize the network's long-term economic returns. Table 1 presents the products of each sink with their production rates when utilising 1 tonne of CO₂. The objective is to identify a feasible design solution for allocating CO₂ between the source and sinks that maximises the system's overall cost over multiple periods. Economic returns and technical capacities of sink applications are the main constraints addressed in the model.

Model Formulation

Maximise

$$\sum_{j=1}^n [R_j - C_j] x_j Q_{total}$$

Subject to
$$\sum_{j=1}^n x_j Q_{total} \leq Q_j$$

$$\sum_{j=1}^n x_j \leq 1$$

Where;
$$C_j = C_{cc} + \sum_{j=1}^n (C_{transport} + C_{OPEX j}) \quad n = 1,2 \dots, 6$$

R_j= revenue

C_j= cost for pcc, transport, opex

X_j= fractional amount allocated to sink j

Q_{total}= total amount 15MT/year

Q_j= Sink j capacity

n= number of sinks

4. Results and Discussion

The proposed methodology is used to implement the model's outcomes using the Excel LP optimisation solver. Two scenarios are implemented in this study: (1) a base case scenario for allocating CO₂ from the source to the sinks depending on the sinks capacity; and (2) a scenario that focuses on testing different EOR features by reducing the amount of CO₂ allocated in different years. *Scenario 1* is a base case scenario which aims to determine the optimal solution for allocating 15MT/year of CO₂ to all 6 sinks. The maximum CO₂ utilization, number of sinks, and revenue are included in the solution. According to the findings, the market prices of the products are one of the key drivers of the techno-economic optimization. As a result, the CO₂ utilisation findings in Table 2 remained constant between years 2005 and 2018 for the optimized sinks. This is due to the price linkage between products, which causes them to shift together, except for wax, since the price remained constant from 2011 to 2018 (Al-Yaeshi et al., 2020).

Table 2: The profile for CCU system for period 2005 to 2018.

Years	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016	2017	2018
Profit \$ (x10 ¹⁰)	1.76	2.43	2.19	3.47	1.87	2.87	3.64	4.15	4.28	4.07	2.08	1.43	2.25	2.47
CO ₂ Utilisation (x10 ⁶)	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35	1.35

The CO₂ utilisation of the system is 13.5x10⁶ tonne/year, which implies that the captured amount of CO₂ from Qatar Gas (15x10⁶ tonne/year) is not fully utilised by the sinks. The allocation throughout the years is relatively in the same range. Some changes or fluctuations in the results from one year to another may be due to product prices fluctuations each year. As shown in Figure 2, the optimal allocation solution is to allocate 67% (9Mt/y) of CO₂ to Dukhan Field Well, which is a very high percentage compared to other sinks. This could be due to the high commodity prices, high production rate, low transportation cost, or lower CAPEX and OPEX compared to other sinks which directly affects the economic measure of the system.

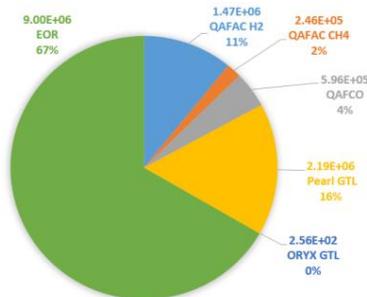

Figure 2: Average CO₂ utilisation by the sinks.

In **Scenario 2**, a simulation using **QASR Reservoir Simulator** (Li and Abushaikha, 2021) is made to examine the natural drive production of oil and CO₂ in Dukhan Field Well (without injecting CO₂ into the reservoir) and the production after CO₂ injection. The natural drive production normally produces a low percentage of the oil inside the reservoir (10 -15%). When CO₂ gas is injected to the reservoir, this can improve the overall oil displacement efficiency it and drives it to the production wellbore, which results in the recovery of a higher percentage of the original oil in place (Massarweh and Abushaikha, 2021). Therefore, different scenarios were conducted in order to examine the reservoirs production in the primary drivee production (no CO₂ injection), when injecting 9Mt of CO₂, and 15Mt of CO₂. Based on this simulation, it is observed that more oil can be produced with CO₂ injection as compared to natural drive production. Figure 3 and 4 illustrates the oil and gas production rate when injecting different CO₂ values. As illustrated in the figures, as the injection rate increases, more production is achieved. This is because the oil greatly inflated as it combined with CO₂ gas, resulting in decreased interfacial tension and viscosity; which results in higher oil and gas recovery.

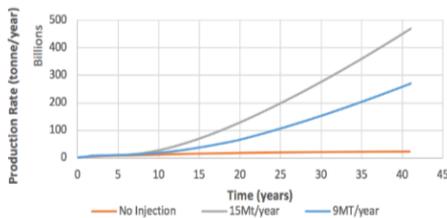

Figure 3: Cumulative Gas Production Rate.

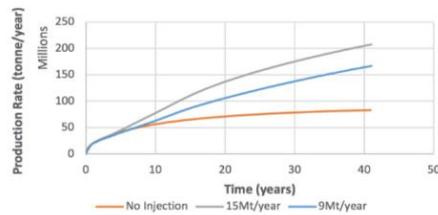

Figure 4: Cumulative Oil Production Rate.

Furthermore, since injecting CO₂ results in producing more CO₂, a sensitivity analysis was made in order to improve the overall system by reinjecting the CO₂ recovered after injection (non-sequestered CO₂) back into the reservoir. By doing so, the required CO₂ amount from Qatar gas each year decreases depending on the production rate in the previous injection (assuming the allocation for all other sinks stay the same). Therefore, in this scenario, it is assumed that Qatargas will allocate 100% of the capacity required for EOR for the first 5 years (9Mt/y) only. Subsequently, this rate will begin to decrease gradually depending on the amount of CO₂ required in this reservoir (see figure 6). Overtime, the allocated CO₂ keeps decreasing until Qatar gas stops allocating CO₂ to EOR since Dukhan Field will have enough “recovered after injection CO₂” from the previous allocations. This scenario improves the sustainability and profit of the system by reducing the amount of CO₂ purchased from Qatar gas annually. As shown in Figure 5, Qatar gas will stop allocating CO₂ to Dukhan Field Well at almost year 21. When comparing the profit from scenario 1 and scenario 2 (Figure 6), it is observed that the profit is constant till year 2010, then, scenario 2’s profit increases further due to the decrease in CO₂ amount allocated.

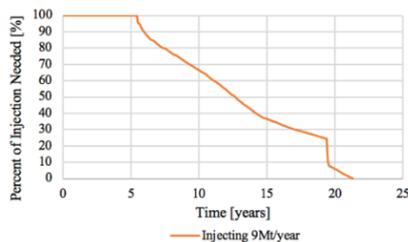

Figure 5: CO₂ utilisation scenario 2.

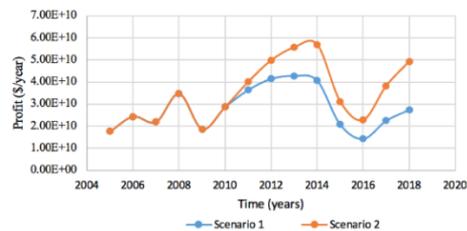

Figure 6: Profit comparison Scenario 1 & 2.

5. Conclusion

The results obtained in this study for both scenarios aims to devise the most effective means for eliminating, reducing, and converting carbon dioxide emissions into a revenue-generating stream. Mixed integer linear programming (MILP) model is used to address CO₂ allocation. The model considers a single CO₂ source (Qatargas) with multiple sinks that use CO₂ as raw material for their production. Two scenarios are considered to allocate CO₂ to different sinks (including EOR) to obtain the optimal solution for each scenario. The outcomes of scenario 1 illustrate that using 13.5 million tonnes of carbon dioxide per year is the best option, with annual profits ranging from 14.3 to 42.8 billion dollars. Dukhan Field Well (EOR) has the highest carbon dioxide utilisation rate, with up to 67 %. Scenario 2 was applied to develop the model further, with the profit increasing annually and the model becoming more sustainable.

Optimal operation of an evaporator for the controlled production of titania nanoparticles

Filippo Tamagnini^a and Sebastian Engell^a

^a*TU Dortmund University, Biochemical and Chemical Engineering, Process Dynamics and operations Group, Emil-Figge-Straße 70, 44227 Dortmund, Germany*
filippo.tamagnini@tu-dortmund.de

Abstract

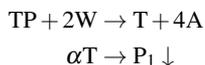

Titania nanoparticles are an important building block for materials with photocatalytic activity or specific optical properties. The production via the hydrolysis of an alcoxide precursor involves a distillation step which is needed to control the final particle size but is time consuming and energy-intensive. The concern of this paper is the optimization of the production process by optimizing the trajectory of a batch evaporator with the goal of maximizing its energy efficiency under predefined production constraints. Depending on the goals, significant reductions in energy consumption are possible, while simultaneously reducing the total processing time. Furthermore, in the situation where electricity from intermittent renewable sources is available, it is possible to tailor the operation of the process to leverage this availability by adapting the input sequence, such that the most energy-intensive phases of the process are performed in the window where energy is available from renewable sources, hence producing a positive economic and environmental impact.

Keywords: trajectory optimization, batch evaporation, titanium dioxide nanoparticles

1. Introduction

Titania nanoparticles have gained attention due to their optical properties, which find application in a very broad range of fields (Ijaz and Zafar (2021)), including photocatalytic materials. The light absorbance properties of nanoparticles depend on the material as well as on their geometrical parameters (Bohren and Huffman (1998)), thus making good control over the production process necessary to fine-tune the photoactivity of the final product.

The synthesis considered here involves the hydrolysis of a titanium precursor (TP) in water (W) to yield dissolved titanium dioxide (T) as well as an alcoholic byproduct (A). Following the hydrolysis, α titanium dioxide units condense to form primary particles (P_1):

The nanoparticles population evolves due to aggregation and breakage towards an equilibrium Particle Size Distribution (PSD). The particle size can be described in terms of the number of primary units in a nanoparticle and in terms of the particle diameter. The first description is useful to model the evolution of the system, the second is used to define measurable goals for the product characteristics. The particle diameter is measured using Dynamic Light Scattering (DLS), which measures the so called Z–Average Particle Size (ZAPS). The typical evolution of the ZAPS during the process is shown in the first plot of figure 1.

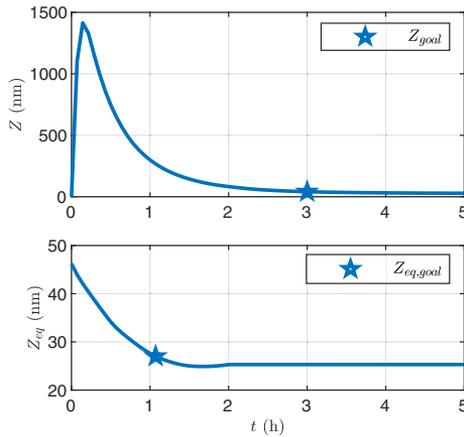

Figure 1: Evolution of the ZAPS and equilibrium ZAPS during the distillation. The times when the product constraints are met are marked with stars in the plot.

find the optimal mode of operation of the batch evaporator that minimizes a measure of cost (processing time, energy consumption or environmental/economic cost) while satisfying the final product constraints. In the optimization, energy can have a time-varying price, e.g. because it is sourced from intermittent renewables, and it is assumed that this availability can be forecasted.

2. Modelling

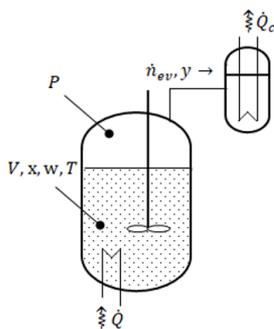

Figure 2: Setup of the plant

Aggregation is a second order process that is limited by the diffusion of the particles through the liquid medium and by the interparticle repulsion (Bal and Bandyopadhyaya (2018)). Alcohols decrease the interparticle repulsion, hence increasing the particle size obtained at equilibrium (Paradisi et al. (2021)). Breakage on the other hand follows first order kinetics and is mainly temperature-driven (Vorkapic and Matsoukas (1999)).

To obtain small nanoparticles sizes, a distillation step is required. The distillation is performed under vacuum, with the power supplied to the system, \dot{Q} and the vacuum pressure, P being the manipulated variables. The setup is shown in figure 2. Heat is supplied through an electric heater, while pressure is controlled through a condenser (also operated electrically). The process is terminated when the particle population has reached the desired size characteristics and the particle size that results at equilibrium after a ripening process is sufficiently small. The goal of this work is to

The state of the system is described by the number of moles of the chemical species n_A, n_W, n_T (alcohol, water and titanium dioxide) and the temperature of the liquid (T). An additional state variable $s \in [0, 1]$ is introduced to describe the normalized fraction of alcohol in the solvation layer of the nanoparticles. Quantities such as the liquid volume $V = (n_A M_A + n_W M_W + n_T M_T) / \rho$, the alcohol fraction in the liquid $x = n_A / (n_A + n_W)$ and the mass fraction of titania $w = \frac{n_T M_T}{\rho V}$ can be computed from the state of the system.

The evolution of the amount of the species is described by their mole balances as shown in eq. 1, where \dot{n}_{ev} is the molar evaporation rate and y the mole fraction of alcohol in the vapor stream in equilibrium with the liquid. The evolution of s , as shown in eq. 2 is a diffusion process driven by the difference between the alcohol fraction in the solvation layer of the particles and the corresponding equilibrium value $K_c x$. The temperature T results from an energy balance (eq. 3) as a function of the heat input \dot{Q} to the system and the heat losses due to evaporation. Constant enthalpy of vaporization H_v and molar heat capacity C_p are used. The evaporation rate is written as a function of the pressure difference between liquid and vapor $\dot{n}_{ev} = k_{ev} \max(P_{ev} - P; 0)$, with k_{ev} a fitting parameter and P_{ev} the equilibrium pressure of the liquid mixture computed using the extended Raoult's law (Wilson model). The heat to be removed by the condenser is $\dot{Q}_c = \dot{n}_{ev} (H_v + C_p (T - T_c))$.

$$\frac{d}{dt} \begin{pmatrix} n_A & n_W & n_T \end{pmatrix}^T = -\dot{n}_{ev} \begin{pmatrix} y & 1-y & 0 \end{pmatrix}^T \quad (1)$$

$$\frac{ds}{dt} = -k_c(s - K_c x) \quad (2)$$

$$\frac{dT}{dt} = \frac{\dot{Q} - \dot{n}_{ev} H_v}{(n_A + n_W + n_T) C_P} \quad (3)$$

The evolution of the population of the nanoparticles is described using a direct moment-based method (Hulburt and Katz (1964)). The k -th moment of the PSD $N_{p,m}$ is defined as $\mu_k = \sum_{m=1}^{\infty} m^k N_{p,m}$. The first moment is directly related to the total number of moles of T as $\mu_1 = \frac{N_A n_T}{\alpha}$, with N_A Avogadro's constant and α the number of T units per primary particle. The dynamics of the k -th moment and the corresponding equilibrium values are given in equations 4-5, where k_a and k_b are the aggregation and breakage rate constants (assumed to be independent of the particle sizes), ϕ_k the k -th moment of the breakage distribution function and, with M_X the molar mass of X and ρ the density of the liquid.

$$\frac{d\mu_k}{dt} = \frac{k_a}{V^2} \left(\frac{1}{2} \sum_{n=0}^k \binom{k}{n} \mu_k \mu_{k-n} - \mu_0 \mu_k \right) + \frac{k_b}{V} \mu_k (\phi_k - 1) \quad (4)$$

$$\frac{\mu_{k,eq}}{V} = \frac{1}{2} \frac{k_a}{k_b} \frac{1}{1 - \phi_k} \sum_{n=1}^{k-1} \binom{k}{n} \frac{\mu_{n,ss}}{V} \frac{\mu_{k-n,ss}}{V} \quad (5)$$

According to the theory of Brownian aggregation, the aggregation process depends linearly on temperature (Lyklema (1991)). Furthermore, it depends on the electrostatic potential between the approaching particles' surfaces, which is strongly influenced by the fraction of alcohol in their solvation layers (Vorkapic and Matsoukas (1998)). A semi-empirical model was used to describe this dependency, with x_a a parameter obtained by fitting steady state particle size-alcohol fraction data. The breakage kinetic constant only depends on temperature with an Arrhenius-like dependency. The choice of the reference temperature T_{ab} in the denominator of (6) is arbitrary, however by using the same temperature for both the aggregation and breakage kinetic constants, T_{ab} is the temperature where the ratio k_a/k_b is at its minimum for a given alcohol fraction. T_{ab} will be used in the optimization as a terminal constraint, as it results in the minimum ZAPS at equilibrium.

$$k_a = k_{a,T_{ab}} \frac{T}{T_{ab}} e^{\left(\frac{k_a s}{k_c x_a}\right)^2} \quad (6)$$

$$k_b = k_{b,T_{ab}} e^{1 - \frac{T}{T_{ab}}} \quad (7)$$

The breakage distribution moments are expressed as a function of the parameter $r \in (0, 1)$ by assuming that a particle of size 1 breaks into fragments of size nr and $n(1-r)$ (Marchisio et al. (2003)):

$$\phi_k = r^k + (1-r)^k. \quad (8)$$

The Z-average diameter of the particles as measured by a DLS instrument is expressed as $Z = Z_0 \left(\frac{\mu_4}{\mu_3}\right)^{\frac{1}{\gamma}}$, with Z_0 the measured diameter of a primary particle and $\gamma \sim 1.9$ the fractal dimension of the particles. The third moment weighted average is used to approximate the weighting behaviour of light scattering instruments (Stetefeld et al. (2016)). $Z_{eq} = Z_0 \left(\frac{\mu_{4,eq}}{\mu_{3,eq}}\right)^{\frac{1}{\gamma}}$ denotes the

measurement obtained from the equilibrium PSD. An important observation is that the moments of the equilibrium PSD in eq. 5 ultimately depend on w , x and T , therefore it is possible to write $Z_{eq} = Z_{eq}(x, w, T)$. During the course of the distillation, the value of Z_{ss} initially decreases due to the depletion of alcohol until a minimum is reached. Past this point, the increase in weight fraction determines an increase in the obtainable particle size, as visible in the second plot of figure 1.

3. Optimization

The optimization problem is formulated in equations 9-18, with respect to the state vector $x(t) = (n_A(t), n_W(t), n_T(t), s(t), T(t), \mu_0(t), \dots, \mu_4(t))^T$ and the input vector $u = (\dot{Q}(t), P(t))^T$:

$$\min_{u(t)} J_n[u(t)] \quad (9)$$

$$s.t. : \quad \frac{dx(t)}{dt} = f(x(t), u(t)) \quad \forall 0 \leq t \leq t_{max} \quad (10)$$

$$x(0) = x_0 \quad (11)$$

$$0 \leq \dot{Q}_c(t) \leq \dot{Q}_{c,max} \quad \forall 0 \leq t \leq t_{max} \quad (12)$$

$$0 \leq \dot{Q}(t) \leq \dot{Q}_{max} \quad \forall 0 \leq t \leq t_{max} \quad (13)$$

$$P_{min} \leq P(t) \leq P_{max} \quad \forall 0 \leq t \leq t_{max} \quad (14)$$

$$Z(t_{max}) \leq Z_{goal} \quad (15)$$

$$Z_{eq}(t_{max}) = Z_{eq,goal} \quad (16)$$

$$T(t_{max}) = T_{ab} \quad (17)$$

$$J_1 \leq t_{max}. \quad (18)$$

Three cost functions are defined: the duration of the process J_1 , the total energy use J_2 and the energy cost J_3 :

$$J_1[u(t)] = \min t \text{ such that: } (Z(t) \leq Z_{goal}) \text{ and } (Z_{eq}(t) \leq Z_{eq}) \text{ and } (T(t) = T_{ab}) \quad (19)$$

$$J_2[u(t)] = \int_0^{t_{max}} \dot{Q}(t) + \frac{\dot{Q}_c(t)}{COP} dt \quad (20)$$

$$J_3[u(t)] = \int_0^{t_{max}} p(t) \left(\dot{Q}(t) + \frac{\dot{Q}_c(t)}{COP} \right) dt. \quad (21)$$

where the Boolean variable $p(t) \in \{0, 1\}$ denotes the energy price (economic or environmental, e.g.: $\text{kg}_{\text{CO}_2}/\text{kW}$) at time t and $\frac{\dot{Q}_c(t)}{COP}$ the electrical power consumed by the condenser. This definition of the energy price is used to simplify the formulation of the problem. In reality, $p(t)$ is a real number varying between a minimum and a maximum. Therefore, the cost function J_3 is more accurately the cost incurred by not buying energy at the lowest price.

The function $f(x(t), u(t))$ is the vector of the right hand sides from equations 1-4. The initial conditions of the system are fixed prior to the optimization from the product recipe and stoichiometry. The particulate system is initialized as a point distribution with $\mu_k(0) = \mu_1 = \frac{N_{AB}V_T}{\alpha}$, $s(0) = 1$ and $T(0) = 30^\circ\text{C}$. The input variables and the heat removed by the condenser have minimum and maximum bounds. The terminal constraints are chosen such that the ZAPS at the end of the ripening step after the process meets the product constraints with the final values of x and w (16), the PSD at the end of the process is sufficiently close to the equilibrium PSD (15), and the temperature of the system is the one for which the minimum ZAPS can be achieved, for given values of x and

w (17). Unless the distillation proceeds significantly past the point where the minimum Z_{ss} is obtained (hence failing to meet the constraint on Z_{ss}) and except for the initial phase of the process where the nanoparticles grow to their maximum size, $Z(t)$ is strictly decreasing and $Z(t) \geq Z_{eq}(t)$ holds. For this reason, once the constraint on Z is met, it is guaranteed to be satisfied until the end of the process. Furthermore, once $T(t) = T_{ab}$ is achieved, any variation would either determine an increase in the duration of the process or the energy expense, making the solution sub-optimal. Thus, during optimization, the terminal constraints can be checked at t_{max} only, while the duration of the process is computed by equation 19. t_{max} can be used to further impose a constraint on the productivity of the process.

To solve the problem, the states and inputs are discretized in time using orthogonal collocation on finite elements (Cuthrell and Biegler (1987)). The time interval from 0 to 6 hours is subdivided in 12 subintervals, within which the inputs are assumed to have a given shape (\dot{Q} piecewise constant, P piecewise linear). Each subinterval is further subdivided in 6 finite elements to control the precision of the solution. The constraints are evaluated at the boundaries of each finite element. $N_c = 3$ collocation points are placed on each finite element, where the states are approximated by Lagrange interpolating polynomials. Continuity is enforced between interpolating polynomials at the boundary of each two finite elements and with the initial conditions. A Radau scheme is chosen for the collocation points for numerical stability. The model and optimization were implemented in python using CasADi (Andersson et al. (2019)), with IPOPT as solver (Wächter and Biegler (2005)).

4. Results

An overview of some results is given in figure 3. It was found that under stringent product constraints and despite being the most energy-intensive mode of operation, the J_1 -optimal input can be up to 10% less energy demanding than the least efficient input policy with the same terminal constraints. The J_2 -optimal operation requires more time to complete the process, but reduces the total energy input by an additional 10%, compared to the J_1 -optimal solution. The trade-off between the duration of the process and the energy expense in the J_2 -optimization can be controlled by choosing t_{max} . For the J_3 -optimization, several scenarios were tested where the energy price (economic or environmental) was set to 0 in a time window between t_1 and t_2 and 1 outside. The J_3 -optimized processes adapts the operation such that the energy input is maximized within the window as shown in figure 4. The total energy use in this scenario can be very close to the optimal energy use if the low price window is not close to the end of the process. The J_3 -optimal operation is less advantageous and less energy-efficient if the window begins close to the end of the process. This is visible in the second J_3 -optimal trajectory in figure 4 and illustrative in figure 3. For this reason it is advisable to schedule the process such that cheap energy is available within the first half of the batch run.

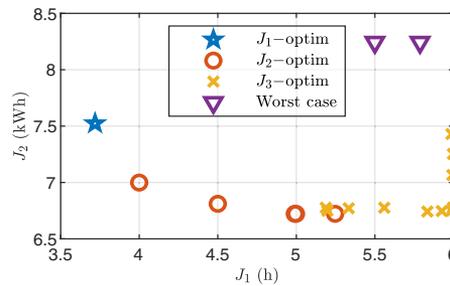

Figure 3: J_1 and J_2 for different optimization scenarios with $Z_{eq,goal} = 25$ nm and $Z_{goal} = 35$ nm. Different J_2 -optimal solutions were obtained by setting $t_{max} \in \{4, 4.5, 5, 5.5\}$ in eq. 18. The J_3 -optimal solutions were obtained by varying the position and size of the cheap energy price window. For these, J_1 reflects the position of the window. The worst case scenarios were computed by maximizing energy for the given product constraints and $t_{max} \in \{5.5, 6\}$.

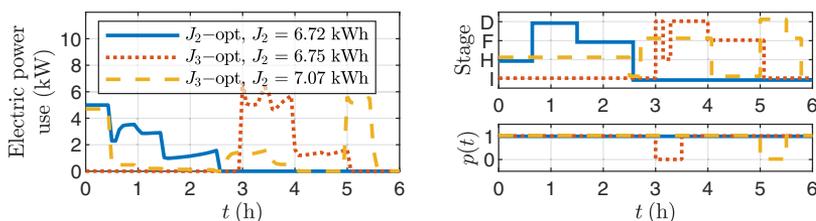

Figure 4: Comparison of the power consumption and process stages in J_2 - and J_3 -optimal solutions for $Z_{goal,eq} = 25$ nm, $Z_{goal,dyn} = 35$ nm for variable energy price $p(t)$. Process stages: Idle (I), Heating (H), Flashing (F), Distillation (D). The total energy use J_2 is given for all scenarios

5. Conclusion and future work

The problem of finding the optimal operation of a batch evaporator was addressed and solved for several objective functions. It was found that improvements in the performance indicators can be obtained, and that using trajectory optimization yields a significant reduction in the total processing time and total energy consumption, compared to the unoptimized operation. Furthermore, the process was found to be flexible enough to efficiently make use of intermittent energy, making it a promising candidate for the application of demand-side response.

Abstract

This work focuses on the development of a mathematical model for the population growth of banana red rust thrips (*Chaetanaphothrips signipennis*) based on a modified temperature-based growth rate with the addition of climatic variables, such as relative humidity, wind speed and rainfall rate. The aim is to enable better prediction of the pest incidence and improve decision making, productivity, as well as quantifying the influence of these variables on the development of red rust thrips. The developed model is then compared with current solutions for predicting the pest incidence, showing improved accuracy (higher than 67%) versus experimental data, for which the state-of-the-art models indicate extremely poor fits.

Keywords: Mathematical modelling; IoT sensors; Precision agriculture; Pests; Organic banana; Red rust thrips.

1. Introduction

Banana is one of the most important food crops in the world, contributing to the food security of billions of people by providing income and employment to rural communities (MINAGRI, 2014). In the last ten years, Peru has joined the large community of organic banana exporting countries, with the main production located on its northern coast, reaching around 223,298 tons of organic bananas exported in 2019 (FAO, 2021). Since 2010, red rust thrips have become a serious issue on local organic banana plantations, causing yield losses of 30%-40% if effective measures are not applied (Lopez et al., 2020).

Currently there are several (organic) products that help to control this pest, but their efficacy depends on the level of incidence present. If the plot is already infested, corrective measures need to be applied with products that cost 7 to 8 times more than the solutions used preventively. Thus, a total infestation of the banana plots is extremely detrimental to the crop and the farmers because, in addition to losing part or all of the production, the cost of recovering from infestation will also increase significantly.

For this reason, tools that help in the decision-making process and enable farmers to reduce as much as possible the impact of these pests on the production are needed. Precision agriculture offers technologies that can support this development. Among these, intelligent sensing, automated data collection, big data analysis and modeling approaches, have the potential to increase

crop yields, detect diseases, pests or weeds early, as well as improve the control, maximize the economic benefits and ensure resource conservation (Annosi et al., 2019).

This research is part of a project aimed at developing tools based on precision agriculture and digitalisation technologies that can help improve the control of pests during the organic banana production. To achieve this objective, an investigation of the pest behaviour is required, to better understand what factors influence their growth throughout the year. In this contribution, the development of a mathematical model for the prediction of the pest population, with application to the banana red rust thrips (the pest that most affects the organic banana production), as a function of the atmospheric variables recorded by IoT sensors located in an organic banana plot (1 ha area) is presented. These models are based on bacterial growth models. By considering other climate variables, such as environmental humidity, rainfall and wind speed, improvement over existing pest incidence prediction models (e.g., the Campbell model (Donatelli et al., 2017)) is sought.

2. Methodology

2.1. Data acquisition

The input data used in the model is collected by a smart sensor network located in the district of Buenos Aires, province of Morropon, department of Piura (Peru). Placed in an organic banana plot, the network consists of two nodes and a weather station illustrated in Figure 1. The station uploads data to the cloud every 15 minutes, so there are 96 data per day. The daily average values are used further for the model.

Figure 1: Weather station (left) and a node (right).

To enable prediction of the pest incidence (the number of thrips on the plot), this parameter needs to be quantified. This task is performed manually and recorded on a weekly basis. For this assessment, the number of eight different types of pests, namely the red rust thrips - *Chaetanaphothrips signipennis*, the mealybug - *Pseudococcus elisae*, the weevil - *Cosmopolites sordidus*, the red spider mite - *Tetranychus spp*, the ceramid - *Ceramidia sp*, the aphid - *Pentalonia nigronervosa* and the whitefly - *Aleurodicus dispersus*, is counted for 25 plants, and averaged to provide an idea on the condition of the plot.

The behavior of the pests has been monitored for almost two years (from November 2019). During this period, it has been observed that, during the summer season, when the maximum temperature reaches values above 30°C, the thrips population increases significantly compared to the other seasons of the year.

2.2. The Campbell Model (CM) for predicting insect growth

Previous work (Campbell et al., 1974) in the area of parasite incidence prediction shows that the growth rate of insects depends on the temperature to which they are exposed (Figure 2). Over a range of temperatures, the relationship between the growth rate and the temperature can be represented by a straight line which, when extended, cuts the x-axis at the temperature threshold (T). Looking at Figure 2, one conclusion that can be drawn is that it is impractical to analyze the average growth rate in the range A domain, due to the high mortality caused by low temperatures. At high temperatures, characteristic of the range C domain, the average rate of development decreases with respect to the linear growth observed in the range B domain. However, this growth rate reduction observed at high temperatures occurs only if the temperature remains constant or fluctuates within a small range for a long period of time, hence it is not normally experienced. Therefore, in practice the field conditions are almost always in the linear section corresponding to the range B domain.

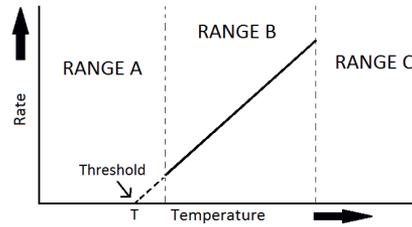

Figure 2: The relationship between the rate of insect development and temperature.

For practical purposes, the growth rate of insects can be approximated by a linear equation (Prasad et al., 2021):

$$\rho = a + b \cdot T \quad (1)$$

The parameters a and b are constants estimated from “experimental” data, with a the intercept of the rate of development, and b the slope relating temperature to the rate of thrips growth, while T is the temperature ($^{\circ}\text{C}$).

2.3. The Modified Campbell Model (MCM)

In the CM, only the temperature is taken into account, while important climatic variables such as rainfall, wind speed and relative humidity, which have an impact on the insect population growth (Elbehri et al., 2015), are neglected. To this end, by considering these variables measured on the plot, an improvement to the prediction of the CM is expected. Thus, the following equation is considered for the rate of growth of insects:

$$\rho = a + b \cdot T + c \cdot H + d \cdot W + e \cdot R \quad (2)$$

Where H is the relative humidity (%), W the wind speed (m/s), and R the rain rate (mm/h), while a ($1/\text{day}$), b ($1/\text{day}\cdot^{\circ}\text{C}$), c ($1/\text{day}\cdot\%$), d ($1/\text{day}\cdot\text{m/s}$), and e ($1/\text{day}\cdot\text{mm/h}$).

2.4. Mathematical Modelling

To describe the population dynamics of insects, Murray’s exponential model of bacterial growth can be used, an implementation considered in (Hernández and Rivera, 2018) to find the parameters and determine the number of microorganisms. This particular case is used to approximate the number of thrips (insects per plant) in an organic banana crop at any instant of time.

$$\frac{dP_T}{dt} = \rho \cdot P_T - \psi \cdot P_T = (\rho - \psi) \cdot P_T = r \cdot P_T \quad (3)$$

Where P_T represents the population of thrips per plant, ρ , the birth rate ($1/\text{day}$), ψ , the death rate ($1/\text{day}$) and r describes the growth rate ($1/\text{day}$).

Two types of pesticides are regularly used on the organic banana plot, and hence considered for this model. The first one is exclusive for rust thrips and is used in a corrective way, being also more aggressive. The second one is the most frequent type of pesticide used, and its application is performed in a preventive fashion for pests such as red spider mites, white flies, thrips, etc. Moreover, its effect is weaker compared to the one used for the rust thrips. For this reason, pesticide spraying terms, F_1 and F_2 , are considered in the model, and expressed based on the degradation of antibiotics in bacteria (Romero Leiton et al., 2011):

$$F_1 = e^{-\varphi_{F_1} \cdot \tau_{F_1}} \quad (4)$$

$$F_2 = e^{-\varphi_{F_2} \cdot \tau_{F_2}} \quad (5)$$

Where F_1 is the concentration of organic pesticide 1, F_2 is the concentration of organic pesticide 2, φ_{F_1} is the degradation rate of pesticide 1, φ_{F_2} is the degradation rate of pesticide 2, τ_{F_1} is the difference between the current day and the day pesticide 1 was sprayed (*day*), τ_{F_2} is the difference between the current day and the day pesticide 2 was sprayed (*day*).

During the third nymphal stage, mature nymphs migrate from the plant to the soil or epidermis and transform into prepupae. At this stage, cleaning of the plot is an influential factor in the thrips population growth, since it directly interferes with their life cycle. If this activity is not carried out, it would result in a significant increase of the number of insects. Therefore, the cleaning term is described in a similar way to the spraying terms, as its impact on the insect population decreases over time:

$$C = e^{-\varphi_c \cdot \tau_c} \quad (6)$$

Where C is the variable representing the cleanliness of the plot, φ_c is the degradation rate of the cleanliness level, τ_c is the difference between the current day and the day on which the cleaning was carried out (*day*).

Unlike the case of Equation 3, where the growth rate is constant, in the following the growth rate is expressed as a function of the crop conditions, such as pesticide spraying and cleaning, which directly affect the thrips population:

$$r = \rho - \psi - \phi_1 \cdot F_1 - \phi_2 \cdot F_2 - \gamma \cdot C \quad (7)$$

Where ρ is the rate of thrips development (*1/day*), ψ is the natural mortality rate (*1/day*), ϕ_1 is the mortality rate from spraying with chemical 1 (*1/day*), ϕ_2 is the mortality rate from spraying with chemical 2 (*1/day*), γ is the mortality rate from the cleaning (*1/day*).

Finally, the rate of change of thrips intensity with respect to time for the modified Cambell model (MCM) is obtained based on the conditions in the crop field:

$$\frac{dP_T}{dt} = (\rho - \psi - \phi_1 \cdot F_1 - \phi_2 \cdot F_2 - \gamma \cdot C) \cdot P_T \quad (8)$$

3. Results

In the following, the predictions for the red rust thrips incidence of the two models described above, the MCM and the CM, are compared. For this purpose, 100 data sets are generated from the experimental data gathered across a period of one and half years. For cross validation, each set has been divided into training (75%) and validation (25%) data. The sets are then used for parameter estimation, and the resulting models' metrics are shown in Table 1.

For the training and validation sets, mean values of 0.78 and 0.66 were obtained for R-squared, while 1.50 and 1.60 were obtained for RMSE, respectively. For the training and validation sets,

average values of 0.80 and 0.70 were obtained for R-squared while for RMSE 1.45 and 1.55 respectively.

Table 1: Model metrics for the CM and MCM: Coefficient of determination (R^2) adjusted and Root mean square error (RMSE)

	R^2 adjusted		RMSE	
	CM	MCM	CM	MCM
Train	0.78	0.80	1.50	1.45
Test	0.66	0.70	1.60	1.55

Figure 3 shows the real data compared to the prediction of the two models. For the MCM, an R^2 of 0.73 and an RMSE of 1.76 were obtained, while for CM these were 0.72 and 1.78, respectively. As the same data is used in the cross-validation, there is not much difference in the results for these metrics, although it seems that the MCM is slightly more accurate than the CM.

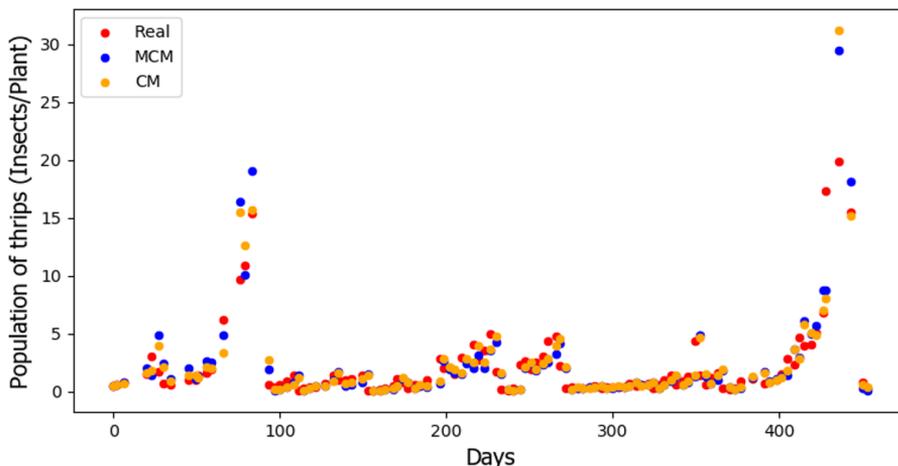

Figure 3: Comparison of model predictions with experimental data used for model development.

When the two models are used for prediction of new data (the validation set), corresponding to the period from July 8 to October 19, 2021, the metrics shown in the Table 2 indicate that the MCM has a better accuracy compared to the CM. Furthermore, it can also be observed that the MCM predictions are not so far away from the real values. At the same time, the CM results indicate a very poor fit.

	CM	MCM
R^2	-1.68	0.67
RMSE	4.00	1.40

Table 2: Metrics obtained for the model predictions for the validation set.

Figure 4 shows the response of the models for the data recorded in the plot during the 103 days corresponding to the validation set. During this time interval, 10 pest evaluations were performed and used to assess the accuracy of the models.

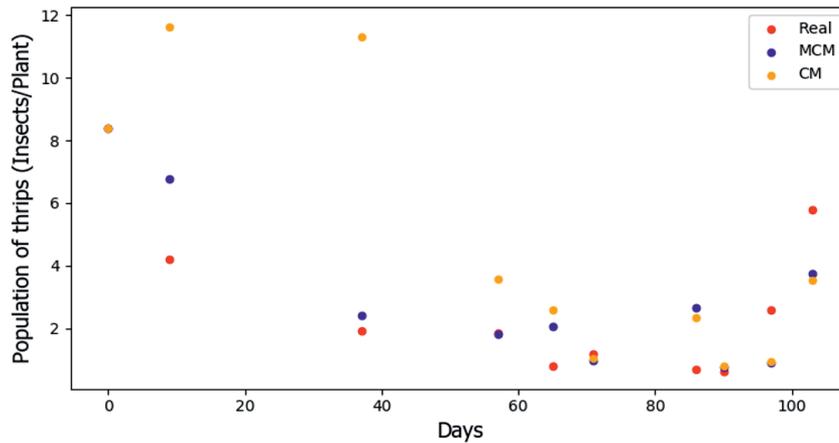

Figure 4: Comparison of model predictions with experimental data used for validation.

4. Conclusions

Understanding the growth behavior of the rust thrips with respect to atmospheric variables enables farmers to take better preventive control measures to avoid infestation as much as possible. In this way, production losses as well as plot maintenance costs can be significantly reduced. This contribution presents the development of a model for the predictions of the thrips incidence in an organic banana plot based on climatic variables. The results show good agreement with the experimental data, providing a solution that can be further implemented in decision-making tools for the organic banana producers.

These can be used in the future work to define and improve the monitoring and control of the pest incidence by defining better fumigation and cleaning schedules that will increase their efficiency and benefit the quality of the final product.

Abstract

The high consumption of fossil fuels is running out the petroleum sources, therefore it is extremely important to improve the efficiency or diversify the industry's main route. To deal with these new processes, the liquid-solid fluidized bed is one of the available technologies. Mastering this complex industrial device requires a better understanding of the intrinsic multi-scale hydrodynamics couplings that play an important role between solid and liquid phases. For that reason, the numerical simulation of multi-phase flow has become a useful tool for examining the particle behavior in fluidized beds. The fluidized bed simulation may be addressed using the Discrete Element Method (DEM-CFD) approach, which is a model that requires a lot of computational effort, because of the large scale of the equipment and the huge number of particles. Hence, for industrial purpose, this approach becomes infeasible, and simulations are carried out in the frame of Euler-Euler model such as implemented in the NEPTUNE_CFD code. But such approach was originally developed for gas-solid flows, then a specific model developments and validation studies are needed for liquid-solid fluidized bed (Gevrin et al., 2008). This is one of the main objectives of the MUSCATS project (N°ANR-19-CE05-0010-02), which is carrying out an innovative multi-scale modelling program for liquid-solid fluidized beds, based on complementary numerical approaches and carefully designed experiments. In a first stage, 3D numerical simulations were performed using the NEPTUNE_CFD code on a laboratory configuration in order to assess the model assumption and to compare the mean and fluctuating fluid and particle velocity predictions with available experiment data from Aguilar-Corona (2008). Thus, some discrepancies on fluid and particle kinetic fluctuating energy and areas of improvement are identified and proposed in order to capture accurately the particle-fluid and inter-particle interactions in the liquid-solid fluidized bed.

Keywords: CFD, Euler-Euler, Fluidized bed, Liquid-solid bed

1. Introduction

The fluidization phenomenon occurs when solid particles are suspended by a fluid, gas or liquid, and they behave like a fluid-like state. The liquid fluidization is widely utilized in several processes such as chemical, petrochemical, hydro-metallurgical, mining, biochemical, pharmaceutical and water treatment (Wang et al., 2014; Nirmala and Muruganandam, 2019). As reported by Kunii and Levenspiel (1994) the bed properties are heavily dependent of the fluid velocity and it plays

an important role over the fluid-dynamics of the equipment, because the flow regime changes in function of the fluidization velocity. For instance, when the fluid acquires enough kinetic energy to support the particles, but without dragging them out, the regime changes from a fixed bed to a fluidized bed with certain intermediate states. As it is a fluid transport equipment, the fluidized bed can be dimensioned based on factors such as pressure loss, the fluid density and viscosity, the particle density, diameter and shape, the fluid velocity and etc (Yates and Lettieri, 2016).

The Computational fluid dynamics (CFD) has been applied to simulate the liquid fluidized bed system and according to Zhang et al. (2013) the models used to simulate the liquid-solid fluidized bed can be divided into two major groups: At a macro-scale it is represented by the Two-Fluid Models (TFM) approach and at meso-scale it is distinguished by the use of CFD coupled with the discrete element method (DEM). The mass and the momentum equations are solved separately for each phase taking into account the momentum transfer between liquid and solid. Hence, the numerical results is strongly dependent on the drag force between the phases and the solid stress (Ren et al., 2021). Many authors has studied the liquid-solid fluidized bed and they noted that the existence of meso-scale structures play an important role over the hydrodynamics and it is not well computed when coarse grid is employed. Beside that, they have investigated the influence of many parameters such as density ratio, fluid viscosity, restitution coefficient, forces acting on particles, turbulence model and etc. They concluded that fluidized bed hydrodynamics results are considerably impacted by turbulence and the drag model (Ren et al., 2021; Khan et al., 2017). In order to investigate the capability and development needs of mathematical modeling and the lack of accurate prediction of fluid and particle agitation for various fluidization velocities, numerical predictions from NEPTUNE_CFD code are compared with laboratory measurements from Aguilar-Corona (2008).

2. Experimental measurement from Aguilar-Corona (2008)

Aguilar-Corona (2008) performed many experiments using a solution of Potassium Thiocyanate (KSCN) 64 % (w/w) and solid particles of Pyrex beads. She investigated many parameters experimentally using a high-speed camera to capture the trajectory of the particles. The experimental results performed by Aguilar-Corona (2008) were used to build the reference case, which is a cylinder consisting of 80 mm in diameter and 500 mm in height. The fluid and particle properties are provided in Tab. 1. For more details see Aguilar-Corona (2008).

Table 1: The fluid & particle properties.

Description	Value
Fluid density	1400 kg/m^3
Fluid viscosity	3.8E-3 Pa.s
Particle density	2230 kg/m^3
Particle diameter	6 mm
Total solid mass	0.624 kg
Initial bed height	9.5 cm
Initial solid packing	0.585
Terminal velocity	0.226 m/s

3. Mathematical modeling and numerical parameters

Three-dimensional numerical simulations are carried out using NEPTUNE_CFD. This Eulerian n-fluid unstructured parallelized multiphase flow software is developed in the framework of the NEPTUNE project financially supported by CEA (Commissariat a l'Énergie Atomique), EDF

(Electricité de France), IRSN (Institut de Radioprotection et de Sureté Nucléaire) and Framatome. The modeling approach for fluid–particle flows is implemented by Institut de Mécanique des Fluides de Toulouse (IMFT) (Neau et al., 2020). The Eulerian n-fluid approach used is a hybrid approach where the transport equations are derived by phase ensemble averaging for the continuous phase and by using kinetic theory of granular flows supplemented by fluid and turbulent effects for the dispersed phase thanks to joint fluid–particle Probability Density Function (PDF) approach. In the proposed modeling approach, transport equations (mass, momentum and fluctuating kinetic energy) are solved for each phase and coupled through inter-phase transfer terms. The momentum transfer between liquid and particle phases is modeled using the drag law of Wen and Yu limited by Ergun equation for the dense flows (Gobin et al., 2003). The collisional particle stress tensor is derived in the frame of the kinetic theory of granular media. The fluid turbulence modeling is achieved by the two equations of $\kappa - \varepsilon$ model extended to particle-laden flows accounting for additional source terms due to the inter-phase interactions (Vermorel et al., 2003). For the dispersed phase a coupled transport equation system is solved on particle fluctuating kinetic energy and fluid–particle fluctuating covariance ($q_p^2 - q_{fp}$). The effects of the particle–particle contact force in the very dense zone of the flow are taken into account in the particle stress tensor by the additional frictional stress tensor. For more details about the model see (Hamidouche et al., 2018; Gevrin et al., 2008).

The constructed mesh is composed of 510.000 cells in size $\Delta x = \Delta y = 0.001$ m and $\Delta z = 0.002$ m. The inlet, outlet and wall boundaries were defined, respectively, as inlet velocity, free pressure outlet and friction for both phases. We ran several simulations using the following fluidization velocities: $U_f = 0.073, 0.09, 0.12, 0.15$ and 0.17 m/s. The inlet velocity was assumed to be homogeneous over the inlet surface. For these velocities tested, the Reynolds Number is ranging from 82 to 378 and the Stokes Number is varying from 0.9 to 6.1. The coefficient of restitution and maximum packing α_p are, respectively, 0.9 and 0.64.

4. Fluidization law

In order to determine the fluidization law, many simulations was performed with different fluidization velocity. Figure 1(a) illustrates, for different U_f , the time average for solid volume fraction, $\langle \alpha_p \rangle$, at the center of the column. As overall trend, the bed height moves upward when fluidization velocity increases, while $\langle \alpha_p \rangle$ drops. In other words, the fluidized bed becomes more diluted when the fluidization velocity is increased. Figure 1(b) presents the mean value of the solid volume fraction averaged over the entire bed height for different velocities. Below you can see the numerical results, experimental value from Aguilar-Corona (2008) and Wen and Yu (1966), Tenneti et al. (2011) & Richardson and Zaki (1954) correlations. The Richardson and Zaki (1954) equation is showed in Eq. 1 and the parameters utilized to plot Fig. 1(b) are $U_0 = 0.226$ m/s and $n = 2.39$.

$$U_t = U_0(1 - \alpha_p)^n \quad (1)$$

Analysing Fig. 1(b) we can see that the numerical results are much more in agreement with Tenneti et al. (2011) and Wen and Yu (1966) correlations, the last one is a correlation that takes into account a homogeneous system without collision. The drag law utilized in our simulations is based on Wen & Yu. Therefore, an investigation using different drag laws seems to be important, as the numerical results were much closer to the correlation than the experimental results. As a result, the findings differ from those obtained in the experiments and Richardson and Zaki (1954) correlation, although for dense regime ($\langle \alpha_p \rangle > 0.3$) the results present a good agreement with the experimental and the correlations.

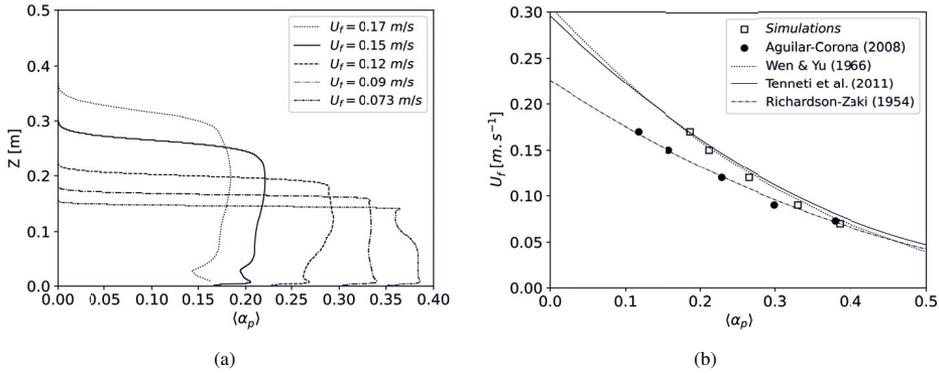

Figure 1: Numerical and experimental results where figure (a) shows $\langle \alpha_p \rangle$ profiles for different fluidization velocities at a central line inside the cylinder and figure (b) shows the spatial average value for $\langle \alpha_p \rangle$ in function of fluidization velocity U_f .

5. Fluid and particle analysis of the total fluctuating kinetic energy

To calculate the fluctuating kinetic energy, some nomenclatures need to be clarified. Where Ψ_k is an ordinary variable and $\widetilde{\Psi}_k$ is the time average taking in account α_k as represented in Eq. 2.

$$\widetilde{\Psi}_{k,i} = \frac{\sum \alpha_k \Psi_{k,i} \Delta t}{\sum \alpha_k \Delta t} \quad (2)$$

In order to calculate the fluctuating kinetic energy in each direction is necessary to compute the 3 terms shown in Eq. 3. Where the first term is the spatial variance of the mean velocity, the second one is the spatial mean of the local temporal variance and the third one is the spatial mean of the random fluctuation of q_k^2 .

$$\alpha_{k,i} = \widetilde{U_{k,i}^2} + \langle \widetilde{u_{k,i}^2} \rangle + \langle 2/3 q_k^2 \rangle \quad (3)$$

For comparisons purposes, the fluid and particle velocity variances are being plotted side by side (see Fig. 2). The $\langle \alpha_p \rangle$ value used to plot the numerical result is the same as the experimental, as the value is being over predicted by the model. As can be seen, the vertical particle variance is being overestimated much more than the others, it is about 3 times larger than the experimental value for $\langle \alpha_p \rangle = 0.12$, however it is well estimated for $\langle \alpha_p \rangle > 0.3$. In contrast, the vertical and the horizontal components for the fluid are being underestimated independently of $\langle \alpha_p \rangle$.

The total fluctuating kinetic energy can be calculated using Eq. 4, where it takes into account all components (x, y, z) to figure out the energy. However, it is known that the horizontal components (x, y) are similar, then, only the x contribution was used to estimate the kinetic energy.

$$E_k = \frac{1}{2} (\alpha_{k,x} + \alpha_{k,y} + \alpha_{k,z}) = \frac{1}{2} (2 * \alpha_{k,x} + \alpha_{k,z}) \quad (4)$$

Using Eq. 4 and results from Aguilar-Corona (2008) we can plot energy for both phases. As it is shown in Fig. 3, the energy prediction value for both phases is decreasing with increasing of $\langle \alpha_p \rangle$. For dispersed phase, the energy is being overestimated until $\langle \alpha_p \rangle = 0.3$, after that, the kinetic energy is being underestimated. The fluid phase is being underestimated independently of $\langle \alpha_p \rangle$. It is worth noticing that the kinetic energy predicted for both phases are approximately of the same order of magnitude, which is not the case for the measured results from Aguilar-Corona (2008).

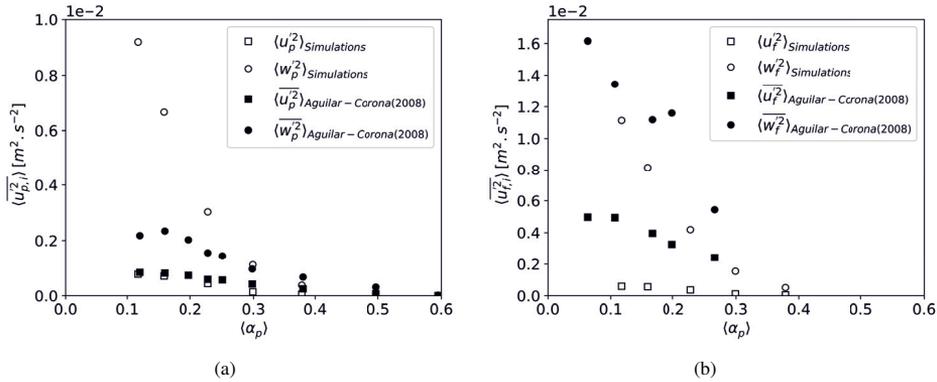

Figure 2: The horizontal and vertical contributions of the spatial mean of the velocity variance for (a) particle and (b) fluid.

