The maps are concatenated in channel dimension and served as input to the following total DOS featurizer, which finally aggregates the integrated feature maps to form comprehensive feature maps covering all the spin and orbital states. The final feature maps generated through all the CNN-based featurizers described above are flattened and concatenated with component information followed by the embedding layer. Finally, it is taken as the input of fully connected neural network (FCNN) to predict formation energy. The key aspects of our model are optimal operation for aggregation of partially projected DOS and chemically inspired architecture considering DOS based on its spin state. This enables the model to maximize the number of high-quality features for formation energy prediction.

The model trained on DFT-calculated DOS from Materials Project (MP) database (JainAnubhav 2013), which includes 66,411 materials and their DOS data in total. Note that the training data consisted of only *s*, *p*, and *d*-block elements, but it is possible to include *f*-block elements in training/test data by integrating extra channels in the model. We generated input representations, which consist of up and down spin states of 9 orbitals from *s* to *d*. Each one comprises an individual input channel (total 18 channels), where StandardScaler of scikit-learn package was applied to remove the mean and to scale to unit variance. After preprocessing 18 channels, we added one extra channel representing a composition of materials, where one-hot encoding of all the elements in our dataset, 110, was used. Tensorflow 2.4.1 and Keras 2.4.0 are used as the backend for the model implementation. The model was trained for 300 epochs with an early stopping algorithm on an NVIDIA GPU with memory and CUDA 11.0. Additionally, we highlight that our model could be universally used for formation energy prediction tasks as it was trained with data consisting of diverse compositions of elements across more than 80.

## 2.2. Prediction Performance

**Table 1.** Prediction performance with 2e-ORR test set for different algorithms.

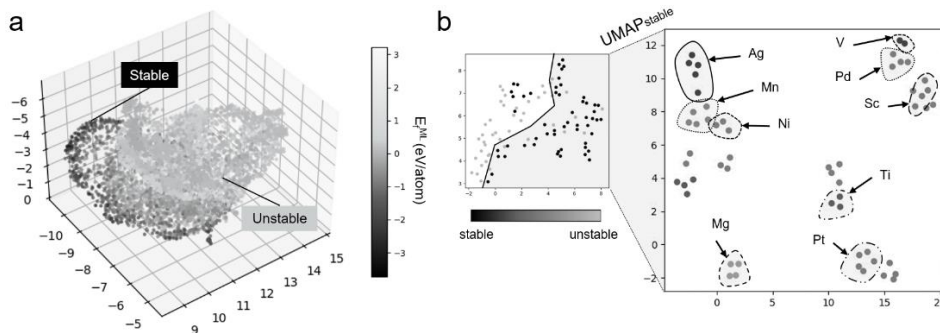

Model	DOS signal-based		DOS feature-based*				
	Proposed	CNN	KRR	SVR	RF	XGBoost	DNN
MAE	<b>0.236</b>	0.273	0.271	0.280	0.356	0.307	0.274
RMSE	<b>0.372</b>	0.397	0.435	0.446	0.562	0.498	0.420

\**d*-band center, Width, Skewness, Kurtosis, Number of fillings, Compositions

We then evaluated the prediction performance of our model and compare it with other ML models based on different input features and algorithms. All models were tested on the same dataset of electrochemical two-electron O<sub>2</sub> reduction reaction (2e-ORR) which contains DOS of 7165 binary alloys, and the overall performances are listed in Table 1. The DOS feature-based models (i.e. kernel ridge regressor (KRR) (SchlkopfBernhard 2018), support vector regressor (SVR) (AwadMarianne 2015), random forest (RF) (BreimanLeo 2001), XGBoost (ChenTianqi 2016), deep neural network (DNN) with two fully connected layers (CourvilleJan 2016)), where 0–4th moment properties of 18 orbitals were used as inputs, underperform compared to the DOS signal-based models (i.e. proposed, CNN (SunDechun 2019)). This result reiterates that only a few existing features are insufficient to properly explain solid materials in the whole dataset. As such, since the excessive simplicity and low flexibility in fitting, these models are difficult to predict as accurately as models that turn all the information on DOS to account. Furthermore, the proposed model here outperforms conventional CNN, highlighting the effectiveness of chemically inspired architecture and CBAM managing input DOS effectively. As a result, our model achieved the highest performance in formation energy prediction with 0.237 eV/atoms of MAE, demonstrating its superior featurization ability.

## 2.3. XAI Interpretation

To unpack the black-box model and confirm the physical interaction between DOS and the formation energy, SHAP analysis was implemented. SHAP is a XAI technique introducing a game theoretic approach to explain the output of the ML model. It decomposes the predicted value into an additive sum of contributions of individual features on input. Due to its guaranteed mathematical background, SHAP values are one of the most-used approaches to understanding ML models. Prior to further analysis, we projected SHAP values obtained from 2e-ORR data into a three-dimensional space using uniform manifold approximation and projection (UMAP) (McInnesLeland 2018) to

**Figure 2.** Visualization of SHAP value distribution for different datasets, generated by UMAP. a) Three-dimensional UMAP for 2eORR dataset. Darker colors indicate low  $E_f^{ML}$ . (b) Two-dimensional UMAP for the single-specie dataset. (left) According to the  $E_f^{ML}$ , less than 0.01 is categorized as stable and others as unstable. (right) Two-dimensional UMAP plotted again with only the data belonging to the stable region.

visualize whether the learned features show a tendency depending on material stability (Figure 2a). The unsupervised analysis displays the continuous change in feature importance on DOS in accordance with the formation energy. Particularly, the darker area, where the data with low formation energy is located close, demonstrates that stable materials share common features on DOS.

Inspired by this result, it is analyzed more specifically what common characteristics appear in SHAP values for materials that are predicted as stable. For ease of analysis, we preliminarily obtained DOS and their SHAP values from various crystal structures, i.e. simple cubic (SC), body-centered cubic (BCC), face-centered cubic (FCC), hexagonal close-packed (HCP), and rhombohedral crystal structure (RHO), for materials consisting of only a single specie, and projected the SHAP values into low dimension. Similar context to the previous result, it is confirmed that the materials predicted as stable and the materials predicted as unstable are distributed in separate regions on UMAP (Figure 2b left). Then, UMAP was performed again targeting only the data that belong to the darker area where 'stable' data are largely located (Figure 2b right). Surprisingly, the data are clustered by the specie, showing that data within the same element share similar features even if having different crystal structures. The similarities are not observed in the data with unstable crystal structures. These results demonstrate the possibility of XAI interpretation that deduces the common properties of stable materials and further uncovers the causal relationship between the electronic structure and the formation energy.

### 3. Conclusion and Future Works

Here we have developed a machine learning model which successfully predicts the formation energy from DOS with superior featurization ability. More importantly, we presented the potentiality of direct XAI interpretation of the DOS signal itself without any prior involvement of human experts in feature restriction. The result shown here is simply that features on DOS have commonality according to their formation energy. Thus, this observation will be developed in future works to reveal the 'which' factor of DOS is decisive in formation energy prediction, and finally, it will shed light on the causal relationship between the electronic structure of materials and the crystal's thermodynamic stability. Ultimately, it will contribute beyond the stability screening by the black-box model to knowledge and hypothesis generation in the field. (Esterhuizen J.A., 2022)

## Abstract

Rainwater Harvesting (RWH) systems can serve a dual functionality as a flood mitigation structure as well as providing local water availability. Optimisation-based design strategies must be transferrable enough to incorporate the influence of the local climate and case-specific catchment area characteristics into the design process, which can be a significant endeavour when required for every individual implementation. To increase the accessibility of optimisation methods in the appropriate sizing of RWH systems, this paper presents a modularised optimisation model, where tank components and dynamics are contained as individual blocks. These blocks can then be pieced together to produce a full system model, allowing optimisation models to be easily built for any combination and design of RWH system. This is implemented with a multi-tank RWH system, where an evaluation of the optimised system configuration showed a good balance between the dual objectives of providing improved flood mitigation and local water reuse, in comparison to an existing system derived through alternative sizing strategies.

**Keywords:** Multi-scale integration, Rainwater harvesting, Stochastic optimization

## 1. Introduction

Large-scale rainwater harvesting (RWH) systems have demonstrated potential as a strategy for simultaneously reducing flood risks by temporarily holding excess water, and minimising water stress by satisfying non-potable water demands with locally harvested water. As the performance of these systems has been demonstrated to be very sensitive to the local climate and catchment area (Semaan, 2020), appropriately sizing these structures has remained a key barrier to further implementations of RWH systems.

Optimisation models have been found to be effective and successful in deriving suitably sized RWH systems (Okoye, 2015; Nnaji, 2017), but with the range of possible system configurations, optimisation-based strategies are not the most scalable of sizing methods since the creation of optimisation models for each individual implementation of a RWH system can require significant time, effort, and expertise. Hence, it is common to find that design guidelines published by public water managers utilise simplified functions, for example of the expected average demand and catchment area to calculate an appropriate tank size. These are normally found to prioritise the flood mitigation objectives, especially in highly developed urban centres as these are likely to have a stable freshwater supply network to satisfy any local water demands. However, this would result in overly sized systems which can reduce the return on investment for the RWH system and incur further costs in the form of utilising the limited space resources available within a city (Matos, 2013).

Hence, to improve the accessibility of and encourage more widespread use of optimisation-model-based strategies for sizing urban RWH systems, this paper proposes

a modularised optimisation model tool. This provides basic optimisation model blocks for a single tank, with a range of possible tank draining configurations which can be further customised through functional constraint blocks. This declarative format would allow individuals with expertise outside of implementing optimisation methods to utilise them as an effective system sizing strategy.

## 2. Methods

The modularised optimisation model is presented in the following sections and applied to a multi-tank RWH system. The tool is used to derive an optimal system size for a multi-tank RWH system, and the output system configuration is evaluated for its ability to achieve the dual objectives of flood mitigation and local water reuse. The computational requirements are measured as a function of the model solution time, as this could be a key factor for increased uptakes of optimisation-model based strategies.

### 2.1. Modular optimization model structure

The proposed modularised optimisation framework consists of function blocks which correspond to the dynamics of a given tank component and build up to a fully stochastic Mixed Integer Linear Program (MILP) model that looks to select an optimal tank height, area, and any applicable orifice heights for the range of rainfall scenarios given to the model.

The component function blocks correspond not only to typical tank dynamics such as the mass balance and flow equations, but also provide design specifications and behaviours including:

- Penalty functions for exceeding threshold overflows or wasted capacities
- Common optimisation objectives including system size reduction, and overflow minimisations.
- Freshwater use for satisfying unmet demand

To provide a turnkey functionality to this framework, further tank configuration blocks were defined which correspond specifically to the different possible combinations of ways a given tank may be drained. These blocks can be initialised immediately and solved when supplied with a desired input parameter set but can also be further supplemented with component function blocks to implement further tank behaviours and or penalty functions for multi-objective systems. A basic implementation workflow for a single tank would hence involve:

- (1) Create a base optimisation model through a tank configuration block
- (2) Add any additional system dynamics and constraints
- (3) Define an objective function, including any penalties
- (4) Populate the model with rainfall, demand, and design parameter options
- (5) Solve the derived model.

Under this framework, multi-tank systems can be implemented and optimised sequentially through a series of much smaller MILPs, which typically would be much more tractable than a single, large optimisation problem.

### 2.2. Case study configuration

The framework was applied to a multi-tank RWH system aimed at simultaneously reducing local flooding risks and providing non-potable water to its service area. This is formed of four specialized tanks, as illustrated in Figure 1. The 'separation' tank serves as an initial receiver for all inflow and acts as a filter that directs flow between the 'harvesting' and 'detention' tanks. These tanks both store water, but separately for the

Figure 1: Multi-tank RWH system configuration and flow interactions

purposes of local reuse and temporarily holding excess to prevent downstream inundation respectively. Finally, a ‘treatment’ tank is used to hold treated, ready-to-use water. Under the modularised framework, each individual tank is optimised individually with non-linear flow divisions within the system managed using an external flow division function. The flow of information between the individual tank optimisation models, as well as their corresponding model outputs, are highlighted in Figure 2. The input data comes from a historical timeseries, which has been segregated into 24-hour rolling window samples. Scenarios are then selected randomly from the set of samples, with the set diversity ensured using a minimum threshold value for a variance measure, defined as the sum of the variance of the rainfall values in each timestep across the entire simulation horizon. When the minimum threshold is not reached, the set is reselected.

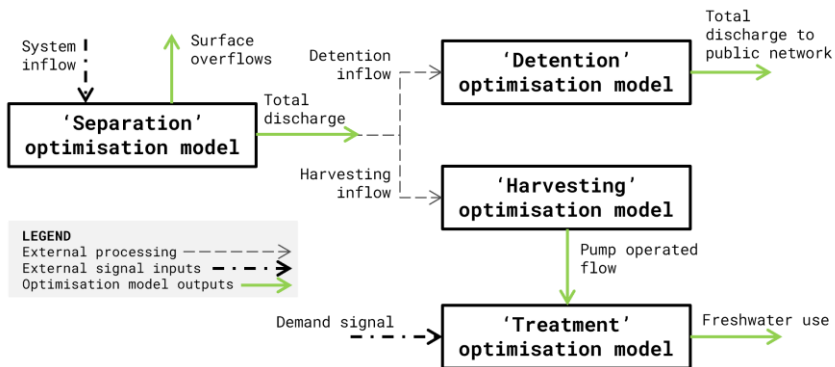

Figure 2: Information flow and interactions between optimisation models in a multi-tank RWH system

Table 1: Implemented objective and penalty functions for each tank optimisation model.

Tank	Objective	Penalty function
Separation	Minimise overflows	Wasted capacity
Detention	Minimise tank capacity	Overflow threshold
Harvesting	Maximise outflow to treatment tank	Overflow threshold
Treatment	Minimise freshwater top-up volumes	Overflow threshold

### 3. Results

The performance of a modularised optimisation model is dependent on the following model parameters:

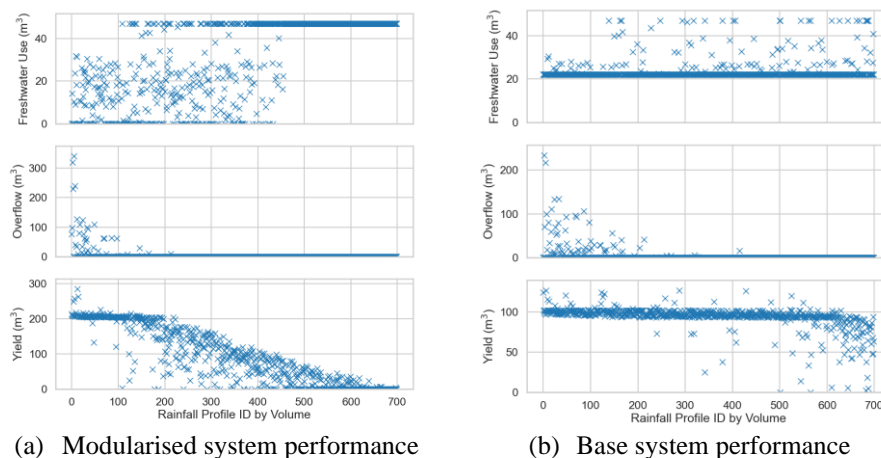

- *System configuration parameters*: The set of possible tank areas, tank heights and orifice heights.
- *Solution time*: The total allowable time for the model to find a solution.
- *Allowable capacity*: The maximum volume of space the derived tank can occupy.
- *Penalty costs*: The penalty values that influence the objective function value, if applicable in the specific model.
- *Stochasticity*: The number of rainfall scenarios used.

The sets of possible parameter values provided for the optimization models are selected as a large possible design space for a system that is to serve a 1.57 ha residential estate. Lower vertical space allowances are used as the underground make-up of a city is typically carefully subdivided between multiple utilities and different layers are hence reserved for distinct, specific purposes. The objective and penalty functions for each of the four tank systems are shown in Table 1, where the overflow threshold penalty assigns a cost to the overflow volume in exceedance of the threshold volume defined for a given timestep, and the wasted capacity penalty function implements a three-tiered cost for any wasted tank volumes above 10% of the total tank capacity.

For effective adoption of a novel sizing strategy, the proposed method needs to be sufficiently easy to implement, whilst providing system configurations that provide adequate levels of flood mitigation and yield collection. Hence, the following subsections discuss the impact of stochasticity on the required solution time and derived solution quality for the modularised optimisation framework.

#### 3.1. Stochasticity and solution time

The model's behaviour as the set of rainfall scenarios increases is characterised by the computational time required to derive an optimal solution. The set of rainfall scenarios is selected separately for each set size to ensure that each set meets the minimum threshold variance value. This was applied to each of the optimisation models in the multi-tank RWH system individually, such that the behaviour of each tank configuration model block can be characterised.

(a) Modularised system performance (b) Base system performance  
**Figure 3:** Scatterplot of key performance indicator values, in order of decreasing input rainfall volume.

The number of scenarios and size of the derived optimisation model have minimal impact on the computational requirement of the individual tank optimisations. On the other hand, the ‘Separation’ tank, which has the highest number of openings and hence constraints and variables, is significantly more computationally intensive than the other tank design types and requires eight-times the amount of computational time to derive an optimal solution.

3.2. Performance of the derived configuration

The output optimal configuration for the full system remained the same despite increasing the number of scenarios used with the modular optimisation model. This optimised output is shown, in comparison to an existing configuration in Table 2. The total time required to derive a full configuration with 25 rainfall scenarios selected with a minimum variance value of 50 was 1.5 hours when implemented on an Intel Core i7-8650U with 16.0 GB ram.

The performance of the derived configuration is determined for its ability to reduce surface overflow risks and provide local water availability using a simulation model. A statistical measure of the key performance indicators is generated by running simulations for 700 days of the highest rainfall volumes extracted from an eight-year historical timeseries, and the KPI values, sorted by descending input rainfall volumes are demonstrated in Figure 3.

Statistical performance metrics are then extracted from these figures to provide quantitative indicators of the system performance. Freshwater use indicates the amount of freshwater required to ensure that local non-potable water demands are fully met. The scatterplots above demonstrate that the existing configuration is limited in its ability to provide water for irrigation purposes in a timely manner and hence has a minimum freshwater requirement for all simulated scenarios. On the other hand, the optimised system is observed to be able to provide for all the required water demand for 16.3% of the simulated scenarios and only fails to provide sufficient water for reuse when the inflow volumes fall below a total of 230 m<sup>3</sup>.

**Table 2:** System configurations for an existing RWH system, and an optimised configuration for the same catchment area.

Tank	Existing configuration		Optimised configuration	
	Height (m)	Area (m <sup>2</sup> )	Height (m)	Area (m <sup>2</sup> )
Separation	1.23	5.02	2.5	80
Detention	2.00	264.52	0.5	10
Harvesting	2.40	38.20	2.5	80
Treatment	2.00	5.00	1.25	100
<b>Total</b>	<b>636.84 m<sup>3</sup></b>		<b>530 m<sup>3</sup></b>	
<i>Orifice</i>	<i>Height (m)</i>		<i>Height (m)</i>	
SH	0.52		1.5	
SD2	0.66		1.75	
DO2	1.8		0.4	

The optimised configuration has a higher peak overflow volume of 285m<sup>3</sup>, but the proportion of scenarios which demonstrated overflow is reduced from 10.86% to 5.86%. Thus, with the optimised configuration, overflow events are less likely to occur, but this comes at the price of having higher overflow volumes if they do. The existing configuration is better at harvesting some amount of water for 99.7% of the simulated scenarios, while the optimal configuration only harvested water in 78.3% of the simulated

scenarios. Hence, the optimal configuration is much better at providing water availability during larger rain events, whilst the existing configuration provides a much more consistent yield performance over the possible range of rainfall volumes.

#### 4. Conclusions

The results demonstrated that the modularised optimisation model can provide a full RWH system configuration for a multi-tank system with low computational time limits of 1.5 minutes. Under this optimisation-based sizing strategy, there is an improved balance between the dual objectives of improving local reuse of harvested water and reducing flood risks, especially in comparison to an existing RWH system configuration which had not been derived using optimisation-based methods.

Thus, the modularised optimisation tool presented in this paper can encourage more implementations of multi-objective RWH systems by improving the accessibility of optimisation-based sizing strategies. Through the tank block framework, optimisation models can easily be built if the desired configuration of discharge openings is known. Further behavioural specifications can also be appended to the model if this is required, and a full optimisation model, specific to the design for the given catchment, can be derived much more quickly in comparison to a full, single optimisation model.

The performance of a stochastic optimisation model, however, remains highly influenced by the data quality used for its input scenarios. Therefore, the performance of the modularised tool continues to be dependent on the availability of high-resolution rainfall data. To mitigate this, there is currently work in progress to integrate such a sizing strategy with a rainfall design model to derive a robust RWH system configuration.

## Abstract

In this paper, mass and momentum balances are used to model and simulate the most significant phenomena occurring in a continuous urban sludge clarifier. This model is designed to be the core of a digital twin in the future. This has two consequences: the choice of a one-dimensional model only and a numerical scheme for simulation that allows a reasonable runtime. We propose a different way of writing of the dynamic model of the clarifier. Instead of using volume fractions and velocity of solid particles as state variables, we use volume fractions and flux of solid particles. This approach, which is used for conservation law systems, gives more stable simulation results for hyperbolic systems.

This paper focuses on comparative discussions of these two different versions of the model. The numerical simulation scheme is presented. In addition, the simulation is compared with experimental data obtained in a full-scale wastewater treatment plant.

**Keywords:** Urban sludge continuous settling, Dynamic mass and momentum balances, nonlinear hyperbolic system, Rusanov numerical approximation

## 1. Introduction

The efficiency of wastewater treatment facilities is a worldwide major problem. Urban wastewater treatment plants are regulated by European directives, such as 91/271/EEC. The biological treatment unit of a treatment plant purifies wastewater before it is released into the natural environment by using a clarifier. The quality of the clarified water strongly depends on the instantaneous hydraulic loads arriving upstream, on the design of the equipment and on the operating conditions. The settling of the sludge in the clarifier enables the separation of more concentrated sludge that is pumped down and clarified water that is released up into the environment in an overflow. Thus, the quality of the plant effluent is highly dependent on the performance of the clarifier. In order to optimize its operation, modelling and simulation are the first steps to perform.

In the literature, the modelling of clarifiers is obtained through mass and momentum balance equations for solid particles. The latter is written as a static or dynamic partial differential equation (Chauchat (2013), Garrido (2003)) or replaced by a constitutive relation representing the velocity of solid particles (Li (2014)). In the case where the

momentum balance is represented by a PDE, the global model is weakly hyperbolic and the position of the so-called sludge blanket corresponds to the front of a shock wave. This shock is related to a discontinuity in the solid particle volume fraction and a peak value in the flux.

In this paper, we present two choices of state variables for the sludge settling modelling in a clarifier (Valentin (2022)) and discuss the simulation results with respect to experimental data.

## 2. A 1-D schematic representation of the clarifier

Fig. 1 shows a 1-D schematic representation of the clarifier. It is connected to the wastewater treatment process at three points, one inlet and two outlets:

- one inlet where the sludge, consisting of fluid and particles, flows into the clarifier by gravity from the upstream biological aeration tank at the volume flow rate  $Q_f(t)$  and with a particle concentration  $C_f(t)$ . The sludge feed is situated at a depth of  $z = z_f$ ,
- one top outlet for clarified water at  $z = 0$ , with a volume flow rate  $Q_e(t)$  and particle concentration  $C_e(t)$ ,
- one bottom outlet for compressed sludge at  $z = z_b$ , with a volume flow rate  $Q_u(t)$  and particle concentration  $C_u(t)$ . Some of the compressed sludge is recirculated back into the aeration tank at a volume flow rate  $Q_{ur}(t)$  and some is extracted from the clarifier at a volume flow rate  $Q_{ue}(t)$  such that  $Q_u(t) = Q_{ur}(t) + Q_{ue}(t)$ .

Figure 1: Schematic view of a clarifier

$A$	$1175 \text{ m}^2$
$A_k$	$0.02 \text{ m/s}$
$\epsilon_c$	$4.1 \cdot 10^{-2}$
$n_r$	$2$
$n_s$	$11$
$\rho_l$	$1000 \text{ kg/m}^3$
$\rho_s$	$1030 \text{ kg/m}^3$
$\sigma_0$	$0.5 \text{ kg/ms}^2$
$z_b$	$2.8 \text{ m}$
$z_f$	$1.8 \text{ m}$

Table 1: Model parameter values

The open-air settler content can be divided into two moving interfaces separating three zones:

- The upper interface is the sludge blanket, located at depth  $z_s(t)$ . It separates the clarification zone (which contains no or very few particles) from the intermediate zone,
- The lower interface is defined by the intermediate/compression threshold and is located at depth  $z_c(t)$  where a change in the particles behaviour occurs as the particle concentration  $C_s(z,t)$  exceeds the critical threshold  $C_c$ . Above this threshold, interparticle stress comes into effect. Under  $z_c(t)$ , the liquid phase flows through a porous network of concentrated particles, Toorman (1996). The model parameter values are given in Table 1.

## 3. A 1-D dynamic model of the clarifier

The knowledge-based model includes two dynamic mass and momentum balances of urban sludge added with physical constitutive equations under standard simplifying

assumptions, Valentin (2022). As the liquid and solid phase densities  $\rho_l$  and  $\rho_s$  are constant, the two most natural state variables are the particle volume fraction,  $\varepsilon_s$ , and the particle flux,  $f_s = \varepsilon_s v_s$  with  $v_s$  the particle velocity. The corresponding hyperbolic system of conservation laws is then defined, if  $\varepsilon_s > 0$ , by:

$$\partial_t \varepsilon_s + \partial_z f_s = \frac{f_{1s}}{\rho_s} \delta_f \quad (1)$$

$$\partial_t f_s + \partial_z \left( \frac{f_s^2}{\varepsilon_s} \right) = \varepsilon_s g \left( 1 - \frac{\rho_l}{\rho_s} \right) - \frac{\partial_z \sigma_e(\varepsilon_s)}{\rho_s} + \frac{r(\varepsilon_s)(\varepsilon_s v_m - f_s)}{\rho_s \varepsilon_s (1 - \varepsilon_s)} + \frac{f_{2s}}{\rho_s} \delta_f \quad (2)$$

with  $\sigma_e(\varepsilon_s)$  the interparticle stress between the particles,  $r(\varepsilon_s)$  the liquid/solid drag force and  $v_m$  the average velocity of the liquid/solid mixture (also the total volume flux of the suspension).  $f_{1s}$  and  $f_{2s}$  are the source terms representing the sludge feed inlet in the particle mass and momentum balances equations respectively. They depend on  $Q_f$  and  $C_f$ .  $\delta_f$  is a Dirac function that represents the location of the sludge feed at  $z = z_f$ . The two boundary conditions are  $v_s(0, t) = -\frac{Q_e}{A}$  and  $v_s(z_b, t) = \frac{Q_u}{A}$ .

Various kind of constitutive equations that describe the compression and drag phenomena have been proposed in the literature, Li (2014).  $r(\varepsilon_s) = \frac{\rho_l g}{A_k} \varepsilon_s^{2/(3-n_r)}$  is proposed in Chauchat (2013) and the following  $\sigma_e(\varepsilon_s)$  expression, that depends on the particle volume fraction, in Garrido (2003). If  $\varepsilon_s > \varepsilon_c$  (in the compression zone),  $\sigma_e(\varepsilon_s) = \sigma_0 \frac{\varepsilon_s^{n_s} - \varepsilon_c^{n_s}}{\varepsilon_c^{n_s}}$  else (in the two other zones),  $\sigma_e(\varepsilon_s) = 0$  (see Table 1).  $\sigma_e(\varepsilon_s)$  is a continuous function on  $[0, z_b]$  but its disadvantage is that it is zero over the upper part of the spatial domain which makes the system weakly hyperbolic only.

Most of the papers in the literature present a model based on a dynamic particle mass balance with the state variable,  $\varepsilon_s$ , coupled with a constitutive equation that gives the so-called batch or hindered settling velocity (Garrido, 2003), (Li, 2014). This motivated us and others, Chauchat (2013), Valentin (2022) to use first the state variables  $(\varepsilon_s, v_s)$  according to the following hyperbolic system of two PDEs:

$$\partial_t \varepsilon_s + \partial_z (\varepsilon_s v_s) = \frac{f_{1s}}{\rho_s} \delta_f \quad (3)$$

$$\partial_t v_s + \partial_z \left( \frac{v_s^2}{2} \right) = g \left( 1 - \frac{\rho_l}{\rho_s} \right) - \frac{\partial_z \sigma_e(\varepsilon_s)}{\rho_s \varepsilon_s} + \frac{r(\varepsilon_s)(v_m - v_s)}{\rho_s \varepsilon_s (1 - \varepsilon_s)} + \frac{f_{21s}}{\rho_s} \delta_f \quad (4)$$

This representation is based on the temporal and spatial derivatives of products such as  $\varepsilon_s v_s$ . As shock waves appear on the two state variables, such product derivatives may lead to mathematical problems. Moreover, the difficulty of numerically solving the model based on the state variables  $(\varepsilon_s, v_s)$  and the oscillations obtained on the spatial profiles of the velocity  $v_s$  led us to return to the more "natural" state variables that correspond to those used in the so-called conservative approach, the particle volume fraction,  $\varepsilon_s$ , and the particle flux,  $f_s = \varepsilon_s v_s$  (equations (1) and (2)) and to include the interparticle stress in the flux.

#### 4. Numerical discretization scheme

The simulations were carried out using explicit Euler time-discretization and an efficient numerical scheme adapted to hyperbolic and weakly hyperbolic nonlinear PDE systems: a finite volume method spatial-discretization with the Rusanov approximation of the fluxes (Godlewski (1996), LeVeque (2002)).

The state variable vector  $x$  and the flux vector  $F_s(x)$  are defined if  $\varepsilon_s > 0$  by  $x = \begin{pmatrix} \varepsilon_s \\ f_s \end{pmatrix}$

and  $F_s(x) = \begin{pmatrix} f_s \\ \frac{f_s^2}{\varepsilon_s} + \frac{\sigma_e(\varepsilon_s)}{\rho_s} \end{pmatrix}$ . The state variables are considered as uniform in each volume

$i$  of the mesh and equal to the average values  $\bar{x}_i^k$  at time step  $k$ .

For time step  $k$  and volume  $i$ , the flux at the input interface  $i - \frac{1}{2}$  is approximated by:

$$F_{i-\frac{1}{2}}^k = \frac{1}{2} (F_s^k(\bar{x}_{i-1}) + F_s^k(\bar{x}_i)) - \frac{\omega_s^k}{2} (\bar{x}_i^k - \bar{x}_{i-1}^k)$$

with  $\omega_s^k = \max(\rho_i^k)$ ,  $\rho_i^k$  the spectral radius of the volume  $i$  which depends on  $\bar{x}_i^k$ .

Then:

$$\bar{x}_i^{k+1} = \bar{x}_i^k + \frac{\Delta t}{\Delta z} (F_{i-\frac{1}{2}}(\bar{x}_i, t) - F_{i+\frac{1}{2}}(\bar{x}_i, t)) + \Delta t (S_1(\bar{x}_i) + S_2)$$

where we assume that  $S_1(\bar{x}_i)$  is a good approximation of  $\frac{1}{\Delta z} \int_{i-1/2}^{i+1/2} S_1(x) dz$

and that the variable time-step  $\Delta t$  respects the CFL (Courant-Friedrichs-Lewy) condition:  $\Delta t = \gamma \frac{\Delta z}{\omega_s^k}$  with  $0 < \gamma < 1$ . As  $\sigma_e(\varepsilon_s) = 0$  in the clarification and intermediate zones, the system is only weakly hyperbolic.

#### 5. Simulation of a transient state experiment of continuous settling

The model simulation is compared to experimental data obtained in a full-scale settler operated under the following transient state scenario (Fig.3): the sludge feed rate was abruptly increased by a magnitude of two from a value corresponding to a stationary profile at  $t = 1.40 \text{ am}$  ( $660 \text{ m}^3/\text{h}$ ) and abruptly decreased  $8 \text{ hrs}$  later ( $370 \text{ m}^3/\text{h}$ ). The flow rates and concentrations at the sludge inlet and outlet were measured on-line as well as the sludge blanket position.

Simulations based on this model were performed with various discretization parameters such as spatial mesh size, convergence condition (Courant-Friedrichs-Lewy). They are compared to the experimental data. Measured sludge feed flow rate,  $Q_f(t)$ , recirculation flow rate,  $Q_{ur}(t)$  and extraction flow rate,  $Q_{ue}(t)$  as well their mean values are given in Fig.3.

An N-node spatial mesh was used to run the simulations of the discretized model presented in section 4. with the constitutive equations and boundary conditions given in section 3.

Figure 3: Applied flow rates

The calculated sludge blanket position  $z_v(t)$  corresponds to the location where the maximum gradient of the solid concentration is reached. Fig 4.a shows that the simulated and measured sludge blankets positions are very close.

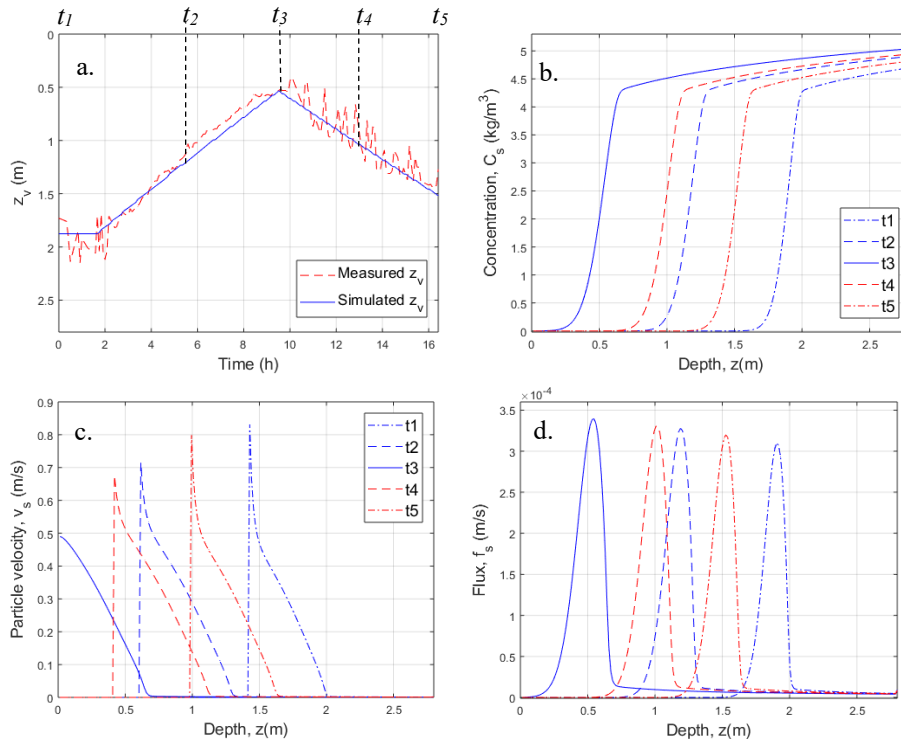

Figure 4: Simulated  $z_v(t)$  and  $C_s(z)$ ,  $v_s(z)$ ,  $f_s(z)$  spatial profiles ( $N=200$ )

Five spatial profiles at  $t_1$ ,  $t_2$ ,  $t_3$ ,  $t_4$  and  $t_5$  are shown in Fig 4.b to Fig 4.d. Fig 4.b presents particle concentration spatial profiles. The particle concentration at the top of the clarifier ( $z=0$ ) is close to zero. It increases sharply at the depth of the sludge blanket and then increases more moderately to the bottom as soon as the critical threshold is exceeded. The effect of the interparticle stress below the critical threshold is also well highlighted.

Spatial profiles  $v_s(z)$  and  $f_s(z)$  are shown in Fig. 4.c and Fig. 4.d. The shock wave is also clearly visible at the "peak" location. The particle velocity at the bottom of the settler  $v_s(z_b)$  is very low compared to the velocity at the sludge blanket position,  $5.3 \cdot 10^{-4} \text{ m/s}$ , and is set by the  $Q_u$  flow rate.

Good results are obtained with this numerical scheme for a mesh size of up to 800 volumes and  $\gamma = 0.99$  in the CFL condition. Choosing a lower  $\gamma$  value gives the same results but with a longer runtime due to a smaller  $\Delta t$ . The runtime of a simulation with 200 volumes on a workstation equipped with an Intel Xeon at 3.8GHz is 8 min 15 s. According to the nature of the numerical scheme, the runtime with  $N = 800$  is 16 times longer that makes 2 hrs 12 min. Although the simulation gives good results with  $N = 800$  with less numerical diffusion, as this model will be the core of a decision support system and then a digital twin, a compromise must be decided. A spatial discretization of  $N = 200$  seems suitable.

## 6. Conclusions

As a conclusion, the well-suited conservative state variables are the volume fraction and the volume flux of the solid particles. The expression of the momentum balance includes the compression stress between the particles based on a nonlinear constitutive law taken from Garrido (2003). A numerical scheme with explicit Euler time-discretization and a finite volume method spatial-discretization with the Rusanov approximation of the fluxes works well. The simulation results are close to experimental results by using a set of well-chosen parameter values. It can be used for prediction and decision support for other scenarios of operation. The runtime with a spatial mesh of 100 volumes is still about 2 min 4 s on a workstation equipped with Intel Xeon at 3.8GHz, which may be a limitation of this approach.

## Acknowledgements

The authors would like to thank the Auvergne-Rhone-Alpes region's PAI 2020 program, along with the C-StaRRE 4.0 project for their financial support, in particular for Hadi ABOU DAHER's internship (Grant number 22PACKR-CVALENTIN-6887).

## Abstract

This paper analyses the intrinsic geometric structure of binodal curves of phase separation diagrams of ternary mixtures. A new computational method is presented, and the efficiency of the proposed approach is tested for the Flory-Huggins model identification of water – acetone – hexadecane mixture.

**Keywords:** liquid-liquid separation, bitangent plane, binodal curve, differential homotopy

## 1. Introduction

Controlling the phase separation in industrial processes requires detailed knowledge of thermodynamic diagrams of multi-component mixtures (Koningsveld et al., 2001). Many computational problems arise in this context: identification of model parameters from the experimental data, localization of phase separation envelopes, detection of multi-phase regions, etc. Despite the enormous progress in this domain in the past decades, there is still a real need for new fast and reliable algorithms, for instance, in industrial applications using bio-sourced mixtures or in polymer production.

This paper focuses on the analysis of liquid-liquid separation of ternary mixtures at constant temperature and pressure. The topological structure of phase separation diagrams is then defined by binodal and spinodal curves delimiting stable, metastable and unstable domains in the composition space. Knowing these domains is crucial for modeling the demixing process in a given mixture. The experimental detection of spinodals that delimits the material stability domain is a highly non-trivial task. Instead, the various techniques allows measuring the composition of coupled coexisting phases, which can be used to establish a reliable model in order to predict the spinodal location *a-posteriori*.

The standard method of numerical computation of binodal curves uses the Newton-Raphson-like iterative algorithm to solve a system of algebraic equations over the mesh covering the state space of the diagram, while the classical least square method is commonly used for model identification. Often this approach fails to meet at least one of the quality criteria characterizing the “good” model: the binodal curve shape and the bundle of tie-lines indicating the coupled phases composition. Inspired by the ideas of D.J. Korteweg (Levelt Sengers, 2002) applied to the topological analysis of the Gibbs free energy surface, in this paper, we propose a new numerical method for computing binodal curves by a kind of differential homotopy method. The key idea is to consider

binodals as the 2D projections of certain smooth curves in 4D configuration space formed by the pairs of points of the phase diagram. This geometrical point of view is presented in Section 2, where a set of ordinary differential equations (ODE) describing the 4D curve as an integral curve of a smooth vector field in 4D space is derived. A conventional ODE solver can numerically compute this curve at desired precision.

In Section 3, the developed approach is tested on the water-acetone-hexadecane mixture, characterized by two non-miscibility binary gaps among its components. The Flory-Huggins model parameters, including the triple interaction term, are computed by solving a non-trivial minNLP problem associated with a criterion, which accounts for the intrinsic geometry of the binodal curve. The computations performed using Mathematica 9 software yield very promising results that meet both quality criteria cited above.

## 2. Binodal and spinodal curves: thermodynamics vs. geometry

### 2.1 Phase coexistence conditions in multi-component mixtures

The physicochemical properties of an  $N$ -component system can be described by the Gibbs free energy  $G(P, T, n)$ , where  $n = (n_1, \dots, n_N)$ ,  $n_i$  being the number of moles of  $i$ -th component,  $P$  the pressure and  $T$  the temperature of the system. Being a homogeneous function of 1-st order with respect to  $n_i$ ,  $G$  can be expressed in terms of chemical potentials  $\mu_i = \frac{\partial G}{\partial n_i}$  as  $G(P, T, n) = \sum_{i=1}^N n_i \mu_i(P, T, n)$ . The infinitesimal changes in the state of the system obey the fundamental Gibbs equation

$$dG = -S dT + V dP + \sum_{i=1}^N \mu_i dn_i \quad (1)$$

where  $S$  and  $V$  are the entropy and the volume of the system.

All expressions above rest valid for each phase of a closed system maintained at thermodynamic equilibrium with two coexisting phases. Numbering the phases by  $a$  and  $b$ , the equilibrium condition reads  $dG = dG^a + dG^b = 0$ . Since in a closed system  $n_i = n_i^a + n_i^b$  and  $n_{tot} = \sum_{i=1}^N n_i$  are constant, it follows that  $dn_i^a = -dn_i^b$ , and hence Eq.(1) implies that

$$T^a = T^b, \quad P^a = P^b, \quad \mu_i^a(P^a, T^a, n^a) = \mu_i^b(P^b, T^b, n^b), \quad i = 1, \dots, n \quad (2)$$

In this paper, it is assumed that both phases can be described by the same thermodynamic model, though in principle, two different expressions can model be used for chemical potentials of phases  $a$  and  $b$ . In addition, only the isobaric isothermal conditions will be considered, so the first two of Eqs. (2) become trivial.

The physicochemical properties of real mixtures are usually expressed in terms of molar, volume or mass fractions. In particular, the Flory-Huggins model used in Section 3 to describe the mixture of a polymer with water and a solvent, employs the volume fractions. Assuming the total volume of the mixture to be equal to the sum of partial volumes of components, and denoting by  $x_i = v_i/V$  the volume fraction of  $i$ -th component and by  $g(P, T, x) = G(P, T, n(x))/R V$  the free Gibbs energy of mixing per unit of volume, Eqs. (2) can be rewritten in the form

$$\begin{aligned} \frac{\partial g^a(x^a)}{\partial x_i^a} &= \frac{\partial g^b(x^b)}{\partial x_i^b}, \quad i = 1, \dots, N-1, \\ g^a(x^a) - g^b(x^b) - \sum_{i=1}^{N-1} \frac{\partial g^a(x^a)}{\partial x_i^a} (x_i^a - x_i^b) &= 0 \end{aligned} \quad (3)$$

In the binary case ( $N=2$ ) these conditions mean that the graph of function  $g(x)$  admits a bitangent line, as it is shown in Fig. 1a.

### 2.2 Ternary case: binodal curves and bitangent planes of the Gibbs free energy surface

To simplify notations, from now on  $g'_i$  stays for  $\frac{\partial g}{\partial x_i}$ , the symbols  $\nabla_x g$  and  $D_x^2 g$  are used for the gradient and for the Hessian of function  $g$ , and  $(|)$  for the scalar product in  $\mathbb{R}^2$ .

In case of ternary mixtures Eqs.(3) describe the specific properties of the surface, referred to as surface  $W$ , defined by equation  $z = g(x_1, x_2)$  in a 3D Cartesian space endowed with coordinates  $x_1, x_2, z$ , as it shown in Fig. 1b. The material stability condition implies that such a surface has a physical meaning only in the sub-domain of the volume fraction space where the function  $g(x)$  is convex:

$$\Omega = \{x = (x_1, x_2): x_1, x_2 \in [0,1], x_1 + x_2 \leq 1, D_x^2 g \text{ is weakly pos. definite} \}$$

The projection on the  $x$ -plane of the set of singular points of surface  $W$ , i.e. the points where  $D_x^2 g$  is singular, defines the spinodal curve of the phase diagram. The first two of Eqs.(3) guarantee the existence of a pair of points  $P_1$  and  $P_2$  on the surface  $W$  with collinear normals, whereas the latter of Eqs.(3) says that these points belong to the same plane tangent to  $W$ . The projection of the segment  $P_1 P_2$  on  $x$ -plane is called a tie-line. The one-parametric family of conodal points  $P_1, P_2$  define two directrices of a certain ruled surface in 3D space. Their projections on the  $x$ -plane correspond to the two branches of binodal curve on the phase diagram. These branches can meet each other at the critical point of the phase diagram. Since by definition the critical point also belongs to the spinodal, these are the only common point between the binodal and the spinodal curves, and the whole binodal curve lies on the same side with respect to the spinodal curve. Fig.1b. illustrates all these concepts for the mixture having one critical point.

### 2.3 Differential equations of binodal and spinodal curves

As it follows from the above analysis, the binodal curves are formed by the pairs of points. So it is natural to describe these curves in the 4D space  $\Sigma = \Omega \times \Omega$  defined as follows:

$$\Sigma = \{ \mathbf{q} = (\mathbf{q}_1, \mathbf{q}_2) \in \mathbb{R}^4 : \mathbf{q}_1 = \mathbf{x}^a \in \Omega, \mathbf{q}_2 = \mathbf{x}^b \in \Omega \}$$

Consider now the three co-dimension one smooth sub-manifolds in  $\Sigma$  associated to the zero-levels of the functions

$$\begin{aligned} F_1(q) &= g'_1(q_1) - g'_1(q_2), \quad F_2(q) = g'_2(q_1) - g'_2(q_2), \\ F_3(q) &= g(q_2) - g(q_1) + (\nabla_x g(q_1)|q_2 - q_1), \quad q \in \Sigma \end{aligned} \quad (4)$$

These sub-manifolds can intersect each other forming a one-dimensional sub-manifold  $\mathbf{B} = \{ \mathbf{q} \in \Sigma: \mathbf{F}(\mathbf{q}) = \mathbf{0}, \mathbf{i} = \mathbf{1}, \mathbf{2}, \mathbf{3} \}$  whose orthogonal projections on two exemplars of  $\Omega$

define the two branches of the binodal curve. In what follows  $B$  will be referred to as the generalized binodal curve. This curve can be seen as the integral curve of the vector field  $\mathbf{q} \rightarrow \mathbf{V}(\mathbf{q}) \in T_{\mathbf{q}}\mathbf{B}$ . By definition,

$$\nabla_{\mathbf{q}} F_i(\mathbf{q})V(\mathbf{q}) = 0, \quad i = 1,2,3 \quad (5)$$

Define a pair of functions  $\Phi_i$  and  $\Psi_i$  such that  $(\Phi_i, \Psi_i)^T = \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_i)(\mathbf{q}_1 - \mathbf{q}_2)$ , for  $i=1,2$ . Then Eqs. (5) are equivalent to the following conditions:

$$\Phi_1 V_1 + \Psi_1 V_2 = 0 \quad \text{and} \quad \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_1)(V_1, V_2) = \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_2)(V_3, V_4) \quad (6)$$

The straightforward computation shows that  $\mathbf{V}(\mathbf{q})$  can be expressed as

$$\begin{aligned} V_1 &= \Psi_1 \det \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_2), & V_2 &= -\Phi_1 \det \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_2) \\ V_3 &= \Psi_2 \det \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_1), & V_4 &= -\Phi_2 \det \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{q}_1). \end{aligned} \quad (7)$$

Clearly, the critical points of surface  $W$  correspond to the singular points of  $\mathbf{V}(\mathbf{q})$ .

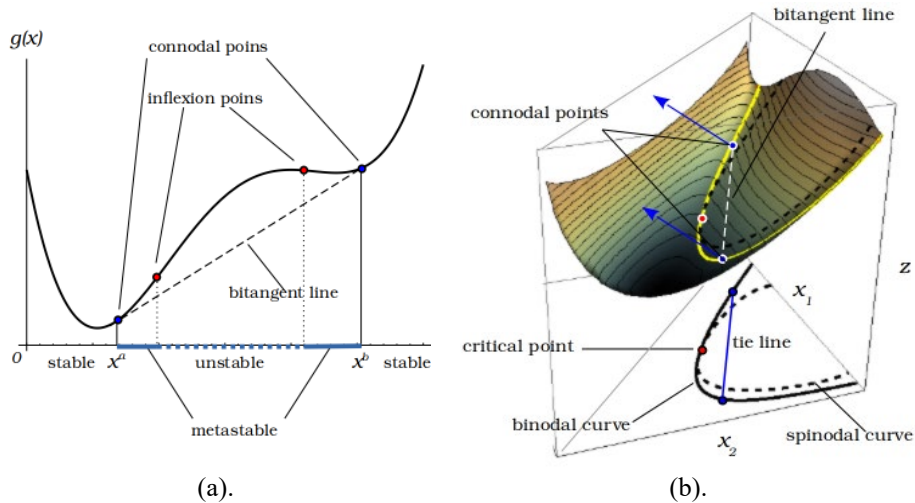

Fig.1. bitangent lines to the free Gibbs energy surface  $W$  in binary (a) and ternary (b) cases, and their projections on the composition space.

**Remark.** The same argument can be used to define the spinodal curve as the integral curve of the vector field  $\nabla_{\mathbf{x}} \mathbf{S}(\mathbf{x})^\perp$ , where  $\mathbf{S}(\mathbf{x}) = \det \mathbf{D}_{\mathbf{x}}^2 g(\mathbf{x})$ .

The described construction is a geometrical interpretation of the differential homotopy method (Allgower and Georg, 2003) for computing smooth curves defined implicitly. Using Eq.(5) instead of Eqs.(3) it is possible to compute binodal curves by a conventional ODE solver without solving the set of algebraic Eqs.(3) or Eqs.(2) by a Newton-Raphson type iterative algorithm, as it is usually done. The only iterative step concerns the computation of the starting point of the generalized binodal (or spinodal) curve, which reduces to a 2D problem. An algorithm based on the same principles was described in detail in N. Shcherbakova et al. 2017 and O. Cots et al. 2021.

### 3. Case study: Flory-Huggins parameters of water-acetone-hexadecane

#### 3.1 The Flory-Huggins model with ternary interaction term

The classical Flory-Huggins model defines the excess free energy of mixing per unit of volume according to the expression

$$g = \varphi_1 \ln \varphi_1 + \frac{1}{N_2} \varphi_2 \ln \varphi_2 + \frac{1}{N_3} \varphi_3 \ln \varphi_3 + \sum_{i,j=1,i<j}^3 \chi_{ij} \varphi_i \varphi_j + \beta \varphi_1 \varphi_2 \varphi_3 \quad (8)$$

Here  $\varphi_i$ ,  $i=1,2,3$  are the volume fractions of water, the solvent and the polymer respectively,  $N_2$  and  $N_3$  are the number of segments in the molecules of the solvent and of the polymer referred to the water segment,  $\chi_{ij}$  and  $\beta$  are the binary and ternary interaction coefficients. In this paper  $N_2$ ,  $N_3$ ,  $\chi_{ij}$  and  $\beta$  are assumed to be constant. Notice that the cross term  $\beta \varphi_1 \varphi_2 \varphi_3$  contains several physical effects. Indeed, it is the simplest possible correction of the Flory-Huggins model that accounts for composition-dependent binary interaction parameters as well as for the failure of the total volume conservation hypothesis when mixing the components. Since the present work aims to propose a generic robust method for binodal identification, it is not necessary to investigate the real physical meaning of the cross term here.

In further computations the volume fractions of acetone and of polymer are chosen as the independent variables so that  $x_1 = \varphi_2$ ,  $x_2 = \varphi_3$  and  $\varphi_1 = 1 - x_1 - x_2$ . Inserting Eq.(8) into Eqs.(4) yields three algebraic conditions to be verified along the binodal curve. Due to the particular form of Eq. (8), these conditions linearly depend on six scalar parameters:  $\chi_{12}$ ,  $\chi_{13}$ ,  $\chi_{23}$ ,  $\beta$ ,  $r_1 = N_2^{-1}$ , and  $r_2 = N_3^{-1}$ .

#### 3.2 Case study: water-acetone-hexadecane

The further analysis is based on the experimental data obtained at  $P = 1 \text{ atm}$  and  $T=23^\circ\text{C}$  using Raman's spectroscopy to measure each species fraction for a given sample. 14 measurements of coupled compositions were acquired defining tie-lines  $q^k \in \Sigma$  (black points in Fig. 2) and 17 non-coupled composition measurements  $x_m \in \Omega$  (white circles in Fig. 2) defining the phase-separation envelope. The latter series contains a pair of points defining the miscibility gap  $x^a$ ,  $x^b$  of the binary mixture acetone-hexadecane. Using Eqs.(3) for this binary mixture,  $\chi_{23}$  and  $N_2$  were computed in terms of  $x^a$ ,  $x^b$ . Analogously,  $\chi_{13}$  and  $N_3$  were found using the miscibility gap limits of water-hexadecane mixture reported in the literature. Due to the significant variation of these data in different sources, the term  $\chi_{13}$  in Eq. (8) was replaced by  $\chi_{13} + \delta$  in the next step of the computation. In this second step the remaining parameters  $\chi_{12}$ ,  $\beta$ ,  $\delta$  were found by solving the following non-linear optimization problem:

$$\min_{\chi_{12}, \beta, \delta} \sum_{k=1}^{14} \frac{F_1^2(q^k) + F_2^2(q^k)}{(1 - F_3^2(q^k))^2} \quad (9)$$

The particular form of criterion Eq.(9) push the minNLP solver toward the solutions which guarantee that each point  $q_k$  corresponds to a pair of points on  $W$  having collinear

normal vectors, whereas the denominator term penalize those pairs of points that do not belong to the same bitangent line.

The described method was implemented using Mathematica 9 package, the result is shown Fig. 2. Grey lines correspond to the measured tie-lines, and the dashed lines denote the computed tie-lines. The thick black curve corresponds to the computed binodal curve, which satisfies both quality criteria discussed above. The right part of Fig.2 shows the acetone vertex zone in high resolution, showing an excellent correspondence between experimental and model identification results.

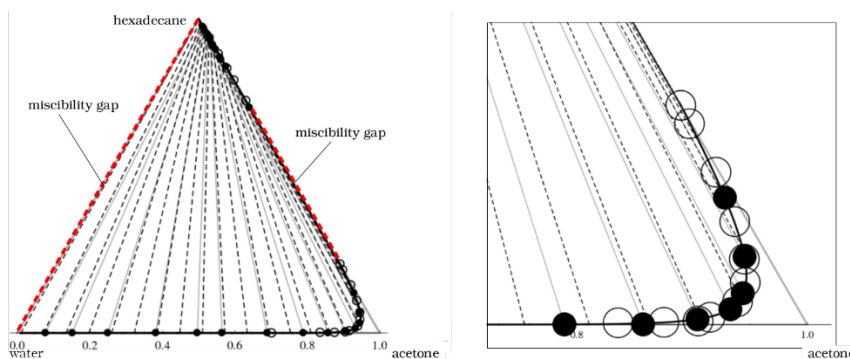

Fig.2: water-acetone-hexadecane mixture, experimental data (black and white points) vs. numerical computation of the binodal curve using Flory-Huggins model (black curve).

#### 4. Conclusion

The geometric description of binodal curves provides a deeper insight into their internal structure. In particular, it allows reducing numerical computation of binodal and spinodal curves to standard ODEs integration, gaining in execution time and accuracy. The numerical method proposed in this paper can be adapted to any thermodynamic model. We plan to implement the resulting differential homotopy algorithm in the next version of the SMITH code (Cots et al, 2021).

## Abstract

The steel industry represents one of the key sectors of our society and it is, therefore, essential to devise new strategies to drastically reduce its carbon dioxide emissions. From this point of view, a potentially beneficial solution would be to replace the carbon sources used in the reduction processes of minerals with hydrogen. This requires a deeper understanding of the kinetics of iron oxide reduction in order to provide crucial elements for selecting the best-operating conditions and designing new technologies. In this work, an mathematical model was developed, based on the assumptions of the shrinking core model, to describe the reaction kinetics and mass transport phenomena occurring during iron ore reduction. Experimental tests were conducted to provide detailed data to support this work. The model results qualitatively agree with what was found in the laboratory tests.

**Keywords:** Hydrogen-based DRI, green-ironmaking, iron oxides, kinetics-modelling.

## 1. Introduction

The aim of reducing greenhouse gas emissions is driving all manufacturing and industrial sectors to seek alternative solutions that are viable in the short term and offer excellent margins for improvement in the years ahead. With around 30% of global direct industrial emissions (2.6 Gt/year), steelmaking represents one of the largest CO<sub>2</sub> emitting sectors (Energy Agency 2020). The classical production process, carried out in a blast furnace (BF), involves the use of iron ores (i.e., iron oxides) which are reduced to metallic iron using carbon monoxide. This gas component is produced at partial oxidation of coal and reacts with the oxygen in the ore to produce iron and CO<sub>2</sub> (Hutny et al. 1991). As a result of the very high operating temperatures of the BF process, which locally exceed 2000°C, iron melts and slag forms in the lower part of the furnace. Developed 40 years ago, the Midrex process represents a possible alternative to conventional iron production. The reduction reaction in this process occurs at lower temperatures than in the BF and it usually operates on reformed natural gas. The gas-solid reactions produce direct reduced iron in solid state (DRI), and thus avoids melting (Atsushi et al. 2010). To achieve the complete decarbonization of this sector, it is necessary to redesign current production facilities and to replace all or most of the carbon source by hydrogen (Patisson et al. 2021). The kinetics of iron oxide reduction by hydrogen has been extensively studied and the literature shows that it is influenced by many factors and parameters. Several studies have focused on the thermodynamics of the reduction. At operating temperatures above 570°C, the reactive network consists of three reversible reactions in series, starting with the reduction of hematite (Fe<sub>2</sub>O<sub>3</sub>) and passing through the intermediates magnetite (Fe<sub>3</sub>O<sub>4</sub>) and wustite (FeO); at lower temperatures, wustite does not form due to its

instability (Zhang et al. 2013). To investigate the kinetic dependence of the reduction on the main operating conditions, several works have examined in depth the effect of temperature (Bernasowski 2014) or the composition of the reducing gas (Wei et al. 2018) on the system. Many authors focused their efforts on the determination of the rate-limiting step of the heterogeneous process and on the importance of diffusion phenomena. For this reason, the study of morphology, geometry, and other properties of the solid is crucial. Several authors have investigated the effect of the size of the iron ore (e.g., particle diameter) (Bonalde et al. 2005; Hou et al. 2012), the initial porosity (Kazemi et al. 2017) or the gas flow rate to assess the resistance to gaseous diffusion around a pellet (Hou et al. 2012). The main mathematical models used to describe the process and evaluate the kinetic parameters are the Avrami Model (Piotrowski et al. 2005), often used in metallurgical work, the Shrinking Core Model (SCM) (Moon et al. 1998) or the Grain Model (Bonalde et al. 2005). As for the assessment of the rate-limiting step, different conclusions have been made, mainly proposing an intraparticle diffusive regime, a kinetic regime, or a variable regime, depending on the reduction stage considered (Lin et al. 2003). Given the variety of experimental conditions and modelling assumptions, a wide range of activation energies, are reported in the literature. The activation energy for individual intermediate reactions or for the whole process can vary between 18 kJ/mol and 246 kJ/mol (Pineau et al. 2006). To accurately describe the chemical kinetics and mass transfer phenomena of the reduction process, an extensive kinetic study is required. This work focuses on the development of mathematical models for the description of iron oxide reduction based on a large set of experiments, which will be useful in the future for the development and design of hydrogen-based DRI processes.

## 2. Materials and methods

### 2.1. Experimental Setup

To support the development of a mathematical model capable of describing the reduction process, several experimental tests have been conducted using an Autochem2910. This device, which is normally used for the characterization of catalysts (e.g., TPR, TPO etc.), makes it possible to study the reduction of iron ores in a small packed-bed reactor. The experimental apparatus consists of a U-tube glass, resistant to high temperatures, with branches of different diameters. Ore fines, loaded in the branch with the largest diameter, is held by a porous support placed above the reduction of the tube diameter. The reactive bed (diameter 8 mm, height approx. 1 mm) consists of hematite powder (purity 97%), with a particle diameter of less than 5  $\mu\text{m}$ . The reduction of hematite was carried out using a gas mixture containing the reducing species ( $\text{H}_2$  purity 99.9%) and an inert gas (Ar, purity 99.9%). The temperature was measured using a thermocouple placed inside the tube. The composition of the gas leaving the bed was analyzed using a thermal conductivity detector (TCD) and a mass spectrometer, from which the degree of iron oxide reduction can be estimated. The tests were conducted isothermally at a specific  $\text{H}_2/\text{Ar}$  ratio and total volumetric gas flow rate.

### 2.2. Mathematical Model

A mathematical model has been developed to describe the reactive and diffusive phenomena present in a bed of iron oxide particles through which a gas mixture containing a reducing gas species flow. The reactive network consists of several equilibrium reactions in series, the number of which varies depending on the operating temperature. Table 1 shows the reactions occurring at temperatures above 570°C:

Table 1. Reaction network,  $T > 570^\circ\text{C}$ , and enthalpies (Zhang et al. 2013)

Reaction fronts ( $j$ )	Reduction reaction	$\Delta H^0$ [kJ/mol]
1	$3 \text{Fe}_2\text{O}_3 + \text{H}_2 \Leftrightarrow 2 \text{Fe}_3\text{O}_4 + \text{H}_2$ Hematite Magnetite	-11.72
2	$\text{Fe}_3\text{O}_4 + \text{H}_2 \Leftrightarrow 3 \text{FeO} + \text{H}_2\text{O}$ Magnetite Wustite	+77.44
3	$\text{FeO} + \text{H}_2 \Leftrightarrow \text{Fe} + \text{H}_2\text{O}$ Wustite Iron	+23.85

To describe the intraparticle reductive process, the mathematical model was developed based on the key assumptions of the SCM, where the reactions only take place on the surface separating two zones within the solid, an unreacted core, consisting of pure solid reactant, and a reacted outer layer, consisting of pure solid product. The reaction interface moves inwards as the core is consumed. By extending the SCM to the series reaction system, three different intraparticle reaction fronts can be described, as shown in Figure 1.

Figure 1. Three-interface SCM, reduction of hematite particle.

### 2.2.1. Mass Balances

The balance equations useful for describing the degrees of reduction of iron oxides over time ( $t$ ) and along the axial coordinate of the reactor ( $z$ ) were expressed as

$$\frac{\partial X_j(t, z)}{\partial t} = \frac{N_j(t, z)}{n_{00} \cdot a_j} \quad (1)$$

where  $X_j$  is the degree of conversion of the  $j$ -th reaction front ( $\text{Fe}_2\text{O}_3$  reduction, etc.),  $n_{00}$  is the initial oxygen content in the system while  $a_j$  is the proportional oxygen content parameter depending on the type of iron oxide considered.  $N_j$  represents the reduction rate of the  $j$ -th reaction front defined under the assumptions of the SCM.  $N_j$  is given by

$$N_j(t, z) = \frac{P}{R_g T} \frac{3}{r_0} \frac{1}{A_j(t, z)|_f} \cdot \left( \frac{R_j(t, z)|_f}{W(t, z)|_f} - y_{eq,j} \right) \quad (2)$$

where  $P$  and  $T$  represent the operating pressure and temperature,  $R_g$  is the gas constant,  $r_0$  is the particle radius of the ore, while  $y_{eq,j}$  represents the fraction of  $\text{H}_2$  at the equilibrium of the  $j$ -th reaction.

In the initial stages of reduction, with the formation of the intermediate species magnetite and wustite, a triple reaction front is established in the particles. Once the reduction of hematite has been completed, at any  $t$  and  $z$  ( $X_1(t, z) = 1$ ), the equations useful for describing the entire reactive process at that specific location must change as the model no longer describes a triple but a double reaction front. Identically, this occurs when  $\text{FeO}$  is the only residual oxide, effectively establishing a single reaction front. The formulae of the coefficients ( $A_j$ ,  $W$ ,  $R_j$ ), which define the reduction rate, are closely related to the

number of available reaction fronts. The value of  $f$  defines the number of reaction fronts present at time  $t$  and the  $z$ -coordinate, according to

$$\begin{cases} \text{if } X_1(t, z) < 1 & f = 3 \quad j = 1, 2, 3 \\ \text{if } X_1(t, z) = 1 \cap X_2(t, z) < 1 & f = 2 \quad j = 2, 3 \\ \text{if } X_1(t, z) = 1 \cap X_2(t, z) = 1 \cap X_3(t, z) < 1 & f = 1 \quad j = 3 \end{cases} \quad (3)$$

As an example, Eqs. (4-5) give the formulas for  $R_1|_{f=3}$  and  $W|_{f=3}$ , which are functions of the terms representing kinetic ( $A_j$ ), intra-particle diffusive ( $B_j$ ) and external diffusive ( $F$ ) resistance, respectively

$$\begin{aligned} R_1(t, z)|_3 &= (A_1 A_2 A_3) \cdot y_{\text{H}_2}(t) + [A_1 A_2 (B_3 + F)] \cdot y_{\text{eq}3} \\ &+ [A_1 A_3 B_2 + A_1 A_3 (B_3 + F) + A_1 B_2 (B_3 + F)] \cdot y_{\text{eq}2} \\ &+ [A_3 B_1 (A_2 + B_2) + A_3 B_1 (A_2 + B_2) + B_1 (A_2 + B_2) (B_3 + F) + A_2 A_3 B_2 \\ &\quad + A_2 A_3 (B_3 + F) + A_2 B_2 (B_3 + F)] \cdot y_{\text{eq}1} \end{aligned} \quad (4)$$

$$\begin{aligned} W(t, z)|_3 &= \{(A_1 + B_1) \cdot [A_3 (A_2 + B_2 + B_3 + F) + (A_2 + B_2) \cdot (B_3 + F)] \\ &\quad + A_2 [A_3 (B_2 + B_3 + F) + B_2 (B_3 + F)]\} \cdot y_{\text{eq}1} \end{aligned} \quad (5)$$

The complex derivation of these equations is reported in the literature (Hara et al. 1974). Examples of typical formulations of the  $A_j$  and  $B_j$  terms are given in Eqs. (6-7) while, in the first instance, due to the small size of the particles, the external transport resistance is considered negligible ( $F=0$ ).

$$A_1(t, z)|_3 = \frac{1}{(1 - X_1(t, z))^{\frac{2}{3}}} \cdot \frac{1}{k_1 \cdot \left(1 + \frac{1}{K_1}\right)} \quad (6)$$

$$B_1(t, z)|_3 = \frac{(1 - X_2(t, z))^{\frac{1}{3}} - (1 - X_1(t, z))^{\frac{1}{3}}}{(1 - X_1(t, z))^{\frac{1}{3}} \cdot (1 - X_2(t, z))^{\frac{1}{3}}} \cdot \frac{r_0}{D_1} \quad (7)$$

where  $k_j$  and  $K_j$  represent the kinetic constant and the equilibrium constant of the  $j$ -th reaction front, while  $D_j$  is the intra-particle diffusion coefficient that depends on the morphological characteristics of the ferrous oxide. The kinetic (Chu et al. 2005), thermodynamic (Zhang et al. 2013), and diffusive (Takahashi et al. 1971) parameters used in the model were taken from the literature.

Under dynamic conditions, two mass balance equations were developed for the gas species involved in the reduction reaction

$$\frac{\partial c_i(t, z)}{\partial t} = \underbrace{-\frac{u}{h} \cdot \frac{\partial c_i(t, z)}{\partial z}}_{\text{Convection}} + \underbrace{\frac{D_B}{h^2} \cdot \frac{\partial^2 c_i(t, z)}{\partial z^2}}_{\text{Diffusion}} + \underbrace{\frac{1}{(1 - \varepsilon_B)} \cdot \sum_{j|f}^3 v_{i,j} \cdot N_j(t, z)}_{\text{Reaction}} \quad (8)$$

where  $c_i$  is the gas concentration in the reactor ( $\text{H}_2$  or  $\text{H}_2\text{O}$ ),  $u$  represents the velocity of the gas,  $h$  is the height of the reactor and  $D_B$  is the axial dispersion coefficient. In the term describing the chemical reaction,  $v$  is the stoichiometric coefficient of the  $i$ -th gas species of the  $j$ -th reaction while  $\varepsilon_B$  is the void degree in the bed. Finally, the sum of the reductive contributions ( $N_j$ ) must consider the number of active reaction fronts.

The boundary conditions of the system of partial differential equations were defined at the reactor inlet ( $z = 0$ ) and at the outlet ( $z = 1$ ):

$$\frac{\partial c_i(t, z)}{\partial z} \Big|_{z=0} = c_{\text{bulk}, i} \quad \frac{\partial c_{\text{H}_2}(t, z)}{\partial z} \Big|_{z=1} = 0 \quad (9)$$

### 2.2.2. Numerical Methods

The mathematical model was developed in MATLAB 2022 by solving the system of partial differential equations, setting 50 grid points for the axial dimensionless coordinates of the reactor. The numerical method used is the finite difference method, which is based on backward differentiation formulas.

### 3. Results

In this work, an intensive simulation study was conducted to assess the responsiveness of the developed mathematical model using kinetic parameters reported in the literature. As an example, Figure 2 shows the main results from a simulation conducted at 600 °C, total gas volume flow rate of 20 mL/min and  $H_2/Ar$ .

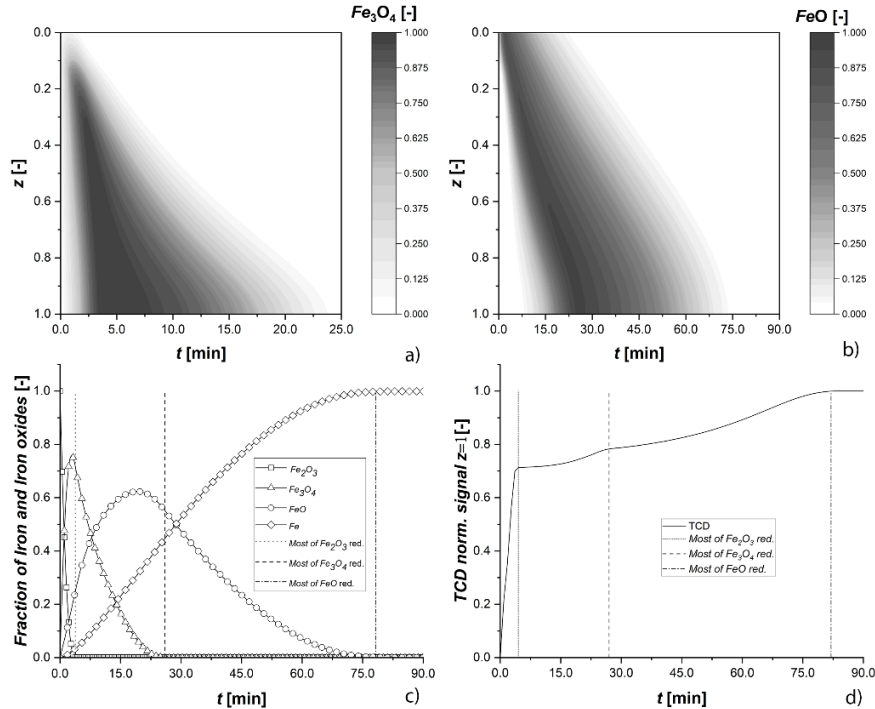

Figure 2. Axial profiles over time of the oxides  $Fe_3O_4$  (a) and  $FeO$  (b). Simulated overall fractions of the oxides and iron over time (c). Simulated TCD signal from off-gas composition (d).

The contour diagrams in Figures 2a and 2b show the axial profiles of the  $Fe_3O_4$  and  $FeO$  fractions in the particles over time, respectively, while Figure 2c shows the overall composition of the system. The reduction of  $Fe_2O_3$  is seen to be completed extremely rapidly, promoting the formation of high amounts of  $Fe_3O_4$  throughout the reactor after only a few minutes. Close to the entrance of the reactor ( $z=0$ ), magnetite does not accumulate in large quantities due to its rapid reduction to wustite, but near the end of the reactor ( $z=1$ ) its accumulation and depletion are considerably slower. The reasons lie in the high consumption of  $H_2$  by the reduction in the overlying areas of the bed and the resistance to intra- and inter-particle transport. Due to hydrogen starvation, the amount of  $H_2$  reaching the lower part of the reactor does not provide the driving force required to reduce the oxides. For this reason, about 25 minutes are required to complete the reduction of  $Fe_3O_4$ . The reaction of  $FeO$  to iron turns out to be the slowest: at the reactor inlet a complete reduction of the particles is observed within about 30 minutes, but close to the outlet the time required is more than doubled. This reveals the impact of the reactor bed height on the overall reaction time. Figure 2d shows a (normalized) TCD signal calculated based on the simulated off-gas composition ( $H_2$ ,  $H_2O$  and  $Ar$ ). This was found to show very many common features with the TCD signals measured in the experiments. Therefore, the objective of forthcoming work is to estimate kinetic parameters of the model by fitting it to the empirical TCD curves. However, the parameter estimation will

not be undertaken until data from a more extensive set of reduction experiments will be available.

#### 4. Conclusions

In this work, an in-depth modeling study was conducted to develop a model capable of describing the entire reductive process of a hematite bed exerted to hydrogen-containing gas. For this purpose, the sensitivity of the model to the variation of several structural parameters was assessed. The acquisition of accurate experimental data using the experimental system make it possible to estimate kinetic parameters of the individual reaction steps, which is the focus of forthcoming work.

## Abstract

Mechanistic models are commonly used in wastewater treatment systems based on microalgae-bacteria consortia to study microalgae-bacteria interactions and for design and control purposes. Generally, in the proposed mathematical models, the parameters concerning the activity of bacteria and microalgae are obtained through calibration or parameter estimation. Microalgae-bacteria models frequently involve many nonlinear differential equations and parameters, which creates difficulties with the optimization for parameter estimation, resulting in non-optimum convergence in some cases. This work deals with formulating the optimization problem in the parameter estimation context. The goal is to propose an improved approach for parameter estimation when several outputs and parameters are involved in the optimization problem. The proposed approach solves a series of increasing-complexity optimization problems to estimate process parameters gradually, avoiding convergence problems.

**Keywords:** Modeling, Parameter Estimation, Optimization, Wastewater treatment.

## 1. Introduction

Microalgae-based technologies for wastewater treatment have received a renovated interest in the last years in the context of resource recovery and circular economy (Muñoz and Guieysse, 2006). The increasing number of microalgae-based applications has contributed to the development of new models for studying the main processes, factors, and variables affecting microalgae growth in different cultures media, including wastewater (Solimeno, Gómez-Serrano and Ación, 2019), (Casagli *et al.*, 2021). Generally, in microalgae-bacteria models, model parameters are obtained through calibration or parameter estimation (Solimeno, *et al.*, 2017), (Casagli *et al.*, 2021).

The main goal of this study is to propose an improved approach for parameter estimation when several outputs and parameters are involved in the optimization problem. The proposed approach solves a series of increasing-complexity optimization problems to estimate process parameters gradually, avoiding convergence problems. The proposed approach represents an alternative to dealing with large optimization problems in parameter estimation, which are common in these systems. Parameter estimation via dynamic optimization is realized in each optimization step to fit simulated outputs to

experimental data. This methodology has been tested in a photobioreactor for wastewater treatment, in which processes concerning the activity of microalgae and bacteria, the influence of sunlight and nutrients concentration in the growth of microorganisms, chemical equilibrium reactions, and transfer of gases to the atmosphere are involved. Parameter estimation has been performed in a four-step optimization sequence. The first optimization step involves only two system outputs and five parameters. Finally, five model outputs were considered in the optimization problem: Total Suspended Solids (TSS) concentration, dissolved Total Organic Carbon (TOC) concentration, dissolved Inorganic Carbon (IC) concentration, dissolved ammonium concentration, and dissolved oxygen (DO) concentration. Simulation results show that model outputs matched with experimental data. The proposed optimization approach results in a better fit between experimental and simulated data and lower convergence time compared to the whole optimization problem.

## 2. Methodology for parameter estimation

The proposed approach solves a series of increasing-complexity optimization problems to estimate process parameters gradually, avoiding convergence problems. The idea is first to formulate one easier parameter estimation problem involving a subset of system outputs and parameters, replacing the other outputs variables with their experimental values, and then use these estimated values as a starting point for the next step of the optimization problem. The approach is oriented to increase the sub-set dimension until all the system outputs are being included in the optimization problem. The sub-sets selection is performed based on sensitivity analysis. Parameter estimation via dynamic optimization is realized in each optimization step to fit simulated outputs to experimental data.

This methodology has been tested in the photobioreactor for wastewater treatment used in the anoxic–aerobic algal–bacterial photobioreactor configuration with biomass recycling described in (Alcántara *et al.*, 2015). The anoxic reactor model and the settler model of this facility were described in (Bausa *et al.*, 2021, 2022). The data used in this study corresponded with 47 days of experimentation, these data were used for parameter estimation and model validation. In this work, the model BIO\_ALGAE 2 (Solimeno, Gómez-Serrano and Ación, 2019) has been used to describe the photobioreactor. The modeling and simulation of the photobioreactor are coded in dynamic simulation software PROOSIS® (EA International, 2022).

### 2.1. Sensitivity analysis

Previous to parameter estimation, the sensitivity analysis was conducted to identify the parameters with the greatest impact on the model outputs. For this purpose, a subset of the most influential parameters on model outputs was analyzed.

Sensitivity analysis was carried out using PROOSIS®. The results of sensitivity analysis indicated that model outputs are especially sensitive to the maximum specific growth rate of microalgae ( $\mu_{\text{ALG}}$ ) and heterotrophic bacteria ( $\mu_{\text{H}}$ ); the decay rate of microalgae ( $k_{\text{death,ALG}}$ ) and heterotrophic bacteria ( $k_{\text{death,H}}$ ); and the gas-liquid mass transfer coefficients for ammonia ( $K_{\text{la,NH}_3}$ ), oxygen ( $K_{\text{la,O}_2}$ ), and carbon dioxide ( $K_{\text{la,CO}_2}$ ). These decision variables agree with decision variables used in other publications on the topic (Casagli *et al.*, 2021), (Solimeno *et al.*, 2017).

#### 2.1.1. Sensitivity analysis as a guide to sub-sets selection

Results of sensitivity analysis are used here also as a guide to determine the best selection of groups of model outputs to consider. In addition, prior knowledge of system dynamic should be considered.

In the first step of the optimization problem, two model outputs were considered: TSS concentration and DO concentration. The TSS concentration is related to many of the processes of the model and its value depends on the concentration of all particulate components in the photobioreactor. Furthermore, DO concentration is involved in many of the processes concerning to microalgae and bacteria activity and mass transfer processes. Both model outputs depend mainly on the maximum specific growth rate of microalgae ( $\mu_{ALG}$ ), the decay rate of microalgae ( $k_{death,ALG}$ ), and the mass transfer coefficient for oxygen ( $K_{la,O_2}$ ).

Inorganic carbon is included as model output in the second step of the optimization. Microalgae use carbon dioxide as a carbon source for growth. As expected,  $\mu_{ALG}$  is the parameter with the greatest influence on IC concentration. Also, inorganic carbon is highly affected by the gas-liquid mass transfer coefficient for carbon dioxide ( $K_{la,CO_2}$ ).

In the third step, TOC concentration is also considered as model output. In microalgae-bacteria processes, heterotrophic bacteria oxidate the organic matter present in the wastewater, for that reason TOC concentration is mainly affected by the maximum specific growth rate ( $\mu_H$ ) and the decay rate of heterotrophic bacteria ( $k_{death,H}$ ).

Finally, dissolved ammonium concentration is included as model output in the fourth step. Ammonium concentration is mainly affected by  $\mu_{ALG}$ ,  $k_{death,ALG}$ , and the mass transfer coefficient for ammonia ( $K_{la,NH_3}$ ). In order to reduce the size of the vector of parameters, mass transfer coefficients for ammonia and carbon dioxide were expressed as a function of the oxygen one (1) (Casagli *et al.*, 2021).

$$\frac{K_{la,j}}{K_{la,O_2}} = \left(\frac{D_{Sj}}{D_{O_2}}\right)^{0.5} \quad (1)$$

where  $D_{Sj}[\text{m}^2\text{s}^{-1}]$  is the diffusivity coefficient for the gas  $j$ .

## 2.2. Parameter estimation

In this work, the fair function estimator (Huber, 2011) is used as a robust objective function  $J$  in the parameter estimation problem. Unlike Least Square Method, the fair function estimator reduces the effect of outliers, thus making it more robust in nature.

Dynamic optimization problem is represented by (2):

$$\min_{\hat{\theta}} J(\hat{\theta}, \theta) = \sum_{i=1}^n c^2 \left[ \frac{|\varepsilon_j|}{c} - \log \left( 1 + \frac{|\varepsilon_j|}{c} \right) \right] \quad (2)$$

Subject to restrictions (3) and (4)

$$\frac{dx(t)}{dt} = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t) \quad (3)$$

$$\hat{\mathbf{y}}(t) = \mathbf{g}(\mathbf{x}(t), \mathbf{u}(t), \boldsymbol{\theta}, t) \quad (4)$$

$$\underline{\boldsymbol{\theta}} \leq \hat{\boldsymbol{\theta}} \leq \bar{\boldsymbol{\theta}}$$

Where  $\varepsilon_j = (y_j - \hat{y}_j) / \sigma_j$  represents the error between available process measurements ( $y$ ) and their estimated values ( $\hat{y}$ ) limited between user-defined minimum and maximum values,  $c \in \mathbb{R}^+$  is a user defined fitting parameter to tune the slope for large residues, and  $\sigma$  is the standard deviation of experimental data. The approach to solving a parameter estimation problem in terms of optimization considers that for each value of the vector of parameters  $\boldsymbol{\theta}$  (decision variables) the model provides one prediction of the system output  $\hat{\mathbf{y}}(\boldsymbol{\theta})$  in each experiment. The same sequence of process inputs  $\mathbf{u}(t)$  is applied to the model. For each sample time  $t$ , the prediction error  $\varepsilon_j(t)$  is an indicator of model goodness. Fig. 1 represents the estimation procedure in sequential optimization context.

**Figure 1.** Estimator in sequential optimization

The dynamic optimization problem for the start-up optimization can be converted into a nonlinear programming (NLP) problem via control vector parameterization technique and a proper procedure for computing the cost function. In this work, the SNOPT nonlinear programming algorithm has been used in the PROOSIS® dynamic simulation environment to solve the optimization problem.

Parameter estimation results for each optimization step were provided in Table 1. Initial values for parameter estimation in Step 1 and decision variables ranges for optimization (Table 1) were defined in agreement with previous results reported in the literature.

**Table 1.** Values of estimated parameters in photobioreactor

Parameter	Value				Limits for Optimization
	Step 1	Step 2	Step 3	Step 4	
$\mu_{\text{ALG}}$ [ $\text{d}^{-1}$ ]	1.627	0.990	1.062	1.062	0.4 – 2
$k_{\text{death,ALG}}$ [ $\text{d}^{-1}$ ]	0.101	0.050	0.050	0.050	0.05 – 0.21
$\mu_{\text{H}}$ [ $\text{d}^{-1}$ ]	1.656	1.000	1.210	1.211	1 – 6
$k_{\text{death,H}}$ [ $\text{d}^{-1}$ ]	0.895	0.900	0.900	0.900	0.12 – 0.9
$K_{\text{la, O}_2}$ [ $\text{d}^{-1}$ ]	13.081	4.000	4.000	4.000	4 – 30

### 3. Results

In each step of the optimization problem, data from first 30 days were used for parameter estimation. Validation was performed using data from days 30 to 47. Figures 2 to 6 show simulation results of Step 4.

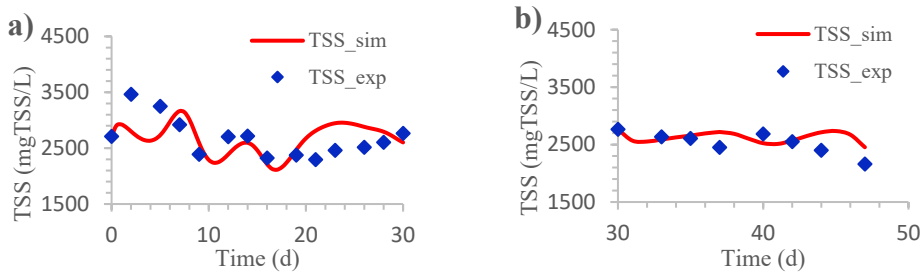

Fig. 2 present simulation results for the concentration of TSS. Fig. 2a) and 2b) represent data set used for parameter estimation and for validation, respectively. Although some discrepancies are observed in transient behavior prediction for TSS concentration, simulated average values are closely with experimental results.

Fig. 3 show simulation results for the dissolved oxygen concentration ( $S_{\text{O}_2}$ ). Fig. 3a) and 3b) represent data set used for parameter estimation and for validation, respectively.

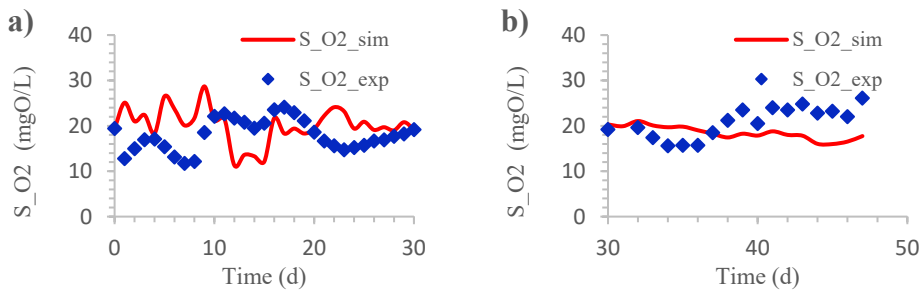

Fig. 4 and Fig. 5 presents simulation results for the Inorganic Carbon concentration and Total Organic Carbon concentration, respectively. Fig. 4a) and 5a) represent data set used for parameter estimation. Fig. 4b) and 5b) represent data used for model validation.

Fig. 6 show simulation results for the dissolved ammonium concentration ( $S_{\text{O}_2}$ ). Fig. 6a) and 6b) represent data set used for parameter estimation and for validation, respectively.