Therefore, we need to improve the mathematical modeling of the phase agitation coupling by a modeling of the fluid turbulence production due to the particle motion. It is worth noticing that the Euler-Euler approach used in this paper, the fluid turbulence modeling is made in the frame of very small particles and small particle Reynolds numbers (Vermorel et al., 2003). Hence, the fluid pseudo-turbulence production in the wakes of the particles is neglected but it need to be accounted for the fluid-particle fluidized beds modelling.

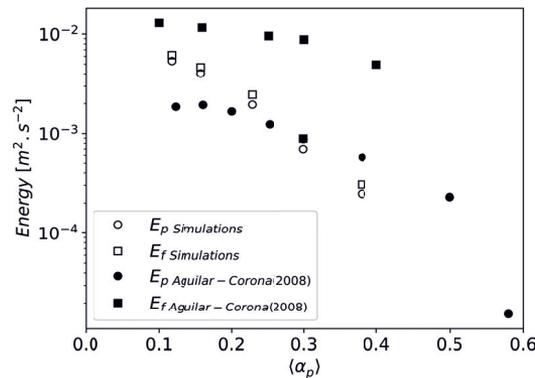

Figure 3: Comparison between particle and fluid fluctuating kinetic energy.

6. Conclusion

Numerical simulations employing the Euler-Euler approach were performed in order to investigate the bias and to understand better the model applied in a liquid-solid fluidized bed. We ran simulations in a completely 3-D fluidized bed that Aguilar-Corona (2008) had examined experimentally. Overall, the spatial mean of the velocity variance is being underestimated by the model, except for vertical particle component, which is being over-predicted for dense regime. It is interesting to note that the agitation of the two phases reduces as the solid concentration in the bed increases and the model was able to catch the flow anisotropy, reflecting the trend seen in the experiments. However, the estimation of the kinetic energy for both phase is roughly of the same order of magnitude,

which is not the case for the measured values from Aguilar-Corona (2008). As a result, we should propose a model capable to compute the pseudo-turbulence production, which ought to increase the fluid velocity fluctuation prediction without causing any influence on the particle fluctuating motion. In other words, the model may predict a higher value to fluid velocity fluctuation and consequently approaching the experimental results.

Abstract

The pulp industry is a high consumer of water, and efforts to reduce water consumption have led to the build-up of non-process elements (NPE), mainly in the bleaching area. These species can jeopardize the plant operability and reduce the product quality. This work aimed to develop a simulation tool to describe the concentration of NPE in pulp suspensions reliably so that it can be used to optimize bleaching sequences. The simulator is based on the Donnan model with parameters estimated from adsorption equilibrium experiments. The model predictions were compared with experimental results, and a good predictive capacity of the model was proved.

Keywords: pulp bleaching, non-process elements, adsorption, Donnan equilibrium.

1. Introduction

Over the last decades, the pulp and paper production industry has made a significant effort to reduce freshwater consumption in the process. Indeed, water consumption in pulp bleaching plants has decreased from 35-50 m³/t AD (air-dried) in the 1980s to ca. 25 m³/t AD in modern plants (Huber et al., 2014). However, further reductions have been explored to make pulp and paper production more sustainable, especially when the mills are located in water-scarce areas or if groundwater is used (Tewari et al., 2009).

Bleaching is the set of operations that follow the pulp cooking process and precede paper production. Here, the residual lignin is oxidized and removed from the pulp along with some chromophore groups responsible for the brown colour of the pulp. In most cases, the chromophore groups are functional groups of the carboxylic type (-COOH) or of the phenolic type (-PhOH) (Bygrave, 1997). Depending on the pH in each stream, these functional groups can act as active sites for the adsorption of metallic elements in the pulp (Rudie and Hart, 2006). The bleaching section comprises several bleaching and washing stages. In the bleaching stages, the pulp reacts with different oxidizing agents to degrade the chromophore groups and then proceeds to one or more washing steps, in which the dissolved compounds (organic and inorganic) are removed. For this reason, this section turns out to be the pulp mill zone that requires the greatest amount of water, generating effluent with high pollutant loads (Tewari et al., 2009).

The optimization of pulp bleaching has involved using reagents with lower environmental risks, but that guarantee high efficiency in removing chromophore groups, requiring

smaller water quantities to wash the pulp. In addition to these measures, the pulp washing is operated in countercurrent, limiting the amount of fresh water introduced into the process and consequently reducing the amount of effluent generated (Huber et al., 2014). This closure in the water circuits led to the build-up of some organic compounds (resulting from the removal of chromophore groups and lignin) and inorganic species. Most of the inorganic species accumulated in the process are denoted as non-process elements (NPE). These are metallic elements not directly involved in the pulp production process but rather introduced as wood constituents (Ulmgren, 1997). The main NPE are calcium, sodium, magnesium, and chlorine (Andrade et al., 2007). The increase in the concentration of chloride in the system, for example, can lead to corrosion problems in the equipment, limiting the possibility of burning the filtrates in the recovery boiler. On the other hand, the accumulation of the remaining metallic elements is associated with scaling problems, fouling, and loss of bleaching capacity (Stratton et al., 2004). Furthermore, metallic cations tend to adsorb on the fiber surface, binding to the functional groups in the pulp, degrading the fiber quality for downstream operations. WinGEMS 5.3 is a software developed to the pulp production processes. However, some limitations have been pointed out in terms of its ability to predict the sorption and scaling phenomena, generating results with large deviations from the industrial data. WinGEMS includes the Langmuir sorption model (Eq. 1, Langmuir, 1918), to predict the amount of sorbed components as a function of the concentration of the component in the solution phase (C , g/L), and the active sites in the pulp in an oven-dried (OD) basis (A , kg/t OD). The model also includes a parameter, B (L/g), that is specific for each NPE.

$$\text{Concentration of sorbed component} = \frac{ABC}{1 + BC} \quad (1)$$

WinGEMS 5.3 contains only the A and B parameters for the Na^+ , Ca^{2+} , and K^+ ions and does not include its variation with pH, although the amount of active sites is clearly dependent on this variable. These assumptions limit and weaken the predictive capacity of the simulator. Due to the lack of accuracy in predicting the adsorption phenomenon and the inability to include very important elements such as magnesium, it is imperative to implement alternative models that solve these limitations, such as the Donnan equilibrium model. This work aimed to develop a computer simulation tool, in MATLAB, to be further integrated with WinGEMS to improve the predictive capacity of the software, allowing to optimize the amount of water introduced in the washing steps, while restricting the formation of precipitates and the adsorption on the fiber.

2. Model development and implementation

The Donnan equilibrium model was initially developed to govern the uneven distribution of ions between two sides of a membrane (Donnan and Harris, 1911) and later applied to pulp suspensions to simulate the adsorption equilibrium (Towers and Scallan, 1996). The pulp suspension is described as two compartmentalized phases called fiber and solution. The fiber phase (F) considers the fiber (including the functional groups) and the water of the internal solution with the dissolved ions bounded to the fiber. The solution phase (S) contains the external water and the ions dissolved in it. The Donnan model considers the existence of two types of functional groups in the fiber (AH and BH , in its protonated form). Table 1 lists all the equations of the model. Depending on the pH, these groups can dissociate, generating negative charges (A^- and B^- , check Eq. 2a and 2b). The dissociation constants (K_{AH} and K_{BH}) of these functional groups are indicated according to Eq. 3a and 3b, considering the molalities (m_i^F) of the various species (i) involved in

the reactions. To calculate the Donnan equilibrium, electroneutrality is assumed in each phase of the system, that is, the net ionic charge is zero. This results in Eq. 4 and 5, where z corresponds to the valence of the ion j or the functional group k . Electroneutrality equations also take into account the ions resulting from the water dissociation in each phase, whose concentrations are calculated according to the dissociation constant ($K_W = 10^{-14}$, at 25 °C) (Eq. 6). The fiber phase is considered a homogeneous phase separated from the external solution. The presence of fixed ionic species, such as carboxylic and other functional groups in fibers induces Donnan equilibrium. Thus, the mobile metal ion concentrations inside and outside the fiber phase are not equal. The Donnan equilibrium expression is described by Eq. 7, where m_j corresponds to the molality of the ion j , z_j the valence of the ion j , and λ the Donnan constant. It is necessary to guarantee the conservation of the functional groups, both in their protonated and deprotonated state, therefore mass balances (Eq. 8a and 8b) to the total amount of groups (Q_A and Q_B) are introduced, where M^F relates to the mass of water in the internal solution, m_{AH}^F and m_{BH}^F , the molalities of the protonated groups, and $m_{A^-}^F$ and $m_{B^-}^F$, the molalities of the deprotonated groups. Finally, it is necessary to close the mass balances for each ionic species in the whole system. Thus, Eq. 9 expresses the balance for each cationic species (C_j) and Eq. 10 for each anionic species (A_j). M^S represents the mass of water in the external solution. Solving the system of Eqs. in Table 1, the λ parameter can be calculated as an implicit function of the solution pH. Commonly, as pH increases, λ also increases.

Table 1. Equations used to simulate the Donnan equilibrium model in a fiber suspension.

$AH \Leftrightarrow A^- + H^+$	(2a)	$K_W = m_{H^+}^F \cdot m_{OH^-}^F = m_{H^+}^S \cdot m_{OH^-}^S$	(6)
$BH \Leftrightarrow B^- + H^+$	(2b)	$\left(\frac{m_j^F}{m_j^S}\right)^{\frac{1}{z_j}} = \lambda$	(7)
$K_{AH} \Leftrightarrow \frac{[A^-][H^+]}{[AH]} = \frac{(m_{A^-}^F)(m_{H^+}^F)}{(m_{AH}^F)}$	(3a)	$\frac{Q_A}{M^F} = m_{AH}^F + m_{A^-}^F$	(8a)
$K_{BH} \Leftrightarrow \frac{[B^-][H^+]}{[BH]} = \frac{(m_{B^-}^F)(m_{H^+}^F)}{(m_{BH}^F)}$	(3b)	$\frac{Q_B}{M^F} = m_{BH}^F + m_{B^-}^F$	(8b)
$\sum_j z_j m_j^F + \sum_k z_k m_k^F = 0$	(4)	$C_j = M^S m_j^S + M^F m_j^F$	(9)
$\sum_j z_j m_j^S = 0$	(5)	$A_j = M^S m_j^S + M^F m_j^F$	(10)

3. Materials and methods

Pulp samples were collected at two points on the bleaching line of a Portuguese pulp and paper mill: p-O2 (after oxygen delignification) and D2 (end of a bleaching sequence). The analysis followed TAPPI procedures. The pulps were acid washed (HCl, until pulp pH of 1.5-2) before analysis. The concentration of functional groups and their dissociation constants were determined by potentiometric titration. The quantification of NPE in the pulp was determined by flame atomic absorption spectrometry (AAS), after acid digestion. The sorption tests were conducted at 60 °C, a pulp consistency of 5% wt., and varying the pH of the experiment using HCl or NaOH solutions. Single-component tests were carried out for Ca, Na, and Mg and multi-component tests were also carried out. The concentrations tested were close to 500, 1000, and 100 mg/kg OD for Ca, Na, and Mg, respectively, in single-component tests. For multi-component tests, the concentrations tested were close to 3000, 30000 and 500 mg/kg OD for Ca, Na, and Mg, respectively.

The Donnan equilibrium model was implemented in MATLAB. The adsorption for the p-O2 sample was simulated in WinGEMS in two different modes: (1) a pulp stream was simulated as the models are implemented in WinGEMS; (2) the Donnan equilibrium values were imported to WinGEMS and equations were solved to calculate the distribution of NPE between the pulp and the solution.

4. Results and discussion

The characterization of the pulps by titration allowed to determine the concentration of functional groups per unit of pulp mass (mmol/kg OD), as well as the dissociation constants of the two types of functional groups. The titrations curves (results not shown) did not reveal the presence of phenolic groups for the pulps p-O2 and D2. Thus, Eq. 2b, 3b, and 8b in Table 1 were not considered in the simulations. These results are in line with what was documented by Zhang (2006), who refers only to the existence of carboxylic groups. The results are summarized in Table 2. The concentration of functional groups significantly decreased during the bleaching process. These values were used to parameterize the Donnan equilibrium simulator in MATLAB.

Table 2. Pulp characterization in functional groups.

Pulp	k_{AH}	pK_A	Q_A (mmol/kg OD)
p-O2	2.51×10^{-4}	3.6	99
D2	1.78×10^{-4}	3.75	47

For the single-component adsorption tests, it was found that generally, the Donnan model fits well with the experimental data for Ca and Mg elements (Fig. 1 a, b, e, and f). For Na, the fit quality is lower, which can be due to technical difficulties in the AAS determination of Na, but the results are also satisfactory (Fig. 1 c and d). For the elements Ca and Na, the prediction of the Langmuir model was calculated, using the constants initially in WinGEMS and the same concentrations used in the adsorption tests and the simulation of the Donnan equilibrium. For Ca, the values of constants A and B were 1.5 kg/t OD and 4 L/g, respectively, which for the concentration of 500 mg/kg OD resulted in the adsorption of 136.4 mg/kg OD of calcium. Under typical industrial conditions, the p-O2 pulp has an alkaline pH value, so this prediction is not suitable, compared to the results presented in Fig. 1a, where all the calcium is sorbed into the pulp, for such pH values. The D2 pulp has a pH between 3.5 and 5, so the Langmuir equation is not adequate to simulate these conditions, as the experimental essays showed that sorbed calcium varies between 200 and 400 mg/kg OD for this pH range (Fig. 1b). For Na, the constants A and B took the values of 2.43 kg/t OD and 53 L/g, respectively, which for the concentration of 1000 mg/kg OD led to the adsorption of 1764.2 mg/kg OD. This value is wrong, since it considers the adsorption of a greater amount of sodium than available, which overestimates its concentration in the fiber. Analyzing Fig. c and d, it was found that, for the conditions tested, all the sodium was sorbed into the pulp. In the case of magnesium, WinGEMS does not include constants to calculate the adsorption equilibrium, but it was found that the Donnan model allowed a good approximation for this element in each of the pulps (Fig. 1e and f).

The Donnan equilibrium simulation for the multi-component system also revealed a good predictive capacity of this model for both samples (Fig. 2). This result is significant since the pulp suspension has several NPE interacting with each other in real systems, influencing the adsorption process. It was observed a slight decrease in the sorbed amount for D2, since under these conditions, the functional groups of the pulp become saturated.

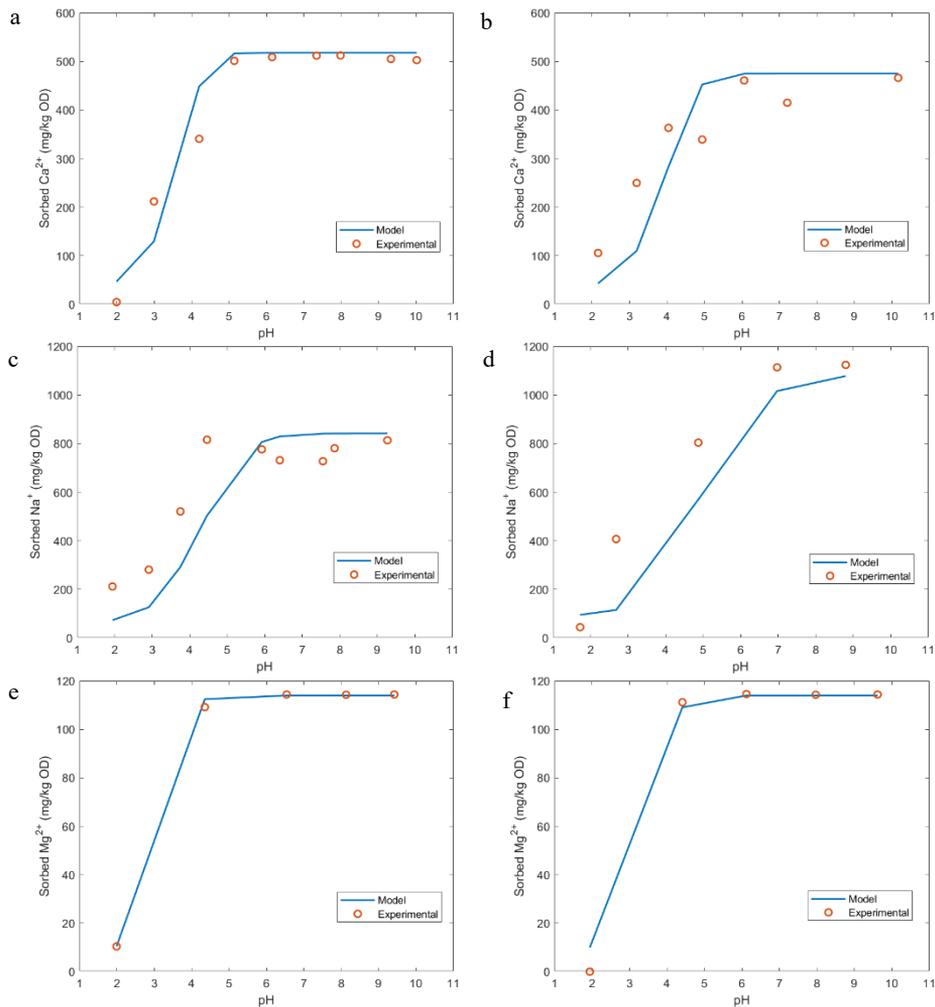

Fig. 1. Adsorption equilibrium for Ca (a and b), Na (c and d) and Mg (e and f), experimental and Donnan model for pulp p-O2 (a, c, and e) and D2 (b, d, and f).

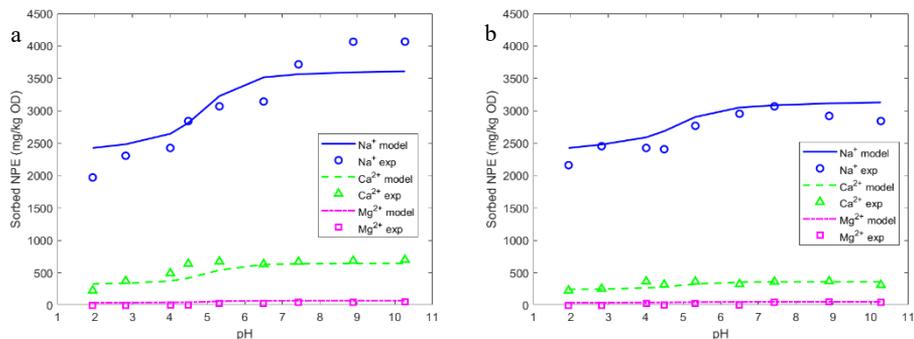

Fig. 2. Multi-component sorption essays and Donnan model: (a) – pulp p-O2 and (b) – pulp D2.

Finally, a stream containing p-O2 pulp was simulated in WinGEMS 5.3 for the experimentally tested conditions (for Ca and Na), considering a pH of 10 in two different modes. In mode (1), the simulation considered the adsorption models available in the software and the results showed that the introduced ions remained completely in the solution phase, demonstrating the limitations of the software. In mode (2), the simulation considered λ value (1.38 at pH 10) calculated in MATLAB script and Eq. 7 (Table 1) that establish the partition between the phases. In this case, the results showed that a certain fraction of these ions (Ca^{2+} and Na^+) are effectively adsorbed in the pulp p-O2. The results in Table 3 are in good agreement with the experimental data showed in Fig. 2a, at pH 10.

Table 3. WinGEMS simulations for p-O2 sample, at pH 10.

	Without Donnan model – Mode (1)		With Donnan model – Mode (2)	
	wt.%	mg/kg OD	wt.%	mg/kg OD

5. Conclusions

This work showed that the Langmuir model implemented in WinGEMS could not predict the adsorption phenomenon in the pulp mill, namely because the concentration of functional groups and pH varies in the different bleaching stages. The Donnan model allowed a good predictive capability for mono- and multi-component systems and it is easily implemented in WinGEMS. Implementing this model to simulate the bleaching line can be valuable for assisting in the optimization of bleaching sequences and configurations, allowing for a reduction in water consumption.

s.macchietto@imperial.ac.uk*

Abstract

Heat treatment processes of liquid dairy products (pasteurisation, sterilisation) are energy, water and wastes intensive. They are normally conducted in an energy integrated system of 3 plate heat exchangers (PHEs), in batch mode heating-cleaning cycles. During cleaning, the whole process is interrupted, causing loss of production. A new semi-continuous pasteurisation process is proposed here comprising a design modification (an additional plate heat exchanger and holding tube), the calculation of (time-varying) pasteurisation time and its use in a new logic for switching between heating and cleaning, and suitable scheduling of equipment in a rotation strategy. All schemes are studied using a detailed distributed dynamic model of the process. The simulation results for a typical high-temperature-short-time (HTST) case study show that the rotational scheduling of the PHEs and tubes results in a semi-continuous operation where milk production can be maintained indefinitely. Substantially higher productivity (+23% throughput), reduced energy, and total cost (-47%) are achieved relative to the traditional batch mode operation.

Keywords: interaction between design and scheduling; dynamic modelling; food processes; heat treatment; fouling and cleaning

1. Introduction and background

The heat treatment of milk, and dairy fluid in general, is typically conducted in an energy integrated system of 3 plate heat exchangers (PHEs) and connecting pipework (Fig. 1a). Cold milk is fed to a preheater (Regeneration) PHE, then a main Heating PHE which uses steam or water utilities. A Holding Tube ensures milk is kept at a high temperature for a sufficiently long time, dictated by preservation requirements. For example, in the high-temperature-short-time (HTST) treatment, milk must be held above 72-75°C for 15-20 s. From the holding tube, the hot milk returns to the preheater for energy recovery against the incoming cold milk, then on to the final Cooler PHE. Fouling requires stopping the process and carrying out a Cleaning in Place (CIP) of the entire system, according to the State Transition Network in Fig.1b. The process is conducted in batch mode, with no production during cleaning. Many studies have discussed the dynamic modelling, fouling deposition and CIP of single PHEs (e.g., Georgiadis et al 1998a, 1998b; Georgiadis & Macchietto, 2000; Manik et al, 2004; Jun & Puri, 2005; Guan & Macchietto, 2018; Sharma & Macchietto, 2021). Only some (e.g., Aguiar & Gut, 2014; Gutierrez et al, 2014; Zhu et al., 2020) integrated individual models into the dynamic simulation of a complete system. We are not aware of papers on the continuous operation of such systems in the presence of fouling. Here, a new process is proposed for continuous milk production, via a design modification (using an additional PHE and holding tube, Fig. 2), novel phase switching logic between heating and cleaning, the flexible use of PHEs and holding tubes in rotation, and suitable scheduling of all operations. For a high-temperature-short-time

(HTST) treatment, it is shown that this leads to higher production and reduced costs. A 2D-distributed dynamic model of all units in the pasteuriser unit is used, as detailed by Zhu et al, 2020. Each PHE model includes fouling kinetics, heat transfer, and deposition on each side plate of each channel and in the tube using a moving boundary for the deposit (Fig. 3). Each point along each plate and tube is characterised by (time-varying) temperature, shear rate, heat transfer rate, fouling deposition, and deposit depth. All modelling and simulations were done using gPROMS 7.0.7 (Process Systems Enterprise).

2. New switching logic using pasteurisation time

A typical process requirement for preservation is to hold the fluid above a certain temperature for a minimum time. In the HTST treatment of milk, this is 72-75°C for 15-20 s. Such milk temperature may be reached in the end of the Regeneration PHE, Heating PHE, holding tube, and initial channels on return to the Regeneration PHE. Temperatures change due to fouling, and direct monitoring of the HTST constraint during heating is not straightforward. Following temperatures at various inlet/exit points gives a partial idea. An alternative is to estimate the amount of deposit on the plates, using simulations models. An often-used criterion (Georgiadis & Macchietto, 2000) is to switch from

heating to cleaning when a critical fouling (a deposit mass density of 16 g/m²) is reached on any plate in a PHE. These are all indirect indicators. A direct way of estimating the actual pasteurisation time is proposed as follows: First, at any given time the temperature profile of milk is established (from the simulation model) along its path from the entrance to the preheater, through the channels in the various PHEs, along the holding tube, to the exit from the cooler (points ①-⑥ in Fig. 2a). This is visualized in a novel diagram (Fig. 4a). Such a diagram can be used to also depict the local distribution at a given time of other variables, such as deposition rates (Fig 4b), heat transfer rates, shear rates, etc. The pasteurisation time (i.e., residence time of milk above the minimum temperature) in each PHE channel, tube, and overall can be calculated from the diagram graphically, and in the model as follows. From Fig. 3a, the gap, e_x , and volume, V_c , in each PHE channel are:

$$e_x(x) = e_j - \delta^L(x) - \delta^R(x) \quad (1)$$

$$V_c = \int_0^L W \cdot e(x) dx \quad (2)$$

where x is a length coordinate, e_j is the channel gap under clean condition, δ^L and δ^R are the deposit thickness on left and right plates, respectively, and W is the channel width. The corresponding equations for the tube model (Fig. 3b) are:

$$R_{flow}(z) = R_i - \delta(z) \quad (3)$$

$$V_{TB} = \int_0^L \pi \cdot R_{flow}^2 dz \quad (4)$$

where R_{flow} is the real radius of flowing fluid, R_i is the inner radius of the tube, δ is the deposit thickness, and V_{TB} is the tube volume. The volume data are used to calculate the pasteurisation time in each PHE channel, τ_c , and tube, τ_{TB} , given respectively by:

$$\tau_c = \frac{V_c}{\dot{V}} \quad (5)$$

$$\tau_{TB} = \frac{V_{TB}}{\dot{V}} \quad (6)$$

where \dot{V} is the volumetric flowrate of milk. Only those locations where the temperature in a channel or tube is higher than the minimum temperature (here, 72°C) are considered in the pasteurisation time calculations. The process fluid can be the hot fluid and/or cold fluid (in the heating PHE milk is the cold fluid, while in the regeneration PHE, milk is on both sides). The overall pasteurisation time, at any instant, is the sum of the pasteurisation times in all channels of all PHEs and in tube. In a clean system, it will start being longer than the minimum HTST requirement, but decreases over time due to fouling. A new termination condition is therefore defined, based on the time-varying pasteurisation time: TC1 (overall pasteurisation time < 15s). Here, both TC1, and the max fouling criterion, TC2 (critical deposit mass density on any PHE plate >16 g/m²) are used in a combined OR logic condition to decide when to switch from heating to cleaning.

3. High-temperature-short-time (HTST) case studies

A HTST pasteurisation treatment is considered, with milk temperature > 72°C for 15 s and initial configuration in Fig. 2a (TCH and TCR are connecting tubes). Milk is fed to PHE1 (used as regenerator), then goes to PHE2 (used as a heater), to holding Tube 1,

back to PHE1 for energy recovery and to PHE4, used as a cooler. Equipment, operation, and model parameters for this typical industrial system are in Zhu et al, 2020, based on Gutierrez et al, 2014. The new PHE and holding tube have the same geometry and configuration as the original ones. Each PHE has 12 plates with flow configuration as in Fig. 5d. Fouling is included in all models, including for TCH and TCR. Inlet flowrates and temperatures are given in Table 1 for two settings. Fig. 4 shows the temperature and deposition rate diagrams for both settings at time $t = 3.8$ h, after starting from a completely clean system. The x axis in the diagrams in Fig. 4 and Fig. 5 is the distance along the milk path in the pasteuriser unit (points ①-⑩ in Fig. 2). The ordinate shows the milk temperature (Fig. 4a) and deposition rate (Fig. 4b) at each point along this path. At the start time $t=0$ (clean conditions) the pasteurisation time for Setting 1 is 16.1 s, above the minimum HTST requirement. Due to fouling, after 3.8 h of operation, the pasteurisation time becomes 15s, thus triggering switching condition TC1. Significant fouling also occurs in the holding tube and at the higher temperature locations in PHE1 and PHE2. With Setting 2, a smaller hot utility flowrate results in a lower top milk temperature and milder fouling, however the pasteurisation time is only 8.8 s even at initial clean conditions, failing to meet the HTST requirement. A similar diagram of the heat flux from the processing fluid (negative values denoting heat transferred to the fluid) to the left-side and right-side plates in each PHE channel is shown in Fig. 5a and 5b, respectively, for Setting 1. Due to the alternance of co-current and counter-current flows in adjoining PHE channels (Fig. 5d), the two are different. A clear, strong relationship is evident between the relative flow directions on the two sides of a plate and heat flux pattern. In co-current flow plates, the heat flux shows a zigzag pattern, while in counter-current flow plates, it shows a piecewise continuous line. Adding up the heat flux on the left and right plates of each channel gives the total heat flux from the processing fluid flowing there (Fig. 5c, with adiabatic tubes). The heat transfer picture is clearly very complex. These strong interactions between equipment, operation and fouling make a detailed dynamic model essential to estimate the actual pasteurisation time and how it changes over time.

Table 1. Inlet stream flowrates (F) and temperatures (T) for two settings (based on Aguiar & Gut, 2014), and resulting pasteurisation times when all units are clean (at time $t = 0$).

Setting	F_{milk} (L/h)	F_{heat} (L/h)	F_{cool} (L/h)	Inlet Milk temperature (°C)	Inlet Hot utility temperature (°C)	Inlet cool utility temperature (°C)	Initial pasteurisation time (s)	Highest milk temperature (°C)	Severity of fouling
1	20	60	60	19.4	90	10.1	16.1	84.9	severe
2	20	20	20	19.4	90	10.1	8.8	76.1	mild

4. Semi-continuous operation with the additional equipment

In a traditional operation, upon detection of excessive fouling after a heating period, the whole unit is cleaned. Here, after the above initial Phase 1 of 3.8 h, only the main heating exchanger (PHE2) and holding tube (Tube 1), heavily fouled, are taken out for cleaning. The equipment is reconfigured in Phase 2 as follows: PHE3 (cleaned), is put in service as a Preheater; PHE1 (mildly fouled from preheater use) becomes the main Heater; The second (clean) tube (Tube 2) is used as holding tube; PHE4 continues its service as a Cooler. When PHE1 or Tube 2 violate the fouling or pasteurisation time conditions, Phase 2 ends, they are cleaned, PHE2 becomes the Preheater and PHE3 the main Heater, with Tube 1 used again. The equipment is operated in a rotation sequence of these three Phases according to the schedule in Fig. 6a. The termination criterion used for CIP is TC3 (residual deposit mass < 0.01 g) on each plate for PHEs, and overall, for tubes. In Phase

1, the CIP time for Tube 1 is 52.7 minutes, leaving negligible deposit, that for PHE2 is 24.8 minutes, leaving a small residual deposit. As the heater, previously used as a regenerator, does not start clean, Phase 2 is shortened to 3.44 h. Phase 3 lasts 3.42 h before a termination condition is triggered (in all cases, TC1). PHEs 1-3 rotate between three tasks (preheating, heating, CIP) according to the STN in Fig. 2b, tubes switch between two tasks (holding, CIP). The three-phase cycle takes 10.7 hours with the schedule in Fig. 6a. The deposit on each plate of each PHE during the full cycle is shown in Fig. 6b-d.

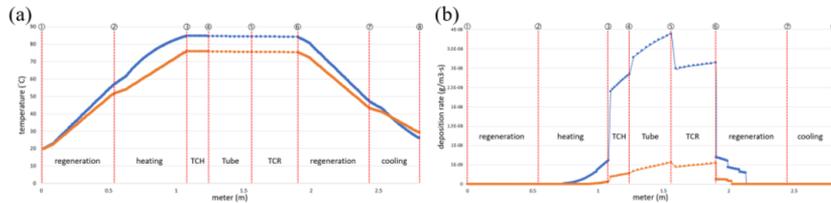

Figure 4. (a) Overall temperature diagram and (b) Total deposition rate diagram for at $t = 3.8h$. Setting 1 denoted as the blue line; Setting 2 denoted as the orange line.

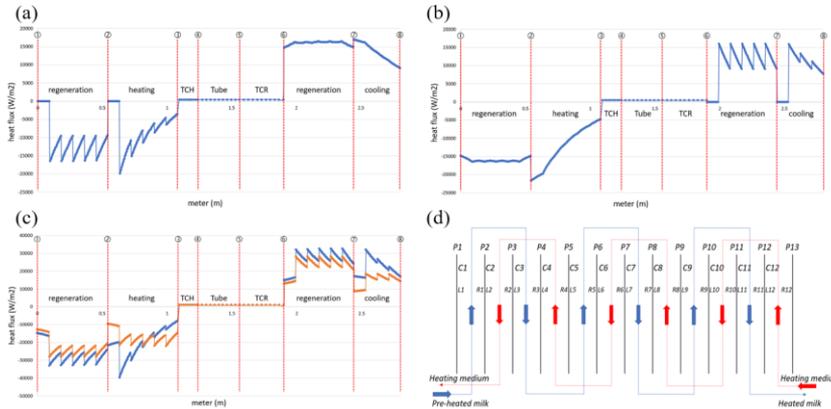

Figure 5. Heat flux from processing fluid, at $t = 3.8 h$, to (a) left plate and (b) right plate; (c) Total heat flux - blue for Setting 1, orange for Setting 2 (d) Flow patterns in the PHE configuration.

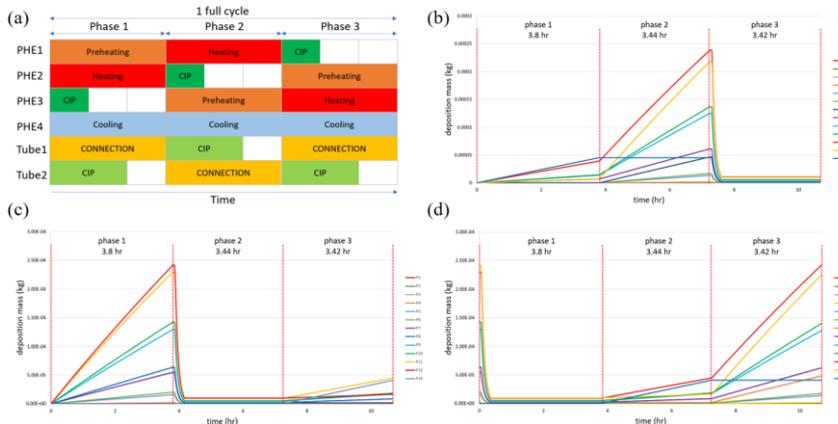

Figure 6. Setting 1 operation: (a) Schedule of 4 PHEs and 2 tubes in three phases; Deposit mass during the cycle on each plate of (b) PHE1 (c) PHE2 (d) PHE3.

After the first cycle, subsequent cycles remain stable and can be repeated indefinitely. The performance of this semi-continuous cycled operation is compared to that in batch mode, which alternates production (heating) and stoppage (cleaning) of the whole system, using the method and cost parameters in Sharma & Macchietto, 2021. For the batch operation, heating is terminated according to TC2 (deposit mass density on any PHE plate $>16 \text{ g/m}^2$) and CIP according to TC3 (residual deposit mass on each PHE plate $< 0.01 \text{ g}$). The semi-continuous mode pasteurises milk continuously with a 23% higher daily throughput, 69% lower cleaning cost, and 47% lower total operating costs.

5. Conclusions

Calculating milk pasteurisation time and its decay due to fouling, based on a detailed dynamic model of the integrated heat treatment process, allows us to monitor directly the key process constraint, and to use it in a new logic for switching between heating and cleaning. The new diagram of key properties of the process fluid along its path offers great insights into the integrated operation dynamics. Adding an exchanger and holding tube to the traditional scheme, using them flexibly in rotation, and suitable scheduling of preheating, heating, and cleaning tasks in individual equipment give additional degrees of operational freedom. Exploiting the interactions between design, dynamics, and scheduling results in a semi-continuous, cyclic operation, with uninterrupted milk production. A case study for a typical HTST heat treatment of milk shows that this semi-continuous mode delivers significantly higher throughput and lower cost than the traditional (batch) operation. As some new equipment is required, a full economic assessment depends on the trade-off between capital and operating cost for the new design. The optimisation of the semi-continuous operation, overall benefit and return on investment is beyond the scope of this paper and will be investigated in future work.

Abstract

Artificial reefs are presented as a possible response to the shrinking biological resource in coastal strip. They are intended to protect, regenerate, concentrate and enhance populations of marine organisms (Miller *et al.*, 2007). The fluid-structure interaction generates changes in the flow regime, resulting in the formation of basins around the reefs by vortices above the structure (Sumer *et al.*, 2001). The mean velocity correlated with the turbulent kinetic energy allows to study the sediment transport process in turbulent flow (Mazzuoli *et al.*, 2020). Modelling of fluid-structure seabed interaction (FSSI) was realized on the software Xflow 2020. The evolution of the burial depth leads to an increase in the turbulent kinetic energy. This evolution correlates with the mean velocity and shows an evolution of the sediment transport in time. The dynamics of a saturated sand was supposed similar to a pseudo viscous fluid (Chávez-Modena *et al.*, 2020; Ouda and Toorman, 2019; Zhou *et al.*, 2014). A two phases flow modelling with a sand defined by the Herschel-Buckley viscous model was realized. The result showed the same transport processes explained by (Mazzuoli *et al.*, 2020). The innovation of this article is to highlight turbulence as the principal reason of reef burial. A predictive method to characterize structure burial during time was showed by multiphase modelling.

1. Introduction

Marine biodiversity is weakened due to climate change leading to an increase in extreme events. Between the years 1982 and 2016, heat waves doubled in frequency and became more intense and widespread (Abram *et al.*, 2019). This type of event causes degradation and loss of habitat such as coral reefs (Ainsworth *et al.*, 2020). Coastal areas are particularly affected by this fragilization due to human overexploitation, ocean acidification, increased salinity, and rising sea levels (Abram *et al.*, 2019). Marine Protected Areas (MPAs) and artificial reefs have shown their usefulness in marine ecosystem recovery (Rees *et al.*, 2020). In the last 3 decades, a large number of artificial reefs have been immersed in coastal areas around the world, including Japan, America and Europe (Santos and Monteiro., 1997; Kim *et al.*, 2001; Jorgensen *et al.*, 2009).

On another side, marine scour is an erosion phenomenon created by the formation of turbulence during fluid-structure interaction. These turbulences cause the displacement of sediments above the structure (Sumer *et al.*, 2001). Several studies have identified different mechanisms and characteristics of scouring around wrecks, large rocks or artificial structures (Werner *et al.*, 1980; McNinch *et al.*, 2001; Quinn., 2006). Important factors influencing

scour processes include object structure and orientation, bathymetry, and seabed geomorphology (Quinn., 2006). However, these reefs get buried in the sand over time. Very few works were conducted on the characterization of artificial reef burial. However, many numerical models of pipeline burial have been studied, using different approaches such as the impermeable wall method (Fuhrman *et al.*, 2014) as well as the study of soil liquefaction (Ye *et al.*, 2013; Li *et al.*, 2018). The purpose of this study is to determine if the main cause of the burial of artificial reefs is scouring and if it is possible to estimate artificial reefs lifetime with numerical modelling. For this purpose, two types of Fluid Structure Seabed Interaction modelling (FSSI) have been performed: a modelling of FSSI of the seabed geomorphology modeled in 3D for the years 2019, 2020 and 2021 to determine the reasons of the changing geomorphology through computational fluid dynamics (CFD) and a second modelling to validate the prediction tool for FSSI modelling considering the behavior of the surface part of the saturated sand as a pseudo viscous fluid (Ouda and Toorman., 2019; Chávez-Modena *et al.*, 2020; Zhou *et al.*, 2014).

2. Environment

Atlantic Land Reef is an association based in the South-West of France. This association is installed since 1999. Three different types of artificial reefs are implanted on the Landes coast. During the years 2019, 2020 and 2021, depth data around these reefs were collected by divers. With these data, a 3D model of 20x20 meters of the geomorphology around the reef was made (**Figure 1**). The burial modelling was done on two types of these reefs with different structures, named Babel and Typi. The modified geomorphology has a bowl shape that grows from 2019 to 2021 and had not the same shape for the 2 artificial reefs studied. All six bowls were modelled in 3D: one 3D modelling was done for each year and for each reef studied. In this paper the results are focus on the Babel reef illustrated in **Figure 1**.

3. Simulation of the interaction fluid structure on the bow

The software Xflow®2020 was used for this study. It resolves the Lattice-Boltzmann Method (LBM) inspired from the Kinetic theory. The turbulence near wall was calculated by the wall function called Wall-Modeled Large Eddy Simulation (WMLES). The dynamics of sediments in turbulent environments were studied by (Mazzuoli *et al.*, 2020). The results obtained from this study could not be analytically compared with the study of Mazzuoli *et al.* (2020) because the sands studied had not exactly the same composition but the physical characteristics of these sands were similar enough to compare the transport process. The threshold of sediment transport in the ocean environment was evaluated by the shield parameter (Li *et al.*, 2020), and this parameter was compared with the turbulence intensity by Mazzuoli *et al.* (2020). The turbulence intensity at ground was displayed in percentage and was calculated using the equation (1):

$$I = \frac{\sqrt{\frac{2}{3}K}}{U} \quad (1)$$

Where U is the mean velocity and k is the turbulence kinetic energy. Numerical simulations performed on the bowls have shown strong turbulence intensity above reefs. The proportion of ground surface with a turbulence intensity of 40 % increased with time as the bowl gets larger (**Figure 1 (a),(b),(c)**). The maximum turbulence intensity also increased over time, representing 42 % in 2019 and 54 % in 2021. The turbulence intensity could be correlated with the water mean velocity at ground level. All the proportion of ground surface with a turbulence intensity higher than 40 % corresponded to a current speed of 0.03 m.s⁻¹. The equation of the turbulent intensity has shown that the maximum turbulence intensity, in correlation with the mean velocity, indicated an increase of turbulent kinetic energy as the bowl was increasing. K went from 2.1 J for the 40 % intensity zones to 11 J for the maximum turbulence intensity. Mazzuoli *et al.* (2020) has shown that a high turbulent kinetic energy correlated with a very low velocity (< 0.05 m. s⁻¹) creates a low sediment transport. Thus, sand grains roll and slide on the ground.

The 20 % turbulent intensity zones near the reef (**Figure 1**, green zone) were concerned by a 1 m.s^{-1} velocity. The turbulent kinetic energy for these areas was therefore 6 J, which represented a non negligible energy (Mazzuoli *et al.*, 2020). The bowl was deepening over the years, resulting in an increasing slope in these areas. The increasing velocity for a turbulent kinetic energy of 6 J resulted in more sediment transport for 2019 but as the bowl increased, the scour reduced for the region.

The regions away from the reef were concerned by a turbulence fluctuation considering space and time. For 2021 the turbulence intensity of regions away from the reef was constant and the geomorphology of these areas was deeper than 2020 which was deeper than 2019 as well as represented in **Figure 1 (a),(b),(c)**. The mean velocity was 0.07 m.s^{-1} for a turbulent kinetic energy of 9 J. This data was higher for regions away from the reef than near the reef which suggested a growing sediment transport in these areas. The transport process could explain a slow scouring above reefs which was occurring over several years. This modelling confirmed our hypothesis that turbulence is possibly responsible for the increase of the bowls and therefore probably plays a key role in for burial of artificial reefs.

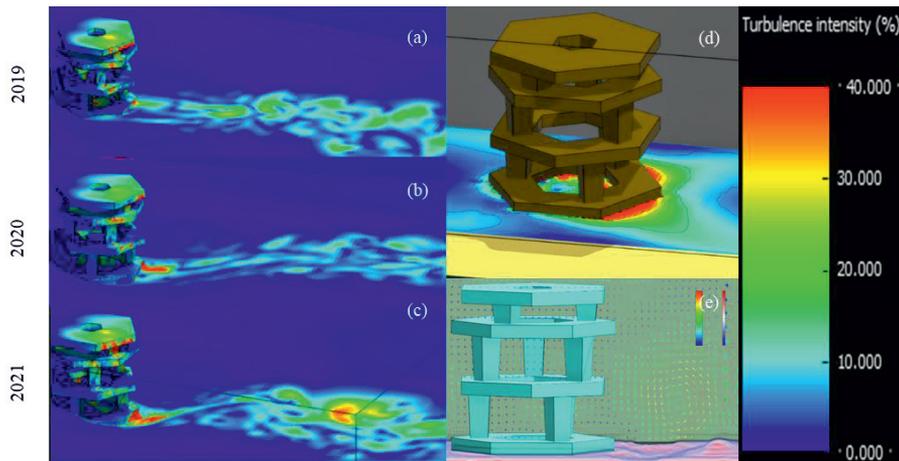

Figure 1: (a-c) Evolution of the turbulence intensity during the year 2019 to 2021, (d) Turbulence intensity at the ground, (e) Interaction turbulence with seabed

4. Multiphase modelling

A multiphase modelling was conducted to determine if the turbulence energy is responsible for burial of artificial reefs. Two types of multiphase modelling were done to validate the transport process observed in experimental measures.

4.1 Rheology of saturated sand defined as a viscous fluid

The rheology data was obtained from literature (Zhou *et al.*, 2014) and defined the behavior of a saturated sand as a viscous fluid. This fluid follows the viscosity model of a power law. The rheological data was determined following a triaxial test which possessed a soil consolidation pressure of 100 kPa. These consolidation pressures values were chosen as the weight of the Babel reef is 11094 kg. Thus, the pressure applied by the reef on the sand corresponded to a force of 109 kPa. The rheological data could be calculated with equations (2) and (3).

$$\tau = \frac{\sigma}{2} \quad \epsilon = \frac{\sigma}{E} \quad (2) \quad (3)$$

Where τ is the shear stress, σ is the stress with $\sigma = 42$ kPa. ε is the strain which can be defined as modulus of elasticity better known as Young's modulus for granular models according to the equation (4) (Massarsch and Tekn., 2015).

$$E = \frac{(1 - \nu)}{(1 - 2\nu)(1 + \nu)17.11} \quad (4)$$

Where ν is Poisson ratio which is equal to 0.49 (Massarsch and Tekn., 2015; Zhou *et al.*, 2014), These data helped to calculate the shear strain and the dynamic viscosity, defined by equations (5) and (6)

$$\gamma = (1 + \nu)\varepsilon \quad \mu = \frac{\tau}{\dot{\gamma}} \quad (5) \quad (6)$$

Where γ is the shear strain and μ is the fluid viscosity. The shear rate velocity is obtained as defined by equation (7).

$$\dot{\gamma} = \left(\frac{\mu}{k}\right)^{\frac{1}{n-1}} \quad (7)$$

$\dot{\gamma}$ is the shear rate velocity, n is the non-dimensional flow index and k is the consistency coefficient. For a consolidation pressure of 100 kPa, n is equal to -0.1 and k is equal to 10.3 according to (Zhou *et al.*, 2014). These parameters obtained by equations (2) to (7) were injected in a viscosity law. The viscosity model chosen was Herschel-Buckley, which is an extension of the power law (Kang and King., 2016), because this viscosity model defines the behavior of a non-Newtonian fluid at threshold. The model is defined by adding the threshold shear stress (τ_0) and the threshold viscosity (μ_0), as defined in the equations (8) and (9).

$$\tau_0 = \tau - k\dot{\gamma}^n \quad \mu_0 = k\dot{\gamma}^{n-1} + \tau_0\dot{\gamma}^{-1} \quad (8) \quad (9)$$

These parameters were used in the following multiphase modelling

4.2 Multiphase simulations

The modelling has shown similar results to the bowl **Figure 1 (a)**. A zone of 40 % turbulence intensity was highlighted near the reef. The water mean velocity near sand was 0.07 m.s^{-1} but the turbulence energy generated by the fluid-structure interaction leads to a velocity reduction of 0.02 m.s^{-1} . The turbulence kinetic energy is therefore 6 J, corresponding to the same transport process as observed in the bowl. The artificial reef was buried of 0.05 m during the first second of simulation and then stabilized. The saturated sand kept the same morphology indicating that no sediment transport occurred over such a short period. The burial corresponded to the stabilization of the structure in the sand. The immobile saturated sand results corresponded to the sediment transport results of the bowls modelling.

4.3 Simulation with strong turbulences

The **Figure 1 (e)** illustrates the sediment displacement and the eddy caused by turbulence energy. The mean velocity of the sand at 0.54s was of 0.11 m.s^{-1} for a turbulence intensity of 49%, which corresponds to a turbulent kinetic energy of 44J. This high turbulent energy is explained by the maximum speed of the vorticity of 2.9 m.s^{-1} . This very high velocity correlates with the turbulent kinetic energy, inducing sediments transport. A bowl is created from a depth of 0.12m at 0.54s. The transport of sediments with strong turbulence energy seemed to correspond with the conclusions of (Mazzuoli *et al.*, 2020). The reef shape induced a different eddy formation in space, creating a different scouring process according to the studied zone. The reef's behavior was the same during multiphase modelling at normal conditions as with multiphase modelling with strong turbulence energy.

7. Conclusions

The modelling of the fluid-structure interaction on the bowls allowed to highlight an evolution of the scouring according to the geomorphology. The interactions between water and reef led to an increase in the turbulent kinetic energy and a reduction of the mean velocity above the structure. These turbulence characteristics resulted in a slow sediment transport and caused bowls expansion encouraging the burial of artificial reefs. Multiphase modelling can predict the burial of artificial structure but the WMLES modelling requires too much calculation time with current technologies. In order to achieve the objective of simulating over several years a Reynolds-Averaged Navier-Stokes equations (RANS) modelling should be experienced at first. Machine learning is being developed in this area and could be implemented in this RANS simulation in order to drastically reduce the amount of computation while keeping a good accuracy on the turbulence modelling.

Abstract

Kriging is a metamodeling technique, consisting in interpolating between observations points, i.e. simulations with the actual model, which is able to produce analytical expressions for both the metamodel and the prediction error in the whole domain. The goal of this work is to illustrate, on two emblematic categories of unit operations (molecular separator and exothermic reactor), how to use this ability to sequentially build a metamodel, by adding new interpolating points in regions where the error between meta- and actual models is high.

Keywords: Metamodeling, Kriging, separation, reactor

1. Motivation

Metamodeling, or surrogate modeling, refers to the production of a simplified model of an actual model. Such techniques are widely used when the actual model is judged inapplicable or with difficulty within a given context, such as: informatic complexity (e.g., communication standards); issues in code coupling (e.g., different spatial or temporal scales); computing efficiency (e.g. optimization, real-time simulations); need to hide information/expertise during implementation etc. In chemical engineering, process models are in general phenomenological ones, with phenomena modelled from molecular scale to plant scale. Challenges arising are therefore to be able to mimic the 'local' behaviors such as stiff non-linearity and discontinuities due to the physicochemical nature of modelled phenomena (activation processes, reactions, thermodynamics, transfer, phase change etc.); while being appropriate in the whole physical domain.

Among metamodeling techniques, Kriging is an interpolation method between observations points, i.e., simulation results with the actual model (Sacks et al., 1989). This method, also called Gaussian process regression, is well-known in chemical engineering and applied to learn various models such as thermodynamic (Zhang et al., 2013) or unit operations ones (Al et al., 2019) in specific fields. As an interpolation method, the prediction error is zero at the observation points, i.e. data sample used for fitting the Kriging metamodel, and increases between them. Therefore, the sample distribution directly impacts the prediction quality of the metamodel, which could lead to poor prediction performances when using the metamodel. One of the main features of Kriging is the ability to provide analytical expressions for both the metamodel (mean of Gaussian processes) and the prediction error in the whole domain (using the variance of the Gaussian processes). It is therefore possible to perform adaptive sampling (see for instance Liu et al., 2017 or Boukouvala and Ierapetritou, 2012) during the construction step of the metamodel, using the 'local' estimation of the prediction error (e.g. a confidence level) in every point of the domain. Regions with behaviors observed in chemical engineering unit operations (e.g. stiff non-linearities such as reaction fronts) are thus detected with the local prediction error, allowing to efficiently explore the search space by refining optimally the design of experiments.

The goal here is to illustrate how to use the ability of Kriging to estimate the prediction error in the whole domain to sequentially build a metamodel; and to evaluate how Kriging is a suitable method to catch such behaviors using two different unit operations models.

2. Test-problems: chemical engineering models for unit operations

Two tests problems are chosen here, in order to cover two categories of unit operations encountered in industrial processes: molecular separation by membrane and exothermic catalytic reactor.

These cases exhibit various physical behaviors (see Figure 1) and numbers of input and output variables. Each case is summarized below, with the chosen parametrization of variables, and expected difficulties from a metamodeling point of view.

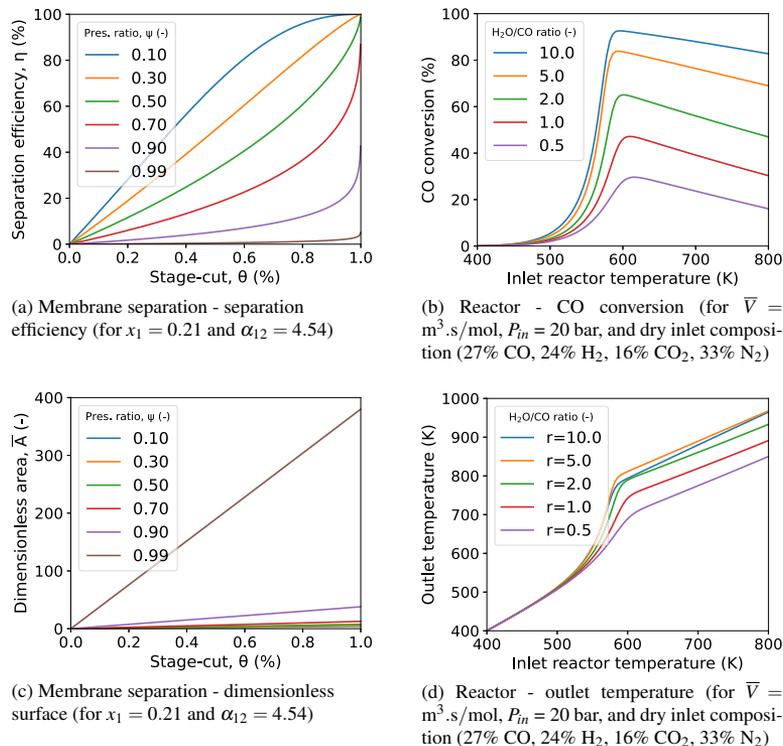

Figure 1: Example of model outputs for the two unit operations

2.1. Case 1. Molecular separation: membrane gas permeation unit (binary mixture)

In this case, a simple gas permeation model is used, assuming crossflow operations, constant permeabilities, and isothermal separation. The physical model requires 4 input variables: mole fraction of the ‘fastest’ molecule in the feed stream x_1 , membrane selectivity α_{12} (ratio of permeabilities), pressure ratio applied between permeate and feed ψ , and design stage-cut θ (desired ratio of flowrate at permeate over feed); and generates 2 output variables: separation efficiency η , and a dimensionless surface \bar{A} . For a complete discussion on gas permeation modeling and dimensionless quantities, see Bounaceur et al., 2017).

With this model, phenomena are mostly linear in the majority of the domain but nonlinear, yet monotonous, profiles occur in the domain boundaries (see for example Figure 1 (a) for high values of stage-cut θ and pressure ratio ψ).

2.2. Case 2. Exothermic catalytic reactor: water-gas shift reaction

The reactor case uses an 1D exothermic catalytic model for water-gas shift reaction ($\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$), using kinetic laws from Hla et al. (2011), under plug-flow and adiabatic operation. The physical model requires 7 input variables: gas mole fractions \mathbf{y} of CO , H_2 , H_2O , CO_2 (N_2 deduced) in the inlet stream, inlet temperature T_{in} and pressure P_{in} , and reactor volume normalized by the inlet flowrate \bar{V} ; and generates 2 output variables from which all quantities can be retrieved: CO conversion rate and outlet temperature.

In this case, there is a strong coupling between all input variables as the model considers both kinetic effects (favored by temperature, stoichiometric reactant ratio and reactor volume) and thermodynamic equilibrium limitations (penalized by temperature and product/reactant ratios). It results in non-monotonous behaviors and very stiff thresholds for the CO conversion (see Figure 1 (b)) within the domain, whose location depends on all input variables.

3. Kriging for metamodeling

3.1. Gaussian processes

Let denote $z(\mathbf{x})$ the output of the numerical model we look to metamodel, with $\mathbf{x} = (x_1, x_2, \dots, x_d) \in T$ denoting the input variables, T being a subset of \mathbb{R}^d (e.g. in case 1, $z(\mathbf{x})$ would be η or \bar{A} and the input dimension is $d = 4$). Kriging framework relies on the assumption that $z(\mathbf{x})$ is the realization of a Gaussian process Z which is completely specified by its mean function $m(\mathbf{x}) = \mathbb{E}[Z(\mathbf{x})]$ and its covariance function: $\text{cov}(Z(\mathbf{x}), Z(\mathbf{x}')) = \sigma^2 r(\mathbf{x}, \mathbf{x}')$. The correlation functions r we are using in this work are the anisotropic $\frac{3}{2}$ -Matérn kernel: $r(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta}) = \prod_{i=1}^d \left(1 + \frac{\sqrt{3}(x_i - x'_i)}{\theta_i}\right) \exp\left(\frac{-\sqrt{3}(x_i - x'_i)}{\theta_i}\right)$ and the anisotropic squared exponential kernel: $r(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta}) = \prod_{i=1}^d \exp\left[-\frac{1}{2} \left(\frac{(x_i - x'_i)}{\theta_i}\right)^2\right]$. The mean function $m(\mathbf{x})$ of the Gaussian process is chosen here to be a constant function $m(\mathbf{x}) = c \in \mathbb{R}$.

3.2. The Kriging metamodel

Let denote $\mathbf{D} = (x_1, x_2, \dots, x_n)$ the design of experiments (i.e. some calculations performed on the actual model) of size n used to train the metamodel, with the corresponding outputs $\mathbf{z} = (z(x_1), \dots, z(x_n))$. Then, following previous assumptions, z is the realization of a Gaussian process and the Kriging model writes:

$$z(\mathbf{x}) = c + \boldsymbol{\varepsilon}(\mathbf{x})$$

with $\boldsymbol{\varepsilon}(\mathbf{x})$ a stationary Gaussian process with zero mean and variance σ^2 and correlation function $r(\mathbf{x}, \mathbf{x}'; \boldsymbol{\theta})$. $Z(\mathbf{x})$ is a conditioned Gaussian $\mathcal{N}(\hat{z}(\mathbf{x}), s^2(\mathbf{x}))$, and its mean and variance can be computed. The mean, hyperparameters $\boldsymbol{\theta}$ and variance σ^2 are estimated from the observations \mathbf{D} and \mathbf{z} using the maximum likelihood estimator. The Kriging mean $\hat{z}(\mathbf{x})$ is the surrogate model that we use to approximate the numerical model $z(\mathbf{x})$ and the Kriging variance $s^2(\mathbf{x})$ is used as a representation of the model mean squared error. As Kriging is an interpolating metamodel, the 'local' error is consequently equal to zero for the observations points and rises between points.

3.3. Adaptive design of experiments and validation

In order to train the Kriging metamodel, we use an adaptive strategy starting from an initial Latin Hypercube Sample (LHS) optimized (through a simulated annealing routine) according to the L2-discrepancy criterion (Damblin et al., 2013). Using this initial design, a first Kriging model is constructed and, using a large validation sample $\mathbf{Y} = (y_1, \dots, y_m)$ and its response by the actual model $z(\mathbf{Y}) = (z(y_1), \dots, z(y_m))$, the quality of the metamodel is evaluated by the means of the absolute relative error $e_{rel,i} = \left| \frac{\hat{z}(y_i) - z(y_i)}{z(y_i)} \right|$ and the Q_2 predictivity factor: $Q_2 = 1 - \frac{\sum_i [\hat{z}(y_i) - z(y_i)]^2}{\sum_i [z(y_i) - \bar{z}]^2}$

with \bar{z} the statistical mean of the sample $z(Y)$. The Q_2 compares the residual variance with the total variance. The closer it is to 1, the more accurate the model is. After the initial training, and if the expected quality is not yet reached, new points are sequentially added to the design of experiments using the prediction error of the metamodel given by its variance $s^2(x)$. Various criterion can be used in order to iteratively add new points (e.g. Jones et al., 1998), here the criterion maximizes the conditional variance $s^2(x)$ i.e. $x_{n+1} = \arg \max_x s^2(x)$ as we seek to control the maximum errors as much as possible. It seeks to add the new points where the metamodel is supposed to perform poorly in order to ensure that the prediction does not fail in some specific areas of the physical space. Figure 2 illustrates this idea on a one-dimensional function ($0.5x^2 + \sin(2.5x)$).

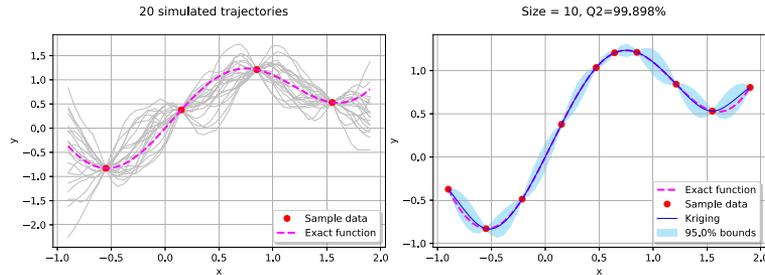

Figure 2: Example of simulated trajectories between 4 sample points (left) and Kriging results with 6 new sample points, sequentially added using prediction error (right)

3.4. Implementation

The Kriging implementation of OpenTURNS (www.openturns.org) is used here, an open-source software for data analysis, metamodeling, and treatment of uncertainties (Baudin et al., 2016).

4. Assessment using the test-problems

In this part, we will present the results obtained on the two tests problems described in 2. The Kriging metamodel is built using a squared exponential covariance for case 1 and a Matérn covariance for case 2. We use an initial LHS of size $N = 100$ and perform $M = 1000$ iterations using the criterion presented in 3.3.

4.1. Case 1: molecular separation

Figure 3 shows the initial design of experiments (blue) and the 300 first additional calculations (orange). The criterion aims at choosing new points on the edges of the physical space and especially on its corner, since the conditional variance has the tendency to strongly increase in these areas. Moreover, this quite classical behavior is reinforced by the fact that the model shows non-linearities around these boundaries, as discussed in 2.1 and shown in figure 1.

After filling these voids, the algorithm tends to add calculation in the other hard-to-predict areas of the physical space such as in the neighborhood of the stage-cut $\theta \sim 0.8$ and the membrane selectivity $\alpha \sim 5$ for instance.

In order to assess the quality of the metamodel, we use a LHS test sample of size 1000. Figure 3 shows the evolution of the Q_2 predictability factor according to the number of iteration and the increasing quality of the metamodel.

As the Q_2 only carries a global estimation of the quality of the metamodel, we also show the box plots evolution of the relative errors according to the number of iterations of the adaptive sampling algorithm for the two outputs of the model: dimensionless \bar{A} and efficiency η in Figures 4. The

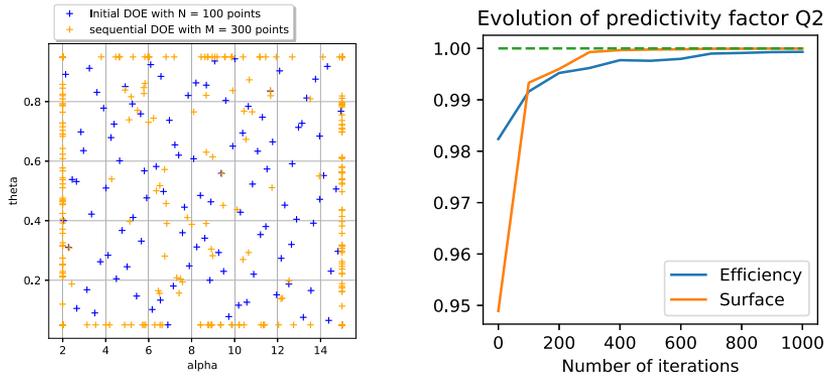

Figure 3: Incremental design of experiment (first 400 points) used to build the metamodel (left) and evolution of Q_2 for case 1 (right)

results are quite satisfactory as we reach, after 1000 iterations, a Q_2 larger than 0.999 for η and larger than 0.9999 for \bar{A} as well as a relative error well-controlled (e.g. 75% of tested points falls under a 3% and 4% relative error for \bar{A} and η respectively) even if some specific areas still suffer from a quite large error. This method has been benchmarked on a neural network constructed from a sample of size 2200 and proved to outperform it from 600 iterations.

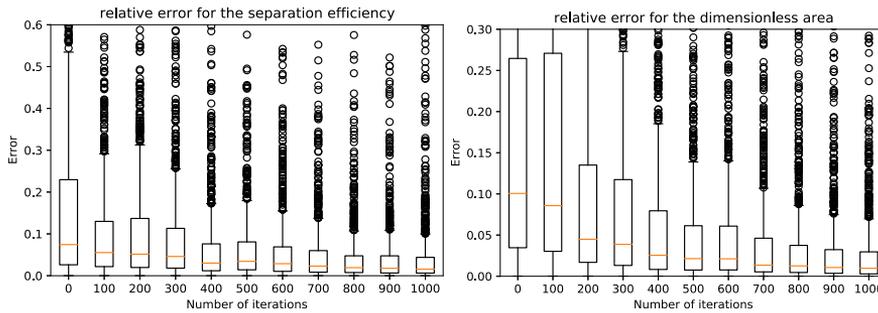

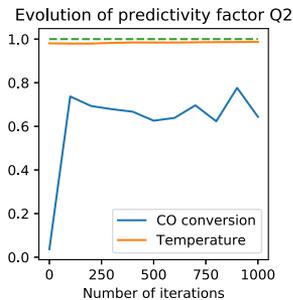

Figure 4: Evolution of the relative error for the separation efficiency η

4.2. Case 2. Exothermic catalytic reactor

Evolution of Q_2 for case 2

This second test-case proves to be more challenging, as it involves a larger number of input variables (7) and more complex physical behavior (see 2.2). If the metamodel manages to approach the outlet temperature quite well ($Q_2 > 0.98$), it reveals to be way less satisfactory to predict the CO conversion, which Q_2 does not exceed 0.8. Figure 5 shows the relative errors for both outputs and if the error on the temperature is acceptable – 75% (resp. 95%) of tested points falls under a 2% (resp. 5%) relative error – it is still far from the accuracy required to justify most metamodel usage in the case of the CO conversion.

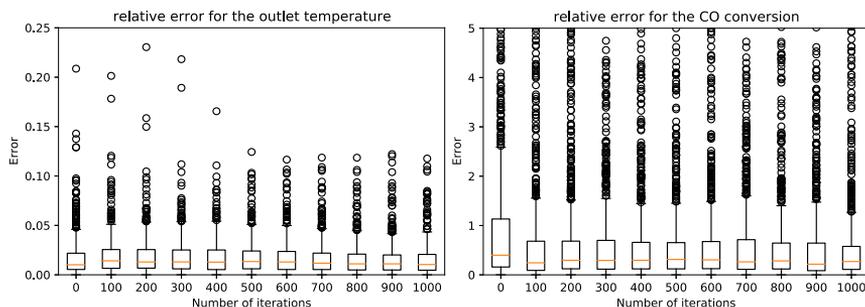

Figure 5: Evolution of the relative error for outlet temperature and CO conversion for case 2

5. Conclusion and perspectives

This work illustrates how to use the ability of Kriging to provide a prediction error in the whole domain, to sequentially add new interpolation points where the metamodel exhibits high error, aiming at reducing the size of the design of experiments (hence time/budget for the metamodel building step), and discrepancies while using the metamodel as it is more refined in regions with high non-linearities (usually difficult to catch by metamodels). This strategy performs remarkably well in the case of molecular separation by gas permeation. The second, more complex, case (exothermic reactor) highlights the limits of the methodology when facing the curse of dimensionality and the increase of the boundaries of the domain, since the algorithm privileges these before filling the areas with strong non-linearities. A coarse first solution is to increase the initial training sample, $Q_2 > 0.995$ for the outlet temperature can be reached with $N = 500$ and $M = 600$. Another possible approach would be to investigate the performance of other criteria, such as the IMSE (Integrated Mean Squared Error).

This first benchmark need to be tested with other criteria for the choice of new points, other types of unit operations, and compared with other sampling strategies (driven or not by the error) and metamodel type, to derive good metamodeling practices for chemical engineers.

Abstract

Muconic acid is a high value product which has gathered interest in applications in the manufacture of new resins, bio plastics, food additives, agrochemicals and pharmaceuticals. Lots of efforts have been made for an economically viable biotechnological strategy for muconic acid production but as of yet have been fruitless. Directed evolution and DBTL cycles hold important promises for the development of future catalysts with high efficiency and productivity. However, process engineering is typically disjointed from these cycles and more often than not the mismatch of kinetics presents a major challenge and a bottleneck in the scaling up of novel bioprocesses.

The paper addresses the integration of metabolomics and experimental data using the optimization and risk analysis of complex living entities (ORACLE) platform combined with clustering and advanced analytics. The methodology consists of six steps. In the first step, the stoichiometry of the system is defined through biochemical data and experimental data are integrated into the model to further constrain it. In the second step, steady state fluxes and metabolite concentrations are calculated based on metabolomics analysis. In the third step, kinetic parameters for every reaction are sampled to fit in with the steady state fluxes based on mechanistic kinetics expressions. In the fourth step, consistency checks and pruning consider the stability of the system and the consistency with experimental data. In the fifth step, the flux control coefficients for the desired metabolite flux are calculated based on the well-established metabolic control analysis (MCA) framework.

In this project, large-scale mechanistic kinetic models for a muconic acid producing *S.Cerevisiae* strain were developed using the aforementioned ORACLE platform. A total of 23500 of potential kinetic models were generated out of which 366(1.58%) passed the pruning step and 70(0.12%) models out of the 372 passed the stability check. Enzymes such as glucose-6-phosphate isomerase (PGI), transketolase (TKT2) and enolase (ENO) had large control coefficients on muconic acid flux.

Keywords: *S.Cerevisiae*; muconic acid; metabolomics; metabolic engineering ; large-scale kinetics;

1. Introduction

Most strain design approaches make the assumption of the system being in steady state and fail to take into consideration the kinetic aspect. Although such techniques provide useful insights and are computationally cost efficient, sometimes they fail to predict potential bottlenecks or rate limiting reactions inside the metabolic network. The current thesis aims to develop large scale metabolic kinetic models for a muconic acid producing yeast using the Optimization and Risk Assessment of Complex Living Entities (ORACLE) workflow. The generated populations of kinetic models will be used as an input for the well-established MCA framework to identify enzymes closely affiliated to muconic acid flux and perform enzyme perturbations to quantify this effect. This way we will be able to develop metabolic strategies while taking into consideration stoichiometry, thermodynamics, kinetics and their interplay.

2. Problem description and workflow outline

2.1.1 Problem description

The development of large-scale metabolic models is a challenging task. The lack of experimental data, the uncertainty of some kinetics parameters available in literature and databases, the uncertainty of the types of mechanisms for every reaction, the errors in metabolomics and fluxomics data are some of the problems (Stanford et al, 2013). Moreover, for every reaction in the system a rate expression along with values of kinetic parameters are required for a kinetic model. Errors also in the thermodynamic properties hinder the ascertainment of a unique steady-state profile for metabolic fluxes and metabolite concentrations. Taking all this into account it is impossible to find a unique kinetics model which describes the physiology but it is possible to produce a population of models that agree with the physiology and statistical analysis on these models can be used to analyse and predict the metabolic responses in the system (Tokic et al, 2020).

The primary challenge will be to produce large-scale kinetic models that are physiologically relevant meaning that their dynamic behaviour is close to the experimentally observed one. The secondary challenge is to identify kinetic models that show “robust” behaviour. Finally, the population of the kinetics models will be used to target key enzymes and offer metabolic strategies for the increase of flux of the desired product.

2.1.2 Workflow outline

The proposed workflow outline is based on the Optimization and Risk Analysis of Complex Living Entities (ORACLE) methodology (Miskovic et al, 2010) (Wang et al, 2004). The ORACLE methodology consists of 7 steps:

- 1) In the first step, the stoichiometry of the system is defined either by biochemical data or genome reconstruction analysis. The genome scale model is reduced to the subsystems of interest. Then, the experimental data are integrated into the reduced model as flux bounds or metabolite concentrations bounds or reaction directionalities. Heterologous reactions are added to the reduced model and gene knockouts are expressed by setting both lower and upper bounds for the linked reaction to zero.
- 2) In the second step, the solution space from Thermodynamic Flux Balance Analysis is sampled. If the thermodynamic properties of a reaction are unknown, we employ

- a Monte Carlo method to predict the reaction ΔG value. Metabolite concentrations and reaction fluxes profiles, that agree with thermodynamics, are generated.
- 3) In the third step, the kinetic parameters for every reaction in the reduced model are sampled using a hit and run sampler. Mechanistic kinetic expressions such as reversible Michaelis Menten are used to describe enzyme kinetics in our formulation. The thermodynamic displacements are calculated during the TFA sampling step. In order to efficiently sample the K_m values, we sample the enzyme saturations. We used simple enzyme saturations expressions in our formulation; $\sigma_E = \frac{\frac{S}{K_m}}{\frac{S}{K_m} + 1}$. Lastly, the v_{max} values are calculated to fit the sampled steady state flux.
 - 4) In the fourth step, the produced kinetic models undergo pruning and stability checks. Pruning reduces the models to those that are physiologically relevant and consistent with the experimental data. The time constants for every metabolite mass balance must be within some physiological bounds to ensure that metabolism is in a quasi-steady state. Stability checks consist of sets of random perturbations to ensure that the generated models show robust model behavior and return to their reference steady state. The models are further screened out based on their stability score.
 - 5) In the fifth step, the stable models are used to calculate flux control coefficients and concentration control coefficients based on a well-established MCA framework. Flux control coefficients C_p^v and concentration control coefficients C_p^x are defined as the fractional change of metabolic fluxes and metabolite concentrations, respectively, in response to a fractional change of system parameters.
 - 6) In the sixth step, advanced statistical analysis and visualization is performed on the produced populations of control coefficients.

3. Case study: Muconic acid production from *S.Cerevisiae*

3.1 Reduced model and experimental data integration

The genome scale model for *Saccharomyces Cerevisiae* used in the current thesis was the yeast8 model⁶⁴. The reduced model contains 5 subsystems that form our metabolic network; Glycolysis, Pentose Phosphate Pathway, TCA cycle, Oxidative Phosphorylation, Shikimate pathway (aromatic amino acids).

The reduced yeast model has 226 metabolites, that makes a total of 226 mass balances. Out of those, 49 are extracellular metabolites. A total of 308 reactions describes the metabolic network out of which 121 are transport reactions, 183 are enzymatic and 1 lumped biomass that describes biomass production and subsequently yeast growth. We added the heterologous reactions for the muconic acid production pathway. According to the experimental data (Wang et al, 2020) the pathway used was the shunting of the shikimate pathway. We assumed that the reactions added took place in the cytosol.

3.2 Kinetic Models

Having generated a big number of TFA samples we screened out 47 samples that produced physiologically relevant kinetic models. We followed through generating 500 parameter sets for every TFA sample, thus resulting in 23500 kinetic models. Only 366 models were within physiological bounds (1,58%). We then proceeded with the stability checks where we performed 200 sets of random perturbations on a short range ($0.8[X_{ref}] \leq [X] \leq 1.2[X_{ref}]$) and on a wider range ($0.5[X_{ref}] \leq [X] \leq 2[X_{ref}]$).

We evaluated the models based on the times they returned to the reference steady state. The two other scenarios were either the models reaching a pathological state (escape) or another steady state.

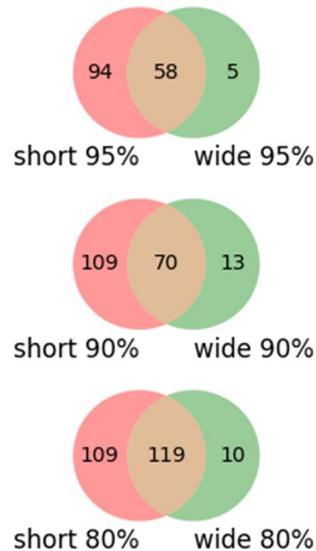

Figure 1. Venn diagrams of models for various stability scores (80%, 90%, 95%) for both ranges of perturbations.

3.3 MCA and enzyme perturbations results

We selected 70 models with stability scores 90% and calculated the muconic flux control coefficients. Based on the enzymes, hinted by the MCA results, that seem to have the most influence on muconic flux we performed some enzyme perturbations and calculated the effect on muconic flux.

We were able to identify the top 20 enzymes that affect muconic flux. Some attractive metabolic strategies that arisen were to increase flux to the Pentose Phosphate Pathway as to increase flux to e4p (PGI↓,TKT2↓,PGL↓) and to increase the dehydroshikimate flux (DHQTi↑). From the MCA results, we deduced that a bottleneck in muconic acid production is the deficiency of e4p in the cell.

For the enzymes that had large control coefficients for the muconic flux we performed some perturbations to calculate the effect on muconic flux. Although, some enzymes that are connected to the Electron Transport Chain (ETC) and are infeasible to regulate, we calculated the effect on muconic flux just for comparison. The candidate enzymes (PGI, TKT2, PGL, DHQTi) showed an increase in muconic flux with varying results. PGI downregulation by 0.5 resulted in 12.5 times bigger than reference muconic flux whereas TKT2 and PGL downregulation by 0.5 resulted in 1.4 and 1.3 times accordingly bigger flux. DHQTi upregulation by 1.5 resulted in 1.8 times bigger than reference muconic flux.

We also tested upregulating the heterologous enzymes (PaAroZ, KpAroY) of the muconic pathway but the increase in muconic flux was insignificant.

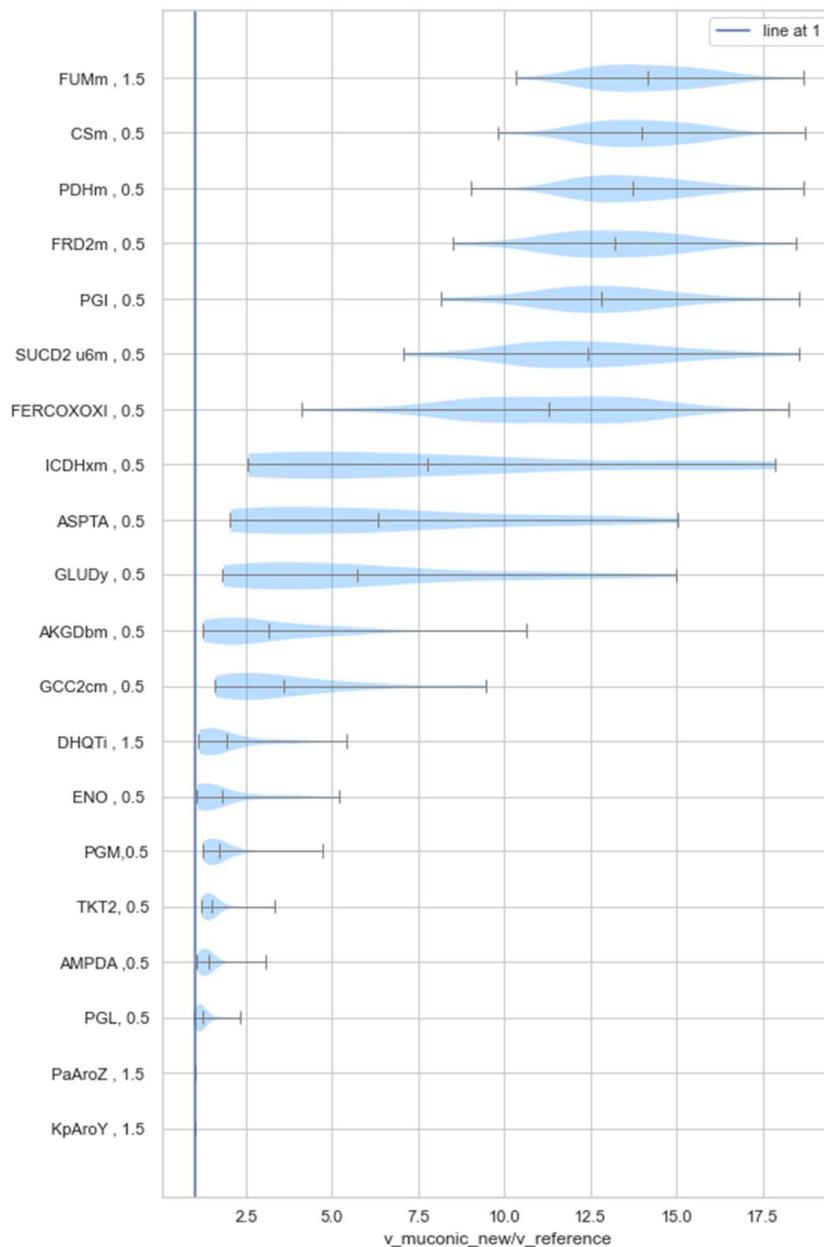

Figure 2: Violin plots of enzyme upregulations and downregulations that lead to an increase in muconic flux. Middle bar corresponds to the mean value. Both extremas also included.

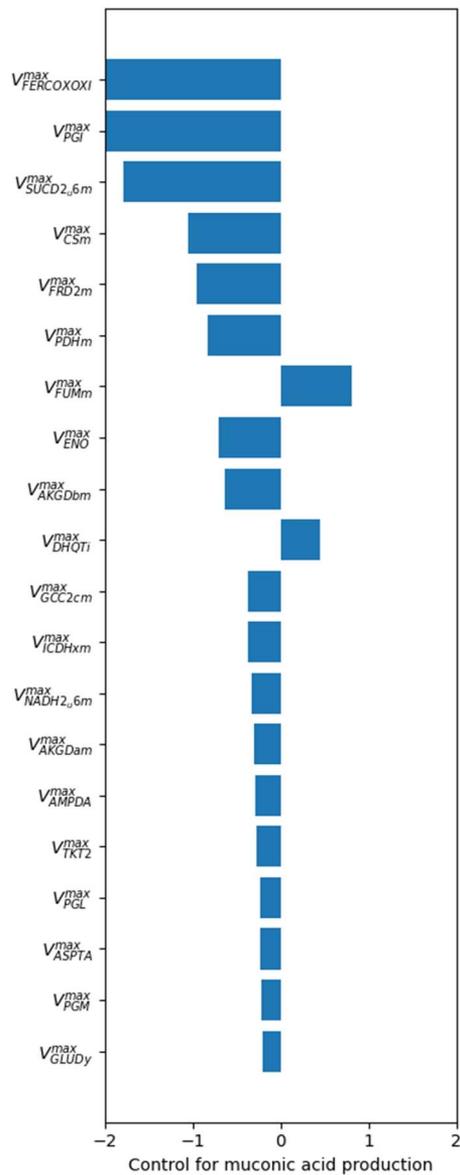

Figure 3: Bar plot of the top 20 enzymes with high muconic flux control coefficients

Abstract

The present work has been devoted to the study, modelling and simulation of a pilot scale pyrolysis plant feed with residual agricultural residues located in Catania, Sicily. A global model representing the process flowsheet was created with Aspen Plus[®] software and was fed with actual experimental data obtained in the existing pilot plant. The aim has been to develop a flexible simulation model in which different types of local agricultural residues could be fed to the reactor and establish the optimal conditions for each case. Raw materials' characterization included ultimate and proximate analysis, and biochemical composition (cellulose, hemicelluloses, lignin, and inorganics contents). All these data were implemented in the simulation for the feedstock definition. The base scenario was established by feeding 35 kg/h of biomass under a pyrolysis temperature between 500 and 900°C. The decomposition of the organic matter was defined as a two-stage process: a first decomposition of the organic fraction into a residual solid fraction (char) and a gaseous mixture, and a subsequent cooling of the mixture to separate the condensable part and to obtain the pyro-oil and the permanent gas stream. This latter stream of gas was used to generate thermal power that could be used to support the energy requirements of the pyrolysis process. To reproduce the degradation of biomass and the resulting evolution of chemical species, a mathematical model, based on the operative temperature and the reaction kinetics was developed. The simulations were designed in order to maximize the gas fraction and minimize the char one. The obtained results were discussed in terms of compound yields, and energetic content of the generated pyro-gas.

Keywords: residual lignocellulosic biomass, simulation, pyrolysis.

1. Introduction

The global energy consumption is still based on the use of fossil resources, even if the need to move towards a sustainable energy market is evident and reflected in legislation and politic agendas worldwide. The increasing energy demand is expected, thus, to be sustained in a big percentage by renewable energies soon, and, among the renewable options, biomass is one of the main pillars (Pang et al., 2021). A wide variety of biomass types can be used for bioenergy generation, but a very interesting option is to get profit of agricultural or forestry residues that are generated in different activities. Cereal straw (Zanzi et al., 2002), olive stones (Benanti et al, 2011), fruit waste (Lam et al., 2016), nut shells (Jahirul et al., 2012) or pruning (Adrados et al., 2017) are some examples of biomass wastes with potential as raw material to produce bioenergy. Thermochemical

processes, such as gasification, combustion, torrefaction, hydrothermal liquefaction, hydrothermal carbonization or pyrolysis, allow the release of the energy stored in biomass (solar energy) in the form of chemical energy (Goyal et al., 2008). The main drawback of biomass as raw material for energy purposes is its low density, which entails the handling and transporting of huge quantities of material, decreasing profitability. Pyrolysis transform biomass in a solid (bio-char), a liquid (bio-oil) and a gaseous stream, through its degradation in the absence of oxygen. Bio-oil is typically transformed into fuels for transportation or for the synthesis of value-added chemicals while bio-char and the gas fraction can be used for heat and power generation (Brown et al., 2013). Pyrolysis is considered as the fundamental thermal conversion process, as it is a well established technology and a crucial step of the combustion or gasification processes (Wang et al., 2017). Different mechanisms take place during pyrolysis, and the obtained products, specially bio-oil, present a complex composition that difficult the modelling of the process (Lam et al., 2019). Several approaches have been developed about the kinetics of the chemical reactions of biomass pyrolysis process (Ranzi et al., 2008; Ranzi et al., 2014; Di Blasi et al., 2008; Fedyukhin et al., 2017) and some researchers have implemented the kinetic parameters in models and simulations (Mabrouki et al., 2015), trying to relate initial feedstock composition, reaction mechanisms and products definition (Peters et al., 2017) in order to define a simplified but accurate way of modelling the products' yields and compositions (Agrifoglio et al., 2021). The process conditions (temperature, heating rate, residence time), strongly determine the distribution and yields of the obtained products (Wang et al., 2017), and a variety of studies cover the relationship between process conditions and products yields and compositions (Kan et al., 2016), for slow (Williams and Besler, 1996), fast (Bridgwater, 2012) and flash pyrolysis (Amutio et al., 2012). Furthermore, recent contributions indicate that the products' distribution and characteristics are heavily influenced as well by the original feedstock composition (cellulose, hemicelluloses and lignin), (Tang et al., 2020; Cheng et al., 2020; Pang et al., 2021). The present work is based on a previous one (Agrifoglio et al., 2021), in which a simulation model for biomass pyrolysis was developed based on experimental data of a pyrolysis pilot plant. The aim was to predict the products' yields and compositions and to estimate the potential of the pyro-gas stream to be used for energetic purposes. The paper proposed as further research the utilization of experimental data to relate these values with other working parameters, such as the heating rate, residence time or particle grind size, as well as to extract more information about the influence of biomass quality and types in the process. From this basis, different raw materials (other types of local biomass lignocellulosic wastes) have been tested and the generated data have been implemented in the model, in order to discuss the previously mentioned influence of the biomass type on the pyro-products distribution. The percentages and composition of the cellulose, hemicelluloses and lignin of the raw material (the predominant molecule in the hemicelluloses fraction or the functional groups in lignin structure), will define the decomposition profile of this specific biomass type with the heating rate and temperature. In particular, olive and peach stones and walnut and hazelnut shells were selected as raw materials and were defined as non-conventional products in the simulation model based on experimental values.

2. Methodology

2.1. Definition of the experimental data for the simulation model

The chemical characterization of the tested biomass types (percentages of cellulose, hemicelluloses and lignin; proximate, ultimate analysis), as well as the calorific values,

were obtained experimentally. These parameters (Table 1) were used as input in the simulation model developed with Aspen Plus[®], to define the biomass decomposition model, which included both primary (gas₁, char) and secondary reactions (gas₂, oil).

Table 1. Proximate and ultimate analyses, chemical composition (dry basis, wt. %) and higher heating values (HHV) of the analysed biomass samples.

		Olive stones	Peach stones	Walnut shell	Hazelnut shell
Proximate analysis (wt. %)	Fixed carbon	7.60	10.3	29.3	27.4
	Volatile matter	82.4	85.4	67.8	70.6
	Ash	3.30	0.30	1.20	2.50
	Moisture	7.01	4.01	9.51	9.02
Ultimate analysis (wt. %, dry basis)	Carbon	50.4	47.1	49.1	46.6
	Hydrogen	5.95	6.40	5.22	5.83
	Nitrogen	0.11	0.25	0.35	0.57
	Sulphur	0.08	0.15	0.09	0.75
	Oxygen	43.5	46.1	45.2	46.3
Chemical composition (wt. %)	Cellulose	19.1	28.2	23.8	20.4
	Hemicelluloses	36.6	23.9	29.6	26.2
	Lignin	43.0	43.3	40.3	48.7
Heating value (MJ/kg)	HHV	21.7	21.3	20.8	21.9

The mass balances were adjusted according with the results of the thermochemical decomposition analysis performed. The evolution of the species involved during the pyrolysis was defined by the derivative of the conversion rate and the kinetic equation (Arrhenius type), as described in the initial work (Agrifoglio et al, 2021). The decomposition of cellulose was defined in two steps, starting with the intermediate “active cellulose” and continuing with the subsequent degradation of it and the formation of levoglucosan (Gorensek et al., 2019). Hemicelluloses degraded into two intermediate compounds from which different decomposition routes generated several minor compounds, among them, xylosan (Ranzi et al., 2014). The lignin decomposition generated different intermediates which further degrade into coumaryl, different alcohols and phenol, among other compounds (Ranzi et al., 2008).

2.2. Design of the simulated process flowsheet

Figure 1 presents the flowsheet of the simulated process with Aspen Plus[®].

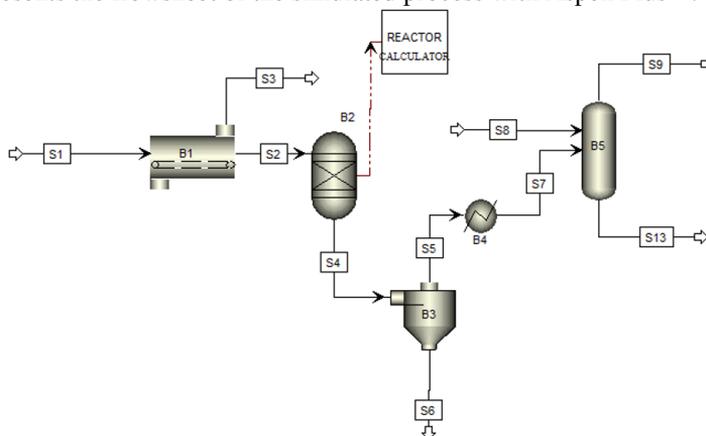

Figure 1. Layout of the simulated process flowsheet.

The base scenario was established by feeding 35 kg/h of biomass under a pyrolysis temperature between 500 and 900°C. Block B1 is a dryer that adjusts the moisture content of the raw material and preheat it before feeding it to the yield reactor (B2), which was connected to a calculator block. The excel sheet coupled to the block include the coefficients to calculate the products yield distribution. The stream exiting from the reactor, S4 is introduced into a cyclone (B3) to separate the gas (S5) and solid (S6) streams. The gas stream is conditioned by cooling (B4) and washing (B5) with fresh water (S8).

3. Results

The yields of char, liquid and gaseous fractions at different temperatures in the range 500-900 °C are reported in Table 2.

Table 2. Yields of char, oil and gas fractions at different temperatures for the studied biomass types.

Products yield wt. %	Temperature °C	Olive stones	Peach stones	Walnut shell	Hazelnut shell
Char	500	34.7	32.1	28.9	30.1
	600	23.3	22.9	26.4	28.2
	700	16.5	16.2	24.2	25.9
	800	13.4	13.3	22.9	23.8
	900	12.1	11.7	21.7	21.4
Oil	500	21.8	20.5	24.5	23.9
	600	18.8	18.0	22.7	21.0
	700	15.6	15.6	19.1	18.7
	800	12.8	12.2	16.3	16.3
	900	9.21	9.00	13.2	13.1
Gas	500	43.5	47.4	46.6	46.0
	600	57.9	59.1	50.9	50.8
	700	67.9	68.2	56.7	55.4
	800	73.8	74.5	60.6	59.9
	900	78.6	79.3	65.1	65.5

It can be seen how the generation of gas increased with temperature for all studied raw materials. The generated products percentages were quite similar for the stones, which reached a 78-79% of gas generation at 900°C. The nut shells achieved about 65-66% of gas at 900 °C. The yield of pyro-gas and char, as a function of the temperature, fitted a polynomial interpolation in all the cases, while the oil yield was described by a linear interpolation (Table 3).

Table 3. Derived analytical interpolations of the products yields.

	Char	Oil	Gas
Olive stones	$y = 0,0171x^2 - 0,1581x + 0,4854$ $R^2 = 0,9981$	$y = -0,0312x + 0,25$ $R^2 = 0,9987$	$y = -0,0166x^2 + 0,186x + 0,2686$ $R^2 = 0,9985$
Peach stones	$y = 0,0136x^2 - 0,1318x + 0,4386$ $R^2 = 0,9987$	$y = -0,0288x + 0,237$ $R^2 = 0,9982$	$y = -0,0119x^2 + 0,1503x + 0,3364$ $R^2 = 0,9998$
Walnut shell	$y = 0,0034x^2 - 0,0368x + 0,323$ $R^2 = 0,9991$	$y = -0,0288x + 0,2784$ $R^2 = 0,9947$	$y = -0,0011x^2 + 0,0531x + 0,4122$ $R^2 = 0,9974$
Hazelnut shell	$y = -0,0006x^2 - 0,0184x + 0,3202$ $R^2 = 0,9996$	$y = -0,0263x + 0,2649$ $R^2 = 0,9967$	$y = 0,0011x^2 + 0,0417x + 0,4184$ $R^2 = 0,9992$

The obtained coefficients of determination (R^2) were close to one in all cases, indicating a very good prediction capability of the model for all the studied raw materials.

As the goal has been to maximize the flow of the gas stream, the temperature of 800°C was selected to evaluate the heating value of the clean gas stream (S9) in order to be combusted and fed to a combined heat and power (CHP) system. At 800 °C, carbon dioxide CO₂ was found to be the predominant component for all studied raw materials, reaching a fraction of 23-29%, followed by hydrogen H₂ (19-26%), methane CH₄ (7-11%) and carbon monoxide CO (6-9%). The water content of this stream was about 15% in all the cases. The values of the flow and HHV of the obtained gas stream are presented in Table 4.

Table 4. Flows and energy content of the produced gas streams.

Biomass type	Pyro-gas		
	Mass flow (kg/h)	Volumetric flow (m ³ /h)	Higher Heating Value HHV (MJ/kg)
Olive stones	20.5	73.2	29.0
Peach stones	21.7	72.9	28.2
Walnut shell	16.4	60.7	16.1
Hazelnut shell	15.9	58.8	17.8

It can be seen that the stone-type raw materials generated a higher volume of gas with higher HHV so, for the purpose of generating electricity and thermal energy in a CHP system, these two raw materials would offer better performance. Nevertheless, the HHVs calculated for the shell-type raw materials were high enough to be considered as valid for the same purpose (Demirbas et al., 2006).

4. Conclusions

The simulation model for biomass pyrolysis created by (Agrifoglio et al, 2021) has been tested by using as input experimental data of four lignocellulosic wastes, two stone-type and two shell-type raw materials. The experimental data of the four tested raw materials were used as input in the simulation model and the results were accurate in all the cases with a good fit. The pyrolysis conditions were selected trying to maximize the gas stream and the obtained values indicated higher yields and HHV for the stone-type raw materials (about 20 kg/h and 28,5 MJ/kg, at 800 °C) even if the shell-type ones were found to generate a gas suitable to be used as feed stream of a CHP unit (59 16 kg/h and 17 MJ/kg, at 800 °C).

Abstract

The urgency of reducing carbon emissions has been constantly reinforced by the scientific community. At the same time, there has been a constant growth in the global energy demand. In this sense, techno-economic-environmental studies are essential to assess the feasibility of new technologies, seeking a carbon neutral economy. The production of biodiesel through an enzymatic route has the potential to enable the manufacture of this biofuel, with a low environmental impact. The use of Crosslinked Enzymatic Aggregates (CLEAs) together with magnetic nanoparticles allows the reuse of the enzyme, possibly reducing operating costs. In this scenario, this work studied the production of ethylic biodiesel, by transesterification of soybean oil with bioethanol, catalysed by the enzyme Eversa® Transform 2.0, immobilized in the form of CLEAs. Two distinct purification processes were assessed: distillation and caustic polishing of biodiesel. Economic feasibility was assessed by the Net Present Value (NPV), with a rate of return of 11% per year, while environmental performance assessment was based on CML-IA midpoint indicators. As main results, the purification by distillation showed better techno-economic-environmental performance, since the distillation process requires fewer separation steps and material inputs, compared to the caustic polishing process. The global sensitivity analysis showed that all variables studied influence the environmental and economic indicator. The base case, with five reuses (value based on the literature), was insufficient to reach an economic performance superior to the current industrial process based on alkaline homogeneous catalysis. And the increase in the number of reuses is important to improve the environmental indicator as well.

Keywords: Biodiesel, LCA, Techno-economic analysis, eversa®transform.

Introduction

The growing global demand for energy, added to policies and legislation to regularize environmental issues, encourages the development of new bioenergy sources and processes (Tom, Sankaranarayanan, and Rodrigues 2019). Biodiesel is a biofuel that has many environmental and social advantages (Ajala et al. 2015). However, the production of biodiesel by chemical catalysis has problems related to the high cost of primary raw materials and many processes necessary for purification (Gebremariam and Marchetti,

2018). In this context, enzymes, which are biocatalysts, perform selective catalysis, which facilitates product purification and has lower energy consumption due to enzymatic reactions occurring under mild conditions of temperature and pressure. However, operational instability and difficulty in recovering free enzymes prevent the application of these biocatalysts in some industrial processes, despite all the advantages of their use (Garcia-Galan et al. 2011). One way around these barriers is to immobilize the enzyme. This technique results in greater chemical and thermochemical stability and contributes to protecting enzyme molecules from denaturation, in addition to enabling easy recovery and reuse of the biocatalyst (Santos, Puna, and Gomes 2020). Crosslinked enzyme aggregates (CLEAs) is an immobilization technique, with low execution complexity and high activity recovery (Amaral-Fonseca et al. 2018). CLEAs have low mechanical stability, which makes enzyme recovery difficult. To overcome this problem, an option is to attach the CLEAs particles to magnetic iron oxide nanoparticles. In this way, the biocatalyst separation can be performed through the use of an external magnetic field, avoiding enzyme compaction, as occurs in other separation methods such as filtration and centrifugation (Kopp et al. 2015).

Miranda et. al (2020) achieved satisfactory results in the production of biodiesel using Eversa® Transform 2.0 immobilized in CLEAs with magnetic nanoparticles in the transesterification of refined soybean oil. Using 12 Uest/g of oil enzyme load, 87.8 ± 0.7 wt % of fat acid ethyl ester (FAEE) yield was achieved after 12 h of reaction, in addition to the biocatalyst maintaining 89.6% of the biodiesel yield produced in the first batch, after five reuses (Miranda et al. 2020). The main objective of this study is to investigate the economic feasibility and environmental impact of biodiesel production catalyzed by Eversa® Transform CLEA with magnetic nanoparticles and its purification by two different routes: biodiesel distillation and caustic polishing with subsequent washing with water. The study was based on a process simulation involving all the unit operations necessary for the product to meet the international standards for biodiesel. A Sensitivity Analysis (SA) was also carried out to identify the process parameters that mainly influence the indicators of economic feasibility and environmental impact.

1. Methodology

1.1. Process Description

The production process of ethylic biodiesel was simulated based on the work of Miranda et al. 2020. Refined soybean oil is fed into the reactor, with excess of hydrous ethanol (oil/ethanol molar ratio 1:6) and the lipase immobilized in the form of CLEA in a vortex flow reactor. The reaction proceeds at 40°C for 12 h. In this step, two reactions occurs transesterification and hydrolysis. Then, the enzyme is recovered through a plate that generates a magnetic field, which collects the CLEAs that are washed with tert-butanol and reused in 5 batches. The solvent used to wash the catalysts is sent to a distillation column for purification and returns to the process. The first step in biofuel purification is decanting, which separates the raw glycerol from the light phase (mainly biodiesel). Then, both streams leaving the decanter are sent to flash for ethanol recovery. After going through the flash, the glycerol reaches a purity of 96%, of double-distilled glycerin. The ethanol goes to a distillation column for purification and returns to the reactor. At this stage, biodiesel already present low concentrations of glycerol, ethanol and water, but still contains a high concentration of Free Fatty Acid (FFA). For the separation of FFA, two process possibilities are tested. The first considers a caustic polishing as proposed in

the work of Miranda et. al (2020). The FFA is neutralized with a 4% (w/v) NaOH solution, the acid reacts with the base and forms FFA salts. A centrifugation step is performed mainly to remove the water added to the NaOH solution. The biofuel is recovered, washed with hot distilled water, and centrifuged (this protocol was repeated three times) to remove any traces of glycerol, alcohol, acid, base or soap that are still present in the biofuel. Then, the removal of water still present is carried out in a flash. The second strategy for FFA removal is a vacuum distillation column in order to remove triacylglycerides, raw materials and other components used in the separation steps (Al-Zuhair et al. 2011; Gebremariam et al. 2019; Sotoft et al. 2010).

The simulation of the process, as well as the calculation of economic feasibility and environmental assessment, were performed in the EMSO Software (Environment for Modeling, Simulation and Optimization). EMSO is an equation-oriented simulator, for academic, teaching and research that provides an environment for simulating and optimizing problems.

1.2. Kriging meta-model

To avoid convergence difficulties typical of steady-state simulations of rigorous phenomenological models of liquid-liquid equilibrium (Decantation) and Liquid-Vapor equilibrium (Distillation Column), metamodels were used to represent these stages (Carpio et al. 2018; Furlan et al. 2012). Therefore, the rigorous models of the distillation and decanter columns were simulated in Aspen Plus and were replaced by meta-models for simulation in EMSO. A universal Kring model was used, built using the "DACE" toolbox, code that adjusts and validates kriging models (Lophaven, Nuelsen, and Sondergaard 2002).

1.3. Economic and Environmental Assessment

The economic feasibility and life cycle assessment (LCA) equations were directly included in EMSO, integrated with the mass and energy balances of the process. Mass and energy balances were used to size the equipment, perform process cost calculations and calculate CO₂ emissions for the production process. This integration between simulation, economic feasibility and LCA facilitates further studies of the process, such as sensitivity analysis.

The data used in the evaluations carried out in this work was based on the Brazilian context in the year of 2020. The Plant was sized to process 17.6 ton/h of refined soybean oil. The metric for calculating economic viability was the Net Present Value (NPV), with a rate of return of 11% per year.

The LCA of this study used the CML Baseline 2000 method. Global warming potential (GWP 100) measured in kg of CO_{2eq} was the impact category chosen. Mass allocation was made between the two products of the process, biodiesel and glycerol.

1.4. Sensitivity Analysis

Sensitivity analysis can determine the parameters that have significant effects on the indicator of biodiesel production. Morris method was used with the following input variables: catalyst reuse number (5 - 30 reuse), transesterification yield (94.9 - 97.9%) and hydrolysis yield (0.87 - 1.41%). The output variables were the NPV and GWP. Yield intervals were selected according to experimental data and enzyme reuse was determined

extrapolating the range obtained experimentally. In the experimental planning, levels equal to 4 were applied and 400 calculations of elementary effects were performed.

2. Results and discussion

2.1. Economic viability

Using the results from material and energy balance together with the prices of raw materials, utilities, labor, and equipment, the techno-economic-environmental performances of the two technology options have been evaluated and presented in Table 1. The total cost of building the plant is US\$ 29.99 million for the purification of biodiesel via distillation and US\$ 30.13 million for caustic polishing. Other studies that use enzymatic catalysis point to an installation cost of 13.5 million for an annual production of 42 thousand tons (Gebremariam et al. 2019). For an annual production of 200 tons, Sotoft et al. (2010) reported an installation cost of 21 million for heterogeneous enzymatic catalysis and 30 million for homogeneous enzymatic catalysis. The values of the study presented were corrected by chemical engineering plant cost index (CEPCI) to the base year of the present work.

Table1: Result of the evaluation techno-economic-environmental of the production of biodiesel catalyzed by CLEA, for different purification methods.

Item	Purification Process	
	Distillation	Caustic Polishing
Annual Biodiesel Production (kg)	141,796,609	139,862,404
Annual Glycerol Production (kg)	13,265,238	13,280,848
Total capital investment cost (US\$)	28,503,448	33,750,667
Total Input (US\$)	914,427,719	915,003,449
Energy (US\$)	358,941	370,668
Utility cost (US\$)	11,210,988	11,758,530
Total Product Cost (US\$)	992,375,455	994,354,866
Revenue (US\$)	180,544,091	178,205,637
Net Present Value at 11% (US\$)	-5,575,617,290	-5,610,014,123
Biodiesel's GWP 100 (kg CO ₂ eq/kg)	2.68	3.73

Caustic polishing is more expensive to implement and operate, resulting in a higher total capital investment cost and total product cost, compared to Distillation. Additionally, the distillation process has a better process yield, as it requires fewer steps to reach the desired standard of purity, which causes less product loss during product purification. However, both purification alternatives have negative profit and, therefore, negative NPV which indicates that the investment is not economically feasible. The high cost of the process is mainly due to the cost of inputs and 85 % of the raw material cost is for the CLEA production. Therefore, it is necessary to increase the number of enzyme reuses, so that this process can become viable. For the process to be economically feasible, at least 475 reuses are required for the distillation and 956 for the caustic polishing process.

2.2. Environmental Assessment

The base cases including transesterification process and two different purification processes have been analyzed with the CML Baseline 2000. The GWP 100 results are shown in Table 1. The enzymatic reaction takes place under mild operating conditions and the absence of soaps and other residues, which makes it possible to apply separation processes with less impact. Vacuum distillation, despite having a higher energy consumption, does not use water and chemicals in the purification step. Therefore, it shows a lower global warming potential.

2.3. Sensitivity Analysis

The standardized elementary effects (SEE) and their mean absolute values were used to select which variables have little effect on the model's outputs. Table 2 shows the mean values (μ) of the elementary effects, the absolute value (μ^*), and the standard deviation (σ). When analyzing the values presented in Table 2, it is evident that the three selected variables have an influence on the NPV and only the hydrolysis conversion can be considered as a variable of low influence in the GWP 100 (for the caustic polishing).

Table 2: Sensitivity analysis results, based on Morris sensitivity analysis.

	NPV			GWP 100			
	μ^*	μ	σ	μ^*	μ	σ	
Distillation	Reuse Number	3.22e+8	1.71+7	8.53e+8	0.67	-0.032	1.712
	Transesterification Conv.	1.11e+9	1.30+8	1.70e+9	2.22	-0.253	3.40
	Hydrolysis Conv.	1.05e+9	-8.79e+8	1.66e+9	2.18	0.162	3.34
	NPV			GWP 100			
	μ^*	μ	σ	μ^*	μ	σ	
Caustic Polishing	Reuse Number	1.79e+9	1.79e+9	1.17e+8	3.58	-3.58	2.33
	Transesterification Conv.	2.84e+8	2.84e+8	1.70e+4	0.13	-0.13	0.05
	Hydrolysis Conv.	1.60e+5	-1.60e+5	4.95e+3	0.001	-0.001	0.001

It is observed, for the caustic polishing process, that the absolute values of μ and μ^* are equal, which indicates a monotonic behavior. Therefore, the sign of the effect of the input variables in the outputs remain the same in all space. This behavior is not observed in the distillation process, showing that the inputs have both positive and negative effects on the output variables. The values of sigma are similar in magnitude to μ and μ^* , which indicates that the SEE values varies substantially. This shows that there will be cross interactions between variables and non-linear behavior. It is important to emphasize that the interpretation of the indices is essentially qualitative and must be used for essentially for factor fixing. To determine the relative importance of the factors, a global sensitivity analysis based on variance must be used (Sin and Gernaey 2009).