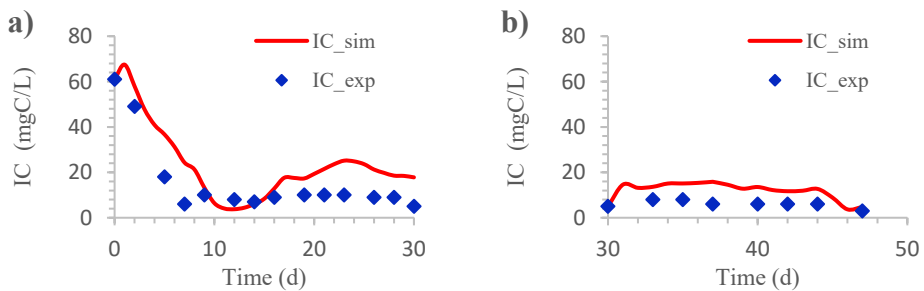

The model was effective in reproducing dynamic behavior of different measured variables.

#### 4. Conclusions

Parameter estimation via dynamic optimization was realized in four optimization steps. The proposed optimization approach results in a better fit between the experimental and simulated data, and lower convergence time with respect to the optimization problem statement considering all the system outputs from the beginning. Future work is oriented to design state-observers to estimate non-measurable variables.

## Abstract

In complex real refinery systems, it is essential to find an optimal plan in a short time to maintain operations' efficiency. An effective tool for industrial use in refinery crude oil scheduling is still lacking. The aim of this study is to develop an optimization tool to support efficient decision-making by ensuring the stability of operations and considering economic profit. An event-based continuous-time Mixed Integer Linear Program is developed to handle crude oil operations from vessels to crude distillation units as well as to satisfy product demands. This new formulation describes real-world operational applications of the TUPRAS Refinery.

**Keywords:** Crude oil operations, Short-term scheduling, Mixed-integer linear programming, Optimization.

## 1. Introduction

In the literature, several approaches have been proposed to handle the management of crude oil scheduling. The early approaches proposed by Shah (1996) and Lee et al. (2002) focused on discrete-time representation. However, recently, continuous-time representation has received great attention since it reduces complexity and problem size. Yadav and Shaik (2012) proposed a state-task-network approach using event-based continuous-time representation to manage crude oil operations. In this study, a similar approach is implemented in a complex petroleum refinery. Therefore, the discrete-time approach model, developed by Dologlu et al. (2022), has been modified as a continuous model approach to better reflect the refinery. Unlike the discrete model, many new features have been added in the continuous-time approach model, such as tank rest times, the amount of crude oil remaining in the pipe at the beginning and after the unloading, the unloading of different crude oils from the same vessel, and the decision of crude oil to be selected in case more than one crude oil arrives on the same day in the plan.

## 2. Model Formulation and Problem Definition

Similar to Dologlu et al. (2022), TUPRAS Refinery including one docking station, 12 tanks and 2 Crude Distillation Units (CDUs) whose structure is illustrated in Fig. 1 is studied in this paper. During a given planning horizon, a vessel arrives at the docking station and different types of crude oil are unloaded from vessel into tanks through pipes. Finally, the appropriate crude oil mixtures in the tanks are charged into the CDUs. Before charging operations, the crude oil mixtures in the tanks must meet the quality

requirements. Moreover, about 50 types of crude oil reach and are processed at the refinery. Having too many types of crude oil can lead to operational difficulties for processing in CDUs due to their specific properties. In addition, since the tanks are not dedicated to a single operation and all the unloading, transfer and charging operations can be carried out in all tanks, the scheduling problem becomes more complex.

Figure 1. An overview of crude oil operations

The system addressed includes  $i \in I$  crude oil tanks and  $h \in H$  crude oil types. Four main operations of the crude oil system are described here as tasks under  $a$  set, and the four subsets are:  $k(a)$ ,  $ar(a)$  and  $as(a)$  for unloading, transfer and charging tasks, respectively. Crude oils' descriptive properties such as American Petroleum Institute (API) and Sulfur are in the  $p \in P$  set. Over the planning horizon,  $k$  vessels arrive at the system as well as operations take place along a chain of  $n$  events. The set of arriving crude oil types is  $K_h$  and  $T_k$  is the set of tanks to which vessel  $k$  can be unloaded. For simplicity, unloading operations are set to specific events.  $nk'$  and  $nk''$  are the set of unloading events, which is for the main unloading and for the remaining part in the pipe, respectively. The following data is used for scheduling the operations: (1) scheduling time horizon,  $PH$ ; (2) arrival time of vessels,  $KT_{k,t}$  (hr); (3) amount of arriving crude oil vessels,  $KV_k$  ( $m^3$ ); (4) demurrage  $DM_k$  (\$/hr) and lay time of vessels  $LT_k$  (hr); (5) crude oil properties  $PR_{h,p}$ ; (6) Tank properties (min. & max. capacity of tanks,  $LC_{ih}$  and  $UC_{ih}$ ; tank rest times after unloading and transfer,  $R$ ); (7) Initial tank volume and compositions,  $VI_{h,i}$  ( $m^3$ ); (8) bounds on the flowrates of the streams for unloading ( $FU_{ih}$ ), transfer ( $FT_a$ ), and charging ( $FC_{as}$ ). Additional parameters are required for problem formulation.  $B_h$  is the set for crude oils that cannot mix with each other. Besides, since the rest time applies only to the tank that receives a transfer,  $A_{ps}$  and  $A_{ng}$  parameters are used to separate receiving and sending transfer tanks for a transfer operation, respectively. Moreover, there are two other vessel types; the first is the optional crudes that planners must choose one out of two or three different crude oil types. There may be more than one optional crude in a planning period, so they were handled in groups.  $GN_k$  is for the group numbers,  $O_i$  is the set of all optional crudes and  $O_l$  is the different types of crude in group  $l$ . Second is the vessels carrying two or three different crude oils and all of them should be unloaded sequentially.  $S_a$  is the set of these concurrent crudes.  $SF_k$  specifies the ones that are not the last one in the unloading sequence so the remaining pipe volume ( $VP$ ) of them is not going to be planned separately since they will be unloaded one after another and  $by_k$  parameter takes value 1 for them. To introduce the limitations for charging operations, the related parameters are set as: The minimum charging hours for a charging task,  $MH$ . Also, the CDUs have minimum-maximum API and maximum Sulfur limits,  $LA_j$ ,  $UA_j$  and  $US_j$ , respectively. The described problem is formulated in Mixed-Integer Linear Programming (MILP) with event-based continuous time representation with the assumption of perfect mixing in the tanks. The optimum values of the following decision variables are determined to minimize the demurrage cost of vessels: (1) the start and end times of all operations,  $s_{a,n}$  and  $f_{a,n}$ ; (2) the

start and end times of operations in tanks,  $ts_{n,i}$  and  $tf_{n,i}$ ; (3) the start and end times of unloading and transfer operations,  $rs_n$  and  $rf_n$ ; (4) the total volume of tanks,  $vt_{i,n}$ , the volume of components in the tanks,  $v_{i,h,n}$ ; (5) the amount of crude oil that flows from one unit to another in unloading,  $bk_{k,n,i}$ , transfer,  $bh_{ar,n,h}$ , charging,  $bs_{as,n,h,i}$ ; (6) delay time of vessel unloading,  $g_k$ ; (7) total amount of flowing,  $b_{a,n}$ . Binary variables for operational decisions are also defined.  $w_{a,n}$  shows if a task is assigned to an event. It also applies to all of the operations in specific,  $wl_{k,n,i}$ ,  $ws_{as,n,i}$ ,  $wtb_{k,n,i}$  for unloading, charging and unloading of the remaining crude in the pipe, respectively.  $w_{k,n}$  represents whether a vessel is unloaded and  $wb_{k,n}$  is the same for unloading the crude in the pipe. The selection of optional crude oils is represented by  $q_k$ .  $e_{n,i}$  shows whether the volume in the tank is above the minimum capacity, and  $t_{n,i,h}$  shows whether a crude oil type exists in a tank.

The objective function is the minimization of the demurrage cost of vessels, Eq. (1). Tank components balance, total tank volume and capacity limits are given in Eqs. (2-4), respectively. The calculation of processed volumes at each event for transfer and charging tasks are handled in Eqs. (5a-b) and for unloading is handled in two different equations for the pipe part and the main part of the crude, Eqs. (6a-b). Eqs (7a-c) guarantee that if any flow occurs at any event, then the binaries take value 1 where M refers to a big number. In Eqs. (8a-10c), timing and sequencing rules are handled for each of the tasks. For continuous operation of CDUs, it is ensured that charging starts from the beginning and total operation time of each CDU should be equal to the time horizon  $PH$ , Eqs. (11a-b). Besides, since transfer operations are not preferred, they are eliminated in Eq. (12).

$$Cost = \sum_k g_k * DM_k \quad (1)$$

$$v_{i,h,n} = v_{i,h,n-1} + \sum_k bk_{k,n,i} + \sum_k wtb_{k,n,i} * VP + \sum_{ar \in A_{ps}} bh_{ar,n,h} - \sum_{ar \in A_{ng}} bh_{ar,n,h} - \sum_{as} bs_{as,n,h,i} \quad \forall n \geq 2, n'_k, n''_k, h \in K_h, i \in T_k \quad (2)$$

$$vt_{i,n} = \sum_h v_{i,h,n} \quad \forall n, i \quad (3)$$

$$LC_i \leq vt_{i,n} \leq UC_i \quad \forall n, i \quad (4)$$

$$FT_{ar} * (f_{ar,n} - s_{ar,n}) = b_{ar,n} \quad \forall ar, n \quad FC_{as} * (f_{as,n} - s_{as,n}) = b_{as,n} \quad \forall as, n \quad (5a,5b)$$

$$f_{k,n} - s_{k,n} = \sum_i wtb_{k,n,i} * \frac{VP}{FU_i} \quad \forall k, n'_k \quad f_{k,n} - s_{k,n} = \sum_{i \in T_k} \frac{bk_{k,n,i}}{FU_i} \quad \forall k, n'_k \quad (6a,6b)$$

$$b_{ar,n} \leq M * w_{ar,n} \quad \forall ar, n \quad b_{as,n} \leq M * w_{as,n} \quad \forall as, n \quad b_{k,n} \leq M * w_{k,n} \quad \forall k, n'_k, n''_k \quad (7a,7b,7c)$$

$$f_{k,n} = s_{k,n} \quad \forall k, n \quad f_{k,n} \geq s_{k,n} \quad \forall k, n'_k, n''_k \quad s_{k,n} \geq f_{k,n-1} \quad \forall k, n \quad (8a,8b,8c)$$

$$f_{ar,n} \leq s_{ar,n} + 60 * 24 * w_{ar,n} \quad \forall ar, n \quad f_{ar,n} \geq s_{ar,n} \quad \forall ar, n \quad s_{ar,n} \geq f_{ar,n-1} \quad \forall ar, n \quad (9a,9b,9c)$$

$$f_{as,n} \leq s_{as,n} + 60 * 24 * w_{as,n} \quad \forall as, n \quad f_{as,n} \geq s_{as,n} \quad \forall as, n \quad s_{as,n} = f_{as,n-1} \quad \forall n > 1, as \quad (10a,10b,10c)$$

$$\sum_n b_{as,n} \geq FC_{as} * PH * 24 \quad \forall as \quad s_{as,n} = 0 \quad \forall n = 1, as \quad (11a,11b)$$

$$w_{ar,n} = 0 \quad \forall ar, n \quad (12)$$

Eq. (13) ensures that all the volume of vessel should be unloaded except the part in the pipe. The main unloading and pipe unloading for each of the vessels are assigned to an event in Eqs. (14a-b). Eqs. (15a-b) state the same condition for optional crudes for the one that is chosen. If there is any unloading in an event, then the binary related to the tank involving also takes the value 1 (Eqs. (16a-b)). Eq. (17) guarantees that one of the crude oils must be selected for each of the optional crude oil vessel groups. Unloading flow boundaries are in Eqs. (18a-b). The unloading can start only after the arrival of vessel and same for optional crudes (Eqs. (19a-b)). In Eqs. (20a-b), the unloading delay time subject

to demurrage cost is calculated for both types of vessels. Eq. (21) ensures that unloading of remaining crude from the previous vessel should start after the next vessel's arriving. After the pipe crude, the main part of the next vessel should be unloaded immediately (Eq. (22)). Vessels are unloaded sequentially and the concurrent crudes in a vessel are unloaded repeatedly, Eqs. (23-24). Eqs. (25a-b) state that the crude in the pipe should be unloaded to the set of tanks  $T_k$  in which the next vessel can be unloaded. Lastly, Eqs. (26a-28b) are about sequencing unloading and transfer operations.

$$\sum_{i \in T_k} bk_{k,n,i} = (KV_k - (VP * (1 - by_k))) * w_{k,n} \quad \forall k, n'_k \quad (13)$$

$$wb_{k,n} = 1 \quad \forall k \notin O_t, n'_k \quad wk_{k,n} = 1 \quad \forall k \notin O_t, n'_k \quad (14a,14b)$$

$$wb_{k,n} = q_k \quad \forall k \in O_t, n'_k \quad wk_{k,n} = q_k \quad \forall k \in O_t, n'_k \quad (15a,15b)$$

$$\sum_{i \in T_k} wt_{k,n,i} \leq w_{k,n} * I \quad \forall k, n'_k \quad \sum_i wtb_{k,n,i} = wb_{k,n} \quad \forall k, n'_k \quad (16a,16b)$$

$$\sum_{k \in O_l} q_k = 1 \quad \forall l \quad (17)$$

$$bk_{k,n,i} \leq M * wt_{k,n,i} \quad \forall k, n'_k, i \in T_k \quad bk_{k,n,i} \geq VP * wt_{k,n,i} \quad \forall k, n'_k, i \in T_k \quad (18a,18b)$$

$$s_{k,n} \geq KT_k \quad \forall k \notin O_t, n'_k \quad s_{k,n} \geq KT_k * q_k \quad \forall k \in O_t, n'_k \quad (19a,19b)$$

$$g_k \geq f_{k,n} - KT_k - LT_k \quad \forall k \notin O_t, n'_k \quad g_k + 24 * PH * (1 - q_k) \geq f_{k,n} - KT_k - LT_k \quad \forall k \in O_t, n'_k \quad (20a,20b)$$

$$s_{k,n} + GN_k * 24 * PH * (1 - q_k) \geq KT_{k+1} - GN_{k+1} * 24 * PH * (1 - q_{k+1}) \quad \forall k \in K_b, n'_k \quad (21)$$

$$f_{k,n} + GN_k * 24 * PH * (1 - q_k) \geq s_{k+1,n+1} - GN_{k+1} * 24 * PH * (1 - q_{k+1}) \quad \forall k \in K_b, n'_k \quad (22)$$

$$s_{k,n} - GN_k * 24 * PH * (1 - q_k) \leq rf_{n-1} \quad \forall k, n'_k \quad (23)$$

$$s_{k+1,n+1} \leq f_{k,n} \quad \forall k \in S_a, n'_k \quad (24)$$

$$wtb_{k,n,i} = 0 \quad \forall k \notin O_t, n'_k, i \notin T_k \quad wtb_{k,n,i} \leq (1 - q_{k+1}) \quad \forall k \in O_t, n'_k, i \notin T_k \quad (25a,25b)$$

$$rs_n \leq s_{ar,n} \quad \forall ar, n \quad rf_n \geq f_{ar,n} \quad \forall ar, n \quad (26a,26b)$$

$$rs_n \leq s_{k,n} \quad \forall k, n \quad rf_n \geq f_{k,n} \quad \forall k, n \quad (27a,27b)$$

$$rs_n \leq rf_n \quad \forall n \quad rs_n \geq rf_{n-1} \quad \forall n \quad (28a,28b)$$

Eqs. (29a, 30b) relates tank and crude oil-based flows to event-based flow amounts. Tank times for operations should be associated with task times and are handled in Eqs. (31a-b) for charging; in Eqs. (32-36) for unloading; in Eqs. (37-38b) for transfer operations considering the tank rest times. Events in the tanks should be sequenced, Eqs. (39a, 39b). Eq. (40) ensures no simultaneous input-output at any event. Simultaneous unloading and transfer operations are also not allowed due to using the same line, Eq. (41).

$$\sum_{i \in T_k} bk_{k,n,i} = b_{k,n} \quad \forall k, n'_k \quad \sum_i wtb_{k,n,i} * VP = b_{k,n} \quad \forall k, n'_k \quad (29a,29b)$$

$$\sum_h bh_{ar,n,h} = b_{ar,n} \quad \forall ar, n \quad \sum_i \sum_h bs_{as,n,h,i} = b_{as,n} \quad \forall as, n \quad (30a,30b)$$

$$\sum_k wt_{k,n,i} + \sum_k wtb_{k,n,i} + \sum_{ar \in A_{ps}} w_{ar,n} + 0.5 * \sum_{ar \in A_{ng}} w_{ar,n} + 0.25 * \sum_{as} ws_{as,n,i} \leq 1 \quad \forall n'_k, n''_k, i \in T_k \qquad (40)$$

$$w_{ar,n} = 0 \quad \forall n'_k, n''_k, ar \qquad (41)$$

If a tank's volume is above the minimum capacity,  $e_{n,i}$  takes value 1 meaning that there is a significant amount of crude that is to be considered for mixing rules, Eq (42). Mixing constraint is handled in Eq. (43). Operational rules for charging are considered as follows: The binding of related variables is given in Eq. (44). Minimum hours of charging for a charging task is handled in Eq. (45). API and Sulfur limitations are given in Eqs. (46-47).

$$e_{n,i} * UC_i \geq vt_{i,n-1} - LC_i \qquad \forall n > 2, i \qquad (42)$$

$$t_{n,i,h} + wt_{k,n,i} \leq (1 - e_{n,i}) + 1 \qquad \forall n'_k \geq 2, i, h \in B_h, k \in K_h \qquad (43)$$

$$\sum_h bs_{as,n,h,i} \leq ws_{as,n,i} * M \quad \forall as, n, i \qquad (44)$$

$$b_{as,n} \geq w_{as,n} * FC_{as} * MH \quad \forall n, as \qquad (45)$$

$$LA_{as} * \sum_i \sum_h bs_{as,n,h,i} \leq \sum_i \sum_h bs_{as,n,h,i} * p_{h,"API"} \leq UA_{as} * \sum_i \sum_h bs_{as,n,h,i} \quad \forall n, as \qquad (46)$$

$$\sum_i \sum_h bs_{as,n,h,i} * p_{h,"Sulfur"} \leq US_{as} * \sum_i \sum_h bs_{as,n,h,i} \quad \forall n, as \qquad (47)$$

### 3. Results and Discussions

The developed continuous-time model is applied for 14-days planning horizon that contains 5 vessels shipped 7 different types of crude oil, 2 CDUs, 12 tanks (2 tanks are in maintenance), including 13 crude oil types. The volume of vessels varies between 40,000 and 175,000 m<sup>3</sup> and the total volume of 5 vessels is about 535,000 m<sup>3</sup>. The MILP model results are shown in Fig. 2 for the first 10 days of the planning horizon.

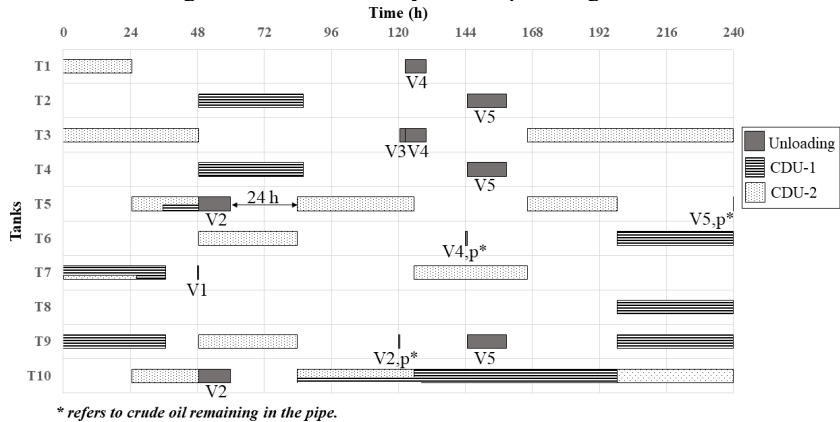

Figure 2. Gantt chart of optimal solution for first 10 days of planning period

Unlike the discrete model developed by Dologlu et al. (2022), in this model, a continuous charge flow is provided to the units. There is a 24-hour rest time in the tanks after unloading. For example, T5 was charged to CDU 24 hours after V2 unload to T5 was completed. The unloading of crude oil remaining in the pipe can be monitored. For example, V1 is the crude oil remaining in the pipe at the start of planning. Immediately after, V2 was unloaded. V3 and V4 are simultaneous incoming vessels and their unloading to the T3 tank appears to be sequentially scheduled. V2 vessel carries 2

different types of optional crude oil. The model made the decision of crude oil in line with the tank occupancy and contents, so as not leading to any demurrage cost.

The main motivation of this study is to compare the computational performance and behavior of models with different time approaches, such as discrete and continuous time, for the real refinery problem. To test the performance of discrete and continuous time models, four cases with different time horizons, 8-days, 14-days, 19-days, and 26-days were studied. All MILP models are executed in GAMS v 28.2.0 on an Intel(R) Xeon(R) Gold 6252 CPU 2.10 GHz machine with 12 GB of RAM using the CPLEX solver. In all cases, the objective function of minimizing the demurrage costs was used. The overall solutions of the four cases are presented in Table 1. When the results of the continuous time model are compared to the discrete time model, the number of constraints, variables, and binary variables is higher, so the model has a longer CPU time. This is because the constraints such as the rest time of the tanks and the evaluation of different unloading states, which were previously ignored in the discrete model, were added to the model to reflect the real refinery case, and the model became more complex. Thus, it is an expected result that the variables, constraints, and CPU time increase in the transition to the continuous model. In addition, as the planning period increased, the number of constraints and variables, and the CPU time increased accordingly for each model time approach.

**Table 1.** Comparison of discrete and continuous time model results

Scenario	The discrete-time approach model				The continuous-time approach model			
	1	2	3	4	5	6	7	8
Planning time horizon (day)	8	14	19	26	8	14	19	26
Number of constraints	781	1594	2382	3633	10977	16008	21101	23690
Number of variables	1440	2796	4046	5920	5178	7541	9960	11191
Number of binary variables	197	350	509	811	926	1306	1696	1888
CPU time (s)	0.28	0.50	2.28	5.98	10.03	149.36	551.80	1567.59

#### 4. Conclusion

In this paper, an event-based continuous time formulation is proposed to address the real-life problem of scheduling of crude-oil operations. Compared to the discrete time formulation, the continuous time formulation provides better production schedules as it reflects the operations of refinery with the added constraints and the continuous time setup. The computation time of the continuous time model increases as more event points are needed to solve refinery-scheduling problems over longer time horizons. Future research will focus on case-specific operational constraints and solving the non-linear problem when the tank contents are uniformly charged to the CDUs as a homogeneous mixture as well as accelerating the model solving time.

<sup>a</sup>*Department of Chemical and Biomolecular Engineering, UTC Institute for Advanced Systems Engineering, University of Connecticut, 159 Discovery Dr, Storrs, CT, 06269, USA. ([george.bollas@uconn.edu](mailto:george.bollas@uconn.edu))*

## Abstract

An advancement of the refined e-NRTL model (Bollas et al., 2008) is used for the modeling of osmotic and activity coefficients associated with aqueous multi-electrolyte systems, with an emphasis on electrolyte systems relevant to concentrated brine solutions. Binary interaction parameters associated with the ions in each electrolyte system are estimated from available activity and osmotic coefficient experimental data. Electrolytes studied are those common in brine solutions (e.g., Na<sup>+</sup>, K<sup>+</sup>, Li<sup>+</sup>, Mg<sup>2+</sup>, Ca<sup>2+</sup>, Cl<sup>-</sup>, SO<sub>4</sub><sup>2-</sup>). Integration of the thermodynamic model in the software package IDAES (Institute for the Design of Advanced Energy Systems), as a thermodynamic property module are presented, and shown to predict various thermodynamic properties (such as activity and osmotic coefficient, and vapor pressure) at higher molalities and temperature ranges. Accurate prediction of solution thermodynamics in brines, then, targets the accurate modeling of brine water treatment systems.

**Keywords:** Concentrated brines, electrolyte thermodynamics, water treatment

## 1. Introduction

Brine solutions are encountered in many natural and industrial processes. Because of their detrimental effects, these highly concentrated salt solutions are rendered dangerous to be disposed of directly to the environment. High salinity in liquid streams is also the major cause of scaling in pipes and equipment. Thus, there is a need to model and develop energy-intensive desalination technologies to increase the reuse of saline waters. Exploration of novel and advanced brine management options is challenging because of the lack of steady state and dynamic simulators that can accurately capture the thermodynamics and kinetics that dominate separation efficiency and processing options. Uncertainty and the high cost associated with the deployment of these systems on a larger scale make modeling a necessity before expensive piloting. The challenge in designing brine wastewater treatment technologies arise because of the high concentration of ions, which when in mixtures are difficult to predict in terms of their impact on the macroscopic properties of the solution. Comprehensive and precise thermodynamic models need to be developed that can accurately predict various thermodynamic properties associated with each ion in the system, over a wide range of molality and temperature ranges.

Electrolyte mixtures are non-ideal even at very low temperature and pressure. To completely model the non-ideality of electrolyte solutions, long-range electrostatic interactions between ions and short-range ion dipole and non-electrostatic interactions should be taken into account. One of the most important thermodynamic properties, which not only quantifies the non-ideality of solutions involving electrolytes but also predicts other properties, is the mean ionic activity coefficient. Thus, it is fundamental to

have models that can accurately predict activity and osmotic coefficients, which can, then, be generalized to excess Gibbs free energy models and predict other solution properties, like enthalpy of mixing and heat capacity. Various activity coefficient models have been used to predict the non-ideal behavior of solutions. The most common of these are the e-NRTL model and its many extensions. The e-NRTL model was first developed for single salt, single solvent solutions. The Pitzer-Debye-Hückel equation was used to model the long-range interactions, while short-range interactions were modeled based on non-random two-liquid, local composition theory. Later, Chen & Evans (1986) modified the model for multi electrolyte systems. The thermodynamics of multi-electrolyte solutions differ largely from single electrolyte systems. Additional terms need to be considered when modeling non-ideality in multi-electrolyte aqueous systems, to cater to increased ions interaction. Besides water treatment, accurate electrolyte models are needed to simulate processes like geothermal energy production, hydraulic fracturing, thermochemical hydrogen production, and pharmaceutical processes (Chen, 2006).

Major ions responsible for salinity and scaling in aqueous solutions include:  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Li}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$ , and  $\text{CO}_3^{2-}$ . Studies have employed extensions and refinements of the e-NRTL model to binary, ternary and quaternary systems involving these ions. (Tanveer and Chen, 2016) developed a thermodynamic model for the aqueous  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$  quaternary system based on the symmetric e-NRTL model. Honarparvar et al. (2017) studied ternary and quaternary systems involving  $\text{Ba}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  using an e-NRTL-based model. The e-NRTL model was also studied for the system containing  $\text{Sr}^{2+}$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2-}$  ions by Honarparvar et al. (2018). Bhattacharia et al. (2015) performed thermodynamic modeling of the  $\text{KCl} + \text{H}_2\text{O}$  binary system, and the  $\text{KCl} + \text{NaCl} + \text{H}_2\text{O}$  ternary system using the e-NRTL model. In this paper, the refined e-NRTL model developed by Bollas et al. (2008) for multi-electrolyte solutions and improved later by Yang et al. (2023) for mixed solvent solutions is applied on 11 aqueous binary systems, with electrolyte concentrations up to their solubility limit, at 298.15 K. The electrolytes studied include three 1-1 electrolytes;  $\text{NaCl}$ ,  $\text{KCl}$ ,  $\text{LiCl}$ , four 2-1 electrolytes;  $\text{MgCl}_2$ ,  $\text{SrCl}_2$ ,  $\text{CaCl}_2$ ,  $\text{BaCl}_2$ ; three 2:1 electrolytes;  $\text{K}_2\text{SO}_4$ ,  $\text{Li}_2\text{SO}_4$ , and  $\text{Na}_2\text{SO}_4$ , and one 2-2 electrolyte,  $\text{MgSO}_4$ . Binary interaction parameters for each aqueous electrolyte were estimated from experimental data on activity and osmotic coefficients. The model predicts accurately the liquid phase non-idealities and through mean ionic activity and osmotic coefficients, providing sound thermodynamic basis for the modeling of process systems that involve brine solutions.

## 2. Thermodynamic Modeling Framework

The refined e-NRTL model used in this work is explained in detail in (Bollas et al. (2008) and Yang et al. (2023)). It expresses the excess Gibbs free energy of the electrolyte solution as a summation of long-range electrostatic contributions, accounting for the ion-ion interactions, and short-range interactions, accounting for local, ion-ion, ion-molecule and molecule-molecule interactions. The model of Yang et al. (2023) describes short-range interactions with a classic NRTL model, but it uses a thermodynamically consistent conversion of the Debye-Hückel equation to model long-range, electrostatic interactions. The short-range model requires two binary interaction parameters  $\tau_{ij}$  and  $\tau_{ji}$ , where  $\tau_{ij} \neq \tau_{ji}$ , and the non-randomness parameter  $\alpha$ . Classically, the value of  $\alpha$  is fixed to 0.2. Binary interaction parameters refer to water-electrolyte and electrolyte-electrolyte pairs, in the case of binary systems. In the case of ternary systems, two electrolytes sharing a common ion in an aqueous system will require six binary interaction parameters; four corresponding to the individual electrolyte-water pairs and two for the electrolyte-electrolyte asymmetric pairs. Other parameters that are treated as adjustable in the model

include the distance of closest approach of the original Debye-Hückel theory, and ionic hydration. Hydration is included to describe its effect on the local composition during the short-range equation formulation. To do this, the mole fractions in the e-NRTL model are replaced by the effective mole fractions of the hydrated solution. To predict the effect of water structure on its neighborhood, hydration numbers are allowed to have negative values. The model with constant hydration numbers can predict mean ionic activity and osmotic coefficients with accuracy at low concentrations. To consider the effect of decreased water activity at increased molality, the stepwise hydration equilibria theory was employed, which accounts for the decreased availability of water molecules as the solution ionic strength increases.

### 3. Methodology

#### 3.1. Thermodynamic Modeling of Binary Systems

The refined e-NRTL model was first implemented to model 11 aqueous binary systems which included two anions ( $\text{Cl}^-$ , and  $\text{SO}_4^{2-}$ ) and seven cations ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Li}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Mg}^{2+}$ , and  $\text{Ba}^{2+}$ ). The model was simultaneously fitted against experimental data from Robinson (1959) of activity and osmotic coefficient with their molality ranging up to the solubility limit of each solution studied, at 298.15 K and 1 atm. The objective function in the non-linear regression algorithm included both the activity and osmotic coefficients to improve model precision and fidelity. Pure component parameters including ionic radii, hydration indices, and effective molar volume were taken at the values estimated with the data of electrolyte solution data reported in Yang et al. (2023). The Average Absolute Relative Deviation (AARD) was calculated for each system.

Table 1: AARD of original e-NRTL, refined e-NRTL with constant hydration and refined e-NRTL model with stepwise hydration equilibria for binary systems relevant to brines.

#### 3.2. Thermodynamic Modeling of Ternary Systems

For the thermodynamic modeling of ternary systems, involving two electrolytes with a common ion in an aqueous solution, six binary interaction parameters are required, four corresponding to the binary systems involved and two corresponding to the electrolyte-electrolyte pair interactions. The binary interaction parameters corresponding to

electrolyte-water pair are fixed to the values fitted by the binary systems model. The electrolyte-electrolyte interaction parameters are, of course, unknown to the model, as these data have not been used in the fitting of binary systems. Commonly, it is reported that these parameters should be of negligible contribution to the model, especially for dilute solutions. However, this is not the case in highly concentrated brines. The electrolyte-electrolyte relevant binary parameters are, thus, fitted against available experimental data of activity and osmotic coefficients for the ternary system. As a first step, the constant hydration model was deployed. The stepwise hydration model will need to identify the affinity of individual ions of the same charge sign to hydration, which is the topic of on-going work. The hydration indices and the corresponding ionic volumes approximated using the binary system model are fixed (to the values obtain from the study of binary systems) during the fitting of parameters of ternary systems.

#### 4. Results

The AARD values of the original e-NRTL model, the refined e-NRTL model with constant hydration and the refined e-NRTL model with stepwise hydration equilibria for all the binary systems studied are provided in Table 1. The corrected Akaike Information Criterion ( $AIC_c$ ) and the Bayesian Information Criterion (BIC) were calculated for both the refined e-NRTL model and the original e-NRTL model. Both information metrics assess the quality of fit of each model and the potential of overparameterization. Lower values of  $AIC_c$  and BIC in the case of the refined e-NRTL model (5313.74 and 7320.13, respectively) compared to those of the e-NRTL model (20080.80 and 21714.84, respectively) indicate a good balance of goodness of fit. The large F-ratio also signifies a statistically good model. To visualize the accuracy improvement with the refined e-NRTL model, as well as the accuracy improvement of the two hypotheses of the impact and mechanism of hydration, the performance of the models is illustrated for three binary systems shown in Figs. 1-3. These correspond to activity and osmotic coefficients of represented 1-1, 1-2, 2-1 binary electrolyte systems, compared against measurements.

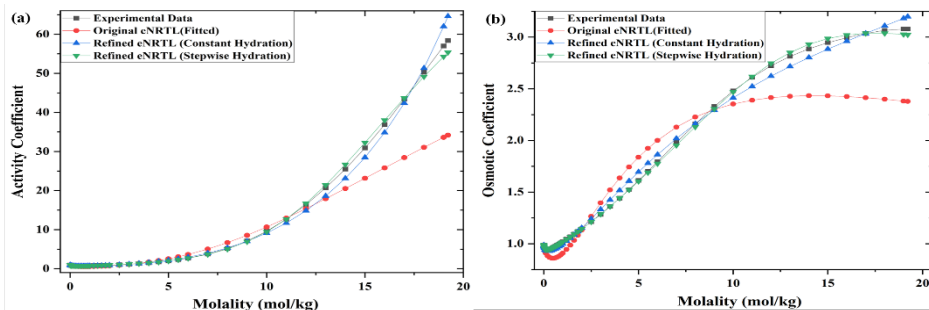

Figure 1: Comparison of the original e-NRTL, refined e-NRTL constant hydration, and refined eNRTL stepwise hydration model for the prediction of (a) activity coefficients of LiCl and (b) osmotic coefficient plot of LiCl.

Fig. 1 presents activity and osmotic coefficients of the LiCl + H<sub>2</sub>O binary system. For these results, the binary parameters of the original e-NRTL model were fitted with the same algorithm used in all other studies, with an objective function that incorporates both activity and osmotic coefficient data. It can be clearly seen that at lower molalities, activity coefficient predictions from all three models are similar and quite accurate. At molalities higher than of 5 mol/kg the stepwise hydration model shows clear superiority.

To further demonstrate the performance of the refined e-NRTL with constant and stepwise hydration assumptions, the Na<sub>2</sub>SO<sub>4</sub> + H<sub>2</sub>O and MgCl<sub>2</sub> + H<sub>2</sub>O binary systems are plotted in Figs. 2 and 3. For the case of Na<sub>2</sub>SO<sub>4</sub> + H<sub>2</sub>O, it can be observed that as the

concentration increases beyond 1 mol/kg, the difference between experimental data and the original e-NRTL model becomes significant, especially in the prediction of osmotic coefficients. However, the results of both the constant and stepwise hydration equilibria assumptions with the refined e-NRTL model are accurate. Activity and osmotic coefficient plots for the  $\text{MgCl}_2 + \text{H}_2\text{O}$  binary system predicted using all the three models are shown in Fig. 3. It can be observed from Fig. 3 that up to molality of 2 mol/kg activity and osmotic coefficients are predicted fairly well by all three models, but beyond that molality range, the stepwise hydration model fits the data best.

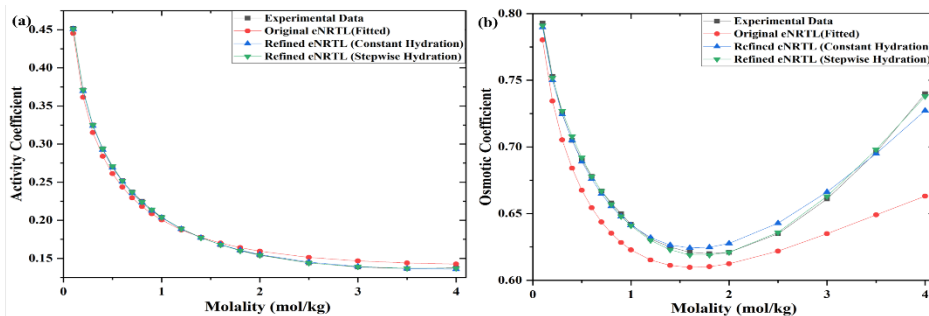

Figure 2: Comparison of the original e-NRTL, refined e-NRTL constant hydration, and refined e-NRTL stepwise hydration model for the prediction of (a) activity coefficient and (b) osmotic coefficient of  $\text{Na}_2\text{SO}_4$ .

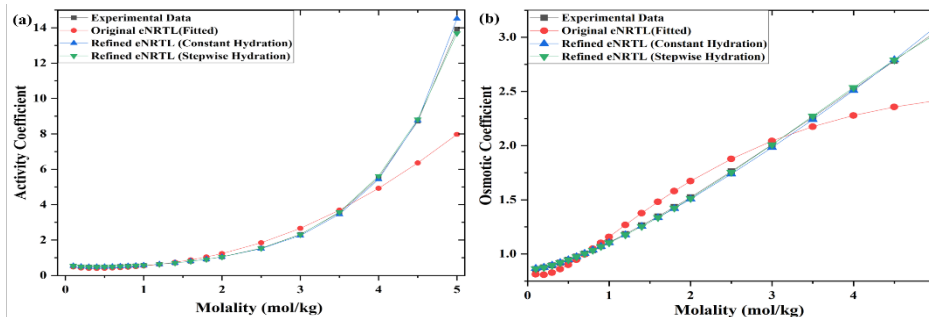

Figure 3: Comparison of the original e-NRTL, refined e-NRTL constant hydration, and refined eNRTL stepwise hydration model for the prediction of (a) activity coefficients and (b) osmotic coefficients of  $\text{MgCl}_2$ .

The ternary  $\text{NaCl-KCl-H}_2\text{O}$  system was studied as an example of ternary systems. Binary interaction parameters for the  $\text{NaCl-H}_2\text{O}$  and  $\text{KCl-H}_2\text{O}$  pairs remain the same for ternary system. The electrolyte-electrolyte binary interaction pairs were regressed against experimental osmotic coefficient data from Dinane et al. (2002). The binary interaction parameters for the  $\text{NaCl-KCl}$  aqueous system are summarized in Table 2. In Fig. 4, the corresponding predicted osmotic coefficient values are plotted against the experimental data. The agreement between model and experiment is very good, by just fitting the electrolyte-electrolyte binary interaction parameters.

## Conclusion

The refined e-NRTL model was used to model the thermodynamics of brine solutions. 11 binary aqueous systems involving the following ion;  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Li}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$  were studied and one  $\text{NaCl-KCl-H}_2\text{O}$  ternary system was studied for validation of the extrapolation ability of the binary models to mixtures of electrolytes. The binary interaction parameters were fitted against experimental data of activity and osmotic

coefficients of binary systems. The osmotic coefficients of the ternary system were predicted with fair accuracy. The simulation was performed on an Intel(R) Core(TM) i7-7700 processor with CPU of 3.60 GHz and 8.00 GB RAM. This thermodynamic model can be extended to predict other thermodynamic properties beyond the osmotic and activity coefficients presented here and at higher molalities. It is also being implemented in the user-friendly environment of IDEAS to develop open-source libraries of property models for highly concentrated aqueous and heterogeneous electrolyte solutions, embedded in block model libraries for processing and separations. These libraries are then intended to be utilized for process synthesis and intensification of brine treatment options.

## Abstract

Scenario generation methods constitute an important aspect towards efficient solution of Stochastic Programming (SP) problems and exploitation of big data. The ability of these methods to consistently provide scenario sets which guarantee stability on the solution of the stochastic programs is determinant of their performance. In this context, we present a modification of the existing Distribution and Moment Matching Problem (DMP) which is formulated as Mixed-Integer Linear Programming (MILP) model. The Nash bargaining approach is employed and the different statistical properties of the DMP are considered as players. Through this game-theoretic approach the impact of the user-defined parameters on the scenario generation procedure is investigated. Results from a capacity planning case study highlight the benefits of the proposed approach with respect to in-sample and out-of-sample stability.

**Keywords:** Scenario Generation; Stochastic Programming; Optimisation; Mixed-Integer Linear Programming (MILP); Nash equilibrium.

## 1. Motivation

Optimisation under uncertainty has emerged as a focal topic within the Process Systems Engineering (PSE) research agenda (Li & Grossmann, 2021; Charitopoulos et al., 2018). Existing mathematical frameworks can tackle optimisation problems under uncertainty for various degrees of risk aversion. In particular, risk-neutral Stochastic Programming (SP) takes advantage of scenario-based formulations to optimise the expected value of the problem over an assumed probability distribution. Recently, research interest has been directed towards the development of scenario tree generation (SG) or reduction approaches, which create a smaller and representative set of scenarios to efficiently solve computationally challenging stochastic programs. Among them, the optimisation-based SG techniques form an important category (Bertsimas & Mundru, 2022). Moment Matching Problem (MMP) is part of the latter and can generate a scenario tree by solving a statistical errors' minimisation problem (Høyland & Wallace, 2001). Recently, Bounitsis et al. (2022) proposed a Mixed-Integer Linear Programming (MILP) model for the Distribution and Moment Matching Problem (DMP), which was shown to overcome the so-called under-specification issues of the Nonlinear Programming (NLP) based counterparts (Calfa et al., 2014).

In this work, we present an extension to the work of Bounitsis et al. (2022) which aims to further enhance stability and performance of the SG framework, by mitigating the impact of the model's user defined parameters. A modification of the DMP MILP model is proposed, in which the Nash bargaining approach is used. The problem at hand is modelled as an MILP following a separable programming reformulation (Gjerdrum et al.

2001; Charitopoulos et al., 2020). Finally, the enhanced quality and stability of the optimisation-based SG methods are validated through bias, in-sample and out-of-sample tests (Kaut & Wallace, 2007).

The remainder of the article is organised as follows: in Section 2 a summary of the main theoretical aspects is conducted while the detailed methodology is outlined in Section 3. In Section 4, the proposed model is employed to evaluate its stability on a capacity planning case study. Finally, conclusions are drawn in Section 5.

## 2. Preliminaries and literature review

### 2.1. Stochastic Programming

In Stochastic Programming (SP) problems the uncertainty is modelled via a known discrete probability distribution. Two-stage stochastic programming (TSSP) is the most common version of stochastic programming problems, in which the uncertainty is revealed at one step. Optimisation problems under uncertainty can be reformulated as stochastic programs using discrete realisations for the uncertain parameters. These are also called scenarios ( $k$ ) and are specified by their values for the uncertain parameters ( $\xi_1, \dots, \xi_k$ ,  $k = \{1, \dots, K\}$ ) and corresponding probabilities of occurrence ( $p_1, \dots, p_k$ ,  $k = \{1, \dots, K\}$ ). TSSP optimises simultaneously the objective function of the first-stage decisions and the expected value of the second-stage costs, which is formulated as:

$$\mathbb{E}[Q(x, \xi)] = \sum_{k=1}^K p_k \cdot Q(x, \xi_k) \quad (1a)$$

Thus, the *deterministic equivalent problem* for the TSSP is given by Eq. (1b):

$$\begin{aligned} \min_{x, z_1, \dots, z_k} \quad & c^\top x + \sum_{k=1}^K p_k \cdot q_k^\top \cdot z_k \\ \text{s. t.} \quad & Ax \leq b \\ & T_k x + W_k z_k \leq h_k, \quad k = 1, \dots, K \\ & x, z_k \geq 0, \quad k = 1, \dots, K \end{aligned} \quad (1b)$$

In this formulation,  $k$  is the index of scenarios,  $x \in \mathbb{R}^n$  denotes the “here-and-now” decisions,  $z \in \mathbb{R}^m$  is the set of the “wait-and-see” decisions and the vector  $\xi = (q, T, W, h)$  contains the data (known or uncertain) of the second stage problem.

### 2.2. Scenario generation methods

In cases of either continuous distributions or a very large number of possible realisations of the uncertain parameters, scenario tree generation methods can be used to create a smaller in size set of scenarios for the uncertain parameters, with specific values and probabilities, which replaces the original uncertainty set for the solution of the TSSP.

#### 2.2.1. Distribution and Moment Matching Problem

Moment Matching Problem (MMP) for scenario tree generation was introduced by Høyland and Wallace (2001) and aims at the minimisation of the errors regarding the considered statistical properties between the original uncertain set and the final reduced set. A typical version of MMP accounts for first four statistical moments (i.e., mean, variance, skewness, kurtosis) and covariance between the parameters. The optimisation-based NLP formulation has been extended to simultaneously match the stochastic distribution of the uncertain parameters by minimising the errors regarding the empirical cumulative distribution function (ECDF) (Calfa et al., 2014). This problem is referred to as Distribution Matching Problem (DMP) and remains NLP. However, it may lack of

stability as it suffers from under-specification issues, in which case either a unique scenario is assigned to several nodes, or zero probabilities are assigned to some nodes.

Recently, both MMP and DMP have been reformulated as MILP problems by employing binary variables to indicate the selection of the scenarios from a known original scenario set (Kaut, 2021; Bounitsis et al., 2022). Regarding DMP, Bounitsis et al. (2022) proposed a scenario generation MILP model using  $L^1$  and  $L^\infty$  norms to minimise the errors regarding the statistical properties. The model was integrated into a framework with copula-based sampling and clustering techniques and its unified impact seems to lead to significant mitigation of the under-specification issues of the NLP model.

### 2.2.2. Stability assessment of scenario generation methods

Stability measures assess the performance of a scenario generation or reduction method by testing its capability to generate different trees which lead to consistent expected values. Considering multiple scenario trees,  $T_c$ , which lead to stochastic solutions  $\bar{x}_c$  of the scenario-based problem and omitting the notation for the “wait-and-see” variables, the in-sample and out-of-sample stability are achieved, if Eqs. (2)-(3) are true respectively (Kaut & Wallace, 2007):

$$f(\bar{x}_c; T_c) \approx f(\bar{x}_{c'}; T_{c'}) \quad (2)$$

$$f(\bar{x}_c; \xi) \approx f(\bar{x}_{c'}; \xi) \quad (3)$$

Regarding Eq. (3) a large reference tree  $R$  can be used as an approximation of the true stochastic process  $\xi$  in order to estimate the out-of-sample stability. Finally, bias is also an important measure for the evaluation of the quality of certain stochastic solutions  $\bar{x}$ :

$$B(\bar{x}) = f(\bar{x}; R) - \min_{x \in X} f(x; R) \quad (4)$$

Bias captures the error that fixed here-and-now decisions,  $\bar{x}$ , impose to the so-called full-space problem (FS) which is solved using the reference tree  $R$  (Kaut & Wallace, 2007).

### 2.3. Nash game-theoretic approach

According to Nash bargaining approach a fair solution for all players of a game can be achieved taking into consideration their initial position. Given a game with players  $t \in T$ , their corresponding objective functions and status quo points prior to joining the game (or generally a lower profit requirement point), denoted as  $\pi_t^{SQ}$ , then a fair solution point,  $\pi_t$ , can be achieved. The bargaining solution fairly contributes the payoff to the players obeying the axioms of Pareto optimality, symmetry, linear invariance, and independence of irrelevant alternatives. For a typical profit maximisation problem, the fair solution maximises the Nash product which is given by (Harsanyi, 1977):

$$\Phi = \prod_{t \in T} (\pi_t - \pi_t^{SQ})^{\alpha_t} \quad (5)$$

where  $\alpha_t$  is the negotiation power of each player  $t$ . Hence, a player  $t$  enters the game only if  $\pi_t \geq \pi_t^{SQ}$ , i.e., if the profit entering the game is greater than its status quo point.

However, the objective function of Eq. (5) is nonlinear and nonconvex leading to computationally challenging problems. An approximate linearisation of the Nash product based on a separable programming approach has been proposed by Gjerdrum et al. (2001). Initially, a convexification is conducted by employing a logarithmic transformation and then the concave Nash product is linearised via a piecewise linear function of  $g$  prespecified grid points. So, the linear approximation of the Nash product is:

$$\tilde{\Phi} = \sum_{t \in T} \sum_{g \in G} \alpha_t \cdot \ln(\tilde{\pi}_{tg} - \pi_t^{SQ}) \cdot \lambda_{tg} \quad (6)$$

where by defining SOS2 variables  $\lambda_{tg}$  and variables for the profit of player  $t$  at grid point  $g$ ,  $\tilde{\pi}_{tg}$ , then the profit of each player  $t$  can be estimated as:

$$\pi_t = \sum_{g \in G} \tilde{\pi}_{tg} \cdot \lambda_{tg} \quad \forall t \in T \quad (7)$$

$$\sum_{g \in G} \lambda_{tg} = 1 \quad \forall t \in T \quad (8)$$

### 3. Methodology and mathematical developments

In the recent study by Bounitsis et al. (2022), performance and stability assessment of the deterministic models were conducted for obtained stochastic solutions from scenario trees of “slightly different sizes” (King and Wallace, 2012). However, results in Bounitsis et al. (2022) indicated that even user-defined parameters of the formulation may affect stability of the deterministic models. In this work, this remark is investigated by conducting stability tests for varying values of user-defined weights of the objective function. Moreover, aiming to improve stability, a modification of the DMP MILP SG model is proposed. The Nash bargaining approach is employed in the terms of the objective function and a separable programming based linearisation of the objective function (Eqs. (6)-(8)) assists to preserve the MILP formulation of the problem. Overall, the modified model can replace DMP MILP in the SG methodology by Bounitsis et al. (2022), which includes the preliminary steps of: (i) statistical analysis of uncertain data, (ii) simulation of distributions, (iii) copula sampling of original scenarios, (iv) clustering. Proposed Nash reformulation of the DMP MILP model is presented for the  $L^\infty$ -norm-based formulation. Let us denote as  $i \in I$  the uncertain parameters and  $m \in M$  the considered statistical moments. Moreover, we introduce an index  $t \in T = \{SM, ECDF, COV\}$  for the terms of the objective function of the original model, which correspond to the players of the game theoretic approach. The model can be written as:

$$\max \sum_{t \in T, g \in G} \ln(\pi_t^{MAX} - \tilde{\pi}_{tg}) \cdot \lambda_{tg} \quad (9)$$

s. t. Eqs. (7)-(8) and

$$\pi_t = r_t^{MAX} \quad \forall t \in T \quad (10)$$

$$r_{SM}^{MAX} \geq W_{im}^{SM} \cdot (d_{im}^+ + d_{im}^-) \quad \forall i \in I, m \in M \quad (11)$$

$$r_{COV}^{MAX} \geq W_{ii'}^{COV} \cdot (c_{ii'}^+ + c_{ii'}^-) \quad \forall i \in I, i' \in I: i < i' \quad (12)$$

$$r_{ECDF}^{MAX} \geq W_i^{ECDF} \cdot e_i \quad \forall i \in I \quad (13)$$

The rest necessary equations of the model and the definition of the deviations ( $d_{im}^+, d_{im}^-, e_i, c_{ii'}^+, c_{ii'}^-$ ) are identical to the original DMP MILP model which can be found in Bounitsis et al. (2022). Eq. (9) is the objective function and aims at the maximisation of the Nash product, which for this case is expressed using parameters  $\pi_t^{MAX}$  as the higher allowable statistical error for each term  $t$ . These can be obtained by solving the original DMP MILP for minimisation of each term separately. Then, Eqs. (11) – (13) capture the maximum errors for each term, i.e., statistical moments (SM), covariance matrix (COV) and ECDF. The weights on the deviations are defined as  $W_{im}^{SM} = \bar{w}_{im}^{SM} / |\bar{M}_{im}|$  and  $W_{ii'}^{COV} = \bar{w}_{ii'}^{COV} / |\bar{C}_{ii'}|$ , where  $\bar{M}_{im}, \bar{C}_{ii'}$  are the estimated statistical properties from the data and  $\bar{w}_{im}^{SM}, \bar{w}_{ii'}^{COV}$  are the user-defined weights. Finally,  $W_i^{ECDF}$  is also a user-defined weight for the error on ECDF.

#### 4. Case Study

A capacity planning problem under uncertainty is studied. Detailed description, model and data can also be found in Bounitsis et al. (2022). Briefly, it is an MILP profit maximisation problem, which selects between 11 candidate processes on the production of 5 final products from 5 raw materials. Uncertainty is revealed in the production yields of processes and/or demands of final products. The bias and stability of DMP NLP, MILP and its proposed Nash-based reformulation is investigated for sets of varying values of  $\bar{w}_{im}^{SM}, \bar{w}_{ii'}^{COV}, W_i^{ECDF}$ . Typical values 1, 10, 50 and, 100 are considered and 37 sets of values are constructed allowing 1 or 2 of the attributes to vary concurrently. Regarding Nash reformulation, 50 grid points are employed for the piece-wise linear approximations. Instances of increasing complexity are examined and are presented in Table 1. MILP models uses copula-based original scenarios as input.

**Table 1:** Instances of scenario reduction in the case study

Instances	Uncertain parameters	Original scenarios	Final scenarios
1	2	1,000	10
2	4	2,000	20
3	8	2,000	40

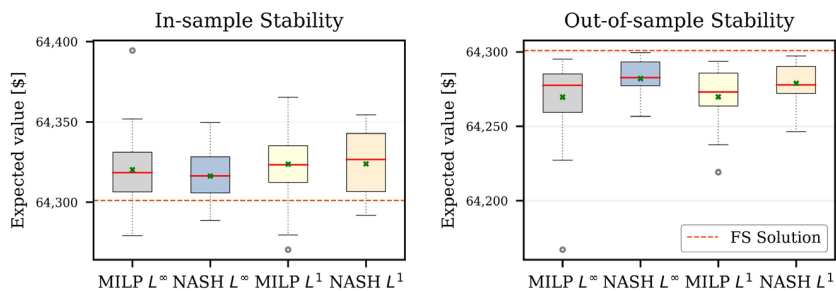

The executions are performed in a Dell workstation with Intel® Core™ i9-10900K CPU @ 3.70 GHz and 32.00 GB RAM. NLP model is solved using the BARON solver, while MILP models using the GUROBI 9.5 solver within GAMS 38.2 modelling system. Although calculation of lower bound constitutes a significant drawback of DMP MILP, the Nash-based reformulations can achieve near optimal solutions in short execution times. Towards a fair comparison, time limit of 1,200s and an optimality gap tolerance of 1% are set for the MILP models.

Firstly, the computational studies reflect the enhanced quality of stochastic solutions that the scenario sets by the considered MILP models provide compared to their NLP counterparts. In particular, NLP SG models suffer from under-specification issues and may generate scenario sets which lead to extreme bias values. Results among examined weights' sets are reported in Table 2 and are indicative of NLP models non-competitiveness. Moreover, Nash-based models lead to the lowest bias values.

**Table 2:** Average (%) bias values for the investigated instances.

Instance	NLP L <sup>1</sup>	NLP L <sup>∞</sup>	MILP L <sup>1</sup>	MILP L <sup>∞</sup>	NASH L <sup>1</sup>	NASH L <sup>∞</sup>
1	1.327	1.383	0.047	0.034	<b>0.027</b>	0.028
2	2.364	2.834	0.048	0.049	0.034	<b>0.029</b>
3	2.761	3.049	0.058	<b>0.042</b>	<b>0.042</b>	<b>0.042</b>

Focusing on the MILP SG methods, the distribution of their expected values for the in-sample and out-of-sample stability (as they are introduced in Eqs. (2) - (3), respectively) are visualised for instance 2 in Fig. 1. While all SG models display similar results for in-sample stability, the proposed Nash reformulations seem to improve the performance of the methods for out-of-sample stability testing, which pertains also to the quality of the provided stochastic solutions. Enhanced stability of the proposed reformulations can be interpreted by the considerably tighter interquartile ranges. Moreover, expected values lie closer to TSSP full-space (FS) solution and indicate improved quality of the stochastic solutions. Ultimately, the results attest that the DMP NLP model is the least stable of the investigated approaches. DMP MILP's stability has been studied in the work by Bounitsis et al. (2022) but is also validated in this work for the case of varying weights of the formulation. Finally, the results demonstrate that combination of DMP MILP with the Nash bargaining approach may further enhance the stability of the SG method.

**Figure 1:** In-sample & out-of-sample stability results for instance 2.

## 5. Conclusions and future directions

Integration of Nash game-theoretic concepts with DMP MILP model can lead to a more stable version of the scenario generation method and further alleviate the under-specification drawbacks of the NLP models for the user-defined parameters. Future work within our research group focuses on: (i) the implementation of optimisation and decomposition techniques to improve the computational performance of the proposed model while maintaining stability, and (ii) the extension to multi-stage setting.

## Abstract

Efficient and robust root finding is a core problem of chemical and process engineering solutions. Thermodynamics, nonlinear systems, finite difference methods for partial differential equations, and optimization are just some examples in which root finding is fundamental. In this work, an algorithm that can be integrated with any local root-finding method is proposed to solve the problem of finding robustly and efficiently all the roots of an objective function in a domain. The method requires the function to be continuous up until the second-order derivative and it is here applied for the one-dimensional case. With the definition of a proper mesh, the first derivative is investigated to find the sub-domains that contain the zeros of the objective function. The study of the derivative guarantees to find those zeros that cannot be identified using only Bolzano’s existence criterion.

**Keywords:** One-dimension, Global Root-finding, Search Grid, Continuous and Derivable Function, Robust and Efficient Solution.

## 1. Introduction

This paper describes a method for solving the problem of computing all the simple roots of a given equation:

$$f(x) = 0 \tag{1}$$

in a predefined interval  $(a, b)$  where  $f: [a, b] \subset \mathbb{R} \rightarrow \mathbb{R}$  is continuous and derivable up to the second order derivative,  $f(x) \in C^2$ . The method proposed may be applied on top of any local root-finding algorithms and the information required is the definition of a search grid and the computation of the function and its continuous first-order derivative. Many different fields of science and technology make use of root-finding methods to solve various problems. One important example is the maximization or minimization of an objective function. In this case, a root-finding method can be applied to the first derivative of the objective function to find the optimum value. Another example of root-finding usage is in the numerical solution of non-analytical thermodynamic equations of state and the flashing problem (Bisotti et al., 2021; Quarteroni et al., 2007). Such problems are at the core of chemical process engineering solutions since the definition of the physical state of a mixture is the first step in fixing the degrees of freedom of a process simulation.

Being able to solve, efficiently and robustly, such thermodynamic problems brings an overall advantage in process modeling and a significant computational time reduction.

In this case, efficiency is defined in terms of the amount of functions evaluation needed to find a solution while higher robustness means a greater probability to find all the solutions in the investigated domain.

The method proposed in this work tries to tackle this challenge by first studying the function derivative to find with certainty all the domains in which the objective function has solutions and find them. This algorithm can be applied on top of any local root-finding solver, and it is based thoroughly on Bolzano's existence criterion (described in Section 2.1). The premise is that, given an appropriate search grid, or mesh, it guarantees to find all the solutions of the objective function inside a predefined domain.

## 2. Method

### 2.1. Basic Concepts

The method developed in this work is based on a very simple and well-known theorem which is Bolzano's existence criterion. It states that when  $f$  is a  $C^2$  function in  $[a, b] \subset \mathbb{R}$  and the following is true:

$$f(a) \cdot f(b) \leq 0 \quad (2)$$

at least a root is guaranteed to exist. However, the criterion does not give any information on the opposite case. If Equation (2) is not true it is impossible to state whether there is or not a solution between  $a$  and  $b$  since there could still be a zero. The application of this criterion to solve the root-finding problem is not new (Brent, 1971; Kearfott, 1987; Wood, 1991).

Thus, for this study, it has been decided to extend Bolzano's criterion using the function derivative since the key mathematical property is that between two adjacent roots  $(a, b)$  of the derivative of a  $f(x) \in C^2$  function, where  $f'(x) \geq 0 \vee f'(x) \leq 0 \forall x \in [a, b]$ ,  $f$  is strictly monotonic. Thus, if Equation (2) is true in the same interval  $[a, b]$ , a single root of  $f$  may only exist. Other authors have proposed different methods for solving this problem, for example by applying the concept of a Dominating Function of the derivative (Ying and Katz, 1989).

The definition of a search grid, or mesh, in this problem, is of utmost importance. Any possible failure of this whole method could be traced back mainly to this step. An appropriate mesh is defined such that it always contains no more than one single derivative root. To do so, a proper understanding of the function under study could be required. Otherwise, the most basic solution is to arbitrarily apply an extremely dense search grid. Some authors have addressed this problem by implementing an adaptive mesh refinement procedure (Gong et al., 2020; Razbani, 2015).

Thus, the case in which Equation (2) is not true that still has a solution can be ruled out if using an appropriate search grid in the first place since it can only happen when the roots of the derivative and the function are strictly coincident.

Should the search domain contain any equality or inequality constraints for  $x$  the problem must be split into multiple sub-problems and solved using the proposed method.

### 2.2. The Algorithm

The proposed algorithm can be briefly described in the following points:

- 1) Input:  $f(x)$ ,  $f'(x)$ , global search domain, local  $f'$  search sub-domains (grid).
- 2) Evaluate  $f$  and  $f'$  at each sub-domain node.
- 3) Select only sub-domains where  $f$  and  $f'$  show a sign change between the nodes.
- 4) Start a local root-finding in the selected sub-domains for  $f'$ ;

- 5) Check for coincident zeros between  $f$  and  $f'$  at local derivative roots.
- 6) Generate new sub-domains, with adjacent non-coincident  $f'$  roots and selected  $f$  sub-domains from Step 2 as nodes.
- 7) Select only sub-domains where  $f$  shows a change of sign between the nodes.
- 8) Start a local root finding in the new sub-domains for  $f$ .
- 9) Collect all the zeros of  $f$  (coincident and non-coincident roots).

A flowchart of this method is shown in Figure 1.

A more in-depth description of the algorithm is reported below:

*Step 1.* The necessary inputs to the problem are defined: the objective function  $f(x)$ , its derivative  $f'(x)$ , the extrema of the global search domain  $[a, b]$  where  $f(x) \in C^2$ , and the local search sub-domain nodes. The latter are crucial for the successful execution of this method. They may be defined arbitrarily but they must be generated in such a way as to always expect one and only one solution of  $f$  inside root-containing sub-domains. If this is accomplished then the robustness is guaranteed, otherwise, the search mesh should be refined accordingly. Having a good knowledge of the objective function to solve should result in a proper definition of the mesh.

*Step 2.* Each node of the local sub-domains is evaluated in  $f(x)$  and  $f'(x)$ .

*Step 3.* Bolzano's existence criterion is applied to evaluate which sub-domain contains a root of the function and its derivative. Thus, Equation (2) is applied to select derivative subdomains with  $f$  roots and  $f$  sub-domains with sign change not bracketed by  $f'$  roots. This redundancy is mandatory to overcome any possible saddle point where the derivative does not change sign but a root still exists.

*Step 4.* Each  $f'$  bounded sub-domain thus selected is investigated using a local root-finding method since it must contain a root. In this Step, it could be advised to apply a bracketing method since it mathematically guarantees convergence and the downside of the slower convergence rate with respect to the open methods should be mitigated given the smaller local sub-domains. However, even an open method can be applied knowing that, in case of non-convergence or convergence outside the selected subdomain, it could be possible to fall back to a bracketing method and restart the root-finding.

*Step 5.* By evaluating the roots found in Step 4 in  $f(x)$  it is possible to uncover any maxima or minima point that touch the axis at the extremum. They are coincident zeros of both  $f(x)$  and  $f'(x)$  and they are collected and saved for Step 9.

*Step 6.* The information gathered in the previous Step is now used to generate new sub-domains for the root-finding of the objective function with non-coincident roots as nodes. Each sub-domain is defined by nodes that are an adjacent pair of roots of  $f'$ , thus not containing a coincident zero in between.

*Step 7.* Again, as in Step 3, Bolzano's existence criterion, see Equation (2), is applied to rule out all the subdomains in which a change of sign is not appearing.

*Step 8.* Inside each newly defined search sub-domain, a local root-finding method can be launched. Also, in this case, it is guaranteed to find a zero which may not be an extremum point thanks to Steps 5 and 6. This guarantee is given by the fact that, if there is a significant change in Step 7 and the derivative is passing through zero at the nodes of the subdomain there is one and only one root available on the objective function. In this Step, the choice of using an open method or a bracketing method is mainly arbitrary. It could be advisable to apply an open method, such as the Newton method if it is possible to generate an appropriate guess value (a trivial guess value could be positioned in the middle of the local sub-domain) for the function under investigation.

*Step 9.* All the roots of the objective function  $f(x)$  found in Step 5 and Step 8 are then collected and the problem is solved.

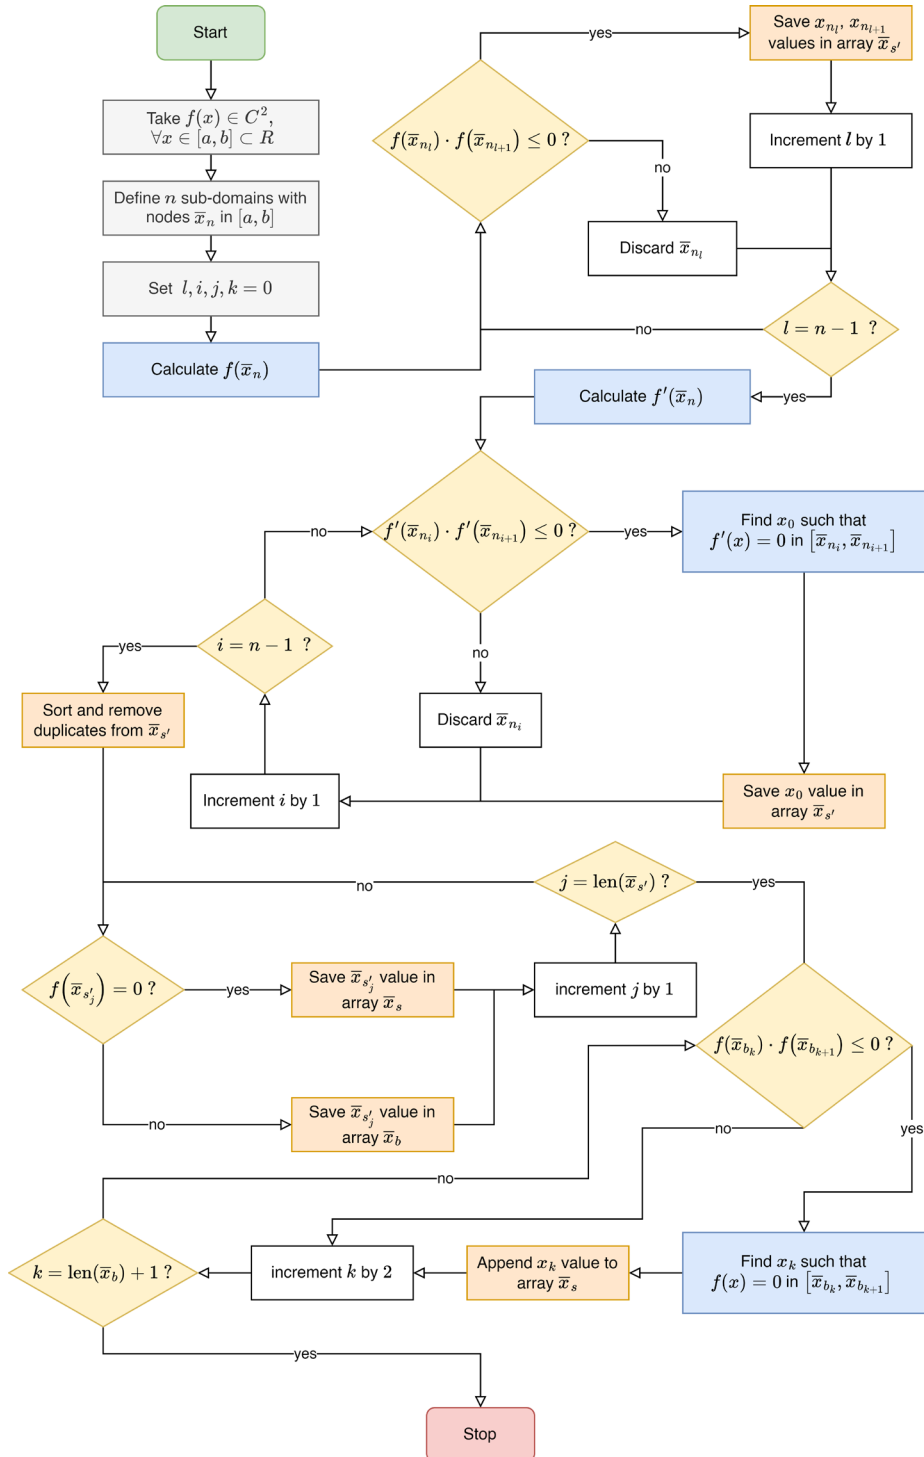

Figure 1: Flowchart of the global root finding algorithm.

### 3. Results & Discussion

#### 3.1. Prototype Function Example

The method described in Section 2 has been applied to the following prototype function:

$$f(x) = \sin^2(x) \cos(x) \tag{3}$$

$$f'(x) = 2 \cos(x)^2 \sin(x) - \sin(x)^3 \tag{4}$$

chosen because it has an analytical solution and shows many coincident solutions to better showcase the method described above.

In Figure 2, the algorithm Steps presented in Section 3.1 are reported for the example function of Equations (4) and (5). In Figure 2.a, the function and its derivative are shown along with the initial derivative search grid. The investigated domain is  $x \in [0,10]$  and the grid presented shows 30 equally distributed sub-domains. In Figure 2.b, Steps 2,3,4 are reported. The filled and dashed lines are the linear interpolation between each value of  $f'(x)$  at each node. The former, indicate sub-domains with a sign change. In Figure 2.c, Steps 5,6,7,8 are shown. The updated search grid is created using the roots of  $f'(x)$ . Grayed areas are the excluded sub-domains given that there is a coincident solution, and the two roots are not adjacent. In Figure 2.d, Step 9 is reported. All the solutions inside  $[0,10]$  are collected and the problem is solved.

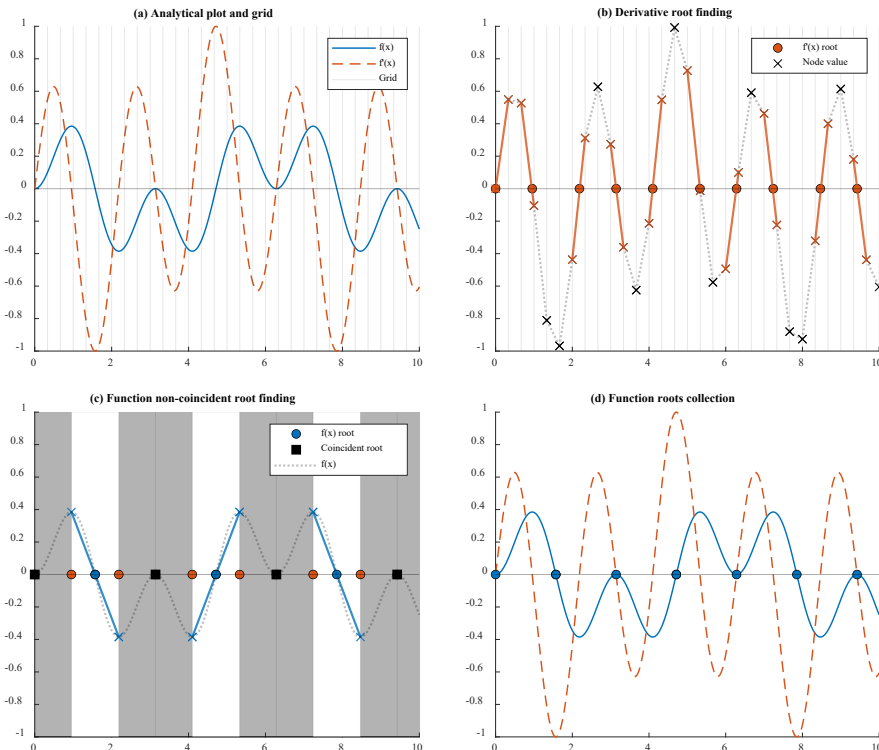

Figure 2: Condensed graphical representation of the algorithm Steps presented in Section 2.2 on the prototype function introduced in Section 3.1.

By using the proposed algorithm, it has been possible to solve the presented root finding problem by only using 12 local root findings (9 for the derivative and 3 for the objective function) and approximately 40 function evaluations (30 for the derivative and 10 for the objective function). If we consider a constant number of 10 iterations for every root-finding problem, we end up with a total of approximately 160 function evaluations. In comparison, by using a more naive solution, which consists of directly launching 30 root-finding solvers (that do not guarantee finding a solution) the results would be that of using 300 function evaluations. Thus, in this case, using this method the computational time required is almost halved.

#### 4. Conclusions

In conclusion, an algorithm has been proposed to solve reliably and efficiently the global root-finding problem of second-order continuous and derivable functions inside a domain. The method applied is based on an appropriate mesh and uses extensively Bolzano's existence criterion to define what subdomains to exclude from the root search. This method could benefit from a parallel computing development, possibly with a cloud approach (Galeazzi et al., 2021), to aid in the solution of chemical engineering problems, especially in thermodynamics.

## Abstract

This work aims to develop a digital twin for a demethanizer column and provide a useful tool for monitoring and quality control of the NGL recovery process. For this purpose, a digital data-driven model was proposed to mimic real dynamics of a cold residue reflux (CRR) unit through the incorporation of physical knowledge. A non-conventional LSTM network arrangement was developed considering training test and validation data sets generated by the process simulator Aspen HYSYS®. This simulation model was built by considering realistic measurement noises to mimic the actual measures in a real plant. The obtained surrogate model was evaluated considering its ability to recreate the operation of the actual distillation column, estimating the temperature and composition transient profiles of the bottom column product and of every stage of the column. Overall, the model developed with the proposed LSTM network arrangement proves capable of successfully reconstructing the actual profiles of all the considered variables.

**Keywords:** Natural gas liquids recovery, LSTM Neural Networks, Digital twin, Distillation Column, Dynamic process simulation

## 1. Introduction

Natural gas is a hydrocarbon mixture constituted mostly of methane and a variable fraction of heavier hydrocarbons known as natural gas liquids (NGL). The latter constitute a source of additional profit as can be sold separately with a higher selling price and used as industrial feedstock materials. Additionally, with NGL separation it is possible to reduce CO<sub>2</sub> emissions related to natural gas combustion. The NGL recovery process under steady-state conditions has been extensively studied in the literature (Kidnay et al., 2011; Chebbi et al., 2010; Getu et al., 2013; Kherbeck & Chebbi, 2015). The associated dynamics of the NGL separation process have been the subject of recent studies and generally focused on the dynamics and control of product quality indices (Luyben, 2013; Chebeir et al., 2019; Mandis et al., 2022). For this, it is essential to have information on the plant composition targets, which can be obtained with the use of expensive composition analyzers. These analyzers also introduce long-time delays in the control loops due to measurements delays. To overcome these drawbacks, the replacement of measured concentrations with accurate real-time estimations represents one of the most widespread approaches. In this type of task, temporal dependencies play a key role to obtain adequate estimations and with the goal of addressing time-dependent problems Recurrent neural networks (RNNs) (Elman, 1990) were developed. One of the most useful RNNs when addressing long time dependency is the Long-Short Term Memory network (LSTM) (Hochreiter & Schmidhuber, 1997), designed to overcome the

problem of the vanishing gradient. LSTM networks have been applied to different types of problems in chemical engineering including digital twin realization for plant monitoring and control (Qu et al., 2020; Zhu & Ji, 2022). A digital twin (Grieves, 2015) consists of a virtual model of whole plants or individual units which is interconnected with the actual equipment. The availability of reliable digital surrogate models is of great interest in the process industry. This tool exchanges information in real-time, and it can predict the dynamic evolution of a process over time. For this reason, a digital surrogate can provide a useful tool for performance monitoring, predictive asset maintenance, production optimization and advanced process control. This work aims to develop a data-driven digital model for a demethanizer column of a CRR unit, which is realized by using LSTM neural network with a non-conventional network architecture. The main goal is to obtain a surrogate model capable of approximating the real dynamics of the column with a much shorter computation time than the process simulator itself. In addition, it is intended to improve NGL recovery control strategies with real-time estimations of control variables.

## 2. Process Description

The dynamic operation of the CRR unit has been modelled in the process simulator Aspen HYSYS® considering realistic operating conditions (Chebeir et al., 2019). The raw gas is fed to the plant with a nominal flowrate of 4980 kmol/h, pressure and temperature of 5818 kPa and 35 °C, respectively, and a gas composition characterized by a low content of liquids (Chebbi et al., 2010). The main unit of the separation process, responsible for the removal of the light component of the raw gas, is the demethanizer column, given by a 30 stages distillation column with a reboiler. The raw gas entering the CRR unit is first cooled and then the liquid fraction is separated utilizing a flash tank. Three resulting feed streams enter the demethanizer column in the 2<sup>nd</sup>, the 8<sup>th</sup> and the 26<sup>th</sup> trays. The column reflux is provided by compressing part of the demethanizer top product with a cryogenic compressor, ensuing a reflux stream of nearly pure methane. Finally, the remaining part of the column product is recompressed for commercialization while the NGL bottom product of the demethanizer column is sent to further separation in the fractionation train.

## 3. Methods

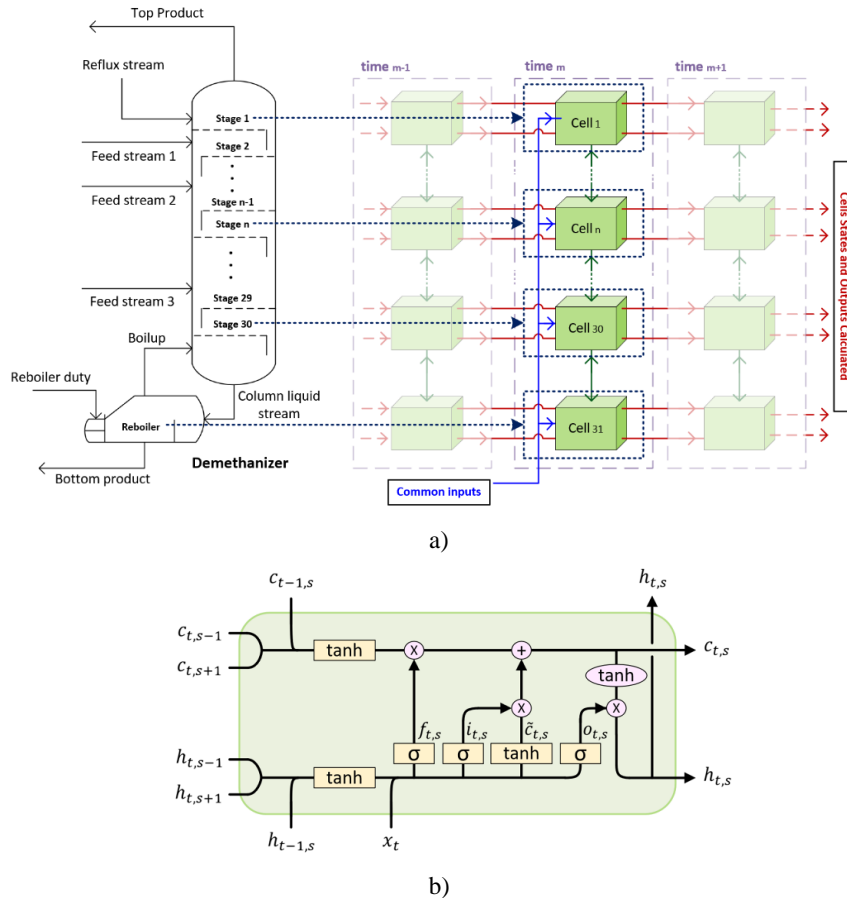

In this work, deep learning methods for the development of RNNs were used to build the surrogate data-driven model. The goals of the neural model were the achievement of accurate estimations for the prediction of the time evolution of temperature and compositions of all column trays and reboiler of the demethanizer column. The considered inputs were given by only easy-to-measure variables: pressure and temperature of all column feeds, reboiler duty, power of the cryogenic compressor and separator pressure and temperature. The selection of RNNs is based on the need to obtain an adaptive neural model capable to capture the existing temporal correlations between the involved variables. In particular, thanks to their ability to overcome the vanishing gradient problem, LSTM networks were used for digital twin realization.

### 3.1. Neural model architecture

In order to design a suitable model to represent the dynamics of the demethanizer column, the LSTM neural networks are arranged considering a particular architecture. The proposed network layout involves the utilization of a dedicated LSTM cell to predict the operations of each stage of the distillation column and the reboiler. Thus, each cell was demanded at modelling the dynamic separation of the corresponding tray, allowing the dynamics inherent in the separation process occurring in each column stage to be captured in the model. Furthermore, bidirectional connections have been applied by modifying the flow of information of a standard LSTM, interconnecting adjacent cells one to another to

account for the interactions between adjacent stages and emulate the action of internal flows within the distillation column. The described model layout, whose structure is schematically represented in Figure 1a, is responsible to approximate the demethanizer operation at a certain instant of time. A schematic representation of a modified LSTM cell is depicted in Figure 1b. As can be seen, in the considered cell (referred to by the subscript  $s$ ), the previous states for the cell are provided by combining the actual previous hidden states and internal cell states ( $h_{t-1,s}$  and  $c_{t-1,s}$ ) with the hidden states and internal cell states calculated by the adjacent LSTM cells (indicated with subscripts  $s - 1$  and  $s + 1$ ) in the current time.

For what concern the terminal cells of the network, mimicking the column top tray and the reboiler, the hidden states from the missing adjacent cell are replaced by the actual measurement of the corresponding variables of the reflux in a case and the liquid stream entering the reboiler in the other.

**Figure 1:** Schematic representation of: overall architecture a) and the modified LSTM cell b).

### 3.2. Datasets

All the data used in the work were generated using the simulated demethanizer column described in section 2 and collected in different datasets for the training, testing and validation campaigns. The datasets employed for training and testing of the neural models, considering a split ratio of 80:20, were two months of simulated plant operation.

Step changes of varying amplitude in the plant feed flow rate were applied with variation peaks of 10% of the plant feed nominal value. To validate the performance of the presented neural model, 2 days of plant operation were simulated by applying step variations of 5% in the plant feed flow rate nominal value.

All the datasets used in this work were registered by considering a sampling time of 20 seconds and without measurement delays, as the data were treated as historical plant data. Moreover, a measurement noise was applied to provide more realistic measured data. The values of the maximum allowed measurement noise applied are shown in Table 1.

**Table 1:** Values of maximum measurement noise considered for input and output data in train, test and validation datasets.

	Duty	Temperatures	Pressures	Concentrations
<b>maximum measurement noise</b>	1.3%*	0.1 [°C]	1.5%*	2%*

\* Referred to the maximum value of the considered variable for the given column stage.

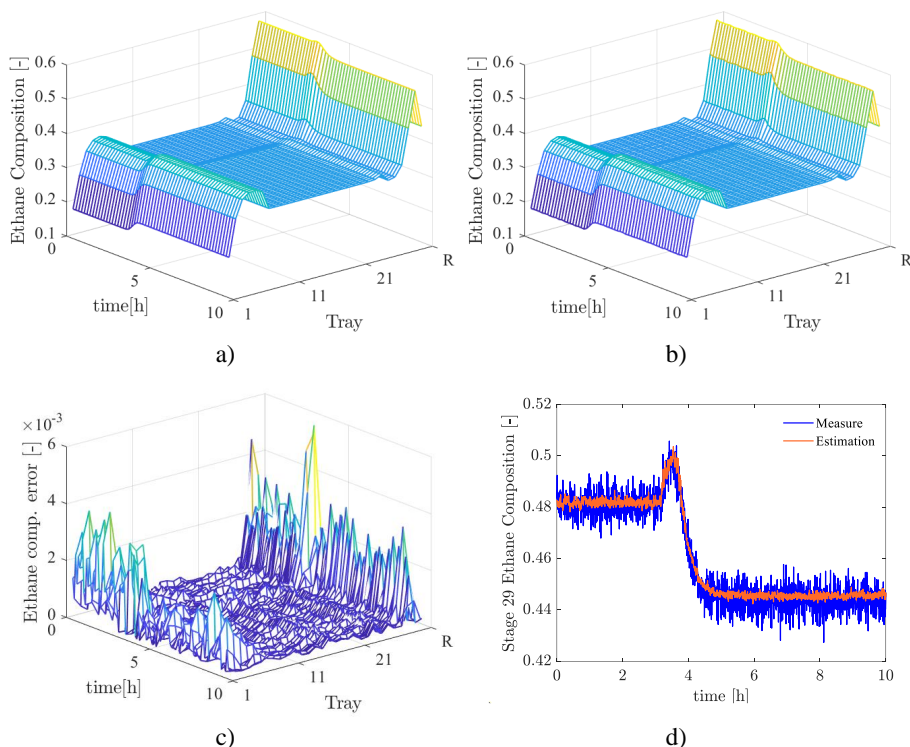

### 3.3. Neural model training

The LSTM neural networks described in section 3.1, have been implemented and trained in the Python programming environment by using the functions available in the open-source library PyTorch. The loss function considered in the optimization problem is given by the Mean Square Error (MSE), while the parameter updating was performed by the Adaptive Moment Estimation optimizer (ADAM) (Kingma & Ba, 2015). The network hyperparameters were obtained by multiobjective optimization using the NSGA-II algorithm available in the pymoo package (Blank & Deb, 2020).

## 4. Results

The performances of the developed neural model are evaluated by considering the column transient profiles predicted by the proposed neural model in the validation campaign for temperature, and key components composition. For sake of brevity, only the results obtained under the worst-case variation represented by the application of a 5% decrease in the feed plant nominal value for ethane composition are reported and shown in Figure 2. The ability of the model to estimate the remaining target variable is assessed by considering the Mean square error (MSE) between the actual and the predicted profiles in the same campaign. Figures 2a and 2b show respectively the actual and estimated ethane transient column profiles. The comparison of these two graphs gives a qualitative indication of the estimation performance of the model for the transient column profile of ethane composition. As it is possible to visualize the proposed model is able to predict the trend of ethane time evolution profile providing an estimation with no detectable deviations from the actual profile. To provide a quantitative measure of the accuracy of the obtained estimation, the estimation error of the column transient profiles for ethane composition is depicted in Figure 2c. Here, it is shown that the proposed neural model can accurately predict the ethane composition transient profiles for all the column trays. The estimation error increase where most of the ethane variations occur, indeed, it increases in the column terminal regions, where most of the separation takes place. The deviations of the predicted transient column profile are always within the maximum error reported in Table 1.

To visualize in detail the estimation obtained, Figure 2d shows the comparison between the estimated ethane composition profile and the measured profile in the tray where the higher estimation error is registered, the 29<sup>th</sup> column tray. As can be seen from the figure, the profile obtained with the neural model can correctly predict the evolution of the composition, with considerably lower variance than the considered measurement.

**Figure 2:** Ethane composition results obtained in the validation campaign under the decreasing variation of plant feed nominal value: actual column profile (a); predicted column profile (b); estimation error profile (c) and transient profiles of 29<sup>th</sup> tray (d).

**Table 2:** Mean square error obtained in the validation campaign under decreasing variation of 5% in the plant feed nominal value.

	Temp.	Methane	Ethane	Propane	Butanes	Pentanes	Hexane
MSE	0.0072	7.33e-7	4.31e-7	7.49e-8	1.22e-8	1.42e-9	2.27e-9

Analogue results are obtained for the temperature and the composition of the remaining components. Table 2 shows the MSE values obtained by considering the predictions of the transient composition profiles in all column trays and the actual profiles, for all the target variables in the validation campaign. As it can be noticed from the obtained MSE value, the use of the proposed model provides an accurate prediction of dynamic temperature profiles. Although it is not apparent from the MSE, it is reasonable to highlight that larger errors have been observed in the last three stages and in the reboiler, where most of the column temperature variation takes place. A possible action for reducing the mismatch is to increase the dataset to be used to train the network, simulating the system in different operating conditions (e.g., impose set-point changes). Concerning the prediction of the remaining components, also in these cases, the model is capable of accurately estimating the evolution over time with estimation errors resulting always lower than the assumed measurement errors, as can be inferred from the obtained MSE values, model's ability to filter the measurement noise is furthermore assessed.

## 5. Conclusions

In this work, a demethanizer column of a simulated CRR unit has been modelled by employing modified bidirectional LSTM neural networks exploring the possibility of its use as digital twins for the column. The results show that the developed neural model can approximate the column trend profiles of the target variables and has a good ability to filtrate measurement noise for the column composition profiles. It also proves to be able to predict the actual trend of the temperature transient profiles quite accurately for most of the column trays and to be a useful tool for temperature monitoring in the final stages of the column and the reboiler. As a result, the presented model may be a suitable candidate as a digital twin of the demethanizer column. On the other hand, the need for concentration measurements yields less attraction to be used as digital twins in a real plant.

## Abstract

Biorefinery converts biomass into energy and high-value bioproducts, such as bio-oil. The combined power and fuel generation is particularly attractive for energy transition and reduction of non-biogenic CO<sub>2</sub> emissions. Biomass conversion requires a series of complex treatments. The development of reliable models is essential for scaling up and designing. Soft-modelling approach provides a simplified description of the system without losing accuracy. This contribution presents a soft model for steam explosion (after impregnation with carbocation scavengers) and enzymatic saccharification (boosted with H<sub>2</sub>O<sub>2</sub>-driven oxidative depolymerization by LPMO enzymes). These are two key pre-treatments for the extraction of carbohydrate fraction prior to pyrolysis of lignin-rich solids to produce the bio-oil. The proposed saccharification model accurately predicts experimental data in the range of interest for steam explosion temperature and enzyme concentrations investigated. This approach can be considered general and is potentially applicable to every kind of biomass.

**Keywords:** biorefinery, steam explosion, enzymatic saccharification with LPMO, soft modelling in COCO, softwood cellulose and hemicellulose valorization.

## 1. Introduction and context

Softwood (such as Norwegian spruce) is a good feedstock for biorefinery. The main aim of the biorefinery is to convert the carbon captured by plants into valuable chemicals (fuels, for instance) or heat & power generation systems via several physical and (bio)chemical treatments (Cherubini, 2010). During downstream processing, biomass undergoes a series of pre-treatments to separate the cellulose/hemicellulose from the lignin fraction. Our model includes three main pre-treatment steps: 1) impregnation of spruce biomass with 2-naphthol, a carbocation scavenger that prevents lignin condensation during the subsequent steam explosion (Pielhop et al., 2016a); 2) steam explosion, which allows the breaking of biomass structure so that the hemicellulose and cellulose become accessible while partially solubilizing hemicellulose (Pielhop et al., 2016b); and 3) enzymatic saccharification, where the hemicellulose and cellulose

fractions are depolymerized into their elemental sugars (i.e., pentose and hexose) by selective catalysts (i.e., enzymes) under mild conditions. We selected this process because it selectively solubilizes the carbohydrate fractions and at the same time yields a less condensed and more reactive lignin for further downstream processes (Pielhop et al., 2017; Hansen et al., 2022). The efficiency of the steam explosion and saccharification steps influences the productivity and the overall yield of the complete biorefinery process. Therefore, the present article focuses on modelling these steps. In our model, we take a closer look at the impact of 2-naphthol impregnation on steam explosion as well as LPMO-aided saccharification of Norwegian spruce. Finally, a sensitivity analysis was performed to detect the most influential parameters in designing and modelling softwood biorefineries based on such upstream processing.

## 2. Purpose and material

The present work investigates the direct scale-up and the process configuration of the upstream processes in a biorefinery described by (Hansen et al. 2022), via direct translation of the reported laboratory-scale biomass treatments. The selected process layout (Figure 1) is based on the experimental setup by (Hansen et al. 2022) with the following modifications: (1) after the steam explosion, the pH of the biomass slurry was set to 5.0 (pH optimum of the cellulases in the subsequent saccharification step) in a single step using NaOH, instead of using an acetic acid/acetate buffer solution and then a caustic solution, for scalability. (2) A filtration stage was added after the saccharification step to separate the lignin-rich saccharification residue (solids) from the sugar solution (liquid/aqueous phase). This step is expected to reduce the residual moisture content of the lignin-rich residue and thus, lead to energy savings in the drying step before the pyrolysis unit.

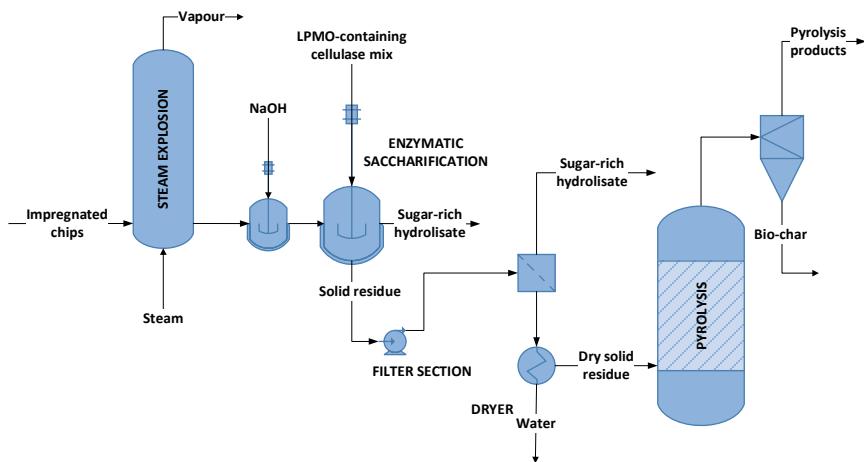

Figure 1 - Simplified layout of the investigated upstream processes of a softwood-based biorefinery. The picture does not include the impregnation step prior to the steam explosion.

## 3. Implementation

The steam explosion and enzymatic saccharification steps were modelled using COCO (a CAPE-open solution) simulation software (Figure 2). Due to the large complexities of bioprocesses, we adopted a soft-model approach instead of a first-principle one. The missing properties (i.e., enthalpy of formation, heat capacity, vapour pressure, and others)

for some components, namely the cellulose, hemicellulose, and lignin constituents, have been estimated using Gani’s methods (Constantinou and Gani, 1994). For the steam explosion step, we implemented a simplified kinetics scheme proposed by Lam (2009 and 2010), which has been suggested to be applicable for softwood in general. Due to the lack of measurements and data points collected during steam explosion, we do not have experimental data to validate the implemented model. For the enzymatic saccharification, on the other hand, the general expression of the soft model was taken from (Theuretzbacher et al., 2015), and it was validated and adjusted using the experimental saccharification data in (Hansen et al., 2022). The proposed model for saccharification conversion fits the experimental data (Figure 3), and the conversion model is a function of the steam explosion temperature ( $T_{SE}$  in  $^{\circ}C$ ) and overall Cellic CTec2 enzyme concentration  $[E]$  expressed in  $[mg/g_{biomass}]$ , as in (Hansen et al., 2022).

$$\gamma(t) = \gamma(0) + h \cdot [1 - \exp(-k_r \cdot t)] \quad (1)$$

Where  $\gamma$  is the conversion at the outlet of the saccharification reactor,  $\gamma(0)$  the conversion at the inlet (called “instantaneous”; in Equation 2),  $h$  an adaptative parameter accounting for the conversion “jump” from the inlet and outlet conditions for ideal infinite residence time (see Equation 3),  $k_r$  the reaction constant (see Equation 4), and  $t$  the residence time.

$$\gamma(0) = 0.8607 \cdot [E] + 4.6 \quad (2)$$

$$h(T_{SE}, [E]) = (0.435 \cdot T_{SE} - 88.227) \cdot [E] + (0.15 \cdot T_{SE} - 24.275) \quad (3)$$

$$k_r(T_{SE}, [E]) = (1.3 \cdot 10^{-4} \cdot T_{SE} - 0.0355) \cdot [E] + (-4.17 \cdot 10^{-3} \cdot T_{SE} + 1.0937) \quad (4)$$

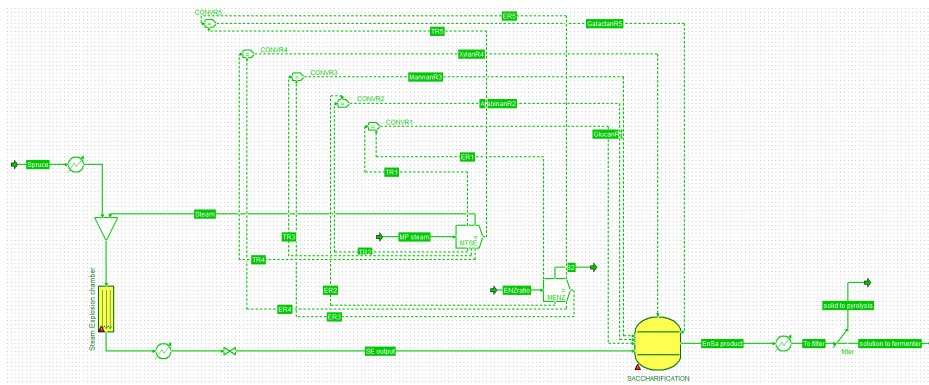

Figure 2 - Flowsheet for the steam explosion and enzymatic saccharification in COCO simulator. Yellow color indicates that the unit is handling a biphasic system of liquid and solid.

The saccharification curves in Figure 3 show that maximum glucose conversion is reached when the biomass undergoes a high-temperature steam explosion ( $220^{\circ}C$ ) and at the highest tested enzyme load ( $8 \text{ g/kg}_{biomass}$ ). The optimal residence time lies around 24 h, after which the saccharification yield reaches a plateau. Thus, longer saccharification times lead to a larger volume without substantial benefit to the process yield. As cellulose and hemicelluloses are depolymerized concomitantly by enzymes (Várnai et al., 2011), a similar yield trend is expected for the saccharification of the cellulose and hemicellulose fractions. Using the models here defined, the steam explosion chamber was simulated as a plug flow reactor and the saccharification reactor (which resembles a CSTR reactor with a large residence time) as a system at assigned conversion. The conversion was estimated

according to the steam explosion operating temperature (i.e., steam) and the concentration of the LPMO-rich enzyme cocktail fed into the saccharification reactor.

Figure 3 - Conversion model for enzymatic saccharification: experimental data (dots) and model (solid line) after the steam explosion (210°C–left and 220°C–right) using different enzyme doses expressed as  $\text{mg}_{\text{enzyme}}/\text{g}_{\text{biomass}}$  (2–blue, 4–orange, 8–grey).

#### 4. Sensitivity analysis and results

Additional parameters for the models were set as follows. The Norwegian spruce composition was adapted from (Wang et al., 2018). Hansen et al. report a residual humidity of 5 wt%. The steam explosion process is supposed to treat 100 kg/h of wet-impregnated spruce. The process requires steam at saturation pressure, corresponding to temperatures ranging from 210°C (18.5 bar) to 220°C (22.5 bar). The ratio between biomass and steam is 1:1 in mass. The steam explosion chamber volume has been set to 29 l (litres) and 58 l; with a fixed diameter of 0.3 m, hence the volume is directly proportional to the residence time. We performed a sensitivity analysis on the steam explosion temperature at two reactor volume levels to assess the impact of the operating conditions of this pre-treatment process on the overall upstream processing steps. Table 1 gathers the different case studies.

Table 1 - Case studies proposed in this work for the sensitivity analysis.

Case	Steam explosion temperature [°C]	Steam explosion reactor volume [l]
1	210	29
2	210	58
3	220	29
4	220	58

Table 2 gathers the increment or decrement in the mass yield of each product with respect to Case 1 (indicated in Table 1). Our main observations are that: (1) remarkably, the lignin fraction seems inert to both steam explosion and saccharification, thus the pyrolysis process is not affected; and (2) the composition of aqueous sugar solution depends on the steam explosion operating conditions. The latter one is partly because hemicellulose (arabinoxylan and galactoglucomannan) hydrolysis starts taking place already during steam explosion, depending on the severity. In Lam's model, hemicellulose hydrolysis is defined as a conversion to sugar (hexose and pentose) monomers and their corresponding degradation products HMF (hydroxymethyl-furfural) and furfural, respectively; the mass flow rate of the sugar monomer or secondary product being derived from the flowrate of its original corresponding polymer. The more severe the steam explosion conditions (i.e., high temperature and pressure) are, the larger the sugar yield from the cellulose and

hemicellulose fractions is after saccharification. Both HMF and furfural are valuable for bio-oil production. We adopted Case 1 as a reference because it represents the operating condition with the lowest yield, but also the one associated with the lowest costs. Figure 4 depicts the products' mass composition at the steam explosion outlet and enzymatic saccharification reactors in the proposed case studies.

Table 2 - Predicted conversion of hemicellulose, increment (positive) or decrement (negative values) in pentose and hexose sugars mass (on biomass dry matter basis), at the outlet of the enzymatic saccharification reactor using Case 1 as the reference case.

Case	Arabinose	Galactose	Xylose	Mannose	HMF	Furfural
2	+7.61%	-94.28%	-95.66%	+14.61%	+12.99%	+7.65%
3	+6.74%	-44.47%	-56.53%	+15.04%	+7.31%	+4.52%
4	+8.72%	-98.65%	-99.20%	+19.90%	+13.67%	+7.92%

Figure 4 - Mass composition (dry weight basis) of the sugar solution obtained at the outlet of the steam explosion (A) and enzymatic saccharification (B) reactors in the four analyzed case studies (CASE). Legend: **lignin** (green), **glucan/cellulose** (grey), **glucose** (black), **mannan** (red), **mannose** (dark blue), **arabinose** (yellow), **HMF** (magenta), and **furfural** (light blue). Not mentioned species (arabinan, xylan, xylose, galactan, and galactose) have negligible content (< 0.1 wt%).

## 5. Conclusions and comments

The results show that the biomass pre-treatment model enables the scale-up of the impregnation–steam explosion–enzymatic saccharification process from laboratory to pilot scale while leading to the identification of the main parameters determining the selective and nearly complete removal of the polysaccharide fraction. At the projected scale, the steam explosion was the most determining step of the studied process setup since it had a direct influence on the subsequent enzymatic saccharification step. Correct tuning of the steam explosion operating conditions led to an optimal process yield. The hemicellulose and cellulose fractions were almost depleted after steam explosion and enzymatic saccharification. Hemicellulose (arabinoxylan and galactoglucomannan) was mainly degraded after steam explosion. The lignin fraction did not seem to undergo major chemical/physical transformation due to the impregnation pre-treatment. This emerges both from the experimental data and the model. Lignin remains in the insoluble fraction in the investigated process since its extraction and valorization require stronger operative conditions as in pyrolysis. The predicted outlet compositions from the steam explosion

and enzymatic saccharification reactors at different steam explosion temperatures (210°C and 220°C) and reactor volumes (29 l and 58 l) point to the following conclusions: (1) A proper design of steam explosion and enzymatic saccharification reactors can lead to a very efficient decomposition of the hemicellulose and cellulose fractions of biomass, respectively, thus generating a lignin-rich solid residue. (2) Increasing steam explosion temperature and reactor volume is a good strategy to substantially improve the solubilization of the polysaccharide content. (3) Glucomannan removal during the steam explosion is significantly slower than arabinoxylan (or galactoglucomannan) removal as the greatest yield increase is observable for the mannose. (3) Larger residence times in the steam explosion chamber are associated with the formation of substantial amounts of secondary products (HMF and furfural). The temperature increment is not enough to fully deplete the intermediate products (galactose and xylose). Even though these are by-products generated from successive pentose and hexose sugars oxidation, they are valuable chemicals which can be blended in biodiesel. (4) High-temperature steam explosion benefits the glucan conversion occurring within enzymatic saccharification. If the temperature is shifted from 210°C to 220°C, the global final glucose yield rises from 50.8% up to 87.7%. On the contrary, steam explosion reactor volume does not impact the performance of downstream unit operations.

## Abstract

Diesel is an important transportation fuel produced in oil refineries, for which the quality should be strictly controlled to meet the diesel engine requirement and minimize associated air pollution issues. A key refining process to improve diesel quality is the diesel hydrotreating (DHT) process. The molecular type homologous series (MTHS) matrix is developed for the molecular characterization of petroleum fractions. The kinetic modelling and reaction modelling are built and improved to discuss the influence of operating conditions on the DHT processes. This work innovates to combine the catalyst deactivation model with the kinetic model to continuously monitor the catalyst deactivation during the DHT processes, which is essential to optimize the reaction operating conditions and maintain constant product yields and quality.

**Keywords:** Diesel Hydrotreating Processes, Optimization, Molecular Characterization, Catalyst Deactivation.

## 1. Introduction

Diesel hydrotreating (DHT) has become one of the essential fundamental processes in the petroleum-refining industry from environmental, technical, and economic points of view for over 60 years (Hoehn et al., 2017). The DHT process is mainly to obtain products with high quality and low content of pollution. In order to fulfill the applicable regulations of product quality, and remove the undesirable compounds, including but not solely limited to sulfur, nitrogen, olefins, and aromatics, the operating conditions of the reactor need to be improved. Establishing reaction modelling and simulation is a useful way to have deep research on phenomena occurring in the DHT reactor. Attributed to effective modelling and simulations, operating conditions, reactor design, catalyst formulation and process configuration would be optimized. In addition, effects of operating variables could be investigated and integration with other technologies could be implemented. (Mederos et al., 2012).

The loss of catalytic activity is a problem of great and continuing concern in the practice of industrial catalytic processes. During the industrial production process, with the extension of the operation time of the unit, the catalyst of hydrodesulfurization will experience a decline in activity. The degree of catalyst deactivation depends mainly on the operating conditions and the properties of the feed (Kohli et al., 2016). The loss of catalytic activity must be compensated by periodic increases in the reaction temperature in order to maintain the constant product yields and quality (Moghadassi et al., 2011). When the catalyst is deactivated or the catalyst activity drops below the economical operation of the unit, it is necessary to shut down the operation for catalyst regeneration

or replacement with a new catalyst, which directly affects the economic benefits of the refinery. The annual cost to the industry for catalyst replacement and process shutdown is in the billions of dollars (Bartholomew et al., 2001). However, catalyst deactivation is inevitable. Therefore, it is significant to develop the catalyst deactivation model to investigate the catalyst deactivation regularity under ultra-deep desulfurization of diesel fuel, which shows practical guidance for refineries on predicting the catalyst usage periods and rationalising the production cycles of units.

In this research, the reaction network of a diesel hydrotreater is generated by incorporating most of the reaction types in this process, including hydrodesulfurization (HDS), hydrodenitrogenation (HDN), hydrodearomatization (HDA), and hydrocracking (HC). The current kinetic model of hydrodesulfurization has been proved by Vanrysselberghe et al. (1998) that expressed the reaction for dibenzothiophenes, which is the hardest sulfur component to remove. The three-phase hydrotreater model developed by Korsten and Hoffmann (1996) can be used in this research which contains a combination of algebraic and ordinary differential equations. The fourth-order Runge-Kutta method is used to numerically solve the first-order differential equations in GAMS.

## 2. Methodology

### 2.1. Molecular Type Homologous Series (MTHS) Method

The molecular type and homologous series method is used to characterize petroleum streams quickly and accurately at the molecular level. Pseudo-components could be generated based on their corresponding distillation profile and density using the pseudo-component approach, where each of them has specific boiling point, density and volume fraction. The molecular composition within each homologous series follows the gamma distribution shown in equations 1 and 2. The MTHS matrix is shown in Figure 1.

Figure 1 Pseudo-components based MTHS matrix

$$PDF(P) = \frac{(P-\eta)^{\alpha-1} \exp(-\frac{P-\eta}{\beta})}{\beta^{\alpha} \Gamma(\alpha)} \quad (1)$$

$$\Gamma(\alpha) = \int_0^{\infty} t^{\alpha-1} e^{-t} dt \quad (2)$$

where P is the property;  $\alpha$ ,  $\beta$ ,  $\eta$  are three parameters of gamma distribution; PDF is the probability density function.

The objective function is to minimize the difference between the measured data and the predicted data:

$$OBJ = \sum_V (W_1 \cdot \frac{T_V^{msd} - T_V^{pred}}{T_V^{msd}})^2 + \sum_{PC} (W_2 \cdot \frac{BP_{PC}^{msd} - BP_{PC}^{pred}}{BP_{PC}^{msd}})^2 + \sum_P (W_3 \cdot \frac{P_P^{msd} - P_P^{pred}}{P_P^{msd}})^2 + \sum_{f \in PIONA} (W_4 \cdot \frac{C_f^{msd} - C_f^{pred}}{C_f^{msd}})^2 + \sum_{e \in (S, N, O)} (W_5 \cdot \frac{X_e^{msd} - X_e^{pred}}{X_e^{msd}})^2 \quad (3)$$

where,  $T$  is the boiling point of the distillation curve;  $BP_{PC}$  is the boiling point of the pseudo-components;  $P$  is bulk properties;  $C$  is the composition of PIONA;  $X$  is heteroatoms content;  $W$  is the weighting factors for each type of the properties;  $msd$  is the measured values;  $pred$  is the predicted results based on the MTHS.

### 2.2. Kinetic Model of Hydrodesulfurization (HDS)

The kinetic model of HDS for the different sulfur compounds has been proposed by previous researchers. The Hougen-Watson rate equation is used to describe the hydrogenation and hydrogenolysis in the HDS process (Vanrysselberghe et al., 1998):

$$r_s = \frac{k_{s,\sigma} K_{H,\sigma} K_{S,\sigma} C_s C_{H_2}}{DEN_\sigma} + \frac{k_{s,\tau} K_{H,\tau} K_{S,\tau} C_s C_{H_2}}{DEN_\tau} \quad (4)$$

With

$$DEN_\sigma = (1 + \sum_i K_{i,\sigma} C_i + \sqrt{K_{H,\sigma} C_{H_2}})^3 \quad (5)$$

$$DEN_\tau = (1 + \sum_i K_{i,\tau} C_i + \sqrt{K_{H,\tau} C_{H_2}})^3 \quad (6)$$

where,  $r_s$  is the reaction rate of the sulfur compound;  $\sigma$ ,  $\tau$  are hydrogenolysis site and hydrogenation site;  $k_{s,\sigma}$  and  $k_{s,\tau}$  are the rate coefficients for the reactions of the sulfur compound on the two sites;  $K_{i,\sigma}$  and  $K_{i,\tau}$  are the adsorption coefficient of component  $i$  on the two sites;  $C_i$  is the liquid concentration of the component  $i$ .

### 2.3. Modelling of Three-Phase Diesel Hydrotreater

The three-phase catalytic reactor, the heart of the HDT unit, is the equipment that needs to be modelled. In HDT reactors, the gas phases ( $H_2$ ) and liquid phases (hydrocarbons) are contacted with the solid phase (catalyst). The reactions occur between the dissolved gaseous reactants and the liquid phase reactants on the surface of the catalyst (Mederos and Ancheyta, 2007). The reactor model created by Korsten and Hoffmann (1996) is used based on the following assumptions:

- The reactor operates under steady state conditions.
- No radial concentration gradients.
- Constant volumetric flowrates through the reactor.
- Constant pressure through the reactor.
- The catalyst particles are completely wetted.

#### 2.3.1. Mass Balance

For component  $i$  of the gas phase:

$$\frac{u_G}{RT_G} \frac{\partial p_i^G}{\partial z} + k_i^G a_L \left( \frac{p_i^G}{H_i} - C_i^L \right) = 0 \quad (7)$$

$$z = 0, p_i^G = p_i^{G,0}$$

For gaseous components in the liquid phase:

$$u_L \frac{dC_i^L}{dz} + k_i^L a_L \left( \frac{p_i^G}{H_i} - C_i^L \right) + k_i^S a_S (C_i^L - C_i^S) = 0 \quad (8)$$

$$z = 0, C_i^L = C_i^{L,0}$$

At catalyst surface:

$$k_i^S a_S (C_i^L - C_i^S) = -v_i \rho_B \xi \eta r_i \quad (9)$$

Where,  $u_G$  is the superficial gas velocity;  $p_i^G$  is the partial pressure of gaseous  $i$ ;  $Z$  is the length of the reactor;  $k_i^G a_L$  and  $k_i^S a_S$  are the gas-liquid liquid-solid mass-transfer coefficient;  $H_i$  is Henry's law coefficient;  $C_i^L$  and  $C_i^S$  are concentrations of component  $i$

in the liquid and on the surface of the catalyst;  $\eta$  is the effectiveness factor;  $r_i$  is the reaction rate.

### 2.3.2. Energy Balance

$$\frac{dT_R}{dz} = \frac{\xi n}{\rho_{BuL} C_p} \sum_{i=1}^n r_i (-\Delta H_i) \quad (10)$$

where,  $C_p$  is the specific heat capacity of the feed;  $T_R$  is the reactor temperature.

### 2.4. Catalyst Deactivation Model

Dong and Gao (2009) analyzed the sulfur content of the product oil samples at different times of catalyst operation to calculate the corresponding hydrodesulfurization reaction rate constants. The relative activity of the catalyst is defined as the ratio of the reaction rate constant at different times of operation to the initial reaction rate constant. The catalyst deactivation models are established as follows:

$$k = A \exp(-E_a/RT) \quad (11)$$

$$A = (1 - nt)A_0 \quad (12)$$

$$k = (1 - nt)k_0 \quad (13)$$

$$n = \rho^{61.305} T_{90\%}^{0.136} f_{Aro}^{0.111} \quad (14)$$

where,  $k$  is reaction rate constant;  $A$  is constant;  $E_a$  is activation energy;  $n$  is inactivation rate constant;  $f$  is total content of bicyclic and tricyclic aromatic hydrocarbons and colloid ( $\omega\%$ ).

## 3. Case study

The bulk properties and composition information of the SRGO stream are given in Table 1.

Table 1. Bulk properties of SRGO stream

Density at 15°C (kg/m <sup>3</sup> )	851.7	Distillation (D86)/ °C	
Sulfur content (m%)	1.51	IBP	220
Paraffin (m%)	44.4	10 vol%	279
Naphthene (m%)	21.9	30 vol%	295
Aromatics (m%)	17.3	50 vol%	310
Multi-ring aromatics (m%)	7.36	70 vol%	328
		90 vol%	359
		95 vol%	376
		FBP	379

The configuration of the reactor and its operating conditions are shown in the Table 2.

Table 2. Configuration of the reactor and operating conditions

Reactor configuration		Operating conditions	
Diameter (cm)	2.54	Temperature (K)	633
Length (cm)	45	Pressure (bar)	6.4
Density of bed ( $kg_{cat}/m^3$ )	780	H <sub>2</sub> /oil	500
Catalyst characteristics		LHSV (hr <sup>-1</sup> )	1.5
Equivalent diameter (m)	$1.30 \times 10^{-3}$	Hydrogen purity (%)	100
Density (kg/m <sup>3</sup> )	1420		
Specific surface area (m <sup>2</sup> /g)	200		

## 4. Results and Discussion

### 4.1. Feed Characterization

SRGO stream is divided into 25 pseudo-components, each having a 10K gap between 448K and 688K. Sulfur compounds are classified into 5 homologous series: SI (thiophene), SII (benzothiophene), SIII (dibenzothiophene), SIV (4-methylthiophene) and SV (4, 6-dimethylthiophene). The distribution of different types of sulfur compounds: thiophenes (TH) are commonly found at temperatures below 220°C, benzothiophenes (BT) make up the majority of the boiling range between 220°C and 257°C, and dibenzothiophenes (DBT) are substantially concentrated at temperatures above 330°C. Figure 2 and Table 3 show the comparison of distillation profiles and properties between the measured and predicted results. The biggest deviation of distillation profiles is at this point when the cumulative volume is 10%, and the biggest deviation of the properties is the content of multi-ring aromatics. These errors are still within acceptable limits.

Figure 2. Comparison of distillation profiles between the measured and the predicted

Table 3. Comparison of the properties between the measured and predicted

Composition & Property	Measured	Predicted	Relative Error (%)
Density, kg/m <sup>3</sup>	851.7	850.8	-0.11
Paraffin(m%)	44.4	43.13	-2.86
Naphthene (m%)	21.9	22.4	2.15
Aromatics (m%)	17.3	18.14	4.93
Multi-ring aromatics (m%)	7.36	7.8	5.83
Sulfur content (m%)	1.51	1.514	0.26

### 4.2. The Pilot Plant Diesel Hydrotreater

The comparison of compositions and properties of the hydrotreated product between the measured and the predicted at the operating condition of 633K, 6.4bar and 1.5 hr-1 are shown in Table 4. The relative error between predicted results and measured results for the nitrogen content is slightly larger, but it is still within an acceptable range. The errors between the predicted and measured for other content are lower than 5%.

Table 4. Composition and properties of the measured and predicted product

	Measured	Predicted	Error (%)
Paraffin (m%)	55.2	53.4	-3.26
Naphthene (m%)	31.8	31.2	-1.89
Aromatics (m%)	12.9	13.4	3.88
N (wtppm)	8.77	9.29	5.93
S (wtppm)	6.02	6.16	2.32

The rising trend of temperature in the axial position of the reactor is shown in Figure 3. It can be seen from the figure that the temperature at the inlet of the reactor rises significantly, and the temperature is in a steady increase after 5% axial of the reactor. This is because the sulfides, especially thiophene and benzothiophene, react rapidly at the inlet of the reactor. Therefore, the temperature also improves rapidly.

Figure 3. Temperature raise trend in the axial position of the reactor

## 5. Conclusion

In this research, the kinetic model and the mass balance of the three-phase diesel hydrotreater model are established based on the MTHS method. The feasibility of the model is confirmed in the case study by comparing the predicted results with the measured results, which is the basis for further work. Future work will include the optimization of the current modelling and the monitor continuously of the catalyst deactivation.

### Abstract

Biorefinery converts biomass into valuable bioproducts. Cellulose and hemicellulose are degraded into simple sugars during enzymatic saccharification, while lignin remains unutilized. Lignin and residual cellulose can be subjected to pyrolysis, a key biorefinery step for improved valorization of biomass. During biomass pyrolysis thousands of compounds are formed, thus, a simplified approach must be adopted for the sake of modelling. Lumped kinetic models address a simplified description of the system by catching relevant features of the product mixture. This contribution presents a pyrolysis model where two previously validated kinetics are merged to get a more effective description of the product distribution. The model provides a quantitative characterization of the main product classes (aldehydes, carboxylic acids, phenols, furans, etc.) and can be used as a numerical tool for roughly scaling up pyrolysis reactors in a softwood-based biorefinery. This approach can be considered general and is applicable to all biomass types.

**Keywords:** biorefinery, pyrolysis, lumped kinetic, lignin valorization, bio-oil production.

### 1. Introduction

Biomass is composed of cellulose, hemicellulose, and lignin. Biochemical conversion of biomass, most commonly including steam explosion and enzymatic saccharification processes upstream, selectively depolymerizes and solubilizes the cellulose and hemicellulose fractions, leaving a lignin-rich solid residue. To increase the biorefinery yield, the lignin-rich residue can be subjected to thermochemical treatment to produce syngas and chemicals via gasification, heat and power via combustion, or bio-oil and biochar via pyrolysis (Kumar et al., 2020; Cherubini, 2010). The present work deals with the modelling of the pyrolysis of lignin-rich residue remaining after steam explosion and enzymatic saccharification of Norwegian spruce. An explicit, rigorous and descriptive model of the pyrolysis process, including thousands of species (considering also all intermediates) and reactions, would lead to a stiff and complex system, as exemplified by a few case studies where detailed kinetics have been adopted (e.g., Corbetta et al., 2015; Ranzi et al., 2014). Such models cannot be implemented in process simulators due to the

lack of thermodynamic properties for most species present in the kinetics and due to the huge dimensions of nonlinear equations which challenge the numerical stability of the software itself (Manca et al., 2001). On the other hand, the lumped kinetics approach brings a substantial simplification of the kinetic schemes without losing accuracy (Ranzi et al., 2008). Lumped kinetics approach entails the simplification of the schemes to a limited number of chemical species (generally less than one hundred) and reactions (less than fifty), which can be handled by simulation software. In this work, we used the lumped kinetics over experimental pyrolysis data from Hansen (Hansen et al., 2022) and verified its capacity to predict product mixture composition.

## 2. Materials and methods

The adopted lumped kinetics describing the pyrolysis of lignin-rich residue is composed of two different kinetics models. The first part describing the conversion of the residual cellulose and hemicellulose fractions was adapted from the model proposed by (Ranzi et al. 2008). The second part describing the conversion of the lignin fraction, on the other hand, was adapted from the kinetics model proposed by Dussan (Dussan et al. 2018). The latter, the lignin-specific part of the model, is composed of four pseudo-lignin building blocks (LIG-1 to LIG-4) as in the model by Dussan (Dussan et al. 2008) while the stoichiometry of lignin pyrolysis reactions was modified. Overall, our lumped kinetics model contained 16 reactions and 49 species describing lignin pyrolysis. The kinetics model has been implemented in MATLAB 2022a code. The pyrolysis reactions occur in a fluidized bed reactor, where solid particles are circulated by the generated gas, and the gas itself guarantees continuous mixing inside the reactor. Thus, we modelled the fluidized bed as an isothermal plug flow reactor (PFR), with the following assumptions to simplify the calculations: the generated gas drags and entrains the small solid particles in a plug flow, while the gas and solid phases are vigorously mixed in the system, and this leads to almost isothermal conditions in the reactor volume. These simplifications provided us with a general simplified model that could be incorporated into a COCO simulation flowsheet, instead of using a descriptive and compute-intensive computational fluid dynamics (CFD) model. Furthermore, this work aims at the preliminary validation of the lumped kinetic model using experimental data from (Hansen et al. 2022).

## 3. Model equations and implementation

The pyrolysis reactor (fluidized bed) has been modelled as an isothermal PFR as follows. The material balance for each compound in the reactor is given in Equation (1):

$$\frac{dn_k}{dV} = \sum_{j=1}^{NR} v_{kj} r_j \quad (1)$$

where  $n_k$  is the mole flow of a generic species and  $V$  is the volume of the reactor (domain of integration of the Ordinary Differential Equations system, ODE). The reaction rate ( $r_j$ ) is defined as:

$$r_j = k_{R_j}(T) \cdot c_{\text{reactant}}^\beta \quad (2)$$

and the reaction order depends on the kinetics model adopted: first order ( $\beta=1$ ) for the cellulose and hemicellulose reactants as in Ranzi (Ranzi et al. 2008) and second order ( $\beta=2$ ) for the lignin pyrolysis as reported in Dussan (Dussan et al. 2018). The concentration of the reactant refers to the reactor volume. Reactions occur both in the solid and gas phases, thus the concentration ( $c$ ) of the  $k$ -th specie should be defined as:

$$c_k = \frac{\dot{n}_k [\text{kmol}\cdot\text{s}^{-1}]}{Q [\text{m}^3\cdot\text{s}^{-1}]} \quad (3)$$

We accounted for the variation of the volumetric flow ( $Q$ ) which is the sum of both solid particles and gas species (in a plug flow the gas entrains the solid), as shown in (4):

$$Q = Q_{\text{sol}} + Q_{\text{gas}} \quad (4)$$

$$Q_{\text{sol}} = \frac{\sum \dot{m}_k^{\text{sol}}}{\sum \frac{\omega_k^{\text{sol}}(\dot{n}_{\text{sol}})}{\rho_k^{\text{sol}}}} \quad (5)$$

$$Q_{\text{gas}} = \frac{\sum \dot{m}_k^{\text{gas}}}{\rho_{\text{gas}}} \quad \text{with} \quad \rho_{\text{gas}} = \frac{P \cdot \sum x_i^{\text{gas}}(\dot{n}_{\text{gas}}) \cdot \text{MW}_i}{RT} \quad (6)$$

In the proposed expressions,  $\dot{m}_k^{\text{phase}}$  is the mass flow of a generic species ( $k$ ) in the corresponding phase (gas or solid),  $\omega$  is the mass fraction,  $x$  is the molar one, and  $\rho$  the density of the phase. Thus, the gas and solid volumetric flows, calculated using Equations (5) and (6), respectively, are continuously updated with the composition of the respective phases from the material balance as the pyrolysis of biomass progresses. For the gas phase, we assumed ideal gas mixture behavior due to the high temperatures reached in pyrolysis ( $T > 500^\circ\text{C}$ ). The model requires additional inputs such as the reaction dimensions and the minimum fluidization velocity. The minimum fluidization velocity was calculated using Fogler's method (Fogler, 2020). For the calculation, we assumed that the lignin-rich biomass particles have a spherical shape with a diameter of 1 mm. It is noteworthy that a spherical shape is responsible for the largest pressure drop requirement to spark fluidization, thus, this is a conservative assumption. Typical dimensions of a pyrolysis reactor for industrial applications were adapted from (Zhou et al., 2019). The kinetic model described in this section has been assembled using MATLAB R2022a. The feed inlet composition is the outcome of previous calculations related to other unit operations for biomass pre-treatment. As feed to the pyrolysis, we selected the biomass that had been steam exploded at  $220^\circ\text{C}$  and saccharified with LPMO-cellulase solution with a dose of  $8 \text{ g}_{\text{enzymes}}/\text{kg}_{\text{biomass}}$  (refer to Note I for details).

#### 4. Results

We compared our model's results with the experimental observation reported by Hansen (Hansen et al., 2022). Then, we performed a sensitivity analysis on the pyrolysis temperature (in the range between  $450$  and  $700^\circ\text{C}$ ). The pyrolysis process generates four main product streams: biochar (including unconverted biomass), syngas (including non-condensable components such as carbon monoxide, methane, and short aliphatic compounds), an aqueous phase, and bio-oil (comprising all other components). Table 1 gathers the results from the model under different scenarios. We considered our data obtained with  $450^\circ\text{C}$  and  $500^\circ\text{C}$  temperatures as relevant to contrast our results against the experimental observations (conducted at  $500^\circ\text{C}$ ) in Hansen's work. Furthermore, we tested different pseudo-lignin building block combinations (LIG-1, LIG-2, LIG-3, or LIG-4 alone or the equimolar combination of all four building blocks; see Table 1) to characterize the biomass treated in the experiments since no details are available to fully describe the lignin fraction with the pseudo-lignin components approach by Dussan. There was a considerable mismatch between the experimental data and the model, with a tendency to overestimate the mass ratio of the bio-oil fraction (Table 1). There are several plausible explanations that could justify these deviations to some extent. First, the simplified model does not account for secondary (decomposition) reactions that generate

lighter, non-condensable components in the gas phase, thus leading to an overestimation of the bio-oil and an underestimation of the gas fraction (Corbetta et al., 2015; Ranzi et al., 2014). Second, Dussan and Ranzi's models consider that a fraction of the gas and bio-oil constituents remain adsorbed to the solids even at high temperatures. Our model, on the other hand, assumes complete separation of the pyrolysis fractions, which, to some extent, could lead to underestimation of the biochar fraction and, at the same time, overestimation of the bio-oil and light gas fractions (compare the values to the ones in brackets in Table 1). Third, in the experimental setup by Hansen (Hansen et al. 2022), pyrolysis products are purged with cold nitrogen gas from a small fixed-bed system. The cold nitrogen may locally quench the solid bed, leading to a lower extent of pyrolysis and, consequently, to a higher amount of unconverted solid residue in the biochar fraction experimentally. Fourth, the mass ratio of the pyrolysis fractions substantially depends on the lignin model composition, i.e. the ratio of the four types of pseudo-lignin building blocks, as shown by the sensitivity analysis in Table 1. In the absence of available compositional data on the lignin-rich residue, the lignin model was approximated with the equimolar composition of the four pseudo-lignin building blocks based on the work by Dussan (Dussan et al. 2018), which may be suboptimal. The pseudo-lignin building blocks *LIG-4* and, to some extent, *LIG-2* are associated with a higher residual solid biochar fraction. Notably, (1) there are many other variables in the model that influence the pyrolysis fraction ratios, and (2) the differences between the outcomes with different building blocks are small compared to how far off we are from the experimental data. Moreover, these lignin building blocks (from *LIG-1* to *LIG-4* in Dussan) may not be optimal representatives of our system. Last but not least, the simplification of the process into a limited number of chemical species and reactions (i.e., the use of lumped kinetics) carries an additional source of error. The supporting material by Hansen (Hansen et al. 2022) reports a detailed product distribution and the classification of the thousands of reported species for the bio-oil fraction only. Estimating the distribution of especially low-boiling temperature species in the bio-oil and light gas fractions is not trivial. All in all, our results indicate that further refinement of the model is needed to reach the experimental outcome.

Table 1 - Comparison of the experimental mass distribution of pyrolysis product fractions between experimental data (Exp data) and model predictions with five pseudo-lignin building block combinations at 450°C and 500°C. Values before brackets assume that some species of the bio-oil and gas fractions remain entrapped in the solid bio-char fraction when recovering the pyrolysis fractions, while values in brackets assume complete separation of the pyrolysis fractions.

Next, we looked further into the impact of pyrolysis temperature on the conversion efficiency (described by the amount of unconverted biomass) and on the distribution of the types of chemicals being formed and consumed during pyrolysis (Figure 1). Pyrolysis was more complete at higher temperatures as indicated by a drop in the fraction of unconverted biomass remaining after pyrolysis (green bars in Figure 1), which can mainly

be attributed to pyrolysis being endothermic and thus thermodynamically favored at higher temperatures. Increasing the process temperature facilitated char formation (brown bars in Figure 1), although overall char formation remained limited (mass fraction <0.08 w/w). Notably, the decrease in the proportion of unconverted biomass at higher temperatures was not comparable to the increase in char formation, resulting in an apparent decrease in the proportion of the solid “biochar” fraction that comprises unconverted biomass and char. In our model, lignin-rich biomass was primarily converted to lighter gaseous compounds and bio-oil species (listed in Figure 2). Water content and thus the amount of aqueous fraction after pyrolysis remained low (mass fraction <0.05 w/w), irrespective of the pyrolysis temperature. The differences between the product distributions above 600°C were negligible. Thus, we can conclude that the optimal temperature window is found between 600–650°C, with the lignin conversion being higher than 90% at such operating conditions.

Figure 1 - Temperature effect on the distribution of pyrolysis products.

Figure 2 - The distribution of chemical compound types in the bio-oil generated at temperatures that are of interest for industrial pyrolysis: 500°C (A), 550°C (B), 600°C (C), and 700°C (D).

The relative proportion of bio-oil compounds formed at temperatures from 500 to 700°C is shown in Figure 2. We limited the upper temperature to 700°C because over that temperature lignin is almost depleted and secondary reactions result in excessive gas production, thus limiting the bio-oil production as described by Corbetta (Corbetta et al., 2015). In general, aldehydes, alcohols, and phenols, which are the main classes present in biofuels (Okolie et al., 2020) were the main constituents of the bio-oil (Figure 2). In particular, the alcohol fraction decreased when increasing process temperature, while the aldehyde and phenol contents followed opposite trends due to their relatively higher stability. Although phenols are valuable chemicals, their removal from bio-oil is preferred before fuel applications due to corrosiveness and low heating values (Fardhyanti et al., 2020). Furthermore, ethers and furans are appreciably formed above 450°C and make up

about one-tenth of the bio-oil from the comparison between Figure 1 and Figure 2. Ketones and carboxylic acids are also present in the bio-oil mixtures in smaller amounts, and the pyrolysis temperature does not seem to affect substantially their formation. To fully evaluate the potential of bio-oil production in a biorefinery concept, the storage stability of the generated bio-oil will have to be considered in addition to composition.

## 5. Conclusions

The present work merged two lumped kinetics models describing pyrolysis of lignocellulosic biomass published by Ranzi for the cellulose and hemicellulose part, and Dussan for the lignin fraction to characterize the thermal conversion of lignin-rich biomass to biofuels. The model shows a qualitatively good agreement over a limited number of experimental data applied to scale up a spruce-based biorefinery combining biochemical and thermochemical conversion routes as in Hansen (Hansen et al., 2022). Although lumped kinetics itself, which simplifies the thermo- and bio-chemical processes into a comprehensive model, presents some limitations to the accuracy of the model, it allows flowsheet implementation and thereby easier and more efficient workflow during scale-up. Sensitivity analysis of the pyrolysis process allowed us to identify the optimal temperature window for operating a large-scale pyrolysis reactor, and, remarkably, it provided a rough estimate of the residual solid (biochar), bio-oil, and light gas fractions, as well as of the product distribution in the bio-oil.

## Abstract

A numerical model of a U-loop bioreactor is developed, with the aim of replicating the mass transfer characteristics of the real system. The bioreactor model includes a multiphase fluid dynamic model, coupled with a population balance model, to simulate the dispersed bubbles in the loop and estimate the gas-liquid interfacial surface area. The results from the numerical model are compared to experimental measurements of the mass transfer coefficient in the downgoing leg of the U-loop. The numerical model of the U-loop bioreactor is able to replicate the qualitative behavior of  $K_L a$  as function of the operating parameters: liquid circulation, gas flow and bottom pressure, however the dependency on operational conditions is under-valued. Further validation of the individual models is required to develop more realistic and robust models, and will contribute to understanding the physical phenomena taking place in a U-loop. The numerical model also provides insights into the qualitative behavior of the multiphase flow in a U-loop bioreactor.

## 1. Introduction

Fermentation has become an increasingly important chemical process in a wide range of applications, from pharmaceutical to bulk chemical and biofuel productions [1]. However, most fermentations are still run as batch processes and lack measurement-based control [2]. Other challenges with operating industrial scale fermentations relates to the inhomogeneous mixing conditions and mass transfer limitations, both related to the fluid dynamics of the system. This induces gradients in the fermenter, that lead to suboptimal conditions for the microorganisms and control issues, both having an impact on the

process economic metrics. Thus, understanding and accurately modeling the fluid dynamic behavior of bioreactors is a key element for predicting the overall behavior of the fermentation process. The main challenge with modeling fluid behavior in large-scale equipment originates from the complex nature of turbulent flow, which limits the accuracy of deterministic models in macroscopic simulations at high Reynolds numbers. Computational fluid dynamics has become a useful tool for investigating hydrodynamic conditions in multiphase systems through modeling of the turbulence and fine discretization of the flow equations. Interesting case studies are the U-loop bioreactors currently used by UNIBIO A/S, a Danish company specialized in the production of Single Cell Proteins through continuous aerobic fermentation of *Methylococcus capsulatus* using methane gas as primary carbon source. An aerobic fermentation using a gaseous substrate, makes mass transfer between the phases of crucial importance to the process. The alternative bioreactor design, U-loop, greatly improves volumetric mass transfer, however, it is not yet fully understood which underlying phenomena are contributing to the enhanced mass transfer. This study therefore looks at developing and validate a numerical model of a U-loop bioreactor to better understand the mass transfer mechanism in such a system.

## 2. Materials & Methods

### 2.1. Description of the system

The design of the U-loop bioreactor consists of two distinguishable parts: the loop (Plug flow) section and the top tank (or degassing unit). Gases introduced at the start of the down-going leg are carried through the loop by the liquid and are finally released in the top tank. A sketch of the system is shown in Figure 1. A pump, located before the gas inlets, is in charge of circulating the liquid through the loop. The U-loop is equipped with static mixers, and a heat exchanger. The pressure in the loop can be adjusted using an expansion valve located after the heat exchanger. This study uses a production scale U-loop with an active volume of 1725 [L], a liquid height of 6 [m] and a loop pipe diameter of 0.4 [m]. The selected operating conditions are similar to the conditions during production (e.g. flowrates and pressure), to mimic industrial process conditions. To investigate the multiphase hydrodynamics, water is used instead of fermentation broth, and the gas phase only includes air and pure oxygen. This simplification is based on the assumption that the mass transfer is mainly driven by convective transport (not diffusion driven) and thus the global liquid phase mass transfer coefficient ( $K_L a$ ) can be assumed equal for all compounds, and independent of the transfer direction. This simplification does consider the mass transfer of CO<sub>2</sub> produced during fermentation. The model can later be coupled with biokinetic equations to predict the transfer rates and resulting concentration profiles for each individual gas.

### 2.2. Experimental Setup

The  $K_L a$  in the U-loop is determined experimentally based on dissolved oxygen measurements. Due to the plug flow nature of the bioreactor, ideal mixing cannot be assumed for the entire system. Therefore, the component mass balance assuming ideal mixing (eq. 1), typically used to determine the  $K_L a$  in stirred tanks, cannot be applied for the U-loop. However,  $K_L a$  can be determined for a section of the loop based on two measurement points and the component mass balance over this loop section. Assuming steady state, and unidirectional mass transfer (i.e. from the gas phase to the liquid phase) the resulting mass balance (eq. 2) is an algebraic equation. Assuming perfect radial mixing, the dissolved oxygen measurements are used to determine the inlet and outlet oxygen concentrations,  $C_{in}$  and  $C_{out}$  respectively. The measurements are performed over

a 1[m] vertical pipe section on the down-going leg of the loop. The dissolved oxygen is measured at the top and bottom of the section, and the pressure is only measured at the top. The equilibrium saturation concentration  $C^*$  of oxygen in water is generally given by Henry's Law (eq.3) and is adjusted for changing pressures.

$$\frac{dC}{dt} = K_L a (C^* - C) \quad (eq.1)$$

$$0 = K_L a (C^* - C) V_L^{section} + F_{in} C_{in} - F_{out} C_{out} \quad (eq.2)$$

$$C^* = He P_{O_2} \quad (eq.3)$$

$He$  being the Henry Constant for oxygen in water (0.0013 [ $mol\ kg^{-1}\ bar^{-1}$ ] or 41.48 [ $g\ m^{-3}\ bar^{-1}$ ] at 25°C [3]), and  $P_{O_2}$  the partial pressure of oxygen (eq. 4).

$$P_{O_2} = y_{O_2} P \quad (eq.4)$$

For this study, the ratio between air and pure oxygen is adjusted to achieve an oxygen inlet concentration of 30%. Since the  $O_2$  liquid concentration  $C$  and saturation concentration  $C^*$  change over the pipe section, the driving force is estimated using the logarithmic mean (eq.5) of the driving force in (eq.6) and out (eq.7) of the pipe section.

$$(C^* - C)_m = \frac{(C^* - C)_{in} - (C^* - C)_{out}}{\ln\left(\frac{(C^* - C)_{in}}{(C^* - C)_{out}}\right)} \quad (eq.5)$$

$$(C^* - C)_{in} = (He P_{in} y_{O_2, in} - C_{in}) \quad (eq.6)$$

$$(C^* - C)_{out} = (He P_{out} y_{O_2, out} - C_{out}) \quad (eq.7)$$

The inlet pressure corresponds to the measurement of the top pressure sensor, and the outlet pressure is estimated from the height difference (eq.8) (neglecting the pressure drop in the pipe). The inlet oxygen fraction in the gas phase  $y_{O_2, in}$  is determined from the ratio of air and pure oxygen (eq.9) and the outlet oxygen fraction in the gas phase  $y_{O_2, out}$  is determined from the mass balance (eq.10):

$$P_{out} = P_{in} + \rho_L g \Delta h \quad (eq.8)$$

$$y_{O_2, in} = \frac{Q_{air} y_{air} + Q_{O_2}}{Q_{air} + Q_{O_2}} \quad (eq.9)$$

$$y_{O_2, out} = \frac{Q_{air} y_{air} + Q_{O_2} - (C_{in} - C_{out}) Q_{Uloop}}{Q_{air} + Q_{O_2} - (C_{in} - C_{out}) Q_{Uloop}} \quad (eq.10)$$

where  $Q_{Uloop}$  represents the circulation flow rate of the liquid phase in the loop,  $y_{air}$  the fraction of oxygen in air (21%),  $Q_{air}$  the inlet flowrate of air and  $Q_{O_2}$  the inlet flowrate of pure oxygen. From equations (eq. 2-10),  $K_L a$  is determined based on the dissolved oxygen measurements in and out, as well as the pressure measurement at the section inlet. The latter measurement is performed at different operating conditions, by changing the liquid circulation rate, the gas inlet flow rate, and the operating pressure in the loop.

### 2.3. Computational Model

The aim of the computational model is to replicate the multiphase physics taking place in the bioreactor to predict the mass transfer rates at different operating conditions. The model will focus on the loop section of the bioreactor, as the area of interest. Therefore, the fluid domain of the numerical model starts immediately after the pump, and ends immediately after the pressure reduction valve. For simplification, the heat exchanger,

and the pipe bends on the horizontal part of the loop are neglected. The static mixers in the loop are modelled as a porous domain for which the model parameters are fitted to match the measurements. In this way, the pressure drop, fluid mixing and impact on the bubbly flow resulting from the static mixers can be recreated, without having to resolve the geometry of the static mixers. Modeling the exact geometry of the static mixers and the complete U-loop would require a fine discretization to resolve the flow, adding to the computational cost of the simulation. The geometry of the computational domain is shown in Figure 2. The fluid domain, as well as the temporal dimension are then discretized, to solve the model equations in a numerical way. Ideally, the discretization should not influence the results. Therefore, a discretization study is performed, where the results from different meshes and timesteps are assessed. Once the geometry has been defined, and discretized, the governing equations to be solved are selected. Based on the liquid phase Reynold's Number (eq.11) of around  $4 \cdot 10^5$  in the pipe section, the flow regime is expected to be fully turbulent. The multiphase flow regime (e.g., Figure 3) depends on many factors (gas volume fraction, superficial gas velocity, pipe diameter and orientation, sparger type, etc. [5]) and is difficult to predict.

Figure 2: Fluid domain for the computational model

Figure 3: Gas-liquid flow regimes in a horizontal pipe (Adapted from [4])

parameters are shown in Table 1. The bubbles are assumed spherical, and the bubble size is modeled with a population balance model (PBM) describing the bubble coalescence and breakup. The bubble diameter is discretized into 5 bins: 0.86mm, 1.78mm, 2,7mm, 3.62mm and 4.54mm. The size fraction of each bin is determined from the population balance model. Finally, the mass transfer model is implemented. Based on the Film theory [11], the oxygen transfer rate can be expressed as shown in eq.13:

$$OTR = K_L a (C^* - C) \quad (eq. 13)$$

where  $OTR$  is the volumetric oxygen transfer rate [ $g m^{-3} s^{-1}$ ],  $C^*$  the saturation concentration of oxygen in water (or oxygen concentration at the surface of the bubble), and  $C$  the bulk oxygen concentration. The interfacial area  $a$  is determined from the PBM according to (eq.14) and (eq.15),  $d_p$  being the mean bubble Sauter diameter and  $r_\beta$  the volume fraction of air.

$$a = \frac{6\tilde{r}_\beta}{d_p} \quad (eq. 14)$$

$$\tilde{r}_\beta = \begin{cases} \max(r_\beta, r_{min}), & r_\beta < r_{max} \\ \max\left(\frac{1-r_\beta}{1-r_{max}} r_{max}\right), & r_\beta > r_{max} \end{cases} \quad (eq. 15)$$

The bubble Reynolds number (eq.12) can provide some insight into the turbulence level at the scale of a single bubble. However, it requires knowing the bubble size and relative velocity.

$$Re = \frac{\rho_L u L}{\mu_L} \quad (eq. 11)$$

$$Re_{bubble} = \frac{\rho_L d_b |\overline{U_G} - \overline{U_L}|}{\mu_L} \quad (eq. 12)$$

For this study, the gas phase is assumed fully dispersed resulting in a perfect bubbly flow. The simulation

Parameter	Value
Multiphase Model	Liquid phase: Continuous Gas phase: Fully dispersed + PBM (Ideal gas at 25°C)

Momentum Transfer Model	Schiller and Naumann [10]

Table 1: Simulation Parameters for the Numerical Study

$r_{min}$  and  $r_{max}$  are model parameters.  $\tilde{\beta}$  is used as a modified volume fraction to avoid the overprediction of the interfacial area at high gas volume fractions, where the assumption of fully dispersed gas phase is no longer valid. The liquid mass transfer coefficient  $K_L$  (eq.16) is determined from the derivation of the Higbie's penetration theory for turbulent Newtonian flow [6]:

$$K_L = 0.301 \left( \frac{D_\phi}{\nu} \right)^{-0.5} (\epsilon \nu)^{0.25} \quad (eq. 16)$$

where  $D_\phi$  is the diffusion coefficient of oxygen in water,  $\nu$  is the kinematic viscosity of water and  $\epsilon$  is the turbulence eddy dissipation generated by the turbulence model.

#### 2.4. Numerical Setup

The simulations are performed on ANSYS CFX 2019R2 on 24 hpc parallel cores, with three different conditions at the boundaries: the liquid phase inlet, the no-slip walls, and the pressure outlet. The relative pressure at the pressure outlet is adjusted to achieve the correct pressure profile in the loop (representing the pressure reduction valve). The gas phase is introduced into the system through a numerical source point with a bubble diameter of 2.7mm. All simulations are run in Transient mode for 200[s] simulation time, to ensure steady state is achieved (circulation time  $\approx 14$ [s]). The fluid is initialized stationary. Due to the unsteady nature of turbulent transient simulations, the results are time averaged over the last 50 [s] simulation time.

### 3. Results and Discussion

#### 3.1. Discretization Study

The simulation is performed for a range of generated meshes (from 15k to 140k mesh elements), each over a range of timesteps (0.001[s] to 0.1[s]). For each simulation, the gas holdup in the system is calculated and used to compare the results. In theory, the results should converge towards a single value as the discretization is made finer.

The optimal discretization is the coarsest discretization that provides similar results as the finer discretization. The results from the discretization study are presented in Figure 4. For the simulations performed with the coarse meshes (<60k elements) the results are inconsistent and depend on the mesh and timestep. For the two finest meshes (>80k elements) the results seem to be independent on the discretization. One outlier is the simulation performed with a timestep of 0.1 [s] yielded a gas holdup above 30 %, whereas the other simulations resulted in gas holdups around 10%. Based on this analysis, the optimal discretization is 83k mesh with timestep of 0.05 [s].

Figure 4: Gas Holdup as function of the number of mesh elements, for different

### 3.2. Model Validation

The measured and simulated  $K_L a$  values are shown in Figure 5. The first run is used for calibration, where the length of the porous domain and  $r_{max}$  were used as fitting parameters. The numerical model is able to replicate an increase or decrease of the  $K_L a$  at different operating conditions, however the

Figure 5: Measured and simulated  $K_L a$  values, at different operating conditions. (Results are normalized due to confidentiality of the experimental results)

dependency on operating conditions is under-valued. The discrepancy between the simulated and measured  $K_L a$  values can be explained by inaccuracies in the modeling, as well as inaccuracies in the experimental method. Regarding the numerical model, the choice of the models to be solved may be inadequate to provide realistic results. Here the choice of using a porous domain to simulate a static mixer may not be sufficient and requires further tuning, or resolving the exact geometry of the static mixer. The assumption of fully bubbly flow regime, which is the basis for the choice of multiphase model, may be inaccurate, which is discussed in the following section 3.3.. Lastly, the PBM may require additional bins and the bubble diameter range represented in the bins could be offset to the actual bubble size distribution in the loop. Regarding the experimental measurements, inaccuracy of the equipment (flowmeter, DO probes) due to calibration or malfunction is a potential source of error. Also, inaccurate assumptions used to derive  $K_L a$  from the experimental data may contribute to the discrepancy.

### 3.3. Discussion

It can be clearly noted that the gas is not distributed homogeneously in the loop. A gas fraction of 23% is reached in the down-going leg, whereas in the upgoing leg, the gas fraction is around 3%. In the horizontal section of the loop, the model predicts a large accumulation of gas in the top half of the pipe, indicating a phase split (gas volume fraction of 37%). This behavior can be expected in such a system, considering the buoyant forces, the bubbles will rise in water, with a velocity depending on the drag force [12]. This means the bubbles rise against the flow direction in the down-going leg, increasing the residence time of the bubbles, in the horizontal section the bubbles rise perpendicular to the flow direction, creating the phase split, and in the upgoing leg the bubbles rise along with the flow direction decreasing the residence time of the bubbles. This leads to an inhomogeneous distribution of  $K_L a$  in the system, which is expected to be larger in the down-going leg, due to the phase split in the horizontal section that leads to a small interfacial surface area, and the low gas holdup in the upgoing leg. This can also be observed in the simulation results, where the  $K_L a$  in the downgoing leg, the horizontal section and the upgoing leg is determined to 1692, 474 and 123 [ $h^{-1}$ ] respectively. The resulting gas volume fractions in some sections of the bioreactor indicated that the flow regime might be different from the assumed bubbly flow. The dispersed gas phase model requires that the bubbles are smaller than the mesh elements. If larger gas structures are expected, the dispersed model is not applicable, and the gas needs to be simulated as a continuous fluid where the gas-liquid interface is resolved. Here, it seems that in some regions of the bioreactor, the gas phase can be assumed fully dispersed, e.g. down- and up-going legs, whereas in other regions the interface needs to be resolved, e.g. in the horizontal loop section where a clear phase split occurs. The  $\tilde{r}_\beta$  parameter is used to

correct the interfacial area, but the momentum transfer model considers only bubbles. Moreover, the validation of the multiphase model and the PBM is crucial for further studies to develop more accurate numerical models. This requires measurements of the multiphase behavior at a deeper level to directly validate each sub-model involved simulation.

#### 4. Conclusion

The numerical model of the U-loop bioreactor is able to replicate the qualitative behavior of the measured  $K_L a$ , however the dependency on operational conditions is under-valued. As many sub-models are involved in the simulation of the bioreactor, it is difficult to evaluate the origin of the inaccuracy in predicting the measured  $K_L a$ . Therefore, further studies should include additional measurements of the multiphase flow (e.i. bubble size distribution, gas superficial velocity), to ensure a more rigorous validation of the sub-models. On the other hand, the numerical model provided insights into the qualitative behavior of the multiphase flow in a U-loop bioreactor, presenting some challenges related to inhomogeneous distribution of the mass transfer potential. The results can be used as a basis for upscaling and improving the design of the bioreactor. However, further studies including further validations are required for the model to be used for accurate prediction of the process, for process optimization and control purposes.

# Effect of vaporisation models on the FCC riser modelling

Thabang W. Selalame, Raj Patel, Iqbal M. Mujtaba, Yakubu M. John

*Department of Chemical Engineering, University of Bradford, Bradford, BD7 1DP, West Yorkshire, UK*

## Abstract

Traditional approach to FCC riser modelling usually involves the modelling of the gas oil feed vaporisation since the cracking reactions occur in the gas phase. The majority of these studies assume instantaneous vaporisation of feed which greatly simplifies the modelling effort. A limitation of this approach is that it greatly overestimates the rates of vaporisation occurring in the riser which may lead to erroneous predictions from the model. In response to this, various models have been proposed in the literature to better model the finite vaporisation rates in the riser. This paper investigates the effect of these various vaporisation models on the predictions from riser models. Specifically, the infinite conductivity and the finite conductivity modelling frameworks are investigated. We show for the first time in this paper that vaporisation models are largely insignificant to the predicted gas oil conversion profiles and gasoline yield for usual operation conditions of FCC risers. Additionally, the effect of vaporisation models on conversion and yield predictions only becomes important for riser nozzles with feed droplets exceeding 2mm in diameter. This is a key finding as it proves the validity of instantaneous vaporisation models for droplets smaller than 2mm.

**Keywords:** Vaporisation, FCC unit, Riser, Modelling, Simulation

## 1. Introduction

Process modelling and simulation have always been important tools used by the petroleum industry to improve safety, efficiency and profitability. Owing to climate change, more emphasis has been put on the accuracy of these models in order to comply with increasingly stringent environmental regulations.

The Fluid catalytic cracking (FCC) unit is one of the most important units in petroleum refinery (Fernandes, Verstraete et al. 2007). For this reason, the modelling of the FCC riser has received substantial commercial and academic attention since the introduction of the process over five decades ago. Significant progress has been made to model the complex hydrodynamics and the reactions occurring in the riser. However, an area that has not been fully explored is that of vaporisation of the feed. Several models have been proposed to study vaporisation of fuel droplets, although most of these studies focus on single droplets evaporating into an infinite and quiescent gaseous atmosphere (Finneran 2021). This is far from the conditions in the riser, where droplets vaporise in complex gas-solid-liquid convective environment. This study investigates the effect of different vaporisation models, that have been previously developed in the literature, on the FCC riser model predictions for feed conversion and product yield. Two droplet frameworks are investigated, infinite thermal conductivity (ITC) and finite thermal conductivity

(FTC) (Miller, Harstad et al. 1998). In the former, spatial temperature variation in the droplet are ignored, while the latter assumes a finite value for the liquid phase and considers the spatial temperature distribution in the droplet as it rises. A majority of FCC riser models in the literature have adopted either the ITC framework (Nayak, Joshi et al. 2005) or assumed instantaneous vaporisation of the feed at the point of injection (John, Mustafa et al. 2019). Very few papers have used FTC in their riser models. As such, the impact of FTC on the riser predictions remain unknown until now.

## 2. Model Description

The catalytic cracking of heavy fraction gas oil in the FCC riser is a heterogeneous gas-solid reaction system. The complex hydrodynamics of the fast fluidised circulating bed have been described previously. The feed to the riser is introduced as atomised spray droplets that first undergoes vaporisation in the initial stages of the riser before reaction can occur. Various models have been proposed to describe the vaporisation dynamics in the riser environment. In this paper, we compare the influence of these models on the conversion and yield profiles in the riser.

The vaporisation problem being investigated in this situation is that of discrete spherical mono-component droplets evaporating in a gas-droplet-solid convective environment. The fluid and far field properties such as temperature, concentration and pressure are varying with the height of the riser due to the cracking reactions. Firstly, the assumption of infinite thermal conductivity (ITC) and diffusivity for the droplet phase is adopted, so that the temperature and concentration is the same everywhere on the droplet. The evolution of the droplet temperature, mass and size with height of the riser bed is given by:

$$m_d C_{pd} \frac{dT_d}{dz} = \frac{\dot{q} - \dot{m} L_v}{v_d} \quad (1)$$

$$\frac{dm_d}{dz} = -\frac{\dot{m}}{v_d} \quad (2)$$

$$\frac{dd_d}{dz} = -\frac{2\dot{m}}{\pi \rho_d d_d^2 v_d} \quad (3)$$

Where  $m_d$ ,  $d_d$  and  $T_d$  are the mass, diameter and temperature of the droplet,  $L_v$  is the latent heat of vaporisation,  $\rho_d$  is the liquid density and  $v_d$  is the velocity of the droplet.  $\dot{q}$  and  $\dot{m}$  are the rates of heat transfer and mass transfer at the droplet surface respectively. During the inert heating phase,  $\dot{m} = 0$ . Closures for  $\dot{q}$  and  $\dot{m}$  are provided via Nusselt and Sherwood number correlations. For convective environment (including the effect of Stefan flow) (Lupo 2017):

$$\dot{q} = \pi d_d^2 Nu k_g \frac{T_d - T_\infty}{d_d} \quad (4)$$

$$\dot{m} = \pi d_d^2 Sh \bar{\rho} D_{vap} \frac{Y_s - Y_\infty}{d_d} \quad (5)$$

$$Nu = \frac{Nu_0 \ln(1 + B_T)}{Le B_T} \quad (6)$$

$$Sh = \frac{Sh_0 \ln(1 + B_M)}{B_M(1 - Y_s)} \quad (7)$$

The subscript s and g represent the conditions at the droplet surface and the surrounding gas respectively. The heat and mass transfer is fully described by the dimensionless numbers:  $B_M = (Y_s - Y_\infty)/(1 - Y_s)$ ,  $B_T = (1 + B_M)^{\frac{1}{Le}} - 1$ ,  $Le = \frac{k_g}{\bar{\rho} D_{vap} C_{pg}}$ ,  $Nu = \frac{hd_d}{k_g}$ ,  $Sh = \frac{k_c d_d}{D_{vap}}$ . The boundary conditions are such that the far field properties (i.e  $Y_\infty, T_\infty$ ) are evaluated in the ambient hydrocarbon

gas mixture and  $Y_s$  and  $T_d$  are at the surface of the droplet. The vapour properties are evaluated at a reference temperature and composition using the 1/3 rule (Csemány and Józsa 2021). Subsequently, the gas and mixture properties are evaluated using the following mixing rules considering the vapour and ambient gas mixture:

$$C_{pg} = Y_{ref}C_{pv} + (1 - Y_{ref})C_{pm} \quad (8)$$

$$k_g = Y_{ref}k_v + (1 - Y_{ref})k_m \quad (9)$$

$$\mu_g = Y_{ref}\mu_v + (1 - Y_{ref})\mu_m \quad (10)$$

$$\rho_g = \left( \frac{Y_{ref}}{\rho_v} + \frac{1 - Y_{ref}}{\rho_m} \right)^{-1} \quad (11)$$

The subscripts “v” and “m” represent the vapour and ambient gas mixture respectively.  $C_p$ ,  $k$ ,  $\mu$  and  $\rho$  properties are evaluated at  $T_{ref}$  and  $Y_{ref}$  for the vapour and evaluated at  $T_\infty$  and  $Y_\infty$  for the ambient gas mixture. The mixing laws in Equations (8)-(11) are based on ideal gas conditions (Csemány and Józsa 2021).

The subscript “0” in Equations (6) and (7) indicates that the correlations for these transport numbers are evaluated in the limit of  $B_M = B_T = 0$  (i.e negligible evaporation). The classical models for  $Nu_0$  and  $Sh_0$  for moderate Reynolds numbers are those provided by Ranz (1952). In this work, we denote this the Classic model. The complexity with heat and mass transfer in the riser environment is that the flow field also consists of catalyst particles which enhance the heat transfer process. Several correlations have been suggested to account for this enhanced heat transfer. In this work the models by Buchanan (1994) and Nayak et al. (2005) are considered. A summary of these correlations is presented in Table 1.

Table 1: Nusselt number correlations for heat transfer to the droplets in the limit of negligible evaporation.

Model name	Reference	Model
Classic	Ranz (1952)	$Nu_0 = 2 + 0.552Re_d^{0.5}Pr^{0.33}$
Buchanan B*	Buchanan (1994)	$Nu_0 = \frac{\left(2 + 0.6Re_p^{\frac{1}{2}}Pr^{\frac{1}{3}}\right)}{\left(1 + \frac{c_{pg}(T_g - T_d)}{L_v}\right)^n}$
Nayak**	Nayak, Joshi et al. (2005)	$Nu_0 = Nu_{0,classic} + \frac{\emptyset \varepsilon_s L_v Pr}{4C_p(T - T_d)} \left( Re_d - Re_p \frac{d_d}{d_p} \right) \left( 1 - \frac{d_p}{d_d} \right)^2$
$Re_d = \frac{\rho_g  v_g - v_d  d_d}{\mu_g}$ , $Re_p = \frac{\rho_s \varepsilon_s  v_g - v_d  d_d}{\mu_g}$ , $Pr = \frac{c_{pg} \mu_g}{k_g}$ , Heat and mass transfer analogy is used to find $Sh_0$ from $Nu_0$ . *During heat up $n = 0$ and $n = 0.7$ during boiling. **The Nayak is the classic model with an extra term that represents the effect of catalyst particles. $\emptyset$ is an adjustable parameter of the model.		

### 3. Results

#### 3.1. Droplet size and temperature

Figure 1 shows the evolution of droplet temperature and size along the height of the riser from the point of feed injection. The Buchanan A model is the limit of infinitely fast heat transfer from catalyst particles to the droplets (Buchanan 1994).

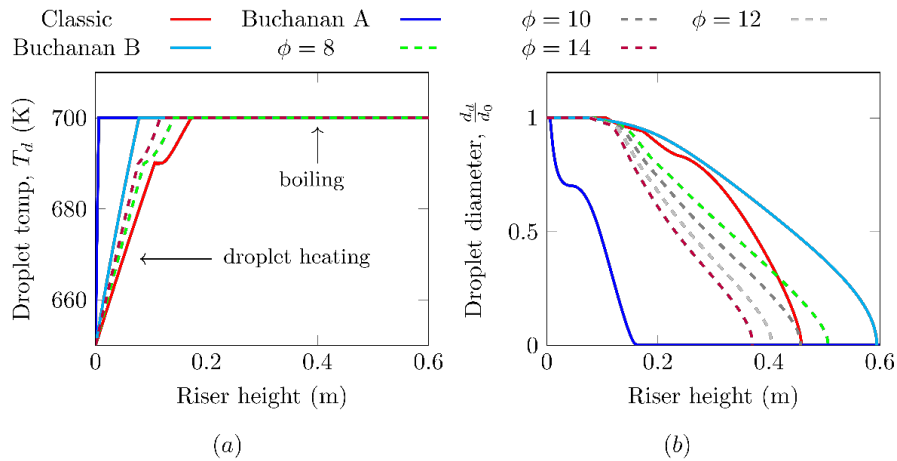

Figure 1: Simulation results for the steady state FCC riser ( inputs:  $\rho_d = 810$ ,  $\varepsilon_{d0} = 0.012$ ,  $d_d = 500\mu\text{m}$ ) comparing between different vaporisation models. (a) Evolution of droplet temperature from initial feed temperature to boiling, and (b) evolution of droplet size up the riser.  $\phi$  is the adjustable parameter in the Nayak heterogeneous model. The Buchanan models feature only inert heating and boiling, whereas Nayak and classic models have vaporisation beginning at  $T_{vap} = 690\text{K}$ .

Figure 2: (a) Predictions of gas oil feed conversion, and (b) gasoline yielded along the riser for the various feed vaporisation models. ( inputs:  $\rho_d = 810$ ,  $\varepsilon_{d0} = 0.012$ ,  $d_d = 500\mu\text{m}$ ). Simulation results are compared against the plant data reported by Derouin, Nevicato et al. (1997).

Figure 1(a) shows that the Buchanan models have higher heat transfer rates in the heat up stages and therefore droplets reach boiling temperature faster. However, the factor  $\left(1 + \frac{c_{pg}(T_g - T_d)}{L_v}\right)^{-0.7}$  in the Nusselt number for the Buchanan B model, which accounts for Leidenfrost effects, greatly reduces the heat transfer during boiling and hence results in longer droplet penetration as shown in Figure 1(b). It is shown in Figure 1(b) that the different vaporisation models predict different droplet penetration at the bottom of the riser. Additionally, all the models predict complete vaporisation within 0.6m from feed injection point, which is  $< 2\%$  of the total height of

the riser. However, Figure 2 shows that these differences do not translate to differences in conversion and yield profiles along the riser. This is a significant finding because it proves that for the ITC vaporisation framework; (a) hydrocarbon cracking reactions in the gas phase are the rate limiting step in the cracking process, and (b) vaporisation models are largely insignificant to the predictions of conversion and yield in the FCC riser, which gives validity to the commonly used assumption of instantaneous vaporisation.

### 3.2. Effect of modelling framework

In Figure 3, simulation for the ITC and the FTC modelling frameworks are compared. Figure 3(b) shows that all the FTC models predict slower vaporisation rates compared to their corresponding ITC counterparts in Figure 1(b). This is due to the spatial temperature variation in the droplet and heat transfer resistance caused by the finite thermal conductivity of the liquid phase. This resistance causes  $T_d$  to take longer to reach  $T_{bp}$ .

Beyond the initial vaporisation of the droplet phase (i.e. in the range  $690 \leq T_d \leq 700$ ), a complex coupling of gas-liquid-solid phases results, which determines the evolution of the gas oil conversion in Figure 3(c). In this temperature range, evaporation is slower since the heat transfer to the droplet is also used for droplet heat up. The added heat transfer resistance in the liquid leads to more energy being used up the droplet phase which leads to lower ambient (surrounding gas and catalyst) temperature and hence lower conversion in the FTC models. We find that exit gas temperatures of the Classic model between ITC and FTC differ by  $\sim 15K$ . An interesting find, is that the FTC models underpredict the conversion of the feed. This is a result of the aforementioned lower ambient temperatures in the FTC models. A fix for this, which has not been shown in this current work, is to use the effective thermal conductivity (ETC) modelling framework, which was developed to correct the liquid thermal conductivity of droplets vaporising in convective environments. In such systems, shear at the surfaces of the droplets causes internal circulations which enhances the heat transfer in the droplet. A common problem in vaporisation modelling for the FCC riser is the difficult in validating the models since conditions are such that experimental determination of vaporisation rates is difficult.

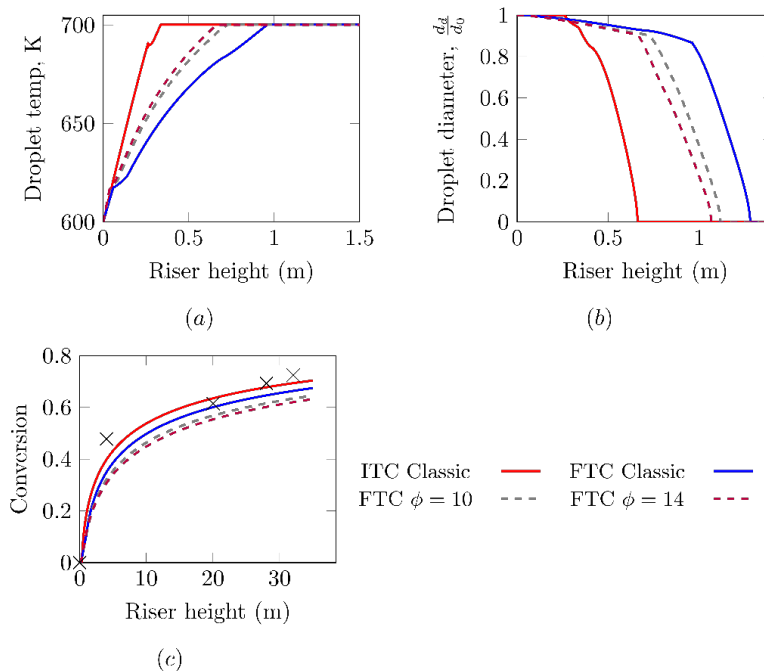

Figure 3:(a) Droplet temperature,  $T_d$ , (b) dimensionless droplet diameter,  $\frac{d_d}{d_0}$ , and (c) gas oil conversion for different models. All models use the same input values: ( $d_0 = 500\mu m$ ,  $T_{d0} = 600$ ,  $T_{vap} = 690$ ,  $T_{bp} = 700$ ,  $\rho_d = 810$ ,  $\varepsilon_{d0} = 0.012$ . For the FTC model framework, initial surface droplet temperature,  $T_{ds0} = 645$ ).

Using the conversion profile data, it is shown in Figure 3(c) that the ITC modelling framework best suits the data. It is also found in this work that this remains true for droplets  $< 2mm$ , beyond which the vaporisation starts slowing the cracking reactions.

#### 4. Conclusions

The ITC and FTC vaporisation modelling frameworks were investigated in the context of the FCC riser modelling and simulation. Both modelling frameworks are able to predict the penetration of the droplet feed up the riser from the point of feed injection. It is revealed that the ITC framework predicts faster vaporisation compared to the FTC, and also shown that the FTC over-predicts the energy transferred to the droplets over their lifetime and therefore leading to under-prediction of the conversion of feed. For most application, the available conversion profile data suggests that the ITC framework is recommended. Importantly within the ITC framework, the various homogeneous and heterogeneous Nusselt and Sherwood correlations do not affect the predicted yield and conversion profiles (which is only valid for  $d_{d0} < 2mm$ ). Beyond this droplet size range, the heterogeneous models should be used for better predictions of conversion.

## Abstract

When exploring prospective mining locations, a central task is modelling rock attributes in the subsurface. The drilling needed to sample these locations is costly, so efficient sampling and reliable interpolation methods are needed. Kriging models (Gaussian Processes) are thus used, with the kernel and its parameters determined from data analysis of preliminary samples and expert judgement. New samples iteratively update the model, targeting exploitation (high ore grades) and exploration (minimising prediction variance).

The problem arises if the chosen kernel is incorrect or high uncertainty affects parameters. This paper thus suggests a joint model-based design of experiments (j-MBDoE) approach to target two objectives: maximising the distinguishability of candidate model predictions and reducing model uncertainty from parameter variance. Three different kernels in an Ordinary Kriging GP were used as candidate models. In-silico data was generated using one kernel and the optimal design strategy iteratively determined sampling locations to maximise model distinguishability with a constraint to ensure improved parameter estimates. Two models could be distinguished and the data approximated well with a limited number of drilling experiments while satisfactorily estimating kernel parameters.

**Keywords:** multiobjective optimization, joint model-based design of experiments, geostatistics, Gaussian processes, Kriging

## 1. Introduction

Geological exploration for metals is gaining relevance as industry seeks to secure supply chains for metals which are critical for industrial processes such as battery production. However, in the past decade, recovery rates and new discoveries have been low. The major bottleneck in mining value-dense metals (e.g. copper or nickel), is the identification and estimation of subsurface deposits. For resource and reserve models, Kriging models (Gaussian Processes) interpolate between sample data, which is obtained by drilling into the ground and taking sample cylinders of rock for visual and chemical analysis. Around targets of interest, closely spaced grids are drilled (infill drilling) for better estimates. Thus, optimal sampling can increase efficiency. Studies and industry practice show better performance of quantitative over qualitative design criteria (Jafrasteh and Suarez, 2020).

Model-based design of experiments (MBDoE) aims to design experiments for objectives such as obtaining the most informative data for parameter estimation (Franceschini and

Macchietto, 2008) or discrimination between candidate models (Schwaab et al., 2006). This paper proposes a joint experiment design approach (Galvanin et al., 2016) to locate samples to discriminate between three different candidate models for subsurface mineral concentrations while at the same time improving the precision of parameter estimates.

A metal concentration profile is generated in-silico by a function describing the spatial correlation of likely concentration grades and a preliminary model is fit based on ten initial samples. From there, the goal is to identify the valid model and its parameters more efficiently than methods such as closely spaced infill drilling. As a metric of success, model fit and parameter estimation statistics for candidate models may be compared.

## 2. Methodology

### 2.1. Fitting models using Gaussian Processes

A Gaussian Process (GP) interpolates between samples (Sahimi, 2011; Rossi & Deutsch, 2014). Its kernel is a correlation function  $R(h)$ , which relates the semivariance  $\gamma(h)$  of likely unsampled concentrations at distance  $h$  and the overall concentration variance  $\sigma_Z^2$ .

$$\gamma(h) = \sigma_Z^2 - R(h) \quad (1)$$

Ordinary Kriging (OK) is a form of GP (Sahimi, 2011) giving the best unbiased linear estimate of the mean expected concentration at unsampled locations  $Z$  using the estimator  $\hat{Z}$ , and the variance of estimates ( $\sigma_{OK}^2$ ) based on the expected square error to the mean.

$$\sigma_{OK}^2 = E[(Z - \hat{Z})^2] \quad (2)$$

The estimator is based on the samples  $Z_i$  and their relative importance weights  $w_i$ .

$$\hat{Z} = \sum_{i=1}^N w_i Z_i \quad (3)$$

The optimal weights  $w_i$  can be found by substituting (3) into (2):

$$\sigma_{OK}^2 = \sigma_Z^2 - 2 \sum_{i=1}^N w_i R(Z, Z_i) + \sum_{i=1}^N \sum_{j=1}^N w_i w_j R(Z_i, Z_j) \quad (4)$$

Introducing constraint (5) ensures the unbiasedness of the calculated predictions, as they no longer depend on a previous estimate of population variance. Substituting (5) into (4):

$$\sum_{i=1}^N w_i = 1 \quad (5)$$

$$\sigma_{OK}^2 = 2 \sum_{i=1}^N w_i \gamma(Z, Z_i) - \sum_{i=1}^N \sum_{j=1}^N w_i w_j \gamma(Z_i, Z_j) \quad (6)$$

Then, minimising the Kriging variance:  $\partial \sigma_{OK}^2 / \partial w_i = 0$ , results in:

$$\sum_{i=1}^N R(Z_i, Z_j) w_i = R(Z, Z_j) \quad (7)$$

This gives a solvable linear system of equations for all unsampled points. It comprises a matrix  $\mathbf{W}$ , for weights of samples at unsampled locations ( $n_s \times n_u$ ),  $\mathbf{P}$ , for correlations between these points ( $n_s \times n_u$ ) and  $\mathbf{A}$ , for correlations between sampled points ( $n_s \times n_s$ ).

$$\mathbf{W} = \mathbf{A}^{-1} \mathbf{P} \quad (8)$$

Finally, the predictions from (3) and (6) are multiplied with  $\mathbf{W}$  for all unsampled points.