3. Conclusions

The replacement of fossil fuels by ethylic biodiesel produced by enzymatic route has great potential for success. However, there are still challenges to be overcome, such as the cost

of enzymes. For the use of Eversa® Transform 2.0 lipase by crosslinked enzymatic aggregates (CLEAs) with magnetic nanoparticles to be viable, it is necessary to increase the number of reuses by 475 and 956 times, for distillation and caustic polishing respectively, or increase the specific catalytic activity of the biocatalyst. The separation of biodiesel produced by enzymatic route, due to the absence of soap and other contaminants, allows the use of different technologies, such as distillation, which proved to be more economical and environmentally friendly than the caustic polishing.

Abstract

In this paper we analyzed the hydrodynamic in a bioreactor which was simulated three-dimensionally applying the Computational Fluid Dynamics (CFD) using the Smoothed Particle Hydrodynamics (SPH) method. The developed model was validated through the comparison between the numerical and experimental data of the internal flow produced by a double Rushton stirred. The performance of the impellers analyzed in this work, named propeller, anchor and Rushton, were compared respect to the mixing time, fluid velocity profiles and mixing efficiency. In the SPH numerical simulations were considered the properties of the viscous fluid obtained in the xylitol production as density $\rho = 1240 \text{ kg/m}^3$ and viscosity $\eta = 1.587 \times 10^{-5} \text{ m/s}^2$. This simulation was performed using the DualSPHysics code based in the Smoothed Particle Hydrodynamics (SPH) method. The numerical results obtained in the validation test shown that the SPH method is capable to reproducing hydrodynamics in stirred tank bioreactors. We compared the hydrodynamic performance of three impellers: anchor, propeller and Rushton, in which it was possible to predict stagnation zones and speed profiles that guarantee a more homogeneous mixing. The optimal impeller for a stirring speed of 200 and 600 rpm is anchor and Rushton for 400 rpm.

Keywords: CFD, hydrodynamics bioreactor, SPH.

1. Introduction

The biotechnology industry has become very important in recent years, due to the high demand for products derived from biological systems. The bioreactor is the main unit process and its design must fulfill certain requirements that are needed to ensure the fermentation process efficiency, such as: the stirring speed, the aeration rate, the heating intensity or cooling rate, and the nutrients feeding rate. The homogeneity of dissolved oxygen and substrate concentration in the bioreactor is set by the impellers.

Biotechnological process depends on the biological reactor in particular on the homogenization of the substrate, oxygen and biomass inside the tank. Therefore, it is important to analyze the hydrodynamics of biological reactors, especially the stirred tank reactors used traditionally in fermentation processes.

The Computational Fluid Dynamics (CFD), is a very useful tool to analyze in detail the hydrodynamics and mixing in bioreactors of stirred tank used in microbial fermentation processes (Gelves et al., 2013). The CFD allows the numerical solution of the transport equations by computational means. It can generate a huge amount of information that in practice could not be obtained experimentally, or they are totally inaccessible by the experimental route, also is an effective strategy to improve or ensure the performance of a process. This tool allows determining axial and longitudinal flow patterns, velocity profiles, mixing times, stagnation points or vortex formation. The CFD has been used for description of mixing in bioreactors by (Tajsoleiman et al., 2019; Delafosse et al., 2014) where they propose a compartment model where the flow rates between two adjacent compartments are easily computed from the velocity fields obtained by CFD. Moreover it has been reported studies of hydrodynamic shear stress generated by different impeller combinations in stirred bioreactors and hydrodynamic performance of coaxial mixers in the mixing of yield-pseudoplastic fluids (Kazemzadeh et al., 2016). The evaluations of gas-liquid mass transfer, oxygen uptake, and dynamic oxygen distribution were reported by (Stickel et al., 2018).

The purpose of this paper is to know the distribution of nutrients within the fermentation process, as well as to determine homogeneity and velocity profiles in order to guarantee the hydrodynamics that promotes mass transfer in three different impellers traditionally biotechnology used anchor, propeller and Rushton.

2. Methodology

The analysis has focused on the hydrodynamics of the tank by means of CFD using the SPH method to describe the flow patterns and velocity profiles inside the reactor with the objective of obtain data that help to decrease the mixing time and minimizing or eliminating stagnation zones.

For this analysis we first performed the numerical validation of the SPH method by comparing the results with those obtained experimentally by De Lamotte et al., (2017). For validation, two Rushton turbines with 4 blades and a diameter of 0.1 m were used for agitation according to the dimensions reported by De Lamotte et al., (2017) in their experiment. The coupling of the momentum equation and the continuity equation was performed. Stirring speeds $\omega = 200\text{rpm}$, fluid density $\rho = 998\text{ kg/m}^3$, kinematic viscosity $\eta = 1 \times 10^{-6}\text{ m}^2/\text{s}$ and a total of 1,250,000 particles making up the fluid, tank and agitator were considered.

Subsequently, we chose 3 impellers: anchor, propeller, and Rushton with a stirring speeds (ω) 200, 400 and 600 rpm and then the hydrodynamic performance and mixing times for each impeller was analyzed. Finally, for each stirrer we determined the mixing time at the stirring speed that showed the highest homogeneity. For the simulations of the hydrodynamics of the stirred tank bioreactor, the following parameters were considered: density $\rho = 1240\text{ kg/m}^3$, kinematic viscosity $\eta = 1.587 \times 10^{-5}\text{ m}^2/\text{s}$, and a total of 500,000 particles in a time of 15 seconds. The height-diameter (h/D) scale ratio of the reactor is 1.5 times. The sizing of the bioreactor and impellers was performed in SolidWorks®, the total volume of the tank is 5 L, with a height of 0.33m, a diameter of tank 0.16m and with 4 baffles to reduce stagnation zones. The impellers have a height of 0.27m.

2.1. Impellers

Stirring and mixing is an operation used to accelerate heat and mass transfer processes. This operation introduces energy into the volume of the fluid, i.e. the kinetic energy of the agitator is transferred to the fluid causing it to move. This operation involves systems that are in a single phase or in several liquid, solid and gaseous phases. For this purpose, agitators have been designed to generate parallel flows to the impeller axis, which are called axial flow impellers; and some that generate flows in radial-tangential direction, which are called radial flow impellers.

The propeller is an axial flow agitator and is used for liquids that are not very viscous. The speed of these impeller varies depending on their size, between 400 and 800 rpm for large propellers and between 1150 and 1750 rpm for the small ones. One characteristic of the propeller is that its blades vigorously shear, or friction, the liquid (Ramirez, 2012). These agitators are used to homogenize, suspend fluids, as well as increase the heat exchange. The propeller agitator used in this study has a diameter $d = 0.06\text{m}$, and a height $h = 0.27\text{m}$ (Figure 1a).

The anchor is a radial agitator, composed of paddles rotating at low to moderate speeds in the center of the tank, impelling the liquid radially and tangentially, with no vertical movement with respect to the agitator, unless the paddles are inclined. The flows are directed towards the tank wall and then continue upward or downward. The anchor-type agitator in this study has a diameter $d = 0.06\text{ cm}$, a height $h = 0.27\text{m}$, and has a deflector plate at a 45° angle (Figure 1b).

The Rushton impeller consist of a driving component with more than four blades, mounted on the same element and fixed to a rotating shaft. They are effective for a wide range of viscosities. When used in low viscous liquids, they produce strong flows, which spread throughout the tank and destroy stagnant liquid masses. The Rushton turbine is ideal for fermentation (Verdugo, 2013). Rushton propeller blades are flat and positioned vertically along the agitation axis, producing a unidirectional radial flow. Two Rushton 4-blade turbines with a diameter of 0.1 m were used for agitation (Figure 1c).

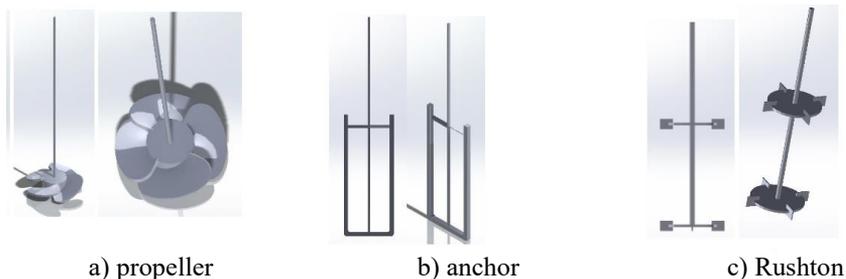

Figure 1. Design of impellers.

2.2 The SPH method

SPH is a Lagrangian, meshless method with applications in the field of Computational Fluid Dynamics. Originally invented for astrophysics in the 1970s (Monagan J, 1992) it has been applied in many different fields, including fluid dynamics (Alvarado-Rodríguez C.E. et al., 2019) and wastewater treatment (Mokos et al., 2015). The method uses points

named particles to represent the continuum and these particles move according to the governing equations in the fluid dynamic. When simulating free-surface flows, no special surface treatment is necessary due to the Lagrangian nature of SPH, making this technique ideal for studying violent free-surface motion. Moreover, the movement of the boundaries can be set easily without the necessity of update the mesh as in the Eulerian methods.

The SPH formalism used in the simulations is reported by (Dominguez et al., 2021) which is set in the DualSPHysics code, in this work only the continuity (Eq. 1), the momentum (Eq. 2) and equation of state (Eq. 3) in the SPH formalism are reported.

$$\frac{dv_a}{dt} = -\sum_b m_b \left(\frac{P_a + P_b}{\rho_a \rho_b} + \sum_b m_b \left(\frac{4v_0 r_{ab} \cdot \nabla_a W_{ab}}{(\rho_a + \rho_b)(r_{ab}^2 + \eta^2)} \right) v_{ab} + \sum_b m_b \left(\frac{\tau_{ab}^j}{\rho_b^2} + \frac{\tau_{ab}^i}{\rho_a^2} \right) \nabla_a W_{ab} \right) \nabla_a W_{ab} + g, \quad (1)$$

$$\frac{d\rho_a}{dt} = -\rho_a \sum_b \frac{m_b}{\rho_b} (v_b - v_a) \cdot \nabla_a W_{ab}, \quad (2)$$

$$P = B \left[\left(\frac{\rho}{\rho_0} \right)^\gamma - 1 \right], \quad (3)$$

where the subscripts a and b are denoted for the mean particle “ a ” and the neighbors particles “ b ”, v is the velocity, t is time, m is mass, P is pressure, ρ is density, v_0 is the kinematic viscosity, τ is the stress tensor, $B = c_0^2 \rho_0 / \gamma$, c_0 is an artificial sound speed, and $\gamma = 7$, and W is the kernel function defined in the SPH method.

3. Results

3.1 Validation of SPH method

The numerical results from the simulation were validated by comparing with the experimental results reported by De Lamotte et al., (2017). The Reynolds number, tank velocity fields and velocity variation were calculated for the case with a stirring speed $\omega = 300$ rpm. The velocity profile obtained by the SPH method versus that obtained experimentally is shown in the Figure 2. The flow distribution is similar, forming two vortices inside the tank similar to the vortices obtained experimentally, likewise the velocity field is in the same range of velocity values (0-2 m/s). With this numerical results the SPH method is validated as a tool for the simulation of the hydrodynamics of stirred tanks.

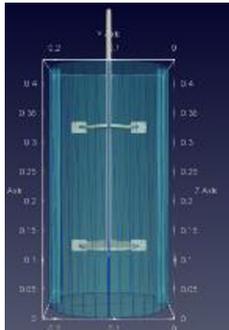

Figure 2. Sizing of the tank used for the simulations.

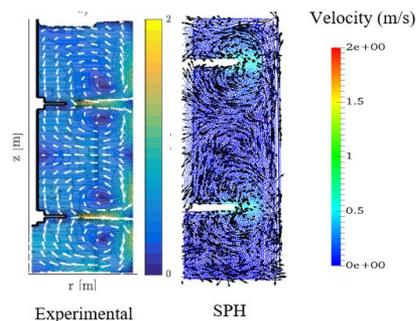

Figure 3. Comparison of velocity profile and vortex formation experimental vs SPH simulation

3.2 Impellers performance

We study the hydrodynamic performance in each speed stirring and each impellers studies for to evaluate possible stagnation zones through of flow pattern impellers. We chose three specific zones within the reactor to evaluate fluid movement within the tank: top, bottom and middle of the biological reactor. The numerical results of the SPH method of propeller, anchor and Rushton impellers for stirring speed of 200 rpm are shown in the Figure 4. This analysis was also performed for speeds of 400 and 600rpm for all stirrers.

In the propeller impeller according to the results obtained from the analysis of the flow stabilization as a function of time (selected points inside the biological reactor), the flow is not homogenized at 15 seconds using 200 rpm, while at 400 and 600 rpm it is stabilized in this time. Addition, with 200 rpm there is no movement in the upper part of the reactor, which suggests a deficient mixing in the tank (see Figure 4a). The other speeds show a better homogenization of speed inside the tank.

According results on the hydrodynamic performance of the anchor impeller, the circulation pattern manifests a radial recirculation behavior in liquid and a turbulent regime at all three speeds. No stagnation zones are shown in any of the stirring speeds studied. In the Figure 4b shown the pattern flow in anchor impeller at 200rpm. The analysis of the three points inside the reactor show flow stabilization time, obtained that for the stirring speeds at 200 and 400 rpm achieved stabilization in 9 and 11 seconds respectively, while the 600 rpm stirring speed needed more than 13 seconds.

In the Rushton impeller the results of the three points of the homogeneity of speed as a function of time shown that the circulation pattern manifests a radial recirculation behavior in liquid and a turbulent regimen (see the top in the Figure 4c). The minimum flow stabilization time in the tank is observed at 400 rpm. For Rushton impeller, there are stagnation points around the blades at the three speeds analyzed.

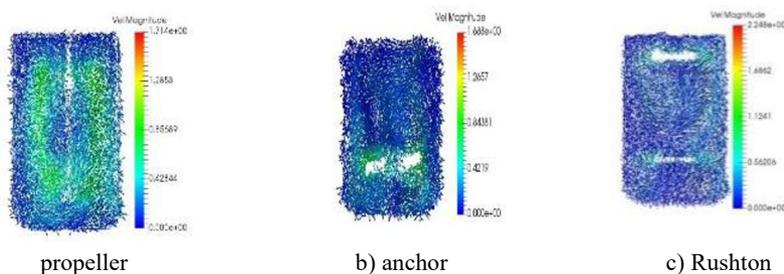

Figure 4. Flow pattern impellers, $\omega=200\text{rpm}$

4. Conclusions

This work presents the numerical validation of the SPH method and its application for the study of three different impellers used in the biotechnological industry: propeller, anchor and Rushton at three different stirred speeds, 200, 400 and 600 rpm. The validation shows good agreement between the numerical and experimental results, so it is concluded that the SPH method is a powerful and versatile tool for the analysis and design of stirred tank bioreactors. According to the results, the best impeller was the Rushton at stirring speed

of 400 rpm, because it does not present vortices and its flow stabilization time is 10 seconds. The propeller impeller shows a low flow stabilization time in the tank requiring more than 15 seconds for a speed of 200 rpm. The anchor impeller shows a similar performance to the Rushton, with flow stabilization time of 9, 11 and 13 seconds for 600, 400 and 200 rpm respectively. In addition, with the analysis of the hydrodynamics of stirred tank bioreactors in SPH, it was possible to predict stagnation zones and velocity profiles that guarantee a more homogeneous mixing.

Acknowledgements

The calculations in this work were partially supported by ABACUS under the CONACyT project EDOMEX-2011-C01-165873. The ABACUS project is thanked for the availability of computational resources.

We are grateful to the Tecnológico Nacional de México for the support for the development of the project "Hydrodynamic analysis of CSTR biological reactors using SPH".

Abstract

The paper explains a generic and systematic approach in the development of embedded models that could be further used for model reduction. The systems approach makes a structured and systematic use of data as they are produced at three distinct stages: simulation assignments by means of spatial differential equations, optimization runs that regress parameters for each simulation, and deep learning training that converts parameters into functions of system variables. Simulation models refer to steady-state operations of closed-circuit grinding models formulated as differential equations with parameters treated as degrees of freedom. Results from this implementation present a consistent accuracy improvement over the model used as basis.

Keywords: Embedded Model, ANN, Deep Learning, Cement Grinding, Ball Mill

1. Introduction

Raw material and clinker grinding are energy intensive processes, consuming 70% of the electricity demand in a typical cement plant, which cumulatively amounts to 2% of global electricity consumption [1]. Due to energy costs, emission restrictions and tight product quality specifications the cement industry is challenged to perform at the highest possible standards; robust and reliable technology in optimization, control and sensor software are important enablers to secure high performance. Still, the industrial processes in the cement industry involve complex multi-phase flow dynamics modelled by breakage distribution function with the rate of breakage determined by probabilistic approach intended to match experimental measurements. The cement industries hold large records of data generated from long times of operation and service in their industrial processes. Deep learning models are already tested successfully to predict environmental performance, even in the absence of first principles [2]. However, one is further challenged to capitalize on the wide range of conventional, yet insightful, models as they are popular for grinding and thermal conversion processing. Model complexity is tackled by limiting assumptions that prevent such models from accuracy and restrict their use to simulation rather than to support decisions and/or assist in the re-engineering of the industrial process. A systematic and combined use of first-principles models with operational data holds a strong promise. In exploiting the underpinning engineering principles supported by the models, one is hopeful to achieve a better analysis of computations and a direct interpretation of their results.

The paper explores the systematic development of embedded models using a ball mill grinding as a pilot. The analytical model is first presented for the ball mill circuit. A conventional approach would directly regress operational data to model parameters. Instead, the paper outlines a methodology where machine learning is applied to convert parameters as functions of process variables. Using a combined stream of model-based and of operational-based datasets, a deep learning model is trained and produced by means of an embedded model. The model capabilities include options to invert the model as well as options to expand it with decision parameters for process design and reengineering.

2. Presentation of first-principle models and parameters

The set of first principles models is presented first alongside parameters to train and connect with real-life data. The feed is considered to consist of a dry mix of clinker, pozzolan, gypsum, limestone and fly-ash, ingredients of common Portland cement. The cement grinding circuit consists of a finishing ball mill that is connected to a SEPAX rotor classifier. The models for the ball mill and the classifier are presented next.

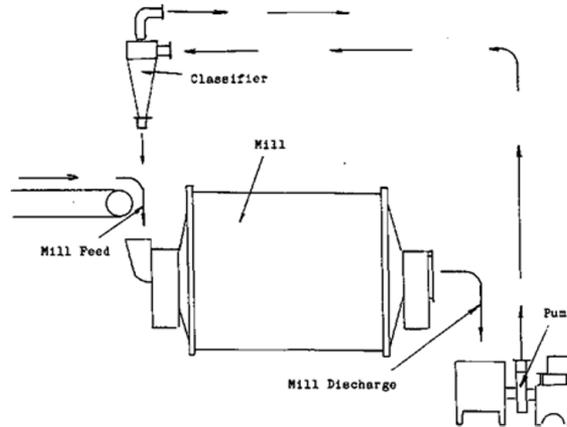

Figure 1: Diagram of a ball mill grinding circuit.

2.1 Ball Mill Model

A first principles model has been presented by Boulvin, *et al.*, 1999 [3]. The model considers cement behaviour inside the mill as solid flow of discretely sized particles. The modelling equations consist of a system of PDEs describing mass flow through convection and diffusion, and particle diameter reduction through breakage. The system of PDEs solve for linear density of cement particles, u_i for each particle size interval, axially distributed over the length of the mill:

$$-v_i \frac{\partial u_i}{\partial z} + D_i \frac{\partial^2 u_i}{\partial z^2} + \sum_{j=1}^9 b_{ij} s_j f(u_j) = \frac{\partial u_i}{\partial t} \quad i \in \mathbb{N}, i \in [1,10] \quad (1)$$

Along with the appropriate boundary conditions:

$$D_i \frac{\partial u_i}{\partial z} \Big|_{z=0} - v_i u_i(z=0) = -q_f w_{fi} - q_r w_{r,i} \quad (1a)$$

$$\frac{\partial u_i}{\partial z} \Big|_{z=L_2} = 0 \quad (1b)$$

Comminution is modelled using the Breakage and Selection function standard. Such models make use of empirical equations to determine the specific rate of breakage of each particle, s_i and the distribution of the diameters, d_i of produced particles, b_i .

$$s_i = ad_i^a \quad (2)$$

A cut-off variation of the Broadbent and Callcott equation [4] is used as breakage function to keep regression parameters to a minimum:

$$B(d_i) = 1 - (1 - d_i/d_1)^{c_3} \quad (3)$$

$$b_i(d_i) = B_i(d_i) - B_{i+1}(d_i) \quad (3a)$$

c_3 expresses the grindability of the material mix. Harder materials tend to break in larger lumps of particles instead of shattering. Linear dependency between the content of the clinker and cement grindability are assumed following.

$$c_3 = c_1 m + c_4 \quad (3b)$$

The effectiveness reduction due to the impact energy cushioning effect of fine holdup accumulation is also accounted for, in the form of the following function. [5]

$$f(u) = u(z)_i e^{-c_n * H(z)} \quad (4)$$

H accounts for the total cement particles mass holdup (of all sizes). Blaine measurements assume cement particles of spherical shape and that Blaine is proportionate to their total surface area. Likewise, product density ρ , is considered constant and independent of the cement composition.

$$Bl = \frac{6c}{\rho} \sum_{i=1}^{10} d_i w_i \quad (5)$$

q_f , $w_{f,i}$ and q_r , and $w_{r,i}$ respectively denote mass flow and weight fractions of i particle size interval in the feed and the recycle streams; they are linear expressions of $\varepsilon(x_i)$ that, in turn, is set by the classifier type. The recycle stream consists of classifier rejects following:

$$q_r w_{r,i} = \varepsilon(x_i) u_i \quad (6)$$

2.2. Classifier Model

The Tromp curve of a SEPAX rotor classifier has a distinct shape which is mostly independent of the operation variables. The classifier is commonly modelled using a Rosin-Rammler model fitted closely to experimental data in order to replicate the characteristic “fish-hook” curve of selectivity over particle diameters. A polynomial equation is fitted for each segment of the curve to match real-life performance.

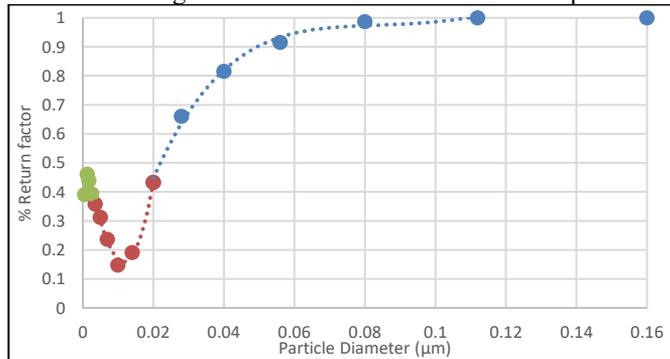

Figure 2: Classifier selectivity for fixed classifier speed and airflow.

The rotor selectivity depends mainly on the feed-rate and the rotating speed. Higher rotating speed increases the classifier’s affinity to smaller sized particles. In essence, as the rotating speed of the classifier varies, the selectivity curve shifts horizontally in a linear manner. To replicate such a behaviour, an effective diameter, z , of the product particles is developed as follows:

$$z_i = x_i + c_2(v_s - v_o) \quad (7)$$

3. Outline of methodology

Given are

- (i). First principles models ($\Sigma 1$ & $\Sigma 2$) as described by (a) the Ball mill model, $\Sigma 1$: Eq. (1-5); (b) the Classifier model, $\Sigma 2$: Eq. (6-7)
- (ii). Sets of real-life data (DS1): This is a dataset of a cement plant ball mill circuit's operation. The dataset originates from a log of hourly semi-steady state measurements for the whole of 2020. Of the log's measurements, DS1 contains: (a) Ball mill dry feed-rate, q_f ; (b) clinker content, m ; (c) Separator speed v_s ; (d) Blaine specific surface, Bl
- (iii). Sets of model parameters (PS1 & PS2). They involve regression parameters within the model $\Sigma 1$ & $\Sigma 2$: $PS1 \equiv \{a, c_1, c_2, c_3, c_4, c_n, c\}$; and a parameter to regress to single data points of DS1: $PS2 \equiv \{c_1\}$

The objective would be the development of an embedded model to convert parameter c_1 as functions of $\{q_f, m, v_s\}$.

The proposed methodology involves the following stages:

Stage 1: Model regression stage where regression parameters are fitted to in-site data.

In this stage, parameters PS1 in integrated model $\Sigma 1$ & $\Sigma 2$ are regressed to plant operation data DS1 by minimizing the objective function:

$$\Phi = \frac{N}{2} \ln(2\pi) + \frac{1}{2} \min_{\theta} \left\{ \sum_{i=1}^{NE} \sum_{j=1}^{NV_i} \sum_{k=1}^{NM_{ij}} \left[\ln(\sigma_{ijk}^2) + \frac{(Bl_{ijk} - \bar{Bl}_{ijk})^2}{\sigma_{ijk}^2} \right] \right\} \quad (8)$$

Stage 2: Data development stage where selected regression parameters are produced to train the model. In this stage, input-output data for machine learning are produced using (a) the set of data from the plant DS1; and (b) outputs from the integration of $\Sigma 1$ and $\Sigma 2$. Dataset DS2 is produced as values of regressed parameters PS2 by minimizing objective function (8).

Stage 3: Neural network training stage using real data inputs and regressed model parameters. The selected parameters are turned to functions of input. In this stage, parameters PS2 are converted to functions of the process input through an ANN trained with (a) the physical input from DS1 and (b) the regressed parameters dataset DS2 produced in (1). $PS3 = f(DS1, DS2)$

Stage 4: Embedded model validation and testing.

4. Implementation

Two identical models of the ball mill, $\Sigma 1$ representing each compartment of the mill are integrated with classifier's model $\Sigma 2$. Simulations of the circuit model $\Sigma 1$ & $\Sigma 2$ are run for steady state operation on gPROMS Model Builder 6.0.4. Parameters PS1 of the model, are regressed to in-site dataset DS1 by minimizing the error of Blaine prediction Eq. (8). Parameters in PS2 of the regressed model (stage 1) are repetitively regressed to each of the individual data points of dataset DS1. A large number of regressions taking account of a wide range of the input values (q_f, m, v_s) take place in this step. Both en masse (stage 1) and individual point regression take place within gPROMS Model Builder Model's Validation Module, which makes use of maximum likelihood estimation algorithm (MLE) for minimizing the objective function value Eq. (8).

Input values (q_f, m, v_s) from DS1 and the complete DS2 dataset is used to train a feedforward ANN in order to determine the function by which they correlate with each other, $c_1 = c_1(q_f, m, v_s)$. The ANN DS1&DS2 are used to train, consists of two 140 neuron hidden layers and a "ReLU" activation function applied to both of them. The output layer instead has a linear activation function. Network training is coded on python using the Tensorflow module and the API Keras and done through "Adam", a stochastic gradient descent optimizer, updating the parameters as follows:

$$\theta_t = \theta_{t-1} - a \frac{\nabla(\theta_{t-1})}{\sqrt{v_t + \epsilon}}$$

While mean squared error (MSE) is used as error function. Then, weights and biases of the trained neurons are acquired and used to replicate the neural model as functions in the gPROMS Model Builder environment. Function, $c_1(q_f, m, v_s)$ replaces the respective constant parameter c_1 of the analytical model, thus forming an embedded one. The Blaine prediction accuracy of the embedded model as well as that of the analytical model with regressed parameters PS1 from stage (1) is tested. The testing of the models' performance occurs in two stages, one for interpolation and one for extrapolation. The testing dataset used for interpolation is picked to match the range and standard deviation of inputs & output in DS1. The extrapolation testing dataset consists of inputs (q_f, m, v_s) . Inputs (q_f, v_s) in specific, are outside of the training dataset's DS1 range, but within a 20% extension from it in either direction. In each testing scenario, the performance of the two models is compared to that of a pure ANN model directly trained to DS1. This ANN consists of 3 hidden layers, the first one containing 128 and the other two 256 neurons each. Both the pure and the integrated ANNs were trained with a low constant learning rate of 0.00001 and a batch size of the entire training sets as training time was not crucial. Both were trained with 2033 data points 20% of which were used for testing. The number of layers and their respective neurons, as well as the number of training cycles were tuned to the end of minimizing the training and testing sets' mean average error without them significantly diverging from one another.

5. Results

All Models' Blaine Prediction Accuracy Comparison:

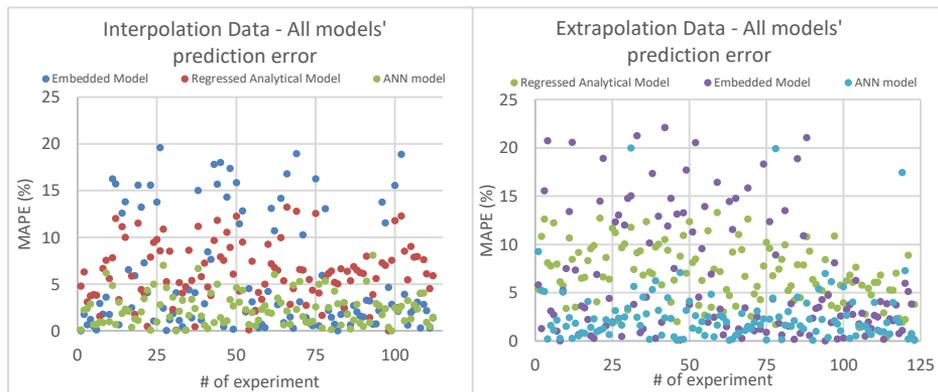

Figure 3a,3b: Comparison of absolute error of measured Blaine of all models on both interpolation and extrapolation validation datasets.

Metric	Pure ANN model/ Interpolation Data	Analytical Model/ Interpolation Data	Embedded Model/ Interpolation Data	Pure ANN model/ Extrapolation Data	Analytical Model/ Extrapolation Data	Embedded Model/ Extrapolation Data
Mean Absolute Percentage Error	2.31%	6.18%	5.57%	2.46%	6.91%	6.37%

Table 1: Comparison of error metrics of all models on both interpolation and extrapolation validation datasets.

While the embedded model outperforms the analytical model on both interpolation and extrapolation performance, it accounts for the largest deviations on both.

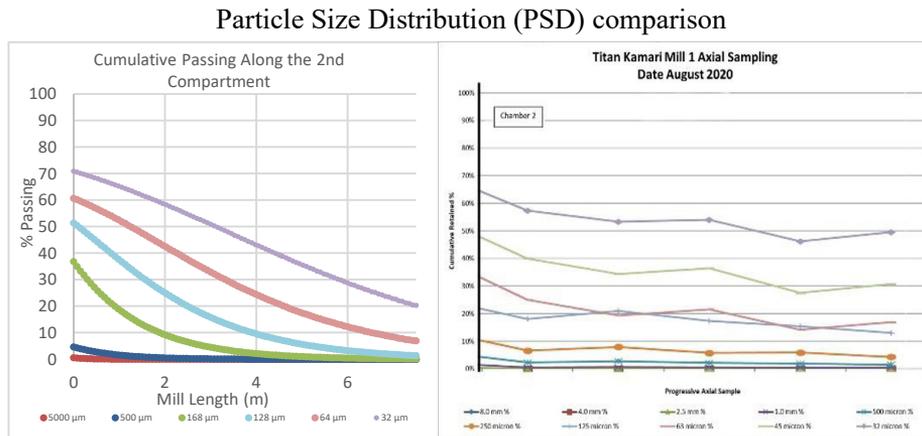

Figure 4a,4b: Comparison of simulated and experimental variability of cumulative passing along the second compartment of the mill.

As no data are available of the conditions the circuit was operating in at the time of sampling, simulations were run using ordinary routine input values. Axial variability of the particle size distribution provided by the embedded model is in agreement with of axial sampling data of the mill, as seen at figure 4a, 4b. Coarse particle passthrough in the second compartment of the mill is estimated by the model to be 4.7% while measured value is 5%. The particle diameter where 50% of passing on mill exit occurs is at 14 μ m while the simulated one is estimated at 32 μ m. This deviation may be a result of sparse discretization of particle sizes.

6. Conclusions

Embedded model is able to achieve higher prediction accuracy in both interpolation and extrapolation conditions while retaining its first principles virtues as the particle size distribution of cement both inside the mill and the product are in agreement with measured values. Further performance increase is expected with the use a larger “input – parameter” training dataset. This methodology is one that would benefit most analytical models fast enough to run enough regressions for the ANN training to be feasible.

Abstract

Biomass processing is considered a strategy changer in the development of new pathways for green energy production, being the thermochemical processes as pyrolysis and gasification part of the main methods used to produce renewable fuels (Mohabeer et al., 2019). The purpose of this work is to perform a simulation of the gasification process of biomass comparing the use of sand and biochar as bed material with the software Aspen Plus®. The simulation is supported and validated by experimental results collected on a pilot fluidized bed. The model includes a biomass pretreatment process and the gasification where the gasifier (a RYield reactor) is supported by a set of correlations obtained in function of the different gasification temperatures. This process allows a good reproduction of the pilot gasifier outlet. An analysis of the effect of the use of biochar as a bed material over the tar reduction on the producer gas is made, applying different gasification agents (H₂O and CO₂) and a temperature variation (600-900°C).

Keywords: Biomass, Gasification, Aspen Plus, Biochar, Fluidized bed, Tar cracking, Simulation.

1. Introduction

The process of biomass gasification consists in the decomposition of organic material (solid or liquid) through the application of heat under the presence of a gasifying agent as CO₂, O₂, steam or a combination of them, which results in the production of biochar and syngas, a mix of gases constituted principally by CO, H₂, CH₄, other light hydrocarbons (C_{≤3}) and tars (Reyes Alonzo, 2020). Due to an incomplete process of gasification and because of the biomass composition, different undesirable products as tars are found in great proportion in the syngas. The tar is a dark, odorous and immensely viscous liquid that contains a diverse amount of aromatic species with one to five rings, oxygenated hydrocarbons and polycyclic hydrocarbons (Gao et al., 2020), they appear in different types depending on the molecular weight of the molecules (Table 1) (Molino et al., 2016). The undesirability of the presence of tar on the gasification process is due to the operational problems such as the reduction of the heating efficiency of the gas and clogging issues in the equipment, caused by the condensation of tar in the zones of low temperature, those issues raise the operational costs due to the application of cleaning devices downstream, being one of the reasons that has made difficult a wider commercialization of the gasification technology (Rakesh N & Dasappa, 2018).

In order to reduce the tar concentration on the producer gas and favorize the production of the syngas, different catalytic bed materials are used for gasification. Bed materials as quartz, feldspar, limestone, etc., have been tested with the aim to find less expensive alternatives to the widely used olivine (Mauerhofer et al., 2018). In this work, the application of biochar as a catalytic bed material is evaluated, since it is considered an economic and accessible alternative in view of the fact that it is a gasification by-product,

and also the biochar has demonstrated to have a good catalytic activity to reduce the tar yield, increasing the syngas production (Abu El-Rub, 2008).

Table 1. Classification of the different types of tar (Molino et al., 2016).

Tar type	Name	Characteristic compound	Examples
1	GC undetectable	Too heavy and cannot be detected with a GC.	Gravimetric tar
2	Heterocyclic aromatics	Water-soluble compounds and tar molecules that contain heteroatoms.	Cresol, Pyridine, Quinoline, dibenzo phenol
3	Light aromatic (1 ring)	Hydrocarbons with single ring.	Xylene, Toluene, Styrene, Fluorene, anthracene
4	Light PAH's (2-3 rings)	Hydrocarbons with two and three rings, which condense at low temperature.	Naphthalene, Indene, Fluorene, Phenanthrene
5	Heavy PAH's compound (4-7 rings)	Hydrocarbons with more than three rings, which condense at high temperature.	Pyrene, Coronene, Chrysene, Perylene

Aiming to describe the phenomena that take place during the biomass gasification, and the syngas composition after the process, different processes simulators are currently used. For this work, we use the simulator Aspen Plus® as a tool to obtain mass and energy balances of the process (Abdelouahed et al., 2012). In literature the biomass is decomposed into its constituents (C, O₂, H₂, N₂, H₂O, S) on a RYield reactor before being feed in the gasifier which could be a combination of the RStoic and RGibbs reactors or a single reactor that transforms those gases into syngas. (Dattatray & Shilapuram, 2019; Zaman & Ghosh, 2021). A significant concern of the use of those models is the fact that they do not represent the actual gasification process which comes along with tars production, leaving aside a major operational problem that could be further observed parametrically using the software, therefore the approach considered is the used by other authors that have model the gasification using empirical correlations obtained from the experimental data gathered after processing the producer gas composition. This process might be convenient, however it cannot be easily extended to other installations (Abdelouahed et al., 2012; Francois et al., 2013).

This article is focused on the modeling of a biomass gasification process through the application of the empirical correlations obtained from previous experiments (Reyes Alonzo, 2020) and the exhibition of the effects of the use of biochar as catalytic bed material over the use of inert material as sand. Also, a comparison of the performance of CO₂ over the use of steam as gasifying agents will be made. Those elements of study have their particularity.

The use of CO₂ as gasifying agent has not been intensively exploited experimentally as the steam due to its energetic downsides, an external heat source is needed in order to maintain the process temperature which is caused by the absence of the partial combustion reaction of biomass that take place when oxidizing agents are used (Sadhvani et al., 2016). However, gasification using CO₂ generates a producer gas with higher energetic values and more efficiency in the tar cracking process when compared with the use of steam (Reyes Alonzo, 2020).

2. Aspen Plus® simulation

The software Aspen Plus ® Version 10 was used in order to obtain a proper reproduction of the results of the composition of the syngas obtained during the process of gasification that was carried out using CO₂ or steam as the gasifying agent. Different units were used to represent the stages of the process (from biomass pre-treatment until solids separation). All the components involved were added on the properties section along with the non-conventional solids: biomass and biochar, which were named as WOOD and CHAR respectively. For this model, the thermodynamic method of Peng-Robinson was selected and the stream class selected was MIXNCPSD for representing the secondary streams containing conventional component, sand and non-conventional solids. The models HCOALGEN and DCOALIGT were selected for enthalpy and density of non-conventional solids were selected. The water was selected as a *moisture component* for the biomass using the *Solid Characterization* menu, where the particle size distribution (PSD) of biomass with an average size from 0.3 mm to 22 mm was considered.

Table 2. Elemental analysis for beechwood pellets and beechwood biochar.

Material	Elemental analysis (wt%)				Proximate analysis (wt%)			
	Carbon (C)	Hydrogen (H)	Nitrogen (N)	Oxygen (O)	Moisture content	Volatile material	Fixed carbon	Ash content
Beechwood pellets	49.35	6.25	<0.01	44.4	6.23	75.4	17.54	0.83
Beechwood biochar	78.24	3.13	0	18.63	0	1.59	93.83	4.58

2.1 Biomass pre-treatment

For the feeding process, the data of the proximate and ultimate analysis of the beechwood was inserted into the stream BIOMASS (Table. 2). This stream goes through the block CRUSHER where the biomass or beechwood pellets (22 mm) are turned into powder with a particle size suitable for the fluidization parameters (~0.3mm). The crushed biomass stream goes through the block DRYER which will reduce the moisture content of the biomass. The configuration ‘Shortcut’ was selected as the operative mode of this block, therefore the amount of moisture contained on the biomass after the drying process was established beforehand.

2.2 Gasification process simulation

The experimental data and the characteristics of the operating conditions of the experimental setup can be found in previous work (Reyes et al., 2020). In the simulation, the pretreated biomass is mixed with the gasification agent (CO₂ or steam) in the MIXER block before entering to the gasifier. The fluidization conditions are established with a flow rate of 1.5 L/min of gasifying agent. The gasifier is modeled using a RYield reactor customized with two calculators with their specific Fortran subroutines representing the

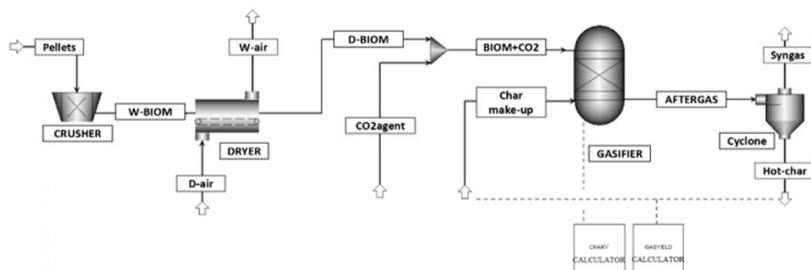

Figure 1. Process flowsheet for the biomass pre-treatment and gasification.

final composition of the gasification products and the incoming amount of biochar into the gasifier. Firstly, the yield of biochar is obtained from the GAS-Y block results and secondly, the block CHAR-Y is executed using this biochar yield as the calculation basis for the biochar entering through the CHARFEED stream as gasifier bed material (Fig. 1). The correlations used on the subroutine of the GAS-Y block represent the yields of each solid, liquid and gaseous specie produced during the gasification. Three sets of correlations were applied in order to represent the gasification with sand and CO₂ and biochar with steam and CO₂ (Table 3).

Table 3. Parameters for the correlations of biomass gasification.

3. Results and analysis

3.1. Effects of the biochar use with different gasifying agents

The process was modeled in Aspen Plus® adjusting temperatures from 600°C to 900°C on the RYield reactor. As expected, the correlations have an approached agreement with the experimental results, which enables different parametric evaluations for this set of temperatures and its impact over the product's yield with a sensitivity analysis. Fig. 2 shows the tar concentration for different temperatures and bed material (sand or biochar). The use of char reduces noticeably the concentration of heavy molecules; this demonstrates its catalytic activity. The good agreement of the model with the experimental process allows the obtention of a proper mass and energy balance of the system (Fig. 3).

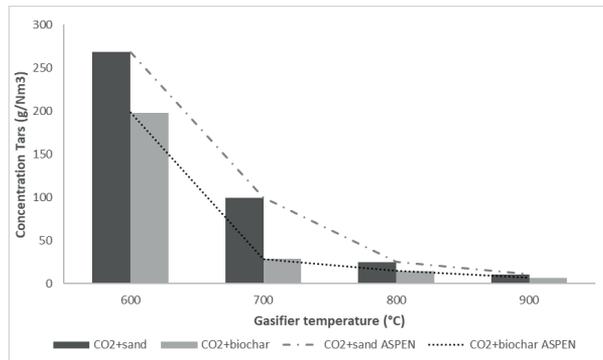

Figure 2. Tar concentration for different temperatures and bed materials.

The material and energy balance for the whole system is easily obtained through the values of the stream and block results. Fig. 3 shows the mass and energy balance for the process using sand and biochar as bed materials. This global balance was made considering external streams and the equipment that consume significant amounts of energy (dryer, crusher, and RYield reactor). There is a slight difference on the amount of heat required for the gasifier when using biochar which corresponds to the need of heat for the type of reaction (endothermic) that are taking place during the process with biochar. There are basically no changes on the yield of syngas and biochar observed in both examples, which opens the question of whether the escalation was effective or whether it is necessary to include a correction.

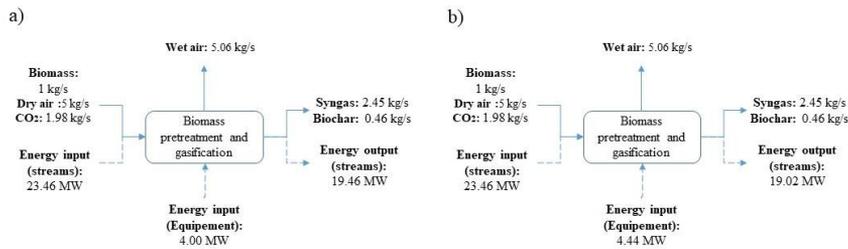

Figure 3. Mass and energy balance for gasification process using sand (a) and biochar (b) as bed materials.

3.2. Effects of the biochar as bed material varying the gasifying agents

The CO₂ and the steam are known for their use as biochar activator (Molina-Sabio et al., 1996), therefore during the experiments, both gasifying agents present a significant decrement of the tar concentration in comparison of the use of sand (Fig. 4). At lower temperatures the catalytic cracking effect over the final tar concentration is higher with the use steam. This can be explained due to the higher porosity of the steam-activated biochar, along with the possible steam reforming reaction that take place during steam gasification.

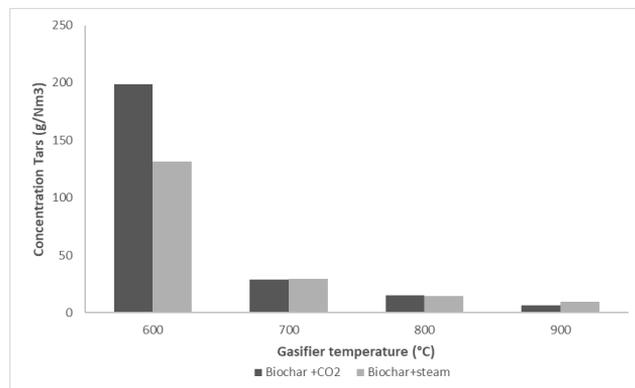

Figure 4. Effects of different gasifying agents along with biochar as bed material.

For a temperature as high as 900°C it can be observed that the CO₂ has a more suitable tar cracking behavior than steam, could be supposed that this temperature might be favorizing other reactions involving the CO₂ itself, but a right conclusion of this phenomena is out of this case of study.

Conclusion

The use of experimental correlations through Fortran subroutines in Aspen Plus® guarantees a good reproduction of experimental results. This modeling methodology allows the evaluation of different parameters such as temperature and energy spending for a specific installation, but since correlations are tailored to the process, their application in another installation would have limitations. The use of the biochar as catalytic bed material was evaluated and as expected, the catalytic activity of the biochar was higher than the activity of sand, this is due to the existence of active pores on the biochar that increase the interaction of the hydrocarbons which facilitates the conversion of tar into lighter molecules. When comparing the energy balance of both processes, a difference in the energy input for the gasifier is perceived and this can be interpreted as an effect of the befall of endothermic reactions that need more heat to be performed. The application of CO₂ and steam as gasifying agents along with the use of biochar, reduces considerably the tar concentration contained on the syngas. The steam shows a better performance in comparison to the CO₂, this is due to the fact that the biochar activated with steam has a higher porosity than the biochar activated with CO₂.

Abstract

This article is devoted to the development of a new approach to modeling aggregation processes and swarming in poly-disperse systems. This approach takes into account multi-particle collisions, what is of fundamental importance at a high concentration of the dispersed phase. Due to the complex hydrodynamic picture in industrial devices the aggregation process is accompanied by multiple collisions and swarming of particles, and it occurs according to various mechanisms. The presented method is an extension of the method previously developed by the authors for the case of a three-dimensional stochastic lattice. Namely, the discrete-event-simulation paradigm (DES) extends in this work to the case of three-dimensional lattices. A three-dimensional array is used for describing aggregation in the case of kinetics limited by the particle diffusion rate (DLA) with allowance to the swarming process. The article provides a description of the algorithm and the results of a computer experiment with comments. Computer simulation of swarming and aggregation in batch and flow reactors has been carried.

Keywords: DLA aggregation, swarming, many-particle collisions, 3-D stochastic lattice.

1. Introduction

The issues of calculating the kinetics and dynamic characteristics of reactors with the formation of a polydisperse solid phase in the working volume are relevant under calculation of various types of industrial apparatuses (Carranza and Coates, 2000). Need in the reliable swarming and aggregation models covers the range from fine chemical technology and pharmaceuticals to environmental cleaning and industrial waste (Maningo et al., 2016).

However, despite the long-standing interest of researchers and the existence of many works, the theoretical analysis of many problems remains poorly developed (Rimer and Ariel, 2017). In this paper, a new approach based on the DES discrete event modeling paradigm (Zeigler et al., 2000) applying to the case of three-dimensional lattices is presented.

The novelty of this approach lies in the fact that it allows one to study the distribution of clusters of different orders over the volume of the reactor at different times, taking into account multi-particle collisions and swarming phenomenon (Carrillo et al., 2010). The contribution of the obtained results to practice lies in the fact that they expand the range of real application of the developed model for describing swarming and aggregation processes in the volume of industrial devices (Zhou et al., 2015, Schmidt et al., 2006). This makes it possible to take into account the peculiarities of the kinetics of aggregation in the apparatus volume (Mogilner and Edelstein-Keshet, 1999). Cases of batch and flow-through tubular apparatus are considered. According to DES (Zeigler et al., 2000, Brener

et al., 2017), the region in which the diffusion and aggregation processes occur is covered by a fixed spatial lattice (Brener et al., 2017). In this paper, we consider a three-dimensional array to describe aggregation and swarming in the case of kinetics limited by the rate of diffusion of particles (DLA). Thus, the characteristic time of aggregation was completely determined by the characteristic time of diffusion of particles, which was assumed to be equal to the time of drift of particles from one cell of the lattice to another. Hereinafter, the term "order of clusters" will mean the number of monomer particles in a given cluster (Wattis, 2006).

2. Algorithm description

2.1. Algorithm for batch reactor

Below, an algorithm is described that corresponds to that presented in (Brener et al., 2017). Namely, at each moment of time, a random selection of the components of the particle drift in the horizontal and vertical directions is made from a given set of characteristic displacements. This set is formed taking into account the dependence of the mobility of a cluster of particles on its order (Naldi et al., 2010).

For clusters of a higher order, the mobility decreases, which corresponds to the well-known physics of random particle drift in the volume (Satyobroto Talukder, 2011). In the model algorithm in this work, it was assumed that a random selection from the cell sequence (-3; -2; -1; 0; 1; 2; 3) for temporal drifts along each of the three spatial axes can be made for clusters of order 1 or 2, and for clusters with orders higher than two, the choice must be made from the sequence (-3; -2; -2; -1; -1; 0; 0; 1; 1; 2; 2; 3). Thus, an increase in the probability of higher-order clusters moving to nearer cells during a time step is simulated.

The behavior of clusters near the walls can also be taken into account in the general case by changing the sequence of random selection of displacements. In a numerical experiment applied to a batch reactor, it was assumed that particles captured in the boundary cells do not move beyond the boundaries of the lattice under consideration (Brener et al., 2017). A cluster of order 1 was initially placed in each cell.

Then the process of random transition of particles from one cell to another cell was simulated at each time step. The aggregation of particles occurs at the moment they enter the common cell of the lattice without any delay (DLA case).

In contrast to the planar case (Brener et al., 2017), two three-dimensional arrays were formed. The first array simulated the entire lattice with particles of different orders obtained in the process of displacement and aggregation at each time step. The second array shows the number of collisions of particles in each cell in each unit of time.

2.2. Algorithm for a flow-through tubular reactor

The algorithm is briefly described below in accordance with the work (Brener et al., 2017, Zeigler et al., 2000). During the calculation, four 3D arrays are generated.

The first array simulates the entire lattice with clusters of different orders obtained in the process of displacement and aggregation in each unit of time.

The second array simulates a similar lattice with clusters that enter the reactor with a fresh flow, which enters the reactor at a given average horizontal velocity.

The third array simulates the situation at the end of the calculated time unit and generates the initial situation for the next unit. It is formed as the sum of the two previous arrays.

The fourth array indicates the number of collisions of particles in each cell in each unit of time.

2.3. Algorithm for swarming description

To adapt the stochastic lattice method to simulating swarming, especially taking into account the aggregation process and the influence of random drift, a special lattice enlargement algorithm was developed, which is presented in this work.

Since it is this stage of modeling that is the principal contribution to the algorithm, some mathematical details are presented below.

The main steps of this algorithm in the case of DLA are as follows.

1. The entire volume of the reactor is dissected into longitudinal layers. Then the following matrices are created: the main matrix of concentrations $C(I, J)$ and a coarse matrix $CO(X, Y)$ of the total number of clusters in blocks, where M, N are the dimensions of the matrix $C(I, J)$ and R, T are the dimensions of the matrix $CO(X, Y)$. Here $R = M / a$; $T = N / b$; and a, b - the dimensions of the coarse lattice block in the each layer (that is, the number of rows and columns of the matrix $C(I, J)$ captured in the block to generate the matrix $CO(X, Y)$).

2. The block with specific coordinates (X_s, Y_s) in the coarse matrix $CO(X, Y)$ is built from the elements of the matrix $C(I, J)$, which consists of rows numbered from $(aX_{s-1} + 1)$ to aX_s and columns numbered from $(bY_{s-1} + 1)$ to bY_s .

3. The element of the matrix $CO_{X_s Y_s}$ must be calculated as the sum d_{kl} of all the elements of the matrix $C(I, J)$ that fall into the block (X_s, Y_s) . Namely:

$$CO_{X_s Y_s} = \sum_{bY_{s-1}+1}^{bY_s} \sum_{aX_{s-1}+1}^{aX_s} d_{kl} . \quad (1)$$

Here the elements d_{kl} should be calculated according to the following algorithm called as *A-algorithm*: if $c_{X_s Y_s} \neq 0$, then $d_{kl} = 1$, otherwise $d_{kl} = 0$. A coarse matrix $COI(X, Y)$ of the total number of orders of clusters in blocks should be calculated similarly to the matrix $CO(X, Y)$. The only difference is that elements $col_{X_s Y_s}$ are calculated using the formula

$$col_{X_s Y_s} = \sum_{bY_{s-1}+1}^{bY_s} \sum_{aX_{s-1}+1}^{aX_s} c_{kl} . \quad (2)$$

That is, it is not necessary to pre-calculate by algorithm (A).