### 2.2. Model-based design of experiments

The optimal experiment design comprises the objectives parameter estimation and model discrimination. Schwaab et al. (2006) propose a discrimination criterion,  $\Psi^{\text{MD}}$  (9), based on the difference in responses  $\hat{Z}$ , their uncertainty  $\sigma$  and the probabilities  $P$  of models  $m$

and  $n$ . New samples reveal information in a Bayesian sense, since, once sampled, the GP must reflect sample values and the variance at the sampled point collapses to zero. So, instead of estimating the probabilities,  $P_m$  (11-12), using the  $\chi^2$  value, the total prediction variance,  $V$  (10) is used. For each coordinate  $(x, y)$  and set of kernel parameters  $\vartheta$ :

$$\Psi^{MD}(x, y, \vartheta) = \sum_{m=1}^{M-1} \sum_{n=m+1}^M (P_m, P_n) [\hat{\mathbf{Z}}_m(x, y, \vartheta) - \hat{\mathbf{Z}}_n(x, y, \vartheta)]^T \mathbf{V}_{m,n}^{-1}(x, y, \vartheta) [\hat{\mathbf{Z}}_m(x, y, \vartheta) - \hat{\mathbf{Z}}_n(x, y, \vartheta)] \quad (9)$$

$$V_{m,n}(x, y, \vartheta) = 2V(x, y) + V_m(x, y, \vartheta) + V_n(x, y, \vartheta) \quad (10)$$

$$\phi_m(\vartheta) = 1 / \sum_{x=1}^X \sum_{y=1}^Y \sum_{k=1}^K V_m(x, y, k, \vartheta) \quad (11)$$

$$P_m(\vartheta) = \frac{\phi_m(\vartheta)}{\sum_{m=1}^M \phi_m(\vartheta)} \quad (12)$$

To quantify parametric uncertainty (Franceschini and Macchietto, 2008), the kernel parameters  $\boldsymbol{\vartheta}$  are perturbed from their initial estimates and the impact on the measured responses (Kriged concentration values),  $\mathbf{Z}$ , is stored in the sensitivity matrix  $\mathbf{Q}$  (13).

$$\mathbf{Q}_{x,y}(\mathbf{Z}, \boldsymbol{\vartheta}) = \begin{bmatrix} \frac{\partial Z_1}{\partial \vartheta_1} \\ \vdots \\ \frac{\partial Z_1}{\partial \vartheta_n} \end{bmatrix} \approx \begin{bmatrix} \frac{\hat{Z}_1 - \hat{Z}_1'}{\vartheta_1 - \vartheta_1'} \\ \vdots \\ \frac{\hat{Z}_1 - \hat{Z}_1'}{\vartheta_n - \vartheta_n'} \end{bmatrix} \quad (13)$$

However, in a GP, the information at a point depends on both the predicted mean and variance. A point with high variance is less informative than a point with low variance. Thus, analogous to the local uncertainty in  $\Psi^{MD}$ , an uncertainty (14) (standard deviation) for each model response and parameter perturbation is defined and stored in  $\mathbf{Q}^{Adj}$  (15).

$$\sigma_{\text{total}} \frac{\partial \hat{Z}_n}{\partial \vartheta_n}(x, y) = 2 \sigma_{\text{exp}}(x, y) + \sigma_{\hat{Z}_n, \vartheta_n}(x, y) + \sigma_{\hat{Z}_n', \vartheta_n'}(x, y) \quad (14)$$

$$\mathbf{Q}_{x,y}^{Adj}(\mathbf{y}, \boldsymbol{\vartheta}) = \begin{bmatrix} 1 & \frac{\partial y_1}{\partial \vartheta_1} \\ \sigma_{\text{total},1} & \vdots \\ 1 & \frac{\partial y_1}{\partial \vartheta_n} \\ \sigma_{\text{total},n} & \vdots \end{bmatrix} \approx \begin{bmatrix} \frac{1}{(2\sigma_{\text{exp}} + \sigma_{y_1, \vartheta_1} + \sigma_{y_1, \vartheta_1'})} \left( \frac{y_1 - \hat{y}_1}{\vartheta_1 - \vartheta_1'} \right) \\ \vdots \\ \frac{1}{(2\sigma_{\text{exp}} + \sigma_{y_n, \vartheta_n} + \sigma_{y_n, \vartheta_n'})} \left( \frac{y_1 - \hat{y}_1}{\vartheta_n - \vartheta_n'} \right) \end{bmatrix} \quad (15)$$

The Fisher information,  $\mathbf{H}_{x,y}(\boldsymbol{\vartheta})$  (16), is the local information about parameters  $\boldsymbol{\vartheta}$ . Its trace gives a scalar criterion known as A-optimality (Franceschini and Macchietto, 2008).

$$\mathbf{H}_{x,y}(\boldsymbol{\vartheta}) = \mathbf{Q}_{x,y}^{Adj} \mathbf{Q}_{x,y}^{Adj T} \quad (16)$$

The joint design criterion,  $\phi^{ID}$  (17), by Galvanin and co-workers (2016) combines  $\Psi^{MD}$  (9) and an A-optimal parameter precision criterion,  $\Psi^{PE}$  (18).

$$\phi^{ID} = \text{argmax}\{\Psi^{MD}\}_{\phi \in D} \quad (17)$$

s.t.

$$\Psi^{PE} = \sum_{j=1}^{N_M} \|\mathbf{H}_j\| / N_M \leq \varepsilon \quad (18)$$

$$\begin{aligned} \varepsilon_{\min} &= \max(\Psi^{PE}) & \text{s.t.} & \max(\Psi^{MD}) \\ \varepsilon_{\max} &= \max(\Psi^{PE}) & \text{s.t.} & \max(\Psi^{PE}) \end{aligned}$$

That is,  $\varepsilon_{\min}$  ensures that the design criterion addresses model discrimination, while  $\varepsilon_{\max}$  allows solutions that fully tilt towards parameter estimation. A slack variable,  $s_0$ , is added to avoid weakly efficient solutions (Mavrotas, 2009). The value of  $\varepsilon$  can be moved between the two extremes in order to explore the Pareto optimal set of suggested samples.

### 3. Case Study

#### 3.1. Definition of candidate models

The candidate models are defined through the correlation function used in the kernel. In these kernels, the parameter  $s$  is the partial sill of semivariogram, which is the maximum semivariance (or minimum correlation) the probabilities of mineral concentration at two points in space will reach, minus the nugget effect. The nugget effect,  $n$ , is the difference in measured value from one point to a point just adjacent to it (on a smaller scale than the model can capture),  $r$  is the range (characteristic length at which the maximum variance between the probabilities of mineral concentration at two points in space is reached) and  $a$  is a numerical parameter. With the bounds  $\delta_{(i,j)}(h)$  represented in a Boolean manner:

$$\delta_{(i,j)}(h) = \begin{cases} 1 & \text{if } h \in (i, j) \\ 0 & \text{otherwise} \end{cases}$$

Table 1 – Kernels used in formulation of candidate models

Type of Kernel (Source)	Kernel Expression
<b>M1:</b> Gaussian (Rossi & Deutsch, 2014)	$\gamma(h) = \left\{ (s) \left( 1 - e^{-\frac{1}{3} \frac{h^2}{r^2}} \right) \right\} \delta_{(0,r)}(h) + s \delta_{(r,\infty)}(h) + n \delta_{(0,\infty)}(h)$
<b>M2:</b> Exponential (Rossi & Deutsch, 2014)	$\gamma(h) = \left\{ (s) \left( 1 - e^{-\frac{1}{3} \frac{h}{r}} \right) \right\} \delta_{(0,r)}(h) + s \delta_{(r,\infty)}(h) + n \delta_{(0,\infty)}(h)$
<b>M3:</b> Spherical (Sahimi, 2011)	$\gamma(h) = \left\{ (s) \left( \frac{3h}{2r} - \frac{1}{2} \left( \frac{h}{r} \right)^3 \right) \right\} \delta_{(0,r)}(h) + s \delta_{(r,\infty)}(h) + n \delta_{(0,\infty)}(h)$

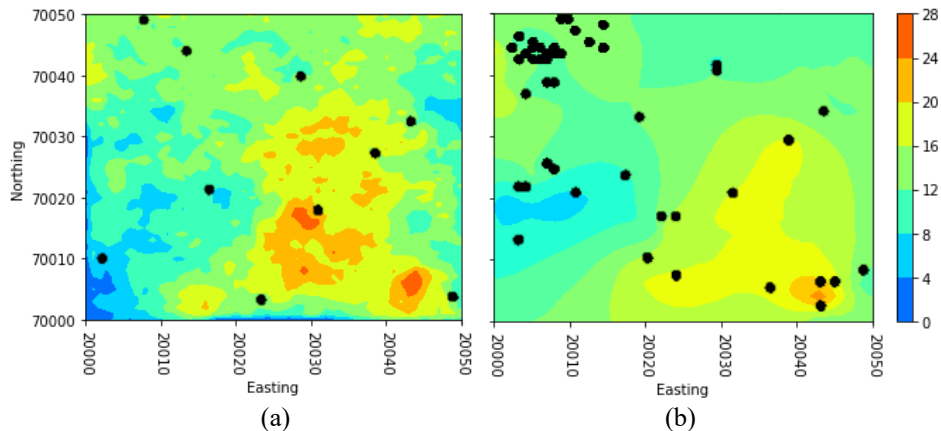

Figure 1 – Metal concentration (g/t) ground truth with initial samples marked in black (a) and (b) final model prediction of metal concentration with all samples marked in black.

### 3.2. Definition of Ground Truth and Design Space

The ground truth (Figure 1) was generated using the spherical kernel (M3 in Table 1) with a range  $r = 40$  hm, sill of  $s = 40$  (g/t)<sup>2</sup>, and nugget effect of  $n = 1$  (g/t)<sup>2</sup> over an area of 51E and 51N (5.1x5.1 km). The design variables are the coordinates of the new sample points (x,y). Ten preliminary samples were taken using Latin Hypercube Sampling.

### 3.3. Experimental Design

Fifteen optimal experiment designs were carried out based on the objectives in (17-18), adding 38 new sampling locations to the 10 preliminary samples. In each iteration, up to three samples were selected from the Pareto front (containing the optimal trade-offs between both objectives). One point was selected at either extreme ( $\epsilon_{\min}$  and  $\epsilon_{\max}$ ) and a third in the middle, unless the maxima for both objectives coincided or were so close that the grid resolution permitted selecting only one location.

### 3.4. Model Identification Results

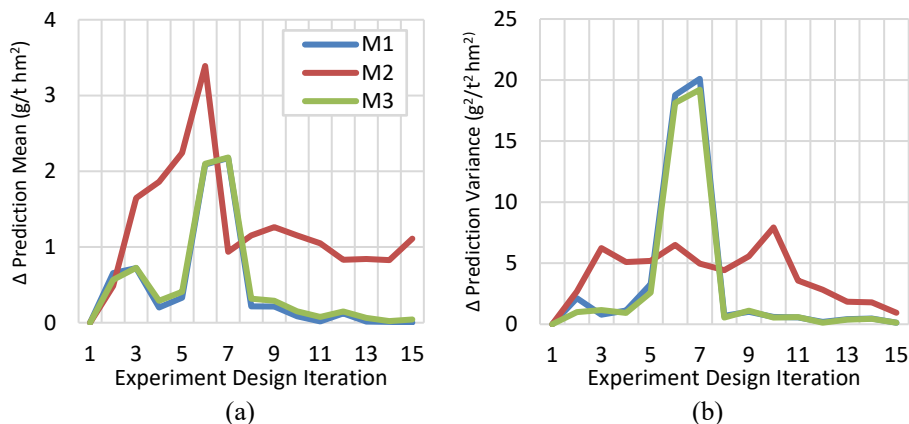

Figure 2 – Change in predicted mean (a) and variance (b) per hectare after 15 designs.

Each design iteration (1-15 in Figure 2) adds new samples that update  $\mathbf{W}$  and with it the predicted mean and variance. The change in their magnitude shows how similar model predictions and new samples are, i.e. a model’s predictive ability. As shown in Figure 2, M1 and M3 predict most new samples well and respond to them indistinguishably, because both kernels produce correlation structures that have similar shapes (and reflect the ground truth). The exception is a spike that results from suddenly improved parameter estimates (shown in Figure 3) that allow the model to capture a previously unknown characteristic of the data. M2 responds differently and shows constant large fluctuations, indicating a failure to represent the ground truth regardless of the design iteration.

The variance of parameter estimates is steadily reduced by new samples and starts converging after 10 design iterations as shown in Figure 3. Although the variances on the estimates for M1 are lower, they converge towards biased values. For M2, the variances are considerably higher, but they converge to the true value for the range and nugget effect. The estimates of the sill parameter, which is related to the maximum variability in the sample population, is systematically underestimated in all models. From Figure 1 (a) and (b) it becomes apparent that this is due to no samples hitting the small areas of tail concentration values. This is a known problem with Kriging interpolation, since tail values are likely to be less represented in the sample set (Rossi & Deutsch, 2014).

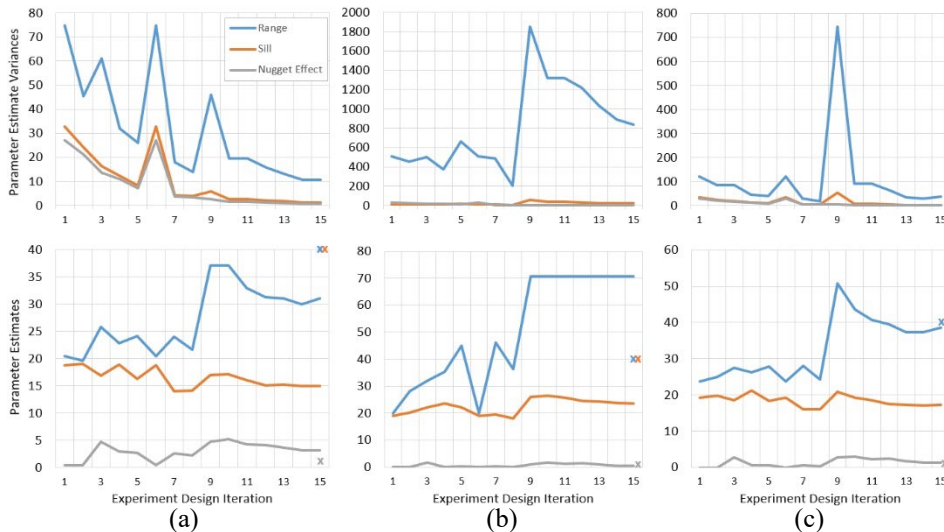

Figure 3 – Parameter estimates: variance (upper plots) and mean (lower plots) for M1 (a), M2 (b), M3 (c) following 15 sample designs. True parameter values are marked by the x.

#### 4. Conclusions

A multiobjective MBDoE approach was applied to 3 Kriging models of an in-silico metal deposit, generated using one of the 3 models. The behaviour of model predictions vs. new samples allowed the exclusion of model M2 that did not correspond to the ground truth. Two models (M1 & M3) had similar predictions and were thus indistinguishable. Parameter estimates steadily improved with design iterations. Only the sill (variance-related) was underestimated in all models, as the tail ends of the concentration spectrum were insufficiently sampled, which is a common problem with Kriging models in geological modelling. The parameter estimates converged to true values in M3 but to biased values in M1. The approach succeeded at improving both design objectives, identifying two models that could have generated the data. Future work will aim to improve the estimation of the sill, e.g. by aiming for high-grade samples, and improve the discrimination capability for similar model outputs, e.g. through explorative designs.

## Abstract

Reinforcement Learning (RL) describes a set of model-free learning rules that enable identification of an approximately optimal feedback control policy function approximation for discrete, time uncertain process systems purely from data. This has led to interest in application of RL to supply chain management problems. However, many RL methods are dependent on estimating noisy first-order directions for policy improvement, and have been developed for video games and computer science applications. Here, we propose a deep RL method tailored for supply chain management. The algorithm deploys a derivative free approach to balance exploration and exploitation of a neural policy's parameter space, providing means to avoid low quality local optima. Additionally, the policy inherits ease in posing risk-sensitive formulations to learn a policy that respects constraints on the conditional value-at-risk. The performance of our algorithm is tested on a benchmark multi-echelon supply chain inventory management problem. The results demonstrate empirical improvements in performance over the first-order RL method, proximal policy optimization, and competitive performance with mathematical programming. Additionally, the risk-sensitive decisions generated can effectively handle low probability, high severity scenarios.

**Keywords:** Reinforcement Learning, multi-echelon supply chain management, inventory optimization,

## 1. Introduction

In recent years, many researchers have proposed methods to incorporate data-driven approaches into strategic and tactical supply chain, and scheduling, primarily for the associated benefits in accounting for uncertainty in decision-making. For example, in the context of long-term planning, Gao *et al.* (2019) proposed a two-stage distributionally robust optimization model, which takes advantage of industrial data to address the optimal design and operations of shale gas supply chains under uncertainty and distributional ambiguity. Distributionally robust optimization has also been exploited for tactical healthcare supply chain management as highlighted in Ash *et al.* (2022). The authors note how the hyperparameters of this approach (i.e. the size of the ambiguity set) could be used to bias the algorithm towards average cost performance or worst-case cost performance. This is a key observation, which underpins the flexibility of distributionally robust approaches. Others works have relaxed the assumption of distributional ambiguity and pursued stochastic optimization approaches. For example, Golari *et al.* (2017),

explored the development of a multi-stage stochastic programming model for inventory control under uncertainty in a renewable energy supply. Robust and multi-parametric optimization has also been investigated (Charitopoulos *et al.*, 2019).

In the context of tactical supply chain management, traditional operations research methods are still posed with practical challenges. In these problems, we are interested in identifying recourse decisions as the system's uncertainty is realized. The challenges primarily relate to accounting for exogenous and endogenous uncertainty in closed loop decisions and the tractability of solving the associated mathematical program recursively. These challenges are compounded by complex network relationships present within the supply chain, and the size of the decision problem tends to grow combinatorially with the supply chain size.

More recently, research focus has been directed towards the development of Reinforcement Learning frameworks to overcome some of the challenges mentioned. For example, a recent work by Hubbs *et al.* (2020) presented a suite of benchmark problems for multi-echelon supply chain inventory management problems and studied the performance of various nominal mathematical programming implementations. Perez *et al.* (2021) extended this work to study divergent multi-echelon supply chains and included benchmark to a number of stochastic mathematical programming implementations. Both works demonstrated application of the RL algorithm, proximal policy optimization (PPO), which relies on estimating first-order directions for policy improvement, and make use of overparameterised policy function approximations. In this work, we attempt to improve the performance of RL and investigate the identification of risk-sensitive policies by making explicit connection between RL and derivative free optimization.

## 2. Reinforcement Learning and Derivative Free Optimization

### 2.1. Markov Decision Processes

Reinforcement Learning describes a set of algorithms, which generally aim to parameterize an approximately optimal policy function approximation that provides control decisions in a closed loop feedback framework, known as the Markov Decision Process (MDP). Finite horizon MDPs are fully defined by a state space,  $\mathbb{X} \subseteq \mathbb{R}^{n_x}$ ; a control space,  $\mathbb{U} \subseteq \mathbb{R}^{n_u}$ ; a conditional probability density function,  $P_{xx'}: \mathbb{X} \times \mathbb{U} \times \mathbb{X} \rightarrow \mathbb{R}_+$ , descriptive of the uncertain, discrete time evolution of the system, from the current state,  $\mathbf{x}_t$ , and control,  $\mathbf{u}_t$ , to a future state,  $\mathbf{x}_{t+1}$ ; a stage cost function  $\varphi: \mathbb{X} \times \mathbb{U} \times \mathbb{X} \rightarrow \Phi_{t+1} \in \mathbb{R}$ , that ranks closed loop decisions at each control interaction; and a finite, discrete time horizon, such that  $t \in \{0, \dots, T\}$ . As decisions are identified within the context of state feedback, optimal decisions are provided by a policy,  $\pi: \mathbb{X} \rightarrow \mathbb{U}$ , which minimizes the expected sum of stage costs,  $Z = \sum_{t=0}^T \Phi_{t+1}$  such that:

$$\pi^* = \underset{\pi \in \Pi}{\operatorname{argmin}} \mathbb{E}_\pi[Z] \quad (1)$$

where  $\pi$  defines a policy that belongs to the set of policies,  $\Pi$ , that satisfy input constraints. It is also worth briefly noting that this implies  $Z$  is a random variable described via some distribution,  $Z \sim p_\pi(z)$ , with values realized together with a given process trajectory,  $\boldsymbol{\tau} = (\mathbf{x}_0, \mathbf{u}_0, \dots, \mathbf{x}_T)$ . In this work, we assume that the problem of identifying a centralized re-order policy for a multi-echelon supply chain can be posed as an MDP.

## 2.2. Reinforcement Learning and derivative-free optimization

RL describes a set of policy learning methods that aim to, in general, identify a parametric policy function,  $\pi(\mathbf{x}; \theta)$ , to approximate the optimal policy. This enables decision-making to generalize across continuous state spaces. The problem then reduces to identifying the policy parameters, such that:

$$\theta^* = \operatorname{argmin}_{\theta \in \Theta} \mathbb{E}_{\pi} [Z] \quad (2)$$

where  $\theta \in \mathbb{R}^{n_{\theta}}$  are the policy parameters and  $\Theta$  denotes the set of allowable policy parameters. The policy parameterization itself is identified through model-free parameter update rules. These are purely data-driven rules that estimate first-order directions to enable local gradient descent steps to improve the performance of policy parameters. However, importantly, although these directions may be estimated independently of gradient information from the dynamics themselves, they are often noisy and expensive to estimate. Additionally, the ultimate policy identified is known to be sensitive to policy initialization, indicating the optimization landscape is often characterized by multiple poor local minima.

Here, it is worth highlighting the strong connections between RL and derivative-free optimization (DFO). In DFO, one aims to identify an approximately optimal solution for a problem independently of gradient information, but rather purely via function evaluations. This is also property of DFO that enables it to optimize measures of objectives that are functions of random variables via, for example, a Monte Carlo method. Popular algorithms typically maintain a population of candidate solutions, evaluate the objective performance of each and then utilize information from the population to coordinate exploration and exploitation of the parameter space. This iterative process enables the DFO algorithm to identify better performing candidate solutions until a computational budget is exhausted or an exit tolerance satisfied. Examples include particle swarm optimization (PSO), evolutionary strategies (ES), and artificial bee colony (ABC), which can all be considered as heuristics inspired by phenomena observed within nature. It is well known that some algorithms are more explorative or exploitative than others. Hybridization of these algorithms has often been used to combine the respective strength of each algorithm to in one search process. Despite the potential application, these algorithms are known to perform poorly in highly dimensional spaces of  $n_{\theta} \geq 1000$ . This means we are required to construct a relatively low dimensional policy parameterization, given current RL practice is to massively overparameterize policy function approximations.

## 2.3. Risk-sensitive decision-making

As reflected in the discussion above, when deploying methods that consider uncertain variables in decision-making, typically one is posed with optimizing for some measure of the objective function. The choice of measure is typically guided by potential risk-tolerance of the operation. Optimizing in expectation is a popular choice, however, in some operations it may be desirable to consider what is happening in the tails of policy performance. For example, the conditional value-at-risk ( $CVaR_{\beta}$ ) defines the expected performance of the policy observed with at least a probability level  $\beta = (0,1)$  under the cumulative distribution function,  $F_{\pi}(z) = \mathbb{P}(Z \leq z | \pi)$  associated with the policy:

$$CVaR_{\beta} = \mathbb{E}_{\pi} [Z | Z \geq F_{\pi}^{-1}(\beta)] \quad (3)$$

$F_{\pi}^{-1}(\beta)$  defines the inverse cumulative distribution function evaluated for probability  $\beta$ . Risk sensitive formulations that leverage the conditional value-at-risk are widely discussed elsewhere. However, in this work, we are interested in a formulation that incentivizes performance in expectation, but provides some notion of probabilistic robustness as follows:

$$\theta^* = \underset{\theta \in \Theta}{\operatorname{argmin}} \mathbb{E}_{\pi}[Z] \quad \text{s. t. } \operatorname{CVaR}_{\beta} \leq b \quad (4)$$

where  $b \in \mathbb{R}$  is a bound that can be set by the implementation together with the probability level,  $\beta$ . This formulation is particularly appealing in supply chains because, for example, it enables one to place a bound on the expected costs observed with a given probability level under the policy.

#### 2.4. Derivative-free optimization for robust reinforcement learning in multi-echelon supply chain inventory management

In this work, we investigate the application of derivative-free optimization for policy learning. Specifically, we hybridize standard in-house python implementations of ABC, PSO, ES and simulated annealing (SA) to more efficiently explore and exploit the parameter space.

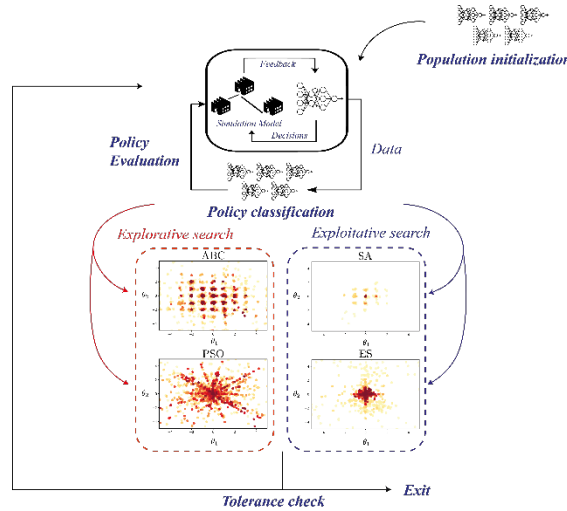

Figure 1: Figurative description of the proposed hybrid derivative free optimization algorithm. Poor performing candidate policies are passed to explorative search methods and high performing policies are passed to more exploitative methods.

Firstly a population of candidate policies is initialized. At each iteration of the algorithm, each of the candidate policies is evaluated within the supply chain inventory management problem and then the population is divided into disjoint sets according to policy performance. For example, the top 25% of policies comprise one subset, the policies ranked in the top 50-25% comprise an additional subset, and so on. The subsets of policies are then passed to one of the given DFO algorithms (ABC, ES, PSO and SA) depending on performance. The worst performing policies are passed to the most explorative algorithms, whereas the best are passed to the most exploitative. In this case, the bottom 50% are passed to ABC and PSO, with the top 50% passed to SA and ES. This is demonstrated by Fig.1.

In case study, we seek to benchmark the performance of our algorithm in a multi-echelon supply chain inventory management problem with integer reorder decisions against the state-of-the-art RL method, proximal policy optimization (PPO), and mathematical programming implementations including offline nominal MILP (i.e. with no recourse decisions) and online shrinking horizon linear programming (with assumption that the integer constraints on decisions can be relaxed in the model and then the solution rounded appropriately).

### 3. Case Study

#### 3.1. Operations Research Gym Benchmark

Here, we utilize the benchmarks and associated code provided by Hubbs *et al.* (2020). Specifically, we consider a supply chain network with  $n_s = 4$  production stages. Stage 0 deals with exogenous consumer demand uncertainty described via a Poisson distribution with a rate of 20 units of inventory. Satisfaction of this demand is handled via a central reorder policy that places inventory order requests from stage  $n$  to  $n+1 \forall n \in \{0, n_s - 1\}$ . Stage  $n_s$  is assumed to have an infinite inventory to supply demand from stage  $n_s - 1$  (and so in principle does not maintain a reorder policy itself). Production and transportation of the product is captured via a deterministic, constant delivery (lead) time.

The problem is defined as an MDP with discrete time dynamics described in Hubbs *et al.* (2020). The state is defined to preserve the Markov property and capture pipeline production and transportation. Specifically, the reorder history of the previous  $L_{max}$  time steps, where  $L_{max}$  is the maximum lead time associated with the delivery of product from all stages, are concatenated together with the current inventory level for stages with finite inventory. In this study  $L_{max} = 10$ . As a result, the state variables,  $\mathbf{x} \in \mathbb{X} \subseteq \mathbb{R}^{(n_s-1)(L_{max}-1)}$ , are defined by the current inventory and the history of  $L_{max}$  controls. The controls,  $\mathbf{u} \in \mathbb{U} \subseteq \mathbb{R}^{n_s-1}$ , are the reorder quantities made at each stage in the supply chain, which are integer values and bounded between zero and an upper bound, which is stage dependent and defined as  $\mathbf{u}_{ub} = [100, 90, 80]$ , respectively. The aim of supply chain management is to maximize the expected net present value (NPV) of the supply chain after 30 discrete time steps. At each time step the cost function,  $\varphi$ , allocates the negative of discounted profit made by the total chain in the most recent time increment, which is comprised by total sales and various costs of holding inventory, procurement and unfulfilled demand at the respective stages.

#### 3.2. Results

Here, we investigate two different formulations. The first formulation (F1) is provided by Eq. 2 and the second by Eq. 4 (F2). The optimization proceeds through unbiased Monte Carlo estimates of the objective measures. In the second formulation, we set the CVaR constraint to  $b = -380$  and probability level  $\beta = 0.9$ .

It is clear from Fig. 2a) that the derivative free approach is able to outperform the policy gradient, PPO method, over the same training budget. Over 1000 Monte Carlo evaluations, the final policy of the hybrid approach observed expected NPV of \$454.0, whereas the offline MILP strategy presented in Hubbs *et al.* (2020) achieved \$378.5, and the shrinking horizon LP achieved \$485.4. In Fig 2b), the results of the approach under the risk sensitive formulation (F2) is presented. It is clear that hybrid algorithm makes progress to maximize expected NPV (Monte Carlo evaluation of the final policy achieves

\$425) and satisfy the constraint on the CVaR (Monte Carlo evaluation of the final policy achieves \$392.4). This provides probabilistic robustness in the policy performance. However, this robustness is at the cost of a greater required computational budget in policy optimization (over formulation F1), and reduced performance in expectation.

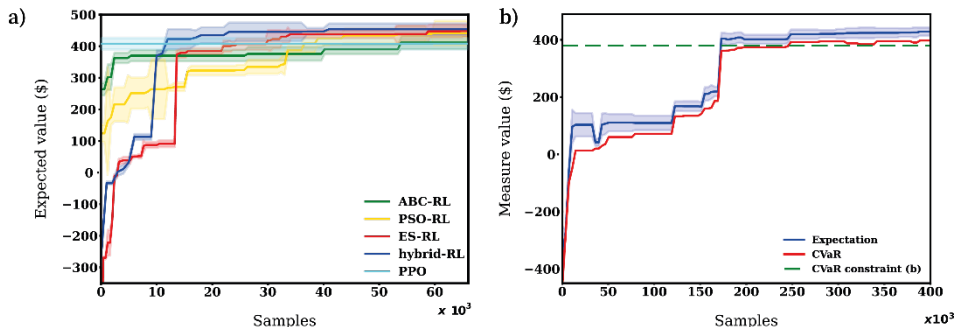

Figure 2: Policy optimization progress of a) the constituent stochastic search algorithms, together with the hybrid DFO algorithm (hybrid-RL) benchmarked against the final results of the state-of-the-art policy gradient method, PPO, evaluated over the same number of samples in F1; b) of the hybrid algorithm under F2. Presented from the perspective of NPV maximization.

#### 4. Conclusions

In this work, we have demonstrated that derivative-free optimization methods are capable approaches to policy optimization tasks in RL in problems observed commonly in PSE and that compact, well-constructed policy function approximations can perform competitively with mathematical programming. RL with function approximation typically provides a nonlinear optimization problem and so derivative free approaches have value in e.g. escaping local minima. Additionally, they provide flexibility in optimizing risk-sensitive formulations via unbiased Monte Carlo estimators. However, it is likely that the limitations of derivative-free approaches in high dimensions will become substantial in industrial-scale supply chain networks. In future work, we will explore representation learning methods and exploit the structure of the supply chain network to reduce the effective dimensionality of these instances. Additionally, thorough comparison to mathematical programming formulations which consider uncertainty will be made.

## Abstract

Controlled radical polymerization (CRP) is a versatile way to control polymer microscopic structures through establishing a dynamic equilibrium between radical and dormant polymers. Atom transfer radical polymerization (ATRP), a typical case of CRP, has the ability to be conducted in mild conditions and produce uniformly distributed polymers. Moreover, the amount of metal addition can be greatly reduced in ATRP processes with the development of photochemical techniques. Photo induced ATRP (photoATRP) has a significant impact on sustainable production in industry. Modeling the microscopic quantities of polymers for photoATRP systems provides insights into the kinetic characteristics. In this work, a Monte Carlo (MC) approach, based on Gillespie's stochastic simulation algorithm, is developed for the photoATRP processes at microscopic resolution. The length dependency of the individual chains on the radical, dormant, and dead polymer information is captured. The polymerization rate of PhotoATRP is sensitive to light irradiation. The polymerization process model of photoATRP systems based on the MC method for temporal control over polymer growth is established. Kinetic characteristics are studied from the developed model under the condition of light source intermittency. The developed MC model is validated against the deterministic method of moments (MoM) and experimental results.

**Keywords:** Monte Carlo simulation; photochemical ATRP; microscopic properties; hybrid multiresolution model.

## 1. Introduction

In past decades, there has been a continuous evolution in controlled radical polymerization (CRP) for enabling to produce well-controlled polymers with narrow molecular weight distributions (MWD) (Pan et al., 2016). Atom transfer radical polymerization (ATRP) is a fundamental technique of CRP. The growth rate of radical polymers is controlled by manipulating activation and deactivation reactions in ATRP (Wang et al., 1995). Light irradiation as external stimuli maintains the stability of polymer

growth through regenerating activators in ATRP systems (Ribelli et al., 2014). These photo induced ATRP (photoATRP) systems provide well-defined and uniformly distributed polymers under mild conditions (Lorandi et al., 2022). The temporal and spatial control over polymer growth in photoATRP can be efficiently achieved upon regulating the applied light irradiation (Dadashi-Silab et al., 2020).

Identifying the microscopic properties of polymers is of great significance and demand for photoATRP processes. Monte Carlo (MC) simulation is a powerful tool to accurately predict the microscopic structure of polymers and provides insights into the kinetic characteristics (Liu et al., 2021). In this work, a dynamic MC model is developed for photoATRP systems at microscopic resolution. Kinetic characteristics of temporal control with light switching are provided based on the developed MC model.

## 2. PhotoATRP systems

In ATRP systems, transition metal complexes and alkyl halides are used to establish the equilibrium between activation and deactivation reactions. Low oxidation state metal complexes as activators activate dormant polymers, and high oxidation state metal complexes as deactivators transform radical polymers into dormant polymers. The mechanistic scheme of the ATRP processes is presented in Figure 1(a). The oxidation-reduction reaction pair presents a trend in the direction of activation in ATRP processes due to the fact that radical polymers are constantly consumed in termination reactions. The concentration of activators decreases as the reaction progress. To maintain the stability of the equilibrium between activation and deactivation, and the concentrations between radical polymers and dormant polymers, a continuous supplement of activators to the reaction system is required. However, in photoATRP processes, activators can be regenerated through light irradiation, as indicated in Figure 1(b). The amount of metal catalyst loadings is decreased in photoATRP (Chen et al., 2016).

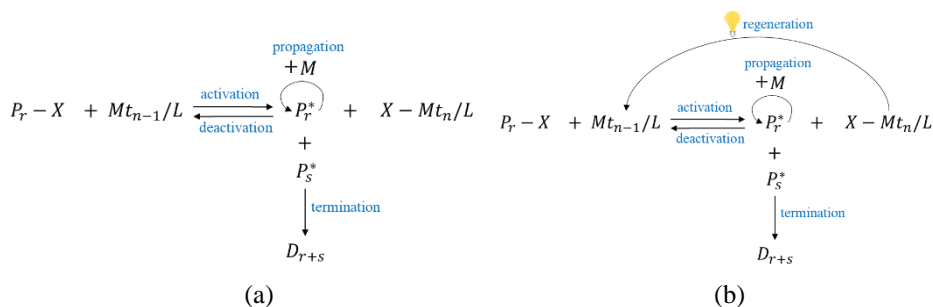

Figure 1 Mechanistic schemes for atom transfer radical polymerization (ATRP) processes. (a) Scheme of conventional ATRP. (b) Scheme of photoATRP.

Radical polymers are formed along with the regeneration of activators in photoATRP processes shown in Figure 1(b). Alkyl halides, ligands, and monomers can also lead to the formation of radicals in a photochemical way. A typical kinetic mechanism for photoATRP is listed in Table 1, where  $P_sX$ ,  $D_s$  and  $P_s^*$  denote dormant polymers, dead polymers, and radical polymers with chain lengths of  $s$ , respectively;  $Mt_{n-1}/L$  and  $Mt_nX/L$  denote activators and deactivators, respectively;  $M$  denotes monomers, and  $L$  denotes ligands. Photo induced reactions 14 – 17 in Table 1 only take place under light irradiation.

**Table 1.** Kinetic mechanism for photoATRP

	description	chemical equation	rate constant
1	activation	$P_0X + Mt_{n-1}/L \rightarrow P_0^* + Mt_nX/L$	$k_{a0} = 2.00 \times 10^3 \text{ mol}^{-1}\text{s}^{-1}$
2	deactivation	$P_0^* + Mt_nX/L \rightarrow P_0X + Mt_{n-1}/L$	$k_{d0} = 5.00 \times 10^7 \text{ mol}^{-1}\text{s}^{-1}$
3	activation	$P_sX + Mt_{n-1}/L \rightarrow P_s^* + Mt_nX/L$	$k_a = 2.00 \times 10^2 \text{ mol}^{-1}\text{s}^{-1}$
4	deactivation	$P_s^* + Mt_nX/L \rightarrow P_sX + Mt_{n-1}/L$	$k_d = 2.80 \times 10^8 \text{ mol}^{-1}\text{s}^{-1}$
5	propagation	$P_0^* + M \rightarrow P_1^*$	$k_{p0} = 7.30 \times 10^2 \text{ mol}^{-1}\text{s}^{-1}$

16		$P_0X + L \xrightarrow{h\nu} 2P_0^*$	$k_{rL2} = 6.20 \times 10^{-6} \text{ mol}^{-1}\text{s}^{-1}$
17		$Mt_nX/L + L \xrightarrow{h\nu} Mt_{n-1}/L + P_0^*$	$k_{rMt} = 1.00 \times 10^{-3} \text{ mol}^{-1}\text{s}^{-1}$

### 3. Dynamic Monte Carlo simulation

In the dynamic MC simulation, the propensity of the  $\mu^{\text{th}}$  reaction of the kinetic mechanism with  $M$  reactions is defined as:

$$R_\mu = k_\mu c_\mu, \forall \mu = 1, 2, \dots, M \quad (1)$$

where  $k_\mu$  is the kinetic rate constant, and  $c_\mu$  is the total concentration of the distinct molecular pairs that will react in the  $\mu^{\text{th}}$  reaction. The probability  $\mathbb{P}_\mu$  for reaction  $\mu$  to take place is given by:

$$R_{SUM} = \sum_{v=1}^M R_v \quad (2)$$

$$\mathbb{P}_\mu = \frac{R_\mu}{R_{SUM}} \quad (3)$$

A random number  $rnd_1$  with uniform distribution in the interval (0,1), i.e.,  $rnd_1 \in \mathcal{U}(0,1)$ , is generated to select one reaction  $\mu$  to occur in the current time interval based on the rule:

$$\sum_{\gamma=1}^{\mu-1} R_\gamma < rnd_1 \cdot R_{SUM} \leq \sum_{\gamma=1}^{\mu} R_\gamma \quad (4)$$

The dynamic time evolution of the kinetic system is described by determining the time interval between two consecutive reactions. To calculate the time interval  $\tau$ , another random number  $rnd_2 \in \mathcal{U}(0,1)$  is generated.

$$\tau = -\frac{1}{R_{SUM}} \ln(rnd_2) \quad (5)$$

The system states are updated after each reaction event, and accordingly, the simulation time is evaluated by the newly calculated  $\tau$ . This process repeats until a preset reporting time or conversion is reached. A detailed discussion can be found in ( Gillespie, 1977).

PhotoATRP processes are studied in this project through building dynamic MC models. In the implementation of the dynamic MC simulation for photoATRP systems, chain length information of radical polymers, dormant polymers, and dead polymers is stored in three individual arrays. The element value in the arrays denotes the chain length of one polymer. The arrays are updated following the selected reaction event. Specifically, if a propagation reaction is selected, an element in the array storing radical polymers is chosen at random, and the value of this element is increased by one. If an activation reaction is selected, one element in the dormant polymer array is chosen randomly and moved into the radical polymer array. If a termination by combination reaction is selected, two elements in the radical polymer array are chosen randomly and removed from the array, and the sum of the two element values is added to the dead polymer array. The instantaneous system states are recorded through tracking each radical, dormant and dead polymer chain.

#### 4. Results and discussions

Simulations for photoATRP systems are conducted through the dynamic MC method and the deterministic MoM. The dynamic MC simulation is capable to provide the microscopic structures of the produced polymers. The deterministic MoM cannot be directly applied to calculate microscopic information for photoATRP systems as the moment equations for all the polymers with diverse chain lengths are difficult to solve due to stiffness. Furthermore, investigations of temporal control over polymerization rate are studied using intermittent light-on and light-off periods. All simulations were performed using Jupyter Notebook on the Anaconda distribution of Python language version 3.8 on a personal computer with RAM 32 GB and Intel i7-10700 CPU core @2.90GHz running Windows 10 OS.

##### 4.1. Simulations of photoATRP for microscopic properties

A batch process where photoATRP takes place is simulated through developing a dynamic MC model and a deterministic method of moments (MoM) model. Tris 2-(dimethylamino)ethyl amine ( $\text{Me}_6\text{TREN}$ ), ethyl 2-bromoisobutyrate (EBiB), Methyl acrylate (MA),  $\text{CuBr}/L$  and  $\text{CuBr}_2/L$  are used as ligands  $L$ , alkyl halides  $P_0X$ , monomers  $M$ , activators  $Mt_{n-1}/L$ , and deactivators  $Mt_nX/L$ , respectively. The initial concentrations of monomers,  $P_0^*$ , deactivators and ligands are  $7.40 \text{ mol} \cdot L^{-1}$ ,  $2.47 \times 10^{-2} \text{ mol} \cdot L^{-1}$ ,  $7.40 \times 10^{-4} \text{ mol} \cdot L^{-1}$ , and  $3.70 \times 10^{-3} \text{ mol} \cdot L^{-1}$ , respectively. For brevity, the reaction conditions and kinetic rate constants can be found in (Ribelli et al., 2014).

As shown in Figure 2(a), the evolution of the average chain length calculated from the dynamic MC simulation is in good agreement with the results from the deterministic MoM and the experiment data. The evolution of concentrations for various reactants versus monomer conversion rate is shown in Figure 2(b). It can be observed that the concentrations of most of the reactants (monomer, activator, dormant polymer, dead polymer, deactivator, and ligand) from the developed dynamic MC model and the deterministic MoM are consistent with the literature (Ribelli et al., 2014). The

concentrations of dead polymers (solid and dashed lines in purple) obtained from this work and the literature diverge during the period of 0% to 20% conversion rate. The concentration lines of dead polymers from this work are smoother. This divergence most likely results due to inaccuracy in the adaptive time-step algorithm of the old version *Predici*, the software that was adopted to do the simulation in the literature. The MWD result of all types of polymers at 80% monomer conversion rate is shown in Figure 2(c). Individual MWD results of radical polymers, dormant polymers, and dead polymers can be calculated by the developed dynamic MC model. It is challenging to obtain such microscopic distribution using the deterministic MoM, which is achieved through deriving and solving a large system of equations in the order of thousands.

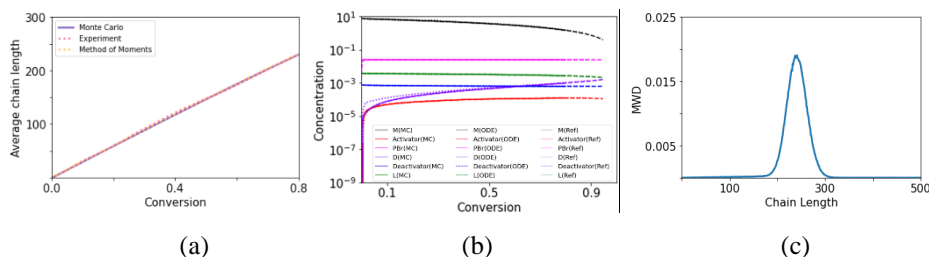

Figure 2 Simulation results for a photoATRP process. (a) Average chain length versus monomer conversion rate; the purple, yellow and red lines denote the results obtained from the MC simulation, MoM model and experiment, respectively. (b) Concentrations of reactants versus monomer conversion rate from different methods. (c) The molecular weight distribution (MWD) at 80% conversion obtained from the dynamic MC simulation, and the corresponding computational time is 9.79 hours. The MWD cannot be obtained from the deterministic MoM model.

#### 4.2. Simulations on the temporal control of photoATRP

Simulations on the temporal control of the photoATRP processes are further conducted with intermittent on/off periods with  $k_{ATRP} = 7.143 \times 10^{-5}$  ( $k_{ATRP} = \frac{k_a}{k_d}$ ). In the implementation of the simulations, the kinetic rate values of photo induced reactions (reactions 14 – 17 in Table 1) are set to zero to simulate the system in dark.

Figure 3 Simulation results of temporal control. (a) temporal control of polymer growth obtained from the dynamic MC simulation and the deterministic method of moments model. (b) MWDs of different polymer types obtained from dynamic MC simulations under conditions of light all-time on and light on/off.

The evolution of the concentration of monomers using the MC and the MoM models is presented in Figure 3(a). We observe that switching the light off decreases the

regeneration rate of radical polymers, leading to slower chain growth. The MWD results of dead polymers and all polymers are shown in Figure 3(b). The solid lines are the simulated results with all-time light irradiation, and the dotted lines are the results using intermittent 5000 second light-on and 5000 second light-off periods. As shown in Figure 3(b), reaction time can be affected by tuning the light on and off, and the MWDs are consistent under various light irradiation modes. It should be noted that the MWDs of each type of polymers at any reporting time and conversion rates can be addressed using the developed MC model. The kinetic characteristics of polymerizations such as the polymerization rate, dynamic average chain length, dynamic concentrations of reactants, under diverse irradiation conditions can be investigated through using the MC simulations.

## 5. Conclusions

In this work, dynamic Monte Carlo models and deterministic Method of Moments models are developed to simulate the photoATRP processes. The developed dynamic MC models are capable to predict the microscopic structures of polymers and provide the kinetic characteristics of the simulated mechanisms on demand. Temporal control over polymer growth was further investigated based on the developed models. As advanced photoATRP systems develop, MC simulation has great application potential in providing a clear understanding of the details of various mechanisms, optimizing the qualities of products, and designing polymerization processes at a microscopic level.

## Abstract

Incorporating methacrylate into microgels allows for their application in catalysis, drug release systems, and enzyme immobilization. Detailed insight into the occurring reactions during the microgel synthesis enables the precise control of the microgel properties. In this contribution, we identify a kinetic model of the copolymerization of N-vinylcaprolactam-based microgels with functional glycidyl methacrylate monomers. We include propagation reaction rate constants calculated via quantum chemical methods. First, we estimate the five most sensitive propagation and initiation and termination rate constants using the enthalpy transfer rate from calorimetry experiments. For the parameter estimation, we use the quantum chemically calculated values as start values and the determined error scopes as bounds in the optimization. We compare our approach of incorporating computed parameter values to similar procedures. The results show that our estimation approach enables a sufficient accuracy of parameter values. Finally, we predict the distribution of functional groups within the microgel with the fully identified model.

**Keywords:** parameter estimation, quantum chemistry, synthesis modeling

## 1. Introduction

Microgels are crosslinked polymer networks with a reversible stimulus-specific swelling response to temperature, pH, or ionic strength. Microgels based on N-vinylcaprolactam (VCL) are temperature responsive and interesting due to their biocompatibility (Saunders 2009). Incorporating comonomers into pVCL microgels allows tuning their functionalities. Glycidyl methacrylate (GMA) is a promising comonomer thanks to its reactive epoxy group that is versatile in subsequent reactions. Hence, pVCL microgels functionalized with GMA experience many applications (Schäfer 2020, Li 2013, Zou 2019).

GMA is more reactive than VCL in the copolymerization leading to the heterogeneous composition of the resulting microgels. Thus, the authors of (Qiu 2005) performed a gradual feeding technique to produce more homogeneous microgels. Under batch

conditions, (Häntzschel 2007) also showed via high-magnification SEM and TEM images that the microgels exhibit a core-shell structure with a GMA-rich core surrounded by a VCL-rich shell. Due to the complexity of the reaction network during microgel synthesis, understanding the relationship between the synthesis conditions and the final composition of the microgels is challenging. Thus, for designing tailored microgels, detailed reaction models provide insights and assist with developing microgels with defined monomer distributions.

In previous contributions, we have developed a mechanistic kinetic model for the aqueous microgel synthesis by precipitation polymerization (Janssen 2017, Jung 2019). To estimate the model parameters, we used a combination of quantum chemical calculations (Kröger 2017) and physical measurements (Jung 2019). We have applied the dynamic model to predict and guide the synthesis of microgels based on monomer N-isopropylacrylamide, comonomer vinyl ferrocene (VFc), and crosslinker N,N'-methylene bisacrylamide (BIS). In contrast to these monomer combinations, parameter values for the propagation rate constants and polymerization enthalpies of GMA/VCL and GMA/BIS systems in an aqueous solution remain unknown.

In our preceding work, we built a mechanistic model based on (Schneider 2020) for synthesizing VCL-based microgels functionalized with GMA. The model contained 14 unknown kinetic parameter values. For model identification, we followed a hybrid approach. First, using transition state theory and quantum chemical calculations, we computed 12 out of 14 parameters, namely the propagation rate constants and polymerization enthalpies of the GMA/VCL and GMA/BIS systems in an aqueous solution. We conducted experiments with four different initial compositions and measured the enthalpy transfer rate during the synthesis using a calorimetric device. Subsequently, we estimated the remaining parameter values of the five most sensitive propagation rates and the initiation and termination rates using the measured enthalpy transfer rate from the experiments. We used the quantum chemically calculated values as start values for the parameter estimation. We also added the computed error bounds from the quantum calculation as optimization constraints during the parameter estimation.

In this contribution, we further analyze the parameter estimation incorporating quantum chemically calculated parameter values. We estimate different combinations of unknown parameter values and conduct an identifiability analysis. Finally, we use the fully identified VCL/GMA microgel synthesis model to predict feeding strategies for a homogeneous microgel composition.

## 2. Materials and Methods

### 2.1. Microgel Synthesis and Reaction Calorimetry

We analyze the precipitation polymerization of VCL crosslinked with BIS and functionalized with GMA. As an initiator, we consider 2,2'-azobis(2-methylpropionamidine)dihydrochloride. Previously, we measured the enthalpy transfer

Table 1 Synthesis composition for experiments in the calorimeter.

Experiment	Molar ratio VCL:GMA	Molar amount of crosslinker BIS
1	90:10	2.0 mol%
2	90:10	2.6 mol%
3	93:7	2.0 mol%
4	95:5	2.6 mol%

rate during the reaction via reaction calorimetry (Nevolianis 2023). Details on the setup and compositions of the conducted experiments can be found in our previous work (Nevolianis 2023). In Table 1, we briefly outline the variations between the experiments used in the current work.

### *2.2. Quantum Chemical Calculations*

In our previous work (Nevolianis 2023), we incorporated propagation rate constants of the VCL/GMA/BIS system that were calculated via quantum chemistry methods. There, we applied conventional transition state theory to determine propagation rate constants. Further, we calculate the enthalpies of reaction using the Gibbs-Helmholtz equation. Computational details can be found in (Nevolianis 2023).

### *2.3. Kinetic Model of Microgel Synthesis*

We employ the reaction system of our kinetic synthesis model (Schneider 2020) and change the parameter values according to the VCL/GMA/BIS system. The main model assumptions are briefly summarized in the following. The dispersed system is modeled in a pseudo-homogeneous phase. The occurring reactions include initiation, propagation, termination, and crosslinking. The efficiency of the initiator decomposition is set to 50% (Jung 2020). The kinetics of the propagation reactions depend only on the radical at the terminal end of the chain, and propagation reactions make up for the enthalpy release. Termination only occurs due to disproportionation, and the kinetics of termination reactions do not depend on the terminal end of the active radical chains. The kinetics of the crosslinking reaction equals the kinetics of a propagation reaction with a BIS monomer.

### *2.4. Parameter Estimation and Identifiability Analysis*

We use the five reaction enthalpy values involving GMA from the quantum chemical computations without further treatment in the synthesis model. We then analyze the sensitivity to identify the most sensitive propagation rate ( $k_p$ ) parameters. Subsequently, we perform parameter estimations to determine different combinations of parameter values. The initiation and termination rates are estimated for all sets as they remain unknown after the quantum chemical calculations. We split the conducted estimations into the following groups:

- 1) Estimate all  $k_{ps}$  with arbitrary start values and bounds
- 2) Estimate all  $k_{ps}$  using the quantum calculations as start values and their error bounds as constraints
- 3) Estimate the five most sensitive  $k_{ps}$  using the quantum calculations as start values and their error bounds as constraints
- 4) Insert all  $k_{ps}$  into the model and only estimate  $k_t$  and  $k_d$

We perform the parameter estimation and the identifiability in Matlab, similar to (Jung 2019), using the presented copolymerization model and the calorimetric measurements. For part of the estimations, the calculated propagation rate constants act as start values, and the calculation uncertainties derived from Gaussian error propagation analysis of the quantum chemical method's uncertainty act as constraints in the optimization problem. For estimation (1), the start values for the propagation rates are 10, and the upper and lower bounds are  $10^{-3}$  and  $10^5$ , respectively.

### 3. Results and Discussion

#### 3.1. Quantum Chemically Calculated and Estimated Kinetic Parameters

The calculated propagation rate constants for the VCL/GMA/BIS system in an ideally diluted aqueous solution at a temperature of 343 K are shown in the second column of Table 3. The applied bounds are presented in the third/fourth column of Table 3. Using the optimized parameter values from estimation (3), our model agrees to 97% on average to the measured enthalpy transfer rate from the experiments.

The results in Table 3 show that the homopolymerizations of GMA and VCL are approximately in the same order of magnitude when calculated via quantum chemistry. The most significant reaction occurs between VCL-radical and GMA. The reaction between GMA-radical and VCL plays a negligible role in the polymerization system. All reactions consuming GMA occur relatively fast. Thus, the experimental observation of a GMA-rich microgel core fits our calculated findings.

Figure 1 Enthalpy transfer rate for experiment 3 and the simulations with the estimated parameter values from estimation (1) to (4).

Table 1 Propagation rate constants [ $\text{m}^3 \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$ ] at 343 K calculated via quantum chemistry and optimized in the parameter estimations with corresponding upper and lower error bound from the quantum chemical calculations. \* denotes estimated parameter values at the bounds.

Reactants	Calculated $k_p$	Lower error bound	Upper error bound	Optimized $k_p$ (1)	Optimized $k_p$ (2)	Optimized $k_p$ (3)	Optimized $k_p$ (4)
VCL-radical / VCL	86.8	10.4	727	28.7	23.8	116	
VCL-radical / GMA	516	61.6	4330	0.403	337	1300	
GMA-radical / GMA	65.5	7.8	549	$10^{-3}$ *	18.2	64.9	
GMA-radical / VCL	4.6	0.5	38.5	1.59	0.74	4.6	
BIS-radical / VCL	34.3	4.1	287	733	9.76	287	
BIS-radical / BIS	8.1	0.967	67.9	$10^{-3}$ *	67.9*		
GMA-radical / BIS	0.74	0.088	6.18	$10^{-3}$ *	2.44		
BIS-radical / GMA	129	15.4	1080	4210	15.4*		
$k_d$ [ $\text{s}^{-1}$ ]		$10^{-7}$	$10^{-3}$	$6.15 \cdot 10^{-7}$	$3.48 \cdot 10^{-5}$	$8.22 \cdot 10^{-6}$	$8.97 \cdot 10^{-7}$
$k_t$		$10^{-5}$	$10^5$	$10^{-5}$ *	244	1480	81.5

The enthalpy transfer rate simulated via the synthesis model containing the respective parameter values is shown in Figure 1, exemplary for Experiment 3. The parameter combinations from estimations (2) and (3) result in the best fit to the experimental data.

Figure 2 Identifiability analysis of selected parameters from estimation (2). The x indicates the optimal parameter value.

The estimation (1) allows a wide solution space with arbitrary start values and bounds gets stuck in a local minimum, indicating the need for deterministic global optimization. The simulation of estimation (4) only has two degrees of freedom and does not sufficiently follow the experimental trend. Altogether, estimation (3) is most suitable, as the fit to experimental data is eminent, and the computational effort is decreased due to reduced parameter values for estimation.

Figure 2 shows the identifiability result for the estimation set (2). For visualization, only the parameters with the most significant variability are shown. Here, all parameters

appear to be sufficiently identifiable except  $k_{p,BIS-BIS}$ .

### 3.2. Process Simulations for Feeding Strategy

The identified model with parameters from estimation (3) allows for the assessment of feeding strategies. We simulate different feeding strategies of GMA to the batch reaction. We focus on two aspects, namely, the ratio of GMA initially in the reactor to the dosing feed and the dosing flow rate. The simulation includes the composition of Experiment 1 (see Table 1) and assumes that 7.5 ml of the total water volume is used for dosing. The ratio of GMA fed to GMA in the reactor varies from 0:1 (all GMA is initially in the reactor) to 1:1 and 1:0 (all GMA is fed to the reactor). Simultaneously, the dosing flow rate is set to 1.5, 3, and 6 mmol/s.

In Figure 3, the results of the simulation scenarios are shown. Here, the combined reaction rate of GMA is depicted over time. The combined reaction rate comprises all reactions where GMA is consumed. When assuming monodisperse particle growth, the time of consumption of GMA correlates to the incorporated position in the microgel. Thus, the combined reaction rate of GMA represents its composition in the microgel.

The progressions of Figure 3 indicate that adding all GMA at a dosing flow of 1.5 mmol/s is likely to achieve a homogeneous composition of GMA in the microgel.

Figure 3 Left: Feeding strategy 1:0, all GMA is fed to the reactor, and the dosing flow rate varies. Right: Feeding strategy 1:1, half of the GMA is in the reactor at the start of the reaction, and half is fed at different dosing flow rates.

#### 4. Conclusions

We studied the precipitation polymerization of VCL/GMA/BIS in an aqueous solution focusing on parameter estimation approaches. We showed that incorporating quantum chemically computed parameter values and their calculation error into the estimation problem improves the optimization result. Based on the identified synthesis model, we were able to derive an improved feeding strategy of GMA to the batch reaction to achieve a homogeneous GMA composition in the microgels by testing different scenarios. Our hybrid approach of quantum chemistry and parameter estimation from experimental data shows the potential of integrating theoretical derivations and semi-empirical knowledge. Further, we laid the ground to design and optimize the functionalization of VCL-based microgels with GMA in the future.

## Abstract

A quantitative model can play an essential role in controlling critical quality attributes of products and in designing the associated processes. One of the challenges in designing a dry granulation process is to find the optimal balance between improving powder flowability and sacrificing powder tabletability, both of which are highly affected by ribbon solid fraction and granule size distribution (GSD). This study is focused on developing a hybrid machine learning (ML)-assisted mechanistic model to predict ribbon solid fraction, GSD, and throughput for the purpose of implementing model predictive control of an integrated continuous dry granulation tableting process. It is found that the predictability of ribbon solid fraction and throughput are improved when modification is made to Johanson's model by incorporating relationships between roll compaction parameters and ribbon elastic recovery. Such relationships typically are either not considered or assumed to be a constant in the models reported in the literature. To describe the nature of the bimodal size distribution of roller compactor granules instead of only using traditional  $D_{10}$ ,  $D_{50}$  and  $D_{90}$  values, the GSD is represented by a bimodal Weibull distribution with five fitting parameters. Furthermore, these five GSD parameters are predicted by ML models. The results indicate the ribbon solid fraction and screen size are the two most significant factors affecting GSD.

**Keywords:** dry granulation, roller compactor, machine learning, hybrid model

## 1. Introduction

The dry granulation process is an important route for producing a solid dosage form in the pharmaceutical industry. The roller compactor is the key unit operation in a dry granulation process. It includes two steps: (1) roll compaction in which powder blends are compressed between two counter-rotating rolls into a ribbon, and (2) milling in which these ribbons are crushed into granules. The benefits of dry granulation include improved blend uniformity and flowability by enlargement of particle size. Powder flowability plays a key role in determining the performance of the tablet manufacturing process and final drug product quality (Lagare et al., 2023). In addition, good powder flowability can reduce powder fouling and improve the on-line sensor performance, such as capacitance-

based particulate flow rate sensor (Huang et al., 2022). However, particle size over-enlargement or over-compression of powders can compromise the tabletability (Herting & Kleinebudde, 2008). Finding the optimal balance between improving powder flowability and sacrificing powder tabletability, which are highly affected by ribbon solid fraction and GSD, becomes one of the challenges in designing a dry granulation process. Therefore, quantitative models to predict ribbon solid fraction and GSD are essential to optimally operate the roller compactor.

Mechanistic models such as Johanson's model (Johanson, 1965) are typically used to describe roll compaction and further predict ribbon solid fraction. However, one of the reasons for the unsatisfactory prediction accuracy of ribbon solid fraction is due to elastic recovery, which is either not considered or assumed to be a constant in the models reported in the literature (Keizer & Kleinebudde, 2020). Population balance models (PBM) can account for the milling step and can be used to predict GSD, but it is complicated to determine the breakage function in the PBM purely based on ribbon fracture physics. Given the unknown physical nature of ribbon elastic recovery and GSD, machine learning (ML) is a preferred alternative to developing a mechanistic model. Moreover, ML and mechanistic model components can be combined into a hybrid model to maintain high physical interpretability and feasibility. Therefore, the primary objective of this work is to develop and validate a hybrid model for the purpose of implementing model predictive control of an integrated continuous dry granulation tableting process.

## 2. Methodology

### 2.1. Parameter Estimation

Given  $n$  experiments and  $m$  output variables, the procedure to estimate model parameters can be formulated as a constrained optimization problem:

$$\min_{\hat{\theta}} J = \sum_{i=1}^n \sum_{j=1}^m w_j (y_{j,i} - \hat{y}_{j,i})^2 \quad (1)$$

subject to  $f(u, \hat{\theta}, \hat{y}) = 0$ ,  $\hat{\theta} \in \Omega_{\theta}$ ,  $\hat{y} \in \Omega_y$

where  $u$  and  $y$  are measurements of input and output variables.  $\hat{\theta}$  and  $\hat{y}$  are estimated model parameters and predicted output variables, bounded in compact sets  $\Omega_{\theta}$  and  $\Omega_y$ , respectively.  $w_j$  is the weighting for residual of output variable  $y_j$ .

### 2.2. Machine Learning

Machine learning models are common alternatives when process outputs are difficult to predict by pure mechanistic models. The multiple linear regression (MLR) model and the neural network (NN) model are employed in this study. The NN models studied consist of one hidden layer, where the hyperbolic tangent function is applied.

### 2.3. Experimental Methods

The material used in this study was a blend of 90 % w/w microcrystalline cellulose Avicel PH102 and 10% w/w acetaminophen. In each experiment, the Alexanderwerks WP120 roller compactor was operated for three minutes to reach a steady state, at which point samples were collected. The ribbons of interest were collected after the powders were compressed into ribbons and then broken into smaller ribbons by the flake crusher. The granulator consists of a two-stage hammer mill with two different screen sizes (screen 1 and screen 2), which produces two granule samples (granule 1 and granule 2). An in-house flowrate sensor based on a Mettler Toledo ME 4001E weighing scale was located at the roller compactor exit to capture the throughput of granules.

In order to measure the ribbon thickness, a Fisherbrand Traceable digital caliper was used to measure thirty ribbons to provide a statistically significant sample size. Geopyc 1360

pycnometer was used to measure the ribbon envelop density ( $\rho_e$ ). The ribbon solid fraction ( $\gamma_R$ ) can be computed as:

$$\gamma_R = \frac{\rho_e}{\rho_t} \quad (2)$$

where  $\rho_t$  is the powder true density, which is measured by an Accupyc II 1340 pycnometer. The GSD of granule 1 and granule 2 samples were measured by the Cauty SolidSizer, which measures the size and area of each particle. In this study, the circular equivalent diameter was used and the cumulative frequency of GSD was volume-based.

### 3. Results and Discussion

The input and output variables of the roller compactor are shown in Figure 1. Ribbon splitting is a phenomenon causing additional uncertainty in the model accuracy and can be avoided when the roll gap and roll pressure are low.

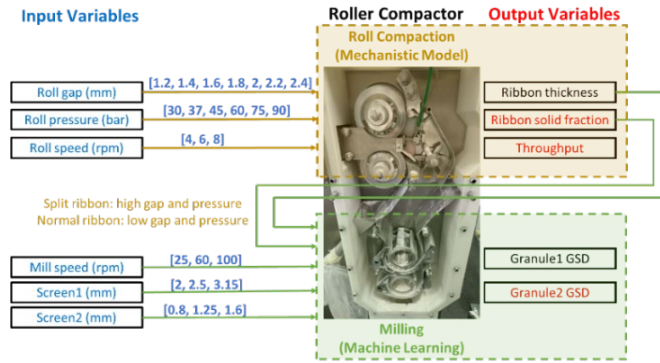

Figure 1. Roller compactor schematic.

#### 3.1 Roll Compaction

When the materials transform from the slip condition to the non-slip condition, the stress gradients in slip region and nip region are equal. The critical angular roller position at which this occurs is known as the nip angle  $\alpha$  and can be calculated by Johanson's model:

$$\frac{4\left(\frac{\pi}{2}-\alpha-\nu\right)\tan\delta_E}{\cot(A-\mu)-\cot(A+\mu)} - \frac{K\left(2\cos\alpha-1-\frac{S}{D_R}\right)\tan\alpha}{\cos\alpha} = 0 \quad (3)$$

$$\text{where } A = \frac{\alpha+\nu+\frac{\pi}{2}}{2}, \quad \nu = \frac{1}{2}\left[\pi - \sin^{-1}\left(\frac{\sin\phi_W}{\sin\delta_E}\right) - \phi_W\right], \quad \mu = \frac{\pi}{4} - \frac{\delta_E}{2} \quad (4)$$

Here,  $\delta_E$  is the effective angle of internal friction and  $\phi_W$  is wall friction angle,  $K$  is compressibility factor,  $S$  is roll gap, and  $D_R$  is roll diameter.

Given roll diameter  $D_R$  and roll width  $W$ , the peak pressure ( $P_{max}$ ) applied on the powders at the minimum roll gap  $S$  is computed as follows:

$$P_{max} = \frac{2P_H A_{cs}}{W D_R F} \quad (5)$$

with the force factor,  $F$ , given by

$$F = \int_0^\alpha \left[ \frac{\frac{S}{D_R}}{\left(1 - \frac{S}{D_R} - \cos\theta\right)\cos\theta} \right]^K \cos\theta \, d\theta \quad (6)$$

where  $P_H$  is hydraulic pressure (or roll pressure) and  $A_{cs}$  is area of the compact surface. Based on a compression power law, the ribbon solid fraction at the gap  $\gamma_G$  can be computed as follows:

$$\gamma_G = \gamma_0 (P_{max})^{\frac{1}{K}} \quad (7)$$

where  $\gamma_0$  is the pre-consolidation solid fraction. However,  $\gamma_G$  is not easily measured because ribbon elastic relaxation makes ribbon density decrease when ribbons are

released from the roll. Given the elastic recovery  $\beta$ , the ribbon solid fraction  $\gamma_R$  is represented as follows:

$$\gamma_R = \frac{\gamma_G}{\beta} \quad (8)$$

Considering mass balance around the roll gap and roll speed  $N_R$ , the mass throughput can be calculated as follows:

$$\dot{M} = \pi D_R W S N_R \rho_t \gamma_G = \pi D_R W S N_R \rho_t \beta \gamma_R \quad (9)$$

In this work, 15 sets of training data and 4 sets of test data are used to validate and evaluate three roll compaction models. First, a data-driven MLR model is built as a benchmark. Secondly, roll compaction mechanistic models are highly sensitive to powder compressibility  $K$  and powder pre-consolidation solid fraction  $\gamma_0$  (Toson et al., 2019). Instead of using common regression approaches to estimate these two model parameters, this study estimates parameters in a constrained optimization framework as follows:

$$\min_{\phi_W, \delta_E, K, \gamma_0, \beta} J = \sum_{i=1}^n [W_Y (\gamma_{R,i} - \hat{\gamma}_{R,i})^2 + W_M (\dot{M}_i - \hat{\dot{M}}_i)^2] \quad (10)$$

Thirdly, elastic recovery is known to be a function of roll compaction parameters instead of a constant. Under the assumption that measured elastic recovery is the ratio of measured ribbon thickness to roll gap, the predicted elastic recovery  $\beta$  is formulated as:

$$\beta_{Model3} = 0.96 + 0.12 \frac{S}{S_0} + 0.03 \frac{PH}{PH_0} + 0.01 \frac{NR}{NR_0} \quad (11)$$

where  $\beta_{Model3}$  has training error MAPE = 4.17 % and test error MAPE = 10.67%. To further improve the elastic recovery predictability, it is worth investigating ribbon splitting phenomenon and other nonlinear ML models in future studies. The prediction performances of the three roll compaction models are summarized in Table 1, which is calculated using the test sets. By incorporating the relationships between roll compaction parameters and ribbon elastic recovery, Model3 has the smallest mean absolute percentage error (MAPE) for both ribbon solid fraction and mass throughput, indicating the best model performance. The parity plot for Model3 is shown in Figure 2.

Table 1. Roll compaction model performance.

Model	MAPE( $\gamma_R$ ) [%]	MAPE( $\dot{M}$ ) [%]
Model1 (MLR)	5.68	9.98
Model2 (Johanson's with constant $\beta$ )	4.40	5.01
Model3 (Johanson's with $\beta = \beta_{model3}$ )	2.86	4.61

Figure 2. Performance of hybrid model of considering elastic recovery model (Model3).

### 3.2 Milling

The hammer milling step commonly produces granules with a bimodal size distribution, which is not adequately described by only using  $D_{10}$ ,  $D_{50}$  and  $D_{90}$  values. Therefore, the entire cumulative size distribution  $D_5, D_{10}, \dots, D_{95}$  measured with the Canty SolidSizer is represented by a bimodal GSD, which can be characterized by a cumulative bimodal Weibull distribution  $Q_3(x)$ :

$$Q_3(x) = a \left( 1 - e^{-\left(\frac{x}{p_1}\right)^{m_1}} \right) + (1 - a) \left( 1 - e^{-\left(\frac{x}{p_2}\right)^{m_2}} \right) \quad (12)$$

where  $a$  is the weighting of the two modes,  $p_1$  and  $p_2$  are the size parameters of the small mode and large mode, respectively, whereas  $m_1$  and  $m_2$  represent the shape parameters of the associated modes. Utilizing these statistical model parameters provides a more interpretable approach to describing GSD and reduces the GSD parameter set from 19 to 5. The bimodal Weibull distribution parameters can be computed by solving an optimization problem:

$$\min_{a, p_1, p_2, m_1, m_2} J = \sum_{i=5,10,\dots}^{95} \left( \frac{i}{100} - Q_3(D_i) \right)^2 \quad (13)$$

subject to  $0 \leq a \leq 1$ ,  $0 < p_1 < p_2$ ,  $1 < m_1, m_2$

To link the roll compaction and milling process, the ribbon solid fraction  $\gamma_R$  and ribbon thickness (*Rtck*) serve as inputs of the milling model. In addition, milling speed (*Mill*) and screen size(s) are also used to predict the GSD described by five bi-modal Weibull fitting parameters. The sensitivity analysis of both granule 1 and granule 2 are shown in Figure 3. The sensitivity analysis was determined by the MLR model coefficient, where inputs and outputs were both rescaled by dividing the minimum values. In terms of weighting  $a$ , ribbon solid fraction of granule 1 is dominated by ribbon solid fraction while that of granule 2 is more sensitive to screen size. For both granule 1 and granule 2, the size parameter  $p_1$  is highly related to ribbon solid fraction. On the other hand,  $p_2$  is dominated by screen size given that screen size determines the upper boundary of the particle size. Shape parameter  $m_1$  is less sensitive to all process inputs compared to the shape parameter  $m_2$ , which is highly impacted by the solid ribbon fraction.

Figure 3. Sensitivity analysis of the milling process.

To evaluate the performance of the milling models, the MAPE of GSD is utilized and can be computed as:

$$MAPE = \sum_{i=1}^n \sum_{p=5,10,\dots}^{95} \left| \frac{D_{p,i}^{pred} - D_{p,i}}{D_{p,i}} \right| \times 100\% \quad (14)$$

The evaluation of the milling models is summarized in Table 2, which is based on 20 training sets and 6 test sets. MLR and NN models are used to predict GSD. The NN models have two neurons in the hidden layer. While increasing the number of neurons can readily make the training error of the NN model smaller than that of the MLR model, the test error can become much worse due to overfitting. The NN model generally can handle nonlinearity better than the MLR model, but some constraints might be hard to enforce, e.g., predicted shape parameters  $m_1$  and  $m_2$  might be less than 1 in the test sets. Figure 4 demonstrates the predictability of the granule 2 GSD by using the MLR or NN models based on six test sets. It is worth noting that there exists a significant mismatch between measurement and NN predictions in Exp 6, but the NN model prediction seems more reasonable considering that screen 2 is 1.25 mm and Exp 6 has a smaller ribbon solid fraction compared to Exp 3, which should result in a smaller GSD. In summary, the

hybrid model successfully predicts GSD, and further investigation of different ML models might be useful to enhance the model performance.

Table 2 Milling model performance.

Model	Granule1		Granule2	
	$MAPE_{train}$ (%)	$MAPE_{test}$ (%)	$MAPE_{train}$ (%)	$MAPE_{test}$ (%)
MLR	9.79	11.21	10.89	8.95
NN	9.66	12.20	13.03	8.37

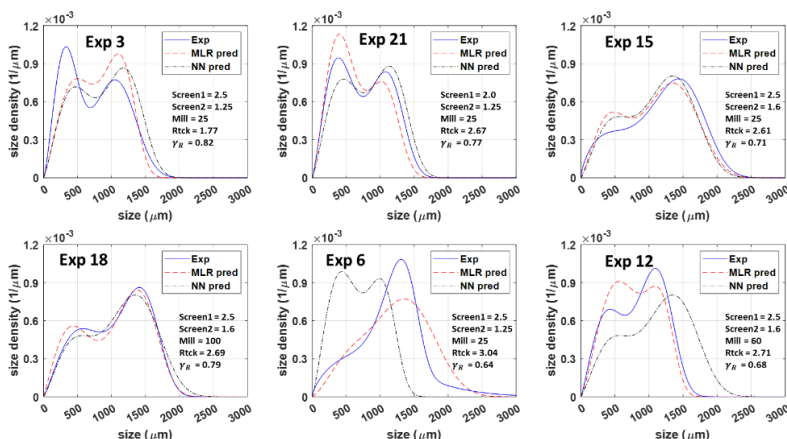

Figure 4. Model performance of granule2 based on test sets.

#### 4. Conclusion

A hybrid model for the roller compactor is proposed that demonstrates satisfactory predictability of ribbon solid fraction, throughput, and GSD. To further improve the model performance, investigation on ribbon elastic recovery and splitting phenomenon and incorporation constraints into ML model could be important. Future work will include relating ribbon solid fraction and GSD to the tablet properties and implementing model predictive control of the integrated dry granulation tableting process.

## Abstract

Modeling and predicting soil moisture is essential for precision agriculture, smart irrigation, drought prevention, etc. Estimating root zone soil moisture from surface or near-surface soil moisture data is typically achieved by solving a hydrological model that describes water movement through soils. Advanced agro-hydrological models today use the Richards equation, a highly nonlinear, degenerate elliptic-parabolic partial differential equation that captures irrigation, precipitation, evapotranspiration, runoff, and drainage. State-of-the-art Richards equation solvers employ either a finite difference, finite element, or finite volume discretization framework in space. In this paper, we introduce a novel computational framework to solve generic  $n$ -dimensional Richards equation by introducing global random walk and deep neural network to a modified finite volume method (FVM). Furthermore, for  $n$ -dimensional Richards equation, we introduce multi-point flux approximation to the FVM framework. Through these innovations, our novel computational framework effectively utilizes the underlying physics behind the Richards equation, which enhances the speed and accuracy of the solution process. Through an illustrative case study, we demonstrate the efficiency and effectiveness of our computational framework and show that it correctly characterizes the physical relationships among soil moisture content, pressure head, and flux.

**Keywords:** Soil moisture, Richards equation, finite volume method, neural network, random walk

## 1. Introduction

Soil moisture is a key hydrological parameter that has significant importance to human society and environment. Accurate modeling and monitoring of soil moisture in crop fields, especially in the root zone (top 100 cm of soil), is essential for improving agricultural production and crop yield with the help of precision irrigation and farming tools. Recent studies also show that monitoring root zone soil moisture at suitable locations and adjusting irrigation schedules accordingly can reduce water use by 40-60% (Sadler et al., 2005). Improved irrigation infrastructures based on soil moisture knowledge could also prevent more than \$30 billion/year in drought related agricultural losses in the US (Khand et al., 2018). This is especially important to US states like Oklahoma, where 41% of total water use goes directly to agricultural irrigation and almost 90% of the land area suffers from drought throughout the year (Droughts.gov, 2022). Estimating root zone soil moisture is typically achieved by solving a hydrological model that describes water movement through soils. Most of the advanced agro-hydrological models today incorporate the Richards equation (Richards, 1931), which captures irrigation, precipitation, evapotranspiration, runoff, and drainage dynamics of water in saturated and unsaturated porous medium such as soil:

$$\frac{\partial \theta(\varphi)}{\partial t} = \nabla \cdot [K(\theta) \nabla(\varphi + z)] - S \quad (1)$$

where  $\varphi$  stands for pressure head,  $\theta$  denotes the soil moisture content,  $K$  is unsaturated hydraulic water conductivity,  $t \in [0, T]$  denotes the time,  $z$  denotes the vertical depth, and  $S$  is the sink term associated with root water extraction, which we ignore without loss of generality. The flux is given by the Darcy's law:  $q = -K(\theta) \nabla(\varphi + z)$ . For unsaturated flow, both  $K$  and  $\theta$  are highly nonlinear functions of  $\varphi$ . For instance, the widely used van Genuchten-Mualem correlations (van Genuchten, 1980) for  $\theta(\varphi)$  and  $K(\theta)$  are:

$$\theta(\varphi) = \begin{cases} \frac{\theta_s - \theta_r}{[1 + (\alpha|\varphi|)^n]^{\frac{n-1}{n}}} + \theta_r, & \varphi < 0 \\ \theta_s, & \varphi \geq 0 \end{cases} \quad (2)$$

$$K(\theta) = K_s \sqrt{\frac{\theta - \theta_r}{\theta_s - \theta_r}} \left\{ 1 - \left[ 1 - \left( \frac{\theta - \theta_r}{\theta_s - \theta_r} \right)^{\frac{n}{n-1}} \right]^{\frac{n-1}{n}} \right\}^2$$

where  $\alpha$  and  $n$  are van Genuchten parameters characterizing different soils, and  $\theta_s$ ,  $K_s$  and  $\theta_r$  denote saturation soil moisture, residual water content, and saturated hydraulic conductivity, respectively. As a result, exact analytical solutions to Equation (1) often do not exist, and numerical solutions rely on discretization of spatial and temporal domains. In particular, the finite volume method (FVM) adopts an integral form of the Richards equation, which captures some valuable physical insights about water flow dynamics (Rathfelder and Abriola, 1994). In addition, FVM is a flexible framework that can be coupled with various other techniques such as the predictor-corrector method (Lai and Ogden, 2015), linearization scheme (Radu et al., 2015), and global random walk approach (Vamos, 2013). Recently, we developed a computationally efficient FVM-based framework for solving the Richards equation by integrating it with adaptive linearization scheme, global random walk method, and multi-layer neural networks (Song and Jiang, 2023). In an illustrative example, we showed that our novel data-driven framework not only generated fast and accurate solutions to the 1-D Richards equation, but also implicitly captured the underlying physical relationships among soil moisture content, pressure head, and flux. In this work, we generalize this computational framework to successfully solving 3-D Richards equation for the first time in the literature.

## 2. FVM Discretization

To apply FVM to Richards equation, we first integrate both sides of Equation (1) to obtain an integral form of the Richards equation over a higher-dimensional control  $V$ :

$$\int_V \frac{\partial \theta(\varphi)}{\partial t} dV = \int_V \nabla \cdot [K(\theta) \nabla(\varphi + z)] dV \quad (3)$$

Next, we can apply the divergence theorem to convert the volume integral on the RHS of Equation (3) into a surface integral over  $S_V$  by introducing the outward pointing unit normal vector denoted as  $\mathbf{n}$ :

$$\int_V \frac{\partial \theta(\varphi)}{\partial t} dV = \int_{S_V} [K(\theta) \nabla(\varphi + z)] \cdot \mathbf{n} dS_V \quad (4)$$

By doing so, FVM is able to incorporate conservation laws, whereas other discretization methods cannot. Specifically, to obtain the discretized version of Equation (4) using FVM,

we discretize the volume integral on the LHS of Equation (4) into a total of  $N_V$  small cells  $V_i$  with  $i = 1, \dots, N_{\omega}$  whose volume is denoted as  $\vartheta_i$ . Each  $V_i$  is associated with surfaces  $\omega_{i,j}$  for  $j = 1, \dots, N_{\omega_i}$  on the RHS of Equation (4) whose area is denoted as  $\mathcal{A}(\omega_{i,j})$ , and we use  $[\cdot]_{\omega_i}$  and  $\mathbf{n}_{\omega_i}$  respectively to denote the operator and outward pointing unit normal vector associated with  $\omega_{i,j}$  upon discretization. Next, to discretize the time domain, we approximate the time derivative  $\partial\theta(\varphi)$  as  $\frac{\theta_i^{m+1,s+1} - \theta_i^m}{\Delta t}$ , where  $\theta_i^{m+1,s+1}$  represents the discretized  $\theta$  in the  $i$ th small cell at the next time step  $m + 1$  and iteration step  $s + 1$ , whereas  $\theta_i^m$  is the converged  $\theta$  value in the  $i$ th small cell at the current time step  $m$ . With this, the discretized version of Equation (4) using FVM becomes:

$$\frac{\theta_i^{m+1,s+1} - \theta_i^m}{\Delta t} \vartheta_i = \sum_{j=1}^{N_{\omega_i}} [K(\theta)\nabla(\varphi + z)]_{\omega_{i,j}} \cdot \mathbf{n}_{\omega_{i,j}} \mathcal{A}(\omega_{i,j}) \quad (5)$$

### 3. Data-Driven Global Random Walk Algorithm

In this section, we introduce a data-driven global random walk (DGRW) approach that seeks to implicitly encapsulate the physical knowledge describing particle movement and conservation within a control volume. Global random walk allows particles to move to neighboring cells simultaneously on any direction or stay in their current cells with a given probability. Thus, in 3-D case, there are a total of seven options for every particle. Let  $n_{i,j,k}^{m,s}$  be the number of particles in the cell  $(i, j, k)$  at fixed-point iteration step  $s$  and time step  $m$ . Correspondingly,  $\delta n_{i',j',k'}^{m,s}$ , where  $i' = i - 1, i, i + 1, j' = j - 1, j, j + 1$ , and  $k' = k - 1, k, k + 1$ , denotes the number of particles moving from cell  $(i', j', k')$  to cell  $(i, j, k)$ . Explicitly, we can write:

$$n_{i,j,k}^{m,s+1} = \delta n_{i+1,j,k}^{m,s} + \delta n_{i-1,j,k}^{m,s} + \delta n_{i,j+1,k}^{m,s} + \delta n_{i,j-1,k}^{m,s} + \delta n_{i,j,k+1}^{m,s} + \delta n_{i,j,k-1}^{m,s} + n_{i,j,k}^{m,s} \quad (6)$$

As we may expect, having such physical knowledge is important for solving Richards equation, which governs the movement of water molecules in unsaturated and saturated soil systems. In fact, Suciú et al. (2021) adopted global random walk concepts and proposed a numerical framework for solving 1- and 2-D Richards equation. In their numerical framework, the authors assumed that the pressure head  $\varphi$  is proportional to the number of particles  $n$  in a cell or control volume. With this assumption, soil moisture content in the cell of interest is simply proportional to the arithmetic mean of the number of particles. While this assumption is valid for diffusion equations (Vamoş et al., 2001), Richards equation is a highly nonlinear convection-diffusion equation, and the exact relationship between  $\varphi$  and  $n$  remains unclear. In fact, we have shown that the numerical framework proposed by Suciú et al. (2021) failed to obtain an accurate solution for 1-D Richards equation (Song and Jiang, 2023).

Since the relationship between  $\varphi$  and  $n$  may not be describable by any basic function, we decide to model the relationship using two multi-layer neural networks (MNNs). Although deep neural network with more layers and neurons could also be used, it is not required as MNN with less number of layers (e.g., 3) is sufficient for learning the relationship between  $\varphi$  and  $n$  given enough neurons in the neural network (Hornik, 1991). In one of the MNNs, we approximate  $\varphi$  as a function of  $n$ ,  $\varphi_{i,j,k} = f(n_{i,j,k})$ , at each fixed time step and iteration step. In the other MNN, we learn the inverse mapping

$f^{-1}$  from pressure head information to the number of particles,  $n_{i,j,k} = f^{-1}(\varphi_{i,j,k})$ . During offline training, we first obtain reference solutions from the global random walk solvers developed by Sucui et al. (2021) (code available at GitHub repository: <https://github.com/PMFlow/FlowBenchmark>). We then add Gaussian noise to these reference solutions to 1) account for the possibly nonlinear relationship between  $\varphi$  and  $n$ , and 2) enhance its generalization performance and the quality of solution obtained (Song and Jiang, 2023). Once offline training is complete, we substitute  $f$  to Equation (5) and derive the following data-driven random walk formulation for the discretized Richards equation:

$$\begin{aligned} n_{i,j,k}^{m,s+1} = & \left[ 1 - \left( r_{i+\frac{1}{2},j,k}^{m,s} + r_{i-\frac{1}{2},j,k}^{m,s} + r_{i,j+\frac{1}{2},k}^{m,s} + r_{i,j-\frac{1}{2},k}^{m,s} + r_{i,j,k+\frac{1}{2}}^{m,s} + r_{i,j,k-\frac{1}{2}}^{m,s} \right) \right] n_{i,j,k}^{m,s} \\ & + r_{i+\frac{1}{2},j,k}^{m,s} n_{i+1,j,k}^{m,s} + r_{i-\frac{1}{2},j,k}^{m,s} n_{i-1,j,k}^{m,s} + r_{i,j+\frac{1}{2},k}^{m,s} n_{i,j+1,k}^{m,s} + r_{i,j-\frac{1}{2},k}^{m,s} n_{i,j-1,k}^{m,s} \\ & + r_{i,j,k+\frac{1}{2}}^{m,s} n_{i,j,k+1}^{m,s} + r_{i,j,k-\frac{1}{2}}^{m,s} n_{i,j,k-1}^{m,s} \\ & + f^{-1} \left( \left( r_{i,j,k+\frac{1}{2}}^{m,s} - r_{i,j,k-\frac{1}{2}}^{m,s} \right) \Delta z - \frac{\theta^{m,s}(n_{i,j,k}^{m,s}) - \theta^{m-1}(n_{i,j,k}^{m-1,s})}{L_{i,j,k}^{m,s}} \right) \end{aligned} \quad (6)$$

where  $r_{i\pm\frac{1}{2},j,k}^{m,s} = \frac{K\left(\theta\left(\varphi_{i\pm\frac{1}{2},j,k}^{m,s}\right)\right)\Delta t}{(\Delta x)^2 L_{i\pm\frac{1}{2},j,k}^{m,s}}$ ,  $r_{i,j\pm\frac{1}{2},k}^{m,s} = \frac{K\left(\theta\left(\varphi_{i,j\pm\frac{1}{2},k}^{m,s}\right)\right)\Delta t}{(\Delta y)^2 L_{i,j\pm\frac{1}{2},k}^{m,s}}$ , and  $r_{i,j,k\pm\frac{1}{2}}^{m,s} = \frac{K\left(\theta\left(\varphi_{i,j,k\pm\frac{1}{2}}^{m,s}\right)\right)\Delta t}{(\Delta z)^2 L_{i,j,k\pm\frac{1}{2}}^{m,s}}$ . Here, we adopt an adaptive linearization scheme inspired by Mitra and

Pop (2019) by adding the term  $L_{i,j,k}^{m,s}(\varphi_{i,j,k}^{m,s+1} - \varphi_{i,j,k}^{m,s})$  on the LHS of Equation (5).