It can be noted that this algorithm is inspired by the ideology of the renormalization group in the modern theory of phase transitions (Kadanoff, 2000). We believe that a universal approach that considers the processes of swarming and aggregation in disperse systems from positions similar to those used in the modern theory of phase transitions to describe ordering in many-particle systems is quite promising.

Of course, this issue is subject to further discussion, since the kinetic features of swarming and aggregation processes are not similar.

At the same time, these processes occur in a certain temporal hierarchy, since the swarming process contributes to the intensification of aggregation. This factor clearly manifested itself in computer simulations, what is shown in the next section of the article.

3. Some results of the simulation

Some results of the simulation are shown in Figures 1, 2, 3. Different color intensities of different blocks of rough matrices correspond to different concentrations of clusters, both without taking into account their orders (cold colors) and different sums of orders of cluster aggregates (warm colors). The blocks were colored using the RGB code of the additive color model (Poynton, 2012). The step of change was 20 units both in the number of clusters and in the sum of their orders. The overall range observed during the simulation was from 0 to 200 units. The dimensions of the computational matrix were 20×20 ; the dimensions of any block of the coarse matrix were 4×4 . The volume of 200×20 was divided into 40×5 horizontally and 4×5 vertically, it turned out a 5×5 coarse scheme.

The calculations were performed for three different initial carrier flow velocity profiles: uniform flow (type 1), symmetric irregular flow (type 2), and asymmetric irregular flow (type 3). The conditional flow rates W for these three cases are equal: 1- $W = 2$; 2- $W_w = 2$ at the walls, $W_c = 6$ on the central axis of the stream; 3- $W_w = 2$ at the upper wall, $W_c = 6$ at the central axis of the flow, $W_w = 4$ at the lower wall. Flow direction from left to right. The order of all particles introduced by the carrier flow into the circuit is taken to be 1. Then particles of different orders appear due to DLA aggregation (Brenner et al., 2017). The pictures presented on the figures correspond to the depth of 5 calculating blocks.

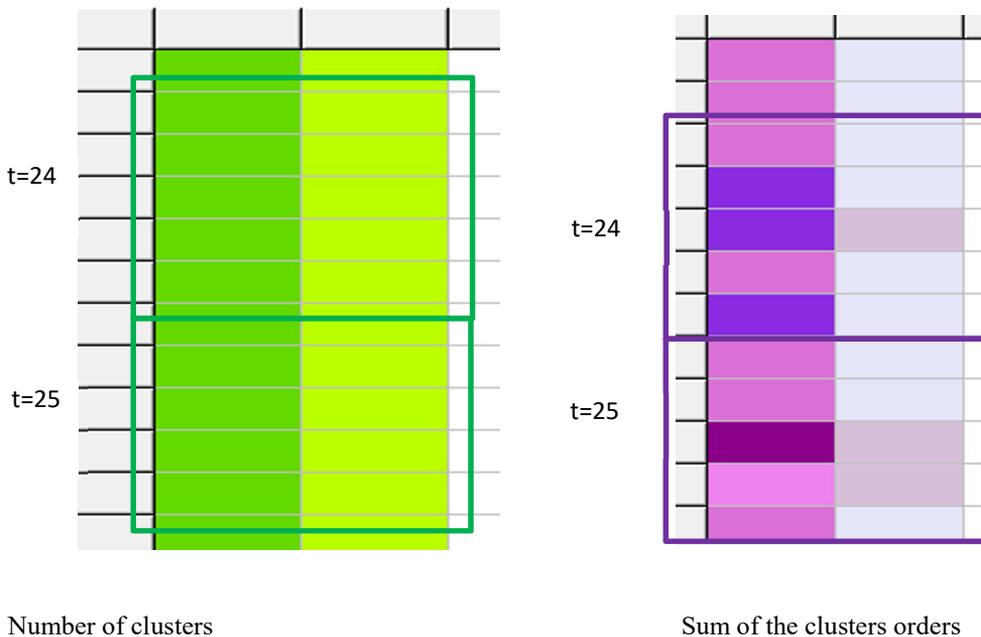

Figure 1. A typical picture with a uniform distribution for time intervals $t = 24, 25$ according to the enlarged scheme 5×5 . $W=2$.

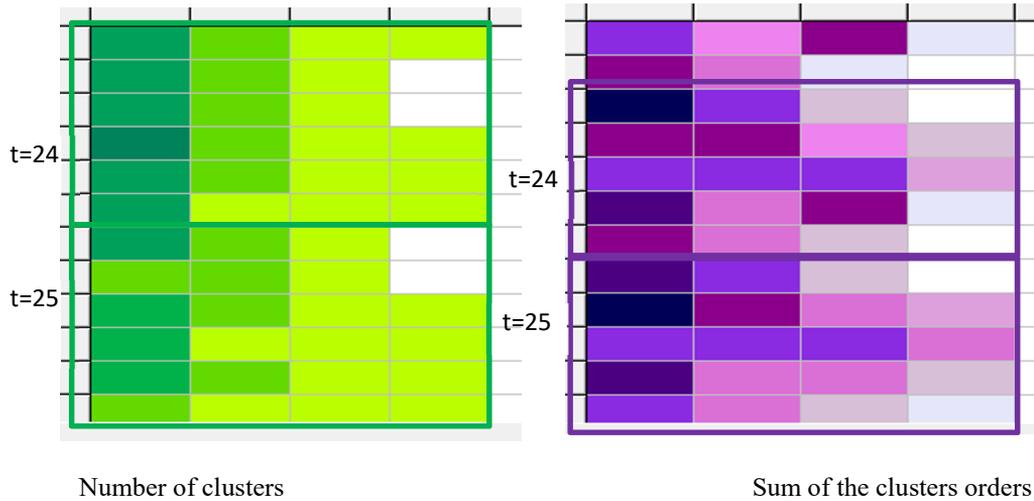

Figure 2. Under the uneven distribution of type 2 for time intervals $t = 24, 25$ according to the enlarged scheme $5X5$. $W_1=2, W_2=6$

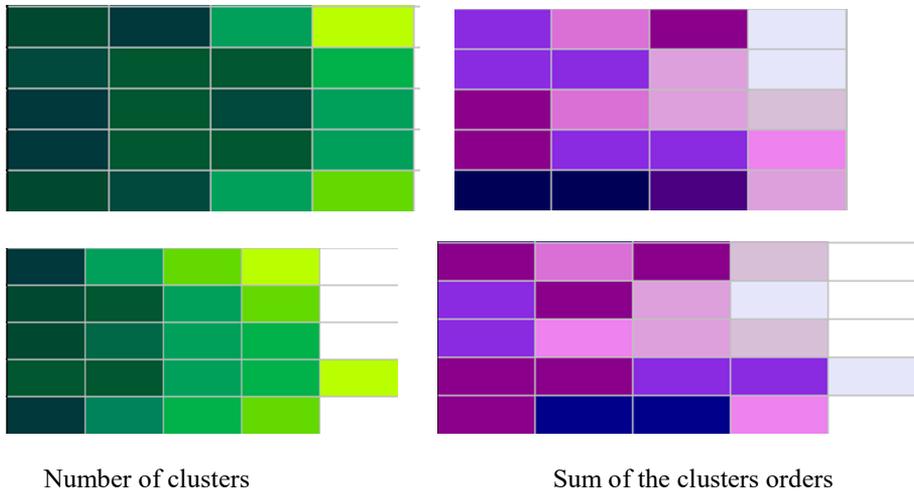

Figure 3. Under the uneven distribution of type 2 for time intervals $t = 24, 25$ according to the enlarged scheme $5X5$. $W_1=2, W_2=6, W_3=4$

As the result of visualizing the simulation results, it is possible to clearly distinguish two swarms of particles formed in a reactor with an uneven profile of the carrier flow velocity. It is clearly seen that the highest cluster orders are observed in the same areas, i.e. the aggregation process is intensified.

4. Conclusion

The results of numerical experiments showed that the change in the number of clusters in a batch reactor occurs at the initial stage of the aggregation process at a much higher rate than this phenomenon was described before by a numerical experiment on a flat lattice. The completion of the process with the formation of a big single cluster is also observed much faster. In a flow-through reactor, the cluster size distribution also changes in the initial section near the reactor entrance, but the length of the transition section is longer than the experiment on a planar grid shows.

The results of numerical experiments demonstrate a clear correlation between the localization of high concentration regions, those swarming formation and regions of a higher total order of clusters of the dispersed phase. The methodology proposed in this paper opens up opportunities for a deeper study of the detected correlation.

Abstract

Neural networks (NN)s have been increasingly proposed as surrogates for approximation of systems with computationally expensive physics for rapid online evaluation or exploration. As these surrogate models are integrated into larger optimization problems used for decision making, there is a need to verify their behavior to ensure adequate performance over the desired parameter space. We extend the ideas of optimization-based neural network verification to provide guarantees of surrogate performance over the feasible optimization space. In doing so, we present formulations to represent neural networks within decision-making problems, and we develop verification approaches that use model constraints to provide increasingly tight error estimates. We demonstrate the capabilities on a simple steady-state reactor design problem.

Keywords: Neural Networks, Verification, Optimization, Surrogate Modeling

1. Introduction

Neural networks (NNs) have seen wide success across engineering disciplines. Their excellent approximation qualities (Hornik et al. (1989)) can reduce challenging problems into tractable computational models and their training procedure can incorporate diverse data sets and expert domain knowledge (Beck et al. (2016)). Successful engineering applications have harnessed NNs in planning, design, and control (Pistikopoulos et al. (2021)) with notable process-systems applications that span: forecasting renewable energy generation (Lee et al. (2016)), predicting distillation dynamics (Sánchez-Ramírez et al. (2020)), and estimating reactor performance (Salah et al. (2016)).

Typical NN applications are concerned with making forward predictions (i.e., NNs are evaluated in a forward-mode), but they are also advantageous in the context of optimization where they can take on the form of *algebraic surrogates*. Such surrogate models can be used to reduce the complexity of underlying equations by replacing them with more tractable formulations. Neural network surrogates have seen successful application in optimizing chemical process operation (Fernandes (2006)), performing process synthesis with super-structures (Henao and Maravelias (2010)), solving stochastic optimization problems to operate distillation columns (Gutiérrez-Antonio (2016)), and representing contingency constraints in security-constrained optimal power flow (Kilwein et al. (2021)).

The *verification* of neural networks is often concerned with finding adversarial inputs (Goodfellow et al. (2015)) using techniques such as mixed-integer-linear-programming (MILP) (Tjeng et al. (2017)), Satisfiability Modulo Theories (Scheibler et al. (2015)), and Lagrangian duality

(Dvijotham et al. (2018)). This manuscript extends verification concepts and addresses the need to verify NNs that are deployed as optimization-based surrogates. In contrast to methods that verify over a specified input space, we propose formulations that verify over constraints involving both the inputs *and* outputs of the neural network. In doing so, we develop optimization problems that verify worst-case NN prediction error subject to known model physics and operational constraints, and we show that incorporating known constraints leads to tighter error estimates than simply verifying over the input space.

2. Optimization with Neural Network Surrogates

We consider the solution of an optimization problem given by, (1),

$$f^*(p) = \min_{x,y,z} f(x,y,z,p) \quad (1a)$$

$$\text{s.t. } y = h(x,p) \quad (1b)$$

$$c(x,y,z,p) = 0 \quad (1c)$$

$$g(x,y,z,p) \leq 0 \quad (1d)$$

$$x^L \leq x \leq x^U \quad (1e)$$

where p represents system parameters which are known inputs for a particular optimization instance, and x , y , and z represent optimization variables. We desire efficient solutions of this problem for different values of the parameters p (e.g., in an online context, or for multi-scenario analysis). For improved solution, we consider instead an approximate formulation where we replace a portion of the model with a neural network surrogate. We assume that the NN surrogate brings some benefit to the optimization problem by facilitating a more tractable computation. This could entail the simplification of (1b) to support more rapid or reliable optimization in an online context, or involve creating a piecewise linear approximation (e.g., using ReLU activation functions) of h to facilitate global optimization approaches. We show the new optimization formulation below, where we approximate h in (1b) with the neural network N in (2b). Here, \hat{y} represents the neural network output, and is an approximation of the original variables y .

$$f_S^*(p) := \min_{x,\hat{y},z} f(x,\hat{y},z,p) \quad (2a)$$

$$\text{s.t. } \hat{y} = N(x,p) \quad (2b)$$

$$c(x,\hat{y},z,p) = 0 \quad (2c)$$

$$g(x,\hat{y},z,p) \leq 0 \quad (2d)$$

$$x^L \leq x \leq x^U \quad (2e)$$

This hybrid modeling approach is common in engineering applications. However, before “deploying” problem (2) in a decision-making application, we wish to verify the accuracy of the neural network approximation. In the next section, we describe a verification formulation that explicitly considers the feasible region of the constraints above and the range on the input parameters p .

3. Formulation of Neural Network Verification Problem

Typical verification approaches seek to determine the maximum error between y and \hat{y} over a pre-defined input space in x and p . However, these approaches can produce errors that are larger than necessary since they allow points in x and p that may not be feasible with respect to the constraints in formulations (1) and (2). Here, we are specifically interested in the accuracy of the neural network over the feasible space of the optimization problem, and we formulate the verification problem (3)

shown below:

$$\begin{aligned}
 & \max_{x,p,y,\hat{y},z} \|y - \hat{y}\|_{\infty} && (3a) \\
 \text{s.t. } & y = h(x, p) && \text{True Model} && (3b) \\
 & \hat{y} = N(x, p) && \text{NN Surrogate} && (3c) \\
 & x^L \leq x \leq x^U && \text{Input Bounds} && (3d) \\
 & p^L \leq p \leq p^U && \text{Parameter Bounds} && (3e) \\
 & \left[\begin{array}{l} c(x, y, z, p) = 0 \\ g(x, y, z, p) \leq 0 \end{array} \right] \vee \left[\begin{array}{l} c(x, \hat{y}, z, p) = 0 \\ g(x, \hat{y}, z, p) \leq 0 \end{array} \right] && \text{Feasibility Constraints} && (3f)
 \end{aligned}$$

Here, the objective function (3a) maximizes the infinity norm over the NN prediction errors. Maximizing other error measures such as mean-squared-error, mean-absolute-error, or individual prediction errors is also possible. The constraints (3b) and (3c) are the same as (1b) and (2b), respectively, which relate the NN inputs to the true model variables y and the neural network outputs \hat{y} . As indicated above, a natural choice of verification constraints are limits on the *input space* of the neural network (i.e., bounds over x and p). While a typical verification formulation would include only (3a)-(3e), we seek to limit the verification to points in x and p that are feasible with respect to the optimization problems (1) and (2).

Our target optimization problem (2) includes feasibility constraints over \hat{y} . However, including only constraints (2c-2d) in the verification problem (rather than the disjunction in (3f)) is insufficient because of errors between y and \hat{y} . Constraints (2c-2d) alone may not sufficiently represent the feasible region in problem (1). Indeed, if the NN accuracy is low, the feasible region for x and p could be significantly underestimated or even empty. Therefore, we search for the maximum error over both the constraints (1c-1d) and (2c-2d) as represented by the disjunction in (3f). With this, problem (3) finds the maximum deviation between y and \hat{y} subject to the constraints of the optimization problem applied conservatively to either y or \hat{y} .

For the case studies in this paper, we consider three formulations to analyze the verification approach. Formulation (V1) represents the typical verification formulation used in the literature which considers only explicit constraints on the input space for x and p . In practice, while we could solve the disjunctive problem (3) directly, it is convenient to solve with each disjunct separately where the solution of (3) is given by the maximum of the solutions from (V2) and (V3) below.

$$\begin{array}{lll}
 \max_{x,p,y,\hat{y},z} \|y - \hat{y}\|_{\infty} & \max_{x,p,y,\hat{y},z} \|y - \hat{y}\|_{\infty} & \max_{x,p,y,\hat{y},z} \|y - \hat{y}\|_{\infty} \\
 \text{s.t. (3b)-(3e)} & \text{s.t. (3b)-(3e)} & \text{s.t. (3b)-(3e)} \\
 \text{(V1)} & \text{(V2)} & \text{(V3)} \\
 & c(x, y, z, p) = 0 & c(x, \hat{y}, z, p) = 0 \\
 & g(x, y, z, p) \leq 0 & g(x, \hat{y}, z, p) \leq 0
 \end{array}$$

4. Illustrative Example: Reactor Optimization with Neural Network Surrogates

We provide an illustrative reactor optimization example where we use NNs (with ReLU activations) to replace nonlinear physics with piecewise-linear approximations. We demonstrate global solution of the verification problem and compare with the input-only formulation given by (V1).

4.1. Reactor Optimization Problem

The problem of interest is a steady-state continuous-stirred-tank-reactor (CSTR) that converts feed components A and B to produce D as depicted by Figure 1 where C is an intermediate and E is a

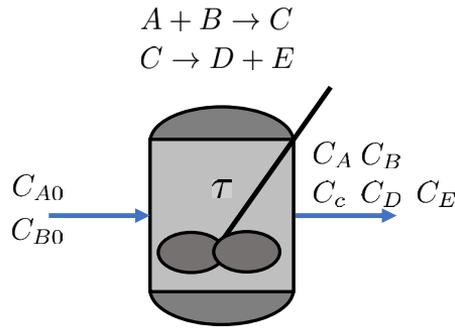

Figure 1: Simple Steady-State CSTR

side product. The overall mass balance is given by (4) (or by (5) in terms of the neural network outputs, \hat{y}).

$$C_i = C_{i,0} - \tau_1^r \quad i \in \{A, B\} \quad (4a) \quad C_i = C_{i,0} - \hat{\tau}_1^r \quad i \in \{A, B\} \quad (5a)$$

$$C_c = C_{c,0} + \tau_1^r - \tau_2^r \quad (4b) \quad C_c = C_{c,0} + \hat{\tau}_1^r - \hat{\tau}_2^r \quad (5b)$$

$$C_i = C_{i,0} + \tau_2^r \quad i \in \{D, E\} \quad (4c) \quad C_i = C_{i,0} + \hat{\tau}_2^r \quad i \in \{D, E\} \quad (5c)$$

We define variables τ_1^r and τ_2^r in (6) to represent the product of τ (the space-time) and the corresponding reaction rate (r_1 or r_2). The reaction rate constants K_i are selected as the parameters p . We also include operating constraints given by (7) which correspond to the minimum conversion and yield the reactor must achieve with $\eta_1=0.9$ and $\eta_2=0.2$.

$$\tau_1^r = \tau r_1 = \tau K_1 C_A C_B \quad (6a) \quad C_D \geq \eta_1 (C_{A,0} - C_A) \quad (7a)$$

$$\tau_2^r = \tau r_2 = \tau K_2 C_c \quad (6b) \quad C_D \geq \eta_2 (C_A + C_B + C_c) \quad (7b)$$

The true design problem as a function of p is then given by (8) where we seek to minimize the space-time τ (i.e., maximize throughput) subject to physical balances and operating requirements. Consequently, we train ReLU-based NNs to replace the associated nonlinear terms and formulate the approximate design problem (9) as an MILP (Grimstad and Andersson (2019)).

$$\min_{\tau} \quad \tau \quad (8a) \quad \min_{\tau} \quad \tau \quad (9a)$$

$$\text{s.t.} \quad \tau_1^r = \tau K_1 C_A C_B \quad (8b) \quad \text{s.t.} \quad \hat{\tau}_1^r = K_1 N_1 (C_A, C_B, \tau) \quad (9b)$$

$$\tau_2^r = \tau K_2 C_c \quad (8c) \quad \hat{\tau}_2^r = K_2 N_2 (C_c, \tau) \quad (9c)$$

$$(4), (7)$$

$$(5), (7)$$

4.2. Verification Problem

The verification problem corresponding to (3) is given by (11) with the NN input and model parameter bounds defined by (10) below.

$$\begin{aligned}
 C_A^L \leq C_A \leq C_A^U, \quad C_B^L \leq C_B \leq C_B^U, \quad C_C^L \leq C_C \leq C_C^U, \\
 \tau^L \leq \tau \leq \tau^U, \quad K_1^L \leq K_1 \leq K_1^U, \quad K_2^L \leq K_2 \leq K_2^U
 \end{aligned} \quad (10)$$

The valid range for the parameters K is given by $K_1=0.31051 \pm 10\% \frac{\ell}{\text{mol-s}}$ and $K_2=0.026650 \pm 10\% \frac{1}{s}$. For this example we seek to maximize the squared prediction error of both τ_1^r and τ_2^r (i.e., we solve verification problems for each output) but it is also possible to formulate mean-absolute

error using integer variables.

$$\max (\hat{\tau}_j^r - \tau_j^r)^2 \quad j \in \{1, 2\} \tag{11a}$$

$$\text{s.t. (8b), (8c) \hspace{15em} \text{Original Model} \tag{11b}$$

$$(9b), (9c) \hspace{15em} \text{NN} \tag{11c}$$

$$(10) \hspace{10em} \text{Input Bounds and Parameter Bounds} \tag{11d}$$

$$[(4), (7)] \vee [(5), (7)] \hspace{5em} \text{Model Constraints OR NN Constraints} \tag{11e}$$

We apply each of the presented verification formulations to our reactor example. In particular, we formulate (V1) with equations (11a-11d). We formulate (V2) and (V3) using these equations along with each of the individual disjuncts in (11e).

4.3. Results

We use TensorFlow 2.3 to train the multi-layer neural network surrogates with increasing numbers of nodes using ReLU activation functions. We use Gurobi 9.1 to solve the non-convex true design problem (8) and the verification problems. The results are presented in Figure 2 and are summarized as follows: (i) (V1) provides the expected global worst-case error over the input space, but we can obtain tighter error bounds using (V2) and (V3) which satisfy the known constraints, (ii) (V3) is tighter than (V2) with smaller networks where the accuracy is poor and the feasible region is poorly approximated, and (iii) worst-case error improves for larger neural networks, but there are likely trade-offs with performance vs accuracy. We also compare the solution

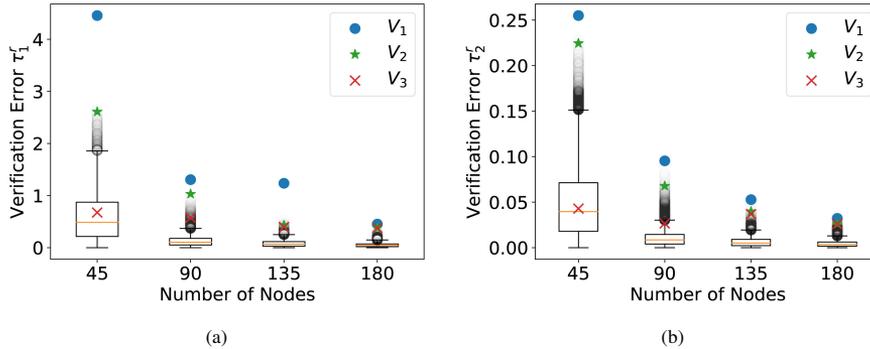

Figure 2: Results for test error (box plots) and verification (colored markers for V1, V2, and V3). Observed errors for τ_1^r (left) and τ_2^r (right) for increasingly larger neural networks.

of (9) for each NN to the true problem (8) using Gurobi 9.1. Table 1 shows each NN prediction and objective value τ which are consistent with the verification findings. Tighter worst-case error estimates correspond with closer approximations of the true problem, but even NNs with considerable error according to (V1) perform adequately as algebraic surrogates when considering the feasible region and their usage within the optimization problem.

5. Conclusions

This manuscript explores verification approaches for neural network (NN) surrogates used within optimization problems. We demonstrated how verification over known constraints produces tighter worst-case NN violations. We presented an illustrative reactor design example to elucidate verification concepts for NNs used as surrogates in an optimization setting.

Table 1: Comparison of results for reactor optimization problem solution for increasingly larger neural networks. Percentages correspond to percent difference from the true global solution.

Variable	True	Error (Relative Error %)							
		45 Nodes		90 Nodes		135 Nodes		180 Nodes	
τ_1^i	0.527	-3.9E-3	(-0.75%)	1.5E-3	(0.28%)	-8.8E-4	(-0.17%)	5.6 E-4	(0.11%)
τ_2^i	0.474	-3.5E-3	(-0.75%)	1.3E-3	(0.28%)	-7.9E-4	(-0.17%)	5.0 E-4	(0.11%)
τ	337.7	-14.5	(-4.29%)	-10.7	(-3.17%)	3.3	(0.99%)	0.17	(0.05%)

Sustainable Analysis of Recent Acid Gas Treatment Schemes for LNG production

Ahmed AlNouss, Saad Al-Sobhi*

Department of Chemical Engineering, College of Engineering, Qatar University. Doha, Qatar

**Saad.al-sobhi@qu.edu.qa*

Abstract

The worldwide growing demand for natural gas consumption increases the pressure on the depletion of natural resources, consequently the significance of natural gas treatment methods. Given the huge investment associated with gas processing plants, selecting optimum and fit-for-purpose treatment methods undergoes a rigorous selection process to allocate the most cost-effective and environmentally friendly treatment scheme to remove contaminants. This study analyzes the sustainability of recent acid gas treatment schemes associated with Liquefied Natural Gas (LNG) production using Aspen simulation techniques. The acid gas treatment process is crucial in LNG production to eliminate the presence of CO₂ and H₂S from the sour feed gases for safety and environmental concerns. The recent advancement in acid gases removal units (AGRU) demonstrates the addition of an enrichment step using a low-pressure pre-flash column of Amine solvent along with a tail gas treatment (TGT) unit. The full-integrated scheme includes low BTX AGRU, Acid Gas Enrichment, Sulfur Recovery Unit, TGT unit, and common regeneration. The techno-economic evaluation demonstrates the excellence of this technology advancement in providing higher efficiency of acid gases removal with some increase in the equipment cost and huge environmental benefits.

Keywords: Acid gas treatment, LNG, Simulation, Sulfur recovery.

1. Introduction

The global energy demand continues to increase, putting more pressure on natural resources, specifically fossil fuels. The processing of these fossil fuels involves heavy treatment methods to eliminate acid gases, CO₂, H₂S, and BTX, avoiding their problems in processing lines. These gases are associated with serious negative environmental and health impacts due to the high toxicity of their combustion effluents, mainly SO₂, CO₂, and particulate matter. Environmental limits on emitting these gases into the atmosphere have been regulated by various environmental agencies and governments worldwide, emphasizing operation plants to improve the treatment methods of acid gases (Gupta et al., 2016). From another perspective, the variation of wellhead and gas processing conditions introduces a challenge for the production plants to treat the changes in acid gas content to achieve required product specifications. All of this places a huge challenge and burden on selecting the optimum scheme to meet environmental standards, respond flexibly to changes in feed gas quality, and ensure economic and technical targets of the different project circumstances. Given the huge investment associated with gas processing plants, selecting optimum and fit-for-purpose treatment methods undergoes a rigorous selection process to allocate the most cost-effective and environmentally friendly

treatment scheme to remove contaminants (Mokhatab and Poe, 2012; Korens et al., 2002). This study analyzes the sustainability of recent acid gas treatment schemes associated with Liquefied Natural Gas (LNG) production by utilizing Aspen simulation techniques. The acid gas treatment process is crucial in LNG production to eliminate the presence of CO₂ and H₂S from the sour feed gases for safety and environmental concerns. Evaluating the improvement in the acid gas treatment schemes depends mainly on the initial conditions of the sour feed gas, specifications of treated sweet gas, and environmental limitations. Performing a case-by-case optimization study is essential to achieve the optimum capital and operating costs and the largest window of operating parameters regarding sour feed gas quality. The most-effective treatment scheme must demonstrate economic effectiveness, accept different feeds, and achieve sulfur specifications in addition to the highest measures of reliability and quality performance.

The subject of selecting the optimum alternative for acid gases treatment and removal has been studied intensively in the literature. Korens et al. (2002) analyzed the performance of different processes applicable for integrated gasification combined cycle while meeting U.S. emission standards. The processes include CO₂ removal and sequestration, hot and warm gas cleanup, tail gas treating unit (TGTU), sulfur recovery unit (SRU), acid gas treatment unit (AGRU), acid gas injection, and mercury removal. They concluded that the current design of many processes would require improvement to meet the future more stringent environmental regulations. Similarly, Mokhatab and Poe (2012) studied the most commonly used processes in gas processing plants and their potential integration with expert process designs. The work attempted to establish different integration of gas processing steps to establish the optimum lineup of gas treatment while considering economics, operability, and flexibility. The processing steps included TGTU, SRU, AGRU, Mercaptans removal unit, and gas dehydration. Gupta et al. (2016) have conducted a recent comprehensive review of acid gas treatment and sulfur recovery designs. The review highlighted the advancement in Claus process design to handle increased amounts of sulfur and reduce the challenges in catalytic reactions and associated operational costs. Pellegrini et al. (2019) analyzed the energy and exergy performance of competing natural purification and liquefaction routes using Aspen HYSYS simulation based on net equivalent methane approach. Results demonstrated the excellence of the recent Dual Pressure Low-Temperature (DPLT) distillation technology over the conventional activated-MDEA technology for CO₂ removal with higher exergy efficiency and lower consumptions. Recently, Zhu et al. (2021) analyzed the absorption of H₂S and CO₂ from multiple gas feeds through sensitivity analysis and orthogonal test method. The study aimed to optimize the concentration and temperature distribution in the sweetening absorber through allocation and multi-feeding operation of gas feeds. The simulation results of the Shandong refinery revealed a 2.55% increase in H₂S purity in acid gas with a reduction in the overall exergy loss and energy consumption by 18.7% and 6.5%, respectively.

The current study objective is to compare and analyze the recent advancement in acid gas treatment with enrichment step and TGTU against the base scheme of AGRU and SRU only. This work is a continuation of the sustainability assessment in the LNG process performed for the helium extraction unit (AlNouss and Al-Sobhi, 2020), boil-off gas utilization in the liquefaction unit (Al-Sobhi et al., 2021) natural gas liquids unit (AlNouss et al., 2018; Al-Sobhi and AlNouss, 2018). Aspen HYSYS is utilized to simulate the flowsheet models of the base and advance schemes while utilizing the economic and environmental assessment features to account for and compare the capital and operating costs along with gaseous emissions.

2. Methodology and process description

The current commercial acid gas removal technologies include the physical solvent-based, the chemical solvent-based, and the mixed chemical/physical solvent-based processes. The physical solvent-based processes are associated with high expenses compared to chemical solvent-based ones, despite their capability of meeting the Claus reaction requirement of sulfur cleanup. Utilization of a mixed chemical/physical solvent stabilizes the tradeoff between the degree of physical solubility of sulfur compounds and H_2S selectivity; hence get benefits from the characteristics of both solvents. Employment of acid gas enrichment (AGE) stage enables higher efficiencies (~98%) in the Claus unit, the mainstay of SRU plant. Further, to enhance the SRU efficiency up to 99.9%, the TGTU is required to scrub out the H_2S generated from the hydrogenation step. The utilization of the AGE and TGTU steps is necessary to be able to meet stringent environmental regulations.

The base acid gas treatment scheme evaluated in this study is illustrated in Figure 1. The raw feed gas first enters the AGRU absorber and is contacted with the amine-based solvent. The solvent used in the study is Sulfinol consisting of Sulfolane (physical) and diisopropanolamine (DIPA) (chemical) mixture. This mixed solvent allows higher solubility of sulfur compounds relative to aqueous amines and better solvent loadings at higher acid gas partial pressures. The treated effluent gas from the absorber leaves from the top towards the dehydration process while the rich solvent recovered at the bottom enters a flash vessel to separate sour fuel gases. The rich solvent stream is further preheated by the lean solvent from the bottom of the regenerator column before entering the column. The acid gases are stripped from the regenerator top and sent to SRU while the lean solvent is recycled to the absorber column. Inside the SRU, the H_2S is oxidized to SO_2 before the Claus units where it is further converted to elemental sulfur and collected as a liquid through cooling. The leftover gas stream is sent to the stack.

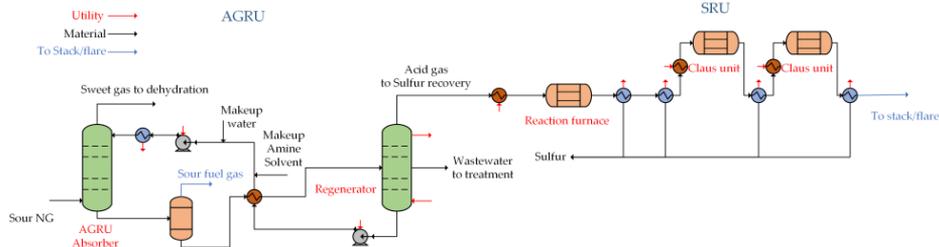

Figure 1: Base scheme of acid gas treatment facility.

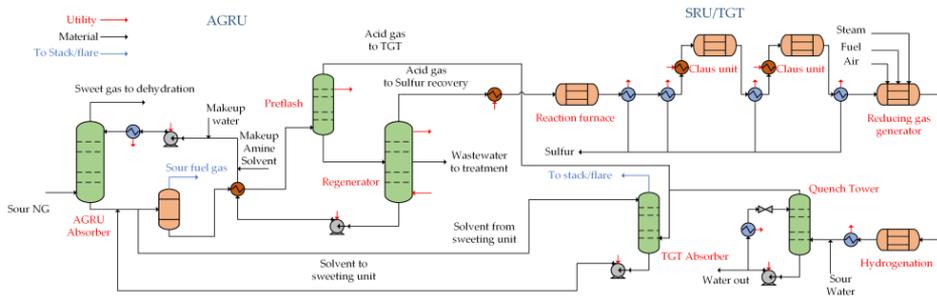

Figure 2: Advanced scheme of acid gas treatment facility.

The recent advancement in the acid gas treatment as presented in Figure 2 demonstrate the addition of enrichment step prior to the SRU and regenerator column and TGTU post

SRU to maximize sulfur recovery. The rich solvent from the flash vessel is sent to a pre-flash column to remove the acid gases partially and send them to TGTU while the remaining part is sent to the AGRU regenerator. The TGTU receives the acid gases from the pre-flash column and the effluent of the SRU unit after hydrogenation and quenching for further acid gas treatment.

The base and advanced schemes have been simulated using Aspen HYSYS software and further used to perform the economic and environmental assessment to account for and compare the capital and operating costs along with gaseous emissions. Despite the inclusion of the Sulsim tool inside Aspen HYSYS software, the SRU simulated as Sulsim sub-flowsheet can't be linked with the built-in economic and environmental analysis tools within Aspen HYSYS. Therefore, the entire system has been simulated using legacy HYSYS tools to estimate the costs and environmental emissions. The feed gas properties are presented in Table 1.

Table 1. Sour NG feed conditions and properties

Property	Value	Element	Composition (mol%)
Price [\$/T] (EIA, 2020)	211	CO ₂	4.95
Temperature [°C]	40	H ₂ S	26.73
Pressure [kPa]	4500	Methane	58.42
Molar Flow [kmole/h]	4185	Ethane	6.93
Mass Flow [kg/h]	100000	Propane	1.98
		Nitrogen	0.99

The economic and environmental emission parameters have then been used to conduct the sustainability assessment based on the sustainability weighted return on investment metric (SWROIM) formulated by El-Halwagi (2017). The conventional return on investment (ROI) is first calculated by dividing annual net economic profit (AEP) by the total capital investment (TCI). Then the equation of SWROIM is utilized to contribute to the rest of the sustainability indicators using weighing factors defined as a ratio of the relative importance of each sustainability indicator to the AEP as presented in Eq.(1). The indicator target is defined in this study to be the highest value from all alternatives. The alternatives are then benchmarked based on ROI and SWROIM.

$$SWROIM_p = \frac{AEP_p \left[1 + \sum_{i=1}^{N_{Indicators}} w_i \left(\frac{Indicator_{p,i}}{Indicator_i^{Target}} \right) \right]}{TCI_p} \quad \text{Eq. (1)}$$

3. Results and discussion

The economic and environmental assessment results revealed an enhancement in the environmental performance of the AGRU with the addition of the TGTU and AGE units despite the increase in capital and operating costs. The recovery of H₂S and CO₂ from the AGRU has increased with the pre-flash enrichment column from 68 and 61% for the base scheme to 78 and 93% for the advanced scheme, respectively. This positive recovery increase is associated with a negative increase in the capital and operating costs from 412 M\$ and 30.5 M\$/y to 433 M\$ and 56.1 M\$/y, respectively, as illustrated in Figure 3.

The addition of the AGE unit has also increased the production of elemental sulfur from 506.4 to 585.0 T/d given the higher recovery of H₂S, which has demonstrated an increase in the product sales from 118.8 to 119.1 M\$/y compared to the base scheme. The prices

of LNG and elemental sulfur used in the study are \$35/MMBTU and \$57/T (Company, 2020; FRED, 2021). Moreover, the environmental impact assessment presented in Figure 4 has demonstrated the excellence of TGTU addition in reducing the Sulfur dioxide and Carbon oxide emissions from 13.2×10^3 and 5.8×10^3 to 7.2 and 308 T/y, respectively. Whereas, the power consumption have increased from 2555.7 to 3671.4 GWh with the addition of AGE and TGTU steps.

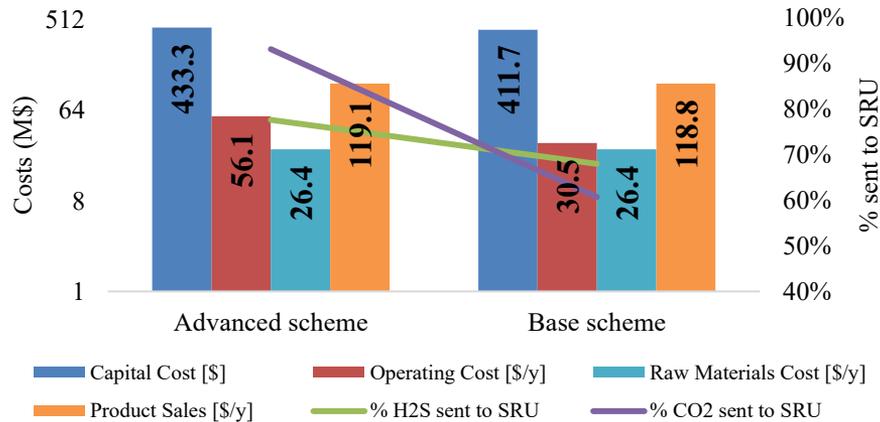

Figure 3: Economic and recovery results.

Table 2. Indicator targets

Property	H ₂ S recovery	CO ₂ recovery	SO ₂ emission [T/y]	CO emission [T/y]	Power (GWh)
Value	78%	93%	13.2×10^3	5.8×10^3	3671.4
w _i	0.25	0.25	-0.25	-0.25	-0.25

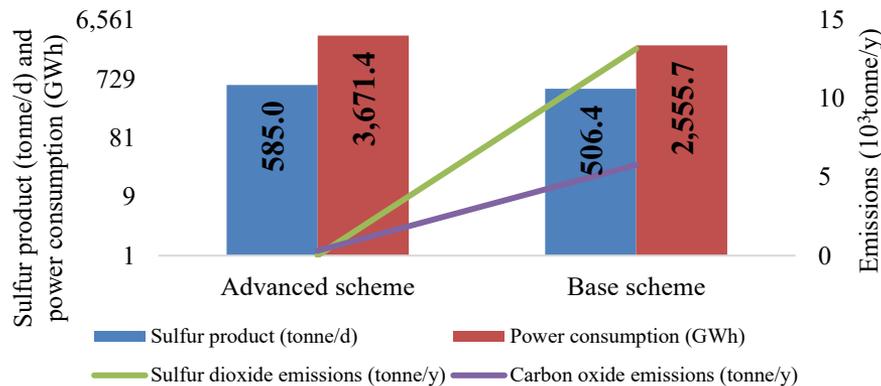

Figure 4: Environmental impacts and energy results.

These results have then been used to measure the SWROIM utilizing Eq.(1) with the indicator targets and weighting factors presented in Table 2. Implementing these weighting factors on the results obtained from the two schemes highlights the sustainability improvement in the acid gas treatment. The SWROIM results demonstrate the improvement in sustainability with the addition of the AGE and TGTU units. The conventional ROI indicated similar results from both schemes given the close capital

costs and product revenue. Whereas, taking into account the positive increase in H₂S and CO₂ recovery along with the positive decrease in SO₂ and CO emissions and the negative increase in power consumption has revealed the increase in sustainability metric for the advanced scheme from 22.1% to 27.4%, while the sustainability metric for the base scheme has decreased from 22.3% to 15.8%.

Table 1. Sustainability results

Parameter	AEP	ROI (%)	SWROIM (%)
Advanced scheme	8.7399x10 ⁷	22.1%	27.4%
Base scheme	8.7412x10 ⁷	22.3%	15.8%

4. Conclusion

Natural gas processing involves heavy treatment methods to eliminate acid gases, CO₂, H₂S, and BTX, avoiding their problems in processing lines. The current study compares the recent advancement in acid gas treatment with the addition of enrichment step and TGTU against the base scheme of AGRU and SRU only. The techno-economic evaluation demonstrated the excellence of this technology advancement in providing higher efficiency of acid gases removal with some increase in the equipment cost and huge environmental improvement.

T2: Product/Process Synthesis and Design

- 100. Promising future for biodiesel: Superstructure optimization from feed to fuel**
Thien An Huynh, Mattia Rossi, Maryam Raeisi, Meik B. Franke, Flavio Manenti, Edwin Zondervan **595**
- 101. Model-based solvent selection for integrated synthesis, crystallisation and isolation processes**
Mohamad H. Muhieddine, Suela Jonuzaj, Shekhar K. Viswanath, Alan Armstrong, Amparo Galindo and Claire S. Adjiman **601**
- 102. Computer-aided solvent design for suppressing HCN generation in amino acid activation**
Lingfeng Gui, Alan Armstrong, Amparo Galindo, Fareed Bhasha Sayyed, Stanley P. Kolis and Claire S. Adjiman **607**
- 103. Improving sustainable CHOSYN's targets through process intensification**
Maricruz Juárez-García, Gabriel Contreras-Zarazúa, Juan Gabriel Segovia-Hernandez, Jose María Ponce-Ortega **613**
- 104. A novel process design for automated quality analysis in an integrated biopharmaceutical platform**
Simon Tallvod, Mikael Yamanee-Nolin, Joaquín Gomis-Fons, Niklas Andersson and Bernt Nilsson **619**
- 105. A multiscale approach towards the use of Urban waste within the energy transition strategy**
Sofía González-Núñez, Lidia S. Guerras, Mariano Martín **625**
- 106. Integration of thermo-chemical energy storage for flexible operation of decarbonized power plants**
Calin-Cristian Cormos, Letitia Petrescu, Ana-Maria Cormos **631**
- 107. Superstructure optimization for sustainable design of an algae biorefinery**
Maryam Raeisi, Thien An Huynh, Meik B. Franke, Edwin Zondervan **637**
- 108. Economic and Environmental Optimization and Feedstock Planning for the Renewable Jet Production Using an Intensified Process**
Raul Mauricio Rivas-Interian, Eduardo Sanchez-Ramirez, Juan Gabriel Segovia-Hernandez, Juan Jose Quiroz-Ramirez **643**

- 109. Heat exchanger networks with different shell and tube configurations**
Jose A. Caballero, Mauro A.S.S. Ravagnani, Leandro Pavao, Caliane B.B. Costa, Juan Javaloyes-Anton **649**
- 110. Considering Environmental and Social Impact in Optimization of a Supply Chain for Bio-Jet Fuel Production**
David Vallejo-Blancas, Juan Gabriel Segovia-Hernández, Eduardo Sánchez-Ramírez, Gabriel Contreras-Zarazúa, Juan José Quiroz-Ramírez **655**
- 111. Superstructure Optimization of Dimethyl Ether Process**
Emrullah Erturk, Erdal Aydin, Sahin Sarrafi, Ozgun Deliismail, Aysel Zahidova, Hasan Sildir **661**
- 112. A Comprehensive Evaluation on the COSMO-SAC-dsp model for Vapor-Liquid Equilibrium Predictions of Refrigerants**
Jiayuan Wang, Tongxin Sa, Lingyu Zhu **667**
- 113. Design and Evaluation Strategies for a Novel Hybrid Trigeration System**
Rachid Klaimi, Sabla Y. Alnouri, Mirko Stijepovic **673**
- 114. Process synthesis for desalination using superstructure optimization on membrane technologies**
Alvaro Martinez-Triana, Mohamed Kanniche, Thibaut Neveux, Christophe Castel and Eric Favre **679**
- 115. A comparison of process synthesis approaches for multistage separation processes by gas permeation**
Thibaut Neveux, Bernardetta Addis, Christophe Castel, Veronica Piccialli and Eric Favre **685**
- 116. Bifurcation analysis of combined agglomeration and layering granulation in fluidized bed spray processes**
Eric Otto, Robert Dürr and Achim Kienle **691**
- 117. Enhancement of energy saving of reverse osmosis system via incorporating a photovoltaic system**
Alanood A. Alsarayreh, Mudhar A. Al-Obaidi, Saad S. Alrwashdeh, Raj Patel and Iqbal M. Mujtaba **697**
- 118. Design and simulation of methanol synthesis using heavy residues with carbon utilization**
Siddig S. Khalafalla, Hussain A. Alibrahim, Fayez Nasir Al-Rowaili, and Umer Zahid **703**

- 119. Integrated process synthesis and design of intensified/hybrid processes**
Shuang Xu, Selen Cremaschi, Mario R. Eden and Anjan K. Tula **709**
- 120. Macroalgae-based integrated biorefinery for hydrocolloids, chemicals and advanced biofuels production**
Andrés I. Casoni, Alejandro H. Pedrozo, Fernando D. Ramos, Vanina Estrada, M. Soledad Diaz **715**
- 121. Design Space Determination of Mesenchymal Stem Cell Cultivation by Dynamic Modeling under Uncertainty**
Keita Hirono, Isuru A. Udugama, Yusuke Hayashi, Masahiro Kino-Oka, Hirokazu Sugiyama **721**
- 122. Deterministic global optimization of multistage layer melt crystallization using surrogate models and reduced space formulations**
Christian Kunde, Ronald Méndez and Achim Kienle **727**
- 123. Model-Based Design Space for Protein A Chromatography Resin Selection**
Steven Sachio, Cleo Kontoravdi and Maria M. Papathanasiou **733**
- 124. Sustainable Energy Systems Design with Heat Pump Technologies for Meeting Peak Heating Demand**
Xueyu Tian, Fengqi You **739**
- 125. Isopropanol/ n -Butanol/ Ethanol separation from diluted fermentation broth by distillation. Process optimization using MILP techniques**
Eszter Toth, Gianluca Mancino, Ludovic Raynal **745**
- 126. Automatic synthesis of hybrid processes using distillation and liquid-liquid extraction for the separation of azeotropic mixtures**
Thulasi Sasi, Mirko Skiborowski **751**
- 127. A framework for optimal and flexible schemes design under uncertainty & sustainable aspects**
Jaime D. Ponce-Rocha, Martín Picón-Núñez, and Ricardo Morales-Rodriguez **757**
- 128. Optimization-based assessment framework for CO₂ utilization to fuels strategies**
Thai Ngan Do, Chanhee You, Minseong Park, Changsu Kim, Seongju Lee, and Jiyong Kim **763**

- 129. A novel approach to continuous extraction of active ingredients from essential oils through combined chromatography**
Constantin Jurischka, Bogdan Dorneanu, Christian Stollberg, Harvey Arellano-Garcia **769**

Abstract

A superstructure model for maximizing the profit of biodiesel production is presented in this work. The superstructure encompasses a wide range of feedstocks (e.g., waste cooking oil, tallow, rapeseed oil and algae), conventional reaction and separation equipment (e.g., continuous stirred tank reactor, decanter and vacuum distillation) and intensified operation units such as membrane reactor and reactive distillation column. The superstructure model is implemented in Advanced Interactive Multidimensional Modeling (AIMMS). The results present an optimal design of a biodiesel production process from waste cooking oil and tallow with a heterogeneous acid catalyst, a reactive distillation column and additional purification steps for producing pure glycerol which is 40% higher in price than technical glycerol. The total annual profit of the biodiesel production from waste cooking oil is 828,697 USD and from tallow is 976,450 USD. The results show that the combination of feedstock selection and implementation of advanced processing technologies to improve biodiesel production can be achieved with the superstructure optimization method.

Keywords: Superstructure, Optimization, Biodiesel, AIMMS, Design.

1. Introduction

Global climate change becomes more severe every year because of the increasing greenhouse gas (GHG) emission. The transport sector which contributes 16.2% of the global GHG emission becomes one of the targets of the European Commission (EC) renewable energies directive (2018/2001/EU) known as "RED II" (Ritchie and Roser, 2020). In RED II, the target for renewable energy in the transport sector is 14% with the share of advanced biofuel being 3.5% in 2030 (Observ'ER, 2020). However, the growth of biofuels has been slowing down recently with an increase of only 6.8% from 2018 to 2019 comparing to 12.3% between 2017 and 2018 because of high production cost and the change for non-food feedstocks (Observ'ER, 2020). Biodiesel, which shared 80.6% of total biofuel consumption in the European Union (EU) transport sector in 2019, plays an important role in the EU strategy to reduce GHG (Observ'ER, 2020). Therefore, the reduction of biodiesel production cost becomes an attractive topic for researchers.

Biodiesel is produced from renewable biobased feedstocks through chemical reactions. The selection of feedstocks is critical to the economic feasibility of biodiesel production because approximately 80% of biodiesel production cost comes from raw material costs (Zhang et al., 2003b). The biodiesel obtained from different feedstocks can be categorized

into three generations. The first generation biodiesel is derived from edible oil. The second generation biodiesel comes from non-edible oil, waste cooking oil and animal fat. The third generation is obtained from micro algae (Fazal et al., 2019). However, edible oils are generally expensive. Using edible oils to produce biodiesel leads to food-fuel debate over the concern of availability of food sources for people. Thus, the research of second- and third-generation biodiesel has become more important.

Besides the feedstocks, taking advantages of process intensification technologies in production can reduce the biodiesel cost. For example, a catalytic reactive distillation process has many benefits for biodiesel production such as lower equipment and operating cost, high productivity and reduced waste (Kiss et al., 2007). Supercritical methods present alternative biodiesel production routes without using a catalyst. Supercritical methanol as a reactant is a popular method which requires few equipment and can use both clean and used oil as feedstock (Gomez-Castro et al., 2013).

Superstructure optimization is a model-based computer-aided method of process systems engineering which can be used to optimize biofuel production process. A superstructure is a collection of numerous technical and feedstock alternatives that can form various possible process flowsheets. The superstructure can be formulated as a mathematical model by using variables, equations and constraints to describe its alternatives and flowsheets. The best flowsheet for predefined criteria and constraints can be identified by solving the model with optimization software tools (Tula et al., 2017).

Superstructure optimization has been increasingly applied in the field of biofuel to optimize the production process. AlNouss et al. (2019) developed a superstructure model of multiple biomass feedstocks and multiple biochemical products which is used to determine the optimal production process in terms of economic and environmentally friendly. Kenkel et al. (2021) presented an open-source generic superstructure optimization for modeling and optimizing of production process which is applied to design a cost optimal plant which produced methanol from captured CO₂.

However, most of published studies focused mainly on one aspect between finding inexpensive feedstocks and developing optimal processes for biodiesel production. A combined strategy of economic feedstock and innovative processes for biodiesel production has not been addressed adequately.

Therefore, the work presents a superstructure model which connects appropriate feedstock selection with process synthesis. In addition to the biodiesel production, the superstructure model comprises glycerol treatment units to increase the value of the by-product. With this superstructure model, an economic optimization is conducted for a production process from feedstock to biodiesel and glycerol. The results of this work will be compared to a conventional biodiesel production process (Zhang et al., 2003a).

2. Superstructure for biodiesel production

2.1. Problem statement

Given are units of feedstocks and reactants with initial flowrates and compositions, and reaction and separation equipment with technical specifications for producing and purifying biodiesel and glycerol. Under conditions that 1) each unit is assigned a logical decision variable and the units are connected to form possible processing routes by logical constraints, 2) the input and output flowrates of each unit are calculated by mass balance constraints, 3) The utility consumption is estimated from the heating, cooling and electricity requirement of each unit which are calculated based on flowrates and technical specifications, 4) The economics of an unit including capital investment and operating costs is calculated from flowrate and utility consumption. Deciding the feedstock and the

processing route to produce biodiesel while complying with the constraints and biodiesel purity as required in EU biodiesel standards, EN 14214. Maximizing the total profit of biodiesel production including biodiesel and glycerol sales.

2.2. Superstructure description

The superstructure model has total 67 units for biodiesel production and glycerol treatment as presented in Figure 1 A) and B). For feedstocks, the superstructure includes three biodiesel generations such as rapeseed oil and canola oil (first generation), waste cooking oil, tallow and linseed oil (second generation), and algae oil (third generation). For reaction, continuous stirred tank reactor, reactive distillation column and membrane reactor with different catalysts are included. For separation, units are vacuum distillations, decanters, acid and base neutralization reactors, water washing columns and hydrocyclones. After purification, the product stream has 96.5 wt.% FAME. Depending on its initial purity, the glycerol separated from the biodiesel production can be disposed as a waste or purified further to sell as crude glycerol (~80 - 98 wt.%), technical glycerol (~98 - 99.5 wt.%) and pure glycerol (> 99.5 wt.%) (Bart et al., 2010).

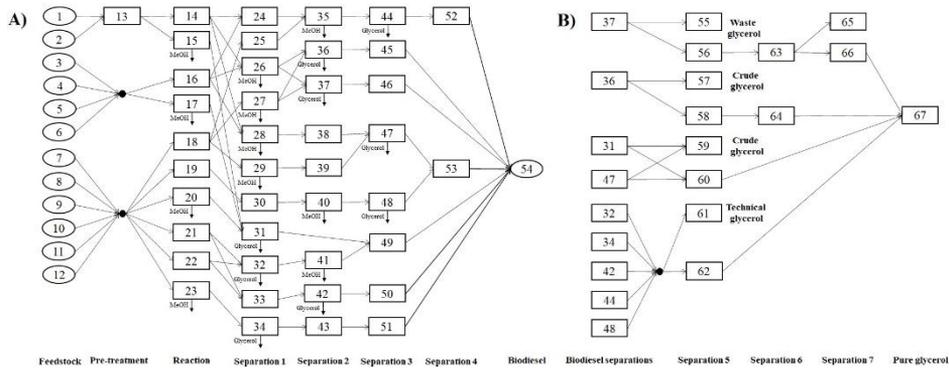

Figure 1: The superstructure for A) biodiesel production and B) glycerol treatment.

2.3. Mathematical model formulation

Each unit, j , of the superstructure has an infeed stream, F , and a reactant stream, R , which come in, and a product stream, P , and a waste stream, W , which come out, as shown in Figure 2.

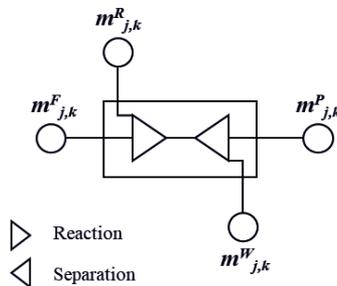

Figure 2: The illustration of streams which come in and out of a unit in the superstructure. Mass balances of a unit is described as Eq.(1) and Eq.(2).

$$m_{j,k}^P = (m_{j,k}^F + m_{j,k}^R + M_k \cdot ER \cdot \alpha_k) \cdot SF_{j,k} \cdot y_j \quad (1)$$

$$m_{j,k}^W = (m_{j,k}^F + m_{j,k}^R + M_k \cdot ER \cdot \alpha_k) \cdot (1 - SF_{j,k}) \cdot y_j \quad (2)$$

where k is a component of the streams (e.g., FAME, MeOH, glycerol, etc.), $m_{j,k}^F$, $m_{j,k}^R$, $m_{j,k}^P$ and $m_{j,k}^W$ are mass flow rates (kg/h) of component k in feed, reactant, product and waste streams, respectively. y_j is the logical decision variable which takes the value of 1 or 0 if the unit is selected or not. $SF_{j,k}$ is the split factor of component k based on how much k in the feed stream split into product stream. ER is the extend of reaction ($kmol/h$) calculated from the conversion of the main component of the feed stream into the main product of the product stream (e.g., from oil into biodiesel) as shown in Eq.(3).

$$ER = \frac{\theta_A \cdot (m_{j,A}^F + m_{j,A}^R)}{(M_A \cdot \alpha_A)} \quad (3)$$

where θ_A is the percent of component A being converted into product and α_A is the reaction stoichiometric number of A. From the extend of reaction, the conversion of another component can be calculated with the molar weight ($kg/kmol$), M_k , and the reaction stoichiometric number, α_k , of that component.

The product stream of a unit is the feed stream of the next one which directly connects to that unit on the same process route.

The energy requirement (kWh), E , of a unit is calculated as shown in Eq.(4).

$$E_j^u = (m_j^F + m_j^R) \cdot \tau_j^u \cdot H \cdot y_j \quad (4)$$

Where u is a type of utility such as heating, cooling and electricity, τ_j^u is the specific utility requirement (kW/kg) of the equipment, H is the total operating hours per year (h).

The equipment cost (USD), EC_j , of an unit is estimated based on the order of magnitude as presented in Eq.(5) (Seider et al., 2016).

$$EC_j = EC_j^{Ref,year} \cdot \left(\frac{m_j^F}{m_j^{F,Ref}} \right)^E \cdot \left(\frac{CE^{2020}}{CE^{year}} \right) \cdot y_j \quad (5)$$

where $EC_j^{Ref,year}$ is the equipment reference cost (USD), $m_j^{F,Ref}$ is the reference capacity (kg/h), CE^{year} and CE^{2020} are the Chemical Engineering Index of the reference year and 2020, respectively.

The total capital investment (USD), TCI , is calculated based on the overall factor method of Lang with the Lang factor for fluid processing plant being 5.93 and the delivery cost of equipment being 5% of total equipment cost (Seider et al., 2016). The total annualized capital investment ($TACI$) is calculated from the TCI with total project lifetime being 20 years and interest rate being 0.1.

The total annual operating cost (USD), $TAOP$, includes feedstock and reactant costs, operating and maintenance cost and total energy cost. The costs of feedstock and reactant are calculated by multiplying mass flow rate with cost per kg and operating hours per year. The operating and maintenance cost can be considered as 2% of the total annualized capital investment (Galanopoulos et al., 2019). The total energy cost is sum of energy costs of each equipment which is calculated from energy requirement, E_j^u , specific costs of electricity, heating and cooling and operating hours.

Maximizing the total annualized profit (USD), TAP , is the objective function of the superstructure optimization as presented in Eq.(6).

$$\max TAP = BDS + GLS + MES - TACI - TAOP \quad (6)$$

where the annual biodiesel sales (USD), BDS , is defined from the biodiesel price and the flow rate of product stream out of units: 45, 46, and 49-53. The annual glycerol sales (USD), GLS is defined from the glycerol grade and the mass flow rate of the glycerol

treatment. To simplify the mathematical model, the pure methanol coming out of separation unit is considered a by-product which reduces the requirement of fresh methanol. The annual methanol sales (*USD*), *MES*, is defined from the methanol stream separating from the biodiesel stream in reactive distillations and vacuum distillations. All the sales are calculated with the product market prices and the total operating hours of the refinery in a year.

The superstructure optimization problem is solved with the AIMMS Outer Approximation Algorithm (AOA) (Duran and Grossmann, 1986, and Viswanathan and Grossmann, 1990). The studies presented an algorithm to solve mixed-integer nonlinear programming (MINLP) problems which may be non-convex. The AOA is using CPLEX 20.1 as MIP solver and CONOPT 4.1 as NLP solver.

3. Results and discussion

The superstructure model is applied for two case studies: For the first case, the feedstock is only waste cooking oil to verify the superstructure model, and for the second case, the feedstocks are from different generations of biodiesel to select the most cost-effective feedstock and processing route. The biorefinery has feedstock flow rate of 1000 kg/h, 8000 operating hours per year and biodiesel output complied with EU standard, EN 14214. All the prices and costs of feedstocks, reactants and equipment are calculated in the year 2020.

In the first case study, the biodiesel is produced from the transesterification of the waste cooking oil (unit 7) by using reactive distillation with heterogeneous acid-based catalyst (unit 20) (Boon-anuwat et al., 2015). The products of the reactive distillation process are recycling methanol and biodiesel-rich stream which is going through a decanter (unit 31) to separate the glycerol. After separating the glycerol, the biodiesel product is purified to achieve purity standards by using a vacuum distillation column (unit 49). The separated glycerol is going through a vacuum distillation (unit 60) to become pure glycerol. The total annual profit of the biodiesel production in this case is 828,697 USD per year.

When comparing with the conventional biodiesel production from waste cooking oil (Zhang et al., 2003b), the superstructure optimal process has higher total annual profit. There are two reasons: First, the application of the heterogeneous acid reactive distillation process which can be used for feedstocks with high content of free fatty acids such as waste cooking oil and tallow and reduce the costs of addition separation steps for methanol and catalysts. Second, the glycerol is purified and sold as pure glycerol with higher price than in the conventional process.

In the second case study with different feedstocks, the optimal result is the biodiesel produced from tallow (unit 8) with the same processing route as the waste cooking oil. The annual profit this process is 976,450 USD per year which is higher than the first case because the price of tallow is lower than waste cooking oil.

4. Conclusion

A superstructure optimization model for biodiesel production which encompasses different generation feedstocks, conventional and process intensification technologies has been developed. The results show that the combination of waste cooking oil and tallow with reactive distillation and heterogeneous acid catalyst can open a promising future for biodiesel. The superstructure optimization is proven as a powerful tool of process systems engineering for biorefinery design by systematically and simultaneously solving multi-constraint problems. For further research, the superstructure model of biodiesel

production will be extended by a heat integration function and the ability of processing multiple feedstocks at the same time for more flexible biorefinery operation.

Abstract

We present a systematic process-wide solvent selection tool based on computer-aided mixture/blend design (CAM^bD) (Gani, 2004) for the integrated synthesis, crystallisation and isolation of pharmaceutical compounds. The method proposed simultaneously identifies the solvent and/or anti-solvent mixture, mixture composition and process temperatures that optimise one or more key performance indicators. Additionally, the method entails comprehensive design specifications for the integrated process, such as the miscibility of the synthesis, crystallisation and wash solvents. The design approach is illustrated by identifying solvent mixtures for the synthesis, crystallisation and isolation of mefenamic acid. Furthermore, a multi-objective CAM^bD problem is formulated and shows that a mefenamic acid with purity of 98.8% can be achieved without significant loss of process performance in terms of the solvent E-factor.

Keywords: Synthesis, crystallisation, isolation, CAM^bD, mefenamic acid.

1. Introduction

Solvents are widely used in the chemical industry to enable a variety of processing tasks. In particular, in the manufacturing of active pharmaceutical ingredients (APIs), a large number of synthetic steps are involved, with several inter-stage isolation and purification units, which require large consumption of solvents to facilitate these process operations (Ott et al., 2014). Recently, the principles of green chemistry have been incorporated in molecular synthesis and process design in order to promote sustainable practices in the chemical industry. In particular, solvent selection has been identified as a key green chemistry research avenue given the strong influence of solvent choice on process performance and product quality (Jiménez-González et al., 2011). One barrier to choosing better solvents is that they have traditionally been selected based on heuristics or time-consuming and expensive experiments. This prevents the practitioner from exploring all possible design choices that optimise the manufacturing process, and highlights the need for more systematic solvent selection tools (Mitrofanov et al., 2012; Brown et al., 2018).

Computer-aided mixture/blend design (CAM^bD) is a promising approach for identifying solvent mixtures that best achieve a specified performance objective, given a set of atom groups

or molecules and a predefined set of target properties (Gani, 2004). CAM^bD has been successful in identifying optimal solvent mixtures for a wide range of applications, including API manufacturing. Jonuzaj et al. (2016; 2018) developed a CAM^bD formulation to select optimal solvent mixtures for separation processes, including crystallisation, in which the number, identity and composition of mixture ingredients were simultaneously identified. Watson et al. (2019; 2021) formulated a solvent mixture design problem to identify the optimal solvents, mixture composition and crystallisation temperatures for the hybrid cooling and anti-solvent crystallisation of APIs. Jonuzaj et al. (2020) proposed a comprehensive mixture design formulation for the integrated crystallisation and isolation of APIs that includes mixture property constraints for both purification stages. However, despite the ongoing efforts in developing integrated solvent selection approaches, a tool that can identify optimal solvents for end-to-end processes is still lacking.

In this work, we present a novel integrated CAM^bD formulation for the design of synthesis, crystallisation and isolation processes. This formulation allows the simultaneous identification of solvents or solvent mixtures, mixture composition and process temperatures that optimise one or more key performance indicators (KPIs). While multiple phenomena need to be taken into account to quantify the effect of solvents on key performance indicators (Folić et al., 2008), we focus on thermodynamic driving forces, i.e., species solubility, in order to obtain a shortlist of solvent candidates that can then be tested through other considerations, such as kinetics, transport properties and crystal shape. The design approach is applied to select solvents for mefenamic acid production, with the aim of maximising process yield. Additionally, a multi-objective problem is formulated to explore trade-offs between the solvent E-factor (SEF) and product purity.

2. Solvent selection approach for integrated synthesis, crystallisation and isolation processes

2.1. Problem Definition

The proposed CAM^bD problem can be used to identify optimal solvent mixtures and process conditions for the integrated synthesis, crystallisation and isolation (filtration, washing and drying) of pharmaceutical compounds. A generic end-to-end process with labelled streams is depicted in Figure 1. This process configuration can represent both batch and continuous processes; for batch processes, each stream would represent the starting or end point of the batch operation. API crystallisation is considered through either pure cooling or hybrid cooling and anti-solvent crystallisation. In order to develop the CAM^bD formulation, a number of sets are defined: set C comprises all components that may appear in any of the liquid streams, set C^K comprises all components that may crystallise throughout the process, set Q comprises all the solvents in the process, set S comprises the solvent candidates from which the process solvents are selected, and set T contains the process stream numbers shown in Figure 1.

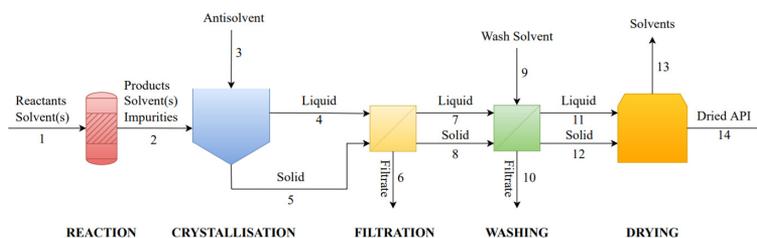

Figure 1: The conceptual flowsheet for the solvent selection problem. For crystallisation, filtration and washing, the labels Liquid and Solid refer to the liquid phase (solvents/dissolved solids) and the solid phase (crystallised solutes) of the corresponding slurry or wet filter cake, respectively.

2.2. MINLP formulation of the integrated CAM^bD problem

The proposed CAM^bD formulation is a mixed-integer nonlinear programming (MINLP) problem derived from a Generalised Disjunctive Programming (GDP) problem using the big-M approach (Jonuzaj et al., 2016). A multi-objective optimisation version is considered so that the overall mathematical structure of the problem can be represented as follows:

$$\begin{aligned}
 \min_{\mathbf{x}, \mathbf{y}} \quad & f_1(\mathbf{x}), \dots, f_P(\mathbf{x}) \\
 \text{s.t.} \quad & \mathbf{h}_0(\mathbf{x}) = \mathbf{0} \\
 & \mathbf{g}_0(\mathbf{x}) \leq \mathbf{0} \\
 & \mathbf{g}_{i,s}(\mathbf{x}) \leq \mathbf{M}_{i,s}(1 - y_{i,s}\mathbf{e}), i \in \{s1, s2\}; s \in \mathcal{S} \\
 & \mathbf{A}\mathbf{y} \leq \mathbf{a} \\
 & \mathbf{x} \in [\mathbf{x}^L, \mathbf{x}^U] \subset \mathbb{R}^n \\
 & \mathbf{y} \in \{0, 1\}^u
 \end{aligned} \tag{1}$$

where each objective function $f_p(\mathbf{x})$, $p = 1, \dots, P$ represents a KPI that needs to be optimised, \mathbf{x} is an n -dimensional vector of continuous variables such as mixture mole fractions, and \mathbf{y} is a u -dimensional vector of binary variables denoting solvent identities. The vector of constraints $\mathbf{h}_0(\mathbf{x})$ describes the models of the reaction, crystallisation and isolation units, the vector of constraints $\mathbf{g}_0(\mathbf{x})$ describes design specifications, the vector of constraints $\mathbf{g}_{i,s}(\mathbf{x})$ describes design and operating specifications that depend on the discrete choices, i.e., solvent identities, $\mathbf{M}_{i,s}$ is a matrix of positive or negative big-M values, \mathbf{e} is a unit vector, and \mathbf{A} and \mathbf{a} are a constant matrix and vector, respectively, used to express the logical relations between the binary variables.

3. Case study: solvent selection for the integrated synthesis, crystallisation and isolation of mefenamic acid

3.1. Problem Description

The synthesis of mefenamic acid (MA), a non-steroidal anti-inflammatory drug with analgesic properties, from 2,3-dimethylaniline (DMA) and 2-chlorobenzoic acid (CBA) is used as a case study. The reaction scheme is shown in Figure 2.

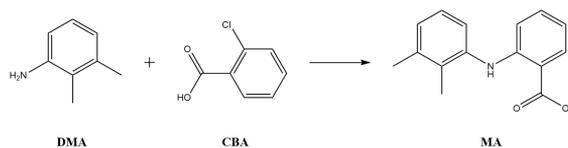

Figure 2: Reaction of 2,3-dimethylaniline (DMA) with 2-chlorobenzoic acid (CBA) to form mefenamic acid (MA)

The CAM^bD formulation identifies solvent mixtures of at most 2 components that optimise selected KPIs, while focusing on the thermodynamic aspects of the process. Two CAM^bD problems are formulated: in the first formulation the process yield is maximised while in the second formulation the SEF is minimised and product purity is maximised. Both formulations include a set of process model equations describing the material balances across the process units, as well as equilibrium constraints describing species solubility, i.e., under-saturation of CBA and DMA during synthesis, crystallisation and washing, under-saturation of MA during synthesis and that MA is at solid-liquid equilibrium during crystallisation and washing. The formulations also include a set of design specifications such as temperature constraints to ensure solvents are in the liquid phase

during operation, miscibility constraints to ensure solvents do not undergo liquid-liquid separation and constraints on the target values/ranges of the selected KPIs. In this case study, n-heptane is used as the wash solvent due to the limited solubility of MA in this solvent (Jonuzaj et al., 2020). Solvents are selected from a list of 43 compounds commonly used in the pharmaceutical industry, constituting a design space of 43 pure solvents and 903 binary solvent mixtures. The main model equations and design specifications are given in Table 1. All symbols are defined in Table 2. The liquid-phase activity coefficients are computed using UNIFAC (Fredenslund et al., 1975).

Table 1: Main CAM^bD model equations and design specifications of the MA case study

Constraint	Equation	KPI Range (where applicable)	Units (where required)
Solubility	$\ln x_{i,t} + \ln \gamma_{i,t} = \frac{\Delta H_{m,i}}{R_g} \left[\frac{1}{T_{m,i}} - \frac{1}{T_t} \right]$	–	–
Miscibility	$\frac{\partial \ln \gamma_{i,t}^{i,j}}{\partial x_{i,t}^{i,j}} + \frac{1}{x_{i,t}^{i,j}} \geq 0$	–	–
Solvent E-factor	$SEF = \frac{\sum_{i \in Q} M_{i,A} + M_{heptane,9}}{M_{MA,14}}$	3.5-20	g Solvents/g API
Crystal Yield	$Y_C = \frac{N_{MA,5}}{N_{MA,2}} \times 100\%$	90-100	%
Process Yield	$Y_P = \frac{N_{MA,14}}{N_{CBA,1}} \times 100\%$	75-95	%
Product Purity	$PP = \frac{M_{MA,14}}{\sum_{i \in CS} M_{i,14}} \times 100\%$	95-100	%
Isothermal reactor operation	$T_1 = T_2$	–	K
2:1 DMA:CBA Feed Ratio	$N_{DMA,1} = 2N_{CBA,1}$	–	mol
Reaction conversion	$x^c = 90$	–	%
Throughput	$M_{MA,5} = 80$	–	kg

Table 2: Nomenclature for the integrated CAM^bD formulation

Symbol	Description	Units (where required)
$x_{i,t}$	Mole fraction of species i in stream t	–
$\gamma_{i,t}$	Liquid-phase activity coefficient of species i in stream t	–
$x_{i,t}^{i,j}$	Mole fraction of species i in a binary mixture of i and j	–
$\gamma_{i,t}^{i,j}$	Liquid-phase activity coefficient of species i in a binary mixture of i and j	–
$\Delta H_{m,i}$	Molar enthalpy of fusion of species i	J/mol
R_g	Universal gas constant	J/mol.K
$T_{m,i}$	Melting point of species i	K
$M_{i,t}$	Mass of species i in stream t	kg
$N_{i,t}$	Moles of species i in stream t	mol

3.2. Results and discussion

The optimisation problems are solved using GAMS version 32.2.0 using the Simple Branch and Bound (SBB) solver (Bussieck and Drud, 2001). Integer cuts are included in the MINLP formulation to generate a ranked list of optimal solutions. For each solution, the following quantities are reported: the identities of solvent components $s1$ and $s2$, the solvent E-factor, the process yield, the product purity, the reaction temperature T_2 , the final crystallisation temperature T_4 , the composition of the solvent in the reactor, defined as the ratio of the mole fraction of solvent 1 to that of solvent 2 in the reactor outlet (stream 2), the composition of the solvent in the crystalliser, defined

as the ratio of the mole fraction of solvent 1 to that of solvent 2 in the crystalliser outlet (stream 4), and the total solvent mass used in the process, i.e., $\sum_{i \in Q} M_{i,4} + M_{heptane,9}$.

Maximising the process yield: The first CAM^bD formulation involves maximising the process yield. Three of the top ten solutions, ranked with respect to the process yield, are listed in Table 3. The first two solutions correspond to cooling crystallisation as shown by the decrease in temperature from T_2 to T_4 and the constant ratio of solvent mole fractions between synthesis and crystallisation. On the other hand, the third solution corresponds to a hybrid cooling and anti-solvent crystallisation process as shown by both the drop in temperature and decrease in the ratio of solvent mole fractions. It can be seen that in all three solutions, the SEF is greater than the lower bound of 3.5 g/g and the difference between T_2 and T_4 is large: T_2 is close to its upper bound of 403 K in the first two solutions and T_4 is at its lower bound in all solutions. This can be explained by the demanding process requirements that favour process yield maximisation. An interesting finding is that the product purity constraint is not active at these solutions, meaning that higher product purity can be achieved in other solutions, albeit at the expense of higher SEF values.

Table 3: Three top solutions of the CAM^bD problem with the objective of maximising Y_P

Solvents	Y_P (%)	SEF (g/g)	PP (%)	T_2 (K)	T_4 (K)	$\frac{x_{s1,2}}{x_{s2,2}}$	$\frac{x_{s1,4}}{x_{s2,4}}$	Total solvent use (kg)
s1: Nitrobenzene s2: n-Butyl acetate	88.10	5.58	98.56	389	290	2.08	2.08	446
s1: Anisole s2: n-Butyl acetate	87.85	7.07	98.95	389	290	0.11	0.11	566
s1: Acetic acid s2: 2,2,4-Trimethylpentane	83.94	9.24	99.30	362	290	6.50	4.13	739

Minimising the SEF and maximising product purity: To explore in more depth the trade-offs between the KPIs, the second CAM^bD formulation is a multi-objective optimisation (MOO) problem that involves minimising the SEF and maximising product purity. The problem is solved using the ϵ -constraint method (Haimes, 1971), in which the SEF is optimised while product purity is constrained by a given lower bound ϵ . The Pareto frontier representing the Pareto-optimal solutions of this MOO problem is shown in Figure 3. It can be seen that a marginal increase in product purity beyond 98.8% requires a significant increase in the SEF. Since the Pareto curve before PP = 98.8% is relatively flat, indicating a small increase in solvent consumption with increasing purity, the solution corresponding to (SEF,PP) = (5.45,98.8) would be a good compromise solution.

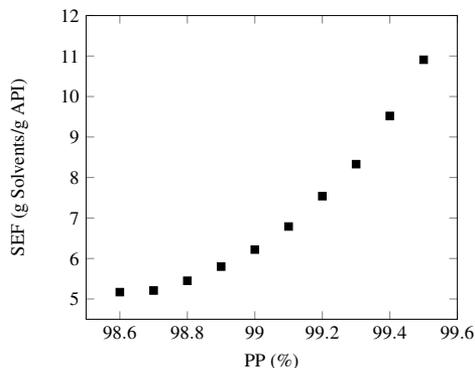

Figure 3: Pareto frontier of the MOO problem of minimising the SEF and maximising PP

4. Conclusion

In this work, a systematic solvent selection approach for the integrated synthesis, crystallisation and isolation of APIs was presented. The proposed CAM^bD formulation identifies the solvent mixtures, mixture composition and process temperatures that optimise selected KPIs, while meeting comprehensive design specifications. The approach was illustrated by identifying solvents for the synthesis, crystallisation and isolation of mefenamic acid. Furthermore, a MOO CAM^bD design problem was formulated and generated different designs with varying SEF/PP values, showing that a PP of 98.8% can be achieved without significantly deteriorating the SEF. The use of CAM^bD to guide experimental solvent screening and explore the synergies between KPIs can help accelerate pharmaceutical process development.

Abstract

A highly toxic compound, hydrogen cyanide (HCN), was discovered to result from the reaction between Ethyl cyano(hydroxyimino)acetate (Oxyma) and diisopropylcarbodiimide (DIC), a popular reagent combination for amino acid activation. The reaction solvent has been found to influence the amount of HCN produced so that judicious solvent choice offers a route to suppressing HCN formation. Given the safety implications and the time-demanding nature of experimental solvent selection, we employ a methodology of quantum mechanical computer-aided molecular design (QM-CAMD) to design a new reaction solvent in order to minimize the amount of HCN formed. In this work, we improve on the original QM-CAMD approach with an enhanced surrogate model to predict the reaction rate constant from several solvent properties. A set of solvents is selected for model regression using model-based design of experiments (MBDoE), where the determinant of the information matrix of the design, known as D-criterion, is maximized. The use of a model-based approach is especially beneficial here as it links the large discrete space of solvent molecules to the reduced space of solvent properties. The resulting surrogate model exhibits an improved adjusted coefficient of determination and leads to more accurate predicted rate constants than the model generated without using MBDoE. The proposed DoE-QM-CAMD algorithm reaches convergence in one iteration. In the future, the main reaction of amino acid activation will be considered to design a solvent that maintains the rate of the main reaction while minimizing HCN generation.

Keywords: computer-aided molecular design, design of experiments, solvent effects

1. Introduction

In the pharmaceutical industry, most reactions take place in the liquid phase, with a solvent used to facilitate the reaction. It is desired not only to achieve a high reaction rate but also to achieve high selectivity and avoid the generation of side products that become impurities, but it can be difficult to achieve these objectives simultaneously. The idea of increasing selectivity by rationally designing a solvent that decelerates the side reaction(s) offers a potentially powerful approach to

address this challenge. However, the process of solvent selection often requires time and resource consuming experiments. Aiming to accelerate the solvent screening process as well as to save resources, quantum-mechanical computer-aided molecular design (QM-CAMD) has emerged as a promising computational tool in recent years (Struebing et al., 2013; Zhou et al., 2015; Grant et al., 2018; Gertig et al., 2019). It relies on the use of a surrogate model for quantum-mechanical (QM) modelling to predict the rate constant of a reaction as a function of solvent properties. This surrogate model is incorporated into an optimization problem to identify a list of promising solvents for further experimental tests. Only a small number of QM rate constant data are used in the training set and the solvents used to generate these data are typically chosen based on qualitative arguments such as the diversity of functional groups. This often results in a surrogate model with limited accuracy. Consequently, the QM-CAMD algorithm often requires several iterations to converge, which increases the computational expense and may lead to a suboptimal solution due to model uncertainty. In a case study of solvent design for a Menschutkin reaction, the surrogate model predicted a rate constant that is 15 orders of magnitude larger than the QM rate constant at the first iteration of the algorithm; it took five iterations for the surrogate model to become accurate enough for the QM-CAMD algorithm to converge (Struebing et al., 2013). To reduce the computational expense, an efficient method that enables the rapid construction of more representative surrogate models is required.

Model-based design of experiments (MBDoe) is a statistical approach used to maximise the information content from a set of experiments by performing them at optimal conditions according to a quantitative statistical criterion (Franceschini and Macchietto, 2008). In this work, MBDoe is used to design an optimal set of computational experiments in which the reaction rates are obtained from transition state theory (TST) by calculating activation free energies (Ho and Ertem, 2016) on a QM-derived free energy surface for the reaction system in different solvents. The only experimental condition (factor) that needs to be determined is the solvent environment that is represented by a continuum solvation model (Marenich et al., 2009) used during the course of the QM calculations. The rate constants are used to regress a multi-variable linear regression (MLR) model as a surrogate for the QM method. Here the model-based approach links the large discrete space of solvent molecules to the reduced space of solvent properties. We apply this MBDoe-enhanced QM-CAMD algorithm in an industrial case study where amino acid activation is accompanied by a side reaction in which hydrogen cyanide (HCN) is formed, with the aim to abate safety concerns (McFarland et al., 2019) by taking the advantage of the effect of solvent choice on the amount of HCN produced in this reaction (Erny et al., 2020).

2. Methodology

2.1. QM-CAMD

The workflows of the original and the enhanced versions of the QM-CAMD approach are shown in Figure 1, which highlights the differences between the two versions. The enhanced QM-CAMD (DoE-QM-CAMD) algorithm uses MBDoe for the selection of the initial solvents, rather than a set of solvents based on intuition. Furthermore, they differ from each other in that the original QM-CAMD includes a conditional operation that determines whether more iterations are required for the algorithm to converge, whereas the enhanced version terminates after one iteration. In the first step of DoE-QM-CAMD, the design objective and constraints of the solvent design problem are defined; a set of initial solvents for surrogate model regression is selected using MBDoe. In the second step, rate constants k_s^L are calculated in the selected solvents $s = 1, \dots, N_s$ using transition state theory (TST) and a model combining quantum mechanics (here M062X/6-31+g(d)) and a continuum solvation model to obtain $\Delta^\ddagger G_s^{o,L}$, the liquid-phase activation energy for the reaction in a solvent s . $\Delta^\ddagger G_s^{o,L}$ is calculated using the thermodynamic cycle (TC) approach (Ho and Ertem, 2016). The rate constants calculated in the initial solvents are then used to regress the

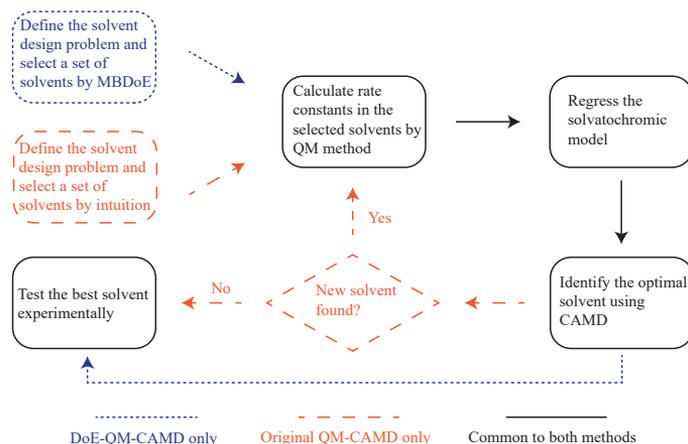

Figure 1: Workflow of QM-CAMD algorithm incorporating MBDoe

solvatochromic model Eq (1) that relates rate constants with the properties of reaction solvents using the following MLR relationship, where the subscript s denotes the solvent:

$$\ln k_s^L = c_0 + c_A A_s + c_B B_s + c_S S_s + c_\delta \delta_s + c_H \delta_{H,s}^2 \quad (1)$$

where $\ln k_s^L$ is the logarithm of the rate constant; A_s is hydrogen bond acidity; B_s is hydrogen bond basicity; S_s is polarity; δ_s is a correction parameter denoting whether the molecule is halogenated ($\delta_s = 0.5$), aromatic ($\delta_s=1$), neither ($\delta_s=0$) or both ($\delta_s=1$); $\delta_{H,s}^2$ is the squared Hildebrand solubility parameter; $c_0, c_A, c_B, c_S, c_\delta, c_H$ are the corresponding reaction-specific coefficients that need to be estimated. In the fourth step, the solvatochromic model is incorporated into a mixed-integer linear programming (MILP) problem, and an optimal reaction solvent is obtained by solving the MILP problem. Because MBDoe is used, the generated solvatochromic model from the MBDoe-selected solvents is expected to be adequately accurate so that the identified optimal solvent can be directly tested in experiments. In the original QM-CAMD algorithm, several iterations through steps 2-4 are often needed: newly found optimal solvents are added to the solvent set for model regression so that the accuracy of the solvatochromic model can be improved.

2.2. Selection of solvents using the D-optimality criterion

MBDoE using the D-optimality criterion is applied to maximize the information content that can be obtained from the QM calculations in the initial set of solvents. For a generic MLR model:

$$Y_i = \beta_0 + \sum_{j=1}^n \beta_j x_{i,j} + \varepsilon_i \quad i \in \{1, 2, 3, \dots, m\} \quad (2)$$

where $x_{i,j}$ are the $j = 1, \dots, n$ explanatory variables corresponding to the i th experiment; β_0 is the intercept; β_j are the coefficients corresponding to each of the explanatory variables; Y_i and ε_i are the measured response variables and random errors at the i th experiment respectively; m is the total number of experiments. In this work, the experiments are computational, so the noise is numerical and depends on the convergence tolerances used. The so-called Fisher information matrix I can be then constructed (Atkinson et al., 2007). The D-optimality criterion consists of maximizing the determinant of the information matrix, $\det I$, which is equivalent to minimizing the volume of the ellipsoid representing the joint confidence region of the model coefficients β_i , thus reducing a measure of the error in the parameters.

7	N-Methylformamide	0.0	7	Nitromethane	-2.3

3. Results and discussion

3.1. A case study: the HCN generation in amino acid activation using Oxyma and DIC

The DoE-QM-CAMD approach is applied to an industrial case study in which the choice of solvent greatly impacts on the safety of the reaction. It has been observed (McFarland et al., 2019) that during amino acid activation using Ethyl cyano(hydroxyimino)acetate (Oxyma) and diisopropylcarbodiimide (DIC), a popular reagent combination, the generation of HCN occurs, raising significant safety concerns when the reaction is scaled up to a manufacturing level. HCN formation has been found to proceed according to the Scheme in Figure 2, resulting from the decomposition of **1**, an adduct of Oxyma and DIC (McFarland et al., 2019). In this reaction, the imine-type nitrogen first attacks the oxime carbon nucleophilically and forms a zwitterionic intermediate **3** via the transition state **2**, the formation of which is also identified as the rate-determining step (RDS) of the whole reaction sequence. Species **3** further decomposes into **4** and HCN via the cleavage of cyanide and a proton transfer. Given the undesirability of this side reaction, our design objective is to minimize the rate constant of the RDS so that HCN generation can be effectively suppressed.

3.2. Solvatochromic model

A list of seven solvents, shown in Table 1, is generated by MBDDoE using the D-optimality criterion. The rate constants of the RDS are calculated using the QM method in the MBDDoE solvents as well as in the solvents used in Struebing et al.'s work for comparison. This latter set of solvents was chosen on the qualitative basis of molecular diversity, and is referred to as Div. By using the QM rate constants as the training data, a MBDDoE solvatochromic model Eq (3) and a Div solvatochromic model Eq (4) are obtained with adjusted R^2 values of 0.83 and 0.26, respectively.

$$\log k_s^L = -13.99 - 2.96A_s + 6.37B_s + 0.12S_s + 2.07\delta_s + 5.47\delta_{H,s}^2 \quad (3)$$

$$\log k_s^L = -16.59 - 5.03A_s + 7.62B_s + 16.26S_s - 0.55\delta_s - 1.81\delta_{H,s}^2 \quad (4)$$

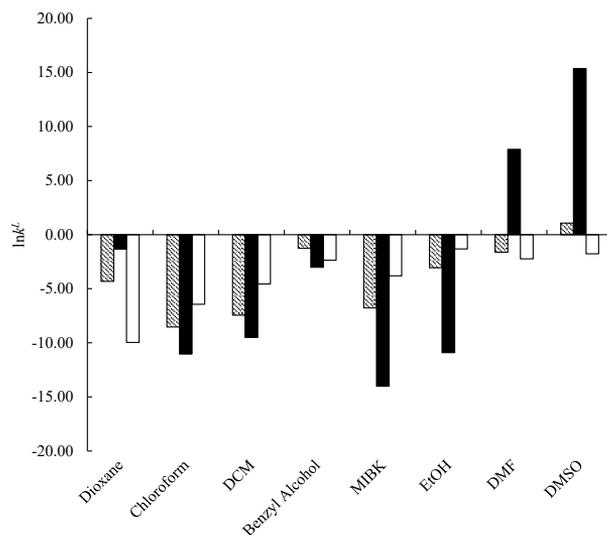

Figure 3: The logarithm of rate constants of the RDS in 8 solvents calculated using the MBDoE model Eq (3), hatched bars, the Div model Eq (4), solid bars and the QM model, empty bars

The larger adjusted R^2 of the MBDoE solvatochromic model demonstrates its better correlation between the fitted model and the input rate constants. Further, a validation set of 8 solvents is used to test the accuracy of the MBDoE and Div solvatochromic models against the QM model. As seen in Figure 3, for all the tested solvents except benzyl alcohol, the MBDoE model predicts closer results to the QM model with a mean average deviation (MAD) of 2.48 log units while the Div model yields a MAD of 8.23. In the case of benzyl alcohol, the predicted $\ln k^L$ by both solvatochromic models (MBDoE: $\ln k^L = -1.25$, Div: $\ln k^L = -3.01$) are in relatively close proximity to the QM model ($\ln k^L = -2.36$).

3.3. CAMD

The MBDoE and Div models are further incorporated into two CAMD problems denoted as MBDoE CAMD problem and Div CAMD problem, respectively. The CAMD problem formulation of Grant et al. (2018), in which additional property constraints are imposed on the boiling points, melting points, toxicities, octanol-water partition coefficients and flash points of designed solvents assembled from 45 atomic groups. The resulting MILP problems are solved in the GAMS software (<https://www.gams.com/>). The results are summarized in Table 2. The Div CAMD model identifies 2,3-dimethylpentane as the optimal solvent. However, the predicted rate constant deviates from that of the QM model by three orders of magnitudes. In contrast, the DoE CAMD model identifies 2,3,4-trimethyl-2-pentene as the optimal solvent and yields a rate constant which is much closer to the value given by the QM model with a deviation of only one order of magnitude. The observed contrast between the two CAMD models is consistent with the model validation results in Section 3.2. In addition, according to the QM model, 2,3,4-trimethyl-2-pentene yields a smaller rate constant than 2,3-dimethylpentane for the RDS of the side reaction that needs to be suppressed. These findings reinforce the hypothesis that the DoE model can provide much more reliable design results.

Table 2: Design results of the MBDoE CAMD problem and Div CAMD problem

	DoE CAMD	Div CAMD
Optimal solvent name	2,3,4-trimethyl-2-pentene	2,3-dimethylpentane
Optimal solvent structure	CH ₃ x 5 CH x 1 C=C x 1	CH ₃ x 4 CH ₂ x 1 CH x 2
k^L Solvatochromic model	$3.37 \times 10^{-6} \text{ s}^{-1}$	$1.13 \times 10^{-8} \text{ s}^{-1}$
k^L QM model	$1.34 \times 10^{-5} \text{ s}^{-1}$	$2.26 \times 10^{-5} \text{ s}^{-1}$

4. Conclusion

In conclusion, an enhanced QM-CAMD framework has been proposed by incorporating MB-DoE at the stage of selecting initial solvents for surrogate model regression. The MBDoE solvatochromic model exhibits better correlation and accuracy when compared to the Div model when using a validation solvent set. The MBDoE CAMD model also provides a better optimal solvent and a more reliable prediction of the QM rate constant for the optimal solvent identified. In the future, the case study will be further extended to the amino acid activation and amidation reaction so that an optimal solvent can be designed and used in peptide synthesis. The proposed approach has the potential to help choose solvents for many organic reactions, and to help improve reaction selectivity with minimal experimental effort.

Abstract

The Carbon-Hydrogen-Oxygen symbiosis networks (CHOSYN) are a set of hydrocarbon processing plants integrated, which pursue a proper use of mass and energy resources, this concept moves towards more sustainable designs for facing the current problem of environmental and climate change by meeting performance targets as environmental concerns and profitability enhancement. This work addresses CHOSYN synthesis using process intensification, which has been widely used for enhancing the performance of industrial processes in terms of economy, environment, and safety. The purpose is to analyze the impact that can be produced through the implementation of process intensification in CHOSYN's performance targets focusing on the intensification of distillation sequences due to the intensive energy use of this separation process. A case study is proposed, the methodology is presented in three stages: intensification of selected flowsheets of the case study, integration of the plants into the CHOSYN, and analysis of results. Thermally coupled equivalent configurations for selected distillation sequences are determined and optimized through the dynamic method known as the moving section method, once obtained these sequences, the different configurations for the CHOSYN are built through a sequential integration method. The performance analysis of the conventional CHOSYN configuration and one intensified option are addressed by the metric known as Sustainability Weighted Return on Investment Metric (SWROIM), which integrates the conventional ROI and sustainability indicators. In this case, the performance targets used for the term of sustainability in the metric are thermal energy savings and CO₂ emissions. In general, the resulting gap between SWROIM values for the conventional network and the intensified alternative measures the total positive impact by intensification over the cost and sustainability indicators of the CHOSYN.

Keywords: process intensification, process integration, resources management

1. Introduction

Carbon-Hydrogen-Oxygen symbiosis networks (CHOSYN) have been recently introduced as a macro system with multi-plant integration among a set of processing plants that deals mainly with hydrocarbon compounds (Noureldin & El-Halwagi, 2015). The integration is carried out through an interception network, where the exchangeable

streams are heated, cooled, pressurized, mixed, or divided as required to make feasible the exchange of streams, chemical conversions are used to obtain needed compounds which are more usable in the network. The main purpose of the integration in the CHOSYN is meeting a proper use of the different mass and energy resources available in the system, through the recycling of the exchangeable streams some sustainability performance targets of the network are improved, for example the reduction of fresh material flowrates, the amount of waste generation, water footprint and heat requirements, or the increase the production of value-added products and the profitability of the network. Nowadays, there is a special attention in the enhancement of all these targets in any process due to the ongoing problems related to the environment, and international agreements against climate change place special emphasis on the reduction of CO₂ emissions and energy efficiency, which force many countries to take action on this matter. In addition to the benefits of the integration to improve the performance targets of the CHOSYN, which have been widely studied and proved, this work proposes to use process intensification (PI) to further improve these sustainability targets. According to the definition of PI, which implies any chemical engineering development that leads to a substantially smaller, cleaner, safer, and more energy-efficient technology (Costello, 2004), it is logical to think that using intensification methodologies can impact the design of the CHOSYN and help to improve these objectives, which is implemented in this work. This work is focused on the intensification of distillation sequences due to the intensive energy use of this separation process, and since thermodynamic efficiency ranges for conventional distillation is 5-20%, using thermally coupled configuration this work seeks important improvements in energy efficiency.

The sustainability enhancement is measured by the SWROIM (Sustainability Weighted Return on Investment Metric), which involves simultaneously the conventional ROI and sustainability indicators (El-Halwagi, 2016), the value of this parameter is relative to the profit of the project and it is used to rank a set of projects according to the economic and environmental performance.

2. Methodology

This work aims to show the impact produced on the CHOSYN performance by applying PI in the distillation sequences of the different processes included in the network, the proposed methodology is divided into three stages: first the intensification of the flowsheets of the selected processes, then the coupled of the intensified processes to the network and finally the evaluation of the targets and the analysis of the results.

2.1. Case study

The case study proposed in this work has been taken from Juárez-García et al. (2021). It is the solution with the lowest cost for a CHOSYN configuration formed by five existing plants, four new plants, and the interception network (see Figure 1). Table 1 shows a summary of the plants and their process capacities.

Table 1. Summary of the Case study

Existing Plant	Processing capacity (ton/day)	Suitable for intensification
ATR (auto thermal reforming of methane)	13400 (syngas)	
Ethylene (steam ethane cracking)	110 (ethylene)	*
PDH (propane dehydrogenation to propylene)	2200 (propylene)	
MTP (methanol to propylene)	300 (propylene)	*
VAM (monomer of vinyl acetate from HOAc)	150 (HOAc)	

New plants	Processing capacity (ton/day)	
Methanol from syngas	882 (MeOH)	
Methanol from CO ₂	2152 (MeOH)	
Carbonylation of MeOH	202 (HOAc)	
Steam methane reforming	253 (syngas)	

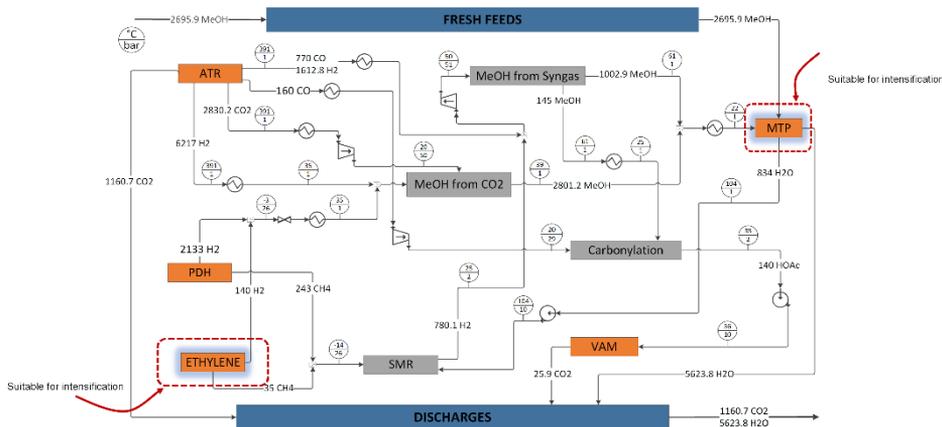

Figure 1. Case study

2.2. Intensification

The case study was simulated using Aspen plus, from the nine processes, two distillation sequences were suitable for intensification, first in the Ethylene production process and second in the methanol to propylene process (MTP). In Figure 2a, the conventional sequence for ethylene purification consists of three distillation columns, in the first column IC-201 the methane and lighter traces are separated by the top stage, the liquid bottom stream goes to the second column IC-202, where butenes and heavier hydrocarbons are separated by the bottom stage, on the top stage the light stream contains ethylene and ethane that are separated in the third column IC-203, the light stream has a composition of 99.9% ethylene. The conventional distillation sequence for purification of propylene is shown in Figure 2b, in the first column CA-401, butenes are eliminated in the bottom stream, and the top stream passes to the second column CA-402, where the propylene reaches a composition of 99.9%.

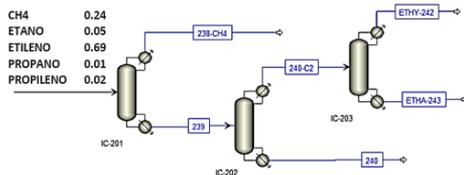

Figure 2a. Conventional sequence distillation of ethylene process

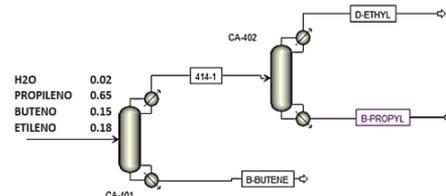

Figure 2b. Conventional sequence distillation of MTP process.

In both cases it was used the method proposed by Hernandez & Jimenez (1996) to obtain the intensified arrangements, according with the efficiency reported in the literature for similar sequences, for the ethylene purification sequence it was selected a arrangement of three columns with two recycles with an energy saving of 20% in regard of the

conventional sequence. For the propylene separation in MTP process the literature indicates that Petluyk column has the best efficiency for similar sequences, despite this, in this case the side stripper arrangement presents a greater energy savings with 20%. The intensified sequences, and the optimization of the inter-connection flows are shown in Figures 3.

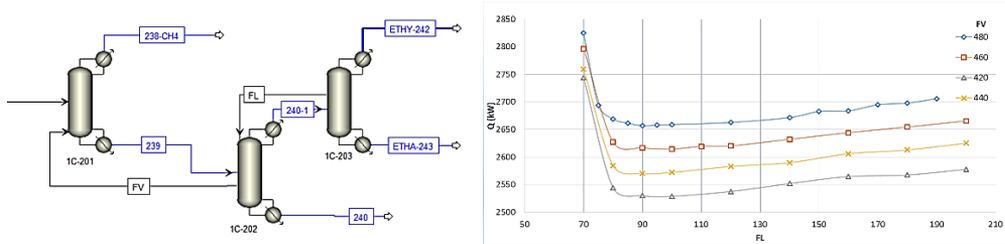

Figure 3. Intensification and optimization of the distillation sequence of ethylene process.

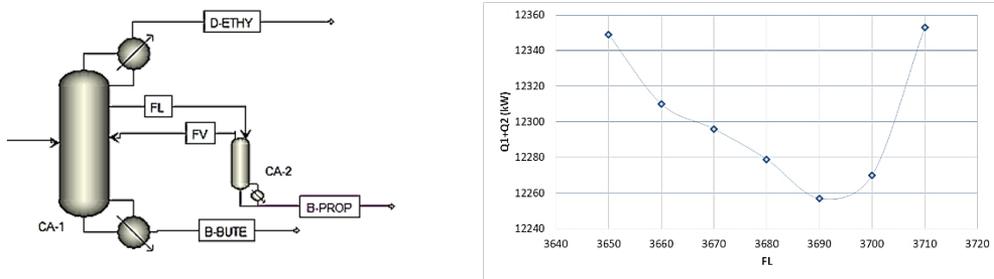

Figure 4. Intensification and optimization of the distillation sequence of MTP process.

2.3. SWROI evaluation

The Sustainability Weighted Return on Investment Metric (SWROIM) allows to measure the economic viability of a project through the conventional ROI (return on investment) and also to include sustainability aspects through sustainability indicators. The conventional ROI can be determined by E.1, which involves the annual economic profit (AEP) and the total capital investment (TCI):

$$ROI = \frac{AEP}{TCI} \quad E.1$$

The SWROI besides includes the term of sustainability as follows:

$$SWROIM = \frac{AEP \left(1 + \sum_{i=1}^{N_{indicators}} w_i \left(\frac{Indicator_i}{Indicator_i^{Target}} \right) \right)}{TCI} \quad E.2$$

Where $Indicator_i$ is the value of the i^{th} sustainability indicator and the $Indicator_i^{Target}$ is the target value for the indicator, it could be the maximum value determined by optimization or the largest value from all project options, w_i is the weighting factor which represents the relative importance for the indicator given by the company and it is a ratio to the economic profit. In particular, this work uses the reduction of CO₂ emissions and the heating savings as sustainability indicators, the targets are set in 20% of heating savings of the conventional configuration since the intensification allows to reach this percentage, and for the reduction of CO₂ emissions 22% of the total emissions of the conventional

configuration taking into account the compromise that Mexico acquired under Paris agreement. The selection of weighting factor is a non-trivial task because it can skew the results, we propose first equal weighting factors for both indicators of 0.1 in scenario A, then give more weight to the emissions indicator with a factor of 0.25 in scenario B, and vice versa in scenario C, this will allow observing how much the decision of this value influences on the final value of the SWROIM. The summary of the sustainability targets and their relative importance is shown in Table 2.

3. Results

Once obtained the intensified options for the distillation sequences a new configuration of the CHOSYN is built using Aspen plus (see Figure 5). For the SWROIM evaluation, it is needed the value of the total capital investment and the annual economic profit. As the case study was described, the cost and the profit are only related to the new plants which represent the new project investment, these values are shown in Table 3.

In this section are presented the resulting values for the SWROIM for the configuration of the CHOSYN when conventional arrangements of distillation columns are used and for the same configuration but using intensified distillation sequences. The value of the conventional ROI is shown in Table 3, the gap between both values is barely appreciated, which means that the investment cost does not greatly differ from one to another option, and the decision-maker could choose indifferently from one to another. When the sustainability targets of reduction of CO₂ emissions and heating savings are included with equal relative importance of 0.1 in scenario A, the SWROIM of the conventional CHOSYN has a value of 67.14 % and this is kept for scenarios B and C because it has the largest values for both indicators, in this same scenario A the SWROIM for the intensified configuration grows to 68.4%. For scenario B where the reduction of emissions has the biggest weight of 0.25 in regards the profit, the SWROIM is 68.81%, with a relative difference of 1.2%. Meanwhile, the SWROIM of scenario C, where the heating savings has 0.25 relative importance, is 69.34% with a relative difference of 2.2%.

Table 2. Targets of the sustainability indicators and their relative importance

Sustainability Indicator _i	Target (Indicator _i ^{Target})	Units	Weighting factor (A)	Weighting factor (B)	Weighting factor (C)
Heating savings	216918	kW	0.1	0.1	0.25
CO ₂ emissions reduction	35021	Ton of CO ₂ /year	0.1	0.25	0.1

Table 3. Results summary for the CHOSYN configurations.

	TCI (10 ⁶ USD)	AEP (10 ⁶ USD/year)	ROI	SWROIM (A)	SWROIM (B)	SWROIM (C)
Conventional configuration	181.219	121.358	67.08%	67.14%	67.14%	67.14%
Intensified configuration	181.055	122.358	67.58%	68.4%	68.81%	69.34%

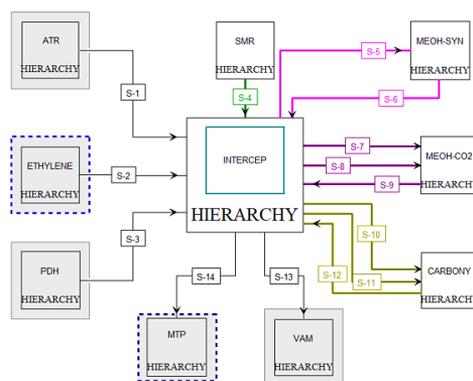

Figure 5. Aspen simulation of the CHOSYN configuration.

Table 4. SWROIM values for the different scenarios and configurations.

Despite the difference between both configurations in the different scenarios seems to be not too important, it is worth mentioning that a difference of 1.2% in the SWROIM only in economic terms represents 2.172 MMUSD and 2.2% 3.98 MMUSD what clearly shows what option is better. Whatever, the relative importance of the sustainability indicators can be changed according to the decision-maker and the company's goals in environmental concerns and provide a range of options suitable to this goals.

4. Conclusions

Process intensification has been implemented for the successful improvement of the sustainability performance targets of the CHOSYN. A case study was proposed to measure this improvement through the SWROIM which involves simultaneously economic conventional metric ROI and a sustainability term, for this work the reduction of the CO₂ emissions and energy savings are the targets to be improved. Notwithstanding in the individual processes, the intensification of the distillation sequences means energy savings up to 20%, this impact is greatly reduced in the macroscopic point of view of the CHSOYN with relative differences of the SWROIM up to 2.2% wich still represents high economic savings mainly related with the operating cost, and an enhancement over the environmental performance targets due the emissions reduction.