In DGRW algorithm, Equation (6) passes through the inverse mapping  $f^{-1}$  learned from MNN to generate Richards equation solutions in terms of the particle distribution in each cell,  $n_{i,j,k}$ . To convert these solutions to physically meaningful solutions such as the pressure head, flux, and soil moisture content, we apply the trained mapping  $f^{-1}$  and Equation (2). We have proven that the DGRW algorithm is convergent, and the total error

can be estimated using  $\varepsilon = \max_i \left\{ \frac{\|f(n_{i,j,k}^{m,s+1}) - f(n_{i,j,k}^{m,s})\|_F}{\|f(n_{i,j,k}^{m,s+1})\|_F} \right\} = \max_i \left\{ \frac{\|\psi_{i,j,k}^{m,s+1} - \psi_{i,j,k}^{m,s}\|_F}{\|\psi_{i,j,k}^{m,s+1}\|_F} \right\}$ , where  $\|\cdot\|_F$  is the Frobenius norm.

#### 4. An Illustrative Case Study

We modify the 2-D benchmark problem of Haverkamp (1977) that describes groundwater reservoir recharge from a drainage trench by extending it to 3-D. The boundary conditions of the problem are set up as  $\Omega = [0\text{m}, 2\text{m}]^3$ , and  $\Gamma_D = \Gamma_{D_1} \cup \Gamma_{D_2} \cup \Gamma_{D_3} \cup \Gamma_{D_4}$ , in which:

$$\begin{aligned} \Gamma_{D_1} &= \{(x, y, z) \in \partial\Omega | x \in [0\text{m}, 1\text{m}] \wedge y \in \Omega \wedge z = 2\text{m}\}, \\ \Gamma_{D_2} &= \{(x, y, z) \in \partial\Omega | x \in \Omega \wedge y \in [0\text{m}, 1\text{m}] \wedge z = 2\text{m}\}, \\ \Gamma_{D_3} &= \{(x, y, z) \in \partial\Omega | x = 2\text{m} \wedge y \in \Omega \wedge z = [0\text{m}, 1\text{m}]\}, \\ \Gamma_{D_4} &= \{(x, y, z) \in \partial\Omega | x \in \Omega \wedge y = 2\text{m} \wedge z = [0\text{m}, 1\text{m}]\}. \end{aligned}$$

The Dirichlet boundary condition on  $\Gamma_D$  results in the drainage process, whereas the Neumann boundary condition is applied on  $\Gamma_N = \partial\Omega \setminus \Gamma_D$ . The z-direction is point

downward into the ground. The initial conditions describing hydrostatic equilibrium are modified as follows:

$$\varphi(x, y, z, t) = \begin{cases} -2 + 2.2 \frac{t}{\Delta t_D} & \text{on } \Gamma_{D_1} \text{ and } \Gamma_{D_2}, T \leq \Delta t_D, \\ 0.2 & \text{on } \Gamma_{D_1} \text{ and } \Gamma_{D_2}, T > \Delta t_D, \\ 1 - z & \text{on } \Gamma_{D_3} \text{ and } \Gamma_{D_4}, \\ q(x, y, z, t) = 0 & \text{on } \Gamma_N, \\ \varphi(x, y, z, 0) = \begin{cases} 1 - z & \text{on } \Omega \setminus \Gamma_D \\ -2 & \text{on } \Gamma_D \end{cases} \end{cases}$$

We use the parameters listed in List (2016) to represent water flow dynamics in silt loam soil, in which  $\theta_s = 0.396$ ,  $\theta_r = 0.131$ ,  $\alpha = 0.423$ ,  $n = 2.06$ , and  $K_s = 0.0496$  in Equation (2). We choose  $\Delta t_D = \frac{1}{16} d$ ,  $\Delta t = \frac{1}{48} d$ , and  $T = \frac{3}{16} d$ . A rectangular 3-D mesh with 9261 nodes is used, where  $\Delta x = \Delta y = \Delta z = 0.1$ . The convergence tolerance  $\epsilon_0$  is set to be  $10^{-5}$ . Each MNN contains 3 layers and 10 neurons. Overall, 9261 noise-added reference solutions from global random walk solvers developed by Suciú et al. (2021) were obtained, with 70%, 15%, and 15% of them being used for training, validation, and testing, respectively. Bayesian regularization is used to train both MNNs.

Figure 1. Pressure head obtained from (a) GRW algorithm, and (b) DGRW approach.

Figure 2. Pressure head obtained from (a) DGRW algorithm, and (b) GRW approach.

Figures 1 and 2 illustrate the pressure head and soil moisture results obtained using the GRW algorithm of Suciú et al. (2021) and our DGRW framework at  $y = 1.7m$  and  $t = T = \frac{3}{16} d$ . In general, our DGRW results show excellent agreement with the GRW results. Nevertheless, we observe that the GRW solutions did not produce jumps in pressure head and soil moisture content in the  $z$ -direction as  $x$  approaches  $1m$  ( $\Gamma_{D_1}$ ), whereas our

DGRW did predict these jumps. As the total simulated time is greater than  $\Delta t_D$ , the initial condition for pressure head should be 0.2m for  $x = [0m, 1m]$  and -2m for  $x = [1m, 2m]$  (Figure 1b). Similarly, jumps in soil moisture and flux in the z-direction are expected at  $x = 1m$  as well. Therefore, by effectively characterizing the complex relationship between pressure head and the number of particles, our DGRW approach is capable of capturing the water flow dynamics embedded in the Richards equation.

## 5. Conclusion

In this work, we propose a novel data-driven DGRW framework to accurately solve 3-D Richards equation for the first time. DGRW synergistically integrates data-driven global random walk theory and FVM to encapsulate physical knowledge and insights describing water flow dynamics in soil systems. We compare the solutions of our DGRW framework and state-of-the-art GRW approach on a 3-D benchmark problem and successfully validate the accuracy and usefulness of our approach in capturing the underlying physics of water flow dynamics.

## Abstract

Many industrial applications involve stirred tanks with no-Newtonian rheology; hence the understanding of those mixing systems is required to improve final products. The present work aims to simulate the hydrodynamic no-Newtonian mixing system comprised of three impellers named: U-Type Anchor, Simple Hybrid, and Anchor with radial counterflow. As an industrial application, the water properties were considered for the Newtonian fluid, the ketchup and melted chocolate are used for shear-thinning and shear-thickening no-Newtonian fluids respectively. The performance is evaluated using power consumption, the homogeneity of concentration, velocity vector fields, and numerical mixing time. A modified version of the DualSPHysics code has been used to obtain the concentration fields and numerical mixing time. For the power consumption, the Herschel–Bulkley–Papanastasiou model was used to calculate the power for the different rheology. The numerical results suggest that the Simple Hybrid has the lowest power consumption and better performance.

**Keywords:** Stirred-Tank, Mixing times, CFD, Numerical simulation, SPH.

## 1. Introduction

Computational Fluid Dynamics (CFD) is a very useful tool to analyze in detail the hydrodynamics and mixing performance of stirred tanks in a variety of impellers. The CFD solves the fluid transport equations by computational methods. This can generate a huge amount of information that could not be obtained experimentally. It may also be used as an effective strategy to evaluate the performance of some processes. On mixing systems with a stirred tank, CFD allows obtaining axial and radial flow patterns, velocity profiles, mixing times, stagnation zones, or vortex formation in order to evaluate the performance of the impeller. In all processes, the agitation conditions vary with respect to the behavior of the different fluids, since these can present Newtonian or non-Newtonian behaviors. Recently, there is a great deal of interest in the performance of stirred tanks with no-Newtonian fluids using CFD. The existing literature on the no-Newtonian mixing system has been carried out by the eulerian-grid approach. Nevertheless, eulerian-grid numerical methods have certain drawbacks in dealing with deformable boundaries, moving interfaces, extremely large deformations, and especially

grid regenerating (Abdolahzadeh et al., 2019). The present work aims to simulate the mixing in different rheology using four not reported close-clearance impellers, namely U-type anchor, anchor with radial counterflow, and simple hybrid. Prior to undertaking the simulation cases, a convergence analysis is carried out to establish adequate particle numbers for developing the simulation cases. Once the particle resolution is obtained by convergence analysis, the performance of impellers is evaluated using the macromixing parameters numerical mixing time and power consumption analysis. Subsequently, the velocity fields within the stirred tank are visualized for identifying pattern flows and possible stagnation zones.

## 2. The SPH numerical model

The SPH numerical model is based on the DualSPHysics model (Dominguez et al., 2022) shown in Eq. (1) to (6)

$$\frac{d\rho}{dt} = -\rho\nabla \cdot \mathbf{v} , \quad (1)$$

$$\frac{d\mathbf{v}}{dt} = -\frac{1}{\rho}\nabla P + \Gamma + g , \quad (2)$$

$$P = B \left[ \left( \frac{\rho}{\rho_0} \right)^\gamma - 1 \right] , \quad (3)$$

where  $\rho$  is the density,  $t$  is time,  $\mathbf{v}$  is the velocity vector,  $P$  is the pressure,  $\Gamma$  is the viscosity dissipative term,  $B$  is a reference pressure,  $\gamma = 7$ ,  $\rho_0$  is the reference density and  $g$  is the gravity acceleration.

The no-Newtonian fluids were simulated using the model reported in the DualSPHysics code based on the generalized Herschel–Bulkley–Papanastasiou (HBP) model (Papanastasiou, 1987; Mitsoulis, 2007). The HBP model can be used to simulate shear thinning or thickening materials in the absence of yield strength.

$$\tau^{ab} = \eta_{app}\gamma^{ab} , \quad (4)$$

$$\eta_{app} = \mu|\gamma|^{n_{HB}-1} , \quad (5)$$

$$\gamma = [\nabla\mathbf{v} + \nabla\mathbf{v}^T] , \quad (6)$$

where  $\tau^{ab}$  is the viscosity stress tensor,  $\eta_{app}$  is the apparent viscosity,  $\mu$  is the viscosity or consistency index,  $n$  is the power law index,  $|\gamma|$  is the magnitude of the symmetric strain rate.

For this work the Eq. (7) was implemented in DualSPHysics follow the work reported by (Tartakovsky & Meakin, 2006) to include the mass transfer in the numerical simulations.

$$\frac{dC}{dt} = D\nabla^2 C - \nabla \cdot (C\mathbf{v}) + \mathbf{v} \cdot \nabla C , \quad (7)$$

where  $C$  is the concentration, and  $D$  is the diffusion coefficient.

The value of concentration is uploaded using the Verlet algorithm and the time step according to the Courant–Friedrichs–Lewy condition. The boundary conditions for Eq. (7) are implemented as Neumann conditions avoiding the mass transfer between the fluid particles to the boundary particles. With Eq. (7) is possible to calculate the mixing time considering advection-diffusion within a stirred tank to compare and evaluate the performance of the mixing between the impellers used in this work.

### 3. Geometry and impellers design

The diameter of tank is  $DT = 0.14$  m, and the height of tank is  $HT = 0.245$  m. Two elliptical capsules with 0.03 m of height are added to avoid stagnant zones on the bottom of the tank. In the Figure 1, it is shown the proposed unusual close-clearance impellers analyzed namely U-type anchor (1a), anchor with radial counterflow (1b) and simple hybrid (1c) defined by INOXPA as impellers for standard tanks. All impellers are used for a wide range of viscosities. The U-type anchor impeller has 4 scrapers that allow the removal of the material that adheres to the interior of the stirred tank. The recommended stirring rate works in a range of 3 and 120 rpm. The anchor with radial counterflow impeller is designed to facilitate radial flow. Its optimum working stirring rates range are from 3 to 120rpm. Finally, the self-designed modified simple hybrid impeller is intended to improve mixing times and fluid homogenization.

Figure 1. Design of the impellers described in section 3.1. a) U-type anchor, b) anchor with radial counterflow, c) simple hybrid.

### 4. Study Cases

The present work aims to simulate the hydrodynamic of no-Newtonian mixing systems using three impellers named: U-Type Anchor, Anchor with radial counterflow, and Simple Hybrid. As an industrial application, the water properties were considered for the Newtonian fluid, ketchup and melted chocolate are used for shear-thinning and shear-thickening no-Newtonian fluids, respectively. The performance is evaluated using power consumption, velocity vector fields, and numerical mixing time.

#### 4.1. Convergence test.

Before proceeding to examine power consumption analysis, numerical mixing time, and velocity fields, it is important to execute a convergence test. The aim of the convergence test is to determine the adequate number of total particles required in the simulation cases. This test consists of increasing the number of particles in order to find the appropriate resolution of the simulation. In this work, the used particle numbers or particle resolution is defined as follows 75, 000, 125, 000, 250, 000, and 500, 000. In order to calculate the velocity profiles at different resolutions, it was selected the next coordinates  $x = 0.036$  m,  $y = 0.036$  m, and  $z = 0.12$  m to evaluate the velocity at different times.

#### 4.2. The mixing time

The mixing time test is one of the most common procedures for determining the performance of stirred tank system. A longer mixing time is mainly associated with an increase in power consumption due to the operation time. Consequently, the cost of energy is also related to the mixing time. Besides, prolonged mixing time also has an adverse effect on the quality of the product, for instance in crystal grains or damaged microorganisms (Abdolahzadeh et al., 2019). The initial condition of the numerical mixing time test is comprised of one solution concentration of  $C_1 = 1 \times 10^{-6}$  kg/m<sup>3</sup> that

filled the superior fluid volume in the tank and another solution concentration of  $C_2 = 3 \times 10^{-6} \text{ kg/m}^3$  for the inferior fluid volume. The volume of each solution is the same and the initial condition of the mixing time system is shown in Fig. 2a. The criteria for fulfilling the mixing time test was that the final solution must have a concentration range between  $(0.49\text{--}0.51) \text{ kg/m}^3$  in 95 % of the fluid, according to reported literature (Delafosse et al., 2014). The diffusion coefficient of the solute was defined as  $D = 7.5 \times 10^{-7} \text{ m}^2/\text{s}$ .

#### 4.3. Power consumption

Power consumption displays the performance of the agitating process depending on the geometry of the impeller and the physical properties of the fluid. In the present work, power consumption ( $P_o$ ) is used as a parameter in order to evaluate the efficiency of the proposed new close-clearance impellers. The Power consumption was calculated using the measure tool post-processing in version 5 of the DualSPHysics code. For a shear-thinning fluid, the parameters of ketchup at 298.8 K were used. The pseudoplastic rheology parameters are defined as follows: a consistency index of  $K = 6.1 \text{ Pa}\cdot\text{s}$ , a power-law index of  $n = 0.4$ , and a density of  $\rho = 1,325 \text{ kg/m}^3$ . For a shear-thickening fluid, the parameters of the melted chocolate at 319.15 K were chosen. The dilatant rheology is defined as follows; a consistency index of  $K = 0.57 \text{ Pa}\cdot\text{s}$ , a power-law index of  $n = 1.16$ , and a density of  $\rho = 1,600 \text{ kg/m}^3$ , respectively. These parameters were taken from the work of (Joyner & Daubert, 2017).

## 5. Results

### 5.1. Convergence test

Figure 2 displays the velocity profiles as a function of time for different resolutions using the simple hybrid impeller. The maximum and minimum velocity values are developed in a range between 0.06 m/s and 0.22 m/s in a periodic way in time. In order to quantify adequate particle resolution, the root mean square error (RMSE) has been used to calculate the closeness between the velocity values for the highest particle resolution and the others lower particle resolutions.

Figure 2. Design of the impellers described in section 3.1. a) U-type anchor, b) anchor with radial counterflow, c) simple Hybrid.

The obtained values of RMSE are  $4.99 \times 10^{-2}$ ,  $1.07 \times 10^{-2}$ , and  $3.14 \times 10^{-3}$  for total particles of 75, 000, 125, 000 and 250, 000, respectively. In summary, the RMSE values from this convergence velocity test suggest that there is no significant difference between the resolutions with 250, 000 or 500, 000 particles. Because of that, it was decided to use 250, 000 for reducing the runtime simulation.

5.2. The mixing time

The mixing time, according to the restriction reported in section 4.2, for each impeller are 306, 804, and 95 seconds for the U-type anchor, anchor with radial counterflow, and simple hybrid, respectively. The simple hybrid impeller has less mixing time compared to the other two impellers based on an anchor geometry. These results can be explained by the flow dynamics within the stirred tank shown in Figure 3. The impellers with anchor geometry produce a mean flow parallel to the wall tank, reducing the movement in the  $z$ -direction, however, the helical geometry produces vortices that induce the movement in the  $z$ -direction improving the blend within the tank.

Figure 3. Velocity vectors within the tank. a) U-type anchor, b) anchor with radial counterflow, c) simple Hybrid.

5.3. Power consumption

In Figure 4 is shown the results obtained from the SPH simulations of the power consumption as a function of time for the Newtonian, shear-thickening, and pseudoplastic fluids at 75 rpm. The most striking result to emerge from Figure 4a is that the simple hybrid demonstrates the lowest power consumption among all impellers. In addition, the simple hybrid has also performed the lowest mixing time, as mentioned in section 5.2. In the opposite case, the anchor with radial counterflow impeller demonstrates the worst performance because it uses the highest amount of power energy consumption. It is suggested not to use Counter-current for this mixing system configuration in a Newtonian fluid. In Figure 4b are shown the results obtained from the power consumption of the ketchup as a pseudo-plastic fluid. What stands out in Fig 4b is the rapid increase of power consumption from 5 W to 45 W for the Simple Hybrid impeller in approximately 3 seconds.

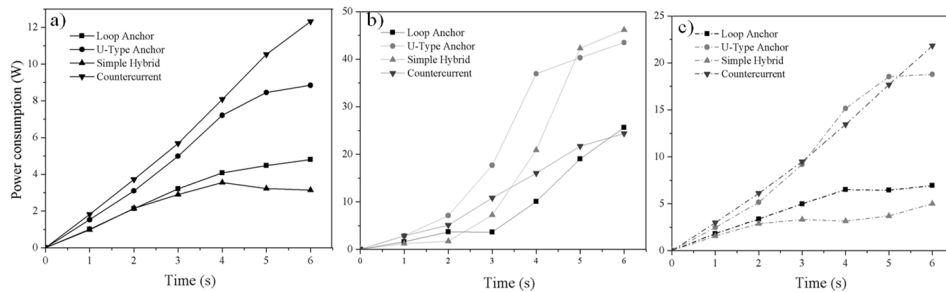

Fig. 4 Power consumption for each impeller and rheology studied.

Conversely, no difference greater than 20 W was observed using Counter-current. These results suggest that the Counter-current promotes the lowest power consumption in pseudo-plastic fluids. However, a mixing time test in a pseudo-plastic fluid may be

recommended in order to gain additional insights into those impellers for future works. In summary, it has been clearly observed from Figure 4b that power consumption in pseudo-plastic rheology is substantially greater than the Newtonian case in all impellers. Finally, in Figure 4c are shown the results obtained from power consumption as a function of time for mixing melted chocolate solution, a shear-thickening fluid, for  $N = 75$  rpm. First, what can be clearly seen in this figure is the similar trend of power input between shear-thickening and Newtonian fluids.

## 6. Conclusions

The aim of the present research was to assess the power consumption in a stirred tank using three studied impellers U-type anchor, anchor with radial counterflow, and simple hybrid for different rheology. The second aim of this study was to investigate the effects in the homogeneity evaluated by the numerical mixing time. The convergence test has determined that the adequate particle number for the proposed mixing configuration is 250, 000 approximately, this means a relationship between the initial distance particle and a diameter of the tank of 0.0162 approximately. On the other hand, the mixing time analysis reveals the importance of a helical blade in the impeller. Thus, the lack of a helical blade in the U-Type Anchor and anchor with radial counterflow impellers presents a poor performance. Thus, this study has contributed to understanding the performance of these unusual impellers. In relation to the study cases simulated, the numerical results suggest that a simple hybrid impeller has a better performance to homogenize and also demonstrates the lowest power consumption in Newtonian and shear-thickening fluids for a low stirring rate of 75 rpm. The investigation highlights the potential usefulness of the SPH method to evaluate the mixing system performance in a variety of rheology from Newtonian to no-Newtonian fluids.

## Abstract

Four surrogate modelling techniques are compared in the context of modelling once-through steam generators (OTSGs) for offshore combined cycle gas turbines (GTCCs): Linear and polynomial regression, Gaussian process regression and neural networks for regression. Both fully data-driven models and hybrid models based on residual modelling are explored. We find that speed-ups on the order of 10k are achievable while keeping root mean squared error at less than 1%. Our work demonstrates the feasibility of developing OTSG surrogate models suitable for real-time operational optimization in a digital twin context. This may accelerate the adoption of GTCCs in offshore industry and potentially contribute towards a 25% reduction in emissions from oil & gas platforms.

**Keywords:** Digital Twin, Surrogate Modelling, Residual Modelling, Gaussian Process Regression, Neural Networks

## 1. Introduction

Installation of combined cycle gas turbines (GTCCs) offshore can reduce emissions from oil & gas platforms by up to 25% [Mazzetti et al. (2014)]. A digital twin (DT) framework for GTCCs may accelerate the adoption of GTCCs by increasing their reliability and performance. To this end, accurate and trustworthy yet computationally efficient dynamic models for crucial GTCC components are needed. The once-through steam generator (OTSG) has been identified as a particularly important component because its response to transients in the gas turbine load largely governs the GTCC's overall behavior. SINTEF Energy Research has previously developed highly accurate Modelica models for OTSGs [Montañés et al. (2021)]. In this work, we explore four data-driven techniques for creating high-speed, DT-suitable surrogate models based on the Modelica model: Linear regression (LReg), polynomial regression (PReg), Gaussian process regression (GPR), and neural networks (NNs). We use these techniques to develop both purely data-driven surrogate models and hybrid models utilizing the residual modelling technique. The goal of this work is to evaluate the feasibility of developing DT-suitable OTSG surrogate models, e.g., for real-time optimization and process control based on model predictive control schemes. The work is intended to contribute towards accelerating the adoption of GTCCs, thereby reducing emissions from offshore energy production. Secondly, it is of general interest to analyze the relative performance of the different techniques studied.

## 2. Once-Through Steam Generators

### 2.1 Background and Motivation

A waste heat recovery steam generator (HRSG) is a heat exchanger boiler system that recovers waste heat from a given heat source by producing steam from feedwater that is circulated through the heat exchanger. In the context of GTCCs, the heat source is the gas turbine exhaust, and the steam produced by the HRSG is passed through a steam turbine to generate electricity. Consequently, in comparison to standalone gas turbines, GTCCs offer significantly increased efficiency, and thus a corresponding reduction in CO<sub>2</sub> emissions for fixed power production.

In this work, we consider once-through steam generators (OTSGs), which are a particular type of HRSGs common in industrial applications. OTSG configurations are the preferred option in volume- and weight-constrained energy system environments, such as offshore oil and gas installations or floating production, storage and offloading systems. High-fidelity, physics-based, dynamic OTSG models facilitate simulation-based studies to better understand the inherent dynamics of the OTSG system, and to conduct control loop and control structure design studies. Traditionally, operation of OTSG systems has predominantly taken place under steady-state conditions. Therefore, it has been sufficient to consider transient conditions in the offline design phase. Faster models suitable for real-time operational optimization have consequently not received much attention. However, as intermittent renewable energy sources enter the offshore energy mix, computationally efficient models applicable to transient conditions are becoming increasingly important. This motivates the present study of surrogate models for OTSGs, i.e., low-fidelity OTSG models that are designed to capture the main characteristics of OTSG transient behavior while offering significant computational speed-up in comparison to traditional high-fidelity models.

## 2.2 High-Fidelity OTSG Modelling

Development of surrogate models generally requires data from which the main characteristics of the considered system can be extracted. In the present work, this data will stem from a previously published high-fidelity (hi-fi), dynamic OTSG model for offshore combined cycle applications [Montañés et al. (2021)]. The model is developed in the Modelica language and utilizes dynamic energy and mass balances to produce a set of differential algebraic equations describing the OTSG's transient behavior.

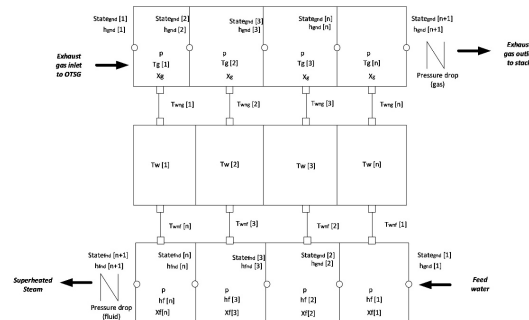

Figure 1: Discretization and main states of high-fidelity OTSG model [Montañés et al. (2021)].

Figure 1 (adapted from [Montañés et al. (2021)]) shows the OTSG model with discretization and main states. The model is based on 1-D lumped pressure flow pipes (for gas and water/steam sides) separated from each other by a wall model (representing the metal wall for heat transfer in a bundle of tubes). A total of  $n$  volumes and  $n+1$  nodes are used to discretize the system in the direction of the flow. Overall, the model includes

physical phenomena related to heat transfer, hydraulics, wall model thermal inertia, dynamic energy and mass balances on both the gas side and the water side [Montañés et al. (2021)]. We consider the OTSG operated under valve-throttling pressure control mode, i.e., with fixed pressure set point of the produced superheated steam [Nord and Montañés (2018), Zotică et al. (2022)]. Important boundary conditions for the model are gas turbine load (exhaust gas inlet mass flow and inlet specific enthalpy) and feed water mass flow rate (which is commonly a manipulated variable for OTSG operation).

### 3. Surrogate Modelling Techniques

In this section, we briefly describe the four surrogate modelling techniques considered in this work: linear and polynomial regression (Section 3.1), neural networks (Section 3.2) and Gaussian Process Regression (Section 3.3). We also describe how we generate the data needed to develop OTSG surrogate models using these techniques (Section 3.4) and how we evaluate the resulting models (Section 3.5). Common for all the surrogate models considered here is that their task is to predict the outlet temperature of the flue gas, as well as the outlet temperature and mass flow of the steam.

#### 3.1 Linear and Polynomial Regression

Polynomial regression (PReg) amounts to approximating some target function  $f(\cdot)$  using a polynomial constructed using  $N_i$  input data variables  $I_i$ , where  $i = 1, \dots, N_i$ . Mathematically, this can be expressed as finding coefficients  $\alpha_{i,n}$  such that

$$\hat{f}_{\text{reg}} := a_0 + \sum_i \alpha_{i,1} I_i + \alpha_{i,2} I_i^2 + \dots + \alpha_{i,N} I_i^d$$

is as close to the true target  $f$  as possible. We say that  $d$  is the degree of the interpolating polynomial. Linear regression (LReg) is simply the special case of  $d = 1$ . We used the Python package `lmfit` [Newville et al. (2014)] to implement our regression models.

#### 3.2 Neural Networks for Regression

Owing to their universal function approximation properties and acclaimed empirical successes, neural networks (NNs) are well suited for surrogate modelling. Here, we consider fully connected feed-forward NNs (cf. [Nielsen (2015)] for an introduction). Such a network with  $n_l$  so-called *layers* can be expressed as

$$\hat{f}_{\text{NN}} = \varphi_{n_l}(\dots(\varphi_2(\varphi_1(Iw_2 + b_1)w_2 + b_2) \dots)w_{n_l} + b_{n_l}),$$

where  $I$  is the NN's input vector, the matrices  $w_1, \dots, w_{n_l}$  (weights) and vectors  $b_1, \dots, b_{n_l}$  (biases) are tunable parameters, and  $\varphi_1, \dots, \varphi_{n_l}$  are non-linear functions known as activation functions. Typically, stochastic gradient descent is used to tune the weights and biases such as to minimize the difference between  $\hat{f}_{\text{NN}}$  and the target function  $f$ . We have implemented our NN models using the Python package `pytorch` [Paszke et al. (2019)]. We use the LeakyReLU activation function with slope parameter 0.01, `pytorch`'s `MSELoss` cost function, the Adam optimizer, and a learning rate of  $1e-5$ .

#### 3.3 Gaussian Process Regression

Gaussian Processes (GPs) are non-parametric, probabilistic kernel methods [Rasmussen and Williams (2006)] that aim to identify an unknown function  $f: \mathcal{R}^{n_u} \rightarrow \mathcal{R}$  from data. It is assumed that the noisy observation of  $f(\cdot)$  are given by

$$y = f(\mathbf{u}) + v,$$

where the noise  $v$  is Gaussian with zeros mean and variance  $\sigma_v^2$ , and  $\mathbf{u}$  is the input, which is assumed to follow a multivariate Gaussian distribution. Smoothness properties of the

underlying function  $f$  are enforced by the choice of mean and covariance function without relying on parametric assumptions [Snelson and Ghahramani (2006)]. A zero mean function and the automatic relevance (ARD) squared-exponential (SE) covariance function are chosen. GP depends on hyperparameters, which are usually unknown and need to be inferred from data. The marginal likelihood is used to estimate hyperparameters. The predictive distribution is the marginal of the normalized joint prior times the likelihood. The integral can be evaluated in closed form. The GP regression model was implemented in Python and the maximisation of the log marginal likelihood was solved with help of the SciPy package [Virtanen et al. (2020)].

### 3.4 Data Generation

Due to the unavailability of suitable operational data from a real GTCC, the high-fidelity OTSG model described in Section 2.2 will be used to create the reference data needed for developing and evaluating our surrogate models. As explained in Section 2.2, the gas turbine load is an essential boundary condition for the model and must therefore be prescribed. To cover a wide range of operating conditions, a randomized time series of one million data points at 1-second intervals, was generated. Every 100 seconds, a load change is occurring with 50% probability. The type of change (step or ramp), the new set point value and the duration of the transition (if it is a ramp) are randomized with the latter two drawn from uniform distributions on [40%, 100%] and [1s, 300s], respectively.

Using the generated gas turbine load sequence, the hi-fi model is used to generate two time series for each of the three outlet variables we aim to predict with our surrogate models. One time series is created using a coarse discretization in the hi-fi model (we call this the low resolution (LR) data), and the other is created using a fine discretization (denoted high resolution (HR) data). The HR data is used as ground truth, both during the model tuning process and the final evaluation. The LR data serves two purposes. Firstly, it can be used as additional input for the surrogate models. Secondly, it will allow us to explore the potential benefit of residual modelling. The concept of residual modelling is to model the residual  $\varepsilon = HR - LR$  instead of the HR data directly [Willard et al. (2022)]. Predictions are then constructed as  $\hat{HR} = LR + \hat{\varepsilon}$ , where  $\hat{\varepsilon}$  is the model's approximation of  $\varepsilon$ . Both the HR and LR data are split into three subsets. The first 980k data points are included in the *training set* (used for tuning model parameters), the next 10k data points go in the *validation set* (used for tuning certain hyperparameters), and the final 10k data points constitute the *test set* (used for evaluating the models).

### 3.5 Model Evaluation

All our surrogate models depend on one or more so-called hyperparameters, i.e., parameters that define a model's structure but are not used directly to compute predictions. Examples include choice of input variables, polynomial degree (PReg), number of layers and neurons per layer (NN) and the number of data points to use for tuning (GPR). To facilitate a fair comparison between the different kinds of models, we conducted a grid search to identify good hyperparameter choices for all models. For each model instance (corresponding to a particular choice of hyperparameters), the normalized root mean squared error (NRMSE) of the models' predictions was computed with respect to the HR test data for each of the three target variables. The sum of the three NRMSEs was taken to represent the overall predictive accuracy of any particular model. For models using old HR data as input, it is important to consider that, when predicting more than one time step into the future, HR data from the previous time step will not be available. Then, the surrogate model's prediction from the previous time step must be used in its place. This may lead to divergent behavior, as is observed for some of our models (cf. Table 1).

## 4. Results

### 4.1 Predictive Accuracy

For each modelling technique and model input choice, Table 1 lists the lowest total NRMSE error observed in our grid search for both normal and residual models using the specified technique and input choice. The available input choices are 1) only inlet data (in), 2) inlet data and LR outlet data (in+LR), 3) same as 2) but also including old HR data (in+LR+old), and 4) same as 2), but also including the residual HR-LR (in+LR+res).

We observe that the most accurate model is a GPR residual model using in+LR+old input. However, several other models achieve comparable performance, and the performance difference between the best PReg, NN and GPR models is generally insignificant from a practical perspective. Even the best LReg models are found to perform quite well, with a NRSME significantly smaller than 1% achievable for all three output variables. Moreover, while the use of LR data appears to be generally beneficial, we observe that only inlet data is sufficient to obtain NRSME values well below 1% for any given output variable. (Note that, in the table, we sum the NRMSE of each predicted variable.) Figure 2 shows the predictions of steam outlet mass flow made by the best model for each modelling technique (bold in Table 1). Based on Figure 2, it is difficult to identify any predominant failure mode for any of the different models.

	in		in+LR		in+LR+old		in+LR+res	
	Normal	Residual	Normal	Residual	Normal	Residual	Normal	Residual
LReg	0.0555	0.0154	0.0089	0.0089	<b>0.0088</b>	0.0514	19.4011	19.3999
PReg	0.0555	0.01525	0.0056	0.0056	<i><b>0.0031</b></i>	NAN	NAN	NAN
NN	0.0562	0.0107	0.0066	0.0061	0.0039	<b>0.0032</b>	0.0406	0.0107
GPR	<i>0.0369</i>	<i>0.0099</i>	<i>0.0045</i>	<i>0.0043</i>	0.0032	<i><b>0.0031</b></i>	<i>0.0036</i>	<i>0.0031</i>

Table 1: Normalized RMSE on the test set, summed over the three output variables, for given model type and input selection. Bold and italics are used for lowest error values in columns and rows, respectively. NAN indicates that the model diverged.

Figure 2: Predictions of steam outlet mass flow by best model within each category, shown along with the corresponding LR and HR data for a short interval within the test set.

### 4.2 Computational Efficiency

We use the number of CPU seconds (wall time) per simulated second of operations (CPUs/s), as measured on a standard, mid-range laptop, to quantify the computational efficiency of the various models. Using respectively the coarse and the fine spatial discretization, we measure 0.00289 CPUs/s and 0.1272 CPUs/s for the hi-fi-model. Thus, the reduced resolution yields a speed-up of roughly 44. In comparison, our linear regression model with only inlet data as input uses around 8e-6 CPUs/s, which

corresponds to a speed-up of roughly 15k. The PReg model is roughly as fast as the LReg model, while the NN and GPR models are roughly 1–1.5 orders of magnitude slower than the LReg model. Consequently, for residual models and models using LR data as input, the LR hi-fi component always dominates the computational expense.

## 5. Discussion

An interesting takeaway from our numerical experiment is that blindly relying on more advanced techniques like neural networks and GPR to be better than simple techniques like regression is not advised. The relation between a model's theoretical representation capacity and its empirical predictive accuracy is not necessarily linear. Indeed, our results show that the relation is not even strictly increasing in general, as 1) our best PReg model outperforms our best NN model, and 2) increasing the number of neurons in the NN (and thereby its representation power) did not improve its accuracy on the *test* set.

Our results also show that the value of hybrid modelling depends on the quality of the physics-based model component, and how that component is integrated into the fully hybrid model. In our case, using LR predictions as input was generally observed to be useful, while residual modelling yielded mixed results. This illustrates the obvious, but easily overlooked fact that residual modelling is only beneficial if the relation between the input data and the residual is simpler than that between the input data and the data to be predicted. This criterion is not always met in practice, as evidenced by our results.

Finally, we conclude that it is feasible to construct OTSG surrogate models suitable for use in real-time optimization procedures within a digital twin framework. This motivates further work, which could include exploration of more advanced neural network-based techniques, such as Long Short-Term Memory networks. Additionally, we believe that looking into the robustness of the methods with respect to noisy data would be valuable from a practical perspective.

## Abstract

In Process systems engineering, first-principles process models are standard. However, all model predictions, including any model-based design or control policy, suffer from imprecision. To increase the reliability of the process model, precise model parameters and model-based design of experiments (MBD<sub>oE</sub>) are essential. That is, experiments have to be designed for the specific purpose of model calibration. The same is true for data-driven engineering concepts. For example, in the case of physics-informed neural networks (PINNs), the first-principles model is incorporated into the structure of an artificial neural network, thus creating a hybrid framework in terms of model calibration. The PINN setting, in turn, results in different parameter sensitivities compared to the standard parameter identification approach, with profound consequences for the precision of parameter estimates. Also, due to the change in parameter sensitivities, traditional MBD<sub>oE</sub> concepts might fail. Alternatively, MBD<sub>oE</sub> strategies have to be adapted for PINN-based parameter identification and more precise parameter estimates. In particular, Monte Carlo simulations are combined with the PINN concept to choose appropriate experimental designs. As a case study, the proposed concept is demonstrated for a distributed-parameter system of an adsorption process model. The changes in parameter sensitivities and parameter uncertainties are critically discussed and, in terms of novelty, presented with the need for a mandatory MBD<sub>oE</sub> adaptation.

## 1. Introduction

Profit margins in the highly competitive and regulated pharmaceutical industry have continuously decreased in the past decades due to increased research and development costs (Behr et al., 2004). In the context of pharmaceutical manufacturing, process systems engineering can be used to design efficient and cost-effective production processes for drugs and other pharmaceutical products. This can involve optimizing the use of raw materials and energy, reducing waste and emissions, and ensuring that the final product meets the necessary quality and safety standards. In addition, process systems engineering can be used to model and simulate different production scenarios, helping to identify potential bottlenecks or inefficiencies in the manufacturing process. To gain an in-depth system understanding of the underlying physical processes, the temporal and spatial resolution of the underlying dynamic processes might be of relevance and interest. Thus,

research activities on distributed parameter systems (DPS) have gained importance over the years. DPSs can be modeled using partial differential equations (PDEs), where, in particular, the model parameters determine the dynamic behavior of the system. However, the literature on parameter identification of PDEs is sparse (Zhang et al., 2017). Alternatively, recent advances in machine learning and artificial intelligence provide new approaches to modeling strategies and parameter identification problems alike. For example, if the process under study cannot be described with first-principles models, ML algorithms are very promising to compensate for that knowledge gap resulting in hybrid process models. However, there is a proven workflow for concepts such as DoE in relation to traditional modeling strategies, but little is known about how these concepts can be applied to hybrid models involving machine learning. Traditionally, the numerical solutions of PDE developed over the past decades typically include the discretization of system domains with mesh-based approaches, including finite differences, finite elements, and finite-volume methods. This strategy has several disadvantages: The individual mesh section is solved separately, and high-resolution systems are computationally expensive. ML technologies to solve these problems are welcome, and PINN methods have recently received a lot of attention (Raissi et al., 2019). In addition to solving PDE systems, the PINN framework enables a new perspective in discovering DPS, i.e., deriving the governing equations and identifying the corresponding model parameters directly. Still, to increase the reliability of the process model, precise model parameters and model-based design of experiments (MBCoE) are essential (Abt et al., 2018). In the case of PINNs, first-principles models are technically incorporated into the structure of artificial neural networks, thus creating a hybrid framework in terms of model calibration (Yazdani et al., 2019) as well. The PINN setting, in turn, results in different parameter sensitivities compared to the standard parameter identification approach (Selvarajan et al., 2022), with profound consequences for the precision of parameter estimates, rarely addressed in the current literature.

## 2. Methodology

### 2.1. Distributed parameter system

Following the notation in (Shukla et al., 2022), partial differential equation systems (PDEs) with the solution  $u(\mathbf{x}, t)$ , including model parameters  $p$ , defined in a domain  $\Omega$  read as follows:

$$f\left(\mathbf{x}; \frac{\partial u}{\partial x_1}, \dots, \frac{\partial u}{\partial x_d}; \frac{\partial^2 u}{\partial x_1 \partial x_1}, \dots, \frac{\partial^2 u}{\partial x_1 \partial x_d}; \dots; p\right) = 0, \quad \mathbf{x} = (x_1, \dots, x_d) \in \Omega, \quad (1)$$

with the boundary conditions:

$$B(u, \mathbf{x}) = 0 \text{ on } \partial\Omega. \quad (2)$$

In process system engineering, PDEs are used to describe the behavior of distributed parameter systems due to their ability to capture the spatial and temporal variation of the system's state variables. The heat equation and the wave equation, for example, are PDEs that describe how heat flows through a material or how waves propagate through a medium, respectively. However, distributed parameter systems can be challenging to analyze and control because the underlying PDEs often have complex solutions that cannot be obtained analytically. Instead, the solution needs to be approximated with numerical methods, which can be computationally intensive. However, several numerical methods, including finite difference methods, finite element methods, and spectral methods are standard in solving PDEs, but the choice of method depends on the specific form of the PDE and the desired accuracy of the solution.

## 2.2. Physics-informed neural networks

Physics-informed neural networks are beneficial for solving partial differential equations because they can handle complex, nonlinear equations that may be difficult to solve using classical numerical methods. These neural networks are trained using both the physical constraints of the problem and the data from the equation, allowing them to learn the underlying patterns and make accurate predictions. Additionally, physics-informed neural networks can be more efficient and scalable than classical numerical methods, particularly for high-dimensional or time-dependent problems. Technically, to solve a parametrized PDE system (Eq. (1)) through PINNs, a deep neural network  $\hat{u}(\mathbf{x}; \theta)$  with trainable meta-parameters  $\theta$  is used. Boundary and initial constraints of the PDE system (Eq. (2)) and the PDE system itself (Eq. (1)) define the system identification problem and are represented in a separate term of the loss function, that governs the neural network training. Emphasis will be taken on the loss function composition in the following section.

## 2.3. System Identification

In PINNs, the loss function is typically composed of multiple terms that reflect different aspects of the problem. The specific terms used in the loss function will depend on the specific problem being tackled, but some common terms include: *Data loss*; this term measures the difference between the predicted output of the neural network and the known data for the problem. For example, if the goal is to solve a partial differential equation with known boundary conditions, the data loss term would measure the difference between the predicted solution and the known boundary conditions. *Physics loss*; this term measures the difference between the predictions of the neural network and the known physical laws and constraints that apply to the problem. For example, if the goal is to simulate the motion of a particle in a gravitational field, the physics loss would measure the difference between the predicted motion of the particle and the known laws of gravity. By combining these different loss terms into a single function, PINNs can learn to predict physical phenomena while also incorporating prior knowledge about the problem. This can help the model to generalize better and make more accurate predictions on unseen data. According to (Shukla et al., 2022), the resulting loss function reads as:

$$\mathcal{L}(\boldsymbol{\theta}, p) = \mathcal{L}^{data}(\boldsymbol{\theta}) + \mathcal{L}^{pde}(\boldsymbol{\theta}, p), \quad (3)$$

with the data loss term  $\mathcal{L}^{data}$  defined for the measurements  $y^{data}$ :

$$\mathcal{L}^{data}(\boldsymbol{\theta}) = \sum_{i=1}^m \sum_{k=1}^K \|y^{data}(\rho_i, t_k) - h(\hat{u}(\rho_i, t_k, \boldsymbol{\theta}))\|_2^2, \quad (4)$$

with the measurement location  $\rho_i \in (0, L)$  at  $K$  discrete time points and the model output  $h(\cdot)$ . Moreover, the physics loss term  $\mathcal{L}^{pde}$  relates to the governing equation as follows:

$$\begin{aligned} \mathcal{L}^{pde}(\boldsymbol{\theta}, p) = & \frac{1}{|\mathcal{J}_f|} \sum_{\mathbf{x} \in \mathcal{J}_f} \left\| f(\mathbf{x}; \frac{\partial \hat{u}}{\partial x_1}, \dots, \frac{\partial \hat{u}}{\partial x_d}; \frac{\partial^2 \hat{u}}{\partial x_1 \partial x_1}, \dots, \frac{\partial^2 \hat{u}}{\partial x_1 \partial x_d}; \dots; p) \right\|_2^2 \\ & + \frac{1}{|\mathcal{J}_b|} \sum_{\mathbf{x} \in \mathcal{J}_b} \|B(\hat{u}, \mathbf{x})\|_2^2, \end{aligned} \quad (5)$$

Thus, the prediction of deep NN  $\hat{u}$  has to fulfill the governing equation system and fit the experimental data. Using the PINN framework for parameter identification relates to total least squares approach for a classical parameter identification problem, i.e., the combination of ordinary least squares (e.g., fitting the data) and input least squares (e.g., fulfilling the equation system), see (Selvarajan et al., 2022) and references therein. However, this also implies that standard MBDoe concepts based on local parameter sensitivities. Fisher information matrix, and the Cramér-Rao inequality may fail (Selvarajan et al., 2022). By deliberately controlling the experimental setup (e.g., sensor

positions, sampling rates, inlet profiles, etc.), a model-based design of experiments can provide more precise and accurate estimates of the model parameters. Practically, the basic prerequisite is that parameter sensitivity and uncertainty measures must be adapted to the underlying problem. In the case of PINN, the physical loss term (Eq. (5)) plays an important role.

### 3. Case study

The adsorption process separates and purifies chemicals and substances. It is used in the chemical, pharmaceutical, and food industries, as well as in environmental remediation and waste treatment, allowing the recovery of valuable resources. For better process understanding and process design, a reliable characterization of the kinetics is essential. In this study, we analyze the use of PINN-based kinetic parameter identification and its implications for the design of experimental concepts to ensure more precise parameter estimates with less experimental effort.

#### 3.1. Mathematical model of the adsorption process

The following assumptions are used in the derivation of a so-called lumped kinetic model (LKM) of the adsorption process: (i) Radial gradients in column concentration were neglected. (ii) The column is isothermal and homogeneously packed. (iii) Constant volumetric flow rate  $v$ . (iv) Lumped contribution of internal and external mass transport resistances represented with a mass transfer coefficient  $k_m$ . (v) The axial dispersion coefficient  $D_{ax}$  is also considered constant. Thus, the governing partial differential equation system of the LKM reads as:

$$\frac{\partial C}{\partial t} = -v_z \frac{\partial C}{\partial z} + D_{ax} \frac{\partial^2 C}{\partial z^2} - \frac{1 - \varepsilon}{\varepsilon} \frac{\partial q}{\partial t}, \quad (6)$$

$$\frac{\partial q}{\partial t} = k_m (q^* - q), \quad (7)$$

where  $t$  is the time and  $z$  is the space coordinate along the column axis;  $C$  and  $q$  are the concentrations in the liquid and solid phases, respectively,  $\varepsilon$  is the bed porosity,  $v_z$  is the average velocity of the fluid,  $k_m$  is the effective linear driving force mass transfer coefficient, and  $D_{ax}$  is the axial dispersion. Note that for the adsorption rate, a linear driving force model (Naidu and Mathews, 2021) is assumed. A detailed description of LKM is reported in the literature (Javeed et al., 2013). The boundary and initial conditions are given by:

$$\begin{aligned} t = 0 \text{ and } 0 \leq z \leq L &\Rightarrow q = 0 \text{ and } C = 0 \\ t > 0 \text{ and } z = 0 &\Rightarrow C = C_0 \\ t > 0 \text{ and } z = L &\Rightarrow \frac{\partial C}{\partial z} = 0 \end{aligned} \quad (8)$$

Simulated data are generated based on the following parameter values:  $t \in (0,1)$ ,  $z \in (0,1)$ ,  $C_0 = 1$ ,  $D_{ax} = 0.4 \times 10^{-4}$ ,  $k_m = 10$ ,  $\varepsilon = 0.8$  and  $v_z = 0.1$  in a dimensionless form. In Figure 1a, the default experimental design is illustrated. Here, it is assumed that three sensor elements are available to measure the concentration  $C$ , where, for the default configuration, the concentration is selected at the inlet ( $z = 0.0$ ), outlet ( $z = 1.0$ ), and in the middle of the column ( $z = 0.5$ ). Furthermore, for the default experimental design, an equal time sampling with  $\Delta t = 0.1$  is postulated, as well as additive white measurement noise with a standard deviation of  $\sigma = 0.01$ .

#### 3.2. PINN-based parameter identification problem and experimental design

Specifically, the following multi-layer perceptron (MLP) setting is applied: two hidden layers, an input and output layer with 16 nodes each, and a classic sigmoid activation function. The PINN-based parameter identification problem was implemented in Julia,

using the packages *Lux*, *NeuralPDE*, and *OptimizationOptimJL*. Furthermore, since the sensor elements at the inlet ( $z = 0$ ) and outlet ( $z = 1$ ) can only measure constant concentration profiles under the given boundary constraints and the considered time horizon, the positions of the sensor elements are optimized to cover the entire dynamic, i.e.,  $C(z_i) = 0$  to  $C(z_i) = 1$ . The optimized sensor layout is shown in Figure 1b with  $z_{opt} = [0.1, 0.3, 0.5]$ . In addition to sensor location, the sampling rate of time recordings is essential as well. Here, the PINN-based MBDoe makes direct use of Eq. (1), i.e., the Pde system does not have to be solved numerically, but the local parameter sensitivities are derived based on the right-hand side of Eq. (1). The resulting parameter sensitivities of  $\varepsilon$  and  $v_z$  are given in Figure 2. As a high parameter sensitivity is crucial for more precise parameter estimates, the sampling interval is adapted accordingly. To this end (Figure 1b), 6 sample points are selected for higher parameter sensitivity regions for  $\varepsilon$  and 5 sample points for  $v_z$ , i.e., the overall number of data points is similar to the default experimental design.

(a) Default experimental design

(b) Optimized experimental design

Figure 1: Dynamic profiles at three different sensor locations of the column/adsorption process. Time points of the actual measurement samples (simulated data) are highlighted.

(a) Parameter sensitivity of  $\varepsilon$

(b) Parameter sensitivity of  $v$

Figure 2: Model parameter sensitivity plot; higher parameter sensitivity are considered for adapting the time sampling of the measurements.

### 3.3. Results

In Figure 3, the resulting parameter estimates are shown. A Monte Carlo simulation concept was used to repeat the PINN-based parameter identification step 200 times for the default and optimized experimental design. These parameter estimates suggest that the changed configuration in the sensor location and the sampling rate leads to a significant reduction in parameter uncertainties when the optimized experimental design configuration is applied. The results also reveal that the PINN-based parameter identification framework has a non-neglectable offset/bias in the parameter estimates, i.e., the true parameter estimates are rarely covered by the scatter plot results. The related mean values and standard deviations are listed in Table 1, indicating a positive effect of the optimized experimental design i.e., lower parameter uncertainties while using the same amount of experimental data.

Figure 3: Scatter plot of the two estimated model parameters, including the result of the PINN-based parameter identification for the default and optimized experimental design.

Table 1: Uncertainties for the default and the optimized experimental design.

Parameter	True value	Mean & Std. (default)	Mean & Std. (optimized)
$v_z$	0.1	$0.0718 \pm 0.0164$	$0.0803 \pm 0.0091$
$\varepsilon$	0.8	$0.9779 \pm 0.1543$	$0.9101 \pm 0.0570$

#### 4. Conclusions

As a result, the data collected using an optimal design is more informative and can be used to estimate the model parameters more precisely for the PINN-based parameter identification framework. This can lead to a better understanding of the process under study and can enable more accurate predictions of the behavior of the system. Additionally, using an optimal design can also help to reduce the number of experiments needed to obtain reliable parameter estimates, which can save time and resources. As demonstrated, while PINNs can be a powerful tool for solving PDEs, they might be less optimal for precise parameter identification. Thus, further research on efficient uncertainty quantification and PINN-tailored design of experiment concepts is needed.

## Abstract

Several systematic methodologies for designing and optimizing conceptual processes have been reported by combining different computer-aided tools, mainly based on process simulators and programming environments that can help to improve any processes significantly. Thus, the objective of this work involves the performance analysis for virtual platforms focused on multi-objective process optimization, using a framework based on identical objective functions (economic, exergetic, and environmental targets), similar algorithms and hyperparameters (NSGA-II), for the separation and purification of the benzene, toluene, m-xylene mixture (BTX). Two computational interfaces were developed: Aspen Plus-Matlab (A) and Aspen Plus-Python (B), both using direct communication based on COM. Results were compared in terms of computational time, objective functions, and state variables values. Finally, both computational interfaces have a similar performance in all terms: interface B showed better computational time, but the use of the utopia-tracking approach let to conclude that interface A has better objective function values.

**Keywords:** Simulation-optimization, MOGA, process simulator, programming environments.

## 1. Introduction

The challenges associated with climate change, population growth, and resource limitations, require innovative solutions due to their inherent complexity and interdisciplinary nature (socio-techno-economic nexus), in this connection, chemical engineers can contribute through Process Systems Engineering (PSE) discipline, that offers techniques and tools for process synthesis, design, optimization and/or control problems at multi-scale levels, based on physical and chemical phenomena (Cameron et al., 2019). PSE techniques have a specific role in problem resolution, where two solution pathways for the synthesis and design of a product/process could be employed: 1) reality: experiment-based solution approach, and 2) virtual reality: typical computer-aided

systems solution approach, which includes a) data and models, b) numerical solvers for simulation and/or optimization, and c) workflows: method or algorithm (Pistikopoulos et al., 2021). Several authors have reported methodologies based on virtual reality problem solutions focused on designing and optimizing chemical processes, combining different computer interfaces, linking process simulators and programming environments with several algorithms, mainly using direct communication through ActiveX-COM technology (Ponce-Rocha et al., 2022; Ruiz-Femenia et al., 2020; Sánchez-Ramírez et al., 2016). However, even though these methodologies have been applied in academic, research, and industrial fields, there is not a rigorous study to compare their performance in terms of objective function values and computational aspects. Thus, the objective of this work is to analyze the performance of two virtual platforms for multi-objective process optimization using identical objective functions (economic, exergetic, and environmental targets) with similar algorithms and hyperparameters (NSGA-II), for a separation and purification scheme, where the computational time, objective functions, and state variables values are used as performance criteria.

## 2. Methodology

### 2.1. Virtual platforms focused on multi-objective process optimization

Both virtual platforms proposed in this study were based on a systematic framework that includes four steps: 1) Optimization formulation: the multi-objective approach, state variables, and constraints definition, 2) Objective functions description: analysis and selection of objective functions associated with three targets: economy, exergy and environment (3E), 3) Optimal design: use of different computer-aided tools such as, Matlab and Phyton as programming environments, which allow the algorithm selection; both were combined with a process simulator (Aspen Plus), 4) Case study: separation and purification scheme.

### 2.2. Optimization formulation

The multi-objective optimization is represented as follows (1):

$$\underset{x}{\text{Min}} \quad \underline{Z} = [Z_k(\underline{x})] \quad k = 1, 2, \dots, k. \quad \text{s.t.} \quad \mathbf{h}(\underline{x}) = 0; \quad \mathbf{g}(\underline{x}) \leq 0 \quad (1)$$

Where  $\underline{Z}$  represents a vector with  $k$  objective functions (3E),  $\underline{x}$  is the vector of state variables: number of stages ( $N_S$ ), feed stages ( $F_S$ ), and molar reflux ratios ( $R_R$ ).  $\mathbf{h}(\underline{x})$  and  $\mathbf{g}(\underline{x})$  are the vectors to model equality and inequality constraints associated with the state variables ( $\underline{x}$ ), mass purities (P), and mass recoveries (R).

### 2.3. Objective functions description

Generally, chemical processes have intrinsic characteristics of high energy consumption associated with the use of utilities such as cooling, heating, and electricity. In this sense, the combination of metrics based on 4E analysis (energy-exergy-economy-environment) has given an improvement in terms of process sustainability (Li et al., 2021; Ponce-Rocha et al., 2022). In this study, three of the four components of 4E analysis were selected to perform an optimization task: economic, exergetic, and environmental aspects.

#### 2.3.1. Economy

The economic target was estimated using the Total Annual Cost (TAC), illustrated in Equation 2, which includes the equipment investment cost and payback period, and the sum of annualized utilities cost, referred to cooling, heating, and electrical services. To estimate the equipment cost the module factor approach introduced by Guthrie and modified by Ulrich was used, furthermore, the value of the chemical engineering plant cost index (CEPCI) was set at 801.30 (February-2022).

$$TAC = \frac{\text{Investment cost}}{\text{Payback period}} + \text{Utilities} \quad (2)$$

### 2.3.2. Exergy

The exergy target considers the exergy losses ( $\sigma T_0$ ), this metric is an adequate indicator to identify energy inefficiencies in the system, which considers the heating and cooling processes ( $Q$ ), separation ( $Sep$ ), and concentration changes ( $Conc$ ) in all the equipment ( $j$ ) and process streams ( $i$ ) (see Equation 3).

$$\sigma T_0 = \Delta \dot{E}x_{In} - \Delta \dot{E}x_{Out}$$

$$\sigma T_0 = \sum_{j=1}^n \sum_{i=1}^m [\Delta \dot{E}x_{Q,j} + \Delta \dot{E}x_{Sep,i} + \Delta \dot{E}x_{Conc,i}] \quad (3)$$

### 2.3.3. Environment

The Life-Cycle Assessment (LCA) methodology enables the computation of environmental impact associated with a process, product, or activity. This methodology is normally applied in four steps (ISO 14040): 1) Goal and scope definition, our target focuses on minimizing the process environmental impact, therefore, a fixed production rate of the feed and products was selected, (“cradle-to-gate” analysis). Ecoindicator-99 (EI-99) is integrated as a life cycle assessment tool, based on 11 categories and 3 specific damage categories: human health, ecosystem quality, and resources. 2) Inventory analysis, this step provides the inputs and outputs of mass and energy, construction materials, and utilities associated with the process, and all the burdens must be expressed per unit of reference (Life Cycle Inventory-LCI). 3) Impact assessment, in this step the process data are translated into environmental information, Equation 4 represents the EI99 compute. Where  $\beta_b$  represents the total amount of chemical  $b$  released per unit of reference flow due to direct emissions,  $\alpha_{b,k}$  is the damage caused in each category  $k$  per unit of chemical  $b$  released to the environment,  $\omega_d$  is the weighting factor for damage in category  $d$ , and  $\delta_d$  is the normalization factor for damage of category  $d$ . 4) Interpretation, the results are analyzed and a set of conclusions or recommendations for the system are formulated (Guillen-Gosalbez et al., 2007; Sánchez-Ramírez et al., 2016).

$$EI-99 = \sum_b \sum_d \sum_k \alpha_{b,k} \beta_b \delta_d \omega_d \quad (4)$$

## 2.4. Optimization tools

### 2.4.1. Multi-objective genetic algorithms

Both virtual optimization platforms were made considering the integration of a Multi-Objective Genetic Algorithm (MOGA) based on NSGA-II: Aspen Plus-Matlab (A) using the gamultiobj suite, and Aspen Plus-Python (B) using the PYMOO package. The hyperparameters for both algorithms were as follows: 50 generations, 200 individuals, 0.8 for mutation crossover, and the mutation function: feasible adaptable for gamultiobj, and polynomial for PYMOO.

### 2.4.2. Utopia-tracking approach

Once the optimal solutions set has been obtained by MOGA, the next challenge consists in selecting the optimal point, mainly when many objective functions exist, and the final solutions are non-dominated. The utopia-tracking approach was selected as an adequate tool to choose the best solution point through minimizing the normalized distances

between the objective function values and the utopic point. Equation 5 shows the formulation for the utopia-tracking approach (Zavala and Flores-Tlacuahuac, 2012).

$$\min \|\Phi - \Phi^{L,s}\|_p = \left( \sum_{i=1}^n |\Phi_i - \Phi_i^{L,s}|^p \right)^{\frac{1}{p}} \quad (5)$$

Where  $\Phi$  is any point in the set of final solutions,  $\Phi^{L,s}$  is the utopia point associated with the minimum value for each individual objective function,  $n$  represents the number of the objective functions (three for this study), and  $p$  represents the  $p$ -norm value (one for this study).

### 2.5. Case study

The case study considered the separation and purification of the benzene, toluene, and m-xylene (BTX) mixture. The NRTL-SRK thermodynamic model was used to calculate the phase equilibria (Cui et al., 2019). Figure 1 shows the separation and purification scheme, based on a direct distillation sequence (D<sub>101</sub>, D<sub>102</sub>). The feed stream (101) used in this study has an equimolar flow of 300 kmol/h at 50 °C and 5 bar. Streams 102, 104, and 105 correspond to the recovered and purified compounds; benzene, toluene, and m-xylene, respectively. Furthermore, the vectors to model equality and inequality constraints are defined below. Two assumptions were made for the objective functions computing: for the TAC estimation a payback period was fixed to five years, in addition, for the EI-99 a process lifetime was adjusted to ten years.

$$15 \leq [N_{S_{D_{101}}}, N_{S_{D_{102}}}] \leq 100$$

$$0.01 \leq [R_{RD_{101}}, R_{RD_{102}}] \leq 15$$

$$1 \leq [F_{S_{D_{101}}}, F_{S_{D_{102}}}] \leq 100$$

$$[P_B, P_T, P_X] \geq [0.99, 0.99, 0.99]$$

$$[F_{S_{D_{101}}}, F_{S_{D_{102}}}] \leq [N_{S_{D_{101}}}, N_{S_{D_{102}}}]$$

$$[R_B, R_T, R_X] \geq [0.99, 0.99, 0.99]$$

Figure 1. BTX separation and purification scheme and optimization constraints.

## 3. Results

Table 1 shows the employed optimal function values for both virtual platforms (VP) based on 3D Pareto front and employing the utopia-tracking approach as a tool to make optimal decisions. Besides, the computational times for each evaluation during the optimization step are shown, as well as the optimal state values. All calculations were made on laptop with an AMD Ryzen 7 5800 H processor @ 3.2 GHz, and 16 GB RAM.

To determine the best optimal results, normalized values of the objective functions were used, thus, the values of  $\|\Phi - \Phi^{L,s}\|_p$  for the results of both virtual platforms were computed, getting a value of 0.45 (interface A), and 0.46 (interface B). For the selection of the optimal point, it was assumed that the objective functions have the same weight.

Table 1. Relevant indicators for the virtual platforms evaluated.

VP	Time (s)	TAC (USD/y)	$\sigma T_0$ (kW)	EI-99 (mPt/y)	N <sub>S</sub> D <sub>101</sub>	F <sub>S</sub> D <sub>101</sub>	R <sub>R</sub> D <sub>101</sub>	N <sub>S</sub> D <sub>102</sub>	F <sub>S</sub> D <sub>102</sub>	R <sub>R</sub> D <sub>102</sub>
A	0.97	2.28E6	216.43	1.59E4	62	30	1.56	53	37	1.97
B	0.94	2.26E6	219.10	1.58E4	47	22	1.56	56	40	1.99
$\Phi^{L,S}$	-	<b>2.26E6</b>	<b>215.03</b>	<b>1.57E4</b>	-	-	-	-	-	-

Figure 2 shows the results, where the black dots correspond to interface A, and the blue dots correspond to interface B. Figure 2.a shows the 3D Pareto front for the final optimal solutions obtained in both virtual platforms, as well as a spider chart to show the relationship between state variables values from both platforms; the dots inside the red circles represent the optimal design for both interfaces and the values are shown in Table 1. Figure 2.b is illustrated to improve the visualization of the three-dimensional plot, thus the objective functions were plotted in 2D arrays, where the values were normalized to have a similar reference system.

a)

b)

Figure 2. a) Comparative 3D Pareto plot. b) Objective functions normalized matrix.

The results showed that both computational interfaces have a similar performance in all terms, as well as a linear relation between economy-environment objective functions, and non-dominated solutions for economy-exergy, and economy-environment. In terms of computational time, (B) showed a better performance and, it might be possible to argue that Python is the best option because it has better performance in the TAC and the EI-99

objectives, but when the utopia-tracking approach is implemented, it is possible to observe that (A) had a lower value in terms of the three objectives normalized sum in the optimization problem, meaning that it is closer to the utopic value of the problem, which was generated through the minimum values obtained from both Pareto fronts. Based on the graphical results shown in Figure 2, it is likely to observe a close optimal solution for both algorithms, nevertheless, the limits and spread of both Pareto fronts are different for each solution and could be associated with the function coding of each step of the MOGA (fitness function selection, crossover, mutation, etcetera).

#### 4. Conclusions

The proposed tools for selecting the best VP allowed concluded that, based on the decision-making criteria results, it was observed a better computational time for the virtual platform based on Aspen Plus-Python (B) (0.94 vs 0.97 seconds). Regarding the objective function, both VP have similar values, but the interface based on Aspen Plus-Matlab (A) obtained a better-normalized distance to the utopic point ( $\Phi^{L-S}$ ) (0.45 vs 0.46). Although utopia-tracking offers a pathway to select the best solution in the optimal data sets from both Pareto fronts, a more detailed study should be carried out, which could tackle other case studies and focus on topics associated with the data set in the Pareto front and their performance indicators (e.g., distribution, convergence, etcetera).

## Abstract

Rising energy demand, depletion of fossil fuels and global warming are driving research into eco-friendly alternative energy technologies. Currently, interest in hydrogen as alternative energy is increasing. Among various hydrogen production technologies, there are three major methods for producing hydrogen by water electrolysis: proton exchange membrane water electrolysis (PEMWE), alkaline water electrolysis (AWE), and anion exchange membrane water electrolysis (AEMWE). AEMWE has been attracting attention in recent years because it has the advantage of overcoming the limitations of both electrolysis techniques; Low current density, low pressure, and use of expensive noble metal catalysts.

High-efficiency hydrogen production and durability are determined by the design of the serpentine and the performance of the catalyst and exchange membrane. That is, the distribution of the temperature and pressure in the electrolyzer and the hydrogen production are affected by the design of the serpentine. Manufacturing and experimenting with various serpentine designs are costly and time-consuming. This can be solved by constructing the water electrolyzer system through computational fluid dynamics (CFD). In addition, it is possible to check the flow phenomena, distribution of pressure, temperature, and current density inside the system.

In this study, a mathematical model of the AEMWE system was established. The model for the electrochemical reaction was implemented through user defined functions (UDFs), and reliability was increased through validation with actual experimental data. This model will be used to analyze the efficiency and durability of the water electrolyzer in various serpentine designs.

**Keywords:** Hydrogen production, AEM water electrolysis, Mathematical modeling, Computational fluid dynamics

## 1. Introduction

Since traditional energy sources such as fossil fuels generate greenhouse gas (GHG) (e.g., methane, carbon dioxide), there is a need for alternative fuels. Hydrogen is considered an alternative energy source because it has a higher energy content than fossil fuels and can significantly reduce GHG. The hydrogen production process is divided into three categories: grey hydrogen produced through reforming of methane and water vapor, blue hydrogen produced by combining grey hydrogen with carbon capture and storage (CCS), and green hydrogen produced through water electrolysis. In particular, green hydrogen significantly reduces carbon dioxide emissions compared to other methods and is considered a more promising method because water is an infinite source.

AEM electrolysis is a method that combines the advantages of alkaline electrolysis and PEM electrolysis, and has various characteristics: First, hydrogen can be produced at low cost by using a relatively inexpensive non-platinum group metal catalyst. Second, the system is easy to handle due to the low operating temperature.

Here, we analyzed various indices for improving performance and durability through mathematical modeling of AEM electrolysis. Through our developed model, it is possible to identify the exact contribution of mass, momentum, and energy transport.

## 2. Mathematical model

Fig. 1 shows the schematic view of AEM electrolysis cell (AEMEC). AEMEC consists of plate, gas diffusion layer (GDL), catalyst layer (CL), and membrane. As a reactant, water passes through the flow channel and GDL in the plate, and the reaction occurs at the electrode. At the cathode,  $OH^-$  ions are generated through the reaction of Eq. (1) and move to the anode. At the anode, water and oxygen are produced through Eq. (2).

The mixture model of ANSYS FLUENT was used to solve the two-phase flow, and the electrochemical model and source terms were applied as UDFs.

Fig. 1. Schematic view of AEM electrolysis cell.

### 2.1. Governing equations

The continuity equation for liquid-gas mixture is expressed as Eq. (3).  $\vec{v}_m$  is the mass-averaged velocity, and  $\rho_m$  is the mixture density.  $\alpha_k$  represents the volume fraction for the k phase.

$$\nabla \cdot (\rho_m \vec{v}_m) = S_m \quad (3)$$

$$\vec{v}_m = \frac{\sum_{k=1}^n \alpha_k \rho_k \vec{v}_k}{\rho_m} \quad (4)$$

$$\rho_m = \sum_{k=1}^n \alpha_k \rho_k \quad (5)$$

The momentum equation for a mixture can be obtained by summing the individual momentum equations for all phases. It is expressed as Eq. (6), where  $\mu_m$  denotes the viscosity of the mixture

$$\nabla \cdot (\rho_m \vec{v}_m \vec{v}_m) = -\nabla p + \nabla \cdot (\mu_m (\nabla \vec{v}_m + \nabla \vec{v}_m^T)) + \nabla \cdot \left( \sum_{k=1}^n \alpha_k \rho_k \vec{v}_{dr,k} \vec{v}_{dr,k} \right) + S_{mom} \quad (6)$$

$$\mu_m = \sum_{k=1}^n \alpha_k \mu_k \quad (7)$$

Drift velocity is related to relative velocity, which can be expressed as:

$$\vec{v}_{dr,k} = \vec{v}_k - \vec{v}_m \quad (8)$$

The energy equation for liquid-gas mixture is given by Eq. (9), where  $k_{eff}$  represents the effective conductivity.  $S_e$  includes volumetric heat sources.

$$\nabla \cdot \sum_{k=1}^n (\alpha_k \vec{v}_k (\rho_k E_k + p)) = \nabla \cdot (k_{eff} \nabla T) + S_e \quad (9)$$

The internal energy  $E_k$  for a compressible phase is given by Eq. (10), where  $h_k$  is the sensible enthalpy for k phase.

$$E_k = h_k - \frac{p}{\rho_k} + \frac{v_k^2}{2} \quad (10)$$

To solve the species conservation equation, the convection-diffusion equation for i th species predicts the local mass fraction of each species,  $Y_i$ . The species transport equation can be represented as follows:

$$\nabla \cdot (\rho \vec{v} Y_i) = -\nabla \cdot \vec{J}_i + S_i \quad (11)$$

$$\vec{J}_i = -\rho D_{i,m} \nabla Y_i \quad (12)$$

The source terms used in each governing equation are listed in Table 1.

**Table 1**  
Source terms of governing equations.

Source Terms	Anode	Cathode
Mass: liquid phase	$S_m = \dot{N}_{H_2O,m} - \dot{N}_{H_2O,evap} + \frac{iM_{H_2O}}{2F}$	$S_m = -\dot{N}_{H_2O,m} - \dot{N}_{H_2O,evap} - \frac{iM_{H_2O}}{F}$
Mass: vapor phase	$S_m = \frac{iM_{O_2}}{4F} + \dot{N}_{H_2O,evap}$	$S_m = \frac{iM_{H_2}}{2F} + \dot{N}_{H_2O,evap}$
Momentum	$S_{mom} = -\frac{\mu}{k} \vec{v}$	
Energy	$S_e = (V_{cell} - 1.48V)i - \Delta H_{vap} \frac{\dot{N}_{H_2O,evap}}{M_{H_2O}}$	
Species: $H_2$	$S_{H_2} = 0$	$S_{H_2} = \frac{iM_{H_2}}{2F}$
Species: $O_2$	$S_{O_2} = \frac{iM_{O_2}}{4F}$	$S_{O_2} = 0$

## 2.2. Electrochemical model

In the electrochemical model, the total voltage is expressed as the sum of open circuit voltage (OCV), activation overpotential, and ohmic overpotential. OCV is the voltage when no current flows and is derived from the Nernst equation.

$$V = E_{OCV} + \eta_{act} + \eta_{ohm} \quad (13)$$

$$E_{OCV} = 1.229 - 0.846 \times 10^{-3}(T - 298.15) + \frac{RT}{2F} (\ln p_{H_2} + 0.5 \ln p_{O_2}) \quad (14)$$

The activation overpotential is related to the electrochemical reaction at the electrode and is expressed by the Butler-Volmer equation (Eq. (15)).

$$\eta_{act} = \frac{RT_a}{2\alpha_a F} \operatorname{arcsinh}\left(\frac{i}{2i_{0,a}}\right) + \frac{RT_c}{2\alpha_c F} \operatorname{arcsinh}\left(\frac{i}{2i_{0,c}}\right) \quad (15)$$

$$i_0 = i_{0,ref} \exp\left[-\frac{E_{act}}{R} \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \quad (16)$$

Ohmic overpotential is a term related to resistance when current flows and is expressed by ohmic's law.

$$\eta_{ohm} = R \times i \quad (17)$$

The relationship between current and voltage is expressed as Eq. (13), and the current according to the applied voltage is calculated through Newton's method through UDFs.

### 3. Results and discussion

Fig. 2 illustrates the validation with the experimental data. When the reference parameters were used in the electrochemical model, there was a difference from the experimental data. To solve this problem, the parameter values were estimated using a genetic algorithm and calibrated to the experimental data

Fig. 2. Comparison between simulation results and experimental data.

Fig. 3 shows the gas volume fraction at the cathode using CFD simulation. In general, the gas volume fraction increases from inlet to outlet. Gas tends to accumulate at the tip of the cell.

Fig. 3. Distribution of the gas volume fraction at the cathode.

In this study, 3-dimensional AEMEC model was constructed by combining a mixture model and an electrochemical model using UDFs. Durability and performance were analyzed by analyzing temperature and pressure distribution and hydrogen fraction in the cell. As future work, we plan to compare the effects of various serpentine designs, and

find the optimal design achieving the highest performance and durability of cell system by optimizing serpentine configurations.

## Abstract

As a method of converting easy-to-measure physical properties into detailed composition of feedstocks through distribution law and optimization calculation, molecular reconstruction method plays an important role in providing refineries with detailed composition data for molecular management. Introducing the knowledge of petroleum components, including the distribution pattern of homologues and the range of distribution parameters, can effectively enhance the effect of molecular reconstruction. We propose an aided optimization method to assist in the molecular reconstruction of crude oil. This method helps the optimization algorithm to obtain faster and more accurate results by using a pre-optimized dataset added to the initial population of the particle swarm optimization algorithm. The proposed aided optimization method was validated on 52 sets of crude oil data and achieved an average objective function reduction to 82.8% of the original and an average optimization time reduction to 87.5% of the original when using approximately 20% of the pre-optimized data points as aided data.

**Keywords:** Molecular reconstruction; Crude oil; Structure-oriented lumping; Pre-optimized dataset; Aided optimization method.

## 1. Introduction

The refining process is the separation, transformation and purification of oil molecules, in which the average molecular weight is gradually reduced, and various types of molecules are gathered together in an orderly manner. As the crude oil resources gradually become heavier, the government's environmental requirements for the production process become more and more stringent, and the description of the refining process becomes more and more detailed until it reaches the molecular level of description. Molecular management is a combined technical solution for petrochemical process system optimization based on the molecular level. Due to the limitations of analytical techniques and production costs, it is often difficult to perform an exhaustive experimental analysis of all oil products (Stratiev et al., 2019). Molecular reconstruction technology has gained wide research and application by using the physical properties that can be quickly measured to obtain detailed molecular compositions through optimization, which provide the basic data for molecular management (Wu and Zhang, 2010).

In recent years, besides the research on the methods and processes of molecular reconstruction itself (Bi and Qiu, 2019), a series of aided methods have been proposed to

introduce information and knowledge in molecular reconstruction to improve the accuracy and computational speed. The aided methods mainly include (a) predicting the range of optimization parameters through historical data, to improve the speed and accuracy (Bi and Qiu, 2018); (b) based on the known distribution law of oil components, the virtual oil components are constructed to find similar oil components to assist in the optimization (Guan and Zhang, 2022); (c) achieving better prediction results by introducing neural network models in the optimization (Ma et al., 2022).

Considering that the distribution law of crude oil is not completely clear, an effective virtual oil fraction cannot be constructed. In this article, we propose an aided optimization method based on the results of molecular reconstruction of actual crude oil components. The similarity components of crude oil are found according to the similarity calculation method. By adding similar components to the initial particle population of the PSO algorithm, an enhancement to the optimization results is achieved. This aided optimization method not only demonstrates the enhancement effect of pre-optimized datasets on molecular reconstruction, but also shows the importance of introducing information and knowledge in molecular reconstruction.

## 2. Methods

### 2.1. Molecular construction based on SOL

The first step in the molecular reconstruction process is to represent molecules appropriately. We chose the structure-oriented lumping (SOL) method as the way to represent molecules and build a molecular library. Based on previous work, we use 21 structural increments to describe the composition of the molecule (Chen et al., 2018). The structure of each molecule can be described by the number of these 21 structural increments. As shown in Figure 1, a two-step approach is used to construct the molecular library by first constructing representative core structures, followed by adding different lengths of side chains to each core structure to complete all the molecules. For the physical properties of the constructed molecules, the group contribution (GC) method is used to calculate the relevant physical properties.

**Figure 1.** Molecular construction steps.

### 2.2. Calculation of mole fraction of molecules

After constructing the molecular library, it is necessary to describe how to calculate the mole fraction of each molecule. Considering the complexity of crude oil, a two-layer homologous series distribution is used to describe the distribution of the molecular library. As shown in Figure 2, the first layer of homologous series distribution is the homologous series distribution of the core structure. There are 19 types of core structures, and each type has 5 core structures. The exponential distribution is used to describe the probability density function in each core structure type, and the histogram distribution is used to describe the mole fraction of each core structure type. The second layer of homologous series distribution is the length distribution of the side chains. Side chains with a length of 1-50 carbon numbers are added to each core structure, and the gamma distribution is used to describe the carbon number distribution of the side chains.

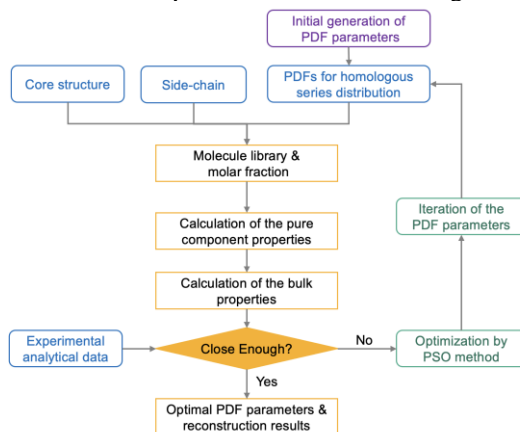

**Figure 2.** The core structure types and the homologous series distribution of the core structure.

According to the two-layer homologous series distribution and probability density function, the mole fractions of all molecules can be calculated. The physical properties of the reconstructed oil can be calculated based on the mole fractions of all molecules, the physical properties of all molecules and the mixing rule.

### 2.3. Optimization of molecular reconstruction of crude oil

The goal of the optimization of the molecular reconstruction is to make the difference between the calculated properties and the experimentally analyzed properties as small as possible, and the flow chart of the optimization is shown in Figure 3.

**Figure 3.** Flow chart of the optimization of molecular reconstruction.

The objective function is the weighted average of the absolute relative deviation values of physical properties, and the optimization variables are the parameters of the probability distribution, with a total of 227 optimization variables. The particle swarm optimization (PSO) is used as the optimization algorithm. The PSO can efficiently search for problems with large solution spaces and find candidate solutions without sufficient information. The particle swarm size is set to 200 based on the number of optimization variables, computational speed, and accuracy. The optimization process is calculated in MATLAB 2022a, and its own PSO algorithm is used for calculation.

### 2.4. Construction of pre-optimized dataset

Based on the molecular reconstruction proposed above, the molecular reconstruction optimization calculations are performed on the 52 sets of crude oil data we have, and the results (values of each optimization variable) are aggregated to obtain the pre-optimized dataset. The pre-optimized dataset will serve as the basic data used by the aided

optimization method to assist other crude oils in molecular reconstruction, and it will also be used as a benchmark for comparing the results of the aided optimization method.

### 2.5. Using pre-optimized dataset to aid optimization

When new crude oil is available for molecular reconstruction, the process of using the pre-optimized dataset to aid in optimization can be divided into 3 steps.

Step 1, find similar data. Find data points in the pre-optimized dataset that are similar to the new crude oil. The Normalized Euclidean distance was used to measure the distance between the new crude oil data and data point in the pre-optimized dataset, which can effectively avoid the influence caused by different units of different properties and no pre-processing of data is required either. All 14 physical properties used in molecular reconstruction were used as the components of the distance calculation. The calculation formula of the Normalized Euclidean distance is shown in Equation 1, where  $u$  is the vector of a data point,  $v$  is the vector of another data point, and  $V$  is the variance of vectors  $u$  and  $v$ . According to the distance formula, the distance between the new crude oil data and all the data points in the pre-optimized dataset can be calculated, and the smaller the value, the more similar the two data set are.

$$distance = \sqrt{\sum_{i=1}^n \frac{(u_i - v_i)^2}{v_i}} \quad (1)$$

Step 2, introduce the pre-optimized data points. Based on the similarity data calculated in step 1, the pre-optimized data are sorted by similarity and the most similar pre-optimized data points are selected in preference. As shown in Figure 4, a certain number of pre-optimized data points are used as part of the initial particle population of the PSO algorithm in the solution of the optimization problem.

**Figure 4.** Initial particle and swarm construction process.

Step 3, perform the optimization calculation. After adding some of the pre-optimized data points to the initial particles, the remaining initial particles for the PSO algorithm are generated using a randomized approach as shown in Figure 4. Using these initial particles, the optimization computation is started following the process shown in Figure 3.

## 3. Results and discussion

The proposed aided optimization method is applied to the molecular reconstruction process of crude oil. Due to the limitation of the size of the available crude oil dataset (only 52 sets of crude oil with physical properties and calculation results data), we adopted the method of selecting one set of crude oil data as the test data one by one and the remaining 51 sets of data as the pre-optimized dataset for the aided optimization. The most similar 3/5/10/20 pre-optimized data points were selected as aided data points in the aided optimization calculation for each crude oil data, respectively. The optimization problem was solved in MATLAB 2022a, and the entire computation was performed on the Intel Xeon 4216 CPU @ 2.1GHz.

First, molecular reconstruction is performed on a set of crude oil data. The same values are used for all optimization parameters except the initial particle population. Calculations were performed for different number of aided data, and the results are shown in Table 1.

**Table 1.** The results obtained with the aided optimization method.

Number of Aided data	0	3	5	10	20
Objective Fun Value	100%	88.4%	82.5%	77.7%	97.4%
Optimization Time	100%	22.8%	19.8%	39.1%	34.4%
Property	Absolute relative error of the calculation result				
Carbon	0.27%	0.01%	0.01%	0.02%	0.11%
Hydrogen	1.70%	0.00%	0.00%	0.05%	0.60%
Sulfur	0.06%	0.00%	0.00%	0.00%	0.00%
Nitrogen	0.06%	0.00%	0.00%	0.00%	0.00%
Paraffins	0.05%	0.00%	0.00%	0.00%	0.00%
Naphthenes	0.06%	0.00%	0.00%	0.00%	0.00%
Aromatics	0.03%	0.00%	0.00%	0.00%	0.00%
5 vol% BP	5.65%	1.35%	0.21%	0.21%	5.65%
10 vol% BP	0.56%	0.13%	1.77%	3.86%	0.10%
30 vol% BP	4.54%	4.18%	0.40%	0.82%	0.31%
50 vol% BP	8.41%	0.17%	0.00%	7.40%	3.07%
70 vol% BP	0.01%	2.65%	3.49%	0.00%	2.31%
90 vol% BP	4.89%	7.17%	7.28%	4.32%	7.11%
95 vol% BP	7.55%	10.97%	10.11%	7.52%	10.11%

The objective function value and optimization time of the molecular reconstruction results without pre-optimized data are recorded as 100%, and the percentage share of the other results with pre-optimized data is calculated. It can be found that the inclusion of pre-optimized data points all reduces the objective function value and optimization time to some extent, respectively.

For the objective function, the value decreases gradually at first with the addition of pre-optimized data points and reaches the lowest level of 77.7% of the baseline value when 10 pre-optimized data are added (about 20% pre-optimized data). This indicates that the inclusion of pre-optimized data points effectively helps the whole population to find better results during the optimization. When 20 pre-optimized data were used (about 40% pre-optimized data), the objective function value increased to 97.4% of the baseline value. This situation indicates that only an appropriate proportion (around 20%) of all pre-optimized data points will work best, and the inclusion of more pre-optimized data points will not effectively help the population to find better results and generate positive effects due to the low similarity between them and the calculated data. By checking the similarity values, it was found that the pre-optimized data with distance values less than 4 had a great aided optimization effect, and the pre-optimized data with distance values greater than 4 had an insignificant or even counterproductive aided optimization effect.

For the optimization time, the addition of the pre-optimized data was also effective, which reached the lowest level of 19.8% of the baseline value when 5 pre-optimized data (about 10% pre-optimized data) were added. The addition of the pre-optimized data provides more information during the optimization and reduces the overall population disorder, allowing the algorithm to converge faster and more accurately. When 10 pre-optimized data are added, the optimization time rises to 39.1% of the baseline value, which is mainly due to the addition of more pre-optimized data, driving the algorithm to go for better results, which increases the number of iterations and makes the optimization time grow. Then, all the data were calculated separately with the aided optimization method, and the results were recorded. The results are compared with those obtained without using the pre-optimized data, and the percentage share of the results is calculated. The average calculation results of all data are shown in Table 2 and Figure 5.