Abstract

This contribution describes a novel process design consisting of the implementation of a high performance liquid chromatography (HPLC) system into an existing integrated biopharmaceutical purification platform in order to extend the possibilities of analysis. This setup is controlled by a custom-made set of software tools, namely the combination of Orbit along with a C# based program called Satellite, which is used to link the HPLC system to Orbit. By using this process design, automated analysis of the continuous process flow is made possible, generating full wavelength spectra, and automated pool quality analysis. These spectra contain at least an order of magnitude more data compared to a standard chromatogram, which can be utilized for further analysis, while the pool quality analyses can be used for making decisions regarding how to proceed with a particular pool. The results of the study show the successful implementation of automated analytic tools to the purification process, which also indicates that the process carries promise as a generalizable platform for Orbit-controlled designs for different analysis purposes.

Keywords: novel process design, chromatographic purification, automated analysis, integrated downstream processing

1. Introduction

We are currently seeing a great need for global accessibility and lower prices of a wide range of vital biopharmaceuticals, e.g. monoclonal antibodies for cancer treatment. With *upstream* processing having seen recent productivity improvements, the on-going paradigm shift towards continuous and integrated *downstream* processes is therefore critical in order to make new, life-saving pharmaceuticals more readily available at a global scale (Ötes et al., 2017). Concrete examples of this paradigm shift is the process design for automated lab-scale production of a recombinant protein presented by Gomis-Fons et al. (2019), as well as the process data utilization to improve data-driven modelling methods by Brestrich et al. (2015). However, while continuous processes may offer many advantages, the optimal performance thereof demands high-speed decision-making based on precise measurements and constantly updating data for real-time monitoring and control (Lee, 2017). Therefore, there is a critical need to implement automated analysis capabilities in order to achieve autonomous production of biopharmaceuticals.

The purpose of the current work is to expand on the process presented by Gomis-Fons et al. (2019), and satisfy the need for advanced analysis by presenting a novel process design, where an HPLC with a diode-array detector was integrated with the aforementioned process and its control software. This is achieved by means of physical integration of the flowpaths of the two machines, as well as integrating the HPLC system control software into Orbit (Andersson et al., 2017) via a

custom-made C# based program. The proposed process design provides two tools with different capabilities: (i) one to analyze the individual eluting peaks from the chromatographic purification, and (ii) one to analyze the continuous process flow over all available wavelengths utilizing the diode-array detector. Thereby, the setup allows for automated quality analysis of specific pools or entire system flows, generating large amounts of data to be used for e.g. data-driven modelling and autonomous control. In order to highlight the advantages of the presented process design and the capabilities of the two added analytical tools, two case studies similar to the one presented in Gomis-Fons et al. (2019) were performed and the results thereof are presented and discussed.

2. Process design

This section describes the hardware configuration of the proposed design and the software setup used to control the process. The work was carried out by connecting the flow-paths of an ÄKTA pure 25 and an Agilent 1260 HPLC by utilizing the loop and injection valves, as well as a flow splitter. In order to integrate the HPLC system and the ÄKTA system, ancillary software was developed and used to link the HPLC hardware with the previously developed control software, Orbit.

2.1. Hardware configuration

In the process described by Gomis-Fons et al. (2019), a recombinant protein is purified in four steps using three bind-and-elute chromatographic columns and one flow-through chromatographic membrane. The purification steps consist of a multimodal chromatography column (Column 1 in Figure 1), a cation exchange column (Column 2), a salt-tolerant interaction chromatography anion exchange membrane (Column 3; operated in flow-through mode) and an anion exchange column (Column 4). The purpose of the loop (Column 5) is to collect fully representative samples of the eluting pools; in order to keep the samples homogeneous, the loop also contains a magnetic stir bar. It should be noted that the ultrafiltration-diafiltration step used by Gomis-Fons et al. (2019) was omitted in the current work in order to reduce complexity.

The complete system of the current work consists of two separate liquid chromatography systems, as presented in Figure 1; an ÄKTA pure 25 running an integrated protein purification process (Gomis-Fons et al., 2019) and an Agilent 1260 HPLC for running online analytics using an ion exchange column and a linear salt gradient. The Agilent HPLC (left dashed box) was connected to the ÄKTA (right dashed box) in two ways. Firstly, the loop valve of the ÄKTA ('LV') and the injection valve of the HPLC ('HPLC InjV') are connected in series, making it possible to fill the HPLC injection loop (Blue 'Inj Loop') from the ÄKTA. The HPLC injection valve was implemented using a two-position/six-way valve. Secondly, a splitter valve (Agilent G1968D Active Splitter) was installed in the flow path of the ÄKTA directly after the UV, conductivity and pH sensors. This splitter valve separates the flow in a ratio of approximately 1:1000, and small off-stream of the splitter is sent to the HPLC sensors through its column valve. Furthermore, a setup of two computers connected over LAN, each running an instance of Orbit, is used to control the physical system and automate the process.

This setup allows for automated HPLC analysis of the peaks during the run, which provides information regarding e.g. in which steps of the purification impurities are removed, and to which extent. Such information of the sample quality can then be used for purification process control. Furthermore, the HPLC system was equipped with a diode-array detector. The purpose of adding a diode-array detector to the process is to greatly increase the wavelength range for absorption measurements. Compared to the standard single or triple wavelengths in an ÄKTA system, the diode array detector in the Agilent 1260 system is capable of measuring every wavelength between 190 nm and 950 nm. This makes it possible to differentiate between species, provided they have different absorption spectra. If the spectra of all pure eluting components or known mixtures thereof

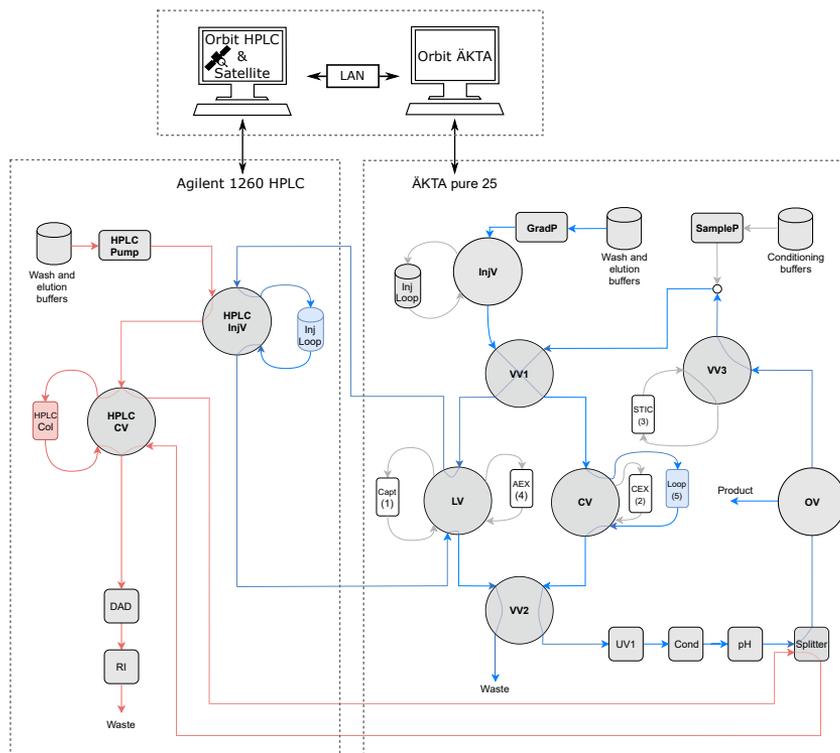

Figure 1: A schematic of the physical system layout and the control software setup.

are known beforehand, it is possible to determine the individual concentrations in real time, subsequently enabling dynamic decision-making regarding pooling (Brestrich et al., 2015), e.g. via partial least square regression (PLS). It should be noted that due to the two analytical tools being connected in series, continuous spectra cannot be taken while a peak analysis is being performed.

Through these two connections, the proposed process design thus provides two important analytical tools: online analytic chromatography on the HPLC, and the use of the HPLC sensors as additional real-time sensors in the process. This hardware configuration thereby allows for automated online analysis of specific peaks as well as continuous multi-wavelength measurements to be taken during a preparative chromatographic run. However, in order to control and/or automate the process, particular software was needed.

2.2. Control software

The control software setup is used to automate peak analysis, in order to find information of the species present in each pool, and diode-array detector measurements of the continuous process flow, which can be used to reveal much more information regarding the contents thereof. The main control software used to automate the process is a generic Python-based Process Analytical Technology (PAT) software interface (Holmqvist and Sellberg, 2016) called Orbit (Andersson et al., 2017), which has been successfully applied in research and development of biopharmaceutical downstream processing (e.g. Gomis-Fons et al. (2019, 2021)). Orbit provides an open-structure framework based on a real-time core, providing opportunities to implement add-ons to be used for process automation and to control a range of instruments. In order to integrate the HPLC-system

into the Orbit framework, a program called Satellite was developed using the Agilent-developed API known as Instrument Control Framework (ICF). Satellite was written in C# and based on a software development kit provided by Agilent. The Satellite program functions as a link between the HPLC hardware and the Orbit software, allowing Orbit to read sensor data and control the functionality of the HPLC.

In order to assert full control of the setup, two separate instances of Orbit were used to run the process. One instance was used to control the ÄKTA system, and the other to control the HPLC. Each Orbit controller instance was defined by a script dictating the specific system behavior. However, the two systems were not operating completely independently. For example, the ÄKTA system needed status information from the HPLC, i.e. whether the HPLC was ready to receive a sample in its sample loop, and the HPLC subsequently needed to know whether to begin an analysis run. This synchronization of the two systems was carried out via a global flag variable, i.e. by writing to and reading from the same variable to indicate whether a particular system is ready to perform an action.

3. Results and discussion

The major results from the two cases are presented as the preparative chromatogram of the first case followed by the analytic chromatograms of the peak quality, and the spectra generated by the HPLC diode-array detector analyzing the continuous process flow during the second case. This spectrum highlights the expected purification, and contains at least an order of magnitude more data than a standard chromatogram, which can be utilized for further analysis, data-driven modeling, and subsequent autonomous control.

In Figure 2, the preparative chromatogram of the first case study is presented, with the three eluting peaks highlighted by shaded areas under the curve. The first peak (close to the 150 minute mark) is from eluting the capture column (Column 1); the second peak is eluted from the second column, flowing through the third column; and the third peak is from the fourth column. It should be noted that the STIC (column 3) is run in flow-through mode, with the flow not passing by the UV detector, which explains why there is no visible peak in the preparative chromatogram corresponding to this column as with the others. However, due to the process design, it is still possible to perform an analytic HPLC run of the sample leaving this column.

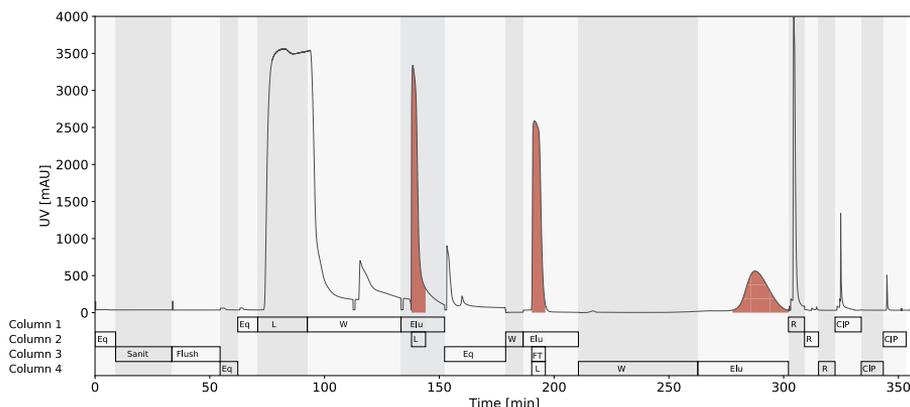

Figure 2: The chromatogram generated by the UV detector of the ÄKTA during the first case, with eluting peaks close to 150 min, 200 min, and 300 min.

The analytic chromatograms of the three peaks are presented alongside the analyses of the feed and the pure product in Figure 3. As can be seen, each step performs a vital function in isolating the product. Firstly, the capture column drastically reduces the impurities present in the feed, and the subsequent columns can be seen to each perform polishing and finishing by further eliminating the majority of the remaining impurities, leaving a single major peak after the AEX column (column 4) at the same eluting time as the pure product. The reason for the reduced peak height compared to the previous is due to the wider final pool during the chromatographic purification, meaning that the concentration in the analysed sample will be lower compared previous, narrower peaks. These results show that the proposed process design is capable of providing the automated analysis capabilities necessary to support continuous manufacturing.

Finally, the continuous spectra from the second case is presented in Figure 4, with the corresponding 280 nm chromatogram highlighted with a bold line. This wavelength is the gold standard for absorbance measurements, but proteins contain different peptide groups highly active in absorbance ranges of 180-230 nm (Carta and Jungbauer, 2010), which can be seen in Figure 4. By measuring at not only a single wavelength, but a range of wavelengths between 210-310 nm, more information can be retrieved regarding which species are present at different times, meaning that the spectra can be used to continuously analyse e.g. mixture compositions. While the nuances are difficult to see by the naked eye, the information existing in the continuous spectra remains for mathematical analysis, e.g. as presented by Brestrich et al. (2014). Utilizing this technology in the proposed process design thus enables automated monitoring of the product quality at a highly detailed level, providing further opportunities to automate decisions in continuous manufacturing.

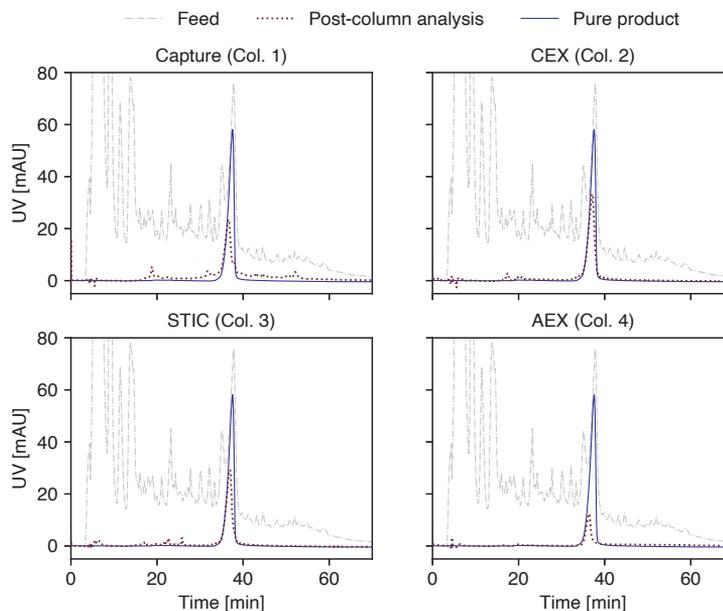

Figure 3: The results from the automated HPLC analysis of the colored peaks in the chromatogram along with the feed and the pure product, showing the performance of each step in the chromatographic purification performed on the ÄKTA pure 25.

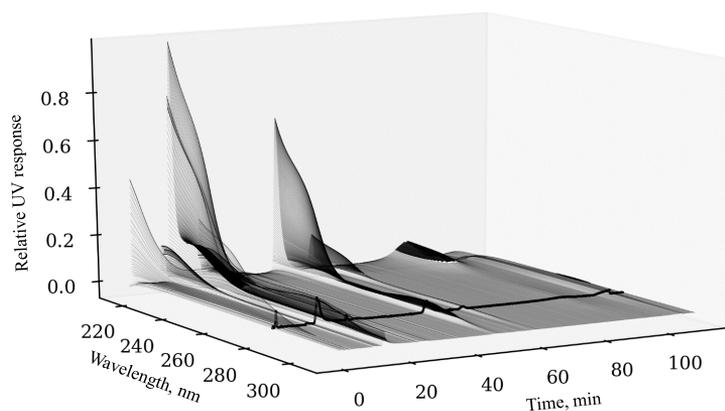

Figure 4: Continuous spectra providing information regarding the composition of the process flow at many more wavelengths than just at 280 nm, marked in bold to highlight the corresponding chromatogram.

4. Conclusions

In conclusion, the study shows that the proposed process design is capable of providing quality analysis information and large amounts of data in an automated fashion, which is a necessary step towards autonomous biopharmaceutical production. Based on the results from the peak analysis, an interesting next step would be to develop a rule-based decision-making algorithm to automate also the decisions on how to proceed with a particular pool. Furthermore, the use of the diode-array detector was shown to have potential in generating data that can also be used for e.g. identifying different species, and data-driven modelling. However, challenges pertaining to having both analysis tools active simultaneously, as well as determining the next step towards autonomous control, remain for the future. Finally, based on the presented results, the concept carries promise as a generalizable platform where customized setups for different purposes can be fully automated and controlled by Orbit.

A multiscale approach towards the use of Urban waste within the energy transition strategy

Sofia González-Núñez, Lidia S. Guerras, Mariano Martín

Department of Chemical Engineering, University of Salamanca, Plz Caidos 1-5, 37008, Salamanca, Spain

Abstract

The use of municipal solid waste and sludge within the waste to power initiative is evaluated following a multiscale approach. At process level, a techno-economic analysis based on systematic process design is developed to determine the optimal operating conditions and to estimate the yield and investment cost of the facilities as a function of the processing capacity. The facility consists of the boiler, the flue gas treatment chain, the steam turbine, and the cooling tower that are modelled using an equation-based approach. Experimental data and first principles are used to model the boiler and the pollutant abatement techniques, while detailed thermodynamics and transport phenomena are used to model the turbine and the cooling tower. Next, at country level, an extended facility location problem is formulated to select the location of facilities for a given budget, aiming at an electricity production cost and water consumption, considering the economies of scale and social indexes to promote the development jobs in regions suffering from depopulation. To produce power at a competitive price, below 0.06 €/kWh, a facility has to process the waste generated at cities above 250 k habitants. For this critical size, the investment cost is beyond 25 M€. At country level, for the major cities in Spain (over 65 across the mainland) it would be possible to produce up to 235 MW from the waste generated with a production cost of 0.05 €/kWh.

Keywords: Waste to energy, pollutants abatement, process design, multiscale

1. Introduction

Waste management is a major issue of our society due to the amount generated annually as well as the challenge its management represents. It is estimated that by 2021, 6.1 Mt/d of municipal solid waste (MSW) will be generated in urban areas (World bank, 2012). In addition to MSW, sludge that reaches a production of 13 Mt in 2020 (EU, 2008), can also be used as a resource. Both show a high potential to contribute to the energy transition. Incineration of MSW presents high potential for electricity generation using a Rankine cycle since the yield of thermal power plants can reach 40%. However, while most of the process studies focus on the thermodynamic yield, a facility that processes MSW requires a flue gas treatment to avoid emitting NO_x, SO₂ but above all heavy metals, dioxins and furans (Hubner et al 2000). Dried sludge can also be used as a resource. The literature is detailed evaluating the power island to compute the energy produced from incineration. However, the flue gas treatment was included in the process in a simplified manner where the models for pollutants removal were based on simple removal rates (Fodor and Klemes, 2012), and no process optimization of such facilities has been addressed. Guerras and Martín developed detailed surrogate models to evaluate the performance of the flue gas treatment technologies for NO_x, SO₂ removal (Guerras and Martín, 2019). This work

focuses on the design of incineration facilities for MSW and sludge evaluating the effect of the scale. A mathematical optimization approach is used for the optimal operation of integrated facilities including waste furnace, gas treatment, the power island, and the cooling system. After a techno-economic analysis, the effect of the scale on the cost is evaluated, to formulate a facility location problem aiming at deciding where to install this kind of facilities at different cities across a country using the available sludge and MSW within range.

2. Methodology

The methodology comprises the analysis at two scale levels. At process level the techno economic evaluation of the transformation of waste, MSW and sludge, into power is analyzed. A scale up evaluation study is required to formulate a facility location problem where the results are required for the exploitation of the waste at country level.

2.1. Process synthesis

The process consists of four sections: the boiler, the flue gas treatment chain, the turbine, and the cooling. The boiler processes the mix of wastes, municipal solid wastes (MSW) with 50% moisture and sludge, 83% moisture, whose composition is found in Lin and Ma (2012), in a blend that can be managed by the boiler, below 10% sludge to avoid issues due to the concentration in water. The model of the boiler provides the energy generated as well as the composition of the flue gas, validated using literature data. The flue gas is processed to remove NO_x, using selective catalytic reduction (R02), next, an electrostatic precipitator (PE01) removes particles followed by Lime Dry Spray process (LSD) for the removal of SO₂. A filter (FM01) followed by an adsorbent bed to remove heavy metals complete the gas treatment chain. The steam generated in the boiler feeds a Rankine cycle with reheating and regeneration. A cooling tower cools down the water used in the condensation of the steam. Figure 1 shows the process flowsheet.

The investment cost is computed using the factorial method based on the equipment cost (Sinnot and Towler, 2019) The estimation of the facility is performed by considering that piping, isolation, instrumentation, and utilities represent 20%, 15%, 20% and 10% of the units. Land and buildings cost is estimated to be 8 M€ (Martín and Martín, 2013). The fees represent 3% of the fixed cost, other administrative expenses and overheads and the plant layout represent 10% of the direct costs (fees plus fixed capital) and 5% of the fixed cost respectively. The plant start-up cost represents 15% of the investment.

2.2. Scale up method

Because of the properties of the factorial method to estimate the costs, the scale up or down as a function of the processing capacity, the cost of the units must be correlated as a function of a characteristic variable of its size or processing capacity (i.e. area, heat load, mass flow rate processed...) If the processing capacity is exceeded, additional units in parallel must be purchased (Sánchez and Martín, 2018)

2.3. Macro-scale analysis

A facility location problem is formulated to select the size and location of the incinerator plants towards the waste treatment and the social impact for a certain budget availability

and targeting a maximum electricity cost. The water consumption of the cooling tower is estimated from the correlations developed in previous work as a function the facility location (Guerras and Martín, 2020).

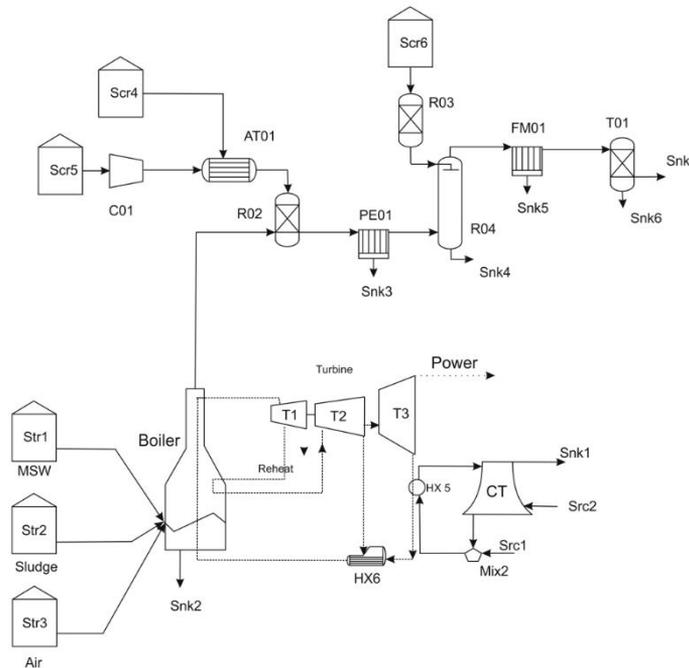

Figure 1.-Process flowsheet

3. Problem definition

3.1. Process modelling and optimization

The process is modeled unit by unit using a combination of mass and energy balances, thermodynamics, rules of thumb and experimental data. The boiler uses experimental data to determine the flue gas composition. To predict the effect of the processing variables on the removal yield of the flue gas treatment processes, such as NO_x catalytic reduction, dioxins and furans removal, the electrostatic precipitator, the SO₂ dry removal (Guerras and Martín, 2021), the filter, and the heavy metal packed tower, surrogate models are developed. In addition, the Rankine cycle is modeled units by unit the three turbines, high, medium and low pressure, where detailed thermodynamics is implemented using surrogate models for the enthalpy and entropy as a function of the pressure and temperature (Martín and Martín, 2013). The cooling tower model is based on evaluating the gas-liquid contact (Guerras and Martín, 2021).

3.2. Macro analysis

The selection of the location of the incinerator plants is a facility location problem (Grossmann, 2021). The aim is to produce power at a competitive price, using the opportunity to create wealth and jobs in regions that are suffering underpopulation issues or/and underdeveloped with respect to the neighbors. The social indexes relative population density, DH, relative unemployment, Ru, and development ratio, DR, of the

location are defined in Heras and Martín (2020) are used to build a composed objective function, eq. (1) where I is the investment.

$$OBJ = \text{Max} \sum_i \left(\text{Jobs}_i \cdot \frac{1}{2} \left(DH_i + \frac{Ru_i}{Ru_{i,\text{max}}} \right) + DR_i \cdot I_i \right) \quad (1)$$

4. Results

This section summarizes the results related to process design and the allocation problem

4.1. Process level

4.1.1. Process yield

The optimization of the process yields the ratios presented in Table 1 in terms of power ratio, turbine operation and cooling requirements. Note that water consumption is location dependent and is not as much as process driven beyond the total cooling load.

Table 1.- Summary of performance values for the operation of the facilities.

Variable	Value	Variable	Value
Boiler		Cooling cycle	
Flue-gas (kg/kg waste)	23.2	Cooling (kJ/kg)	1579
Ashes (kg/kg waste)	0.10		
Power island			
W1/W2/W3 (kJ/kg)	620/178/538	Turbine Extraction	0.16
P1/P2/P3/P4 (bar)	154/11/5.8/0.08	P(kJ/kg)	1335.3

4.1.2. Economics

The economics of the facilities are a function of the scale. Therefore, several cities across the territory are used examples such as Madrid (M), Barcelona (B), Santiago (Sa), Valencia (V), Seville (S), Gijon (Gi), Granada, (G), Pamplona (P), and Salamanca (Sal). Table 2 summarizes the results. We consider only the city and not the rest of the province, since waste collection since it is assumed that the recollection infrastructure is already in place and these facilities only change the end of use, from landfill to incineration.

Table 2.-Summary of economic parameters of facilities in different places

City	M	B	V	S	Gi	G	P	Sal	Sa
Habs (k)	3266	1637	794	689	270	232	201	144	96
P(MW)	39.2	18.8	12.6	11.8	3.8	4.0	1.9	2.0	1.3
I (M€)	67.3	46.6	39.0	37.9	27.1	26.9	23.7	24.0	22.8
E (€/kWh)	0.013	0.018	0.023	0.025	0.049	0.05	0.086	0.08	0.112
Water (L/kWh)	1.55	1.59	1.67	1.72	1.50	1.56	1.47	1.45	1.51
Jobs	325	227	189	184	130	131	115	117	111

The investment ranges from 23 M€ for a 100k habitants place to the 67 M€ of Madrid. Smaller facilities can create up to 111 jobs, including indirect ones, while larger ones can generate over 325 jobs. The production costs range within an order of magnitude from 0.013 €/kWh to 0.11 €/kWh. The contribution of the cooling section increases as the facility is smaller, while that of the gas treatment or the boiler decreases. The contribution of the turbine is always within 15%

4.2. Distributed production

Based on the previous study, it is possible to develop surrogates to estimate the production and investment costs of the facility as a function of the waste processed as well as the jobs generated and the water consumption as a function of the climate of the location. The facility location problem is formulated as in eq. (2). The results can be seen in Figure 2.

Max Obj

$$\begin{aligned}
 I_i &= f_1(W_i(\text{kg} / \text{s})) = -0.0172(W_i(\text{kg} / \text{s}))^2 + 2.0797(W_i(\text{kg} / \text{s})) + 20.829 \cdot y_i \\
 0.25 \cdot W_{\text{Avail},i} &\leq W_i \leq y_i \cdot W_{\text{Avail},i} \\
 P_i(\text{MW}) &= f_2(W_i(\text{kg} / \text{s})) = 1.336(W_i(\text{kg} / \text{s})) \\
 \text{Jobs}_i &= 0.57 \cdot (1 + 7.5) \cdot I_i \\
 C_{p,i}(\text{M€} / \text{yr}) &= f_3(W_i(\text{kg} / \text{s})) = 1.2533(W_i(\text{kg} / \text{s}))^{0.32} \\
 C_{\text{electricity}} \sum_i P_i(\text{MW}) \cdot 1000 \cdot 8760 &= \sum_i C_{p,i} \\
 C_{\text{electricity}} &\leq C_{\text{market}} \\
 \sum_i I_i &\leq \text{Budget} \\
 \text{Water}_{\text{consumption}}(\text{L} / \text{kWh}) &= -2.297 \cdot 10^{-4} \cdot T^2 + 0.798 \cdot H^2 + 7.090 \cdot p^2 + 2.200 \cdot 10^{-2} \cdot T \cdot H \\
 &+ 2.993 \cdot 10^{-2} \cdot T \cdot p - 0.515 \cdot H \cdot p - 1.533 \cdot 10^{-2} \cdot T - 1.417 \cdot H - 12.574 \cdot p + 7.6256
 \end{aligned} \tag{2}$$

Figure 2a shows that for a budget of 250 M€ and an electricity cost of 0.06 €/kWh, most of the locations make full use of the waste, but the largest city selected, Seville, only processes 83% of the waste for a power production of 9.8 MW. There are places with just 25% usage whose selection is more towards the social benefit of creating jobs, i.e. Toledo and Almería. The water consumption of the system is 1.673 L/kWh and the production capacity reaches 27 MW. For a budget of 500 M€, a larger number of locations was selected to the north, due to the depopulation suffered over the last years and the combination with lower GDP. Most of the same ones already chosen for the lower budget remain but the capacity of processing increases such as in the case of Seville, while Murcia and Cartagena were selected within the region of Murcia. The total power production reaches 55 MW while the water consumption decreases to 1.649 L/kWh

5. Conclusions

A multistage approach is presented for the valorization of urban waste. At process stage, a techno economic evaluation of a facility consisting of waste incineration, flue gas treatment to remove pollutants such as NO_x, SO₂, heavy metals and PDDFs, a steam turbine and a cooling tower to evaluate the water energy nexus. The units are modelled in detailed based on thermodynamics, first principles, industrial data and rules of thumb. Next, the investment and production costs are estimated.

A 1.336 MW/kg of mixed waste can be produced. For the facility to produce power at a competitive price, it has to process the waste generated at cities above 200k habitants. At country level, a facility location problem is formulated using a combined social index to favor economic growth. For the major cities in Spain (over 65 across the mainland) it would be possible to produce 235 MW from the waste generated with a production cost

of 0.05€/kWh and a total investment of 1700 M€. While the average costs are competitive, at regional level, some regions would produce at a high cost and only the national strategy would justify the production of power from waste beyond a waste management technology.

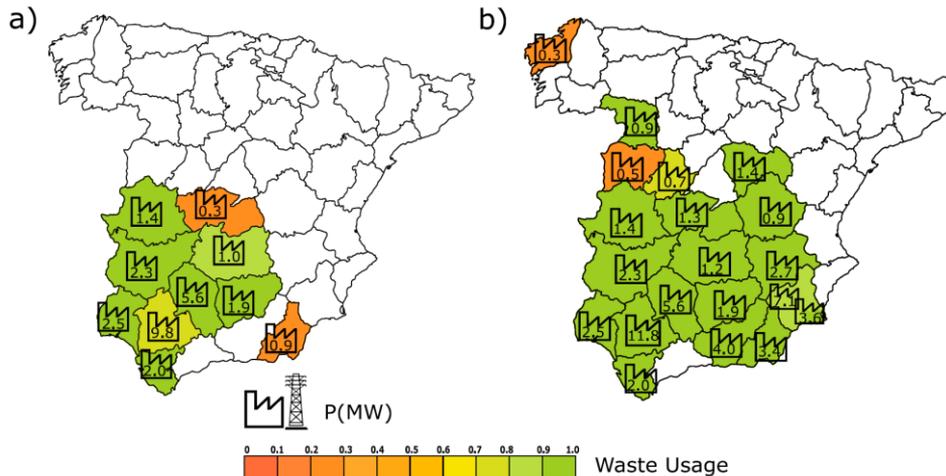

Figure 2- Facility location as a function of target cost of electricity and budget. a) I=250 M€; 0.06 €/kWh; b) 500 M€; 0.06 €/kWh

Integration of thermo-chemical energy storage for flexible operation of decarbonized power plants

Calin-Cristian Cormos, Letitia Petrescu, Ana-Maria Cormos

Babes-Bolyai University, Faculty of Chemistry and Chemical Engineering, Chemical Engineering Department, Arany Janos 11, Cluj-Napoca, RO-400028, Romania

Abstract

This work evaluates the integration of an innovative thermo-chemical energy storage system based on calcium-derived sorbents for flexible operation of decarbonized coal-fueled super-critical power plant. The reactive gas-solid cycle is used for both power plant decarbonization as well as a time-flexible thermo-chemical energy storage system in conjunction to a 500 MW net power output plant with 90% carbon capture rate. Overall techno-economic and environmental implications of flexible decarbonized power plant with calcium-based thermo-chemical energy storage system were evaluated using process flow modeling and thermal integration. For comparison reason, similar decarbonized power plant operated in base-load conditions as well as a non-capture power plant were also considered. As the results show, the utilization of calcium looping cycle for time-flexible thermo-chemical energy storage system in conjunction to a decarbonized fossil-based power plant bring significant benefits in term of reducing the specific capital cost (down to about 8%), the electricity production cost (down to about 3.6%), the CO₂ capture costs (down to about 3.5%), all compared to the base-load operation of similar decarbonized power plant. Although very promising in delivering better techno-economic performance indicators, the calcium looping technology still requires significant scale-up efforts from the current development level (up to 10 MW) to full industrial sizes.

Keywords: Thermo-chemical energy storage, Calcium looping cycle, Decarbonized power plants, Flexible power plant operation, Techno-economic evaluation.

1. Introduction

The energy sector is facing fundamental challenges in the transition to a low carbon economy as well as in relation to the higher penetration of renewable energy sources. The need to reduce the carbon emissions can be done by various methods e.g., switch to renewables, improving energy efficiency along the whole chain from production to utilization and deployment of Carbon Capture, utilization and Storage (CCUS) technologies. Since fossil fuels are still the dominant energy source for key utility and industrial sectors (e.g., heat and power, metallurgy, construction materials etc.), the CCUS options have a great potential to significantly contribute to the reduction of greenhouse gas emissions to meet the global environmental targets.

The renewable energy sources show a accelerate increase of their share but solar and wind applications are highly time-intermittent which put an additional operational burden to the back-up capacities most of them based on conventional fossil fuels. The energy storage technologies represent a very promising solution to accommodate the time-variability of the renewable energy sources. Various energy storage methods are available, some of them being already commercial to large scale (e.g., pumped hydro power, compressed air) others being in research stage (e.g., thermo-chemical storage).

Thermo-chemical energy storage has a great potential for development due to significantly higher energy density and improved energy efficiency (Yan et al., 2020). This paper is assessing the techno-economic implications of the Calcium Looping (CaL) cycle as both an energy-efficient CO₂ capture technology and a thermo-chemical energy storage option. As evaluated case study, a super-critical coal-based power plant operated in both base-load and load-following (flexible) conditions was considered. The key innovative elements of this paper in respect to the current state of the art are: evaluation of CaL technology for both decarbonization and thermo-chemical energy storage purposes and detailed techno-economic evaluation of 500 MW decarbonized power plant with thermo-chemical energy storage facility to improve its load following capabilities.

2. Integration of calcium looping system for power plant decarbonization

The calcium looping cycle for the post-combustion CO₂ capture is based on the following reversible chemical reaction:

The conceptual layout of CaL cycle has two reactors: one carbonation reactor in which the flue gases coming from the power plant are decarbonized according to above reaction and one calcination reactor in which the calcium carbonate is decomposed back to calcium oxide (sorbent regeneration) releasing the captured CO₂. Since the calcination reaction is endothermic, additional fuel has to be oxy-combusted to cover the reaction heat duty. Both reactors are operated in a Circulated Fluidized Bed (CFB) mode. The thermo-chemical energy storage based on CaL system uses the sorbent storage facilities in both regenerated and carbonated forms (Astolfi et al., 2019). The environmental impact of CaL cycle is minimal considering the usage of natural limestone as sorbent.

The CaL cycle was integrated into a coal-based super-critical power plant. The non-captured power plant concept (noted as Case 1) is based on current development stage. The design of decarbonized power plant integrating calcium looping cycle (noted as Case 2) is presented in Figure 1. The decarbonized power plant was assessed in two distinct situations: Case 2.a - base-load condition (according to the design presented in Figure 1) and Case 2.b - flexible (load-following) condition in which two high-temperature storage facilities (located between the carbonator and calcination reactors) were introduced for regenerated (calcinated) and carbonated sorbent material (Cormos, 2020).

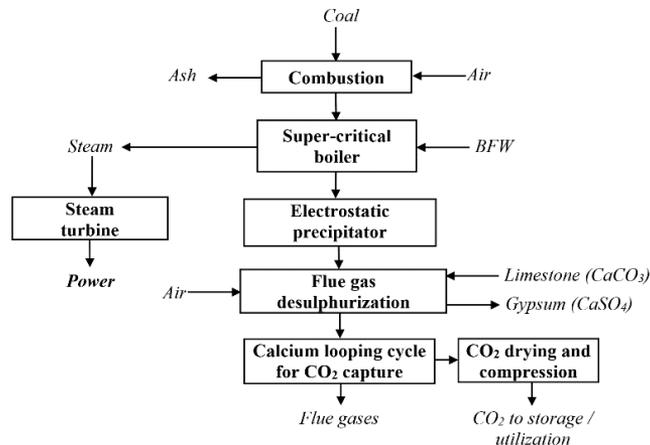

Figure 1. Decarbonized super-critical power plant integrating the CaL cycle

The design assumptions are presented in Table 1 (Cormos, 2020). All evaluated concepts were simulated using process flow modelling software ChemCAD (version 7.1.8). The CaL model was validated by comparison against experimental data from Astolfi et al., 2019 (see Figure 2 - left). For energy optimization, a detailed pinch thermal analysis was performed. Figure 2 - right presents the hot and cold composite curves for the CaL unit.

Table 1. Design assumptions of evaluated gasification-based poly-generation systems

Unit	Design assumptions
Coal composition (dry) and its calorific value	72.30% C, 7.45% O, 1.69% N, 4.11% H, 0.56% S, 13.89% ash; Moisture: 8%; Calorific value: 25.35 MJ/kg
Super-critical steam cycle	Steam temperature: 582°C / 580°C / 580°C Steam pressure: 290 bar / 75 bar / 20 bar Steam turbine efficiency: 88 - 90% Final steam expansion pressure: 45 mbar
Flue gas desulphurization	Wet (limestone slurry) desulphurization unit Desulfurization efficiency: >98%
Calcium looping cycle for post-combustion CO ₂ capture	Carbonation reactor temperature: 500 - 600°C Calcination reactor temperature: 800 - 950°C Carbon capture rate: 90%
CO ₂ processing unit (drying and compression)	Moisture removal unit: Tri-ethylene-glycol (TEG) Final compressing pressure at plant gate: 120 bar CO ₂ purity (vol.): min. 95%, max. 2000 ppm CO, max. 250 ppm water, max. 4% non-condensable gases
Auxiliary units	Energy consumption for coal handling: 0.5% of thermal input Heat exchanger minimum temperature difference: 10 °C Heat exchanger pressure drops: 1 – 3% inlet pressure

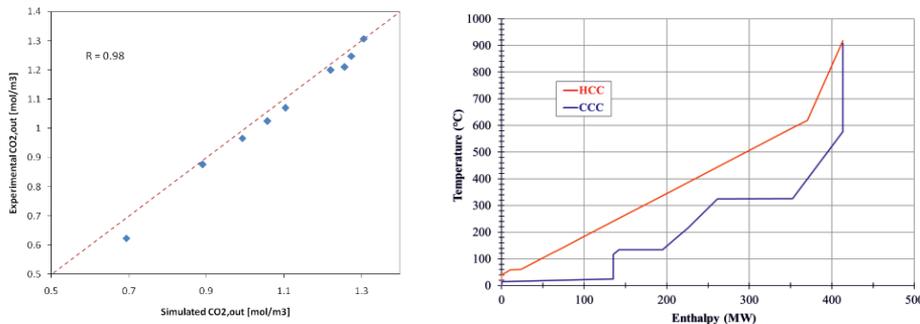

Figure 2. Validation of CaL unit (left); Thermal integration of CaL unit (right)

3. Techno-economic assessment of decarbonized power plant concepts

The first investigated power plant operation scenario was based on base-load conditions. In this case, no sorbent storage is needed. The evaluation of techno-economic performances for both decarbonized and non-capture power plant concepts was based on integrated assessment methodology as presented in a separate paper (Cormos and Dinca, 2021). Table 2 presents the main techno-economic performance indicators for base-load operation condition. It can be observed that introduction of decarbonization feature using CaL cycle implies an energy penalty for CO₂ capture of about 6.1 net efficiency percentage points. This energy penalty for post-combustion CO₂ capture is significantly reduced compared to other carbon capture technologies. For instance, the reactive gas-liquid absorption using alkanolamines (benchmark method considered in the literature) has an energy penalty of about 10 net percentage points (Koronaki et al., 2015).

Table 2. Base-load operation: Key performance indicators

Performance indicator	UM	Case 1	Case 2.a
Coal flow rate	t/h	165.00	200.01
Coal lower heating value (LHV)	MJ/kg	25.35	
Coal thermal energy	MW _{th}	1,161.87	1,408.46
Gross power output	MW _e	529.10	596.50
Fuel processing consumption	MW _e	5.80	7.04
CO ₂ capture and conditioning unit	MW _e	-	47.21
Power block consumption	MW _e	23.30	22.45
Ancillary power consumption	MW _e	29.10	76.70
Net power output	MW _e	500.00	519.80
Net power efficiency	%	43.03	36.90
Carbon capture rate	%	0.00	90.00
Specific CO ₂ emissions	kg/MWh	800.40	70.15
Specific primary energy consumption for CO ₂ avoided	MJ/kg CO ₂	-	1.95
Capital cost	M€	747.25	1,237.26
Specific capital investment cost	€/kW	1,490.00	2,474.00
Operational & maintenance cost	€/MWh	28.70	35.12
Levelized cost of electricity (LCOE)	€/MWh	70.99	80.52
CO ₂ removal cost	€/t	-	39.75
CO ₂ avoided cost	€/t	-	46.98

The economic penalty for decarbonization is also significant, all economic indicators showing increases e.g., the specific investment cost by about 66%, the operational & maintenance cost by about 22%, the levelized cost of electricity by about 14%. The CO₂ avoided cost is about 47 €/t which underline once more the attractiveness of CaL technology considering the current CO₂ emission tax which is currently in the range of 50 - 60 €/t (Ember, 2021). Following the evaluation of power plant base-load operation, a flexible load-following pattern was considered. The load-following is very important considering the integration of time-intermittent renewables. Table 3 shows the considered flexible operational cycle over one week. This operational cycle was chosen based on daily load-following pattern which is common in Central Europe (Astolfi et al., 2019).

Table 3. Weekly time operation cycle of decarbonized power plant

Monday to Friday		Saturday to Sunday
6 AM to 1 PM	10 PM to 5 AM	0 AM to 12 PM (all day)
7 PM to 9 PM	2 PM to 6 PM	
100%	50%	50%

To comply with this flexible operation scenario, the calcium looping cycle was modified by introduction of sorbent storage facilities in both regenerated and carbonated forms. Figure 3 presents the conceptual design of a flexible CaL cycle with high-temperature solid sorbent storage. Each sorbent storage has a storage temperature close to the reactor to which the solid is fed. Considering the weekly time operation cycle of decarbonized power plant as presented in Table 3, the flue gases flow to be treated for CO₂ capture is about 73% for the Monday to Friday period, 50% for the weekend and about 66.5% on average for the whole week. For base-load operation, the flue gases flow generated by the power plant to be treated for decarbonization is about 2,000 t/h with 12.4 % vol. CO₂.

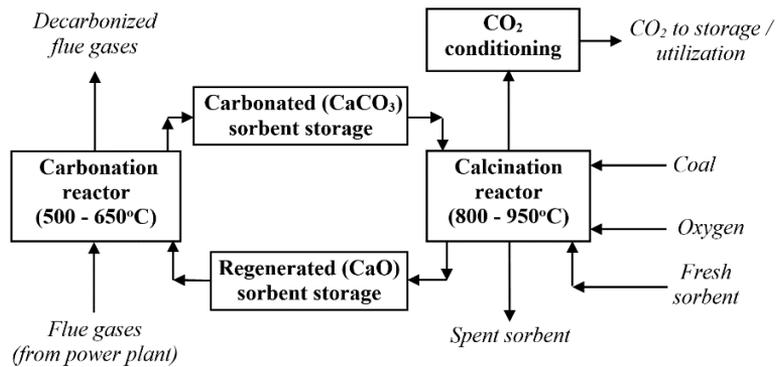

Figure 3. Flexible operation of calcium looping cycle

When the grid power demand is reduced, the power plant output as well as the flue gas to be treated for decarbonization are also reduced. For time-flexible operation, the same carbon capture rate (90%) was considered as in the case of base-load operation. To cope with power load-related variations, the calcium looping unit is to be operated in a flexible scenario considering the sorbent storage. The overall size of CaL unit as well as solid storage facilities were calculated based on the weekly operation cycle. The size of CaL unit for flexible operation was reduced to about 74% of the nominal base-load case leading to a significant capital cost reduction. A part of this capital cost reduction was used for the sorbent storage but considering the complexity of CaL design in comparison to the storage unit, there is an overall investment cost reduction for the flexible design. The time variations of power plant load and carbonated and regenerated solid storages are presented in Figure 4. As operation strategy, when the power plant operates at nominal load (100 %), the carbonated storage facility is gradually filling up with the correspondent discharge of the regenerated storage facility. At reduced power plant output (e.g., during the night or during the weekend), the process is reversed with accumulation of regenerated sorbent material for the next peak-time operation of the plant.

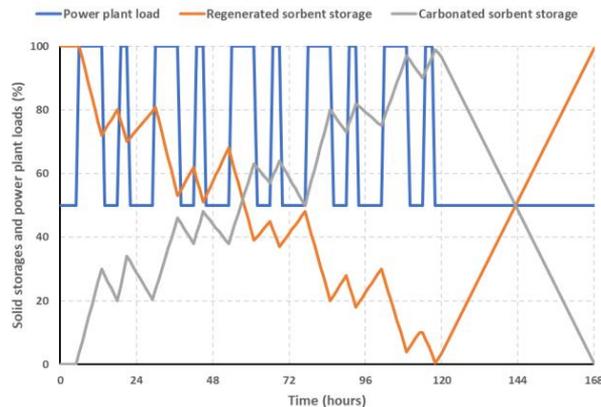

Figure 4. Weekly variations of plant load and regenerated / carbonated solid storages

As explained above, the reduction of CaL size leads to an overall capital cost reduction (although some of this reduction is used for the sorbent storage facility) with positive economic results. The comparison of key techno-economic indicators for the base-load (Case 2.a) and flexible-load (Case 2.b) decarbonized power plant is presented in Table 4

Table 4. Comparison of nominal and part-load operation of decarbonized power plant

Performance indicator	UM	Case 2.a	Case 2.b
Calcium looping cycle size factor	%	100.00	74.00
Specific power plant investment cost	€/kW	2,474.00	2,278.00
Operational & maintenance cost	€/MWh	35.12	34.85
Levelized cost of electricity (LCOE)	€/MWh	80.52	77.60
CO ₂ avoided cost	€/t	46.98	45.30

As shown, the flexible operation of decarbonized power plant fitted with sorbent storage option has better performance than base-load operation e.g., reduced investment cost by about 8%, reduced electricity production cost by about 3.6% and reduced CO₂ avoided cost by about 3.5%. However, it must be stated that further technological developments are needed for both calcium looping system as well as for high-temperature storage.

4. Conclusions

The present work assesses the potential techno-economic benefits of flexible thermo-chemical energy storage system based on the calcium looping cycle applied for a decarbonized super-critical power plant. The solid sorbent storage feature was used to increase the load-following capability of the power plant. As the results show, the flexible power plant operation brings significant advantages in comparison to the base-load case (reduction of all assessed economic indicators).

**m.raeisi@utwente.nl*

Abstract

In this study a superstructure of an algae biorefinery to produce added value products (pigments, omega-3, glycerol, biodiesel, biogas, and fertilizer) from microalgae is developed. From the superstructure optimization follows a cost optimal production pathway that consists of an open pond, sedimentation and flotation, flocculation/centrifugation without a dryer, hydrothermal liquefaction, organic solvent pigment extraction, N-butanol lipid extraction, lipid production, and anaerobic digestion. The profits of the algae biorefinery depend on the types of wastewaters. 107 million Euros income can be earned annually using 0.2 million tons of influent wastewater. The total profit of an algae biorefinery that uses influent wastewater as feedstock is approximately two times higher than the wastewater of wheat straw biorefinery. 63 million Euros income can be earned annually using 0.6 million tons of influent wastewater. Furthermore, the total profits of algae biorefinery in each season are calculated by using real data of sunlight periods of the Netherlands. Summer is the best season with more than 36 and 22 million Euros profits for algae biorefineries when using influent wastewater and wastewater of wheat straw biorefinery, respectively. Calculating total profits of algae biorefinery by considering fix value for durations of sunlight has more than 30% error.

Keywords: Algae biorefinery, added-value products, superstructure, MINLP.

1. Introduction

Among various types of biomass, microalgae are considered valuable due to their high growth rate and photosynthesis efficiency (Fernández-Linares et al., 2017). Microalgae are oceanic microorganisms that grow in wastewater using carbon dioxide and sun or artificial light. The capability to capture carbon dioxide and treat wastewater makes this microorganism one alternative to solve environmental issues (Assis et al., 2019). In addition, algae have a high potential to serve as source for various added-value products. Despite microalgae's vast environmental and economic benefits, high-cost extraction process from them must be overcome to extend its industrial application. Two approaches (heuristics and superstructure optimization) are typically employed to design an added value production process. The heuristic method is founded on rules acquired from experience and comprehension of unit operations. Although, this method is very fast, it does not propose a certain route for evaluating different cases (Mencarelli et al., 2020). The superstructure method relies on optimization algorithms and mathematical models to determine a cost-effective production pathway of all alternatives (Tula et al., 2017). Rizwan et al. (2013) proposed an optimal production pathway of producing biodiesel from microalgae by optimizing superstructure. The goal of this study was to maximize

biodiesel yield/ operating margins with(out) minimizing waste. The feedstock was defined as one block of the superstructure (Rizwan et al., 2013). Galanopoulos et al. (2019) formulated a superstructure for an integrated algae biorefinery. The wastewater stream of a wheat straw biorefinery was linked to the superstructure to produce glycerol, biodiesel, bioethanol and levulinic acid (Galanopoulos et al., 2019). The duration of sunlight was assumed 12(h) per day.

The role of wastewater as an important feedstock for the algae biorefinery has not been considered sufficiently. Choosing an appropriate wastewater source will improve the chance of applying the algae biorefinery concept at an industrial scale. In this study, a superstructure is developed to optimize the pathway for producing added-value products from microalgae using two different types of wastewaters. The profits of the algae biorefinery for each wastewater composition are calculated. Total profits of algae biorefinery in each season are calculated based on actual duration sunlight data.

2. Superstructure optimization

2.1. Process description

First, carbon dioxide and wastewater with nutrients are fed to the cultivation interval to grow microalgae. Microalgae (*Haematococcus Pluvialis* ($CO_{0.378}H_{1.65}N_{0.123}P_{0.005}S_{0.007}$)) (Ba et al., 2016) consume wastewater nutrients for regenerating and growing with the following molar reaction equation.

Four options are available in this interval (open pond, flat plate photobioreactor, bubble column photobioreactor, turbo column photobioreactor). To separate water from microalgae, it should pass a harvesting (gravity sedimentation and filtration or flotation), a dewatering (filter press, centrifugation, flocculation), and a drying interval. Before going through pigment extraction (chemical solvent or supercritical fluid extraction), the microalgae cells are disrupted (by for example: hydrothermal liquefaction, high-pressure homogenization, bead beating, microwaving, sonication). Subsequently, the lipids of the microalgae are extracted by Hexane, n-butanol, or supercritical carbon dioxide extraction. The products of lipid extraction are then transferred to a lipid production interval to produce omega-3, biodiesel, and glycerol. At the remnant intervals biogas and fertilizers are produced. To produce various bioproducts from microalgae, different technologies and processes can be selected. A mapping of all possible combinations of these technologies lead to a superstructure, as shown in figure 1. The superstructure can be converted to a mathematical model by defining an objective function and various variables and constraints.

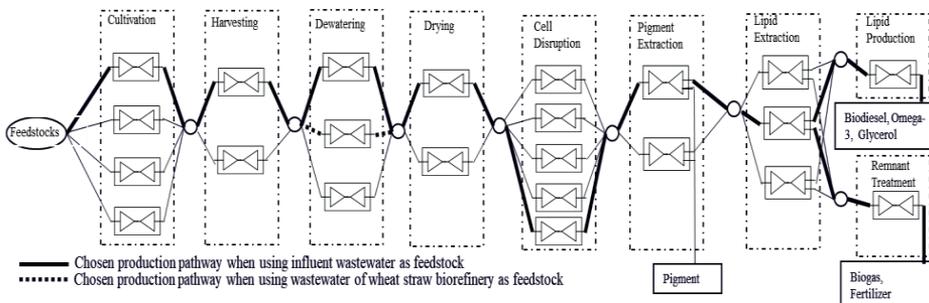

Figure 1: developed superstructure with chosen production pathway

2.2. Problem statement

Given are the composition of wastewater and products and the topology of the superstructure with all pathways. Furthermore, each interval's economic specifications, technical properties (split factors and yields), and utility requirements are given. Under conditions of logical constraints (only one technology option at each interval is selected) and where steady state mass and energy balances hold. The operating and investments costs are based on the flow rates. The decisions to be made are which technology options should be selected for each interval that maximize the revenues (profit minus costs).