**Table 2.** The average calculation result of all data.

Number of Aided data	0	3	5	10	20
Objective Fun Value	100%	89.7%	85.5%	82.8%	89.1%
Optimization Time	100%	91.4%	85.1%	87.5%	101.3%

**Figure 5.** The trend of calculation results with the number of aided data.

According to Table 2 and Figure 5, when 10 pre-optimized data points are added, the average objective function value reaches the lowest level, reaching 82.8% of the baseline value. When 5 pre-optimized data points are added, the average optimization time reaches the lowest level, reaching 85.1% of the baseline value. Considering the objective function value and optimization time together, the best results can be achieved when 10 pre-optimized data (or about 20% pre-optimized data) are added in molecular reconstruction.

#### 4. Conclusions

In conclusion, this novel work proposes an aided optimization method for molecular reconstruction of crude oil based on a pre-optimized dataset. With the pre-optimized dataset and similarity calculation, the results of historical molecular reconstruction can be introduced into the optimization of the molecular reconstruction as crude oil distribution knowledge, which plays an important role in enhancing the optimization results. By the characteristics of the PSO algorithm, the added pre-optimized data can effectively lead the whole population to a better solution, while the optimization time is simultaneously reduced due to the addition of more information and knowledge. The effectiveness of the proposed aided optimization method is verified on crude oil data and shows the potential for future application to real industrial scenarios to further improve the accuracy and speed of molecular reconstruction.

# A Global Optimization Algorithm for the Solution of Mixed-Integer Quadratic Adjustable Robust Optimization Problems under Endogenous Uncertainty

Byungjun Lee<sup>a</sup>, Styliani Avraamidou<sup>a\*</sup>

*<sup>a</sup>Department of Chemical and Biological Engineering, University of Wisconsin-Madison, 1415 Engineering Dr, Madison, WI 53706, USA*

## Abstract

This work proposes an algorithm for the solution of the two-stage mixed-integer quadratic adjustable robust optimization (ARO) problem under endogenous uncertainty. This class of ARO problems is often used in Chemical Engineering application such as scheduling and control problems, but there are only a handful of approaches attempting to solve them. For our developed approach, the two-stage ARO problem is firstly reformulated as a tri-level mixed-integer quadratic programming problem, and the exact and global solution is obtained using multi-parametric programming. The proposed algorithm was verified and compared with other approaches such as the affine decision rules, the column-and-constraint generation algorithm, and full enumeration of extreme points. We showed that our algorithm has the ability to solve ARO problems that, to our knowledge, cannot be solved by any other algorithm. To assess the efficiency and the performance of the proposed algorithm, a computational study was performed.

**Keywords:** Adjustable robust optimization (ARO), Endogenous uncertainty, Multi-parametric programming, Tri-level programming

## 1. Introduction

Adjustable robust optimization (ARO) is an extension of robust optimization (RO), which includes recourse decisions in the second stage (Ben-Tal et al., 2009). In Chemical Engineering, the ARO problem formulation can be applied to solve a vast array of multi-stage decision making problems under uncertainty, such as batch scheduling problems (Shi and You, 2016) and explicit model predictive control (Tejeda-Iglesias et al., 2019). Although several methods have been proposed for the solution of this class of problems, including affine decision rules (Ben-Tal et al., 2004) and column-and-constraint generation algorithm (Zeng and Zhao, 2013), most solution methods are limited to the solution of continuous linear ARO problems, and solving the mixed-integer quadratic ARO problems still remains a challenge.

In this paper, we apply a multi-parametric programming approach to solve the two-stage mixed-integer quadratic ARO problems under endogenous uncertainty, as an extension of the previous work on the linear ARO problems (Avraamidou and Pistikopoulos, 2020). Section 2 presents the general formulation of the ARO problems and presents our solution algorithm. Then the proposed algorithm is verified with several numerical examples, and its advantages over the previously known algorithms are discussed in section 3. Lastly, section 4 presents the relation between the computational time and the total number of variables.

## 2. ARO through multi-parametric programming

The two-stage mixed-integer ARO problem with a convex quadratic objective function can be expressed as (1). The first-stage variable ( $x$ ) is called “here-and-now” decision, which is determined prior to the realization of uncertainty ( $u$ ). The second-stage variable ( $y$ ) is called “wait-and-see” decision, which is determined after the uncertainty is revealed.

$$\begin{aligned} & \min_x (Q_x x + c_x)^T x + \max_{u \in \Omega_u} \min_y (Q_y y + c_y)^T y \\ & \text{s.t. } A_x x + A_y y + A_u u \leq b \\ & \quad x \in X := \mathbb{R}^{p_c} \times \{0, 1\}^{p_b}, \quad y \in Y := \mathbb{R}^{q_c} \times \{0, 1\}^{q_b}, \quad u \in U := \mathbb{R}^{r_0}. \end{aligned} \quad (1)$$

In this work, uncertainty is assumed as a function of “here-and-now” decisions. This type of uncertainty is referred to as endogenous uncertainty, where “here-and-now” decisions constrain the feasible region of uncertainty (Lappas and Gounaris, 2018). At the initial step, problem (1) is reformulated as a tri-level mixed-integer quadratic programming (T-MIQP) problem (2).

$$\begin{aligned} & \min_x z^{(1)} = (Q_x x + c_x)^T x + (Q_y y + c_y)^T y \quad (1^{\text{st}} \text{ level}) \\ & \text{s.t. } \min_{u \in \Omega_u} z^{(2)} = -(Q_y y + c_y)^T y \quad (2^{\text{nd}} \text{ level}) \\ & \quad \text{s.t. } \min_y z^{(3)} = (Q_y y + c_y)^T y \quad (3^{\text{rd}} \text{ level}) \\ & \quad \text{s.t. } A_x x + A_y y + A_u u \leq b \\ & \quad \quad x \in X := \mathbb{R}^{p_c} \times \{0, 1\}^{p_b}, \quad y \in Y := \mathbb{R}^{q_c} \times \{0, 1\}^{q_b}, \quad u \in U := \mathbb{R}^{r_0}. \end{aligned} \quad (2)$$

The tri-level problem (2) is then solved using multi-parametric approach based on the generalized piecewise affine decision rules (Avraamidou and Pistikopoulos, 2019). First, the 3<sup>rd</sup> level MIQP problem is solved to obtain the parametric solution  $y(x, u)$  for each critical region. Similarly, resulting set of 2<sup>nd</sup> level MIQP problems are solved to find the parametric solutions  $u(x)$ . Then resulting set of single-level MIQP problems are solved for  $x$ , and the exact and global solution is selected after applying comparison procedure. The comparison procedure removes unfeasible critical regions and finds the optimum solution that minimizes the objective function  $z^{(1)}$  among the remaining critical regions. The proposed algorithm is also illustrated in Figure 1.

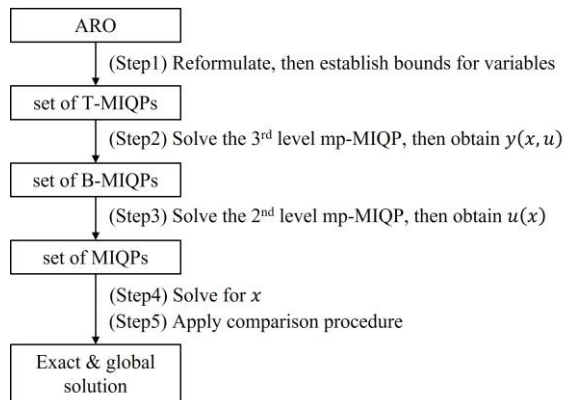

Figure 1. Algorithm to solve two-stage quadratic MI-ARO problem.

### 3. Numerical Examples

The first numerical example (3) has a convex, quadratic objective function in the first stage, which is a function of “here-and-now” decisions.

$$\begin{aligned}
 & \min_x 2x_1^2 + x_1x_2 + 3x_2^2 + \max_{u \in \Omega_u} \min_y 12y_1 + 18y_2 \\
 \text{s. t. } & x_1 + x_2 \leq 10 \\
 & y_1 \geq u_1 - x_1 \\
 & y_2 \geq u_2 - x_2 \\
 & x_1, x_2 \geq 0, y_1, y_2 \geq 0 \\
 & \Omega_u = \{u: 12.1 \leq u_1 \leq 26.3, 13.2 \leq u_2 \leq 30.4\}
 \end{aligned} \tag{3}$$

Problem (4) represents the tri-level formulation that is recast from the original two-stage ARO formulation (3).

$$\begin{aligned}
 & \min_x z^{(1)} = 2x_1^2 + x_1x_2 + 3x_2^2 + 12y_1 + 18y_2 \\
 \text{s. t. } & \min_{u \in \Omega_u} z^{(2)} = -(12y_1 + 18y_2) \\
 & \text{s. t. } \min_y z^{(3)} = 12y_1 + 18y_2 \\
 & \text{s. t. } x_1 + x_2 \leq 10 \\
 & y_1 \geq u_1 - x_1 \\
 & y_2 \geq u_2 - x_2 \\
 & x_1, x_2 \geq 0, y_1, y_2 \geq 0 \\
 & \Omega_u = \{u: 12.1 \leq u_1 \leq 26.3, 13.2 \leq u_2 \leq 30.4\}
 \end{aligned} \tag{4}$$

The proposed approach was verified by comparing it with both the affine decision rules and column-and-constraint generation algorithm. The objective function value and the corresponding optimum solution for each approach are summarized in Table 1.

Table 1. Objective function value and the corresponding optimum solution through multiparametric programming (MP), affine decision rules (AD), and column-and-constraint generation (CC).

Algorithm	$z^*$	$x_1^*$	$x_2^*$	$y_1^*$	$y_2^*$	$u_1^*$	$u_2^*$
MP	825.23	2.35	2.61	23.95	27.79	26.30	30.40
AD	825.23	2.35	2.61	23.95	27.79	26.30	30.40
CC	825.23	2.35	2.61	23.95	27.79	26.30	30.40

The second numerical example (5) has a convex, quadratic objective function in the second stage, which is a function of “wait-and-see” decisions.

$$\begin{aligned}
 & \min_x 3x_1 + 2x_2 + 1500x_3 + 6000x_4 \\
 & \quad + \max_{u \in \Omega_u} \max_y (6y_1^2 + 5y_2^2 + 9y_3^2 + 4y_1y_2 + 2y_1y_3 + 6y_2y_3) \\
 \text{s. t. } & x_1 + 2x_2 + 3x_3 + 4x_4 \leq 30 \\
 & y_1 \geq u_1 - x_1 - x_2 \\
 & y_2 \geq u_2 - 8x_3
 \end{aligned}$$

$$\begin{aligned}
 &y_3 \geq u_3 - 15x_4 \\
 &x_1, x_2 \geq 0, x_3, x_4 \in \{0, 1\}, y_1, y_2, y_3 \geq 0 \\
 &\Omega_u = \{u: 10 \leq u_1, u_2, u_3 \leq 20\}
 \end{aligned} \tag{5}$$

In this case, the affine decision rules are not applicable due to the nonlinear terms of uncertainties in the second stage, which are known to be computationally intractable in general. For the column-and-constraint generation algorithm, the sub-problem is non-convex, after using KKT conditions to transform the bi-level sub-problem into a single-level problem. Therefore, the multi-parametric approach has an advantage over the other two algorithms when the ARO problem includes the quadratic terms of “wait-and-see” decisions.

After the tri-level reformulation of the problem (5), POP toolbox (Avraamidou and Pistikopoulos, 2019) was used to obtain the third-level parametric solutions  $y(x, u)$  and second-level parametric solutions  $u(x)$ . The decision rules for each critical region in the 3<sup>rd</sup> level and 2<sup>nd</sup> level are summarized in the Table 2.

Table 2. Decision rules and critical region definition for the 3<sup>rd</sup> level and 2<sup>nd</sup> level.

Level	Critical Region	Decision Rules	Additional Critical Region Definition
3	CR <sub>1</sub>	$y_1 = -x_1 - x_2 + u_1,$ $y_2 = -8x_3 + u_3$ $y_3 = -15x_4 + u_4$	$-50 \leq x_1 + x_2 - u_1 \leq 0,$ $-50 \leq 15x_4 - u_3 \leq 0,$ $6x_1 + 6x_2 + 16x_3 + 15x_4 - 6u_1 - 2u_2 - u_3 \leq 0,$ $2x_1 + 2x_2 + 40x_3 + 45x_4 - 2u_1 - 5u_2 - 3u_3 \leq 0,$ $x_1 + x_2 + 24x_3 + 135x_4 - u_1 - 3u_2 - 9u_3 \leq 0$
	CR <sub>2</sub>	$y_1 = -x_1 - x_2 + u_1,$ $y_2 = -8x_3 + u_3$ $y_3 = 0$	$-50 \leq x_1 + x_2 - u_1 \leq 0,$ $15x_4 - u_3 \leq 0,$ $3x_1 + 3x_2 + 8x_3 - 3u_1 - u_2 \leq 0,$ $2x_1 + 2x_2 + 40x_3 - 2u_1 - 5u_2 \leq 0,$ $x_1 + x_2 + 24x_3 - u_1 - 3u_2 \leq 0$
	CR <sub>3</sub>	$y_1 = 0,$ $y_2 = -8x_3 + u_3$ $y_3 = -15x_4 + u_4$	$x_1 + x_2 - u_1 \leq 0,$ $-50 \leq 15x_4 - u_3 \leq 0,$ $16x_3 + 15x_4 - 2u_2 - u_3 \leq 0,$ $40x_3 + 45x_4 - 5u_2 - 3u_3 \leq 0,$ $8x_3 + 45x_4 - u_2 - 3u_3 \leq 0$
	CR <sub>4</sub>	$y_1 = 0,$ $y_2 = -8x_3 + u_3$ $y_3 = 0$	$x_1 + x_2 - u_1 \leq 0,$ $15x_4 - u_3 \leq 0,$ $8x_3 - u_2 \leq 0$
	Common	—	$x_1 + 2x_2 + 3x_3 + 4x_4 \leq 30,$ $-8x_3 + u_2 \leq 52,$ $x_1, x_2 \geq 0, x_3, x_4 \in \{0, 1\},$ $10 \leq u_1, u_2, u_3 \leq 20$
2	CR <sub>1,1</sub>	$u_1 = 20,$ $u_2 = 20,$ $u_3 = 20$	$x_1 + x_2 \leq 20,$ $3x_4 \leq 4$ $6x_1 + 6x_2 + 16x_3 + 15x_4 \leq 180,$ $2x_1 + 2x_2 + 40x_3 + 45x_4 \leq 200,$ $x_1 + x_2 + 24x_3 + 135x_4 \leq 260$
	CR <sub>2,1</sub>	$u_1 = 20,$ $u_2 = 20,$ $u_3 = 0$	$x_1 + x_2 \leq 20,$ $3x_1 + 3x_2 + 8x_3 \leq 80,$ $x_1 + x_2 + 20x_3 \leq 70$
	CR <sub>3,1</sub>	$u_1 = 0,$ $u_2 = 20,$ $u_3 = 20$	$x_1 + x_2 \geq 0,$ $3x_4 \leq 4$ $4x_3 + 5x_4 \leq 16,$ $8x_3 + 45x_4 \leq 80$
	CR <sub>4,1</sub>	$u_1 = 0,$ $u_2 = 20,$ $u_3 = 0$	$x_1 + x_2 \geq 0,$ $2x_3 \leq 5$
	Common	—	$x_1 + 2x_2 + 3x_3 + 4x_4 \leq 30,$ $x_1, x_2 \geq 0, x_3, x_4 \in \{0, 1\}$

Lastly, CPLEX was used to solve the resulting single-level mixed-integer quadratic programming problem. Table 3 summarizes the 1<sup>st</sup> level objective function values for all the critical regions, and only the first critical regions  $CR_1$  and  $CR_{1,1}$  were selected from the comparison procedure. Therefore, the optimum solution is  $x = [13, 7, 1, 0]^T$  and  $y = [0, 12, 20]^T$  with objective function value 7313. This value exactly matches with the optimum objective function value obtained from the full enumeration of extreme points.

Table 3. Objective function values and optimum solutions in the 1<sup>st</sup> level.

$CR_i$	$CR_j$	$z^*$	$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	$y_3$	$u_1$	$u_2$	$u_3$
1	1	7313	13	7	1	0	0	12	20	20	20	20
2	1	2050	10	10	0	0	0	20	0	20	20	0

4	1	2000	0	0	0	0	0	20	0	0	20	0

#### 4. Computational Implementation

To evaluate the performance of the proposed algorithm, computational time of randomly generated mixed-integer ARO problems was measured. The ratio of the number of variables for continuous  $x$ , binary  $x$ , continuous  $y$ , binary  $y$  was set to be 1 : 1 : 1 : 1, and the number of constraints is set to be equal to the total number of variables. Note that the solution time was measured using Intel Core i7 at 80GHz and 16GB RAM, MATLAB R2022b, and IBM ILOG CPLEX Studio 12.10.0.

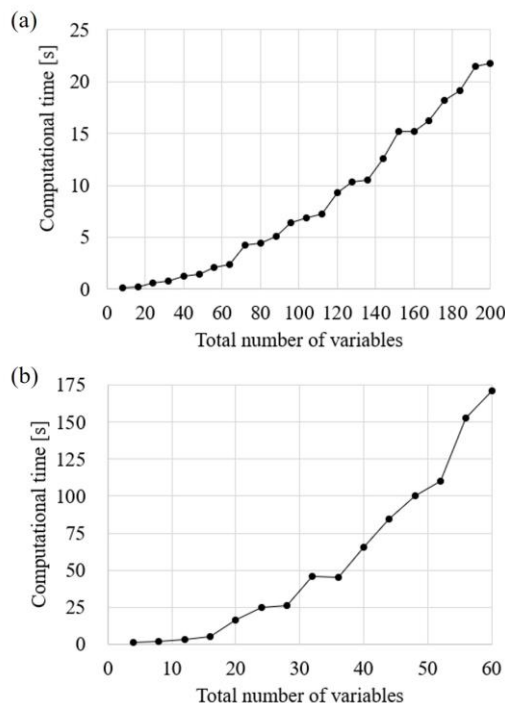

Figure 2. Measured computational time versus total number of variables for the (a) MILP-MILP structure and (b) MIQP-MIQP structure of the ARO problem.

Figure 2 represents the relation between the average computational time over five experiments and the total number of variables for the MILP-MILP structure and MIQP-MIQP structure of the ARO problem. Figure 2 also shows the exponentially increasing trend in the computational time as the total number of variables increases. In addition, it takes about 175s to solve the MIQP-MIQP structure of the ARO problem with 60 variables, about 70 times longer computational time compared to the MILP-MILP structure.

## 5. Conclusion

In this work, we developed an algorithm for the solution of the two-stage mixed-integer quadratic ARO problem under endogenous uncertainty. Initially, the ARO problem is reformulated into the tri-level mixed-integer quadratic programming problem, and it is solved multi-parametrically using the general piecewise affine decision rules. By solving the problem from the lowest level (3<sup>rd</sup> level) to the highest level (1<sup>st</sup> level), the exact and global solution is obtained after applying the comparison procedure. For the ARO problem with a quadratic objective function in the first stage, the proposed algorithm was verified by comparing its global solution with the global solutions from affine decision rules and column-and-constraint generation algorithm. In addition, we showed that these two well-known algorithms cannot solve the ARO problem with a quadratic objective function in the second stage, while our algorithm is able to solve this type of problem. Lastly, we analyzed the performance of the proposed algorithm by measuring the computational time for the randomly generated ARO problems with MILP-MILP structure and MIQP-MIQP structure.

## Abstract

During the past decade, deep learning models have shown great potential in chemical process fault diagnosis. However, a major assumption accepted by default in these previous studies is that the training and testing data possess the same feature distribution, which is generally invalid in industrial applications. The ability of data-driven models to generalize on various operation conditions are limited due to their tendency to overfit the training dataset. Motivated by the development of transfer learning, domain adaptation is utilized in this paper to settle the problem of knowledge transfer under the distribution discrepancy between the training and test datasets. The proposed model Dynamic Adversarial Adaptation Network (DAAN) can dynamically and quantitatively evaluate the importance of these two distributions and achieve accurate classification performance. Empirical evaluations based on Tennessee Eastman process validate the applicability and practicability of DAAN, which achieves the state-of-the-art transfer results in terms of diverse operating conditions and fault types.

**Keywords:** Domain adaptation; Fault diagnosis; Transfer learning; Tennessee Eastman process

## 1. Introduction

Fault diagnosis plays a significant role in chemical processes to avoid severe accidents. In recent years, significant advances have been made towards fault diagnosis with the assistance of deep learning. However, the excellent performance of current intelligent fault diagnosis methods based on deep learning is mainly attributed to the availability of large amounts of labeled failure data which is laborious and heavily dependent on experience. The entire equipment usually runs in a normal state and accessible fault samples are scarce as well (Qin et al., 2022). Another limitation on the practical application of these fault diagnosis methods is the continual changes in operating conditions. The distribution discrepancy between source training data and target test data makes a high requirement for the transferability of the diagnosis model (Wu et al., 2020).

In industrial production, the variation of ambient temperature and raw material components contribute to diverse working modes. When the fault samples in the test dataset are lack of labels and the training and testing data are subject to different distributions, the performance of most intelligent diagnostic models deteriorates considerably (Qin et al., 2022). Transfer learning puts forward an emerging frame to address the above problems. The concept of domain in transfer learning represents the

corresponding data space and the data distribution. In this study, the source domain refers to the data space and distribution of the labeled training data, while the attribute of the unlabeled test data is known as the target domain. The challenge of transferring the learned knowledge from the source domain to the target domain is defined as the domain shift phenomenon. This problem makes the source domain classifier lose its generalization ability in the target domain. Domain adaptation is a preferred solution to the domain shift issue, aiming to develop a cross-domain classifier which can extract domain-invariant features to bridge the distribution discrepancy (Li et al., 2019). Fig.1 illustrates the principle of domain shift and domain adaptation.

The latest studies reveal that deep neural networks can learn transferable features sufficiently with unsupervised domain adaptation algorithms, such as maximum mean discrepancy (MMD), multiple kernel MMD and joint MMD (Long et al., 2017). Some innovative works raise deep transfer learning methods in the field of computer vision, including Domain Adaptive Neural Network (DANN) (Ganin et al., 2017) and Domain Adaptive Ensemble Learning (DAEL) (Zhou et al., 2021), but it is still rare to discover a powerful cross-domain fault diagnosis method for chemical processes.

In this paper, a novel adversarial domain adaptation transfer learning model called Dynamic Adversarial Adaptation Network (DAAN) is proposed for fault diagnosis in industrial chemical processes. The diagnostic framework is composed of four modules, a shared feature extractor for feature learning, a label classifier for category prediction, a global domain discriminator for marginal distribution alignment and local subdomain discriminators for conditional distribution alignment. Deep residual shrinkage network is designed as the backbone of the feature extractor to achieve multiscale characteristics from time-series data. The adversarial learning mode with an adaptive weighting strategy can dynamically and quantitatively evaluate the relative importance of marginal and conditional distribution. The alignment of the source and target feature space is finally realized through the overall learning proceed.

The rest of the paper is organized as follows. In Section 2, the module structures and the diagnosis framework of DAAN are introduced in detail. Section 3 elaborates the experiments on Tennessee Eastman process and compares the results among different popular transfer learning models. The conclusion and outlook of the proposed model are summarized in Section 4.

Fig.1. Illustration of domain shift and domain adaptation.

## 2. Dynamic Adversarial Adaptation Network

The proposed model Dynamic Adversarial Adaptation Network is displayed in Fig.2. Its skeleton consists of a feature extractor  $G_f$ , a label classifier  $G_y$ , a global domain discriminator  $G_d$  and a local subdomain discriminator  $G_d^c$ . In DAAN,  $G_f$  extracts the key features of data followed by  $G_d$  and  $G_d^c$  achieving the adaptation of marginal and conditional distributions respectively. The dynamic adversarial factor  $\omega$  performs a quantitative evaluation of these two distributions. Under the action of  $G_y$ , the DAAN model is trained efficiently with the Gradient Reversal Layer (GRL) (Yu et al., 2019).

### 2.1. Feature Extractor

The raw data from different domains are directly fed into a shared feature extractor for certain generic characteristics. Deep residual shrinkage network is employed as the extractor which can obtain powerful feature learning capability and eliminate the noise-related information. The feature extractor includes multiple residual learning blocks and each of them is composed of convolution operation, batch normalization, activation function, and short connection. The structure of residual shrinkage building unit is a variant of classical ResNet, and a range of units are stacked to form the deep network. Sigmoid and rectified linear unit (ReLU) as non-linear transform tools are adopted to promote model convergence and alleviate the problem of gradient vanishing.

### 2.2. Domain Adaptation Network

#### 2.2.1. Label Classifier

The label classifier  $G_y$  focuses on the discrimination of the input sample label from the source domain. With the effort of the supervised information and the extracted deep features, the classifier is trained based on the cross-entropy loss formulated as:

$$L_y = -\frac{1}{n_s} \sum_{\mathbf{x}_i \in \mathcal{D}_s} \sum_{c=1}^C P_{\mathbf{x}_i \rightarrow c} \log G_y(G_f(\mathbf{x}_i)) \quad (1)$$

where  $C$  is the number of classes,  $P_{\mathbf{x}_i \rightarrow c}$  is the probability of  $\mathbf{x}_i$  belonging to class  $c$ .

#### 2.2.2. Global Domain Discriminator

The global domain discriminator  $G_d$  takes the responsibility of align the marginal distributions between the source and target domains. Its loss objective function can be calculated in the formula:

$$L_g = \frac{1}{n_s + n_t} \sum_{\mathbf{x}_i \in (\mathcal{D}_s \cup \mathcal{D}_t)} L_d(G_d(G_f(\mathbf{x}_i)), d_i) \quad (2)$$

where  $L_d$  is the domain discriminator loss and  $d_i$  is the original label of the input sample.

#### 2.2.3. Local Subdomain Discriminator

The local subdomain discriminator  $G_d^c$  is designed to align the conditional distributions between the source and target domains. Its representation ability of merging multimode structure in two distributions makes the discriminator carry out more fine-grained domain adaptation. The local subdomain discriminator can be regarded class-wise to match the multi-domain data associated with the same class, and the global domain discriminator is able to be split into multi-class local subdomain discriminators. The output of the label predictor  $G_y(\mathbf{x}_i)$  indicates the matching degree of each data point  $\mathbf{x}_i$  to be categorized further. Therefore, the loss function of  $G_d^c$  can be described as:

$$L_l = \frac{1}{n_s + n_t} \sum_{c=1}^C \sum_{\mathbf{x}_i \in (\mathcal{D}_s \cup \mathcal{D}_t)} L_d^c(G_d^c(\hat{y}_i^c G_f(\mathbf{x}_i)), d_i) \quad (3)$$

where  $L_d^c$  represents the cross-entropy loss of the subdomain discriminator associated with class  $c$ .  $\hat{y}_i^c$  signifies the predicted probability distribution over the class  $c$  of the input sample  $\mathbf{x}_i$ .

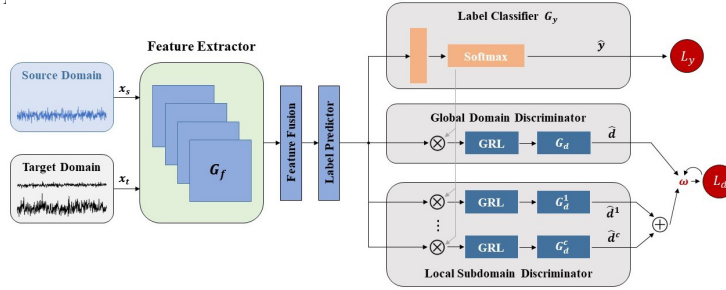

Fig.2. Architecture of Dynamic Adversarial Adaptation Network.

### 2.3. Dynamic Adversarial Training

Domain adversarial adaptation borrows the principle of Generative Adversarial Networks (GAN) to assist the model to learn transferable features. The adversarial learning procedure is a two-player game accompanied by the domain discriminator  $G_d$  and the feature extractor  $G_f$ . The former aims to distinguish the source domain from the target domain, while the latter keeps making puzzles for the former by extracting domain-invariant features. During this course, the parameters of  $G_f$  are optimized by maximizing the loss of  $G_d$ , and the ones of  $G_d$  are trained by minimizing the loss. With the loss of the label classifier  $G_y$  minimized, the loss function can be formalized as:

$$L(\theta_f, \theta_y, \theta_d) = \frac{1}{n_s} \sum_{x_i \in \mathcal{D}_s} L_y(G_y(G_f(x_i)), y_i) - \frac{\lambda}{n_s + n_t} \sum_{x_i \in (\mathcal{D}_s \cup \mathcal{D}_t)} L_d(G_d(G_f(x_i)), d_i) \quad (4)$$

where  $\lambda$  is a trade-off parameter. As the training converges, the parameters  $\hat{\theta}_f$ ,  $\hat{\theta}_y$ ,  $\hat{\theta}_d$  come to the optimized state.

$$(\hat{\theta}_f, \hat{\theta}_y) = \arg \min_{\theta_f, \theta_y} L(\theta_f, \theta_y, \theta_d), (\hat{\theta}_d) = \arg \max_{\theta_d} L(\theta_f, \theta_y, \theta_d) \quad (5)$$

The dynamic adversarial factor  $\omega$  is creatively built to evaluate the relative importance of the marginal and conditional distributions. In DAAN, the global  $\mathcal{A}$ -distance of the global domain discriminator and the local  $\mathcal{A}$ -distance of the local subdomain discriminator can be denoted as:

$$d_{\mathcal{A},g}(\mathcal{D}_s, \mathcal{D}_t) = 2(1 - 2(L_g)), d_{\mathcal{A},l}(\mathcal{D}_s^c, \mathcal{D}_t^c) = 2(1 - 2(L_l^c)) \quad (6)$$

where  $\mathcal{D}_s^c$  and  $\mathcal{D}_t^c$  represent samples from class  $c$ . Eventually, the dynamic adversarial factor  $\omega$  is estimated as:

$$\hat{\omega} = \frac{d_{\mathcal{A},g}(\mathcal{D}_s, \mathcal{D}_t)}{d_{\mathcal{A},g}(\mathcal{D}_s, \mathcal{D}_t) + \frac{1}{C} \sum_{c=1}^C d_{\mathcal{A},l}(\mathcal{D}_s^c, \mathcal{D}_t^c)} \quad (7)$$

$\omega$  starts to be initialized as 1 in the first epoch. The pseudo labels of the target domain can be obtained after each iteration, so the local distance for class  $c$  can be computed with cross entropy. Therefore, the learning objective of DAAN is concluded as follows:

$$L(\theta_f, \theta_y, \theta_d, \theta_d^c |_{c=1}^C) = L_y - \lambda((1 - \omega)L_g + \omega L_l) \quad (8)$$

### 2.4. DAAN-based fault diagnosis framework

The framework of the proposed DAAN-based fault diagnosis method is shown in Fig.3. The dual-stage procedures include offline training and online application. Historical data

collected from the chemical process are utilized for model design. Benefitting from the transferred knowledge, the diagnosis network monitors the online process and outputs the fault classification result.

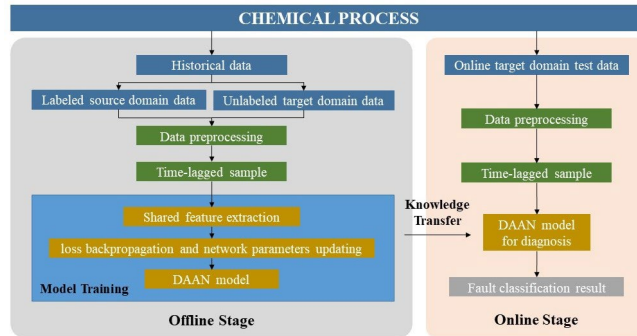

Fig.3. DAAN-based fault diagnosis framework.

### 3. Case Studies

In this section, the benchmark Tennessee Eastman process (TEP) is applied to evaluate the performance of the proposed model. TEP is widely used in chemical process monitoring tasks. The unit operations of TEP contain a reactor, a condenser, a recycle compressor, a vapor-liquid separator and a stripper. In this paper, the experiments are based on the revised version (Bathelt et al., 2015) which can be downloaded at <http://depts.washington.edu/control/LARRY/TE/download.html>. 19 fault types and 5 steady-state operating modes are introduced in this research to explore the multimode fault diagnosis performance. The fault types and working conditions are selected in the same way as the previously published work, and the datasets are prepared followed by its experience (Wu et al., 2020).

When the labeled fault data in the source mode and only one-batch unlabeled fault data in the target mode are involved in the training dataset, the unsupervised anomaly diagnosis tasks are presented to verify the model effectiveness. Different common transfer learning models are adopted in comparison with the proposed DAAN model, such as traditional deep transfer networks composed of stacked auto-encoder (DTN), domain adaptation networks along with CNN (DAN-CNN) and joint adaptation networks along with CNN (JAN-CNN). The fault identification performances are exhibited in Table 1. The average accuracy rates are calculated and summarized in Table 2. The classification results show the efficiency and robustness of DAAN.

#### 4. Conclusions

In the present work, Dynamic Adversarial Adaptation Network is designed for fault diagnosis application in the chemical process. This adversarial domain adaptation model mainly consists of three components, label classifier, global domain discriminator and local subdomain discriminator with a powerful feature extractor attached to the front. Comprehensive results demonstrate that the model can obtain superior diagnostic performance compared with other transfer learning models. Further work is being conducted to improve this model, such as further alleviating the need for labeled data in the source domain and tapping its potential for industrial process tasks.

## Abstract

Hydrogen (H<sub>2</sub>) has gained vital importance in reducing greenhouse gas emissions. Due to its low energy density, the long-time storage and long-distance transportation of H<sub>2</sub> is a challenging issue. Liquefaction is a practical approach to enhance energy density; however, it is an energy and cost-intensive technique. In addition, variation in H<sub>2</sub> composition (ortho H<sub>2</sub>/para H<sub>2</sub>) with respect to temperature is exothermic, adding heat load to the refrigeration cycle. Most conceptual studies do not incorporate this heat load in specific energy consumption (SEC). This study presents two case scenarios, i.e., with heat load (adiabatic) and without heat load (isothermal), to produce liquid H<sub>2</sub> (LH<sub>2</sub>) through stepwise cooling with an ortho to para conversion. The proposed adiabatic and isothermal processes show SEC of 12.2 and 6.9 kWh/kg, respectively. The adiabatic process requires a large quantity of refrigerant flowrates, i.e., 46 kg/s, compared to the isothermal process (26 kg/s). In both cases, 100% saturated LH<sub>2</sub> is produced with 99.7 % para conversion. This study can help achieve a sustainable green energy economy by enhancing the overall H<sub>2</sub> value chain.

**Keywords:** Hydrogen liquefaction, Clean energy, Ortho-para conversion, Adiabatic process, Isothermal process.

## 1. Introduction

The greenhouse gas emissions have now become a prime focus of industrialists and environmentalists owing to their negative impact on the atmosphere. These emissions can be reduced by introducing and promoting clean energy. Hydrogen (H<sub>2</sub>) is extensively considered a clean and multi-purpose energy carrier that can be used in every sector of life, such as transportation, electricity generation, and industry [1]. H<sub>2</sub> importance cannot be emphasized more than the global H<sub>2</sub> demand is increased by approx. threefold since 1975 [2]. Due to this increasing demand and clean characteristics, H<sub>2</sub> may take the place of conventional fuels in the near future. For that purpose, intercontinental or intercountry transportation of H<sub>2</sub> is vital for the global energy mix. Alongside transportation, long-time H<sub>2</sub> storage is also of primary importance, especially in the case of excess H<sub>2</sub> or excess electricity as both H<sub>2</sub> and electricity are interconvertible.

Commercially, H<sub>2</sub> is liquefied in a three-stage process: pre-cooling (up to -193 °C), cooling (up to -243 °C), and liquefaction (up to -253 °C) [3]. Liquid nitrogen (N<sub>2</sub>) is used as a refrigerant in the pre-cooling phase, while a combination of JT valves or expanders and H<sub>2</sub> itself is used in the subsequent stages. In recent times, mixed refrigerants (MR) have been suggested as an alternative to pure liquid N<sub>2</sub>. Numerous studies have suggested different compositions of low-boiling hydrocarbons and N<sub>2</sub> as constituents of MR [4].

Similarly, helium (He) and neon (Ne) are also considered alongside  $H_2$  in the cooling and liquefaction stages. The main objective behind trying different refrigerants and process configurations is to reduce the specific energy consumption (SEC) and improve the liquefaction process's thermodynamic (exergy) efficiency [5]. Industrial processes have SEC in the range of 12–15 kWh/kg $_{LH_2}$  and efficiency as low as 20–30% [6]. In an ideal case, the SEC for hydrogen liquefaction is  $\sim 2.7$  kWh/kg $_{LH_2}$  [7]. This large gap between the ideal and the real process motivates the researchers to design conceptual processes wherein different MR compositions, and process configurations have been proposed. The sole objective of such processes is to bring down the SEC value as close to the ideal case as possible.

The additional challenge associated with the  $LH_2$  process is ortho to the para conversion of  $H_2$  isomers. At 25 °C,  $H_2$  constitutes 75% ortho and 25% para having opposite rotational movement. The energy level of the ortho state is higher than the para-state, which means that by decreasing temperature, ortho  $H_2$  tends to convert to para  $H_2$  to maintain equilibrium by releasing energy. However, this ortho-to-para conversion (OPC) is slow due to the low rate of reaction, i.e.,  $0.0114\text{ h}^{-1}$ , and exothermic in nature, which releases a large amount of energy high enough to evaporate  $LH_2$  [8]. Recently, Riaz et al. [9] have discussed the significance of OPC reaction and its heat of reaction on the energy consumption for the production of  $LH_2$ . In another study, Son et al. evaluated different OPC reactor configurations to mimic the actual process configurations [10]. In commercial plants, catalysts are embedded inside heat exchangers. In this way, the heat of the reaction is dissipated inside the heat exchanger. Similarly, liquid  $N_2$  and liquid  $H_2$  are also used as fluid media for isothermal operation.

The OPC reaction heat is critical to the SEC of the process. It is pertinent to discuss the issues and solutions adopted by the researchers from a process systems viewpoint. The literature survey shows that many integral studies have employed isothermal OPC reactors ignoring the reaction heat. Only a few studies, such as Riaz et al. [9] and Son et al. [10], have discussed the importance of this OPC reaction heat. In the present study, two process configurations are proposed considering the heat of the reaction and process simplicity. The proposed process employs two refrigeration cycles and two reactor configurations: isothermal and adiabatic. Both these configurations are evaluated based on energy and exergy perspectives to evaluate their maximum thermodynamic potential.

## 2. $H_2$ liquefaction process

$H_2$  liquefaction is an energy-intensive process mainly because of low boiling point of  $H_2$  and exothermic OPC reaction. The process description and simulation details are provided in following subsections.

### 2.1. Process description

The proposed process is divided into two cases based on the reactor configurations.

Case I: Isothermal process

Case II: Adiabatic process

The  $H_2$  feed stream ( $n\text{-GH}_2$ ) is fed to a cryogenic heat exchanger (CHX-1) for pre-cooling. In CHX-1, the temperature is decreased from 25°C to  $-193.2^\circ\text{C}$  (see Figure 1). After that,  $H_2$  is fed to the equilibrium reactor (R-1) to convert 25% p- $H_2$  to 43% p- $H_2$ . In case I, stream H4 is fed to CHX-2, where the temperature is further reduced to  $-252^\circ\text{C}$ . In case II, stream H4 temperature increases to  $-183.2^\circ\text{C}$  due to exothermic OPC reaction (see Figure 2). For further cooling stream, H4 is sent back to the first heat exchanger, CHX-1, where the temperature is reduced to  $-193.2^\circ\text{C}$ . Then stream H5 is fed to CHX-2 to cool it till  $-252^\circ\text{C}$ . The outlet stream is fed to another equilibrium reactor (R-2) to convert

43% p-H<sub>2</sub> into 99.7% p-H<sub>2</sub>. The outlet stream H8 is at the temperature of -252°C due to heat being recovered through energy stream (Q) with a heat flow of -394.6 kW. Finally, H<sub>2</sub> is liquefied at 21 bar. The pressure of stream H8 is reduced to the LH<sub>2</sub> storage pressure of 1.3 bar by passing it through the expander K-5. At the K-5 outlet, 100% saturated liquid H<sub>2</sub> is obtained.

Case I is shown in Figure 1. In case I, the precooling MR (PMR) consists of C<sub>1</sub>, C<sub>2</sub>, C<sub>3</sub>, n-C<sub>4</sub>, i-C<sub>4</sub>, n-C<sub>5</sub>, and N<sub>2</sub>. The PMR is first compressed and cooled in a series of compressors and coolers. Then, the PMR is cooled further in CHX-1 and expanded in expander. The outlet stream of expander is used to reduce temperature of hot streams.

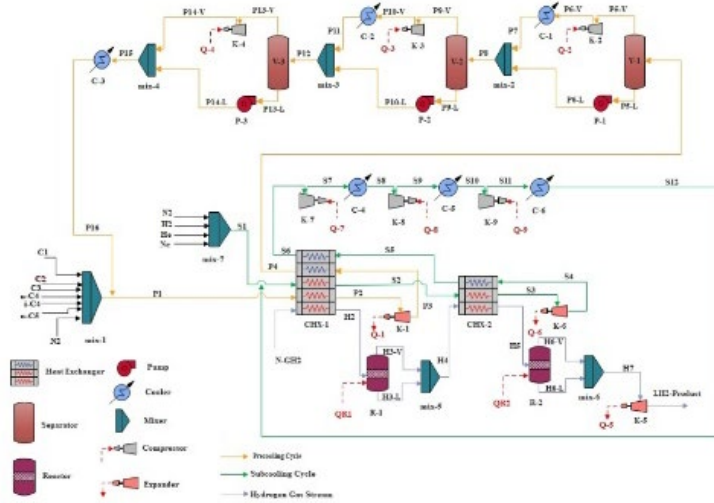

Figure 1 process flow diagram of case I

Case II is shown in Figure 2. In case II, the liquefaction MR (LMR) consists of H<sub>2</sub>, He, and Ne. The LMR is first compressed and cooled in a series of compressors and coolers. Then, the LMR is cooled further in CHX-1 and -2 and expanded in expander. The outlet stream of expander is used to reduce temperature of hot streams in CHX-1 and -2.

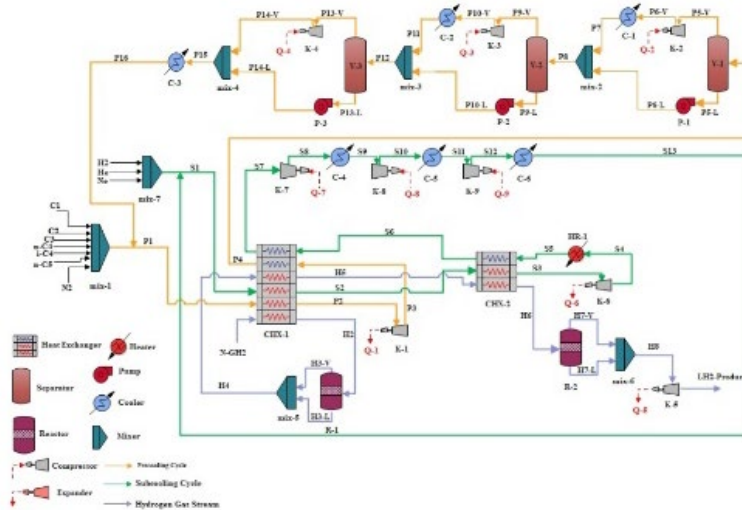

Figure 2 process flow diagram of case II

### 2.2. Process simulation

The proposed process was simulated in Aspen HYSYS v11 using the Peng–Robinson thermodynamic fluid package [11] for refrigerants and the Modified Benedict Webb Rubin equation of state for H<sub>2</sub>. The feed conditions and design parameters were selected based on the base case, as shown in Table 1. The efficiency of the compressor and expander was adjusted to 75% and 80%, respectively.

**Table 1** Design parameters for the H<sub>2</sub> liquefaction process [4]

Design parameters	Values
Feed temperature	25 °C
Feed pressure	21 bar
Feed flowrate	1 kg/s
Feed composition (mole fraction)	[oH <sub>2</sub> /pH <sub>2</sub> ] = [0.75/0.25]
Pressure-drop across aftercoolers	0 bar
Pressure-drop across CHXs	0 bar
Temperature aftercooler	22 °C
H <sub>2</sub> liquefaction rate	100 %
Liquid H <sub>2</sub> pressure	1.3 bar

### 2.3. Energy analysis

The energy analysis of this study is conducted in terms of SEC. The design variables (Table 2), which include refrigerant mass flow rates, suction pressure, and discharge pressure of refrigeration cycles, are varied to observe their effect on the SEC.

### 2.4. Exergy analysis

Exergy analysis is an excellent tool for analyzing process inefficiencies based on the second law of thermodynamics. Exergy is of mainly two types: physical and chemical, which is calculated as:

$$ex_{ph,i} = (h_i - h_o) - T_o(s_i - s_o) \quad (1)$$

$$ex_{ch,i} = \sum x_i e_i^{CH} + RT_o \sum x_i \ln x_i \quad (2)$$

Where  $ex_{ph,i}$  and  $ex_{ch,i}$  is denoted as physical and chemical exergy,  $x_i$  is denoted as the mole fraction of  $i^{\text{th}}$  component in a stream and  $e_i^{CH}$  is referred to as standard chemical exergy of  $i^{\text{th}}$  component taken from [12]. The physical exergy values are taken from Aspen Hysys<sup>®</sup> stream properties, whereas chemical exergy values are calculated using equation 2. The exergy analysis is performed by calculating the exergy destruction of each piece of equipment. Exergy destruction of equipment explains the deviation of equipment performance from an ideal scenario. The higher the exergy destruction, the lower the process performance. The formulas used to calculate the exergy destruction of equipment can be found elsewhere [13].

## 3. Results and discussion: Process analysis

### 3.1. Energy analysis

In this study, the design variables, including refrigerant flow rates and suction/discharge pressures, were analyzed with respect to SEC. Table 2 lists the design variables, constraints, and the SECs of the base case and the proposed cases.

**Table 2** Design variables and SEC of the base case, case I, and case II

PMR cycle	Base case	Case I	Case II
Suction / Discharge pressure (bar)	1.5 / 13.0	1.1 / 18.0	1.1 / 11.0
Refrigerants flowrate (kg/s)	84.7	19.3	31.4
CMR cycle			
Suction / Discharge pressure (bar)	2.9 / 35.6	-	-

Refrigerants flowrate (kg/s)	33.0	-	-
<b>LMR cycle</b>			
Suction / Discharge pressure (bar)	3.7 / 25.0	1.4 / 26.0	1.3 / 15.5
Refrigerants flowrate (kg/s)	1.9	7.1	16.4
<b>SEC (kWh/kg<sub>LH2</sub>)</b>	<b>6.45</b>	<b>6.96</b>	<b>12.19</b>

According to Table 2, case II has the highest energy consumption of 12.19 kWh/kg<sub>LH2</sub> among all cases. Compared to the base case, SEC has increased by 8% and 53% in proposed cases I and II, respectively. Since the proposed cases have only two cycles (PMR and LMR), CMR will not be discussed. In addition, the suction pressure is reduced in PMR and LMR to withstand the MITA value within the exact range of 1-2 °C. Also, it is observed that the refrigeration load on the PMR cycle increases when suction pressure decreases. As a result, SEC increases. However, high suction pressure cannot achieve the desired cooling temperature. Therefore, the pre-cooling temperature was adjusted from -153.2 °C to -193.2 °C, reducing the LMR cycle's energy load. Moreover, the PMR cycle of the base case shows the highest MR flow rate (84.7 kg/s), with C<sub>1</sub>, C<sub>2</sub>, and C<sub>4</sub> contributing the most. On the other hand, the overall refrigerants flow rate is 78% and 60% less in the proposed case I and II, respectively.

Further, in proposed case I, PMR cycle, 19.26 kg/s of MR is utilized, whereas 31.382 kg/s is consumed in proposed case II. Moreover, all PMR refrigerants' flow rates are reduced in proposed cases, except C<sub>3</sub>, N<sub>2</sub>, and n-C<sub>5</sub>, whose mass flow rate is increased. This is because only low boiling refrigerants are not energy efficient. So, an optimal blend of high and low boiling refrigerants is required to reduce energy consumption. In the LMR cycle, a new refrigerant was added, Ne, besides H<sub>2</sub> and He, to reach the required H<sub>2</sub> liquefaction temperature (-252.3°C). Here, a total mass flow rate of 7.06 kg/s and 16.4 kg/s is used in the proposed cases. Also, compared to the base case, a large amount of H<sub>2</sub> and He utilized 64.5% and 84% more in both proposed cases I and II, respectively.

### 3.2. Exergy analysis

Table 3 presents the exergy destruction values of each piece of equipment of the base case and the proposed cases.

**Table 3** Equipment-wise exergy destruction of the base case, case I, and case II

<b>Equipment</b>	<b>Case I (kW)</b>	<b>Case II (kW)</b>
Compressors	4158.32	7542.97
Pumps	0.99	0.1
Coolers	4174.19	12083.33
Separators	195.36	-294.5
Reactors	-693.61	479.42
Expanders	20087.02	5582.97
CHXs	4824.24	16170.68
<b>Total</b>	<b>32746.5</b>	<b>41564.97</b>

The results of the proposed cases cannot be compared with the base case because of different process configurations. Therefore, the only case I and II are discussed in this section. In case-I, the expanders share 61% (20087.02 kW) of exergy destruction out of the total equipment destruction because their low-temperature operation promotes high exergy destruction. The CHXs show 4824.24 kW of exergy destruction. On the other hand, a high exergy destruction source in case-II caused by CHXs with 38.9 % (16170.68 kW). The main reason for exergy destruction in heat exchangers is the huge temperature difference between inlet and outlet streams. For example, in both cases, feed enters CHX-1 at 25°C, and its outlet temperature is -193.2°C (pre-cooling). Similarly, other streams also have a temperature gap of more than 50°C between in and out streams. Also,

compressors share a significant amount of exergy destruction. Since OPC is an exothermic reaction, it contributes to exergy destruction as well. However, the energy gain from the OPC reaction is recycled, so it is calculated as inlet energy for reactors. Furthermore, the exergy destruction of reactors and phase separators in case-II shows a negative value which is thermodynamically not possible. Here the negative sign may appear due to the impact of other equipment. Since it is a cascaded process, all equipment is related to each other. Overall, case II has higher exergy destruction than case I.

#### 4. Conclusions

In this study, the proposed case I is energy efficient as compared case II. The case II is energy intensive because of additional heat load of OPC reaction on refrigeration cycles. However, the case I is energy intensive as compared to the base case. Similarly, the exergy destruction analysis results conclude that the case I is 21.2% efficient than the case II. In case II, the CHXs are the major source of exergy destruction.

## Abstract

Microbubble technology has been used in various industries to improve the mass transfer efficiency of applications. Although conventional bubble generators using venturi and swilling nozzles are useful, their low gas throughput is insufficient for industrial pollutant reduction. Hence, this study developed an optimal microbubble cap structure with a high gas throughput and microbubble generation rate using an image processing based overall mass transfer coefficient (OMTC) calculation model. Micro bubble cap with brim structure was developed, and the bubble generation pattern by varying the brim size was analyzed in a lab-scale microbubble system. Bubble diameters were measured using image processing and OMTC was calculated using bubble size. The observed bubble size range was approximately 0–250  $\mu\text{m}$ , and the bubble generation ratio was the highest at a 5-mm-brim size. When calculating the OMTC of  $\text{H}_2\text{S}$  in water of 50  $\mu\text{m}$  or less, the value increased by more than 50% compared to other brim-size cases. Therefore, at brim sizes of 5 mm, the dispersion and production of microbubbles were active, and they were expected to endow high mass transfer efficiency.

## 1. Introduction

Microbubbles are used in various fields, such as water treatment, reactors, nuclear power, and air pollutant reduction (Yup Y. et al., 2021). In the various industries, they are used either for the formation of a large interfacial area between the gas and liquid phases, the generation of radicals, or long interaction time in flow field. The principle of utilization of microbubble is that it creates an environment that enables gas–liquid interaction. Particularly, the gas–liquid interaction is a significant factor in the field of air pollutant reduction. Microbubbles have recently been used to remove air pollutants and increase reduction efficiency using bubble scrubber system (Hyundo P. et al., 2021).

Microbubbles have a role in absorbing air pollutants in a liquid state. Therefore, it is important to generate many small-sized bubbles and create an environment for enhancing mass transfer efficiency by expanding the interfacial area (Al-Mashhadani. et al., 2012).

Microbubbles are generated mainly using a small venturi structure or a sparger-type pressurized generation method (Ali, M. et al., 2013). Although this method is suitable for generating microbubbles, it is difficult to use in the air pollutant reduction field to quickly purify considerable gas owing to low gas throughput. Therefore, a novel microbubble generator is needed.

Confirmation of the bubble size must be an essential step to design the bubble generator. Because it is possible to calculate overall mass transfer coefficient (OMTC) from the bubble size data, which is a significant value in air pollutants removal process (Yup Y. et al., 2023). Nevertheless, previous studies cannot calculate OMTC because they cannot determine the volume of the flow field, which is three-dimensional data, due to limitations in image data. Therefore, we presented a OMTC calculation model that determines bubble size and volume of the flow field by using concept of camera depth of the field and image processing method. This study focuses on an optimal structure for a bubble cap is determined using an OMTC calculation model.

## 2. Methodology

### 2.1. Setup of lab-scale microbubble system

This study proposed a novel structure that induces bubble breakage by adding a brim structure that prevents large bubbles from rising. Bubble caps with various brim widths (0, 5, 10, 15, and 20 mm) were fabricated using 3D-printing to investigate the tendency of bubble generation pattern and OMTC to vary depending on the brim width.

A simple experimental device was created to confirm the bubble generation pattern by brim structure. The device has a rectangular structure with an acrylic body, and its width and height are 300 and 500 mm, respectively. Additionally, a vacuum suction blower draws air from the top of the rectangular structure. The induced airflow passes through the air velocity indicator and generates bubbles in the bubble cap installed in the center of the bottom of the experimental device. Water was filled to a height of 10 cm from the bottom of the experimental device. A detailed airflow diagram and component descriptions are shown in Fig. 1.

Fig. 1. Bubble generating system experimental setup

2.2. Image processing based overall mass transfer coefficient calculation model

A DSLR camera (SONY A7M3) and a 24 mm-Laowa macro-lens, were used to extract images of the bubbles generated. Pictures were taken using the camera at a height of 1 cm from the bottom of the experimental device. The photographed images were then processed to measure the bubble size. Image processing was performed using OpenCV-Python, and the shape of the bubble was detected using Gaussian blur, Canny edge detection, and morphology transformation functions. Figure 2 shows a sample image generated by the image processing process for bubble size measurement.

Gaussian blur step is a role in suppressing noise in the image, and the Canny edge detection step determines the bubble edge based on the gradient value of brightness. Then, in the morphology transformation step, the closed curve converts to a contour by filling the curve and determining the contour area to calculate the bubble's size. Finally, the extracted bubble size data calculates the number of bubbles and the average bubble size and displays it as the resulting image in Fig. 2.

Fig. 2. Sample image of the image processing process for bubble size measurement

The mathematical model for determining OMTC to confirm the mass transfer efficiency due to the formation of microbubbles begins with the following equation.

$$\frac{\partial C_A}{\partial t} + \frac{\partial(uC_A)}{\partial z} = c \cdot A_{\text{surf}}(C_A^* - C_A) = k_{\text{ov}}(C_A^* - C_A) \quad (1)$$

$$A_{\text{surf}} = \frac{6\phi_{\text{gas}}}{d_{\text{sm}}} \quad (2)$$

where  $C_A$  represents the concentration of gas component A in a gaseous state,  $C_A^*$  represents the concentration of A in equilibrium with the current liquid,  $u$  represents the gas velocity, and  $A_{\text{surf}}$  represents the interfacial area concentration. Additionally,  $\phi_{\text{gas}}$  is the volume ratio of the bubble in the flow field, and  $d_{\text{sm}}$  is the Sauter mean meter of bubbles. Equations (1) and (2) can be used to extract bubble size data from several bubble images in a short time and determine OMTC.

$$\phi_{\text{gas}} = \frac{V_{\text{tb}}}{V_{\text{ff}}} \quad (3)$$

where  $V_{\text{tb}}$  is the sum of bubble volume in the flow field, and  $V_{\text{ff}}$  is the volume of flow field.  $V_{\text{ff}}$  is determined from the camera the depth of field.

$$V_{\text{ff}} = A_{\text{ip}} C_{\text{dof}} \quad (4)$$

$A_{ip}$  is the area where bubbles are detected in the image through image processing, and  $C_{dof}$  is the depth of field.

### 3. Results and Discussions

#### 3.1. Bubble size distribution analysis

The best way to analyze the bubble formation pattern is to determine the bubble size distribution (BSD). The BSD analysis method is a common method used for multi-phase processing. This study also checked the bubble size distribution to confirm the bubble formation pattern according to the bubble cap's brim width. The confirmed result is shown in Fig. 3.

Fig. 3. Bubble size distribution graph according to the brim width of the bubble cap

As can be observed from the figure, when the brim width is 5 mm, bubbles between 25 and 50  $\mu\text{m}$  are generated the most. This shows a frequency (that is, 0.34), which is approximately 40% higher than that of bubble caps with other brim width structure, and the bubble generation ratio of 50  $\mu\text{m}$  or less was approximately 38%. Additionally, in the brim widths of 0, 10, 15, and 20 mm, bubbles between 50 and 75  $\mu\text{m}$  were generated with the highest frequency, and the frequency of bubbles between 75 and 100  $\mu\text{m}$  tended to increase as the brim width increased. The benefits of microbubbles with a size less than 50  $\mu\text{m}$  are numerous. Particularly, the interaction time between phases can be maintained for a long time because the buoyancy of small bubbles enables them to stay in the flow field for a long time without rising and disappearing.

### 3.2. Statistical analysis of bubble generating pattern

Fig. 4. Results of average bubble size, standard deviation, number of bubbles analysis for generated bubbles

Since the generation of bubbles is accompanied by complex mechanisms and microbubble is generated by various sizes, it is challenging to identify bubble generation patterns visually; hence, identifying the pattern of bubble formation using a statistical analysis method is essential. Therefore, the standard deviation for the average bubble size and number of bubbles was determined and is shown in Fig. 4. The average bubble size was 70.4 µm, which was the smallest in the 5-mm-brim structure. Additionally, 89 bubbles were generated in the observed flow field, which was confirmed to be higher than for other conditions. Where a brim structure creates bubbles of small average size, the standard deviation is lower than when the brim width is 0 and 10 mm. Hence, when the brim width is 5 mm, microbubbles can be well dispersed. Therefore, it is considered to have a characteristic of actively forming turbulence so that many bubbles can be generated.

### 3.3. Result of overall mass transfer coefficient

Identifying and determining the OMTC in the air pollutant removal process can be an index for selecting process conditions in which actual mass transfer is active. Thus, this index can be used to determine the mass transfer efficiency and improve the process's efficiency under various process conditions. Particularly, the mass transfer effect for the bubbles generated using the novel brim structure must be evaluated because the generation of bubbles of a size of 50 µm or less has a positive effect on the mass transfer efficiency. Figure 5 shows the OMTC for H<sub>2</sub>S, a representative air pollutant, which was determined for bubbles less than 50 µm.

Fig. 5. OMTC calculation results for bubbles less than 50  $\mu\text{m}$

This outcome demonstrated that the OMTC was at its highest when the brim width was 5 mm. It showed an approximately 50% higher value than the other conditions.

#### 4. Conclusion

In this study, a bubble cap structure that generates a large number of microbubbles with high gas throughput is developed, and the optimal structure of the bubble cap is determined using image processing based OMTC calculation model. Bubble cap structure was then used to confirm the bubble generation pattern according to the width of the additional brim structure that prevents air from rising. A case study was conducted according to the bubble cap brim width (0, 5, 10, 15, and 20 mm) inside a bubble generator system made of acrylic.

Under the condition of brim 5 mm, the rate of formation of bubbles less than 50  $\mu\text{m}$ , which shows the microbubble characteristics, was as high as 38%. Additionally, the highest amount of bubble formation was observed under the 5-mm-brim condition, and the average bubble size was also determined to be the lowest at 70.4  $\mu\text{m}$ . Furthermore, the OMTC value was established to validate the effect of bubbles less than 50  $\mu\text{m}$  on  $\text{H}_2\text{S}$ , a representative air pollutant. OMTC, 4.67E-15 ( $\text{s}^{-1}$ ), was the highest in the 5-mm-brim condition, where bubbles of less than 50  $\mu\text{m}$  were frequently generated. According to these results, the 5-mm-rim bubble cap, in which bubbles of less than 50  $\mu\text{m}$  were induced by the dispersion and destruction of bubbles and appropriate location of turbulent flow, is considered the most suitable structure for removing air pollutants. The structure can only be used to create bubbles of specific size. Additionally, in future studies, we expect to enhance accuracy of OMTC calculation model through gas removal experiments.

## Abstract

Heterogeneous azeotrope distillation is often preferred industrially over homogeneous azeotrope distillation due to the ease of recovery of the entrainer and the transition across a distillation boundary in the decanter. In a previous study, the synthesis problem for separating an Ethanol and Water mixture by using benzene as an entrainer was solved using a low aggregation superstructure comprised of functional distillation and decanter modules where the utility cost was minimized (Okunishi, 2019). The solution was interpreted to obtain a realistic process. This work optimizes the interpreted solution using a modified Simulated Annealing Algorithm. The new solution makes it possible to reduce the overall energy consumption and the total annual cost of the process. Also, an interface between Python and Aspen Plus® is proposed, and it allows the reduction of convergence problems caused by the complexity of the optimized scheme.

**Keywords:** Stochastic Optimization, Azeotropic Distillation, Process Simulation, Aspen Plus – Python interface, modified Simulated Annealing Algorithm.

## 1. Introduction

A heterogeneous azeotropic mixture creates a new azeotropic point by adding a specific third component called entrainer to the binary system. Thus, in heterogeneous azeotropic distillation, a mixture having a composition that exists in the two liquid phase region is separated into an organic phase and an aqueous phase by a decanter. This work proposes the post-optimization of a synthesis problem that departs from the concept of unit operations and proposes functional modules. Hasebe et al. (2015) proposed distillation modules to separate a ternary mixture in previous work. The objective function was the utility cost minimization, and the optimal process structure was interpreted near the minimum reflux condition. Later, the methodology for the design of the separation scheme of the ethanol/water mixture using benzene as an entrainer that was implemented by Okunishi (2019) was taken through the solution of a superstructure. Since the interpreted solution was done assuming a large number of stages in each column section, it can be improved if the equipment cost is included to find a better compromise between equipment cost and operation cost. Therefore, the previous study is complemented with a rigorous simulation of the process that makes the process even more realistic, that is, to a real reflux relationship with finite dimensions.

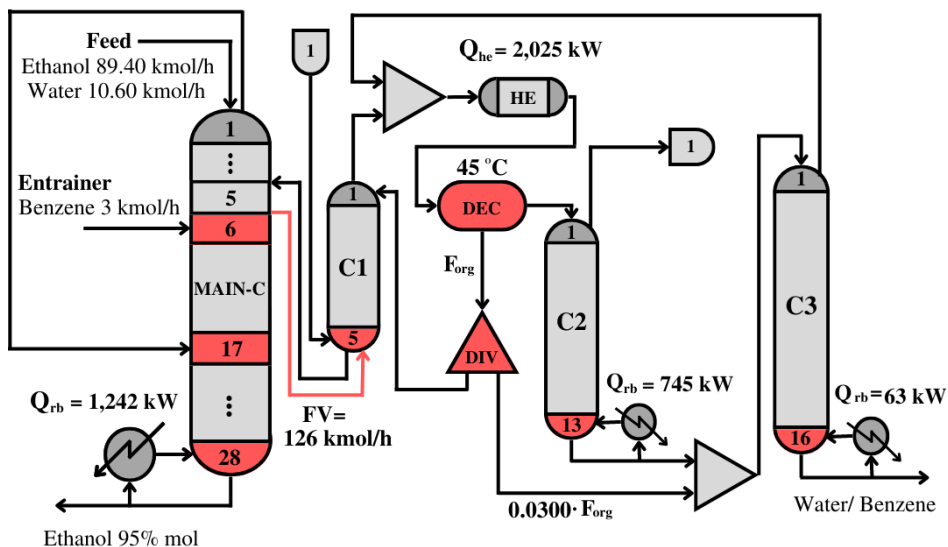

Three distillation columns formed the distillation process. The first column was a thermally coupled distillation column with a side rectifier, and the ethanol product was obtained at the bottom. Then, the top vapor entered the decanter, and part of the organic

stream was recycled to the first column. The aqueous stream was fed to the second distillation column, where water was concentrated at the bottom. In the third column, the water-rich stream was mixed with some of the organic stream to take all possible ethanol and benzene to concentrate water towards the column's bottom. For rigorous model simulation, this work uses an interface between the free access programming language Python and the chemical process simulation software Aspen Plus V12®. A modified Simulated Annealing Algorithm (m-SAA) stochastic algorithm was proposed by Cabrera et al. (2021). The problem was solved by minimizing the Total Annual Cost (TAC).

## 2. Methodology

### 2.1. Case Study

The scheme of the base case is shown in Figure 1. It was designed using Aspen Plus® software with the NRTL thermodynamic model. An ethanol/water mixture of 100 kmol/h (89.4% mol of ethanol, 10.6% mol of water) is fed to the system in the main column (MAIN-C). 3 kmol/h of fresh benzene is fed into the system. Optimization is done using the RADFRAC module for the distillation columns. The pressure of all columns is 1 atm, and the pressure drop was neglected. In MAIN-C, ethanol is obtained at a purity of 95 mol%, and in C3, water is obtained with the same purity.

**Figure 1.** Heterogeneous azeotropic distillation processes (Base case)

MAIN-C is the main column where the ethanol/water and benzene mixtures are feed. Here, the ethanol is also recovered in the bottom. C1 is the rectifier of MAIN-C. HE is the condenser of C1. DEC is the decanter after the C1 condenser that recovers the benzene and sends it to C2, and DIV is a splitter of the organic phase between C1 and C3. The reported value of the splitter is the fraction of flow that goes to the mixer that connects to C3. C3 is the column where water is removed from the process, and a part of the benzene is recovered. Figure 1 shows the solution with process optimal structure after interpreting the synthesis problem for separating mixtures forming heterogeneous azeotropes. Although the process structure is optimal, the number of stages, feed stages, or flows between columns have not been optimized but simulated at near minimum reflux

conditions. Therefore, this work solves a post-optimization problem that finds the best structural and operating conditions that minimize the Total Annual Cost (*TAC*).

In Fig. 1, the variables proposed to optimize the design problem are shown in red. In general, they represent a direct impact on the thermal load of the reboilers of each distillation column since the number of stages of each one and the conditions and amount of organic solution entering these will have a direct impact on these values. The design was proposed based on the number of modules present in the solution by Okunishi (2019).

## 2.2. Mathematical treatment

The case study was optimized according to the objective function shown in Eq. 1.

$$\begin{aligned} \text{Min}(TAC) &= f(N_{MAINC}, N_{C1}, N_{C2}, N_{C3}, Div_{DIV}, T_{DEC}, FV_{MAINC}, N_R, N_F) & 1 \\ \text{s. t.} \quad R_i(x) &\geq 99.5 \% \quad \& \quad CC = 1 \end{aligned}$$

$R_i(x)$  is the vector associated with the recovery percentage (for ethanol and water) that was 99.5 %. Since it is quite a complex simulation, placing a design specification on it will increase the number of iterations to reach convergence. For that reason, a penalty is proposed to the *TAC* in case the fixed purity of 95% mol is not met for the ethanol in MAIN-C. For the calculation of the cost (*FOB*) Eq. 2 is used.

$$FOB \left( \frac{USD}{year} \right) = OC + \frac{\left( \frac{CEPCI \text{ in } 2019}{CEPCI \text{ in } 2003} \right) (C_{Shell} + C_{Plates} + C_{Comp} + \sum_{j \in CS}^{i \in HS} C_{Exchanger \ i,j})}{\text{Recovery time (Year)}} \quad 2$$

The *FOB* modules were calculated using the Guthrie method (Turton et al., 2018) with a payback time of 5 years using the CEPCI value corresponding to the one for 2019. The adjustment is used under the  $F_C$  criterion that relates to the purity (In mole fraction) of the system, as shown in Eq. 3.

$$F_C = 1 + [0.95 - Purity_{EtOH}] \quad 3$$

This correction factor is multiplied by the *FOB*, so the *TAC* calculation is adjusted, as shown in Eq. 4.

$$TAC \left( \frac{USD}{year} \right) = FOB \cdot F_C \quad 4$$

This correction factor  $F_C$  allows us to adjust the *TAC* to the desired purity so that if the purity is higher, the technology will be less expensive. If the purity is low, the technology will be more expensive than the one calculated. The *CC* refers to a convergence criterion by the simulation in Aspen Plus V12®, which can take two values as described in Eq. 5.

$$CC = \begin{cases} 0 & \text{then } TAC = 2,000,000 \text{ \$/year} \\ 1 & \text{then } TAC \text{ calculated by Ec. 4} \end{cases} \quad 5$$

The value of  $CC$  equal to zero indicates that the simulation does not converge for the optimization variables proposed by the algorithm in that iteration. Therefore, it is penalized with a large  $TAC$  (i.e., 2,000,000 \$/yr.). The penalty value in Eq. 5 was determined by sensitivity analysis sufficiently large. The bounds on the variables for optimization are presented in Table 1.

**Table 1.** Optimization Variables

Variable	Description	Optimization bounds [lower, upper]	Variable type
$N_{MAINC}$	MAIN-C Stages	[20, 37]	Discrete
$N_{C1}$	C1 Stages	[3, 10]	Discrete
$N_{C2}$	C2 Stages	[6, 20]	Discrete
$N_{C3}$	C3 Stages	[8, 25]	Discrete
$Div_{DIV}$	Divider	[0.0150, 0.2000]	Continuous
$T_{DEC}$	Decanter Temperature (°C)	[40, 65]	Continuous
$FV_{MAINC}$	FV Flow (kmol/h)	[90, 135]	Continuous
$F_R$	Fresh Benzene Feed Stage	[7, $N_{MAINC}-3$ ]	Discrete
$F_F$	MAINC Dome Vapor Recirculation Feed Stage	[4, $N_R-2$ ]	Discrete

The optimization variables followed analogous to the work reported by Alcántara-Maciel et al. (2022) as shown in Eq. 6.

$$L_{Ni} = (L_{Upper} - L_i) / (L_{Upper} - L_{Lower}) \quad 6$$

$L_{Ni}$  is the value of the normalized variable  $L_i$ ,  $L_{Upper}$  is the upper limit of variable  $i$  and  $L_{Lower}$  is the lower limit of variable  $i$ . The algorithm works with random values from 0 to 1. For discrete variables, a rounding function is used. This technique ensures that the search range of the variables in the optimization does not go outside the limits defined in Table 1. Concerning dependent variables, this technique allows us to define some limits based on previous variables so that we have dynamic limits that do not limit the search space. The algorithm determines the variables in the descending order shown in Table 1.

The optimization algorithm used is the modified Simulated Annealing Algorithm (m-SAA) proposed by Cabrera et al. (2021), which is capable of manipulating integer variables more effectively than the typical continuous relaxation of the method. Four annealing of 225 iterations each were used, having a total of 900 iterations that ensured at least 100 iterations per variable to be optimized.

The Spyder IDE 5.2.2 (Spyder, 2022) was used to develop and execute the Python code to run the interface with Aspen Plus. The overall implemented interface is shown in the schematic presented in Figure 2. The computer used for this optimization has an Intel(R) Xeon(R) W-3235 CPU at 3.30 GHz with 48 GB of RAM.

**Figure 2.** Optimization-simulation software interface

### 3. Results and Discussion

The post-optimization results are shown in Table 2 and compared with the base case.

**Table 2.** Design variables and optimal operating specifications for the different cases.

Variable	Base Case	Proposed solution by the post-optimization
$N_{MAINC}$	28	25
$N_{C1}$	5	5
$N_{C2}$	13	6
$N_{C3}$	16	19
$Div_{DIV}$	0.0300	0.1082
$T_{DEC} (^{\circ}C)$	45.00	53.52
$FV_{MAINC} (kmol/h)$	126.00	91.84
$F_R$	17	20
$F_F$	6	4
$TAC (USD/year)$	572,551	462,636
Total heat duty (Reboilers only) (kW)	2,050	1,466
Condenser duty (kW)	2,025	1,488

Figure 3 shows the optimal scheme in post-optimization.

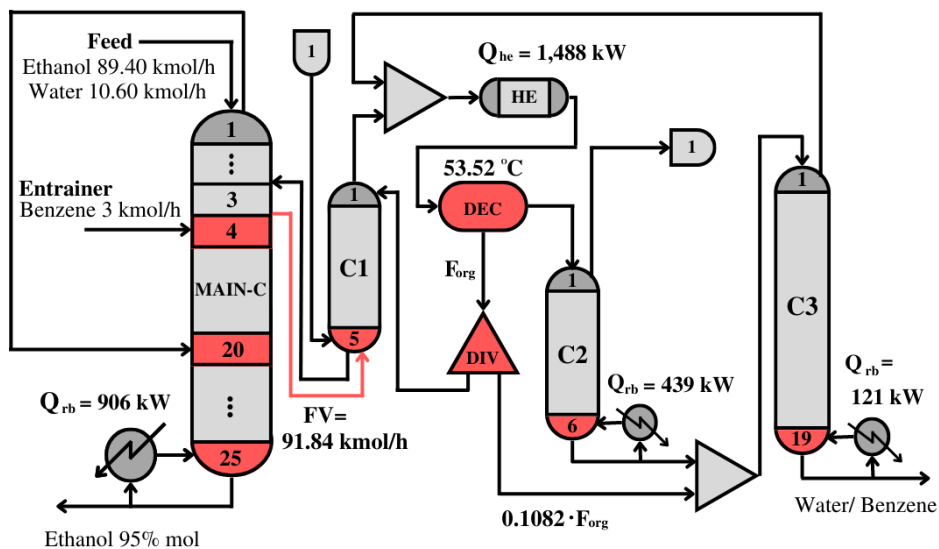

Figure 3. Optimal solution given by m-SAA

In the last solution, the number of stages in the C1 and C3 columns were similar, but the C2 column needed only a few stages. In the base case, the decanter temperature was assumed to be 45°C, but in the best case, a higher temperature (53.5°C) was better because decanters, in general, decrease their separation efficiency when they are operated at low temperatures, this is confirmed by the studies carried out by Skiborowski (2015). In our system, the recirculation flow (Organic) to C1 is less due to the division reflected by the splitter, and this generates lower heat duty in the reboiler of the main column (MAIN-C). The vapor interconnection flow of the first column was 27% lower than that obtained in the base case, which resulted in the reboiler duty reduction in columns MAIN-C and C2. Thus, the overall energy consumption of the process was reduced.

The recycles flows of column C3 (which is rich in organic phase), the one between column C2 and C1 and the recirculation of vapor in MAIN-C reduce the heat of the reboilers in MAIN-C in the same way and C2, the same occurs with the FV interconnection flow. This energy reduction directly reduce the area of the reboilers, and consequently minimize the cost of the TAC in post-optimization. In the case of the C3 column, the reboiler load increases because it receives a greater amount of organic phase flow, but this increase is small compared to all the energy saved in MAIN-C and C2.

#### 4. Conclusions

The proposed problem was solved using an interface with the Python programming language and the Aspen Plus V12® process simulator. The TAC base case was USD 572,551/year. The TAC of the optimized process using the m-SAA stochastic optimization algorithm was 462,636 USD/year, which implies a saving of 109,914 USD/year, which is a saving of approximately 20% for the process obtained at near minimum reflux condition. Using the m-SAA algorithm and rigorous models allows us to have a robust design, which in the case of this work, also implies a saving in its TAC. Using the proposed interface between Python and Aspen Plus V12® reduces the convergence problems caused by the complexity of the optimized scheme. The use of an

optimization algorithm as post-optimization was effectively used to improve the operating and structural conditions from the original design proposed by synthesis optimization.

## Abstract

Python has become an open-source interpreted programming language that has recently gained popularity. The implementation of interface codes for process optimization between process simulators and closed-source programming languages has been widely reported. This paper presents an interface between the commercial chemical process simulation software Aspen Plus and the open-source programming language Python using the PYMOO (Multi-Objective Optimization in Python) package developed by Blank et al. (2020). This analysis was performed on a Heat-Integrated Distillation Column (HIDiC) previously optimized by Herrera-Velázquez et al. (2022) was taken as a case study. Multi-objective (NSGA-II) and single-objective (GA and PSO) optimization algorithms were used to minimize economic and energy criteria. Mathematical handling techniques such as normalization of variables and pseudo-normalizations of the objective functions were implemented to improve the solutions and to reduce the computation time during optimization.

**Keywords:** Global Optimization, Stochastic, PYMOO, Aspen Plus-Python Interface, HIDiC.

## 1. Introduction

Interfaces between process simulation and optimization software are increasingly becoming more utilized for developing new processes. Stochastic algorithms are particularly interesting because they can link process simulators, which contain material and energy balances represented by highly non-linear equations. The Python programming language has gained popularity among scientists and engineers to solve various mathematical problems. Nevertheless, its capabilities have not been exploited for solving chemical processes.

This work proposes an interface framework between the commercial chemical process simulation software Aspen Plus V12® and the open-source programming language Python. The PYMOO (Multi-Objective Optimization in Python) package developed by Blank et al. (2022) was used to optimize the studied process. This work takes the optimization of a Heat Integrated Distillation Column (HIDiC) to separate a binary mixture of benzene/toluene from a previous work (Herrera-Velázquez et al., 2022). For single optimization, the minimization of an economic criterion, the Total Annual Cost (TAC), was considered. The minimization of energy consumption was also considered for multi-objective optimization because there is a trade-off between energy reduction

resulting from heat integration and cost increase due to expensive electricity and compressor costs. Particle Swarm Optimization (PSO) and Genetic Algorithm (GA) were used for single optimization. In contrast, the Non-Dominated Sorting Genetic Algorithm (NSGA-II) was used for multi-objective optimization. The NSGA-II algorithm, which is integrated with the PYMOO package, follows the general scheme of a genetic algorithm and contains a modified survival selection and binary mating, where each individual is compared by rank and crowding distance (Deb et al., 2002). The PSO (Particle Swarm Optimization) algorithm, which is also included in the PYMOO package, uses the concept of particle swarming to guide its search, each particle possessing a velocity and strongly influenced by the best solutions found, both locally and globally (Kennedy et al., 1995).

## 2. Methodology

### 2.1. Case Study

The process described in Figure 1 is simulated using Aspen Plus V12® software and the Peng-Robinson thermodynamic model was used. The feed is 50/50 kmol/h of benzene/toluene. By design specifications, each product must be obtained with a purity of 99.9% mol for both components. Optimization is done using the RADFRAC module for the distillation columns. The pressure in the STR column is 1 atm, while for the REC column, the pressure is PR times the STR pressure.

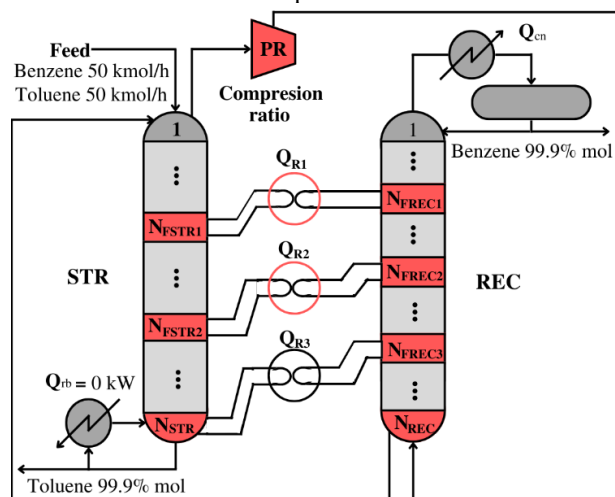

Figure 1. Heat Integrated Distillation Column

In the figure,  $N_{STR}$  and  $N_{REC}$  are the total stages of the stripping and rectification columns, respectively.  $PR$  is the compression ratio (i.e., the pressure in the rectification column divided by the pressure in the stripping column),  $Q_{R1}$  and  $Q_{R2}$  are the loads of the exchangers that perform the energy integration between the column zones,  $N_{FSTRj}$  and  $N_{FRECj}$  are the stages in which the integration is carried out for each exchanger. In the case of  $N_{FREC3}$ , it is the stage that connects with the exchanger that acts as a reboiler in STR.

### 2.2. Mathematical treatment

The case study was optimized according to the objective function shown in Eq. 1.

$$\text{Min}(TAC, Q_{COMP}) = f(N_{STR}, N_{REC}, PR, Q_{R1}, Q_{R2}, N_{FSTR1}, N_{FSTR2}, N_{FREC1}, N_{FREC2}, N_{FREC3}) \quad 1$$

$$s.t. \quad P_i(x) \geq 99.9 \% \text{ mol}, \quad R_i(x) \geq 99.5 \% \quad \& \quad CC = 1$$

$P_i(x)$  and  $R_i(x)$  are the constraint vectors associated with percent mol purity (99.9% mol for benzene and toluene) and percent recovery (99.5% for benzene and toluene), respectively. These constraints are integrated into the simulation as design specifications. The  $TAC$  objective function is given in Eq. 2:

$$TAC \left( \frac{USD}{year} \right) = OC + \frac{\left( \frac{CEPCI \text{ in } 2019}{CEPCI \text{ in } 2003} \right) (C_{Shell} + C_{Plates} + C_{Comp} + \sum_{j \in HS} C_{Exchanger \ i,j})}{Recovery \ time \ (Year)} \quad 2$$

OC is the operating cost. The  $TAC$  modules were calculated using the Guthrie method (Turton et al., 2018) with a payback time of 3 years using the 2019 CEPCI.  $Q_{COMP}$  is the value calculated by Aspen Plus of the module COMP (Compressor). Guthrie's method, and  $Q_{COMP}$  are a function of the variables presented in Eq. 1. The  $CC$  refers to a convergence status by the simulator Aspen Plus®, which can take two values as described in Eq. 3 and modify the Total Annual Cost ( $TAC$ ) for non-converged simulations.

$$CC = \begin{cases} 0 & \text{then } TAC = 2,000,000 \text{ \$/year} \ \& \ Q_{COMP} = 300 \text{ kW} \\ 1 & \text{then } TAC \ \& \ Q_{COMP} \text{ calculated by algorithm} \end{cases} \quad 3$$

The value of  $CC$  equal to zero indicates that the simulation does not converge for the optimization variables proposed in the iteration by the algorithm. The values of  $TAC$  and  $Q_{COMP}$  given in Eq. 3 are penalty values determined by sensitivity analysis, such that they are sufficiently larger than the values expected by the simulations that converge. The bounds on the variables for optimization are presented in Table 1.

**Table 1.** Optimization Variables

Variable	Optimization bounds [lower, upper]	Variable type	Units
$N_{STR}$	[15, 30]	Discrete	--
$N_{REC}$	[15, 30]	Discrete	--
$PR$	[2, 3]	Continuous	--
$Q_{R1}$	[100, 600]	Continuous	kW
$Q_{R2}$	[100, 600]	Continuous	kW
$N_{FSTR1}$	[2, $N_{STR}$ ]	Discrete	--
$N_{FSTR2}$	[ $N_{FSTR1}+1$ , $N_{STR}-1$ ]	Discrete	--
$N_{FREC1}$	[2, $N_{STR}-3$ ]	Discrete	--
$N_{FREC2}$	[ $N_{FREC2}$ , $N_{STR}-2$ ]	Discrete	--
$N_{FREC3}$	[ $N_{FREC3}$ , $N_{STR}-1$ ]	Discrete	--

The variables have been normalized similarly to Herrera-Velázquez et al. (2022), as shown in Eq. 4, to compare the multi-objective and single-objective results with respect to the previous study and to determine the advantages and disadvantages of the efficiency and effectiveness of the proposed platform

$$L_{Ni} = (L_{Upper} - L_i) / (L_{Upper} - L_{Lower}) \quad 4$$

where  $L_{Ni}$  is the value of the normalized variable  $L_i$ ,  $L_{Upper}$  is the upper limit of variable  $i$ , and  $L_{Lower}$  is the lower limit of variable  $i$ . The algorithm works with random values between 0 and 1, and a rounding function is used for discrete variables. The use of dynamic bounds ensures that the search range of the variables in the optimization does not go outside the limits defined in Table 1, which was done similarly to Alcántara-Maciél et al. (2022). This technique considers the bound of dependent variables. The algorithm defines the variables in the order shown in Table 1.

A case study was proposed in which a pseudo-normalization is performed, such that the  $TAC$  is intended to be left in the same order of magnitude as  $Q_{COMP}$ . For this, the first run of 100 iterations is made, and the rounded value of the mean  $TAC$  over  $Q_{COMP}$  is taken, as shown in Eq. 5.

$$FACTOR = (1/100) \sum_{i=1}^{100} (TAC_i / Q_{COMP,i}) \quad 5$$

For this case study, the  $FACTOR$  value is 5,000. The new objective function results from dividing Eq. 4 by the obtained  $FACTOR$  value.

The NSGA-II method was used for multi-objective optimization for 30 generations with 100 individuals with the Augmented Scaling Feature (ASF) decomposition method, a well-known metric in the multi-objective optimization with weights of 0.2, 0.4, 0.5, 0.6 and 0.8 (Wierzbicki., 1980). This study for this method has 3,000 iterations. The ASF method works since the Pareto front is already generated and does not interfere with the NSGA-II method. Therefore, the results from the weights are determined once the algorithm obtains the Pareto front.

The single-objective optimization was performed also using the PSO and GA method included in the PYMOO package for the same optimization variables, but only using the  $TAC$  objective function and, subsequently, the  $Q_{COMP}$  objective function. For the GA case, 30 generations of 100 individuals are used to obtain a sweep of 3,000 iterations. In the case of the PSO algorithm, freedom was given to run the optimization and terminate it if there was no improvement in the objective function after 500 iterations.

The Spyder IDE 5.2.2 (Spyder, 2022) was used to develop and execute the Python code to run the interface with Aspen Plus V12. The overall implemented interface is shown in the schematic presented in Figure 2. The computer used for this optimization has an Intel(R) Xeon(R) W-3235 CPU at 3.30 GHz with 48 GB of RAM.

Figure 2. Optimization-simulation software interface

### 3. Results and Discussion

Table 2 summarizes the time and convergence percentage of executed simulations during the  $TAC$  minimization using Eq. 2 and the results calculating the  $TAC$  using the proposed

pseudo-normalization. For the sake of comparison, the results for the base case by Herrera-Velázquez et al. (2022) are also reported.