2.3. Mathematical model

The developed superstructure consists of 9 intervals and 23 options (as described in process description section). A mixed-integer nonlinear programming (MINLP) was developed to optimize it. Steady state mass and energy balance and also economic scale and logical constraints are applied for each option of the superstructure.

2.3.1. Mass balance

Flows with a component (k) can enter or leave of each interval (j) as shown in figure 2. The $m_{k,j}^U$, is the mass flow (t/h) that comes from previous interval or feedstock (for the first interval of biorefinery). This flow combines with reactant flow ($m_{k,j}^R$)(t/h), if solvents are needed, to produce input flow($m_{k,j}^{IN}$) (t/h) (Eq.(2)). The reactant flow can be calculated with concentration factor $x_{k,j}$ as demonstrated in Eq.(3). This fraction factor is defined by amount of basic component in the upstream flow.

$$m_{k,j}^{IN} = m_{k,j}^U + m_{k,j}^R \quad (2)$$

$$m_{k,j}^R = x_{k,j} \cdot m_{k,j}^U \quad (3)$$

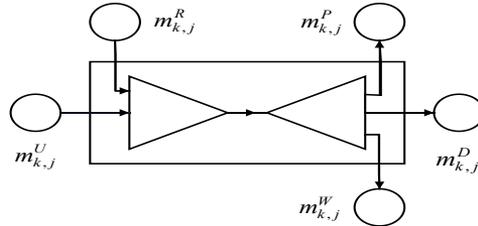

Figure 2. mass flows enter/leave the intervals (j)

The flow after reacting and distribution ($m_{k,j}^{OUT}$) (t/h) can be calculated by Eq.(4). In this equation, the $CF_{k,j}$, $S_{k,j}$ and $D_{k,j}$ are conversion factor (yield), mass stoichiometric coefficient and distribution coefficients, respectively. If there is no reaction or distribution in the block, the sum of these two parameters becomes zero. Thus, the input mass flow equal to output mass flow.

$$m_{k,j}^{OUT} = m_{k,j}^{IN} + m_{k,j}^{IN} \cdot CF_{k,j} \cdot (S_{k,j} + D_{k,j}) \quad (4)$$

After reacting or distributing, the output flow is divided to downstream flow ($m_{k,j}^D$) (t/h), waste flow ($m_{k,j}^W$) (t/h), and product flow ($m_{k,j}^P$) (t/h) by defining split factor(SF)(as shown in Eq.(5)).

$$m_{k,j}^{OUT} = SF_{k,j}^D \cdot m_{k,j}^{OUT} + SF_{k,j}^W \cdot m_{k,j}^{OUT} + SF_{k,j}^P \cdot m_{k,j}^{OUT} \quad (5)$$

2.3.2. Energy balance

Electricity U_j^E (kWh), heating U_j^H (kWh), and cooling U_j^C (kWh) are considered as utilities in this model. The required energy is calculated in a similar manner as with the mass balance. Eq.(6) shows energy balance, where SUC_j is an utility factor.

$$U_j = \sum_k m_{k,j}^{IN} \cdot SUC_j \quad (6)$$

2.3.3. Logical constraints

The logical constraints are setup to ensure the selection of only one technology at each interval. A variable (y_j) is defined and should be multiplied by each downstream flow. The summation of this variable for each stage of biorefinery should be an equal one.

2.3.4. Economy of scale

The annualized investment cost (AIC) (*Euros*) is calculated by Eq. (7)-(9), where $TIPC$, LT , IR , K^{ENG} , EC_j^{ref} , m_j^{ref} , IDX_j^{2020} , IDX_j^{ref} are total interval installation cost (*Euros*), the lifetime, the interest rate, engineering coefficient, reference cost (*Euros*), reference mass flow, cost index in 2020, reference cost index, respectively. Furthermore, the P^{Land} (*Euros*) is land price.

$$AIC = TIPC \cdot \frac{IR \cdot (IR+1)^{LT}}{(IR+1)^{LT}-1} \quad (7)$$

$$TIPC = K^{ENG} \cdot \sum_j EC_j^{ref} \cdot \left(\frac{\sum_k m_{j,k}^{IN}}{m_j^{ref}} \right)^{f_j} \cdot \left(\frac{IDX_j^{2020}}{IDX_j^{ref}} \right) + LC_j \quad (8)$$

$$LC_j = P^{Land} \cdot \frac{m_{Algae,1-4}^{OUT}}{Productivity_{Algae,1-4}} \quad (9)$$

The operating cost is a summation of raw material, utility, operating and maintenance, and waste treatment costs. The selling value is calculated by multiplying the total product mass flow, the product prices, and the operating hours per year. The selling values are decreased from the summation of annualized investment and operating costs to obtain total profits. The objective of this study is to maximize the total profits.

3. Results

Durations of sunlight determine the growth of the microalgae and subsequently the quantities of extracted products. These values are not the same in different seasons. The average sunlight periods in the Netherlands are 12.5, 15, 11.5, 8.5 (h) for spring, summer, autumn, and winter, respectively (Slegers, 2014). These sunlight periods are used to calculate the total profits of algae biorefinery. Furthermore, two types of wastewaters are considered in this study. The average compositions of influent wastewater of Netherlands in 2018 and wastewater of a wheat straw biorefinery (Galanopoulos et al., 2019) can be found in Table 1. 10% of mass flow of each type of wastewater are entered into the superstructure to consider the role of feedstocks on total profits and cost-effective production pathway. Approximately, 0.2 million tone influent wastewater and 0.6 wastewater of wheat straw biorefinery's are considered as the feedstocks of these biorefineries, annually.

Table1: composition of wastewater (Galanopoulos et al., 2019, stateline, 2021)

Component	Influent wastewater (t/h)	Wastewater of wheat straw biorefinery(t/h)
H_2O	224.59	824
NH_4^+	76.37	0.949
PO_4^{2-}	11.88	0.988
SO_4^{2-}	-	1.166

A mixed-integer non-linear programming (MINLP) model is implemented in the Advanced Interactive Multidimensional Modelling (AIMMS) software version 4.82.3.29 64-bit. The Outer Approximation Algorithm (AOA) combines the CONOPT 4.1 solver for the non-linear part and the CPLEX 20.1 solver for the integer part.

The cost-effective production pathways of producing added value products from microalgae using two types of wastewaters are shown in figure 1. The open pond, sedimentation and flotation, centrifugation without a dryer, hydrothermal liquefaction, organic solvent pigment extraction, N-butanol lipid extraction, lipid production, and anaerobic digestion are chosen when using influent wastewater. The mass percentage of water in wastewater of wheat straw biorefinery (824 t/h) is more than mass percentage of water in wastewater of influent wastewater biorefinery (224.59 (t/h)). It is economically beneficial to choose flocculation for dewatering intervals when using wastewater of wheat straw. Thus, the cost-effective production pathway for producing added value products when using wheat straw biorefinery wastewater is the open pond, sedimentation and flotation, flocculation, hydrothermal liquefaction, and organic solvent pigment extraction, N-butanol lipid extraction, lipid production, and anaerobic digestion.

The total profits of the algae biorefinery for each season when using each type of wastewaters are calculated (as shown in figure 3). Summer is the best season with the highest profit for both algae biorefineries due to long sunlight periods and a high amount of microalgae and extracted products. Using influent wastewater of Netherlands makes more profits for the algae biorefinery compared to another type of wastewater. The total profit of an algae biorefinery when using influent wastewater of Netherlands as feedstocks can be reached to 107 million Euros annually. The profit of this biorefinery is approximately two times higher than the algae biorefinery when using wastewater of wheat straw biorefinery as feedstock. Microalgae (*Haematococcus Pluvialis*) can be grown in typical Dutch influent wastewater more effectively than another type of wastewater due to the high ratio of nutrients. Furthermore, the low amount of water of influent wastewater is helped to have low investment and operating costs.

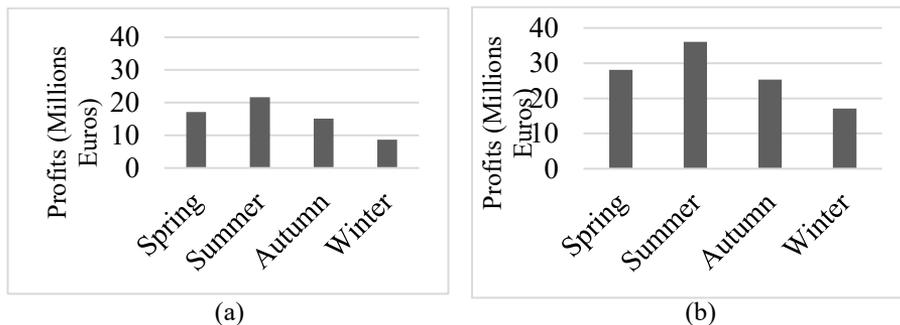

Figure3: profits of algae biorefinery in each season when using a) wastewater of wheat straw biorefinery b) influent wastewater as a feedstock

It is more common to assume fix value for sunlight periods (12 (h)) when calculating the total profits of algae biorefinery (Galanopoulos et al., 2019). With this assumption, the total profits of algae biorefineries when using wastewater of wheat straw biorefinery and influent wastewater are 93 and 163 million Euros, respectively. By considering real data of sunlight periods, the total profits of algae biorefineries are estimated 63 and 107 million Euros when using wastewater of wheat straw biorefinery and influent wastewater, respectively. Approximately 30% error are made by considering fix value for sunlight duration. Thus, this parameter has an important role in calculating the total profit of algae biorefinery.

4. Conclusion

The pathway of open pond, sedimentation and flotation, flocculation/centrifugation without a dryer, hydrothermal liquefaction, organic solvent pigment extraction, N-butanol lipid extraction, lipid production, and anaerobic digestion is chosen as the cost-effective production process for added-value products from microalgae. Types of wastewaters determine the appropriate technology of dewatering interval (flocculation/centrifugation). The incomes of 107 million Euros and 63 million Euros can be obtained annually using 0.2 million tons and 0.6 million tons of influent wastewater and wheat straw biorefinery's wastewater, respectively. Total profits of algae bioenergy with real data of sunlight duration of different seasons and an assumption fixed value (12 h) of sunlight periods are compared. This common assumption increases the estimated value of the total profits of algae biorefinery with different feedstocks.

Abstract

Biojet fuel is able to be produced from lignocellulosic biomass having ethanol as intermediate. However, the whole process faces challenges related to high production costs and environmental impact as well as the feedstock annual availability. In this paper, an intensified process for biojet fuel production is presented, which includes sugarcane bagasse and corn stover planning within a superstructure scheme with steam explosion and diluted acid pretreatments. By employing stochastic optimization, the total annual cost (TAC) and the ecoindicator-99 (EI99) were minimized to meet sustainability goals. The purification zone of ethanol was intensified and schemes of vapor side stream column (VSSC) and dividing wall column (DWC) were evaluated and compared against the conventional extractive distillation. TAC savings of 5.56% and 5.02% for VSSC and DWC schemes, respectively, were achieved. Also, EI99 reductions of 1.72% and 2.92% were recorded for VSSC and DWC schemes, respectively. As results of the planning, 95.3% of annual feedstock is sugarcane bagasse, from which 54% is sent to acid pretreatment. Regarding to the corn stover, 72% is sent to acid pretreatment.

Keywords: stochastic optimization, process intensification, biojet fuel, lignocellulosic biomass, ethanol.

1. Introduction

In recent years, the production and consumption of fossil jet fuel have increased as a consequence of a rise in the number of passengers and goods transported by air. Despite the low demand caused by COVID-19 pandemic, a rise in the services offered by the sector is expected again. In an economic context still dependent on scarce oil, this represents a problem as well as the inherent environmental impact throughout the life cycle of this fuel. Given this, a promising solution is the use of biojet fuel as renewable aviation fuel. Previous research has widely explored the route of oils to obtain biojet (Rivas-Interian, 2021). However, the feedstock for the oil path, their water and land requirements, and maturation times have proven not to be entirely sustainable. In contrast, the route of alcohols offers an alternative since they can be produced from sugars present in the widely available lignocellulosic biomass. Thus, in a framework of circular economy, the use of lignocellulosic residues allows the production of alcohols necessary to obtain biojet fuel. Besides, the tools provided by process intensification make it possible to design a sustainable process with low environmental impact and capable to achieve energy savings. However, the use of biomass to produce biofuels is limited by the availability of the feedstock, which affects the supply chain. For this reason, an

adequate feedstock planning is necessary to take into account the time and frequency of the harvest. The goal of this work was to carry out the feedstock planning and the optimization of the entire biorefinery in terms of economic and environmental objectives.

2. General description of the process

The overall process of biojet production from lignocellulosic biomass requires the production of intermediate alcohols. The general scheme of alcohols production from lignocellulosic agro-waste involves steps of i) biomass pretreatment, ii) enzymatic hydrolysis, iii) fermentation of sugars, and iv) purification of the alcohols produced.

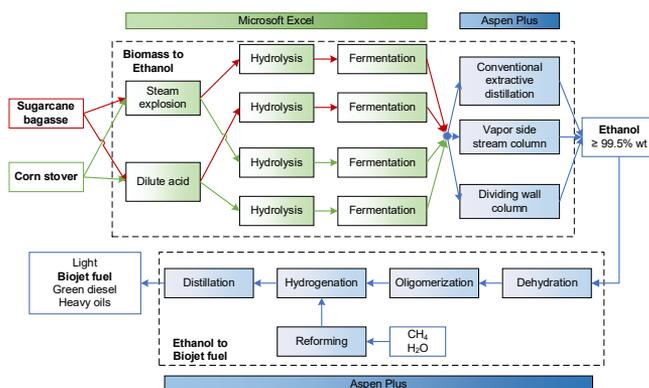

Figure 1. Complete superstructure for biojet fuel production process (Rivas-Interian, 2021)

Once the alcohols have been obtained, they are sent to the alcohol-to-jet (ATJ) process to be upgraded to biojet fuel through steps of v) dehydration to ethylene, vi) oligomerization to olefins, vii) hydrogenation to paraffins, and viii) distillation of hydrocarbon fractions where biojet is contained. Ethanol has recently been approved as raw material allowing the biojet fuel produced from it to be mixed with conventional jet fuel up to 50%.

An area of opportunity concerns to the purification of ethanol. Extractive distillation has relatively high costs and, despite this, remains as the main choice for large-scale ethanol production. Its high costs and energy consumption have been widely demonstrated. For this reason, a first approach on the path to sustainability is its intensification. By intensifying this zone, economic and environmental improvements can be achieved and an energy-efficient, cheaper, and greener process can be obtained as reported (Kiss & Suszwalak, 2012).

3. Case of study

To create a feasible market of biojet fuel in Mexico, it is necessary to meet a demand of at least 5.5% conventional jet fuel with biojet fuel (SENER, 2017), which equals 258 million liters. The production of biojet fuel from ethanol involves a series of steps that implicates the production of ethanol from lignocellulosic biomass. The availability of biomass limits the whole process, making it necessary to consider the temporality of the crops and, therefore, of their waste generated within the planning of the feedstock. To satisfy the demand of biojet fuel during a period, more than one feedstock has to be considered. Also, to leverage the number of available pretreatment technologies and their ability to break biomass, more than one pretreatment has to be evaluated regarding its

efficiency and profitability in order to find the most optimal route. The planning of the feedstock and the diverse combination of feedstocks and pretreatments make it possible to organize the process within a superstructure scheme.

3.1. Feedstock and pretreatment selection

Based on the information provided by the Mexican Agricultural and Fisheries Information Service, sugarcane bagasse and corn stover were selected as feedstocks, as they were the most abundant biomasses in Mexico during 2018. Additionally, they can be potential substrates for ethanol production since they have high sugar content and are renewable, cheap, and readily available feedstocks. On the other hand, steam explosion and dilute sulfuric acid were selected as pretreatments based on their low energy consumption per tonne of dry biomass and per gallon of bioethanol reported by Conde-Mejía, et al. (2012).

3.2. Process modeling

According to a modular manufacturing scheme, the whole process was modeled separately in two parts: lignocellulosic biomass to ethanol, and ethanol to biojet fuel. This makes possible to locate the plant of ethanol near to harvest sites and the plant of biojet fuel near to the airports thus reducing supply chain costs, increasing the flexibility of the whole process, and allowing the production network to react to dynamic supply and demand developments (Finkbeiner, et al., 2020).

The biomass-to-ethanol process was designed according to the superstructure scheme by combining the two feedstocks and pretreatments. To model the pretreatment, enzymatic hydrolysis, and fermentation of this module, kinetic data were obtained from literature and fitted to regression equations. This reaction train was modeled in MS Excel. For the fermentation, the *S. cerevisiae* strain was considered. The purification zone of ethanol as well as the module ethanol-to-biojet fuel were modeled in Aspen Plus V8.8, by employing the thermodynamic models of NRTL and ENRTL, respectively. Since the cost of separation represents a well-known area of opportunity, it was intensified by proposing a column sequence with vapor side stream and a column sequence of dividing wall (DWC) as intensified schemes.

As could be seen, the previous superstructure, along with the ATJ process, was modeled with highly non-linear and potentially non-convex equations. Besides, the existence of degrees of freedom allows solving the design problem as an optimization problem. Finally, the superstructure to be optimized is shown in Figure 1.

4. Process optimization

The search of the design and operation parameters that maximize savings and minimize environmental impact implies an optimization work. Such objectives as well as the optimization technique are described below.

4.1. Objective functions

To assess the sustainability of the process, the total annual cost (TAC) and eco-indicator-99 (EI99) were selected as objective functions. TAC allows quantifying the economic performance of a process based on its characteristics, while EI99 measures its

environmental impact in terms of human health, ecosystem quality and resource depletion. They were calculated with the Equations 1 and 2, respectively:

$$TAC = \frac{\frac{\text{Capital cost}}{\text{Recovery time}} + \text{Operation cost}}{F_k} \quad (1)$$

$$EI99 = \frac{\sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k}}{F_k} \quad (2)$$

Where F_k is the reference mass flow, β_b is the total amount of chemical b released per unit of reference flow due to direct emissions, $\alpha_{b,k}$ is the damage caused in category k per unit of chemical b released to the environment, ω_d is a weighting factor for damage in categories d , and δ_d is the normalization factor for damage of category d . The unit of measurement employed for EI99 is the ecopoint, which represents one-thousandth of the annual environmental load of an average European inhabitant. The capital cost was calculated by employing the Guthrie's method. Likewise, for the production process of ethanol, the annual production of alcohol was included to satisfy a demand of 5.5% of conventional jet fuel in Mexico with biojet fuel (SENER, 2017). The objective function is stated as follow:

$$F_{obj}(\vec{X}) = \begin{cases} \text{Min}(TAC, EI99) \\ \text{Max}(EtOH) \end{cases} \quad (3)$$

Pressures, temperatures, acid/enzyme concentrations, residence times, reflux ratios, and solvent/feed ratios were considered as continuous decision variables. Also, total stages, feed/solvent/side stream stages were considered as discrete decision variables. In total, 132 continuous and 21 discrete variables were counted for biomass-to-ethanol process. For ethanol-to-biojet process, 25 continuous and 5 discrete variables were also counted.

4.2. Stochastic optimization

To optimize the case of study, the Differential Evolution with Tabu List (DETL) (Srinivas & Rangaiah, 2007) stochastic method was employed. This is acknowledged for its ability to locate the global optimum regardless of the parameters of the problem, its small number of evaluations of the target function, and its efficiency in terms of computation times. This method was responsible for choosing the most suitable design parameters, operating conditions, and monthly feedstock to achieve an optimal design. It was implemented using a hybrid platform that incorporated MS Excel and Aspen Plus. There, a vector of decision variables is sent to MS Excel by using a dynamic data exchange with COM technology. Also knowing that a distributed configuration as lower cost than a centralized configuration (see Section 3.2), the process was optimized separately in two blocks: biomass-ethanol and ethanol-biojet. The following parameters were used: 120 individuals, 1000 generations, tabu list of 50% of the total individuals, tabu radius of 0.0001, and crossover and mutation probabilities of 0.9 and 0.3, respectively.

5. Results

5.1. Feedstock planning

As a result of the optimization, to produce enough ethanol to reach the biojet demand, 8 357 524 tons/year of sugarcane bagasse should be required of which 54% is sent to acid pretreatment; and 408 970 ton/year of corn stover, of which 72% is subjected to acid pretreatment. Only 15% and 0.85% of the bagasse and corn stover available in Mexico were employed. The most of the feedstock used annually is acid-pretreated sugarcane

bagasse (Figure 2) since the bagasse has a higher content of hexoses and it is the cheapest feedstock, so the optimization method tends to choose it as the most suitable. It is important to highlight that in some months one pretreatment is preferred over the other one. This is partially due to the randomness of the stochastic method to choose the best alternative. However, an additional objective would be necessary, either for security, occupational health or controllability for the results to show homogeneity.

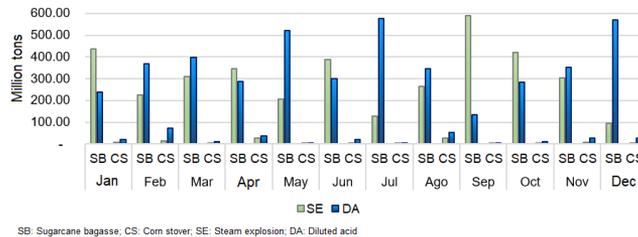

Figure 2. Annual feedstock planning

5.2. Optimization of ethanol process

The maximum ethanol production was achieved at 79 894 kg/h (679 100 ton/year) with a purity greater than 99.5% by weight, at a minimum TAC of 0.656 USD/kg ethanol and a minimum EI99 of 0.414 ecopoints/kg ethanol (Figure 3). In this case, more ethanol production is expected to demand larger equipment and more energy and feedstock, which becomes an increase in the total annual cost and in the ecoindicator.

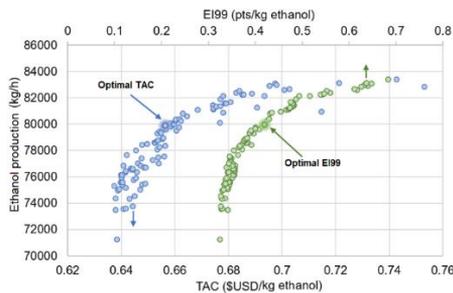

Figure 3. Pareto front for biomass - ethanol process (no separation sequence).

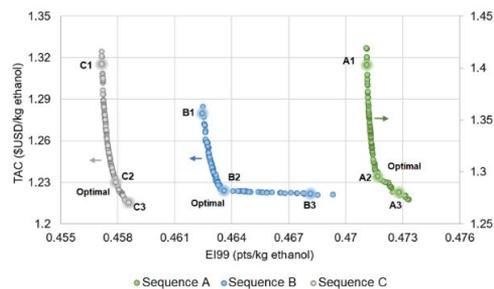

Figure 4. Pareto front for biomass - ethanol process (with separation sequence).

Figure 4 shows the Pareto front for optimal ethanol production with the separation sequence, according to Figure 3. For the three sequences, the high EI99 values result from the increasing steam required in the reboilers, while the high TAC values are related to large equipments and amounts of solvent. The point where these objective functions reach their minimum is discussed. It can be also observed that for the conventional sequence (A) a minimum TAC and EI99 of 1.295 USD/kg ethanol and 0.4716 ecopoints/kg ethanol were achieved, respectively. Taking the conventional extractive distillation as reference, the column sequence with vapor side stream (B) achieved reductions of 5.56% in the TAC and 1.72% in the ecoindicator while the dividing wall column sequence (C) achieved savings of 5.02% in the TAC and a decrease of 2.92% in the ecoindicator. It was also observed that the sequence B used less solvent than the sequence C. The amount of solvent contributed with about 75% to the TAC of the separation sequences.

5.3. Optimization of biojet process

Figure 5 shows the Pareto front ethanol-to-biojet process optimization. The high EI99 values are attributed to the greater environmental impact inherent of hydrocarbons in the process. Finally, the optimal design is capable of producing 224 206 ton/year (266 912 m³/year) of biojet fuel, which meets a 5.72% demand for conventional jet fuel in Mexico.

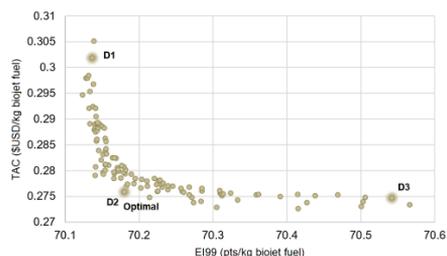

Figure 5. Pareto front for ethanol – biojet fuel process.

To have an idea of how profitable the design is, the minimum selling price of biojet was calculated. Thus, at the optimal point it was equal to 1.653 USD/liter, while the sale price of conventional jet fuel in Mexico in 2020 was 0.414 USD/liter, which indicates that the entire process is still not profitable.

6. Conclusions

The sugarcane bagasse was the most promising feedstock due to its low price and high sugar content. Also, to separate the produced ethanol the intensified scheme of vapor side stream provided the major savings and ecoindicator reductions respect to the conventional sequence, which was attributed to the minor use of solvent. However, despite the efforts for reducing total annual cost, the biojet fuel is not capable of competing with conventional jet fuel in Mexico. To achieve this, the intensification of reaction zone in biomass-to-ethanol process, the cofermentation of glucose and xylose, and the intensification of ethanol-biojet process is suggested. Besides, with the intensification of the second process, a reduction in ecoindicator values would be achieved.

Abstract

In a growing energy consumption world, energy efficiency has become mandatory. In this context, the design of heat exchanger networks (HEN) is of crucial importance, but most of the approaches to HEN design consider only shell and tube (S&T) heat exchangers with a perfect countercurrent heat transfer. However, the 1-2 heat exchanger, (one shell pass, and two tubes pass), is likely the most common in the chemical industry. In this work, we present a two steps sequential algorithm that allows the design of HEN to capture the main details of the heat exchangers (number of tubes pass, number of shells, logarithmic mean correction factors) that influence the cost estimation. The first stage is based on an extended transportation model. It uses the concept of temperature intervals and considers the possibility of heat transfer between the hot and cold streams inside those intervals. Then, it is possible the a priori calculation of the logarithmic mean temperature difference between matches, the efficiency factor, and the number of shells in series, maintaining the area linear in the model. The second step uses a superstructure with all the possible alternatives in which the heat exchangers predicted by the first stage model can exchange heat to design the final heat exchanger network.

Keywords: HEN, Energy Integration, Shell and Tube heat exchangers.

1. Introduction

Due to the importance of the efficient use of energy and its economic and environmental implications heat integration has consolidated as a topic of great interest in process engineering. However, the optimal design of a HEN is a very difficult problem for at least two reasons: the models are highly non-linear and non-convex, and the number of possible matches grows exponentially with the number of process streams. Obtaining a globally optimal solution is very difficult with the actual computational capacity. Furman and Sahinidis, (2001) showed that this is an NP-hard problem in the worst sense. Of remarkable importance was the appearance of pinch analysis (Flower and Linnhoff, 1980). Pinch analysis uses the first and second principles of thermodynamics to determine the minimum energy consumption without the necessity of specifying any HEN. Energy-related targets were extended with area heat transfer estimations that could lead to an a priori annualized cost estimation of the network with a 5-10% accuracy (Linnhoff and Ahmad, 1990). Finally, heuristics rules were developed to synthesize a feasible network with the minimum utility consumption and try to approach the minimum number of heat exchangers.

The increase in computer processing capacity motivated the development of automated strategies for HEN design. Particularly, mathematical programming models were a success in getting better solutions than heuristic approaches, at least for small to medium size problems. Initially, optimization methods followed the steps of pinch analysis: Minimum energy consumption, determination of the minimum number of matches, and final HEN design (Biegler et al., 1997)

A drawback of the sequential approaches is that decisions in a given stage cannot be modified in the following ones. To overcome that drawback, simultaneous approaches were proposed, in which the energy and the structure of the HEN are done in a single model. The more successful simultaneous model was developed by (Yee and Grossmann, 1990). The model known as SYNHEAT is a stage-wise approach that sacrifices some alternatives to maintain the model robust. Since its appearance a good number of improvements have been proposed, for example, to include isothermal streams, multiple utilities (Ponce-Ortega et al., 2009), non-isothermal mixing (Huang et al., 2012), algorithms for reaching the global optimum (Chang et al., 2020) or a large number of works using metaheuristic (Pavão et al., 2018). Despite its success, the major limitation of SYNHEAT is that the superstructure does not contain some heat exchanger arrangements that could eventually form part of the optimal solution.

Implicitly in most of the works on HEN, it is the assumption that all heat exchangers are shell and tube (S&T) heat exchangers with perfect countercurrent flow. While S&T are ubiquitous in the chemical process industry, most of them include multiple tube passes and eventually more than a single shell placed in series. The inclusion of detailed heat transfer parameters, pressure drops, and mechanical aspects like shell and tube bundle diameters, internal and external tube diameters, number of tubes, number of baffles, number of shells in series, tube arrangement, fluid locations, etc. are commonly not included, but they can have an important impact of the HEN performance and total cost. Some models that simultaneously design the HEN and the equipment details are, for example, (Ravagnani and Caballero, 2007) or the excellent work by Kazi et al., (2021) In this work, we present a two-stage sequential model inspired by the works by Nemet et al., (2018) and Caballero et al., (2021) that tries to capture the most important parameters of each heat exchanger into a HEN without performing a rigorous design of all the mechanical details to get a cost-optimal HEN. The first stage relies on the concept of temperature intervals and takes the form of an extended transportation model. With this approach is possible to calculate a priori the logarithmic mean temperature difference, its correction factor (F_t), and the number of shells in series for any combination of heat exchange between a set of intervals for a hot stream and another set of intervals for a cold stream. So, the area estimation is maintained linear in the model. In the second stage, we solve an NLP in which we postulate all the possible ways in which the matches predicted by the first model can exchange heat.

2. Methodology

The problem we are dealing with can be stated as follows: given is a set of hot and cold process streams for which the inlet and outlet temperatures, heat flows, and individual heat transfer coefficients are known and assumed constant. Given is also a set of hot and cold utilities for which the inlet and outlet temperatures; individual heat transfer coefficients; and unitary costs are also known. The objective is to design a practical heat exchanger network formed by 1-2 S&T heat exchangers with minimum total cost.

The model consists of two sequential stages. In the first one, we determine the streams that are exchanging heat, including utilities, as well as a good estimation of inlet and

outlet temperatures, heat exchanged, number of shells in series, logarithmic mean temperature, and its correction factor for each heat exchanger. In the second stage, using as starting values the results from the first one, we determine the structure of the HEN.

2.1. Stage 1: Extended transportation model overview.

A comprehensive description of the model cannot be included here due to space restrictions. Instead, the main characteristics of the model are presented in Figure 1.

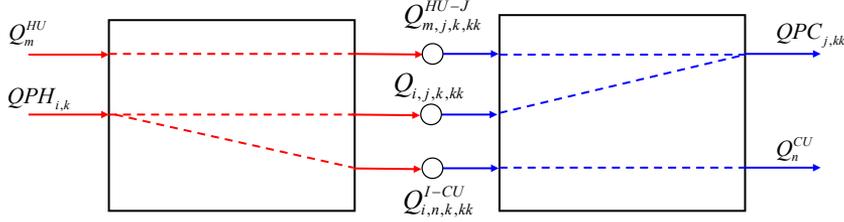

Figure 1. Representation of the transportation model. Different possibilities of heat transport between a hot stream i and a hot utility m with a cold stream j and a cold utility n between intervals k and kk .

Once the temperature intervals have been established, it is possible to calculate the amount of heat provided to each interval by all the hot process streams or demanded by the cold process streams. A hot stream can exchange ('transport') heat to any cold stream in intervals at lower temperatures ($k^{\text{hot}} \geq k^{\text{cold}}$). The transportation model is equivalent to performing energy balances in points 1, 2, 3, and 4 of Figure 1:

$$QPH_{i,k} = \sum_{\substack{kk \in INT \\ kk \geq k}} \sum_{j \in CK_{j,kk}} Q_{i,j,k,kk} + \sum_{\substack{kk \in INT \\ kk \geq k}} \sum_{n \in CUK_{n,kk}} Q_{i,n,k,kk}^{I-CU} \quad \forall (i,k) \in HK_{i,k} \quad (1)$$

$$QPC_{j,kk} = \sum_{\substack{k \in INT \\ kk \geq k}} \sum_{i \in HK_{i,k}} Q_{i,j,k,kk} + \sum_{\substack{k \in INT \\ kk \geq k}} \sum_{m \in HUK_{m,k}} Q_{m,j,k,kk}^{HU-J} \quad \forall (j,kk) \in CK_{j,kk} \quad (2)$$

$$Q_m^{HU} = \sum_{k \in HUK_{m,k}} \sum_{(j,kk) \in CK_{j,kk}} Q_{m,j,k,kk}^{HU-J} \quad \forall m \in HU \quad (3)$$

$$Q_n^{CU} = \sum_{kk \in CUK_{n,kk}} \sum_{\substack{(i,k) \in HK_{i,k} \\ kk \geq k}} Q_{i,n,k,kk}^{I-CU} \quad \forall n \in CU \quad (4)$$

The minimum energy cost can be calculated by minimizing the cost of utilities in previous equations. If we assume pure countercurrent heat exchangers, the calculation of the area is straightforward, because it can be calculated as the summation of the areas of heat exchanged by two streams in the different temperature intervals (Caballero et al., 2021; Nemet et al., 2018). However, the efficiency factor F_t and the Number of shells in series for a 1-2 S&T heat exchanger, depend on the inlet and outlet temperatures of the hot and cold streams. To deal with this problem we introduce a variable W_{i,j,k_1,k_2,k_3,k_4} that takes the value of 1 if the hot stream i exchanges heat starting in interval k_1 and finishing in interval k_2 with cold stream j in the intervals k_3 to k_4 . And zero otherwise. Dealing with a six-index binary variable makes the problems intractable except for small instances. Fortunately, it is not necessary to define the variable W as binary because it can be forced to take integer values using the binary variables $YH_{i,j,k}$ and $YC_{i,j,k}$. that take value 1 if hot

stream i /(cold stream j) is exchanging heat with cold stream j /(hot stream i) in interval k , using a set of logical relationships.

As we know the inlet and outlet temperatures of each one of the temperature intervals we can calculate a priori the logarithmic mean temperature ($LMTD_{k1,k2,k3,k4}^P$), its efficiency factor ($Ft_{k1,k2,k3,k4}^P$), and the number of shells in series ($NShells_{k1,k2,k3,k4}$) for each combination of feasible inlet and outlet temperature intervals, and each hot and cold stream. Now, the determination of those values for each heat exchange can be written as:

$$LMTD_{i,j} = \sum_{k1} \sum_{k2} \sum_{k3} \sum_{k4} LMTD_{k1,k2,k3,k4}^P W_{i,j,k1,k2,k3,k4} \tag{5}$$

$$Ft_{i,j} = \sum_{k1} \sum_{k2} \sum_{k3} \sum_{k4} Ft_{k1,k2,k3,k4}^P W_{i,j,k1,k2,k3,k4} \tag{6}$$

$$NShells_{i,j} = \sum_{k1} \sum_{k2} \sum_{k3} \sum_{k4} NShells_{k1,k2,k3,k4}^P W_{i,j,k1,k2,k3,k4} \tag{7}$$

Then the area of a given heat exchanger can be calculated as:

$$Area_{i,j} = \frac{1}{U_{i,j} LMTD_{i,j} Ft_{i,j}} \sum_{k \in INT} \sum_{kk \in INT} Q_{i,j,k,kk} \tag{8}$$

The cost of a heat exchanger is calculated using the following expression.

$$Cost_{i,j}^{HE} = NShells_{i,j} Cf_{i,j} + NShells_{i,j} Cv_{i,j} \left(\frac{Area_{i,j}}{NShells_{i,j}} \right)^\beta \tag{9}$$

To maintain the model linear the cost equation is substituted by a linear piecewise approximation.

2.2. Stage 2. Superstructure optimization.

The first stage calculates the matches between streams, but it does not provide information on the arrangement of streams (i.e. series, parallel, or any combination of them). See Figure 2. The resulting MINLP model is highly non-linear and non-convex, however, the initial values obtained from the first stage help to get an initial feasible solution from which to start the optimization. We cannot guarantee a globally optimal solution, but numerical tests have shown that usually high-quality solutions are obtained.

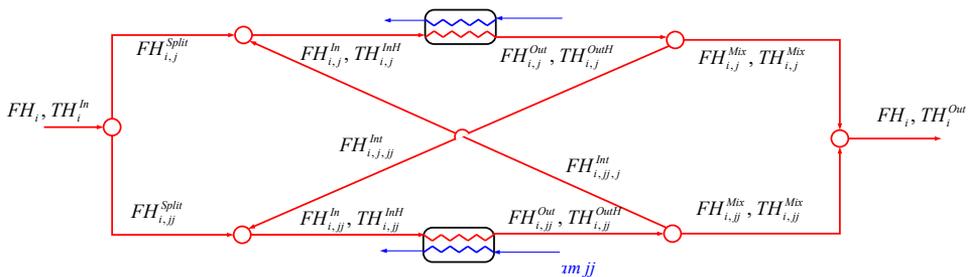

Figure 2. Scheme of the superstructure in which a hot stream i can exchange heat with two cold streams j and jj . The superstructure can be extended to cold streams and any number of heat exchanges.

3. Example

To illustrate the model, we present the results of a well-known benchmark problem modified to deal with 1-2 S&T heat exchangers. The problem was proposed by Linnhoff and Ahmad, (1990) and is one of the most used benchmark problems in the HEN synthesis literature. Being a medium-scale problem, it has five cold and four hot streams, a hot oil as hot utility and water as a cold utility. All relevant data are presented in Table 1.

Table 1. Data for the example.

Stream id.	Inlet T (°C)	Outlet T (°C)	CP (kW/°C)	h (kW/m ² K)	Cost (\$/kW _Y)
H1	327	40	100	0.5	
H2	220	160	160	0.4	
H3	220	60	60	0.14	
H4	160	45	400	0.3	
C1	100	300	100	0.35	
C2	35	164	70	0.7	
C3	85	138	350	0.5	
C4	60	170	60	0.14	
C5	140	300	200	0.6	
HU1	330	250	-	0.5	60
CU1	15	30	-	0.5	6

HE cost = NShells [Cf + Cv(Area/NShells) ^β]	Cf	Cv	β
	2000	70	1.0

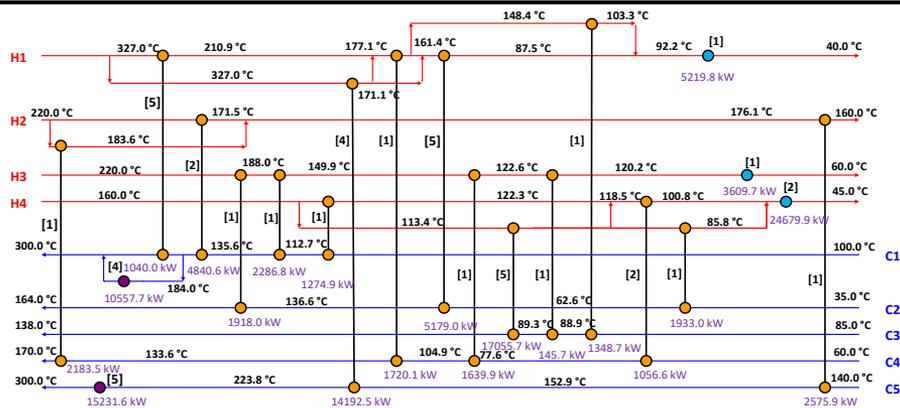

Figure 3. Heat exchanger network obtained. Square brackets indicate the number of Shells.

The models were implemented in GAMS (GAMS Development Corporation, 2021) using CPLEX as MILP solver and BARON as MINLP solver on a PC machine working under windows (i7 2.90 GHz, 32.0 GB). The MILP problem was solved to global optimality within a 5% optimality gap. In the case of MINLP problems BARON is not able to close the optimality gap, however, it can find very good solutions in the first minutes of execution. We stopped the BARON execution after 3600 seconds of CPU time. The

optimal solution has a total annualized cost of 3085 k\$/year. 1547.4 k\$/year in hot utilities; 201.1 k\$/year in cold utilities and 1336 k\$/year in an annualized cost of capital expenditures. Figure 3 shows the final configuration of the HEN and the main results obtained after the optimization.

Conclusions

In this work, we have presented a model that explicitly includes the most relevant parameters to accurately estimate the cost of a HEN that includes 1-2 S&T heat exchangers. We use a two-stage algorithm, in the first stage, using the concept of temperature intervals, it is possible the a priori calculation of the logarithmic mean temperature difference between matches, the efficiency factor, and the number of shells in series. The second step uses a superstructure with all the possible alternatives in which the heat exchangers predicted by the first stage model can exchange heat to design the final heat exchanger network.

Abstract

The growing contribution of aviation industry to climate change has led to the search of new energy sources in the short to medium term. Biofuels appear to be a potential alternative to the fossil fuels, also they are a promising solution to mitigate climate change. Nowadays, the agricultural residues (AR) are one of the most promising feedstocks to produce biofuels due to their high availability. However, their use at industrial scale requires overcoming some challenges such as their seasonal availability and their dispersed geographic distribution. In order to face these challenges, in this work has been proposed a multi-period supply chain (SC) to produce bio-jet fuel in Mexico through the alcohol to jet (ATJ) process using corn stover and sugarcane bagasse as raw materials. The supply chain considered implementing a centralized or decentralized configuration as a result of an optimization based on sustainability criteria, such as economic, environmental and social aspects, which are net profit, eco-indicator 99 (EI99) and jobs generation, respectively. The results show that it is possible to cover 5.5% of jet fuel consumption in Mexico, also an economic incentive of \$115 million is required for the process to operate at break-even with an environmental impact of 7.48 billion ecopoints per year and 5,594 jobs generated.

Key words: Supply chain, Bio-jet fuel, Agricultural residues, Biorefinery.

1. Introduction

Air transport is a cornerstone in current globalization, it supports about 4 billion passengers yearly, around 61 Mt of freight, which represents US\$3.5 trillion in world economic activity, before the SARS-CoV-2. In the specific case of Mexico, the aviation industry represents 3.5% of country's GDP, also in 2018 the air transport mobilized around 98 million passengers generating 1.4 million jobs. The International Air Transport Association (IATA) estimates that the air transport will double in the next 20 years, representing a considerable environmental impact, as global jet fuel consumption generates around 2-3% of carbon dioxide (CO₂) emissions due to human activity. As a result, IATA has proposed to reduce CO₂ emissions from air transport up to 50% by 2050, using 2005 as a baseline (Domínguez-García et al., 2017). In this sense, Bio-jet fuel represents a promising alternative to conventional jet fuel since its properties are very similar to those of the latter, which would allow taking advantage of the existing storage

and distribution infrastructure, also they are even currently used in aircraft up to 50% mixed with conventional jet fuel according to the norm ASTM D7566-11.

The ATJ process appears to be a promising route to produce bio-jet fuel as the technologies involved are widely known in the fuel and chemical industry, this process transforms alcohol into jet fuel through several steps such as dehydration, oligomerization, and hydrogenation (Wang and Tao et al., 2016). Moreover, bioethanol is currently the most produced biofuel worldwide and cellulosic biomass, such as AR have gained great attention as a promising raw material in biofuel production due to its wide availability, do not compete with food needs and are low cost. Typically, one part of AR are used as fodder for livestock or to protect the soil from erosion while the other is burned, generating even more CO₂ emissions than air transport. However, the high cost of transporting and storing biomass due to its heterogeneous geographic and temporal distribution, as well as its low energy density and high moisture content have greatly limited the incursion of biomass in large-scale biofuel production.

Therefore, to overcome the inherent problems of using biomass, in this work was proposed a SC to cover between 5.5-50% of jet fuel consumption in Mexico using the most common lignocellulosic residues of the country. The SC considers the production of bio-jet fuel from the ATJ process considering the production of ethanol from corn stover and sugarcane bagasse available in the Mexican field. As well as sustainability criteria such as the economic, environmental, and social aspects via the maximization of net profit, the minimization of EI99 and the evaluation of job generated by the SC, respectively.

2. Methodology

Considering that in Mexico around 586 Mt of AR are generated per year, this work evaluated the potential of two of the most abundant residues to be used as raw materials to produce jet-fuel. These residues are corn and sugarcane bagasse. A centralized and a decentralized configuration were proposed for the design of the SC (see Figure 1). Firstly, the biomass is sent directly from the harvest sites to the biorefineries for processing, while in the second biomass is densified in pretreatment depots to reduce the transportation costs prior to final processing in a biorefinery.

To consider the seasonal availability of AR, a multi-period inventory planning with an one year of time horizon was considered, which was divided into twelve time periods ($t \in T$) one for each month of the year. On the other hand, the geographic distribution of AR was considered through the production of corn and sugarcane in the 32 states of the Mexican Republic, taking a yield for residues of 110% and 34% per ton for grain corn and sugarcane, respectively (Muro Reyes et al., 2013). The 32 states of Mexico were considered as regions, in which the AR are available, also it is considered that in the centroid of each region is located all the biomass of the region, at the same time in these regions lies the potential location for pretreatment depots and biorefineries at 10 and 20 km from the centroid, respectively.

The Rhumb line method was employed to compute the distances between centroids, pretreatment depots, biorefineries and markets, while the latitude and longitude required by the method were obtained from Google Maps.

The supply chain design is considering the bio-jet fuel production by the ATJ process, in which biomass is first converted into ethanol and then into jet fuel. This process can be divided into four main stages: the pretreatment stage using mineral acids stage, which release the sugar contained in the biomass, the second stage includes the sugars fermentation and ethanol purification, the third stage includes the ethanol dehydration to

ethylene and finally the last stage consists of the oligomerization and hydrogenation of ethylene into bio-jet fuel, gasoline and diesel. The date for ATJ process was taken from (Rivas) This supply chain considers that this four stages can exist in a single facility called biorefinery, but at the same time it considers that the pretreatment stages can be located in a different place called preterm facility. The aim of pretreatment facilities is to convert biomass from nearby harvesting centers to sugars which are more energy dense products to reduce the transportation costs. Therefore, a decentralized scheme could be a more efficient scheme than traditional biorefinery scheme. The bio-jet fuel, gasoline, diesel as well as the sales of ethanol as an oxygenate for gasoline haven been considered the main products. The current markets of these products are also considered the potential markets of this supply chain, owing to they have existing infrastructure for oil derived products. Figure 1 shows the superstructure considered for this supply chain.

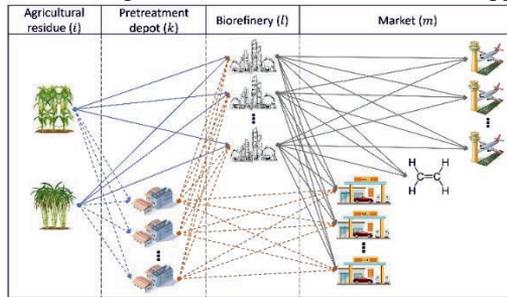

Figure 1. Supply chain superstructure

In this work the maximization of the net profit and minimization of eco Indicator 99 (EI99) have been considered as objective functions to evaluate the performance of the supply chain solutions. The net profit was chosen to determine the economic feasibility of the supply chain, whereas the EI99 evaluates the environmental impact of supply chain. Although there are other newer methodologies for assessing environmental impact, the EI99 is easy to implement and the data for this indicator are easy to obtain. A cradle-to-grave assessment with hierarchical perspective for EI99 was considered, this perspective offers an offset between the effects at short and long term effects. Additionally, other different parameter are presents and evaluated in order to have a broader and more sustainable perspective for the different supply chain solutions, this additional metrics are the CO₂ emissions and the jobs generated by the supply chain. The Jobs and Economic Development Impact (JEDI) method was used to calculate the jobs generated.

3. Mathematical model

The mathematical model for the supply chain consists of a multiperiod Mixed Integer Lineal Programming (MILP) model, which was implemented in the software Gams in order to solve it.

The model considers the biomass storage at the harvest sites, which was modeled by a mass balance as shown in the following equation:

$$A_{j,i,t}^{RM} = A_{j,i,t-1}^{RM} (1 - \gamma_{i,t}^{RM}) + C_{j,i,t}^{RM} - \sum_l BER_{j,i,l,t}^{RM} - \sum_k BEDP_{j,i,k,t}^{RM} \quad i \in I^{RM}, j, t \quad (1)$$

Where $A_{j,i,t}^{RM}$ and $A_{j,i,t-1}^{RM}$ represent the inventory level of biomass at a harvest site for a specific time and a previous period, respectively. $\gamma_{i,t}^{RM}$ represents the loss factor coefficient by AR degradation, while $BER_{j,i,l,t}^{RM}$ and $BEDP_{j,i,k,t}^{RM}$ are the shipment of AR i from the

harvest site j to the biorefinery l and to pretreatment depot k , respectively. Finally, $C_{j,i,t}^{RM}$ is the AR consumption at the harvest site, which is restricted as follows:

$$C_{j,i,t}^{RM} \leq \varphi_{j,i,t}^{RM} \quad i \in I^{RM}, j, t \quad (2)$$

Where $\varphi_{j,i,t}^{RM}$ is the availability of AR i in harvest site j in a period period t . The shipments of biomass to biorefineries are constrained as follows:

$$BER_{j,i,l,t}^{RM} \leq DBCC_{j,i,t}^{RM} \cdot y1_{j,i,l}^{RM} \quad i \in I^{RM}, j, l, t \quad (3)$$

Here $DBCC_{j,i,t}^{RM}$ is the sum of the AR stored level and the available AR at harvest site j at time t and $y1_{j,i,l}^{RM}$ is the binary variable to enable the shipment of AR across the arc $j \rightarrow l$. However, the product $DBCC_{j,i,t}^{RM} \cdot y1_{j,i,l}^{RM}$ represents a nonlinearity that was reformulated according to the following mathematical arrangement proposed by Floudas (1995):

$$BER_{j,i,l,t}^{RM} \leq h1_{j,i,l,t}^{RM} \quad i \in I^{RM}, j, l, t \quad (4)$$

$$DBCC_{j,i,t}^{RM} - \sum_t \varphi_{j,i,t}^{RM} (1 - y1_{j,i,l}^{RM}) \leq h1_{j,i,l,t}^{RM} \quad i \in I^{RM}, j, l, t \quad (5)$$

$$h1_{j,i,l,t}^{RM} \leq DBCC_{j,i,l,t}^{RM} \quad i \in I^{RM}, j, l, t \quad (6)$$

$$h1_{j,i,l,t}^{RM} \leq \sum_t \varphi_{j,i,t}^{RM} \cdot y1_{j,i,l}^{RM} \quad i \in I^{RM}, j, l, t \quad (7)$$

Where $h1_{j,i,l,t}^{RM}$ is the bilinear product to maintain the linearity of the model. The mass balance at biorefineries and pretreatment depots was carried out in a similar way. In order to guarantee a constant supply a cyclic inventory planning was considered, which consists of that the storage level in the last period ($t=T$) is equal at the beginning period ($t=0$), according to the following equation for AR:

$$A_{j,i,t=0}^{RM} = A_{j,i,t=T}^{RM} \quad i \in I^{RM}, j \quad (8)$$

Finally, the objective functions were formulated as follows

$$\max Z = \left(\overbrace{CAR + TC + PC}^{Netprofit} + \overbrace{EIAR + EIT + EIP}^{EJ99} \right)$$

Where CAR , TC , PC are the costs by biomass use, transportation cost and processing cost, respectively. On the order hand, $EIARE$, EIT and EIP represents the environmental impact by biomass uses, transportation and processing, respectively. This multi-objective optimization problem was solved using the ε -constrained method to find a tradeoff between the objectives.

4. Results

The model proposed consists of 27,264 binary variables, 672,013 continuous variables and 1,313,649 constraints. It was solved in an average time of 51,173s using a computer with a 3.00GHz i5-8500 processor with 4GB of RAM using CPLEX method with a relative gap of 1%. Figure 2 shows the Pareto front of SC optimization. In all cases, a 5.5% demand for aviation fuel is covered, as this represents the lowest environmental impact and the lowest level of subsidy required or the highest netprofit. Therefore, the difference between the upper and lower bound in the Pareto front corresponds to the AR transporting activities in each SC design. The upper region the SC design considered two biorefineries while in the lower region only one biorefinery is located, as shown in Figure 3.

Since Jalisco and Veracruz are the main producers of sugarcane, which is the most used biomass in the ATJ process, the biorefineries are installed near the harvest sites to reduce the transportation cost and the environmental impact. because the supply chain is not cost-effective a decentralized scheme is not selected for the model in order to reduce the transportation costs.

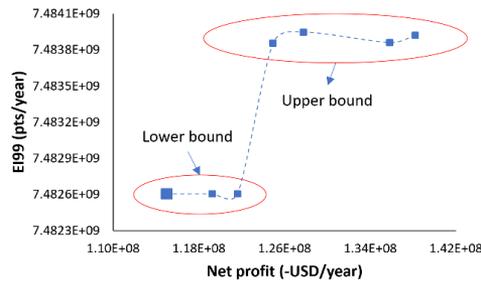

Figure 2. Pareto front for bio-jet fuel SC

It is important to mention, that for economically feasible supply chain, this decentralized scheme has proved reduce the cost and environmental impact of the process. Owing to the transportation activities increase in the upper region the environmental impact increase too, thus the benefit of the economy of scale is reduced because these two have a lower processing capacity than the biorefinery in the lower bound, which explains the behavior of the Pareto front. Moreover, the centralized configuration was preferred in the resulting SC designs because AR pretreatment and ethanol production, operations considered in the pretreatment depots, are the main drawbacks in the ATJ process, these steps represent 59% of the entire SC cost (see Figure 4a).

Figure 3. (Left) SC design lower bound (Right) SC design in upper bound.

The big dot in the lower region corresponds to the best SC solution. This solution considers a centralized configuration where only one biorefinery is installed. This solution has 5,594 jobs generated and the EI99 is around 7.48 billion points per year. Additionally, it requires a subsidy of US\$115 million to be profitable. On the other hand, the CO₂ emissions per kilogram of product commercialized as well as the energy return on investment (EROI) are 2.38 kgCO₂/kg and 1.14, respectively.