**Table 2.** Summary of efficiency results for the TAC pseudo-normalization proposal.

Optimization Algorithm	Use of pseudo-normalization of TAC	Execution Time (Hours)	Convergence Percentage
Herrera-Velázquez et al. (2022) - SA	NO	3.87	99.99%
PYMOO GA	NO	1.42	99.40%
	YES	1.18	99.30%
PYMOO PSO	NO	0.68	99.22%
	YES	0.69	99.22%
PYMOO NSGA-II	NO	1.19	98.70%
	YES	1.16	99.16%

For both GA and NSGA-II, the pseudo normalization reduces the optimization execution time of 16.90% and 2.52%, respectively. However, for PSO, the time increases 1.47%. The results reported in Table 3 for the TAC are those obtained by the pseudo-normalized TAC, the same for those reported in NSGA-II. In the case of the NSGA-II, only the best result between the values of the ASF weights is reported. Figure 3 shows the obtained Pareto Front, as well as each of the solutions obtained by each method.

**Table 3.** Design variables and optimal operating specifications for the different cases.

Variable	Herrera-Velázquez et al. (2022) SA	PYMOO PSO		PYMOO GA		PYMOO NSGA-II
	TAC	TAC	COMP	TAC	COMP	ASF (0.5,0.5)
$N_{STR}$	25	23	30	23	30	27
$N_{REC}$	22	21	30	21	30	24
$PR$	2.0014	2.0000	2.0000	2.0001	2.0000	2.0000
$Q_{R1}$	121.37	210.94	227.50	232.34	377.16	148.09
$Q_{R2}$	102.89	231.39	101.34	298.05	280.51	199.77
$N_{FSTR1}$	14	20	27	20	27	23
$N_{FSTR2}$	17	22	29	22	29	26
$N_{FRECI}$	4	2	2	2	2	2
$N_{FRECI2}$	14	3	3	3	3	3
$N_{FRECI3}$	15	4	4	4	9	4
TAC (USD/year)	548,786	512,196	528,674	512,188	527,952	517,249
$Q_{COMP}$ (kW)	122.94	118.10	115.69	118.17	115.73	116.23
Iteration for optimum	231 of 3,000	901 of 1,675	2,478 of 3,000	2,729 of 3,000	2,976 of 3,000	2,646 of 3,000
Time (Hours)	3.87	0.69	1.34	1.18	1.28	1.17

**Figure 3.** Pareto front solution for SA included (right) and SA not included (left)

#### 4. Conclusions

It was possible to successfully implement the Python-Aspen Plus interface, applying the PYMOO package for a single-objective (PSO and GA) and multi-objective (NSGA-II) optimization. The pseudo-normalization of the TAC improves, on average, from 2% to 17% of the computation time for the GA and NSGA-II algorithms. The best algorithm for the single-objective optimization is the PSO, while the best solution for the multi-objective problem was the ASF(0.5,0.5). The advantage of PYMOO was the reduction of computation times. They are reduced by more than 50% to those used with SA, which makes it an attractive option for its application to complex processes. The SA algorithm can be used for complex processes where convergence is the priority. This work can be extended without loss of generality to solve intensified chemical processes. It can be of interest for improving current interfaces used in Process Systems Engineering.

### Abstract

In this work, a generic design method has been developed for the design of isocratic and gradient SMBs for multi-component systems. Based on the general method by (Migliorini et al., 2000b), the method is simplified and extended to enable multi-component systems, gradient SMB operation and any isotherm. The method has been verified through two case studies. For the first case study, an analytical solution is possible and the error using this method is insignificant. For the second case study, the system is solved through numerical simulation and the method is verified. With this method, the design of gradient SMBs can be performed with any isotherm and multi-component systems in a simple way.

**Keywords:** Design methods, Mechanistic Modelling, Gradient SMB

### 1. Introduction

In the biopharmaceutical industry, chromatography is a workhorse unit operation. Chromatography is typically operated in batch mode, although there are many benefits when transitioning to continuous operation such as reduced capital expenditure, higher capacity utilization, a better-controlled process, reduced utility consumption, higher purity and higher yield (Schmidt-Traub et al., 2020). For batch chromatography, applying a gradient can increase productivity and enable complete separation. This concept can also be transferred to a simulated moving bed (SMB), called gradient SMB. The corresponding True Moving Bed (TMB) is shown in Figure 1. The concept is that in section 1 and section 2, where desorption takes place, a low-affinity zone is created to lower the affinity of the components to the resin, whereas in section 3 and 4, a high-affinity zone is created. For liquid chromatography, this can be done by altering the solvent composition, salt concentration, pH or temperature. The most common gradient operation in SMB is based on altering the modifier concentration in the feed and desorbent. Comparing

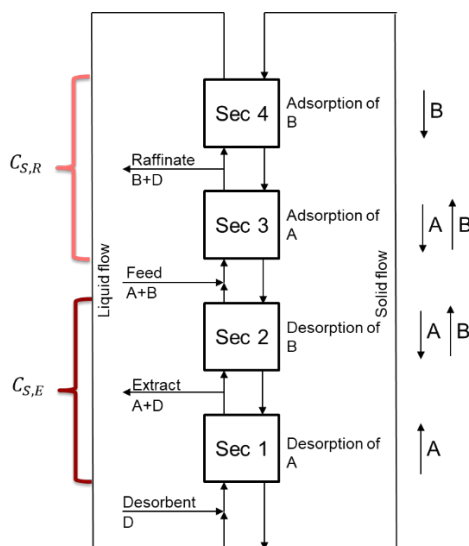

Figure 1: Schematic of a gradient TMB for a binary separation with component A and B and desorbent D. Sec refers to the section,  $C_{S,E}$  and  $C_{S,R}$  are the modifier concentration in extract zone (sections 1-2) and raffinate zone (sections 3-4), respectively.

gradient SMB to isocratic SMB, there are many advantages such as increased productivity, reduced eluent consumption, reduced production cost and increased product concentration both in closed-loop configuration and open-loop configuration (Kim et al., 2017). A particular challenge with implementing continuous chromatography such as gradient SMB is the design of the operation. Modelling chromatography and SMB processes is very complex as there are many phenomena taking place simultaneously which results in a set of complex coupled partial differential equations (Schmidt-Traub et al., 2020). Furthermore, there are multiple design variables which can make the optimal design computationally expensive. For the gradient SMB, there are two additional design variables i.e., the modifier concentration in the feed and desorbent. Therefore, the design of a SMB is typically performed by designing an ideal TMB, shown in Figure 1. A TMB has steady-state solutions whereas a SMB has cyclic steady-state solutions. The ideal TMB steady-state solutions to the quasi-linear first-order partial differential mass balance equations are solved, assuming isotherm equilibrium. Constraints are set up for each section of the TMB. Solving these equations results in operational conditions for each section of the TMB. For the mid-zone (sections 2 and 3 in Figure 1) where feed is added, the operational range for the internal flowrate ratios results in a ‘triangular diagram’ i.e., a region of complete separation, composed of three lines: w-b line, w-r line and r-a line. The feasible flow rate ratios can then be converted to SMB flow rates (Migliorini et al., 2000). Migliorini et al. developed a design method that works for any isotherm, but it is not stated explicitly how the method should be applied for neither gradient SMB nor multi-component systems (Migliorini et al., 2000b). Abel et al. developed a design method for gradient SMB for binary systems with Langmuir isotherms (Abel et al., 2004). Lee et al. developed a SMB design method for multi-component systems with any isotherm, but it is not specified explicitly how to incorporate gradients (Lee et al., 2021). Frederiksen developed a design method for any isotherm, and the method can be applied to gradient SMB but only for binary systems (Frederiksen, 2004). With this, there is a need for a design method that can be applied to multi-component systems, gradient SMB with any isotherm. This work proposes a design method for gradient SMB for multi-component systems and any isotherm. The method is verified with SMB simulations in CADET (Leweke & von Lieres, 2018).

## 2. Methodology

### 2.1 Design method

For designing the SMB, the dimensionless flowrate ratio,  $m_j$ , is often used. It describes the flow rate of the liquid phase per solid flow rate based on the TMB. The dimensionless flow rate ratio is given in eq. (1) (Migliorini et al., 2000b).

$$m_j = \frac{Q_j^* t^* - \epsilon_t V_c}{(1 - \epsilon_t) V_c} \quad (1)$$

Where subscript  $j$  refers to the section,  $Q^*$  is the SMB flowrate,  $t^*$  is the switching time for the SMB,  $\epsilon_t$  is the total porosity and  $V_c$  is the volume of the column.

For multi-component systems, the total number of solutes,  $U$ , are separated into raffinate components, 1 to  $n$ , and extract components,  $p=n+1$  to  $U$ .

For each section, there are constraints on the flow rate ratios that ensure complete separation. For section 1, the constraint on  $m_1$  should ensure that the solid phase is completely regenerated i.e., the most adsorbed component is completely desorbed, mathematically given in eq. (2) (Migliorini et al., 2000b).

$$m_1 \geq m_{1,min} = \frac{\partial q_U}{\partial C_U} \Big|_{C_U=0} \quad (2)$$

Where  $q$  is the solid phase concentration and  $C$  is the mobile phase concentration. The constraint for section 4 ensures that the least retained component does not overflow into section 1. The constraint is given in eq. (3) (Migliorini et al., 2000b).

$$\frac{\epsilon_p}{\epsilon_p - 1} \leq m_4 \leq m_{4,max} = \frac{q_C(C_{1,R})}{C_{1,R}} \quad (3)$$

Where subscript R refers to the raffinate concentration which can be obtained from an overall mass balance (Migliorini et al., 2000b). If having multiple components in the raffinate stream, determining  $m_{4,min}$  in eq. (3) requires setting up overall mass balances and isotherm equations for each component in the raffinate stream. The constraints for sections 2 and 3 ensure that the net flow of extract components, components p to U, is towards the extract outlet and the net flow of raffinate components, components 1 to n, is towards the raffinate outlet. Along the w-b line in the separation region, the minimum  $m_2$  required to desorb the most retained raffinate component, component n, is investigated. Hence, the w-b line is drawn by solving the mass balance over section 2 for component p to U and using the minimum  $m_2$  (Migliorini et al., 2000b), given in equation 4.

$$m_2 = m_{2,min} = \frac{\partial q_n}{\partial C_n} \Big|_{C_n=0} \quad (4a)$$

$$(m_3 - m_2)C_{i,F} = q_{i,2} - m_2 C_{i,2} \text{ for } i \in p \text{ to } U \quad (4b)$$

Where subscripts F and 2 refer to feed and section 2, respectively. In the determination of  $q_n$  in eq. (4), only the extract components and modifier concentration in section 2 ( $C_{S,E}$ ), are considered. Along the r-a line, the maximum  $m_2$  to desorb the least retained extract component, component p, is determined (Migliorini et al., 2000b). Combined with mass balances over section 2 for components p to U, the r-a line is drawn by solving equation 5.

$$m_2 = m_{2,max} = \frac{\partial q_p}{\partial C_p} \quad (5a)$$

$$(m_3 - m_2)C_{i,F} = q_{i,2} - m_2 C_{i,2} \text{ for } i \in p \text{ to } U \quad (5b)$$

where only the extract components and modifier concentration in section 2 are considered in the determination of  $q_p$  in eq. (5). The determination of the w-r line is more complicated as it describes the interaction between sections 2 and 3. Along the w-r line, the maximum  $m_3$  to let the least retained extract component, component p, overflow in section 3 is determined (Migliorini et al., 2000b). This is combined with a mixing balance at the feed node as well as with mass balances for extract components in section 2 and raffinate components in section 3 (Frederiksen, 2004). Whereas Frederiksen used this consideration for binary systems, it is here extended to multi-component systems. The equations for the w-r line are given in equation 6.

$$C_{p,B} = \frac{C_{p,2}m_2 + (m_3 - m_2)C_{p,F}}{m_3} \quad (6a)$$

$$m_3 = \frac{q_{p,3}}{C_{p,\beta}} \quad (6b)$$

$$(m_3 - m_2)C_{i,F} = q_{i,2} - m_2 C_{i,2} \text{ for } i \in p \text{ to } U \quad (6c)$$

$$(m_3 - m_2)C_{j,F} = m_3 C_{j,3} - q_{j,3} \text{ for } j \in 1 \text{ to } n \quad (6d)$$

Where subscript  $\beta$  refers to the point just after the feed node. For the w-r line, this method differs from the method of (Migliorini et al., 2000b) as this method does not involve a numeric integration. The solute concentrations and modifier concentrations used for the determination of the isotherms must be considered carefully and are given in Table 1.

## 2.2 Numeric SMB simulations

To verify the method, SMB simulations were set up in CADET (Leweke & von Lieres, 2018). A SMB setup with four columns in a 1:1:1:1 configuration was considered. The ideal mass balance for the SMB process for each component was used (Schmidt-Traub et al.,

Table 1: Concentrations to use in the isotherms for the determination of the w-r line.

Isotherm	Solute Concentrations	Modifier concentration
$q_{p,3}$	$C_{p+1..U,3} = 0$ $C_{p,3} = C_{p,\beta}$ $C_{1..n} = C_{1..n}$	$C_s = C_{s,3}$
$q_{i,2}$	$C_{p..U,3} = C_{p..U,3}$ $C_{1..n} = 0$	$C_s = C_{s,2}$
$q_{i,3}$	$C_{p..U,3} = 0$ $C_{1..n} = C_{1..n}$	$C_s = C_{s,3}$

2020). To convert the flow rate ratios to SMB flow rates, equation 1 was used together with mass balances over each section. The column parameters  $\epsilon_t$  and  $V_C$  were set to 0.83 and  $7.854e-5 \text{ m}^3$ , and a switching time of 180 seconds was used. The values for  $m_1$  and  $m_4$  were set conservatively such that  $m_1 = 1.5 m_{1,min}$  and  $m_4 = 0.5 m_{4,max}$ . Simulations were run until cyclic steady state was achieved. Complete separation was defined as when purity  $\geq 0.995$ .

## 2.3 Isotherms

To demonstrate that the method is not restricted to a single isotherm, the two most used isotherms, the Langmuir and Steric Mass Action (SMA), were considered (Kumar & Lenhoff, 2020). Assuming equilibrium, the Langmuir and the SMA isotherms are shown in eq. (7) and eq. (8), respectively (Brooks & Cramer, 1992; Schmidt-Traub et al., 2020).

$$q_i = \frac{H_i C_i}{1 + \sum_{h=1}^U K_{L,h} C_h} \quad (7)$$

$$q_i = C_i A_i \left( 1 - \sum_{h=1}^U \frac{q_h}{q_{max,h}} \right)^{v_i} \quad (8)$$

Where  $H$  is the Henry's constant,  $K_L$  is the Langmuir equilibrium constant,  $A = K_{eq} \left( \frac{\Lambda}{c_s} \right)^{v_i}$  is the initial isotherm slope,  $q_{max} = \frac{\Lambda}{\sigma + v}$  is the maximum binding capacity,  $K_{eq}$  is the SMA equilibrium constant,  $\Lambda$  is the ionic capacity,  $C_s$  is the modifier concentration,  $v$  is the characteristic charge and  $\sigma$  is the shielding factor.

### 3. Results and discussion

The design method was applied to two case studies. First, the method was verified by determining the separation regions for a multi-component isocratic SMB with the multi-component Langmuir isotherm. For this case, there is a design method based on the analytical solution of the TMB which the proposed design method was compared to (Migliorini et al., 2000a). The comparison of the two methods for determining the separation regions is shown in Figure 1 with parameters shown in the figure. The comparison shows that the proposed design method determines almost the same separation region as the method of (Migliorini et al., 2000a) with insignificant differences. This verifies that the design method can be used for multi-component systems with the competitive Langmuir isotherm. For the second case study, the separation region is determined for separating lysozyme from ribonuclease A and cytochrome c using gradient SMB with *NaCl* as modifier and parameters from (Meyer et al., 2020). The section 1-2 *NaCl* concentration was set to 200 mol/m<sup>3</sup> and the section 3-4 *NaCl* concentration was set to 300 mol/m<sup>3</sup>. The separation region and the numeric simulation results are shown in Figure 2 where the green dots indicate a complete separation and red pentagons indicate incomplete separation. Figure 2 shows that the separation region determined with the design method agrees well with the numerical SMB simulations. Some of the numerical simulations show complete separation outside the separation region. The deviation between the simulation results and the separation region from the design method is probably because the modifier concentrations fluctuate due to cyclic nature of the SMB, which has previously observed experimentally (Li et al., 2007) and not accounted for in the design method. Additionally, the assumption made by Frederiksen which avoids the numeric integration compared to Migliorini also leads to a small deviation, but this should not be significant (Frederiksen, 2004; Migliorini et al., 2000b). Despite the minor deviation, this verifies that the design method can be used to make an initial design of multi-component gradient SMBs using the SMA isotherm, though the design method is not limited to the SMA or Langmuir isotherms. Design methods based on the ideal mass balance form an initial step towards an in-depth design and optimization. In preparative chromatography, non-ideal phenomena such as mass

Figure 2: Separation region for  $m_2$  and  $m_3$  with parameters from (Lee et al., 2021) where  $H = [7.062, 5.297, 3.850, 2.888]$ ,  $K_L = [0.0321, 0.0321, 0.0175, 0.0175]$  L/g. M2000 refers to the method in (Migliorini et al., 2000a).

Figure 3: Separation region for  $m_2$  and  $m_3$  where the parameters  $\Lambda = 1200$  mol/m<sup>3</sup>,  $K_{eq} = [35.5e-3, 1.59e-3, 7.70e-3]$ ,  $\nu = [4.7, 5.29, 3.7]$ ,  $\sigma = [11.83, 10.6, 10.00]$  and  $C_{F,i} = 1$  mol/m<sup>3</sup> were used (Meyer et al., 2020).

transfer resistance and axial dispersion can be significant and can cause a spreading of the components, thus complicating the separation (Schmidt-Traub et al., 2020). For an in-depth design and optimization, a more complex model that takes these non-ideal phenomena into account is required. Here, this design method can provide good initial guesses for optimizing the operational flowrates.

#### 4. Conclusion

In this paper, a straightforward and versatile design method for isocratic SMBs and gradient SMBs was proposed. The design method can be applied to any isotherm and multi-component systems. Through two case studies, the design method was verified for the SMA and the Langmuir isotherms. This method can serve as an initial step in designing operational flowrates. For a more in-depth design and optimization, a complex model that takes phenomena such as axial dispersion and mass transfer resistance into account is required.

## Abstract

A biopharmaceutical manufacturer might submit a DS definition as part of the regulatory approval application, in which case process parameter (PP) deviations within this space are not considered a change and do not trigger a regulatory post approval procedure. While several methods exist for finding a DS described by non-linear PP ranges, here we introduce a novel method for finding linear combinations – a DS definition often preferred due to its operational simplicity. We use a numeric optimizer to find the design space with the largest parameter space volume that results in critical quality attribute (CQA) boundaries within acceptance criteria, predicted by a regression model. A precomputed approximation of tolerance intervals is used in inequality constraints to facilitate fast evaluations of this boundary using a single matrix multiplication. Correctness of the method was validated against different ground truths with known design spaces.

**Keywords:** design space; biopharmaceutical development; ICH Q8; numeric optimization; parameter space

## 1. Introduction

The ICH Q8 guideline for pharmaceutical development defines the design space (DS) as “the multidimensional combination and interaction of input variables (e.g., material attributes) and process parameters that have been demonstrated to provide assurance of quality” (ICH, 2017). The process parameters (PP) described here are generally identified in the risk assessment or process development phases and are considered critical when sufficient evidence was found that they affect the output of a unit operation, i.e., a critical quality attribute (CQA). A design space is comprised of the ranges of these critical process parameters that result in CQA values within acceptable limits. For the biopharmaceutical manufacturer a DS definition can be submitted as part of the regulatory approval application, in which case PP deviations within this space are not considered a change and therefore do not trigger a regulatory post approval procedure. For operators, the DS constitutes a valuable guideline document for controlling a process. While ICH Q8 does not recommend a specific form or method for describing a DS, it provides examples for non-linear and linear combinations of parameter ranges in the form of contour plots (appendix 2c in guide). Non-linear combinations describe the DS as a set of

rules, or parameter ranges conditioned on other parameters, e.g., “PP1 is allowed to move between -1 and 1 if PP2 is lower than 0.5”. Linear combinations of parameter ranges on the other hand are independent of each other. While the former description generally represents a larger space to operate in and methods for computing it can be found several publications (Kim & Kwak, 2002) (Kusumo, et al., 2020), the latter might be preferred due to its operational simplicity and is the subject of this contribution. Figure 1 shows the different types of design space graphically.

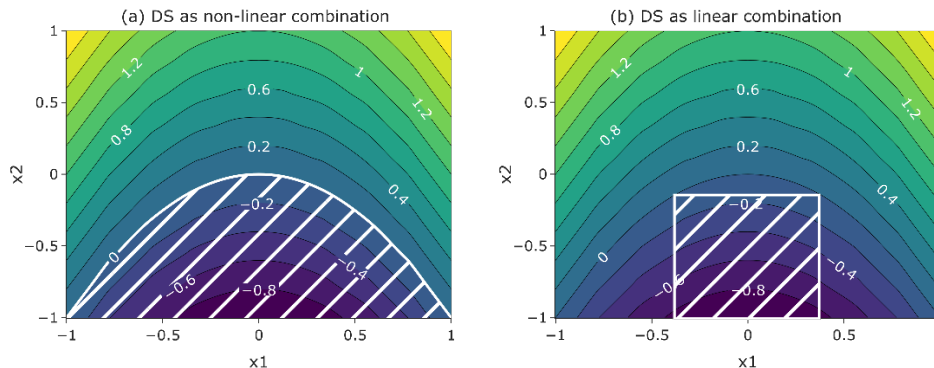

Figure 1: The design space for the function  $f(x_1, x_2) = x_1^2 + x_2$ , where  $f(x_1, x_2) \leq 0$ , shown in the contour plot as a non-linear (a) and linear (b) combination of input parameters  $x_1$  and  $x_2$ , as defined in (ICH, 2017).

So far, definition of a design space does not incorporate any measure of statistical uncertainty, i.e., the contour shown in Figure 1 directly represents the predicted mean CQA values from the model. In the context of biopharmaceutical process validation, we suggest a more conservative approach. To accurately quantify uncertainty inherent in the regression model due to analytical and process variability, we replace predicted CQA values with the upper and lower boundary of a tolerance interval that incorporates nominal levels of both confidence and coverage. These boundaries are then used to validate acceptance limits in a conservative manner.

In this contribution we present a method for finding a design space comprised of linearly independent parameter ranges, or hyper-rectangles when considered geometrically, while treating CQA predictions conservatively.

## 2. Method

### 2.1. Tolerance Interval Approximation

The method proposed here uses a series of numeric optimizers, inequality constraints and approximations specific to polynomial regression models commonly found in process characterization and validation in the biopharmaceutical domain. Such models regress CQAs on PPs and material attributes while considering parameter interactions and quadratic effects. These higher-order effects are relevant to the shape of the response surface and therefore to the optimization problem. While regression model predictions can be computed simply by multiplying the design matrix  $X$  by the vector of learned coefficients  $\hat{\beta}$ , the computation of tolerance intervals can be complex and generally involves multiple evaluations of probability density functions (PDF). For example, one

of the simplest equations for calculating TI boundaries around predictions is the one used in ordinary least-squares (OLS) models:

$$\hat{y} \pm \sigma \sqrt{\frac{(n-p)\chi_{1;\psi}^2 \left(\frac{1}{n_i^*}\right)}{\chi_{n-p;\alpha}^2}} \quad (1)$$

Like all tolerance intervals, this formulation contains nominal parameters for the proportion of the population to be included in the interval,  $\psi$ , as well as the confidence level  $\alpha$ . In addition, critical values for the  $\chi^2$  distribution are calculated as well as the “effective number of observations” vector  $n_i^* = \frac{\hat{\sigma}^2}{se(\hat{y}_i)^2}$ . As the evaluation of TI boundaries is used in several of the inequality constraints described in the following sections, this is considered a bottleneck and is replaced by an approximation. To that end, a central composite design (CCD) containing all possible 3-level combinations PPs (min, max, center point) is created and its columns extended to include all interaction and quadratic effects. A variable selection step eliminates all unnecessary effects, and we are left with a parsimonious model describing the relationship between PPs and TI. Consequently, interval boundaries can be computed by multiplying observations with the vector of TI model coefficients, here denoted as  $\tau_l$  and  $\tau_u$  to distinguish them from the coefficients of the original model,  $\hat{\beta}$ . Note that all steps involved in forming this approximation can be vectorized efficiently using linear algebra libraries, which is why the proposed method is much faster than computing the true TI in each iteration of the optimizer. To illustrate this, results of a performance evaluation are presented in section 3.

### 2.2. Optimization Objective and Constraints

With the TI approximation in place, we can now define the optimization objective:

$$\text{maximize} \quad f(x) = \prod_{i=1}^p x_{p+i} - x_i, \quad x \in \mathbb{R}^{2p} \quad (2)$$

$$\text{subject to} \quad c_1(x), \dots, c_{2^{p+1}+5p+2}(x) \geq 0 \quad (3)$$

Where  $x$  is the vector of parameters to be optimized, comprised of the lower parameter boundaries in the first  $p$  elements and the upper boundaries in the next  $p$  elements, with  $p$  being the number of factors in the model. One can see that (2) simply maximizes the volume of the hypercube spanned by lower and upper parameter ranges.

To meet all requirements for a valid design space, a total of  $2^{p+1} + 5p + 2$  inequality constraints is defined. First, the parameter space to be searched is constrained by ensuring that a parameter’s lower range boundary is smaller than its upper boundary.

$$c_i(x) = x_{p+i} - x_i, \quad i = 1, 2, \dots, p \quad (4)$$

Oftentimes the design space is required to contain each parameter’s setpoint, so that  $x_i \leq s_i \leq x_{p+1}$ . This is expressed as the inequality constrains

$$c_i(x) = s_i - x_i, \quad i = 1, 2, \dots, p \quad (5)$$

$$c_i(x) = x_i - s_i, \quad i = p + 1, \dots, 2p \quad (6)$$

Similarly, optimization of the parameter space should only be performed within the screening range boundaries  $b_l$  and  $b_u$ . As our main optimization algorithm does not support natural boundaries, this is implemented as inequality constraints:

$$c_i(x) = x_i - b_{l,i}, \quad i = 1, 2, \dots, p \quad (7)$$

$$c_i(x) = b_{u,i} - x_i, \quad i = p + 1, \dots, 2p \quad (8)$$

The remaining constraints address the evaluation of the TI. To that end, the approximation generated in the pre-optimization step is used to calculate boundaries around CQA predictions that capture model uncertainty. These boundaries are then compared against the upper and lower acceptance limits  $a_l$  and  $a_u$  in each of the  $2^p$  corner points of the hyperrectangle:

$$c_i(x) = x_* \tau_l - a_l, \quad i = 1, 2, \dots, 2^p \quad (9)$$

$$c_i(x) = a_u - x_* \tau_u, \quad i = 1, 2, \dots, 2^p \quad (10)$$

$x_*$  denotes a corner point, taken from all possible combinations of upper and lower parameter ranges in  $x$ . As the TI approximation is generally not a linear one but at least a second-order polynomial,  $x$  is expanded to  $x_*$  to contain the same quadratic and interaction effects as  $\tau_l$  and  $\tau_u$ .

Evaluating the TI at corners alone does not guarantee a valid design space, as curvature in the response surface might lead to parameter ranges between corner points that exceed acceptance limits. To resolve this problem, a final inequality constraint uses a nested optimization step to find minima and maxima of the TI boundaries inside the hypercube:

$$c(x) = \operatorname{argmin}_x(x_* \tau_l) \tau_l - a_l \quad (11)$$

$$c(x) = a_u - \operatorname{argmax}_x(x_* \tau_u) \tau_u \quad (12)$$

While these last constraints might seem to make (9) and (10) redundant, having both TI checks in place can improve convergence of the optimizer in certain scenarios. Furthermore, one or the other can be deactivated in practice, depending on the type of optimization problem.

### 2.3. Optimization Algorithms

From the problem described in section 2.2 one can infer the prerequisites for the optimization algorithm. To find a design space, we want to minimize a single, scalar-valued function that is subject to inequality constraints as well as boundaries, though this last requirement can also be implemented as inequality constraints, see (7) and (8). COBYLA (Constrained Optimization BY Linear Approximation) was chosen as the main optimization algorithm, as it meets those requirements and, as a gradient-free method, shows reasonable robustness against converging in local minima (Powell, 1994).

For the nested optimization problem in (11) and (12), where boundaries and no inequality constraints are needed, a fast L-BFGS-B algorithm was used to find minima and maxima within the hyperrectangle (Byrd, Lu, Nocedal, & Zhu, 1995).

Due to minor inaccuracies introduced by the TI approximation as well as COBYLA convergence conditions in certain cases, we recommend a final ‘‘refinement step’’ where

COBYLA results are passed to a gradient-based SLSQP optimizer (Kraft, 1988). Here, the same constraints are used as in the main optimization step, except that the true TI calculation is used, as opposed to an approximation. Although iterations are much slower, only a few are needed for convergence as we expect the input to be already near the ideal DS.

### 3. Results

To evaluate efficiency and effectiveness of the proposed method we compared results with a known design space, calculated by a grid-based method that discretizes the problem space and evaluates the TI at each point. This is illustrated in Figure 2.

Figure 2: Parameter ranges calculated by both the proposed method and the reference method.

As is to be expected, the volume of the DS is larger in the method based on numeric optimization because it is not constrained by discrete grid points with finite limited resolution. Furthermore, due to parameter interactions, a change in one range can affect other ranges, which overall results in the substantial deviations of parameter ranges shown in in Figure 2. However, the main benefit of the proposed method is improved computing time. Performance evaluation results of an implementation in Python are reported in Figure 3. Due to the exponential increase of the parameter space over the number of parameters added, computing time of a discretization method also grows exponentially, which is not the case with the method based on numerical optimization.

Figure 3: Performance evaluation of the proposed method using both the TI approximation and the true TI, as well as the reference method.

#### 4. Conclusion

In this contribution we outlined a novel method for finding a design space comprised of linear combinations of PP ranges. The relationship between CQA and PPs is represented as a polynomial regression model and its prediction is used to evaluate whether CQAs meet acceptance criteria. Conservative estimation methods are vital in the biopharmaceutical domain, which is why the boundaries of tolerance intervals are used for evaluation of ACs instead of the predicted CQA. As the TI calculation can be complex, an approximation is generated in a pre-optimization step that can be used to calculate the TI by performing a single matrix multiplication. COBYLA is used for the minimization of the main objective, and we suggest refining results with a SLSQP optimizer that uses the true TI instead of an approximation. Performance evaluations show that the proposed method results in design spaces with a larger volume when compared to PP space discretization methods, and that they can be calculated in a fraction of the time. We believe that this approach will facilitate a robust definition of the design space for biopharmaceutical development that reduces patient risk by employing conservative estimators while allowing manufacturers to maximize control ranges. Future work will include a case study where performance is evaluated in a real-world scenario.

## Abstract

As of today, natural gas is one of the most widely deployed energy sources and its transport relies on large-scale infrastructures managed by the expertise of transmission system operators. In this framework, this paper proposes a Mixed-Integer-Linear-Programming model and a decomposition algorithm to optimize the operation of gas networks. The model aims to minimize the CO<sub>2</sub> emissions from compressor stations by optimizing the unit commitment of the gas-turbine-driven compressors, their loads and the dynamic operation of the network. The formulation includes the detailed linearization of the performance maps of the machines, their technical limitations, the dynamic conservation equations of the pipes, and the operating constraints of control valves. On top of this, the algorithm is capable of handling flow reversals in pipes, being suitable also for networks with cyclic topology. The resulting large scale MILP is extremely challenging to solve, and therefore we developed a decomposition algorithm to speed up the computational time. The decomposition algorithm is composed by two MILP levels, where the master level contains a simplified model of the compression stations and of pipe friction, while the lower level is the actual detailed model. The aim of the master level is to remove unused compression stations and to fix the flow direction in pipes in the lower level, thus reducing the size of this second problem. At the end of each bilevel iteration, an integer cut is added to the master problem to explore different combinations of committed stations. The algorithm is effectively tested on the Italian gas network case study, featuring 112 pipes and 9 compressor stations, each composed by 3-5 units.

**Keywords:** Gas network, MILP, decomposition, compression stations, Optimal operation.

## 1. Introduction

Natural gas is currently one of the most widely deployed energy sources and its transport is ensured by large-scale infrastructures, composed by pipelines, valves, and compressor stations. Nowadays, the management of these networks relies on the expertise achieved by the operators. Nevertheless, as the energy transition moves forward, transmission system operators (TSOs) are required to cope with new trends, making the role of optimization tools crucial, as they could help TSOs in their upcoming decisions.

The current literature on gas network optimization covers different optimization purposes, such as minimization of gas compression cost tackled by Liu et al. (2020) and Zlotnik et al. (2015), the stability of operation addressed by Hoppmann-Baum et al. (2021), or gas quality satisfaction. The optimization models can be divided in steady-state and dynamic, where only dynamic models are capable of capturing transient behaviors and considering the pipeline inventory. Nevertheless, very few dynamic approaches allow optimizing the on/off commitment of turbo-compressors, and for large networks they use heuristic rules to solve the optimization problem.

This work addresses the optimal dynamic operation of large gas network with the optimization of on/off commitment of turbo-compressors. The problem is formulated as a Mixed-Integer Non-Linear Program (MINLP), and then it is linearized into a Mixed-Integer Linear Program (MILP). Since also the MILP turns out to be extremely large to be solved in reasonable computational time, we developed a decomposition algorithm capable of finding solution in much shorter time.

## 2. Problem statement

The dynamic model addresses the optimal operation of the gas network so as to minimize the CO<sub>2</sub> emissions related to compression work. The formulation is as follows.

### “Given:

- the topology of the network;
- the performance maps of compressors and of the gas turbines driving them;
- import and consumption profiles across the network;
- air temperature forecasts;

### Determine:

- the operating mode of the compressor stations;
- the unit commitment and the operating point of each gas-turbine-driven compressor (GTDC);
- pressures and mass flow rates across the network;

### so as to minimize the CO<sub>2</sub> emissions and comply with the following constraints:

- conservation laws in pipes;
- technical limits of GT and natural gas compressors;
- compressor stations and control valves discrete operating modes;
- pressure bounds across the network.”

## 3. Optimization model

The MINLP formulation and the linearized MILP are described in Ghilardi et al. (2022). We report hereafter the main of features of the model.

### 3.1. Pipes and control valves

The gas dynamics within the pipes are governed by a system of differential equations depending on time  $t$  and space  $x$  (monodimensional flow). Mass (1), momentum (2) and energy conservations, and gas equation of state (3) depends on gas properties (density  $\rho$ , speed  $u$ , composition  $c$ , temperature  $T$ ), and pipe features (diameter  $D$  and elevation  $z$ ).

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} = 0 \quad (1)$$

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial(\rho u^2)}{\partial x} + \frac{\partial p}{\partial x} + \rho g \frac{\partial z}{\partial x} + \frac{c_f}{2D} \rho |u| u = 0 \quad (2)$$

$$p = Z(p, T, c) \cdot \rho \frac{R}{MM} T \quad (3)$$

The energy conservation equation can be omitted with the hypothesis of isothermal flow, while the kinetic and the inertial term of gas momentum equation can be neglected due to low speed of gas and large time discretization of the optimization (hourly basis). The differential system is discretized in space with the staggered grid method of Patankar (1980), and in time with backward Euler. As part of the linearization for the MILP model, we adopted an average  $\bar{Z}$  in (3), an average gas density for the friction term in (2), and a piecewise linear (PWL) approximation of the function  $|u|u$ . This second step is responsible for the introduction of the binary variable  $y_D$  related to flow direction.

Control valves (CV) are directed elements that continuously adjust the outlet pressure according to setpoints. They are commonly arranged in parallel with a bypass valve which, on the other hand, is undirected (backward flow can occur), and is discretely regulated, e.g. open/closed. The operation of this subsystem (control-bypass valves) can be mathematically modelled with three discrete modes: “regulating”, “closed” or “reverse-flow”. In “regulating” mode, the gas flows from the inlet to the outlet of the CV reducing its pressure to meet the setpoint; in “closed” mode both the bypass and the CV are closed, and the pressures at their boundaries are thus decoupled; in “reverse-flow” mode the gas flows backward in the bypass valve with a negligible pressure drop.

### 3.2. Compressor stations

Compressor stations consist of a set of GTDCs arranged in parallel, and, by assumption, they can compress NG along one direction only. The station can be “active” if there is at least one running machine, or, vice versa, it can run in “closed” or “bypass” mode.

Each GTDC is characterized by an operating point with a rotational speed  $N$ , inlet pressure  $p_{in}$ , mass flow rate  $w$ , outlet pressure  $p_{out}$ , and fuel consumption  $w_{fuel}$ . The variables  $p_{out}$  (4) and  $w_{fuel}$  (5) are functions of the other variables according to the polynomials  $f_1$  and  $f_2$ , resulting from the best-fit of technical maps. It must be noted that  $w_{fuel}$  depends also on ambient temperature  $T_0$ , due to its effect on GT efficiency.

$$p_{out} = f_1(w, N, p_{in}) \quad (4)$$

$$w_{fuel} = f_2(w, N, p_{in}, T_0) \quad (5)$$

These non-convex polynomials are linearized following the convex-hull approach of Makkonen and Lahdelma (2006), discretizing the operating region into binary sub-regions. Moreover, other linearized constraints are added: the choking and the surge curve for the centrifugal compressor, and the load range for the gas turbine, as a function of  $N$ .

### 3.3. Objective function

The objective function to be minimized is the CO<sub>2</sub> emitted by gas-turbines driving the NG compressors, defined by NG emission factor  $f_{CO_2}$  and fuel consumption  $w_{fuel}$  of each machine  $m$  at time  $t$ . Moreover, a penalty term is added to prevent frequent start-ups and account for the direct and indirect CO<sub>2</sub> emissions emitted during start-up.

$$\min \sum_{t \in \mathcal{T}} \left[ \sum_{m \in \mathcal{M}} f_{CO_2} \cdot w_{fuel}(t, m) + \sum_{m \in \mathcal{M}} f_{start} \cdot y_{start}(t, m) \right] \quad (6)$$

## 4. Decomposition algorithm

The presented MILP problem for the operation of half-day of the whole Italian gas network, with a time resolution of 1 hour and a spatial resolution of pipe finite volumes of 200 km features 4108 binary variables, 24453 continuous variables, 74992 constraints. Gurobi, one of the best available MILP solver, fails at finding a feasible binary solution in 10 hours. To address this issue, we developed a decomposition technique composed by two levels (Figure 1), where the master problem (MP) and the detailed lower-level (DP)

are solved over the iterations  $k$  to progressively refine the solution. The MP presents a simplified model of compressor stations and of pipe friction, and it is launched to determine the set of inactive stations  $\mathcal{S}_0^k$  and the direction of the flow  $y_D^k$  within the pipes  $p$ . Once these specifications are established, the DP can be solved in the resulting reduced space. Meanwhile, an integer cut is added to the MP to discard the combinations of active stations already explored from the next solutions. After a sufficient number of iterations  $\bar{k}$ , the algorithm is terminated and the best incumbent solution is maintained.

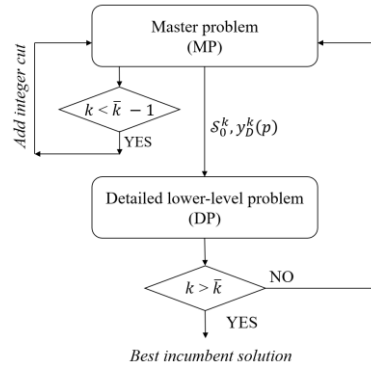

Figure 1. Block diagram of the bilevel decomposition algorithm

#### 4.1. Master problem

The master level MP is a simplification of the original MILP (1)-(6), with regard to the compressor station and the pipe friction model. These two simplifications are intended to reduce the complexity of the problem and especially to decrease the binary variables. Examining first the pipe model, the PWL representation of  $|u|u$  in the friction term is replaced by a straight line  $\bar{u}u$  with a constant slope  $\bar{u}$  for each pipe. This procedure eliminates the binary variable related to flow direction.

As far as the compressor station model is concerned, we defined for the problem MP a single convex hull (CH) for each station operating region (Figure 2), thus removing all individual GTDCs variables (unit commitment and operating point). In this way, the only remaining stations binary variables are those related to their configuration (see 3.3).

Figure 2. Operating map of a compressor station featuring 4 units projected into space ( $w_{tot}$ ,  $p_{out}$ - $p_{in}$ ) with its original convex hull (dashed), and reduced vertices convex hull (continuous).

The above cited convex hull is computed off-line by a series of (CHP) subproblems, one for each value of ambient temperature  $T_0$  and station operating point ( $p_{in}$ ,  $p_{out}$ ,  $w_{tot}$ ). Each subproblem (CHP) is obtained by applying the original MILP (4)-(6) to a single station, and by imposing, as boundary conditions, the coordinates of the operating point at stake. The (CHP) subproblem establishes whether the analyzed operating point is feasible and, if the response is positive, it computes the minimal fuel consumption  $w_{fuel,tot}$ . Therefore, the convex hull of the feasible points only is established and the

number of vertices of the resulting polyhedron is reduced to strike a balance between the number of variables and the accuracy the approximation. The graphical representation of this procedure into the bidimensional space ( $w_{\text{tot}}, p_{\text{out}} - p_{\text{in}}$ ) is provided by Figure 2 for a fixed  $p_{\text{in}}$  of 50 bar. Once the final CH of the operating region of each station is assessed, the compressor stations variables in MP – when the station is deemed as “active” – are computed as a convex combination of the vertices  $v$  of the polyhedron.

#### 4.2. Detailed lower-level problem and integer cuts

The lower level detailed problem (DP) exhibits all the constraints and variables described in (1)-(6), but it has a reduced size compared to the original problem. The DP defines the optimal unit commitment and load of the GTDCs within the resulting reduced space by the MP. Nevertheless, due to the approximations of this MP model, the induced choice of committable stations on DP might be sub-optimal. To mitigate this effect, at the end of each iteration  $k$ , an integer cut is progressively added to the MP to exclude the previous explored solutions. This cut (7) guarantees that, in the next iterations, at least one of the previously uncommitted stations ( $s \in \mathcal{S}_0^k$ ) is activated within the time horizon  $\mathcal{T}$ .

For the practical reasons, given the long computational time, the iterative algorithm stops when the best found solution is not improved for three consecutive iterations.

## 5. Results

The presented algorithm is applied to a simplified version of the Italian network (Figure 3), still featuring a very complex topology with many loops, 112 pipes, 20 GTDCs arranged in 9 stations, and 16 control valves.

Figure 3. Italian network case study: compressor stations (blue), control valves (red) and pipes (black)

The MILP has been modelled with Pyomo and solved with Gurobi till a gap of 5% on a laptop computer with Intel i7 CPU and 32 GB RAM. The model is applied for the operation of 12 hours in a test scenario featuring a large number of uncommitted stations and backward flow in many pipes. For the practical implementation of the algorithm, the computational time must be limited to about 6 hours. Thus, the iterative MP-DP algorithm stops when the solution is not improved for 3 consecutive iterations.

With a time resolution of 1 hour, the first MP features 14781 continuous variables, 442 binary variables, 18927 constraints, while the DP features 8436, 696 and 74992, respectively. Table 1 depicts for each iteration  $k$  the computational time, the stations  $\mathcal{S}_1^k$  activated by the MP, and the objective function of the DP.

In all the iterations, the compressor station S2 (at the North-East boundary), the station S9 (near the South border), and S4 are always activated, while different choices of stations along the South-Central pipeline are explored using the integer cut. Among these

solutions, the optimal one is found in the first iteration, as shown in Table 1. Further investigations are needed to define the optimal number of iterations across different scenarios, finding a compromise between optimality and computational load. Nevertheless, it must be underlined that the overall computational time can be reduced in any case by adopting a coarser time grid in MP (without impacting the time resolution of the final solution), and by solving each  $MP^{k+1}$  in parallel with  $DP^k$  (Figure 1).

<b>k</b>	<b>MP time</b>	<b>DP time</b>	<b><math>S_1^k</math></b>	<b>Objective function</b>
1	1135 s	2125 s	S2, S4, S7, S9	586
2	1094 s	2580 s	S2, S4, S8, S9	646
3	1830 s	5811 s	S2, S4, S6, S9	659
4	1910 s	4489 s	S2, S4, S6, S8, S9	614

Table 1. Results of the Italian network case study. The table shows the computational time required to the master problem (MP), the detailed-lower level problem (DP), the activated stations  $S_1^k$  by the MP, the optimal CO<sub>2</sub> emissions [tonCO<sub>2</sub>].

## 6. Conclusions

This work presents a Mixed Integer Linear Programming algorithmic framework for optimizing the operation of large gas networks including commitment decisions of the turbo-compressors. The model is characterized by the dynamic equations of the network and the performance maps of gas-turbine-driven-compressors. Since the detailed MILP model is too large also for the best available MILP solvers, a decomposition algorithm has been developed. The simplified master problem is firstly launched to define the set of inactive stations and the flow direction within the pipes. Then, the detailed lower-level problem is solved in the resulting reduced space, providing a more accurate solution. Integer cuts are progressively added to the master problem to explore different combinations of active stations, and mitigate the possible sub-optimality of the decomposition. The proposed algorithm is applied to half-day operation of the Italian gas network, which consists of 112 pipes, 9 compressor stations, each one containing 3-5 gas-turbine-driven compressors. For the case study, the first iteration of the bilevel model is solved in less than 1 hour on a laptop computer, and proved to be the best solution across all explored iterations. These results suggest that the algorithm could be applied in decision support systems of transmission system operators. Further development of the research can apply the algorithm to different case studies to assess the optimal number of iterations to be adopted over different scenarios, and to develop some heuristics to speed up the solution.

## Abstract

Biodiesel is an ideal substitute for traditional diesel under the requirements of sustainable and low-carbon issues because of its low-temperature chamber gas emission ratio and good adaptability to the characteristics of existing vehicle engines. However, biodiesel has yet to be fully industrialized due to the traditional batch production mode. Based on the rapid development of microreactor technology that can be used for continuous production, this paper studies the influence of shape parameters of a T-shaped microreactor on biodiesel yield through the enzymatic synthesis of biodiesel from biodiesel castor oil and methanol to prepare fatty acid methyl ester. An automatic simulation optimization platform is thus established based on computational fluid dynamics simulation and derivative-free optimization algorithms. The optimization work makes biodiesel yield increase by 86% compared with the initial result.

**Keywords:** Derivative free trust region algorithm, Microreactor, Geometric optimization, Automatic CFD simulation

## 1. Introduction

With the rapid global increase of market competition along with the requirements on safety and environmental issues, the search for sustainable chemical production systems is becoming increasingly important. Biodiesel has been widely regarded as a green alternative to fossil counterparts because of its low-temperature chamber gas emission ratio and good adaptability to the characteristics of existing vehicle engines. However, traditional biodiesel production is mainly carried out in the batch reactor, which takes a long time and consumes much energy and thus hinders its further development and potential large-scale industrial applications.

Benefiting from additive manufacturing and flow chemistry, the new continuous biodiesel production equipment represented by microreactors has started getting attention from academia and industry because of its excellent mass and heat transfer characteristics. However, the selection of microreactor geometric parameters is still determined by experience, lacking a systematic optimization approach (Liang, 2020). Based on the Derivative-Free Trust Region (DFTR) algorithm (Charles A et al., 2017) and the Computational Fluid Dynamics (CFD) simulation, this paper proposes an integrated framework for optimally discovering the geometric parameters of the T-shaped microchannel reactor. In general, the proposed framework can automatically run the CFD simulator based on the offered parameters by DFTR. Accordingly, the information from the CFD simulator feeds DFTR for seeking next-round parameters.

The proposed framework is applied to a biodiesel production example where triglyceride is chosen as the feedstock (Zarejousheghani et al., 2016). Facing the mixing problem caused by the two-phase laminar flow boundary in the reactor channel and the low diffusion coefficient of reactants, this example assumes that the laminar flow boundary can be broken by adding a groove to improve the mixing effect. The main objective is to maximize the yield of biodiesel. The results indicate the feasibility and effectiveness of the proposed framework. The yield of biodiesel associated with the designed microreactor is increased by 86% compared to the existing ones. The designed microreactor is now being fabricated to get further experimentally validated.

## 2. Reaction

As shown in Fig.1, the production method of enzyme-catalyzed reaction of triglyceride (castor oil) and methanol in a microreactor was selected, and the amount of fatty acid methyl ester obtained from the reaction was regarded as the final biodiesel production.

Figure 1. Reaction-producing biodiesel from triglyceride

Fig.2 illustrates that the reaction process can be explained by a ping-pong mechanism (Zarejousheghani et al., 2016): (1) The enzyme attacks triglycerides, producing and activating enzyme triglyceride conjugates. (2) The conjugates rearrange to form the enzyme and free fatty acid chain complex and release glycerol. (3) Alcohols link with enzymes in the activated state to release the final product, fatty acid methyl ester, and free enzymes.

Figure 2. Reaction mechanism

Experimental data (Zarejousheghani et al., 2016) shows that the inhibition effect of methanol in the production process can be ignored so that the reaction mechanism can be characterized approximately by the ping-pong mechanism without inhibition.

$$r = \frac{k[E_0][TAG][Me]}{K_{mTG}[Me] + K_{mA}[TAG] + [TG][Me]} \quad (1)$$

$[E_0]$  represents the enzyme concentration in the reaction system,  $[TAG]$  and  $[Me]$  are the molar concentrations of triglyceride and methanol respectively. The meanings of other parameters and their estimated values are shown in Table 1.

Table 1. Reaction kinetics parameters

Parameter	Meaning	Value
-----------	---------	-------

$k(\text{mmol} \cdot \text{ml}^{-1} \cdot \text{s}^{-1})$	Maximum reaction rate	0.0208
$K_{mTAG}(\text{mmol} \cdot \text{ml}^{-1})$	Michaelis constant	10.54
$K_{mMe}(\text{mmol} \cdot \text{ml}^{-1})$	Michaelis constant	10900.42
$K_{iMe}(\text{mmol} \cdot \text{ml}^{-1})$	Inhibition constant	3976.48

In addition to reaction kinetics, the diffusion coefficient between reactants in the reaction system is also an indispensable parameter in the actual modeling process. In this work, the diffusion coefficient of alcohol in the oil phase is estimated by Wilke Chang's empirical formula. The diffusion coefficient of methanol to triglyceride is approximately  $1.8 \times 10^{-10} \text{ m}^2/\text{s}$ , the diffusion coefficient between lipase and other phases is approximately  $5 \times 10^{-11} \text{ m}^2/\text{s}$ , the diffusion coefficient between other substances is approximately  $10^{-9} \text{ m}^2/\text{s}$ .

### 3. Reactor

#### 3.1. Initial reactor

The traditional T-type microreactor is selected as the reactor for biodiesel synthesis. The raw materials enter from both ends of the reactor respectively, and the reaction and mixing are carried out in the reaction channel.

Figure 3. Initial T-shaped Microreactor

Table 2. Geometric parameters and feeding conditions of initial T-type reactor

Variable	Value
Pipe diameter	0.5 mm
Pipe length	10 mm
Branch length before the two-phase intersection	3 mm
Triglyceride feed flow rate	0.1 mm/s
Methanol feed flow rate	0.6 mm/s
The mass fraction of enzyme in the methanol feed solution	1%

#### 3.2. Reactor optimization

Due to the low interphase diffusion coefficient, the contact of reactants forms a laminar boundary, which hinders the diffusion and reaction process of substances. It is feasible to break the original laminar flow by adding grooves to improve the mixing condition. The optimization problem in this work is established by taking the geometric parameters related to the grooves as optimization variables.

Figure 4. Geometric parameters of the groove of T-type reactor

Constrain the range of each variable: (1)The starting position of the groove is required to be 0.5 mm away from the intersection of two phases; (2)The length of the inclined front section, horizontal section, and rear inclined section of the groove shall be between 0.01 mm and 2 mm; (3)The depth of the two grooves is required to be between 0.05 mm and 0.45 mm to avoid the appearance of too small flow passage cross-section; (4)The deviation angle of the groove centerline is set between 0 and  $2\pi$ ; (5) To simplify the model, the second groove is required to be generated after the first groove.

$$\begin{cases} 0.5 \leq L_1^1 \leq 10, & 0.5 \leq L_1^2 \leq 10, & 0.01 \leq L_2^1 \leq 2, & 0.01 \leq L_2^2 \leq 2 \\ 0.01 \leq L_3^1 \leq 2, & 0.01 \leq L_3^2 \leq 2, & 0.01 \leq L_4^1 \leq 2, & 0.01 \leq L_4^2 \leq 2 \\ 0.05 \leq L_5^1 \leq 0.45, & 0.05 \leq L_5^2 \leq 0.45, & 0 < \theta^1 \leq 2\pi, & 0 < \theta^2 \leq 2\pi \\ L_1^2 + L_2^2 + L_3^2 + L_4^2 \leq 10, & L_1^1 + L_2^1 + L_3^1 + L_4^1 < L_1^2 \end{cases} \quad (2)$$

Table 3. Geometric parameters of the groove of T-type reactor

Variable	Meaning
$L_1^1/mm$	Distance from the beginning of groove 1 to the entrance
$L_2^1/mm$	Length of the front section of the inclined section of groove 1
$L_3^1/mm$	Length of the horizontal section of groove 1
$L_4^1/mm$	Length of rear section inclined section of groove 1
$L_5^1/mm$	Depth of groove 1
$\theta^1$	Deviation angle of groove 1 centerline
$L_1^2/mm$	Distance from the beginning of groove 2 to the entrance
$L_2^2/mm$	Length of the front section of the inclined section of groove 2
$L_3^2/mm$	Length of the horizontal section of groove 2
$L_4^2/mm$	Length of rear section inclined section of groove 1
$L_5^2/mm$	Depth of groove 2
$\theta^2$	Deviation angle of groove 2 centerline

### 4. Integrated framework

#### 4.1. Computational fluid dynamics modeling

Empirical formulas in the macro process cannot be directly applied to a micro-scale reactor. The numerical simulation method of solving the fundamental equations in fluid mechanics, computational fluid dynamics (CFD), is used to model the reaction process in the microreactor. Ansys series software was used to complete the modeling process of geometric modeling, mesh generation, and computational fluid dynamics.

#### 4.2. Derivative-free trust-region algorithm

CFD can only obtain the output results under given input conditions, so the optimization process needs an optimization method that does not rely on derivative information. We use a derivative-free trust-region algorithm to solve the problem.

Under the variables and constraints given in section 3.2 to be optimized, the constraint problem  $\max f(x)$  is constructed to maximize biodiesel yield. Table 4 shows the algorithm framework:

Table 4. The framework of the derivative-free trust-region algorithm

1. Initial point  $x_0$ , trust region radius  $\Delta_0$
2. Establish approximate function model  $q(x_k + s) = f(x_k) + g^T s + \frac{1}{2} s^T B_k s$
3. Solve the problem  $\max q(x_k + s)$  to obtain  $s$
4. Calculate the ratio of the actual objective function descent to the approximate function model descent
5. Update the trust region radius according to the ratio
6. Output the final result if the termination conditions are met. If not, return to step 2.

#### 4.3. Framework

A fully automatic simulation optimization platform is established based on the modeling and optimization method. The framework is shown in Figure 5.

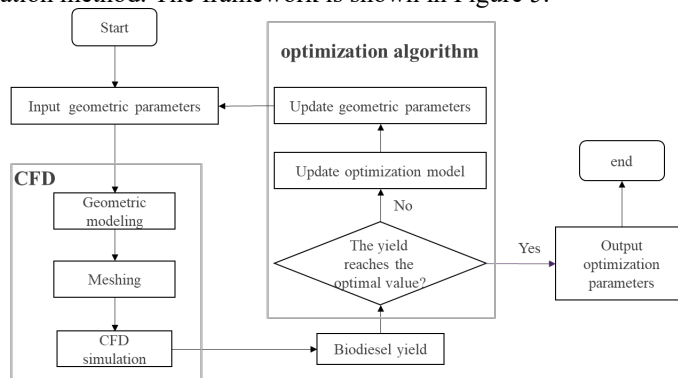

Figure 5. Operation framework of simulation optimization platform

## 5. Analysis and discussion

With the goal of maximizing the yield of biodiesel, this work calculates the conversion rate of triglyceride at the outlet interface obtained by CFD simulation as the objective function:

$$\max f = \frac{\sum c_{FAME}}{\sum c_{FAME} + 3 \sum c_{TAG}} \quad (3)$$

Forty feasible groove shapes were selected by Monte Carlo random sampling, with the corresponding diesel yield obtained through CFD simulations. The quality of grids generated in the automatic CFD simulation process is higher than 0.4, the quantity of grids is about 500000, and the calculation accuracy error is about 2%. The groove shape with the highest biodiesel yield was selected as the initial point, and the biodiesel yield was 4.86%.

Figure 6. The product distribution of the initial reactor

After the normalization of variables, the initial trust region radius is selected as 0.05, and the trust region radius less than 0.001 is taken as the termination condition of the trust region algorithm.

As shown in Figure 5 above, according to the geometric parameters and trust region, select the points in the trust region to carry out CFD simulation to establish the proxy model, calculate the proxy model to obtain the best geometric parameters, and carry out CFD simulation to get the calculation results. If the results do not meet the convergence conditions, update the radius of the trust region and the proxy model, and repeat the process. If the result meets the convergence condition, output the optimized geometric parameters and terminate the operation. Each iteration requires about 91 function value calculations. After about 1000 times function value calculation, iterative convergence is achieved. The final yield of biodiesel is 9.03%.

Figure 7. The ratio of optimization result to initial result varies with the number of iterations

The circle size represents the trust region radius size.

Figure 8 shows the geometry of the microreactor under the final optimization results and the product distribution in the reactor at this time. The simulation results show that the

optimization process can effectively improve the two-phase mixing condition and promote the reaction.

Figure 8. The geometric shape and product distribution of the optimized microreactor

Table 5. Geometric parameters of the optimized microreactor

Parameter	Value	Parameter	Value
$L_1^1/mm$	1.266	$L_1^2/mm$	3.754
$L_2^1/mm$	0.328	$L_2^2/mm$	1.168
$L_3^1/mm$	0.437	$L_3^2/mm$	0.187
$L_4^1/mm$	1.371	$L_4^2/mm$	0.998
$L_5^1/mm$	0.297	$L_5^2/mm$	0.450
$\theta^1$	141.5°	$\theta^2$	257.7°

## 6. Summary

An automatic simulation optimization platform has been established, and the biodiesel yield has been successfully improved using a derivative-free trust-region algorithm and CFD. The optimization platform can be extended to more extensive geometric shape optimization research in the future.

## Abstract

Recently, active learning methods have been used to solve large and complex problems. The underlying principle is the construction of computationally cheap surrogate models, which are able to mimic the original problem with a high-level of accuracy. In complex energy systems, (non-linear) simulation models (e.g. generated using Aspen Plus) have grown larger. In the field of process system engineering, these models need to be repeatedly used to optimize operating conditions. The use of surrogate models reduces the required optimization time. However, the quality and the way to obtain these surrogates is crucial. In this work an active learning approach is coupled with a genetic algorithm, that ensures the selection of points that are relevant from the optimization perspective. Nine different surrogate methods are tested. Our results show that artificial neural networks and random forest are the best performing algorithms, with mean square error up to two orders of magnitude better than other more simplistic approaches. A biogas separation case-study is used to validate the approach.

**Keywords:** Active Learning, Surrogate models, Genetic algorithm, optimization, superstructure

## 1. Introduction and state-of-the-art

In the field of Process system engineering (PSE), superstructure-based optimization is a common approach for both synthesis and design stages<sup>1</sup>. The backbone of a superstructure is a set of interconnected units (or blocks), that combined are able to generate solutions that meet desired specifications and constraints. Such units are often modeled as black-boxes (BB); thus their accuracy is critical for generating insightful results. These BB models try to capture, via a mathematical formulation, the relation between inputs and outputs. This can be a challenging task, especially if complex mathematical models (e.g., CFD) or large flowsheeting diagrams (e.g. Aspen or Belsim Vali) are required to describe conversion processes. Lengthy computational times and converge issues are among the main concerns with such modelling strategies.

Surrogate models (or metamodels) are a way to by-pass the limitations of complex simulations, while keeping a high-level of accuracy. This type of supervised machine learning is able to explore features between input and output data in a computationally cheap way. They can then be used in superstructure-based optimization, allowing one to obtain fast and reliable results. In the field of PSE, the most used surrogate strategies are Kriging models (or Gaussian processes) and Artificial Neural Networks (ANN)<sup>2</sup>, justified by the built-in error measure of the former, and the adaptability to practically any type of data structure of the latter. Examples of such applications can be found for large scale superstructure-based optimization<sup>3</sup> or even to replace state-of-the-art solvers in deterministic global optimization<sup>4</sup>.

Building surrogates can be a simple task if large amounts of useful and reliable data are available. Unfortunately, this is often not the case. One technique is to run the simulation model for an extremely large number of points. This is the domain of Deep Learning (DL). Provided enough time and results, DL can build a very accurate (and cheap to run) surrogate model. However, obtaining such data can be (computationally) expensive. Active learning (AL) is another domain of machine learning that leverages the capacity of an algorithm to learn and ‘smartly’ decide which sample points need to be simulated. Points are selected in regions for which the surrogate level of accuracy is the lowest, and therefore running the expensive simulation program will bring the largest amount of information. The algorithm decides based on the evaluation of a specific function (called learning function)<sup>5</sup>.

An AL approach is by itself a good improvement compared with greedy DL strategies. For optimization purposes, one would like to have an extremely accurate surrogate model in the points that are assessed during the optimization stage - rather than a good overall method, that underperforms in the most critical points. In this regard, a way to cover the most ‘interesting’ space domains for optimization is by using a genetic algorithm (GA) - a nature-inspired meta-heuristic. Such evolutionary strategy has been extensively used for optimization. A review on its properties, advantages and limitations is given in<sup>6</sup>.

This work departs from the literature by coupling two ‘smart’ approaches with the goal of building surrogate models. A GA complements the use of an AL approach, particularly by guiding the surrogate building strategy in the direction that is most interesting from the optimization perspective. The method was tested and validated in a superstructure-based optimization approach for the chemical-absorption separation of biogas.

## 2. Methodology

### 2.1. Mathematical formulation and overview

The goal of the GA-AL approach is to create the function  $f$  that is able to accurately predict the output(s) of interest. An overview of the methodology is shown in Figure 1. There are four macro blocks, explored below.

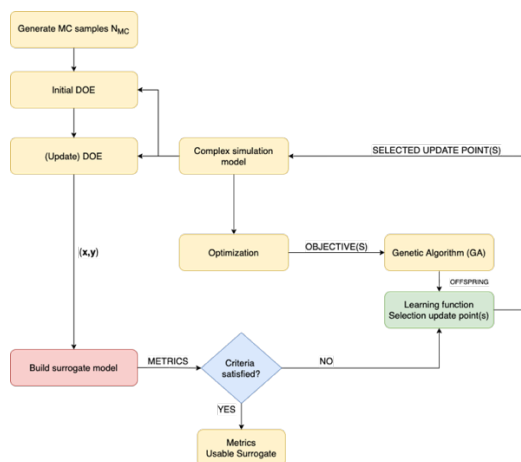

Figure 1 – Simplified block diagram of the GA-AL approach.

#### 2.1.1. Design of experiments (DOE)

The DOE is the section responsible for the initial number of (expensive) simulation runs and the connection between the surrogate building framework and the simulation code. The initial number of samples is a topic of debate. We have adopted the  $\max\{n_s + 2, 12\}$ , in which  $n_s$  is the number of parameters (also known as

dimensions), following the suggestion of Hong et al<sup>7</sup>.

### 2.1.2. Surrogate methods

Table 1 summarizes the list of methods used, comprising simple ones (such as least squares and inverse distance weighting), Kriging-based approaches and more advanced ones such as ANN or Random forests. For this stage, ML python libraries were used, together with the python package ‘smt’ based on the work of Bouhlel et al.<sup>8</sup>, where the pros and cons of each strategy are also discussed and the complete mathematical formulation provided.

Table 1 - Surrogate methods used

Acronym	Surrogate method
LS	Least squares
KRG	Kriging
KPLS	Kriging + partial least squares (PLS)
KPLSK	2-step Kriging + PLS
GEKPLS	Gradient-enhanced Kriging + PLS
IDW	Inverse distance weightings
RBF	Radial basis function
ANN	Artificial Neural Network
RF	Random Forest

### 2.1.3. Learning function

The learning function decides which point ( $\mathbf{x}$ ) (which is in reality a  $n_s$ -dimension vector) needs to be integrated in the DOE set. An adaptation of the potential risk function (PRF) as described in Hong et al.<sup>9</sup> is used (eq. 1). It consists of an exploration ( $e_r$ ) and exploitation ( $e_i$  in blue) approach, that is weighted by the parameter  $\tau$ . The numerator is the distance between any future point and the DOE points, whereas the denominator is the maximum distance within the current DOE points (of size  $m$ ). For the exploitation,  $y(x_i)$  is the real simulation result on the DOE points,  $\xi$  is the limit value (equivalent to the limit-state value) and  $r(x)$  is given by eq. 2, where  $\hat{y}$  represents the surrogate model answer.

$$e_{PRF}(\mathbf{x}) = e_r(\mathbf{x}) \cdot e_i(\mathbf{x}) = \frac{\min_{x_i \in \mathbf{x}} |\mathbf{x}_i - \mathbf{x}|}{\max_{x_i, x_j \in \mathbf{x}} |\mathbf{x}_i - \mathbf{x}_j|} \cdot \exp\left(-\tau \frac{r(\mathbf{x})}{\max_{x_i \in \mathbf{x}} y(x_i) - \xi}\right), i, j = 1, 2, \dots, m, \tau > 0 \quad (1)$$

$$r(\mathbf{x}) = \begin{cases} \hat{y}(\mathbf{x}) - \xi, & \hat{y}(\mathbf{x}) \geq \xi \\ \xi - \hat{y}(\mathbf{x}), & \hat{y}(\mathbf{x}) < \xi \end{cases} \quad (2)$$

### 2.1.4. Stopping criteria

The stopping criteria (eq.3) defines the level at which the surrogate model is good enough to be used without further refinement. The criteria is a convergence based one, adapted from Hong et al.<sup>9</sup>;  $\hat{\mu}_i$  and  $\hat{\sigma}_i$  are, respectively, the estimated expected value and standard deviation, obtained using the surrogate model, in the GA offspring points. The threshold ( $\varepsilon_{th}$ ) is set to  $10^{-5}$ . In addition, a stopping criterion on the number of runs (100 runs) is included to avoid extremely lengthy surrogate training.

$$\varepsilon = \max\left(\frac{\hat{\sigma}_i}{\hat{\mu}_i}\right) \leq \varepsilon_{th} \quad \forall i \in \text{Offspring} \quad (3)$$

## 2.2. Case-study

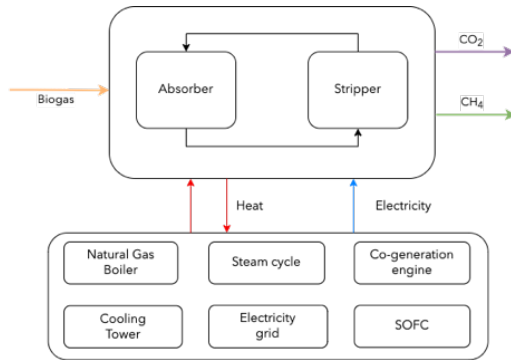

Figure 2 – Superstructure-based approach for biogas separation. The set of technologies was modeled according to Castro-Amoedo et al.<sup>10,11</sup> The average annual (2021) energy price was queried using the approach described in Santecchia et al.<sup>12</sup>

The GA-AL method is applied to the total cost minimization of a biogas (60% CO<sub>2</sub>, 40% CH<sub>4</sub>) chemical absorption separation (Figure 2). This chemical separation was modeled according to Sharma et al.<sup>13</sup>; the parameters used for surrogate building are described in Table 2, and the total heat duty is the surrogate output. The superstructure problem is formulated as a mixed-integer linear programming (MILP), following the approach described in Castro-Amoedo et al.<sup>14</sup>.

### 2.2.1. Performance evaluation

The evaluation of the GA-AL approach is based on **four** criteria. The first is the number of total (expensive) model evaluation per surrogate method ( $N_{mtd}^{eval}$ ); the second is the beta approximation ( $\beta_{rank}$ ) (eq. 4), which measures how close a given method (mth) is from the reference expected value ( $\beta_{ref}$ ), which was obtained using a Monte Carlo simulation with  $10^5$  points. The third (eq. 5) is a trade-off between the first and second criteria, with  $N_{med}$  being the median number of model evaluations. Lastly, MSE (eq. 6) represents the mean square error. To avoid the bias introduced by the set of initial points, twenty replications were performed for each surrogate method.

Table 2 – Parameters, range and output

Inputs	Range
Absorber temperature	40-60°C
Stripper temperature	90-120°C
Absorber diameter	15-20 m
Stripper diameter	5-12 m
Absorber tray space	0.6-1.2 m
Stripper tray space	0.6 –1.8m

$$\beta_{rank} = \left| \frac{\hat{\beta}_{mtd} - \beta_{ref}}{\beta_{ref}} \right|, \text{ with } \hat{\beta} = \frac{\hat{\mu}_{mth}}{\hat{\sigma}_{mth}} \quad (4)$$

$$\Delta = \beta_{rank} \cdot \frac{N_{mtd}^{eval}}{N_{med}} \quad (5)$$

$$MSE = \sum_{i=1}^{N_m^{eval}} (y(x_{test,i}) - \hat{y}(x_{test,i}))^2 \quad (6)$$

### 3. Results and Discussion

The systematic evaluation of each approach is based on evaluating the performance criteria for the different strategies. Figure 3 (a) summarizes the results for the set of surrogate models tested. As suggested, random forest and artificial neural networks outperform the others, scoring the lowest MSE and being close to the reference expected value ( $\beta_{ref}$ ). This demonstrates the capacity of such algorithms to adapt to any kind of mathematical structure, even with limited amount of data.

(a)

(b)

Figure 3 – (a) surrogate models performance based on the four criteria performance criteria; (b) MILP objective function range

noting that additional features, such as enhanced-gradient (GEKPLS) or the use of partial least squares (KPLS) do not bring advantage. Indeed, for the same average number of runs, an increase (by one order of magnitude) in MSE is recorded.

The surrogate model is part of a superstructure that minimizes the total cost of separating CO<sub>2</sub> from a biogas mixture. At the level of the MILP, the quality of the surrogate influences the GA choice of points and consequently the range of costs. This is visible in Figure 3 (b). Regardless of the surrogate model, the fine tuning of the operating parameters bound the separation process between 81 and 92 EUR/ton of CO<sub>2</sub>.

### 4. Conclusions

In this work, a genetic algorithm is coupled with an active learning methodology to generate surrogate models. Such combined approach harvests the best of both methods:

As suggested, random forest and artificial neural networks outperform the others, scoring the lowest MSE and being close to the reference expected value ( $\beta_{ref}$ ). This demonstrates the capacity of such algorithms to adapt to any kind of mathematical structure, even with limited amount of data.

On the other hand, RBF and IDW underperform, due to the combination of a large number of runs required but also a poor approximation to the reference. Their MSE is one order of magnitude greater than the best performing methods, despite the larger number of samples. This might be due to the rather simplistic approach of both methods.

The standard Kriging (KRG) is, after ANN and RF, the best performing algorithm. It brings advantage compared to the least squares (i.e. linear regression) approach. However, it is worth

the genetic algorithm guides the active learning search to the points that are more relevant to the optimization problem at hand, whereas the active learning ensures finding the most interesting point to be simulated and then executed at the MILP optimization interface. Nine surrogate methods were tested in a biogas separation case study. Artificial neural networks and random forest are the best performing algorithms, followed by a standard Kriging formulation. On the other hand, the radial basis function and the inverse distance weighting algorithms have shown the worst performance. Moreover, the coupling of Kriging metamodel with additional features such as enhanced-gradient or partial least squares did not prove advantageous. The cost of separating CO<sub>2</sub> and CH<sub>4</sub> from a biogas mixture was simultaneously assessed, with costs ranging between 81 and 92 EUR/ton of CO<sub>2</sub>.

The approach here presented is modular and can accommodate any type of surrogate method, learning function or stopping criteria. Future work will address a more comprehensive set of stopping criteria and their effect on surrogate accuracy, as well as a systematic ranking system. In addition, high-dimensional problems (with more than twenty parameters) will be tested, show-casing the use of this framework for any type of PSE problem.

# Data-driven Distributionally Robust Joint Chance-Constrained Optimization for Industrial Utility systems under Uncertainty

Hanxiu Li, Liang Zhao\*

*Key Laboratory of Smart Manufacturing in Energy Chemical Process, Ministry of Education, East China University of Science and Technology, Shanghai 200237, China*

## Abstract

The motivation to improve the energy efficiency of utility systems is resonating more intensely since the issue of carbon neutrality was put forward. However, the energy demand uncertainty brings challenges for utility systems modeling and optimization. This paper proposed a multi-objective optimization framework for minimizing operating cost and environmental impact simultaneously. The environmental impact is defined using the life cycle assessment method, and the operating cost consists of the resource consumption of the utility system. A data-driven distributionally robust joint chance-constrained (DRJCC) approach is proposed to deal with the uncertainty of steam demands. The data-driven ambiguity set is constructed based on Wasserstein distance, which contains the empirical distribution and is incorporated into the DRJCC framework. The dual representation for the worst-case probability transforms the problem into a deterministic non-convex reformulation. The proposed method is verified by a case study from an industrial ethylene plant. The results demonstrate that the total cost and environmental impact reduce as the confidence coefficient increases. In addition, the Pareto frontier enables us to select the optimal solutions flexibly, which may minimize the operational cost while the environmental standard is satisfied.

**Keywords:** industrial utility system, Wasserstein ambiguity set, distributionally robust joint chance-constrained program, life cycle assessment, multi-objective optimization.

## 1. Background

Emission reduction and energy saving have become the main concerns for the petrochemical industry in the carbon-neutral era. New technology and method applied to improve efficiency and decrease environmental burden is necessary for sustainable development in the next few decades. Process modeling, optimization, and environmental assessment have been focused on for this issue. An improved simulation and optimization method was presented for the sustainable development of utility systems (Varbanov et al., 2020). Ioannou et al. reviewed the role of process systems engineering tools in assessing and optimizing production patterns for alternative chemicals based on renewable resources (Ioannou et al., 2021). A consequential life cycle optimization framework was developed to determine the optimal chemical recycling technology (Zhao and You, 2021). Čuček et al. reviewed the methods of footprints which are defined as indicators and used to measure sustainability (Čuček et al., 2012). With continuous research on system optimization under uncertainty in recent years, stochastic and robust optimization methods were proposed to improve the system's robustness. As a combination of robust and stochastic programming, the distributionally robust chance-

constrained program provides a strategy that can adjust the relationship between system reliability and the optimal cost (Ding et al., 2022; Xie and Ahmed, 2016).

As one of the indispensable roles in the process industry, the utility system is generally responsible for providing power and heat for the industrial manufacturing process. Therefore, the deterministic multi-objective model based on life cycle assessment is constructed first. Then, the uncertain parameters of steam demand are collected from the historical data. An improved data-driven DRJCC framework with a Wasserstein ambiguity set is presented, and the deterministic model is reformulated in the dual form for the utility system. Finally, a case study of the utility system is presented to verify the effectiveness of the proposed method.

## 2. Deterministic Multi-objective Model Based on Life Cycle Assessment

A deterministic multi-objective framework for getting the optimal solutions with sustainability based on economic and environmental factor is proposed in this section.

### 2.1 Objective function

The operating cost and environmental indicator based on LCA method are defined as sustainability objectives. According to the list of the energy and material consumed in the system, we can calculate operating cost as:

$$\begin{aligned}
 COST = & \sum_{bo} \sum_i P_{i,bo}^{Fuel} \cdot M_{i,bo}^{Fuel} + p^{Ele} \cdot \left( \sum_{mo} M_{mo}^{Ele} + \sum_m M_m^{Ele} \right) + \\
 & p^{Water} \cdot \left( \sum_{lv} M_{lv}^{Water} + \sum_m M_m^{Water} \right) + \sum_m p_m^{De} \cdot M_m^{De} \quad (1) \\
 & i = \{Coal, NG\}, m = \{FGD, SCR\}
 \end{aligned}$$

The life cycle assessment method of CML 2001 was applied for evaluating the environmental load and helped to design the environment-friendly system (Guinée et al., 2001). The total emissions produced in chemical production are composed of direct emissions and indirect emissions. Direct emissions are mainly from the burning of fossil fuels. Equation (2) states the emission of CO<sub>2</sub> and equation (3) indicates the emissions of SO<sub>2</sub> and NO<sub>x</sub> under controlled conditions of the flue gas treatment process. The emissions generated by the exploitation, processing, transportation of upstream resources and power production are the indirect emission, which is presented in (4). By weighting the four impact factors, a single environmental assessment index is finally obtained in (5).

$$DE_{CO_2} = \sum_i F_{CO_2,i} \cdot M_i^{Fuel} + F_{CO_2,FGD} \cdot M_{FGD}^{De} \quad (2)$$

$$DE_k = Produce_k \cdot (1 - \theta_k), \quad \theta_k \in [0,1], k = 1, 2, \dots, 12 \quad (3)$$

$$IE_k = \sum_j LCI_{k,j} \cdot M_j, \quad j = \{Coal, NG, Ele, Water, Lim, Amm\} \quad (4)$$

$$IMPCT = \sum_n \frac{\sum_k LCI_{k,n} \cdot (IE_k + DE_k)}{F_n^{Normalization}}, \quad n = \{ACI, GWP, EUT, HTP\} \quad (5)$$

### 2.2 Constraints

The steam demand constraints, power demand constraints and variables range constraints of the proposed utility system are given in equation (6)-(8)(Zhao and You, 2019).

$$W_t^E + W_t^{ST} \geq W_t^{Demand}, \forall t \quad (6)$$

$$\sum_i f_{le,i}^{in} - \sum_j f_{le,j}^{out} \geq d_{le}, le \in \{HS, MS, LS\} \quad (7)$$

$$x^{\min} \leq x \leq x^{\max} \quad (8)$$

### 3. Data-Driven DRJCC Model for the Utility System

#### 3.1 Data-driven uncertainty sets for DRJCC

The chance-constrained approach can be applied to control the system reliability to a predefined level directly, and help to decide the optimal solutions. The distributionally robust chance-constrained approach over Wasserstein ambiguity set, defined in equations (9) and (10), is presented (Ho-Nguyen et al., 2021) to handle this problem. The ambiguity sets  $F_N(\theta)$  are sets of probability measures and defined as the  $\theta$ -radius Wasserstein ball of distributions around the empirical distribution  $\hat{\mathbb{Q}}_N$ . It ensures that all probability distributions of uncertain constraints satisfy with a given probability threshold within the selected Wasserstein distance from the empirical distribution.

$$d_W(\mathbb{Q}, \mathbb{Q}') := \inf_{\Pi} \left\{ \begin{array}{l} \mathbb{E}_{(\tilde{\mathbf{u}}, \tilde{\mathbf{u}}') \sim \Pi} [\|\tilde{\mathbf{u}} - \tilde{\mathbf{u}}'\|_*], \\ \Pi \text{ has marginal distributions } \mathbb{Q}, \mathbb{Q}' \end{array} \right\} \quad (9)$$

$$F_N(\theta) := \left\{ \mathbb{Q} : d_W(\hat{\mathbb{Q}}_N, \mathbb{Q}) \leq \theta \right\} \quad (10)$$

However, the uncertainty involves three levels of steam demand constraints, which can be considered as a joint chance constraint. The joint chance constraint with right hand side uncertainty is reformulated as an individual chance constraint by enforcing the worst-case CVaR approximation method (Chen et al., 2022). The set (11) with demand uncertainty is reformulated as (12).

$$S(\mathbf{x}) := \left\{ \mathbf{x} : \mathbf{b}_p^T \tilde{\mathbf{u}}_i + d_p - \mathbf{a}_p^T \mathbf{x} > 0, p \in [P] \right\} \quad (11)$$

$$\chi_{DR}(S) := \left\{ \mathbf{x} \in \mathcal{X} : \max \left\{ \begin{array}{l} \exists t \geq 0, \mathbf{r} \geq \mathbf{0}, \\ 0, \min_{p \in [P]} \frac{\mathbf{b}_p^T \tilde{\mathbf{u}}_i + d_p - \mathbf{a}_p^T \mathbf{x}}{\|\mathbf{b}_p\|_*} \end{array} \right\} \geq t - r_i, i \in [N], \right. \\ \left. \varepsilon t \geq \theta + \frac{1}{N} \sum_{i \in [N]} r_i \right\} \quad (12)$$

where  $\mathbf{a}_p \in \mathbb{R}^K$ ,  $\mathbf{b}_p \in \mathbb{R}^L$ ,  $d_p \in \mathbb{R}$  for all  $p \in [P]$ , and  $\|\cdot\|_*$  is the dual norm (Boyd and Vandenberghe, 2006).  $\theta$  is used to adjust the size of Wasserstein ball.  $\varepsilon$  is the desired safety factor between 0 and 1, which requires a group of  $m$  inequalities affected by uncertainty jointly satisfied the probability of at least  $1 - \varepsilon$ .

#### 3.2 Multi-objective optimization with DRJCC framework

We use the weighted-sum method to find the Pareto frontier (Deb and Deb, 2014), the operating cost and environment impact objectives are formulated as follows,

$$\min \lambda \text{COST} + (1-\lambda) \text{IMPACT} \tag{13}$$

where  $\lambda$  is the weighting coefficient and satisfying  $\lambda \in (0,1)$ . The solutions of the multi-objective problem will strongly depend on the changes of weighting coefficient.

We present the DRJCC formulation considering uncertain steam demands distributions (Chen et al., 2022; Xie, 2021). All constraints involving demands  $\tilde{d}$  are reformulated in the dual form of DRJCC and shown as follows.

$$\varepsilon t \geq \theta + \frac{1}{N} \sum_{i \in [N]} r_i, \tag{14}$$

$$M(1 - z_i) \geq t - r_i, i \in [N], \tag{15}$$

$$\sum_{i \in [N]} z_i \leq \lfloor \varepsilon N \rfloor, \tag{16}$$

$$\left( \sum_t a_{p,t}^{in} f_t^{in} + a_{p,t}^{ext} f_t^{ext} \right) + \sum_j a_{p,j}^M (1 - y_j) F_j^S + \sum_{lv} (a_{p,lv}^{in} f_{lv}^{in} + a_{p,lv}^{out} f_{lv}^{out}) - d_{p,i} \Big) / \|m_p\|_* \tag{17}$$

$$+ (d_{p,i} - q_p) / \|m_p\|_* \geq t - r_i, i \in [N]_p, p \in [P],$$

$$\left( \sum_t a_{p,t}^{in} f_t^{in} + a_{p,t}^{ext} f_t^{ext} \right) + \sum_j a_{p,j}^M (1 - y_j) F_j^S + \sum_{lv} (a_{p,lv}^{in} f_{lv}^{in} + a_{p,lv}^{out} f_{lv}^{out}) \Big) / \|m_p\|_* \geq t, \tag{18}$$

$$p \in [P],$$

$$f_t^{in, \min} \leq f_t^{in} \leq m_t^{in, \max}, \forall t \in T, \tag{19}$$

$$f_t^{exh, \min} \leq f_t^{in} - f_t^{ext} \leq f_t^{exh, \max}, \forall t \in T \tag{20}$$

$$\mathbf{z} \in \{0,1\}^N, t \geq 0, \mathbf{r} \geq 0. \tag{21}$$

Then, the multi-objective problem with joint demand uncertainties is converted into a deterministic MINLP problem, which can be solved by the existing solvers easily.

### 4. Case study

The case of the utility system with four steam grades (SS, HS, MS, LS) for an ethylene plant is presented (Zhao et al., 2014). There are three boilers, four extractions turbines, sixteen backpressure turbines with backup motors, two let-down valves in the given utility system. The demand parameters are collected from the process historical database. The data is not uniformly distributed over a specific range of operating conditions, which can be regarded as a multi-modal, interrelated and asymmetric uncertain parameter set. The superstructure of the utility system and uncertain parameters are given in figure 1.

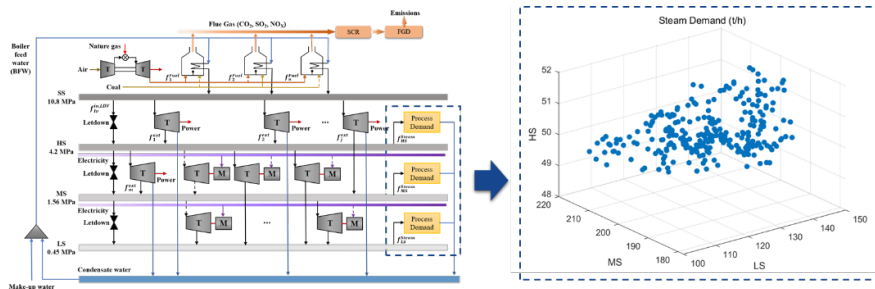

Figure 1. The uncertainty parameters from historical operation data.

Resources consumed by the system and their prices are shown in Table 1. The environmental impact categories and indicators are obtained from the CLCD and openLCA (Ciroth, 2007; Liu et al., 2010).

Table 1 The resources consumed in the system.

	Coal (ton)	Nature gas (ton)	Electricity (kWh)	Water (ton)	Limestone (ton)	Ammonia (ton)
Price (CNY)	800	2700	0.55	0.16	350	3500

We test four joint risk tolerance  $\varepsilon$  which are 0.05, 0.1, 0.15 and 0.2 and set the Wasserstein radius to  $\theta \in \{0.05, 0.1, 0.15, 0.2\}$ . All problems are solved with BARON solver. Figure 2 shows the trend of cost and environmental impact with changes of  $\varepsilon$  and  $\theta$ .

Figure 2. The trend of cost and environmental impact.

The operating cost and environmental impact increase along with the system reliability requirements when the value of risk tolerance decreased from 0.1 to 0.05. On the other hands, extending the Wasserstein radius also increases the economic and environmental burden, which means that the conservation of the solution increases.

Figure 3 shows the Pareto frontier of the multi-objective solutions when  $\varepsilon=0.05$  and  $\theta=0.05$ . Points A and C represent the minimal operating cost environmental impact solutions. Point B is the optimal solution which is supported by the TOPSIS method.

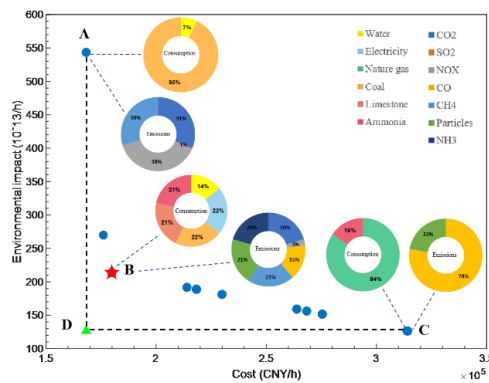

Figure 3. The Pareto frontier of operating cost and environmental impact.

Furthermore, the resources consumption and emissions of different solutions are shown in the pie charts. The total cost ranges from 168,220 to 314,176 CNY per hour, and environmental impact ranges from 126.53 to 543.42 units per hour.

## 5. Conclusion

An improved DRJCC method with Wasserstein ambiguity set framework was proposed for the utility system optimization based on LCA. Under steam demand uncertainties, it sets economic and environmental objectives and optimizes chance constraints to obtain a trade-off between operating cost, and environmental impact. A case study of utility system in ethylene plant is presented to verify the effectiveness of the proposed method.

### Abstract

Chemical process simulation and optimization have the characteristics of high-dimensional and non-linear, which make the simulation higher computational cost or even more difficult to converge. Using surrogate models to replace mechanistic models is an effective way to reduce computational complexity and ensure the accuracy of results. Though the Kriging surrogate model has a stronger nonlinear approximation, it is still difficult to deal with high-dimensional problems. Therefore, this paper investigates the parallel EGO algorithm integrated with the surrogate model, and applies the model to the typical chemical process. Taking eight multi-peak test functions as test cases, it is found that the accuracy and convergence speed of the parallel EGO algorithm is obviously improved. Finally, it is applied to the study case of the two-stage ammonia absorption refrigeration process. The results show that the simulation error is less than 0.01%, and the optimization time is reduced from 9846 s to 3705 s.

**Keywords:** surrogate model; parallel efficient global optimization algorithm; Multi-parameter optimization; process simulation.

### 1. Introduction

Process simulation and optimization are the basis for achieving energy saving and emission reduction in the chemical field. Due to the complex engineering design problems with high-dimensional and nonlinear characteristics, the optimization of operating parameters using just traditional process simulation software is often ineffective. To effectively solve this problem, some researchers [1-2] proposed building surrogate models relying on data-driven. The computationally fast surrogate model was used to replace the computationally time-consuming mechanism model, thus greatly reducing the number of computations of time-consuming objectives and constraints. The surrogate models [3-7] commonly used in engineering are polynomial response surface (PRS), radial basis function (RBF), artificial neural network (ANN), support vector regression (SVR), and Kriging surrogate model. Rosma et al [8-9] established PRS and RBF surrogate models for turbines and complex fitness functions and used particle swarm optimization algorithms to dynamically update the models. Yang et al [10] used the ANN surrogate model to optimize the process operation parameters of the crude oil distillation unit to maximize the oil production rate. Singh et al [11] used three surrogate models (SVR, RBF, Kriging) combined with an efficient multi-objective optimization algorithm to identify the Pareto frontier of cyclone separator design with the minimum number of simulations. Compared with the traditional optimization methods, the above-mentioned surrogate-based optimization algorithms can reduce the time-consuming simulation computation in the optimization process. However, this optimization

algorithm is too dependent on the sample sets and often requires a large number of samples to be fitted or trained to obtain more reliable results.

To solve the shortcomings of the above optimization algorithms, Jones et al [12] proposed the EGO (Efficient Global Optimization) algorithm. This approach uses fewer sample points to train the Kriging surrogate model and continuously selects the point with the largest value of the EI (Expected Improvement) function as the update point during each iteration. The Kriging surrogate model is continuously updated to find the global optimal solution. This approach can be used to solve the black-box problem but also to speed up the convergence and obtain higher accuracy and computing efficiency.

Based on the superiority of the EGO algorithm, the parallel EGO (Pseudo Efficient Global Optimization) algorithm is proposed based on it in this paper. The algorithm uses parallel computing techniques to select multiple update points for computation during each iteration, thus speeding up the optimization speed of the EGO algorithm. It was applied to 8 multi-peak test functions and the two-stage ammonia absorption refrigeration operation optimization case. The results show that the approach can optimize all variables online in real-time with high accuracy and efficiency, which has a greater value for engineering applications.

## 2. Parallel EGO algorithm

### 2.1 Kriging surrogate model

The Kriging model [13] consisting of  $m$  samples has a total of  $2m+2$  parameters, which can be obtained by the maximum likelihood estimation [14]. Finally, the predicted value and variance of any point  $x$  can be obtained:

$$\begin{cases} \hat{y} = \hat{\mu} + r^T R^{-1}(y - \hat{\mu}) \\ s^2(x) = \hat{\sigma}^2 \left[ 1 - r^T R^{-1} r + \frac{(1 - R^{-1} r)^2}{R^{-1}} \right] \end{cases} \quad (1)$$

### 2.2 EI criterion

For the unknown point, it can be regarded as a normally distributed random variable with mean  $\hat{y}(x)$  and standard deviation  $s(x)$ , it can be expressed as  $Y(x) \sim N(\hat{y}(x), s(x))$ . If the minimum objective function value in the current sample point is  $f_{\min}$ , then the improvement of the unknown point to the current optimal solution can also be regarded as a random variable:

$$I(x) = \max(f_{\min} - Y(x), 0) \quad (2)$$

Solving the mathematical expectation of  $I(x)$  can get the expression of the EI function as:

$$EI(x) = (f_{\min} - \hat{y}(x)) \Phi \left( \frac{f_{\min} - \hat{y}(x)}{s} \right) + s(x) \phi \left( \frac{f_{\min} - \hat{y}(x)}{s} \right) \quad (3)$$

where  $\phi$  and  $\Phi$  represent the probability density function and the cumulative distribution function of the standard normal distribution. It can be found from equation (3) that the EGO algorithm mainly searches for the minimum value  $\hat{y}(x)$  or maximum value  $s(x)$  as an update point by maximizing the EI function in each iteration, and finds the optimal solution after several iterations.

### 2.3 PEI criterion

The main role of the influence function is to approximate the changes brought to the EI function when iteratively updating the Kriging surrogate model, and its equation is as follows:

$$IF(x, x^{(h)}) = 1 - Corr[\varepsilon(x), \varepsilon(x^{(h)})] \quad (4)$$

where  $x$  is an arbitrary unknown point and  $x^{(u)}$  is an update point. The PEI (Pseudo Expected Improvement) function is constructed by multiplying the initial EI function by the impact function of the update point, and its equation is as follows:

$$\begin{aligned}
 PEI(x, q-1) &= EI(x) \cdot IF(x, x^{(m+1)}) \cdot IF(x, x^{(m+2)}) \cdots IF(x, x^{(m+q-1)}) \\
 &= EI(x) \cdot \prod_{i=1}^{q-1} [1 - \text{Corr}[\varepsilon(x), \varepsilon(x^{(m+i)})]] \\
 &= EI(x) \cdot \prod_{i=1}^{q-1} \left[ 1 - \exp\left(-\sum_{k=1}^d \theta_k |x_k - x_k^{(m+i)}|^{p_k}\right) \right]
 \end{aligned}
 \tag{5}$$

From the above derivation, it is clear that the parallel EGO algorithm can achieve parallel computation by maximizing the PEI function to get  $q$  update points in each iteration. This provides a new breakthrough for solving time-consuming chemical simulation optimization problems and improves optimization efficiency.

### 3. Numerical experiments

The proposed parallel EGO algorithm is compared with the EGO algorithm. The number of iterations required to find the global optimal solution for eight representative classical multi-peaked test functions is shown in Figure 1. Each data point in the figure was obtained by averaging each point by testing 10 times using 10 different initial designs.

Fig.1 Iteration history curves of different optimization algorithms on test functions. (a) Six-hump. (b) Branin. (c) GoldPrice. (d) Hartman3. (e) Shekek15. (f) Shekek17. (g) Shekek10. (h) Hartman6.

From Figure 1, it can be found that the proposed parallel EGO algorithm performs significantly better than the EGO algorithm no matter how many update points are selected in each iteration. Meanwhile, the convergence speed is significantly faster with the number of update points increasing.

It can be found from the time variation curves in Figure 2 that with guaranteed accuracy, the proposed parallel EGO algorithm is higher efficiency and stronger adaptability when more points are added in each circulation.

Fig.2 Running time of different multi-peak test functions

## 4. Multi-parameter optimization of two-stage ammonia absorption refrigeration

### 4.1 process description

The two-stage ammonia absorption refrigeration unit is an important part of the low-temperature methanol washing waste heat and cooling power co-generation system. Based on this, Aspen Plus is used to model and simulate it. The flowchart of its is shown in Figure 3.

Based on the analysis of key parameters by Liu et al [15], 15 decision variables to be optimized were determined. And the coefficient of performance COP (the ratio of evaporator load to the sum of flasher and distillation tower load) was chosen as the optimization objective for optimization.

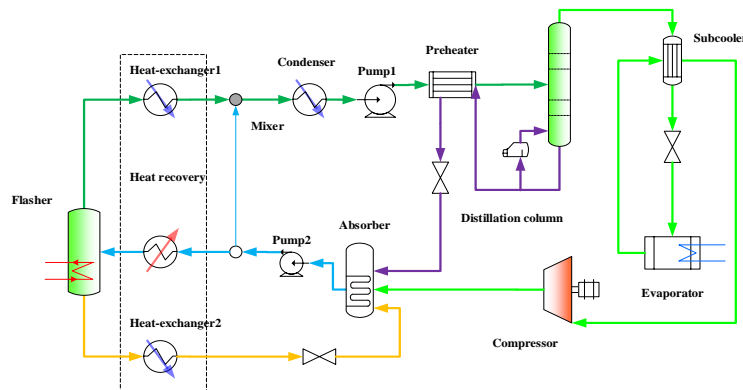

Fig.3 Schematic diagram of the two-stage ammonia absorption refrigeration process

### 4.2 Results and Discussions

The predicted values using the Kriging surrogate model are compared with the actual values as shown in Figure 4. The mean square error of the model is  $2.35 \times 10^{-3}$ , indicating that the constructed Kriging surrogate model predicts very accurately and can replace the original two-ammonia absorption refrigeration simulation model. Meanwhile, the time required for the numerical calculation of the original simulation model is 21013s, while Kriging only requires 0.383s, so the calculation time is significantly reduced.

Fig.4 Comparison between predicted and actual values of Kriging model

The iteration curves of the standard EGO algorithm and the parallel EGO algorithm are shown in Figure 5. It can be found from the figure that the standard EGO algorithm requires 330 iterations to converge. In contrast, for the parallel EGO algorithm, the number of iterations gradually decreases to 29 as the number of points updated per circulation increases. The optimization convergence speed is improved by 91.2%. The results show that the parallel EGO algorithm converges faster than the standard EGO algorithm; the optimal solution obtained by the proposed parallel EGO algorithm is also better than the standard EGO algorithm when 600 iterations are ended.

Fig.5 Optimization iteration curves

Fig.6 Running time

The relationship that the computation time required by each algorithm relative to the number of update points per iteration is shown in Figure 6. It can be found that under the condition that the maximum number of iterations is set to 600, the time required by the standard EGO algorithm is 9846s, and the time required by the parallel EGO algorithm is 5898-3705s. It is obvious that the parallel EGO algorithm requires less computation time than the standard EGO algorithm, and the operation efficiency is improved by 62.37%.

## 5. Conclusions

This paper proposed an online real-time parallel EGO optimization algorithm based on Kriging surrogate model for solving computationally intensive and time-consuming optimization problems of chemical process operations. The proposed parallel EGO algorithm uses the PEI criterion to select multiple update points in each iteration for parallel computation. The algorithm is tested on eight test

functions of dimensions 2 to 6. The experimental results show that the parallel EGO algorithm proposed in this paper can significantly improve the convergence speed of the standard EGO algorithm; it has higher efficiency and robustness than the standard EGO algorithm in all eight test problems. In addition, when the proposed parallel EGO algorithm is applied to the parameter optimization of two-stage ammonia absorption refrigeration, under the condition of ensuring higher accuracy, using relatively less training data to approach the multi-parameter optimal solution, the obtained solution is also significantly better than the standard EGO algorithm. The convergence speed is improved by 91.2% compared with the standard EGO algorithm.

## Abstract

Water availability is of crucial importance to industry; therefore, optimal management of this resource has garnered increased importance. This work focuses on industrial water treatment networks (WTN) optimal design models, and can be divided in two sections. The first section addresses the modification of typical mathematical routines to implement efficient and rigorous effluent formulations, using an integer disaggregated formulation. The second section considers network piping expenditures, employing a two-step methodology to account for the discontinuous classes of commercialized piping.

**Keywords:** WTN optimization, MINLP, effluent modelling, piping, disaggregated model

## 1. Introduction

WTN models have been the subject of various publications in the past (e.g., Galan and Grossmann, 1998), although the effluent description has been somewhat simplified. Field observation of WTNs brings various additional features: a network can have multiple discharges; these can account for a significant fraction of the network OPEX; and they can be tariffed according to discontinuous concentration classes. Patrocínio *et al.* (2022) considers more detailed modelling of effluents employing indicator variables. This formulation has the downside of introducing new non-linearities in the mathematical model. In this work, a disaggregated formulation is suggested to rigorously model the effluent section of WTNs.

The second section of this work addresses the introduction of piping related expenses in the optimal grassroots design of WTNs, considering the nature of the diameter classes in which pipes are commercialized. Some authors (Alnouri *et al.*, 2014; Caballero and Ravagnani, 2019) already consider this characteristic. In this work, a two-step disaggregated methodology is proposed to model these equipment expenses, according to discontinuous pipe diameter classes.

## 2. WTN disaggregated model

The water treatment network superstructure (Figure 1) is composed by water flow producer nodes (set  $i$ ) and consumer nodes (set  $j$ ). Subsets of wastewater sources ( $ww \subset i$ ), treatment units ( $tu \subset i \wedge tu \subset j$ ) and multiple effluents ( $ef \subset j$ ) are defined. Superstructure connections between the same treatment unit are forbidden (with the set  $par_{i,j}$ ). Eq. (1) models that outlet flow from nodes  $i$  ( $F_i^{nd}$ ) is the sum of flows from  $i$  to  $j$

( $F_{i,j}$ ) and eq. (2) models the inlet flow in nodes  $j$ . Eq. (3) establishes that the flow from wastewater sources is defined by the parameter  $f_{ww_i}$ .

Figure 1 WTN superstructure.

The problem is further specified by a set of network contaminants (set  $co$ ), with eq. (4) as the mass balance of contaminants in the inlet of consumer nodes ( $C_{j,co}^{in}$ ,  $C_{i,co}^{out}$  are the inlet and outlet concentration of nodes  $j$  and  $i$ ). Eq. (4) contains the only non-linearity of the model, as two continuous variables are multiplied. From eq. (5), the outlet concentration of wastewater sources is fixed by the parameter  $c_{i,co}^{outWW}$  and eq. (6) defines the removal of contaminants in treatment units, through parameter  $rr_{j,co}$ . Eq. (7) establishes an upper limit for the inlet concentration of  $j$  ( $c_{j,co}^{lim}$ ). Note that each treatment and effluent node may contain inlet concentration limits. Effluents can be further classified into regular or special effluents ( $se \subseteq j$ ). The costs of the former are simply a tariff ( $cost_j^{RE}$ ) multiplied by the effluent flow, and special effluent costs are related to discontinuous contaminants concentration classes (set  $tcl$ ) of specific contaminants ( $tar \subseteq co$ ), with the highest activated class as the one tariffed. Here a disaggregated formulation for modelling the discharge of special effluents is used, avoiding the non-linearities resulting from the multiplication of integer and continuous variables. The inlet flow and concentration in the special effluent nodes are partitioned ( $F_{j,tcl}^{nd-tcl}$ ,  $C_{j,co,tcl}^{cl}$ ), according with the tariff classes (eqs. (8)-(9)) and only one partition is activated (eq. (10)), introducing the binary variable  $Y_{j,tcl}^{tcl}$ . Eqs. (11)-(12) guarantee that the concentration for the activated class is lower or equal to the upper bound concentration for this class ( $ub_{j,co,tcl}^{cl}$ ). Eqs. (13)-(14) assign the inlet flow of the node to the activated class, using an upper bound flow for node  $j$  ( $f_j^{nd-up}$ ). The lowest possible class is activated, as higher cost tariff classes are penalized by the objective function (eq. (15)). This function includes the operational costs of the treatment units ( $cost_j^{treat}$ ) multiplied by their inlet flow, and the costs of regular and special effluents.

$$F_i^{nd} = \sum_{j|par_{i,j}} F_{i,j}, \forall i \quad (1)$$

$$F_j^{nd} = \sum_{i|par_{i,j}} F_{i,j}, \forall j \quad (2)$$

$$F_i^{nd} = f_{ww_i}, i \in ww \quad (3)$$

$$\sum_{i|par_{i,j}} F_{i,j} C_{i,co}^{out} = F_j^{nd} C_{j,co}^{in}, \forall j, \forall co \quad (4)$$

$$C_{i,co}^{out} = c_{i,co}^{outWW}, i \in ww, \forall co \quad (5)$$

$$C_{j,co}^{in} rr_{j,co} = C_{j,co}^{out}, j \in tu, \forall co \quad (6)$$

$$C_{j,co}^{in} \leq c_{j,co}^{lim}, \forall j, \forall co \quad (7)$$

$$C_{j,co}^{in} = \sum_{tcl} C_{j,co,tcl}^{cl}, j \in se, \forall co \quad (8)$$

$$F_j^{nd} = \sum_{tcl} F_{j,tcl}^{nd-tcl}, j \in se \quad (9)$$

$$\sum_{tcl} Y_{j,tcl}^{cl} = 1, j \in se \quad (10)$$

$$C_{j,co,tcl}^{cl} \geq 0, j \in se, co \in tar, \forall tcl \quad (11)$$

$$C_{j,co,tcl}^{cl} \leq ub_{j,co,tcl}^{cl} Y_{j,tcl}^{tcl}, j \in se, co \in tar, \forall tcl \quad (12)$$

$$F_{j,tcl}^{nd-tcl} \geq 0, j \in se, \forall tcl \quad (13)$$

$$F_{j,tcl}^{nd-tcl} \leq f_j^{nd-up} Y_{j,tcl}^{cl}, j \in se, \forall tcl \quad (14)$$

$$Cost^{Network} = \sum_{j \in tu^j} cost_j^{treat} F_j^{nd} + \sum_{\substack{j \notin tu^j \\ j \in se^j}} cost_j^{RE} F_j^{nd} + \sum_{\substack{j \in se^j \\ tcl}} cost_{j,tcl}^{SE} F_{j,tcl}^{nd-tcl} \quad (15)$$

### 3. Piping investment and operational expenditures

The grassroots design of WTNs must account for piping expenses, with a cost that depends on the flows and distances between the network nodes. Furthermore, pipes are manufactured according to discontinuous diameter classes. This work proposes a two-stage procedure to incorporate these discontinuous classes in the WTN design model, performing a correspondence between the flows and the pipe classes costs and incorporating that correspondence in a mathematical optimization model, using a disaggregated strategy.

#### 3.1. Pre-processing stage

The pre-processing stage consists in an *a priori* correspondence between flows and the pipes cost. Firstly, the pipe optimal diameter ( $d_p^{opt}$  - Peters *et al.*, 2003) is computed (eq. (16)) using a set of  $p$  wastewater flows values ( $F_p$ ). Secondly, the optimal diameter is corresponded with the commercial pipe diameter, with a simple mixed integer linear model – eqs. (17)-(19), where  $d_p^{opt}$  is assigned to a pipe class (set  $pcl$ ), using a binary variable  $Z_{p,pcl}^{Pipe-Class}$ . Eq. (17) forces the assigned class diameter to be greater-or-equal than the optimal diameter, eq. (18) ensures that one pipe class is corresponded to each flow  $p$ , and the objective function (eq. (19)) imposes that the difference between the assigned class diameter and optimal diameter is as small as possible.

$$d_p^{opt} = \left( \frac{F_p}{3600} \right)^{0.45} 0.593, \forall p \quad (16)$$

$$Z_{p,pcl}^{Pipe-Class} (d_{pcl}^{class} - d_p^{opt}) \geq 0, \forall p, \forall pcl \quad (17)$$

$$\sum_{pcl} Z_{p,pcl}^{Pipe-Class} = 1, \forall p \quad (18)$$

$$\min \sum_{p,pcl} Z_{p,pcl}^{Pipe-Class} (d_{pcl}^{class} - d_p^{opt}) \quad (19)$$

The correspondence obtained will be similar to Figure 2, relating individual sch. 40 pipe costs, (per meter length) for several inner diameter classes.

Figure 2 Individual pipe costs as a function of flow.

### 3.2. WTN disaggregated piping costs model

The proposed disaggregated technique is similar to the one presented for special effluents (section 2). The flow between nodes  $i,j$  is partitioned ( $F_{i,j,pcl}^{pcl}$ ) regarding the number of piping classes (eq. (20)). A new binary variable ( $Y_{i,j,pcl}^{pipe}$ ) is introduced to assign  $F_{i,j,pcl}^{pcl}$  to a class  $pcl$  (eqs. (21)-(22)), using the lower and upper bounds for each class ( $f_{pcl}^{lb}$ ,  $f_{pcl}^{ub}$ ). Eq. (23) assures that, at most, one class is activated. The inequality operator is important as it allows that a null flow does not activate a piping class. Yearly costs of installing a pipe in connection  $i,j$  ( $Cost_{i,j}^{Pipe-install}$ ) are modelled by eq. (24), considering an annualization factor ( $af$ ), labor/material cost factors ( $bm^{Pipe}$ ), distance between nodes ( $d_{i,j}^{nd}$ ) and cost of activated pipe class ( $cost_{pcl}$ ). Eq. (25) expresses the operational costs of pipe between nodes  $i,j$  ( $Cost_{i,j}^{Pipe-oper}$ ), where a maintenance factor ( $of^{Pipe}$ ) is multiplied by  $Cost_{i,j}^{Pipe-install}$ .

$$F_{i,j} = \sum_{pcl} F_{i,j,pcl}^{pcl}, \forall i, \forall j \quad (20)$$

$$F_{i,j,pcl}^{pcl} \geq f_{pcl}^{lb} Y_{i,j,pcl}^{pipe}, \forall i, \forall j, \forall pcl \quad (21)$$

$$F_{i,j,pcl}^{pcl} \leq f_{pcl}^{ub} Y_{i,j,pcl}^{pipe}, \forall i, \forall j, \forall pcl \quad (22)$$

$$\sum_{pcl} Y_{i,j,pcl}^{pipe} \leq 1, \forall i, \forall j \quad (23)$$

$$Cost_{i,j}^{Pipe-install} = af \cdot bm^{Pipe} \cdot d_{i,j}^{nd} \sum_{pcl} Y_{i,j,pcl}^{pipe} \cdot cost_{pcl}, \forall i, \forall j \quad (24)$$

$$Cost_{i,j}^{Pipe-oper} = of^{Pipe} Cost_{i,j}^{Pipe-install}, \forall i, \forall j \quad (25)$$

$$TCost^{Yearly} = H \cdot Cost^{Network} + \sum_{i,j} (Cost_{i,j}^{Pipe-install} + Cost_{i,j}^{Pipe-oper}) \quad (26)$$

The original objective function is replaced by eq. (26), and total network cost is computed ( $TCost^{Yearly}$ ) considering the yearly operation of the wastewater network (multiplying the original WTN model objective function by the number of operational hours, in a year –  $H$ ), and adding the piping yearly installation and operational expenditures.

### 4. Application Examples

The results presented in this section were obtained using an AMD Ryzen 7 4800H computer with 16 GB of RAM, and GAMS 40.3.0.

#### 4.1. Large industrial example of Galan and Grossmann (1998)

The last example of Galan and Grossmann (1998) was used to create the first application example of these techniques. The original problem specification was extended to account for different treatment unit operational expenditures (Table 1) and 2 effluent nodes with different limiting concentrations (Table 2). Effluent 1 is a special effluent with different concentration tariff classes (Table 3). Effluent 2 has a discharge cost of 0.1 €/t.

Table 1 Treatment units operating cost.

Unit	X1	X2	X3	X4	X5
Cost (€/t)	0.1	0.18	0.25	0.25	0.8

Using the WTN disaggregated model, the optimal network has an hourly operation expenditure of 106.97 €/hr, and the special effluent EF1 represents 53.8% of the total network cost, with 128.1 t/hr and concentrations within Class 1. Effluent EF2 has a flow of 12.9 t/hr, and corresponds to 1.2% of the total network cost. Here, the *ANTIGONE* solver was used, with a time limit of 1 hour, resulting in an optimality gap of 20.8%.

To consider the pipe investment together with the operational expenditures, using the procedure of section 3, distances between nodes were randomly generated within [10;300] meters, for correspondences  $(ww^{nd};tu^{nd})$  and  $(ww^{nd};ef^{nd})$ , and [5;50] meters for correspondences  $(tu^{nd};tu^{nd'})$  and  $(tu^{nd};ef^{nd'})$ . Piping classes were constructed based on Figure 2, but aggregating several classes and using median cost values as represented in Table 4. *af* was assumed as 0.207, *bm<sup>Pipe</sup>* as 17 (per recommendation of Woods, 2007), *of<sup>Pipe</sup>* as 0.2 (Peters *et al.*, 2003) and *H* as 8000 operating hours.

Table 2 Effluents concentration limits.

	C1 (ppm)	C2 (ppm)	C3 (ppm)	C4 (ppm)	C5 (ppm)	C6 (ppm)
ef1	100	100	100	100	100	100
ef2	0	0	200	500	200	0

Table 3 ef1 tariff classes.

	Cost (€/t)	C2 (ppm)	C3 (ppm)	C4 (ppm)
c11	0.44	[0;50[	[0;30[	[0;30[
c12	0.54	[50;85[	[30;55[	[30;55[
c13	0.72	[85;100]	[55;100]	[55;100]

When computed *a posteriori* for the solution of the WTN disaggregated model, piping investment and operational expenditures correspond to an annual network cost of 975.1 k€. Utilising the WTN disaggregated model with piping costs included, the optimal solution found improves 2.75%, with an annual network cost of 948.3 k€. The local solver *SBB* was used in this case, with an imposed optimality gap of 0.1%, requiring 11.15 hours of wall clock time for this solution.

Table 4 Pipe classes costs and flow intervals.

	pcl1	pcl2	pcl3	pcl4
Cost (€/m-l)	6.98	12.51	16.13	43.02
F (t/hr)	[0;9.4]	]9.4;24.4]	]24.4;39.5]	]39.5;141]

$d_{i,j}^{nd}$  is a crucial parameter regarding the savings reported by the WTN disaggregated piping costs model (in comparison to the computation of those expenditures *a posteriori* with the WTN disaggregated model), and the computational solving time. When the originally generated distance is decreased by 20% ( $0.8 d_{i,j}^{nd}$ ), the savings and wall clock computation time of the WTN disaggregated piping costs model drop to 1.96% and 3.03 hours. In a 30% decrease ( $0.7 d_{i,j}^{nd}$ ), the drop is to 1.5% and 1.43 hours.

#### 4.2. Sines Refinery wastewater treatment network

The proposed methodologies were applied to an industrial scenario, using data from the Sines Refinery wastewater network, in Portugal, composed by 11 wastewater sources, 5 treatment units, two effluent nodes and 6 contaminants. One of the effluent lines is a special effluent node, with 5 tariff classes, regarding 5 of the contaminants, and the costs associated with that node account for 42% of the WTN expenditures. Applying the optimization model of the first section achieves a 33.6% reduction in the total wastewater network costs. The solver utilized was *ANTIGONE*, with a wall clock time limit of 1 hour, resulting in an optimality gap of 14.2%.

To account for piping expenditures,  $d_{i,j}^{nd}$  was obtained with the refinery plot plan and, using a similar procedure to the previous example, 5 pipe classes were considered, as well as the parameters regarding  $af$ ,  $bm^{Pipe}$ ,  $of^{Pipe}$  and  $H$ . When these expenditures are considered, posteriorly and independently of the optimization routine, WTN savings drop to 7.9%. Optimizing the network using the WTN disaggregated piping costs model allows a further increase of WTN savings to 10.4% (with local solver SBB, and an imposed optimality gap of 0.1%, expending 3.04 hours of wall clock time).

## Conclusion

This work demonstrates that WTN effluents tariffs cannot be disregarded, in WTN optimization models, focusing in the relevance of discontinuous effluent discharges, as demonstrated by the example of Sines Refinery. Furthermore, piping expenditures are modelled in a more realistic manner, avoiding introducing further non-linearities in the routines. The proposed methodology has the downside of demanding a moderate degree of computational effort, which should be addressed in future work.

## Abstract

Reducing our environmental impact is the greatest challenge of our time and affects all areas of the chemical, biochemical, and pharmaceutical industries. The use of sustainable and biodegradable solvents in downstream processes, such as deep eutectic solvents (DESs), is one essential step in this direction. While many studies have focused on the investigation of- the thermo-physical properties of DESs, relatively little attention has been paid to solvent regeneration in the context of a closed-loop process, assuming a simple recovery due to the negligible vapor pressure of the DES. In order to evaluate the suitability of this assumption, the current work performs an optimization-based process design for the recovery of furfural from a diluted fermentation broth by liquid-liquid extraction, comparing a previously screened DES with toluene as an established organic solvent. The comparison reveals important limitations of the DES due to considerable water content in the raffinate and the high boiling point resulting in a more complex and energy-demanding process.

**Keywords:** process optimization, liquid-liquid extraction, distillation, solvent selection, green solvent.

## 1. Introduction

While deep eutectic solvents (DESs) were first proposed as an alternative to ionic liquids less than 20 years ago (Abbott et al., 2003), with 200 publications during the first ten years (Smith et al., 2014), publications have rapidly increased to more than 7000 in the last ten years, primarily addressing synthesis and solvent properties. DESs can be considered as molten salts with a eutectic point near or below room temperature due to hydrogen bonding and have been promoted with excellent application potential in the chemical, biochemical, and pharmaceutical industries (Hansen et al., 2021), showing low vapor pressure, production cost, and toxicity, as well as good biodegradability. These characteristics deem DESs environmentally friendly and cost-effective competitors to established organic solvents and ionic liquids. Most studies on fluid separation process applications focus on the investigation of thermodynamic properties, such as vapor pressures, densities, boiling and decomposition temperatures, or partition coefficients and selectivities (Salleh et al., 2017). On the other side, studies on the evaluation of closed-loop process performance, considering solvent recovery, of DES-based processes are still scarce. Larriba et al. (2018) studied the dearomatization of gasoline by liquid-liquid

extraction with six different DESs based on choline chloride. Based on experimental investigations paired with simulation studies, they selected a promising sustainable alternative to commonly applied organic solvents. However, the study does not consider the investigation of a complete process flowsheet with solvent recovery and a closed recycle. Han et al. (2022) examined such a closed-loop flowsheet in Aspen Plus for the dehydration of acetonitrile with glycolic acid:choline chloride(3:1) by extractive distillation. They found a substantial cost reduction compared to the benchmark process considering ethylene glycol as solvent. Shang et al. (2019) studied the dehydration of ethanol by extractive distillation using choline chloride:urea(1:2) as mass separating agent. The results based on a closed-loop process indicate a potential reduction in the annualized costs as well as the energy consumption of the process.

While the low vapor pressure implies a simple thermal regeneration of the DES, the high boiling temperature and limitations regarding the degradation temperature are potentially detrimental factors that need to be considered for the closed-loop process, including solvent regeneration. To evaluate the tradeoff of these factors, a rigorous optimization of the closed-loop flowsheet, including solvent recovery, is required. In the current study, hybrid extraction-distillation processes for the purification of furfural from an aqueous fermentation broth using decanoic acid:thymol(1:1) as DES and toluene as established organic solvent are evaluated as optimal design problems. Furfural is widely applied as a herbicide, fungicide, and insecticide in agricultural production and a flavoring agent in the food industry (Yong et al., 2020). Additionally, Furfural is one of the top bio-based chemicals due to its numerous reaction products, like fuel additives and value-added chemicals (Yan et al., 2014).

## 2. Methodology

As a first step for the targeted evaluation, a suitable DES for the considered separation has to be identified. Thermodynamic properties need to be modeled before a comparison with the established organic solvent can be made based on rigorous model-based process optimization.

### 2.1. Selection of a Deep Eutectic Solvent

For liquid-liquid extraction, the applicability of a solvent is restricted by the acceptable loss in the raffinate stream, while the economic performance is strongly linked to the amount of solvent required for a feasible separation. Therefore, the distribution coefficient is commonly considered a key performance indicator for extraction performance in an early evaluation step. Thermal recovery of the solvent by means of distillation has to adhere to the boiling and degradation temperature of the DES, which may limit the operating range of a distillation column. Consequently, to prevent degradation and the resulting product pollution and loss of solvent, the DES needs a comparably high degradation temperature to enable an efficient solvent recovery.

For the current example of furfural purification, Dietz et al. (2019c) provide the necessary data for selecting a suitable DES. In an experimental investigation of ten different DESs, decanoic acid:thymol(1:1) (Deca-Thy) was identified as the solvent with the highest distribution coefficient for liquid-liquid extraction of furfural (Dietz, 2019a). Based on investigations of the thermal decomposition of comparable DESs (Dietz, 2019a), a degradation temperature of 190 °C was assumed for Deca-Thy, which is only slightly lower than the highest decomposition temperature reported by Dietz et al. (2019a), for dodecanoic acid:atropine(2:1). However, Deca-Thy provides a distribution coefficient that is about 12 times higher compared to dodecanoic acid:atropine(2:1). Thus, it is

selected as most interesting DES for the current application and compared with toluene, as widely applied benchmark organic solvent (Dietz, 2019c).

### *2.2. Thermodynamic Properties*

While the previously described data allows for an initial selection of promising solvent candidates, a variety of thermodynamic properties have to be modeled reliably for a model-based assessment of the respective processes. Besides the pure component ideal gas heat capacity, vapor pressure, and enthalpy of evaporation, which are needed to evaluate the energy balance and thermal regeneration in the hybrid extraction-distillation process, especially the binary interactions for the liquid-liquid and vapor-liquid equilibrium (LLE, VLE) have to be known.

Parameters for pure component properties and activity coefficient models for water, furfural, and toluene are available and exported from Aspen Plus databases DB-PURE32 and APV88 LLE-ASPEN/APV88 VLE-IG, respectively. For modeling the DES and its interactions, similar to other studies (Han and Chen, 2018; Dietz et al., 2019b; Dai et al., 2022), it is assumed that the DES can be modeled as a single pseudo component, for which the ideal gas heat capacity is estimated by the group contribution method by Joback and Reid (1987) for decanoic acid and thymol individually and averaged for the DES. The DIPPR equation for the ideal gas heat capacity is fitted to the obtained data for the process optimization. The vapor pressure is predicted using the perturbed-chain statistical associating fluid theory (PC-SAFT) (Gross and Sadowski, 2001) with the pure component parameters published by Dietz et al. (2019b) and a ratio-specific individual constituent approach. The extended Antoine equation is fitted to the predicted data and used in the optimization-based design. Based on the vapor pressure, the enthalpy of evaporation is assumed to be constant and calculated using the Clausius-Clapeyron equation.

In order to avoid the application of the comparably complex PC-SAFT model in the process optimization, the non-random two-liquid (NRTL) model is considered as a surrogate model to describe the LLE and VLE within the process optimization. Therefore, the NRTL parameters are fitted to predicted equilibrium data determined by the PC-SAFT model. The binary interactions of furfural and Deca-Thy are determined by regressing VLE data at pressures of 0.05, 0.1, and 0.2 bar to ensure a correct phase behavior at vacuum conditions around 0.1 bar. In contrast, the binary interactions of water and Deca-Thy are obtained by regressing LLE data at a pressure of 1 bar. The  $c_{ij}$  parameter is fixed at 0.3 and 0.2 for VLE and LLE regression, respectively.

### *2.3. Rigorous Process Optimization*

In order to perform a techno-economical evaluation of the processes with the considered solvents, toluene, and Deca-Thy, a rigorous superstructure optimization based on equilibrium-stage models is performed. The general process configurations do, however, differ due to the different solvent properties. Since toluene is light-boiling compared to furfural, it is obtained as the top product in the solvent recovery column (cf. Figure 1). In contrast, Deca-Thy is heavy boiling and, as such, recovered as the bottoms product in the solvent recovery column (cf. Figure 2). More importantly, furfural is the intermediate boiling component in this mixture. On the basis of the individual process structures, a superstructure model is built, allowing for individual sizing of the extraction column and the rectifying and stripping sections of the distillation column. The respective mathematical models are extended with constraints on product purities as well as sizing and costing models (Biegler et al., 1997), resulting in mixed-integer nonlinear programming (MINLP) problems for the techno-economical designs, which are solved by a series of successively relaxed nonlinear programming (NLP) problems with the respective equilibrium calculations performed via a set of external functions

(Skiborowski et al., 2015). The models and the polyolithic solution strategy are implemented in GAMS 34.3.0, and SNOPT is used to solve for local optimality.

### 3. Process Optimization

For both processes, a feed stream of 5 mol% furfural and 95 mol% water with a flow rate of 100 mol/s (about 7900 kg/h) is assumed. For the wastewater stream comprising the raffinate and the water-rich phase of the decanter, a furfural content  $x_{FF} < 0.01$  mol% is defined, and the product stream is constrained to a purity of  $x_{FF} > 99.9$  mol%. A depreciation time of ten years with an interest rate of 6% and 8000 working hours per year are set for the calculation of the total annualized costs (TAC). For both solvents, a price of 1000 \$/t (846.5 €/t) is assumed to account for solvent make-up streams. As utilities, cooling water at 25 °C (0.05 €/t), low-pressure steam at 10 bar (14 €/t), and high-pressure steam at 25 bar (16 €/t) are considered. The superstructure consists of a liquid-liquid extraction column with a maximum number of 15 (initial) stages and a distillation column with a maximum number of 80 (initial) stages.

Figure 1 shows the optimization results for the benchmark solvent toluene. The TAC of the process is about 194.4 k€/y and is largely determined by the operating costs, which represent about 69%. The furfural purity in the optimized process even exceeds the desired specification, avoiding unnecessary solvent makeup. Apparently, there is no reduction in the number of stages for the extraction column due to the comparably low investment costs, considering only a column shell with simple sieve tray inlets. In contrast, the cost of potential solvent makeup and increased flow rates in the distillation column would increase the TAC significantly compared to the reduced cost of the extraction column.

Figure 1: Optimized process flowsheet for the separation of furfural (FF) and water (W) using toluene (TOL) as the solvent in the liquid-liquid extraction (LLX) column

The results for the Deca-Thy-based process are presented in Figure 2. The high boiling temperature of Deca-Thy requires an alternative process design resulting in a three-column setup, including a liquid-liquid extraction, a distillation column for solvent recovery, and a heteroazeotropic distillation column for further purification of furfural. The solvent recovery is carried out in a vacuum column with a pressure of 0.1 bar to avoid the degradation temperature of Deca-Thy. The heteroazeotropic distillation is optimized separately based on the model and solution strategy presented by Kruber and Skiborowski (2022). Due to the furfural losses in the heteroazeotropic distillation, the overall furfural recovery drops slightly from 99.8% to 99.3%, whereas the furfural losses would also add

up to the wastewater stream. The TAC of the process is about 246.4 k€/y with almost the same capital expenditures as for the toluene process of about 60.5 k€/y. The increase in the TAC originates exclusively from an increase of 39% in operational expenditures, which is caused by the increased energy demand as well as the use of high-pressure steam (25 bar) in the vacuum column. Notably, the solvent-to-feed (S/F) ratio is significantly lower for the DES, which aligns with the increased distribution coefficient reported by Dietz et al. (2019c). Yet, the thermodynamically derived low S/F ratio should be considered with care, as phase ratios between 1:10 and 10:1 are usually considered for practical application (Goedecke, 2006).

As for toluene, the extraction column is utilized at its maximum number of stages due to the low investment costs. However, the distillation column uses less than half the stages compared to toluene, which is expected based on the extremely low vapor pressure of the DES. The main limitation of the DES is caused by the high cross-solubility of water in the solvent phase, due to which the additional purification in the heteroazeotropic distillation column is required, which counteracts the savings due to the smaller vacuum column. This not only causes a more complex and energy-demanding process but would also complicate the operation of the process.

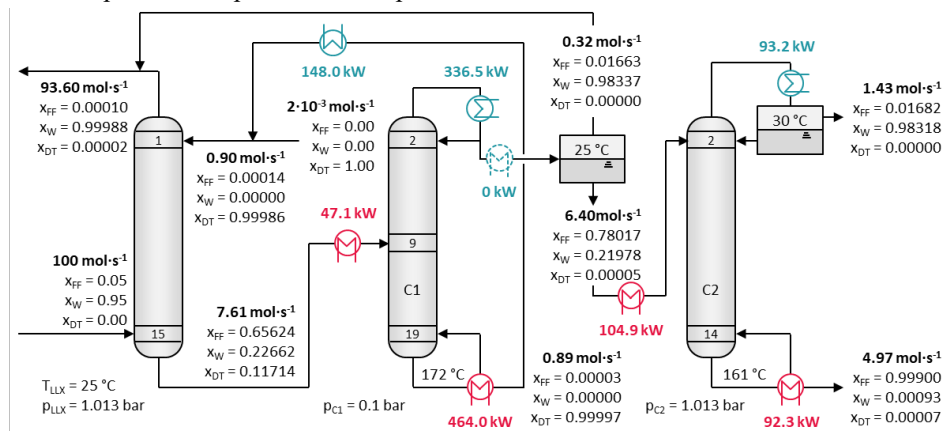

Figure 2: Optimized process flowsheet for the separation of furfural (FF) and water (W) using decanoic acid:thymol (DT) as the solvent in the liquid-liquid extraction (LLX) column

#### 4. Conclusion & Outlook

In order to evaluate the potential benefits of a DES, this work considers the purification of a diluted furfural stream by hybrid extraction-distillation processes by means of a rigorous optimization-based design. DESs are often examined based on simple thermodynamic properties and, therefore, recommended based on their low toxicity, flexibility, and particularly low vapor pressure, which implies an easy thermal regeneration. While all these properties are favorable for solvents, the high boiling temperature can result in a higher energy demand and the necessity for more costly heating utilities. The results illustrate the importance of a holistic consideration of solvent and process design to evaluate if the desired thermodynamic properties of the DES really translate into economic benefits for the overall process. It was shown that thermodynamic properties alone could not directly indicate economic savings. Although the recovery of Deca-Thy from the extract phase is simple, the high cross solubility of water requires further product purification and results in higher TAC of 246.4 k€/y compared to 194.4 k€/y for the toluene-based process. Especially for the purification of high boiling

organic compounds in diluted aqueous streams, a volatile solvent may be a favorable choice since the value product will not be an intermediate boiling component that can be separated without additional unit operations. In addition, the assumed degradation temperature for Deca-Thy is rather optimistic, and experimental studies indicate a much lower thermal stability resulting in even higher process cost.

In conclusion, DESs provide many favorable properties which make them interesting solvent candidates, but their suitability should be evaluated based on closed-loop process flowsheets that consider the effort for solvent recovery for each solvent candidate to gain more reliable information with respect to the process performance. In the future, the consideration of rigorous process models during the design and selection of DESs for separation processes should be further investigated, extending the scope to applications in extractive distillation and heteroazeotropic distillation. With the knowledge gained for the furfural purification, alternative DESs can be considered to improve the process performance and find a green alternative to the presented benchmark process and other interesting solvent candidates, such as butyl chloride (Nhien et al., 2017).

## Abstract

Industrial symbiosis networks enable efficient resource sharing between companies and, thereby, generate otherwise unachievable profits. This work studies the multi-actor process integration problem that arises when addressing utility exchange involving different companies. The aim is to find stable profit allocations by combining process integration principles with game theory methods. The profit table provides the necessary information to solve the cooperative game that takes place in the industrial park. For the case study, a simplified utility exchange model is developed and the proposed decision-making framework is applied to it, in order to highlight the importance of knowledge about the potential pitfalls of the employed profit allocation methods.

**Keywords:** cooperative game theory, process integration, decision-making, steam

## Introduction

Collaboration in industrial symbiosis networks potentially leads to profits over standalone operation. These profits may be of any kind (economic, environmental, social ...). While non-cooperative interaction between the actors may be analyzed to find optimal decision-making strategies (Hjaila et al., 2017), it is not ensured that the combined profit of all actors is efficient, i.e. as high as if the actors were selflessly cooperating. Especially, in industrial parks it is reasonable to assume that companies may bargain in a cooperative manner: they can form binding agreements to fairly share the generated profits, regardless of whether an individual member would suffer losses if no allocation occurs. Fair cost and profit allocation was studied before for various case studies (Chin et al., 2021; Hiete et al., 2012) but no study considered utility exchanges via steam transfer so far. To that end, a utility exchange model and the corresponding case study are contributed. Moreover, this work makes a significant step towards a generalized framework for decision-making in general multi-actor process integration problems.

## Problem Statement

For the given multi-actor process integration problem (*utility exchanges*) in an industrial park find the highest possible total economic profit and apply allocation methods to fairly distribute the profit among the participants. Check if the allocations are stable, i.e. that an individually rational actor would be likely to accept the proposal.

## Methodology

The allocation of profits requires the prior knowledge of the potential profits that can be obtained in the grand coalition and all sub coalitions. To that end, a simplified utility network model is proposed based on works by Galvan-Cara et al. (2022) and Kim et al. (2010). The original model complexity is reduced by omitting the multi-period problem, reducing the number of steam levels, etc. Material, energy and economic balances are maintained. The resulting set of equations is summarized in (1)-(13) and it contains no binary decisions. Thus, the minimization problem is a linear program (LP).

- High-pressure steam (HS) and low-pressure steam (LS) headers:

$$\dot{m}_{HS,i}^{demand} + \dot{m}_{HS,i}^{vent} + \sum_j \dot{m}_{HS,i,j}^{exc} + \dot{m}_{HS,i}^{turbine} + \dot{m}_{HS,i}^{letdown} = \sum_{b_{HS}} \dot{m}_{i,b_{HS}}^{boiler} \quad \forall i \quad (1)$$

$$\dot{m}_{LS,i}^{demand} + \dot{m}_{LS,i}^{vent} + \sum_j \dot{m}_{LS,i,j}^{exc} = \dot{m}_{LS,i}^{turbine} + \dot{m}_{LS,i}^{letdown} + \sum_{b_{LS}} \dot{m}_{i,b_{LS}}^{boiler} \quad \forall i \quad (2)$$

- Boiler mass balance:

$$\dot{m}_{i,b}^{boiler} = Cal_b \cdot \dot{m}_{fuel,i,b}^{purchase} \cdot x_{i,b} \quad \forall i, b \in b_{HS} \cup b_{LS} \quad (3)$$

- Turbine and letdown units:

$$\dot{m}_{HS,i}^{turbine} = \dot{m}_{LS,i}^{turbine} + \dot{m}_i^{cond} \quad \forall i \quad (4) \quad \dot{m}_{HS,i}^{letdown} = \dot{m}_{LS,i}^{letdown} + \dot{m}_i^{letdown} \quad \forall i \quad (7)$$

$$\dot{m}_{LS,i}^{turbine} = Split \cdot \dot{m}_{HS,i}^{turbine} \quad \forall i \quad (5) \quad \dot{m}_i^{letdown} = Fill \cdot \dot{m}_{HS,i}^{letdown} \quad \forall i \quad (8)$$

$$P_i^{turbine} = Yield \cdot \dot{m}_{HS,i}^{turbine} \quad \forall i \quad (6)$$

- Water units:

$$\dot{m}_{water,i}^{demand} + \sum_b \dot{m}_{i,b}^{boiler} + \dot{m}_i^{letdown} = \dot{m}_{water,i}^{purchase} + \dot{m}_i^{cond} \quad \forall i \quad (9)$$

- Electricity units:

$$P_i^{demand} + \sum_b P_{i,b}^{boiler} = P_i^{turbine} + P_i^{purchase} \quad \forall i \quad (10)$$

- Economic balances:

$$C_i^{raw} = C^{elec} \cdot P_i^{purchase} + C^{water} \cdot \dot{m}_{water,i}^{purchase} + \sum_b C_b^{fuel} \cdot \dot{m}_{fuel,i,b}^{purchase} \quad \forall i \quad (11)$$

$$C_i^{transport} = \frac{1}{2} \cdot \sum_{s \in \{HS, LS\}} \sum_j \beta_s \cdot (\dot{m}_{s,i,j}^{exc} + \dot{m}_{s,j,i}^{exc}) \cdot L_{i,j} \quad \forall i \quad (12)$$

$$C = \sum_i (C_i^{raw} + C_i^{transport}) \quad (\text{subject to minimization}) \quad (13)$$

Where  $i, j$  is the set of plants and  $b$  is the set of boilers. Figure 1 shows the superstructure of the utility system in a plant and visualizes the balances from the model. Utility costs for fuel, water and electricity are considered. Steam exchanges can lead to savings in all utility purchases at the cost of pipeline construction and operation.

Figure 1. Simplified utility system superstructure for each plant.

### Cooperative Game Theory and Profit Allocation:

Multi-actor process integration problems such as the utility-exchange problem presented herein can be adjusted for every existing sub coalition by introducing binary parameters that restrict flows to only allow exchanges between the sub coalition members. The resulting profits are always positive with respect to the standalone case because any participant may decide to not collaborate if no individual profit is in sight. Figure 2 shows the steps followed in this work which is part of a general framework that is to be presented in future work. The profit table in the Figure is an arbitrary example with three players.

The profit table results from solving the process integration problem for the  $2^N$  coalitions, where  $N$  is the number of players. Using the information about the worth of each coalition, various solution concepts can be applied to fairly distribute the profits to the members of the coalition. We developed the Python package “*pyCoopGame*” which implements various well-known single-point solution concepts and stability criterion checks for any given profit table. In this work we employ four solution approaches of which the following descriptions briefly outline the underlying intuition.

The core concept (Gillies, 1959) is not a solution approach but a stability criterion that checks if a given profit allocation is efficient and acceptable for individually rational players. That means, an allocation is stable and lies in the core if the total profit equals the profit of the grand coalition and no sub coalition can ensure higher payoff for all members. The Shapley value (Shapley, 1988) makes use of the profit table to determine the marginal contribution of every member to every coalition and calculates a weighted average of the marginal contributions. The Nucleolus (Puerto & Perea, 2013) is the allocation that minimizes the largest dissatisfaction of all coalitions. Dissatisfaction is the difference between the worth of the coalition and the sum of the profits allocated to the coalition members. The  $\tau$ -value (Tijs & Driessen, 1986) is the efficient allocation that lies between the utopian allocation where each player receives their marginal contribution to the grand coalition and the minimum rights allocation. The least core solution (Maschler et al., 1979) is the profit allocation where the relaxed  $\varepsilon$ -core set is just composed of a single point.

It should be noted that these four approaches are selected based on their popularity but others may be chosen depending on the use case. Luo et al. (2022) give a good overview of recent developments and applications, as well as current challenges, of cost and profit allocation solution concepts applied to operations management.

Figure 2. Solving a profit allocation problem in a multi-actor process integration case.

### Case Study

The multi-actor process integration problem studied in this work is a utility exchange problem adapted from the Yeosu industrial complex as shown in Figure 3. The game is redefined to include three players (10, 12 and 15) and the utility system is adapted to the previously presented simplified model.

The resulting parameters are summarized in Tables 1, 2 and 3. Demand values for VHS and HS as well as MS and LS are aggregated over the four time periods.

Table 1. Final annual demand values

	HS [kton]	LS [kton]	Water [kton]	Electricity [MWh]
10	5707	0	1908	952
12	0	111	476	396
15	3878	1042	1588	1272

The economic parameters shown in Table 2 are updated to match current market conditions. The fuels are coal (1), methane (2) and fuel oil (3).

Table 2. Economic parameters and calorific content of fuel

Parameter	Value	Unit	Parameter	Price [\$/ton]	$Cal_b$ $\left[ \frac{kg\ steam}{kg\ fuel} \right]$
Water Price	0.500	\$/ton	Fuel 1	205	8.9
Electricity Price	150.0	\$/MWh	Fuel 2	290	18.5
Pipe Operation ( $\beta$ )	0.436	\$/km/t	Fuel 3	1174	15.9

The distance between plants is kept unchanged.

Table 3. Distance between companies

Plants	Distance	Plants	Distance	Plants	Distance
10 ↔ 12	2.319 km	10 ↔ 15	2.193 km	12 ↔ 15	1.237 km

The utility system of each plant is changed to correspond to the simplified utility model. As can be seen from Figure 3 (right), in scenario 1 plant 10 has a HS coal boiler and a turbine, plant 12 has a LS fuel oil boiler and plant 15 has a HS methane boiler, a turbine and a LS fuel oil boiler. In scenario 2 plant 10 has a methane boiler but no turbine. Results for the whole complex using the original parameters from Galvan-Cara et al. (2022) are also provided.

Figure 3. Yeosu industrial complex (Kim et al., 2010) and scenarios.

## Results and Discussion

Solving the process integration problem for all coalitions in scenario 1 and 2 leads to the profit tables as shown in Table 4 and 5. Most of the profit in scenario 1 is due to the fuel that plant 10 saves by not using its coal boiler and importing instead HS from plant 12, which has a more cost-efficient methane boiler. Further savings are generated by LS exchange of plant 12 and 15 with 10. In scenario 2 the big savings from plant 10 are not feasible because plant 15 already has a methane boiler. Thus, the only savings come from LS exchange with plant 12, which has a limited demand for this utility.

Applying the single-point solution concepts leads to the profit allocations in Figure 4 and 5. In scenario 1, Shapley, Nucleolus and  $\tau$ -value yield similar results that follow a simple intuition: plant 10 and 15 both need to be present to generate the large benefits, so both should receive similar payoffs. Plant 12 also has a contribution but its impact is way smaller so it can't claim as much payoff. It is not surprising that these three payoff vectors are indeed stable. However, it is non-intuitive that plant 15 and 10 should receive such asymmetric payoffs according to the least core solution. This outcome follows from the property of the least core method which always yields a solution on the edge of the feasible core allocation set, granted it is non-empty.

In scenario 2 the profit is largely determined by plant 12 accepting LS from either 10 or 15 until its demand is satisfied. Plant 10 is in the most powerful position and can claim the largest payoff. The results of the Nucleolus,  $\tau$ -value and least core methods are stable and they allocate the payoffs to plants 12 and 15. The latter is preferred over plant 10 due to the slightly closer geographical proximity. Plant 10 is not engaged in the final utility exchange so not assigning payoff to this player is intuitive. However, the Shapley value assigns a significant share of the payoffs to both players 10 and 15 due to their marginal contribution to the sub coalitions. This result is not stable and reveals one of the main weakness of the Shapley value, the most popular approach used in literature. These two scenarios demonstrate that allocation methods should be selected with care, being aware of their potential pitfalls.

Figure 6 shows the results for the whole industrial park. The Nucleolus is not included here as its calculation for games with many players becomes computationally unaffordable. The remaining profit allocations are very different and this is due to the fact that the core for this 15-player game is empty. In this kind of situations, the rules of the game may be adjusted by means of taxation and incentives (Chin et al., 2021).

Table 4. Profit Table (scenario 1)

Coalition	Profit
{10,12}	5,290,864 \$/year
{10,15}	36,673,525 \$/year
{12,15}	6,127,690 \$/year
{10,12,15}	42,804,345 \$/year

Table 5. Profit Table (scenario 2)

Coalition	Profit
{10,12}	6,074,326 \$/year
{10,15}	0 \$/year
{12,15}	6,127,690 \$/year
{10,12,15}	6,127,690 \$/year

Figure 4. Allocations (scenario 1)

Figure 6. Allocations (complete industrial park). Total profit: 7,157,500 \$/year

## Conclusions

The application of cooperative game theory methods (and the associated profit allocation) to industrial symbiosis networks facilitates the decision-making and may create trust between the actors by proposing payoff vectors that are intuitive and stable. The presented study demonstrates this on a simplified utility exchange case study. Moreover, a significant step towards the generalization of a profit allocation framework for multi-actor process integration problems is done. Such a framework requires knowledge about strength and weaknesses of the available methods. Future work will further formalize this framework, characterize the allocation methods and demonstrate on a wide variety of process integration problems how decision-making can be systematically improved using cooperative game theory.

# Operational optimisation of steam power system under uncertainty using time series prediction optimization model with **Markov** chain

Kenian Shi, Jingyuan Zheng, Siyu Yang\*

*School of Chemical Engineering, South China University of Technology, Guangzhou, 510640, China*

## Abstract

The stochastic programming and robust optimisation methods have been proposed to solve the operational optimisation of industrial energy system under uncertainty. However, these methods can not comprehensive the stability and economy at the same time. This paper proposes a two-stage time series prediction optimization model with **Markov** chain to solve this problem. The steam demand value is predicted by the method of scenario generation and reduction. Taking the steam power system of a coal-to-gas enterprise as an example, the corresponding optimization model is established, and the predicted steam value is put into the optimization model to solve. The results show that the optimization method in this paper combines the advantages of high economy of stochastic programming and high stability of robust optimization, which provides a new way to solve the uncertain optimization problem of steam power system.

Keywords: Steam demand uncertainty, time series prediction optimization, Markov chain, Scenario generation and reduction.

## Introduction

In the operation of steam power system, there are various uncertain factors (uncertain changes of operating temperature, pressure and flow rate), which will eventually lead to uncertain changes of steam demand <sup>[1]</sup>. The uncertainty of steam demand can lead to the blind production of steam power system, producing more or less steam than the demand. The former will lead to the venting of steam and waste resources, while the latter will affect the safety and stability of the production. Therefore, it is of great theoretical and practical significance to study the operational optimisation of steam power system under uncertainty.

At present, the methods to solve the uncertain optimization problem include stochastic programming <sup>[2]</sup> and robust optimization <sup>[3]</sup>. The main difference between these uncertain optimization methods lies in the description of uncertain parameters and solving algorithm <sup>[4]</sup>. Stochastic programming is only applicable to the uncertain optimization problems whose uncertain parameters can be expressed as probability distribution, but not to the uncertain optimization problems with non-probability distribution <sup>[5]</sup>, and it cannot avoid high risks in the process of system planning <sup>[6]</sup>. The robust optimization expresses the uncertain parameter as the uncertain parameter set and considers the optimization scheme in the worst case <sup>[7]</sup>.

Each method has its own advantages and disadvantages. Robust optimization has high stability but is too conservative. Stochastic programming has high economy but poor stability. At present, few optimization methods can comprehensive the stability and economy at the same time. This paper

proposes a two-stage time series prediction optimization model with Markov chain to solve the coexistence problem of economy and stability.

### 1. Methodology

The time series prediction of steam demand can be divided into two stages. In the first stage, multiple working conditions are divided based on the distance of three levels of steam. In the second stage, the steam demand is predicted based on the probability of state transition under each working condition, which mainly includes scenario generation and scenario reduction.

#### 1.1. Multiple working condition division

Due to the high volatility of the three levels of steam, it is necessary to classify them to improve the overall efficiency and economy of the steam power system. In this paper, a clustering algorithm is used to classify the annual steam demand [8] The annual demand for three levels of steam can be divided into five operating conditions.

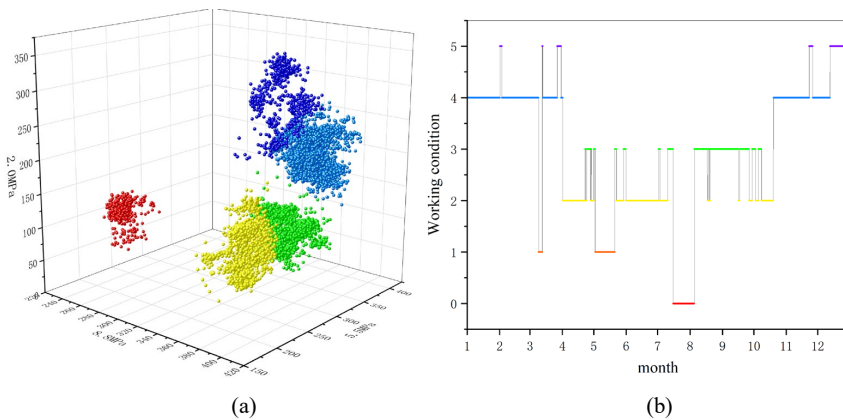

Fig.1 (a)、(b) -Results of steam demand division

The division results of annual steam demand conditions were plotted with time as the abscissa, as shown in Figure 1. There were six operating conditions including parking conditions (operating condition 0).

#### 1.1.2 Scenario generation

The principle of scenario generation is based on the random process of Markov chain, and the probability of the random occurrence is determined by the probability of transition between different states in the research object [9]. Suppose the state of steam demand sequence in the current scenario is  $\dots X_{t-2}, X_{t-1}, X_t, X_{t+1}, X_{t+2} \dots$ , Then the probability of the steam demand state at time  $X_{t+1}$  only depends on the state  $X_t$  at the previous moment:

$$P(X_{t+1} | \dots X_{t-2}, X_{t-1}, X_t) = P(X_{t+1} | X_t) \tag{1}$$

In this paper, the steam state is evenly divided into 10 states, the probability transition matrix of three levels of steam can be constructed by statistics of probabilities of transition under different working conditions. According to the state transition probability matrix, the state of the next hour can be predicted continuously until the set prediction time is generated. The prediction time in this paper is 24h.

#### 1.1.3 Scenario reduction

The number of scenarios generated is very large, if all of them are considered, the efficiency of subsequent optimization problems will be seriously affected, and feasible solutions cannot even be

obtained [10]. Therefore, the scenario reduction method is needed to eliminate redundant scenarios. The scenario reduction method used in this paper is the simultaneous backward reduction method [11]. The principle of this method is to minimize the probability distance between the initial scenario set and the scenario set saved after reduction, which makes the reduction process easier [12]. The Dr Distance model is shown below:

$$\min D_r(P, Q) = \left\{ \sum_{i \in I} \sum_{j \in J} p_i \|\varepsilon_i - \tilde{\varepsilon}_j\|^r \right\}^{1/r} \quad (3)$$

Where,  $\|\cdot\|$  is norm, the Euclidean distance is used here, so  $r=2$ .

The number of reserved scenario cuts is generally 10. Figure 2 shows the result of reducing 2000 scenarios generated by the scenario generation to 10. As you can see in Figure 2, the reduced results include all representative cases from minimum to maximum.

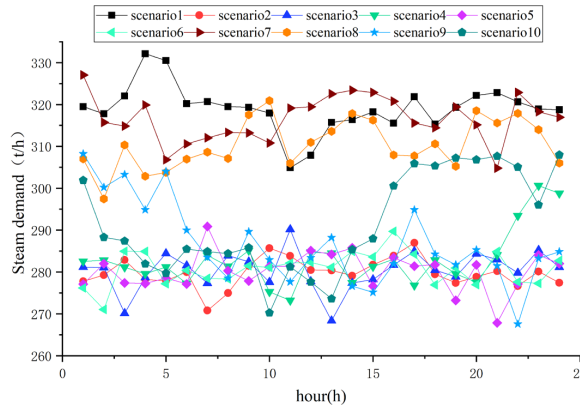

Fig.2 The results of scenario reduction

#### 1.4 Determine the number of initial scenarios $S_p$

Take the maximum and minimum values of reserved 10 scenarios at each moment to form the upper and lower bounds of the prediction interval. The prediction results of the three levels of steam are shown in Figure 3.

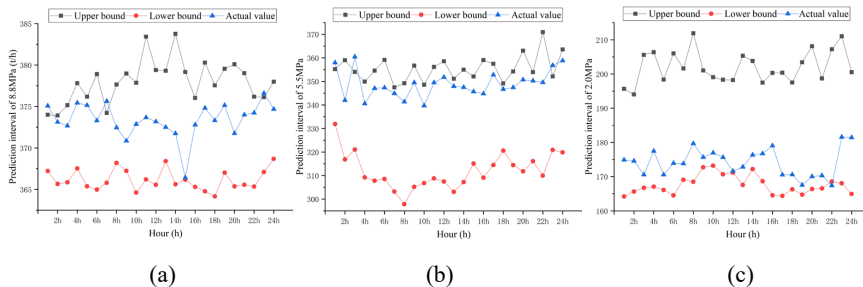

Fig.3 (a), (b), (c)-Prediction interval of 8.8MPa、5.5MPa、2.0MPa

From the prediction intervals of the three level of steam, it can be seen that the actual values of the predicted results of 8.8MPa, 5.5MPa and 2.0MPa are well within the prediction intervals. In order to meet the actual steam demand, the upper bound value is taken as the predicted value of each level of steam.

The upper bound of the prediction interval is related to the number generated in the scenario generation process. The range of the scenario generation number  $S_p$  is 500–5000. When the scenario

generation number is 5000, the upper bound value tends to be stable. Therefore, by comparing the number of other generated scenarios with the upper bound of  $Sp=5000$ , the number of scenarios generated for different levels of steam is determined, as you can see in Figure 4.

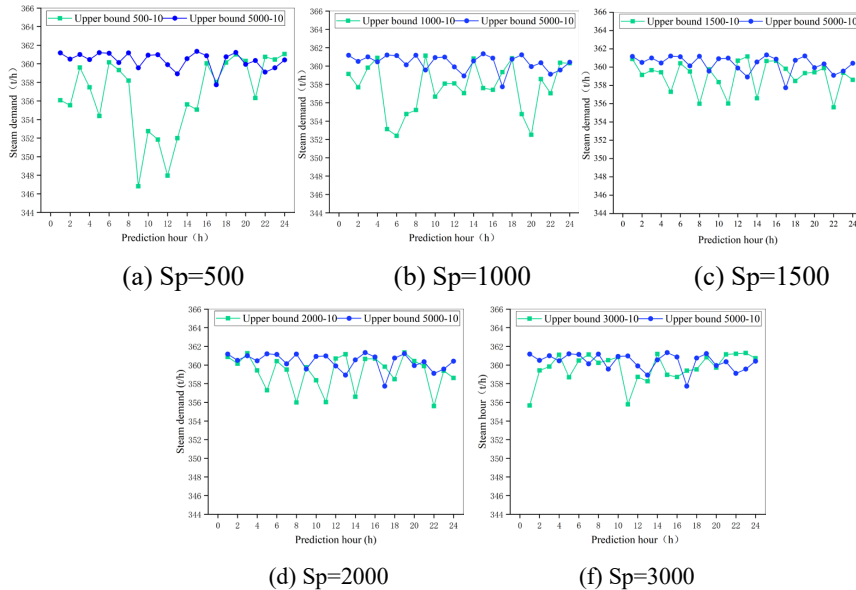

Fig.4 Comparison between the number of different generated scenarios and  $Sp=5000$

For 8.8MPa, the number of scenarios  $Sp$  is 500. In the same way, the number of scenarios  $Sp$  is 1500 for 5.5MPa, the number scenarios  $Sp$  is 1000 for 2.0MPa.

## 2. Case study

### 2.1 The prediction results of one month steam demand

The example is the steam power system of a coal-to-gas plant. According to the extracted historical data of steam demand, the prediction results for one month are as follows in Figure 5.

Fig.5 (a)、(b)、(c)-Prediction results of 8.8MPa、5.5MPa and 2.0MPa

As can be seen from Figure 5, the stability (the predicted value is greater than or equal to the actual value) of the three levels of steam is respectively 87.1%、79.4% and 76.2%.

### 2.2 Steam power system

The flow diagram of steam power system is shown in Figure 6. B1-B4 is the boiler. CN100T is 100MW high pressure extraction type direct air cooled turbine unit, CB30T is 30MW high pressure back pressure turbine unit. Insufficient power and high pressure steam are purchased from outside.

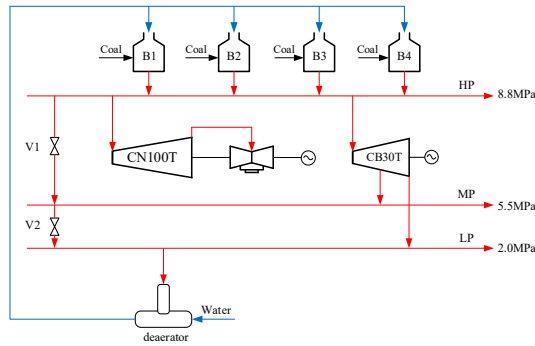

Fig.6 The flow diagram of steam power system

2.3 Analysis of optimization results

In this paper, sequential quadratic programming method was adopted to solve the steam power system model. The objective function is the operating cost, and the monthly steam demand value predicted based two-stage time series prediction model with Markov chain is brought into the optimization model. The comparison of various costs before and after optimization of each optimization method is shown in Table 1.

Table 1 Cost of each optimization method before and after optimization

Cost /10 <sup>4</sup> ¥	Before optimization	This paper optimization	Robust optimization	Stochastic programming
Coal	5871	5721	5828	5694
Water	867	834	859	827
Purchased electricity	0	0	0	0
Purchased steam	0	0	0	0
The total cost	6738	6555	6687	6521
Cost saving	—	183	51	217

As shown in Table 1, the cost savings of the three optimization methods were 1.83 million yuan, 510,000 yuan and 2.17 million yuan respectively.

The optimized stability and economy of the three optimization methods are shown in Figure 7.

Fig.7 The optimized stability and economy of the three optimization methods

By comparing the stability and economy of the three optimization methods, the two-stage time series prediction optimization model with Markov chain in this paper takes into account the advantages of high economy of stochastic programming and high stability of robust optimization, and its stability and

economy are between stochastic programming and robust optimization.

### 3. Conclusion

In this paper, a two-stage time series prediction optimization model with Markov chain method is proposed. The first stage is based on spatial distance expression to divide multiple operating conditions, and the second stage is based on state transition probability expression to predict the demand value of steam 24h before the day through the method of scenario generation and reduction. This method is used to solve the operation optimization problem of a steam power system of coal-to-gas. The optimization results show that:

- (1) The stability of the three levels of steam demand prediction is between that of stochastic programming and robust optimization.
- (2) The cost savings of one-month prediction optimization can save 1.83 million yuan, and its economy is between the stochastic programming and robust optimization.
- (3) The proposed method combines the advantages of robust optimization and stochastic programming and has better performance.

## **Abstract**

An approach for the calculation of simultaneous phase and chemical-reaction equilibria and stability that does not require any assumptions on the number of stable phases and is applicable to any number of reactions is presented. It is based on an extension of the dual extremum principle concept for non-reactive systems (HELD) formulated in terms of the Helmholtz energy, where additional constraints are introduced that relate molar amounts and extents of reaction. The extended R-HELD algorithm is applied to reacting mixtures such as the esterification of acetic acid and the formation of methyl tert-butyl ether.

**Keywords:** Phase stability, reacting mixtures, SAFT- $\gamma$  Mie equation of state.

## **1. Introduction**

The calculation of equilibria in multiphase, multi-reaction systems is an important subject of study in chemical engineering thermodynamics. The inclusion of chemical reaction equilibria in multiphase equilibria gives rise to significant challenges in terms of thermodynamic consistency and numerical complexity. In reacting systems, stable phases may vanish or emerge as a consequence of the chemical reactions, making it difficult to determine the number and compositions of the phases coexisting at equilibrium. Two main classes of approaches have been presented to overcome these issues (Smith, 1980; Seider and Widagdo, 1996). In the first class, a non-linear programming approach is used to minimize the Gibbs energy function with a fixed number of phases (Castillo and Grossmann, 1981; Lantagne, et al., 1988). In the second class, phases are added (or removed) iteratively and the stability of each solution is tested (Gautam and Seider, 1979). This has led to approaches to solve simultaneously multiphase stability and equilibria in the presence of chemical reactions; (Michelsen, 1989; Gupta et al., 1991; Smith et al., 1993; Jiang et al, 1996). These approaches allow for a good compromise between effectiveness and efficiency, but the search for the correct number of stable phases can lead to numerous iterations or convergence to local minima. In our current work, an approach is developed to obtain the stable state comprising one or more phases without making initial assumptions on the number of phases nor restricting the number of components in each phase. To this end, we extend the seminal work of Mitsos and Barton (2007) on the determination of the phase stability of non-reactive multicomponent mixtures via the dual-extremum principle (DEP). We adopt the Helmholtz energy formalism of Pereira et al. (2010; 2012), who recast the DEP in terms of temperature,

pressure, and mole numbers as natural variables, a formulation which is better-suited to the use of state-of-the-art equations of state such as SAFT- $\gamma$  Mie. Building on the DEP, a new phase stability and equilibria algorithm, HELD (Helmholtz energy Lagrangian dual) algorithm is developed, which we now extend to the reactive systems (R-HELD). In Section 2, we outline the extension of the DEP to reacting systems. In Section 3, we embed this stability criterion within the R-HELD algorithm. The performance of the algorithm on reacting systems with one or two phases is illustrated in Section 3.

## 2. A phase stability criterion for systems at chemical equilibrium

The extension of the DEP of Mitsos and Barton (2007) and of its Helmholtz energy counterpart (Pereira et al. 2010) to reacting systems is presented without proof. We formulate an optimization (dual) problem such that the set of all global solutions admitted by the dual problem is exactly equal to the set of stable phases of the mixture of interest. We consider the (trivial) single-phase minimisation of the Gibbs energy for a reacting system. Given  $C$  components,  $R$  independent reactions, temperature  $T_o$ , pressure  $P_o$  and total mole fractions  $N_{i,0}$ ,  $i = 1, \dots, C$ , the minimisation of interest can be expressed using the molar volume,  $V$ , and the vector  $\Xi$  of (molar) extents of reaction,  $\xi_r$ ,  $r = 1, \dots, R$ , as independent variables and including a material-balance constraint:

$$G_V = \min_{\Xi, V} A(T_o, P_o, \mathbf{N}(\Xi)) + P_o V$$

$$\text{s. t. } N_i(\Xi) - (N_i^0 + \sum_{r=1}^R \nu_{i,r} \xi_r) = 0, i = 1, \dots, C, \quad (1)$$

$$V \in [\bar{V}, \bar{\bar{V}}], \Xi \in \mathbb{R}_+^R$$

where  $A$  is the Helmholtz energy,  $N_i$  is the number of moles of species  $i$ ,  $\nu_{i,r}$  is the stoichiometric coefficient of component  $i$  in reaction  $r$ ,  $\bar{V}$  and  $\bar{\bar{V}}$  are lower and upper bounds on the volume, respectively. The application of the first-order optimality conditions for Problem (1) results in

$$-\left(\frac{\partial A(T_o, V^*, \mathbf{N}(\Xi^*))}{\partial V}\right)_{T, \xi_{r=1, \dots, R}} = P(T_o, V^*, \mathbf{N}(\Xi^*)) = P_o, \quad (2)$$

indicating that the molar volume at the solution  $(\Xi^*, V^*)$  corresponds to pressure  $P_o$  (Nagarajan et al., 1991), and

$$\sum_{i=1}^C \mu_i(T_o, V^*, \mathbf{N}(\Xi^*)) \nu_{i,r} = 0, \quad r = 1, \dots, R, \quad (3)$$

enforcing chemical-reaction equilibria for all  $R$  reactions. Thus, these conditions do not need to be stated explicitly as constraints, and Problem (1) is equivalent to the minimisation of the Gibbs energy at  $(T_o, P_o, \mathbf{N}_0)$  for a phase at chemical equilibria.

We now recast Problem (1) in terms of the set of transformed compositional variables proposed by Ung and Doherty (1995). These  $C - R$  compositional variables exhibit useful properties such as independence of the extents of reaction, summation to unity, and thermodynamic consistency. Using the summation to unity property, variable  $C - R$  can be eliminated. The resulting vector of  $C' = C - R - 1$  variables is denoted by  $\hat{\mathbf{x}}$ . The primal problem of Pereira et al. (2010) can then be reframed as

$$\widehat{G}_V^p = \min_{\hat{\mathbf{x}}, V} A(T_o, V, \hat{\mathbf{x}}) + P_o V$$

$$\text{s. t. } \hat{x}_{i,0} - \hat{x}_i = 0, i = 1, \dots, C'$$

$$\hat{\mathbf{x}} \in \mathcal{X}, V \in [\bar{V}, \bar{\bar{V}}] \quad (4)$$

where  $\mathcal{X}$  defines the domain of the compositional variables. The Lagrange function, corresponding to Problem (5), is given by

$$\widehat{L}^V(\widehat{\mathbf{x}}, V, \boldsymbol{\lambda}) = A(T_o, V, \widehat{\mathbf{x}}) + P_o V + \sum_{i=1}^{C'} \lambda_i (\widehat{x}_{i,o} - \widehat{x}_i), \quad (5)$$

and the dual of Problem (4) is given by

$$\widehat{G}^D = \max_{\boldsymbol{\lambda} \in R^{C'}} \min_{\widehat{\mathbf{x}} \in \mathcal{X}, V \in [\overline{V}, \overline{V}]} \widehat{L}^V(\widehat{\mathbf{x}}, V, \boldsymbol{\lambda}) \quad (6)$$

Under the assumption that the solutions of the inner problem in Problem (6), i.e., the minimisation of the Lagrange function, lie in the interior of sets  $\mathcal{X}$  and  $[\overline{V}, \overline{V}]$ , the solution set of Problem (6) describes the stable state of the reacting mixture at  $(T_o, P_o, \mathbf{N}_o)$ .

### 3. The reactive HELD (R-HELD) algorithm for reacting systems

Using Problem (6), we extend the implementation of the HELD algorithm (Pereira et. al, 2012) to enable the identification of all stable phases of systems undergoing chemical reactions. The implementation makes use of a multistart approach combined with a SQP solver to solve any nonlinear problem. Thus global optimality cannot be guaranteed.

#### 3.1. Stage 1: Initialization.

Primal problem (4) admits a trivial solution at  $\widehat{\mathbf{x}} = \widehat{\mathbf{x}}_o$ , where  $\widehat{\mathbf{x}}_o$  is found by solving for chemical equilibria at the specified conditions. This yields an upper bound on the minimum Gibbs energy of the system. The tangent-plane distance criterion is applied at  $\widehat{\mathbf{x}}_o$  to determine whether the single phase is stable. If a negative value of the tangent-plane distance is found, the algorithm proceeds to Stage 2. Otherwise, it terminates.

#### 3.2. Stage 2: Identification of candidate stable phases

An iterative search for all global solutions of Dual problem (6) is carried out. At iteration  $k$ , (i) given a guess vector  $\boldsymbol{\lambda}^k$ , the (inner) minimisation of the Lagrange function yields a lower bound (LBD<sup>V</sup>) on the minimum Gibbs free energy and a solution  $(\widehat{\mathbf{x}}^k, V^k)$ , which is used to construct an approximation of the inner problem by substitution into Eq. (5) and, (ii) an approximate Dual problem, constructed from all solutions to the inner problem up to iteration  $k$  is solved with respect to the  $C'$  Lagrange multipliers. This outer problem yields an upper bound (UBD<sup>V</sup>) on the minimum Gibbs energy and a new guess  $\boldsymbol{\lambda}^{k+1}$ . The iterations continue until the gap between the lower and upper bounds converges to a specified tolerance,  $\varepsilon$ , i.e.,  $|\text{UBD}^V - \text{LBD}^V| \leq \varepsilon$ .

#### 3.3. Stage 3: Material balance

The total Gibbs energy, calculated using all the phases identified so far, is minimised, subject to the overall mass balance. If the problem is found to be feasible, further criteria are applied, including checking the gap between the total Gibbs energy and the upper bound found in Stage 2 and ensuring that the necessary conditions for phase and chemical equilibria are satisfied across all species. This latter check is important to ensure the accuracy of the calculations – the convergence tolerance can be tightened if this is not met and Stage 2 to achieve increased accuracy / identify missing phases.

## 4. Results

We assess the performance of the extended R-HELD algorithm for several multicomponent reactive systems at conditions where the system is stable as in a single phase or coexists in several phases in the presence of chemical reactions. Our approach

only requires knowledge of the stoichiometry of each reaction and the enthalpies and entropies of formation of each species at the selected standard state, here, the ideal gas at 298.15 K and 1.013 bar. All mixtures are modelled with SAFT- $\gamma$  Mie equation of the state (Papaioannou et al., 2014) with parameters reported in Haslam et al. (2021) and in the supporting information.

#### 4.1. Single stable phase with reaction equilibria

We consider the liquid phase synthesis of methyl tert-butyl ether (MTBE) from isobutene (IB) and methanol (MeOH) at 16 bar. The predicted chemical-reaction equilibria surfaces (CES) are presented in Figure 1 for temperatures from 323.15 K to 353 K and initial methanol/isobutene molar ratio from 0.1 to 1.6, with data from Izquierdo et al. (1992).

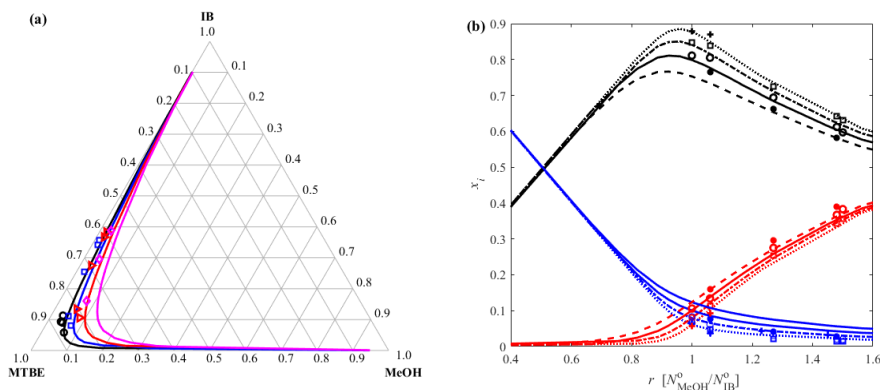

Figure 1: Reaction equilibria for the system isobutene, methanol, and methyl tert-butyl ether at 16 bar: (a) CES at 323.15 K (black circles), 333.15 K (blue squares), 343 K (red triangles), and 353 K (magenta diamonds). (b) Composition profiles for reactants and products as a function of initial MeOH/IB ratio: IB (blue), MeOH (red), and MTBE (black) at 323.15 K (crosses), 333.15 K (squares), 343 K (circles), and 353 K (filled circles). Continuous curves are predictions using SAFT- $\gamma$  Mie and R-HELD and symbols are experimental data (Izquierdo et al. 1992)

The quaternary reactive mixture arising from the esterification of acetic acid with ethanol acetic acid [(Ac.Ac) + ethanol (EtOH)  $\rightleftharpoons$  ethyl acetate (Et.AcO) + water (H<sub>2</sub>O)] is modelled with R-HELD at conditions where one phase is present (1.013 bar and 293.15 K). The predicted CES is presented in Figure 2 as a concentration tetrahedron and is seen to be in excellent agreement with the experimental data of Golikova et al. (2017). The CES is seen to limit feasible compositional space that can be reached.

#### 4.2 Simultaneous phase and chemical reaction equilibria

We present in Figure 3 the calculation at conditions at which phase and chemical equilibria interact for the mixture IB, MeOH, MTBE (5 bar, 342.25 to 378.29 K), together with the molecular simulation data of Lisal et al. (2010). In Figure 3a, the CESs in the vapour and liquid phase (blue) and the bubble and dew curves (black) are seen to intersect at the solutions of the simultaneous phase- and chemical-equilibrium problem.

## 5. Conclusions and outlook

We have extended the dual extremum principle as a criterion for fluid-phase stability, as proposed by Mitsos and Barton (2007), to include chemical reactions. Specifically, we have extended the Helmholtz energy formalism proposed by Pereira et al. (2010), combined with the compositional transforms of Ung and Doherty (1995). The approach,

presented here without proof, is consistent, general, and can be applied to multicomponent and multi-reaction systems coexisting at phase equilibria. We have implemented this within the framework of the HELD algorithm for non-reactive systems (Pereira et al., 2012). The extended R-HELD algorithm has been tested successfully with ternary and quaternary mixtures with one or two stable phases, using the SAFT- $\gamma$  Mie equation of state. Broadening the scope of the HELD algorithm allows us to consider challenging mixtures that exhibit simultaneous phase and reaction equilibria.

Figure 2 - CES for the esterification reaction of acetic acid 323.15 K and 1.013 bar computed with SAFT- $\gamma$  Mie and R-HELD (continuous-dotted envelope) and measured experimentally (symbols)

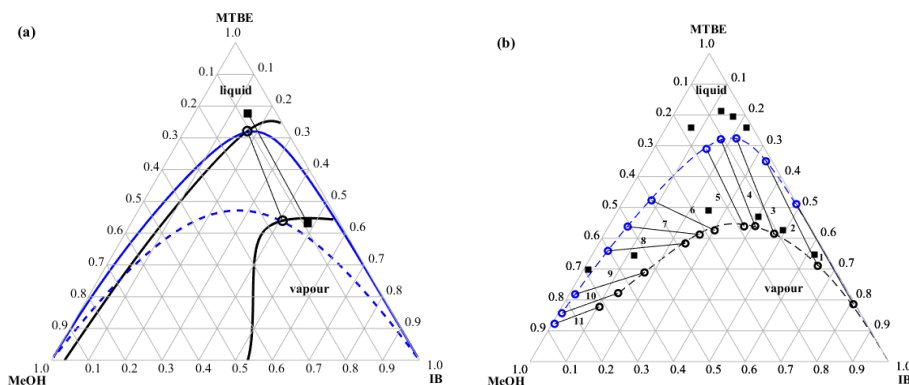

Figure 3: Mixture of IB, MeOH and MTBE at 5 bar (a) CES at 360 K. Black continuous curves indicate non-reactive VLE; continuous and dotted blue curves represent the prediction of the single-phase chemical reaction equilibria (CES) in the liquid and vapour phase respectively. The light solid lines represent reactive tie lines. (b) Complete simultaneous reaction + phase equilibria, with reactive tie-lines (circles connected by solid lines) 1) 342.25 K, 2) 351.8 K, 3) 358.4 K, 4) 360.15 K, 5) 360.65 K, 6) 363.25 K, 7) 365.19 K, 8) 367.15 K, 9) 372.81 K, 10) 376.13 K, 11) 378.29 K. Filled black squares are molecular simulation data (Lisal, et al., 2000).

## Abstract

The steam Rankine cycle (SRC) is a mature technology adapted to high temperatures and has a high electrical efficiency. However, the cost-effective and environmentally-sound utilisation of biomass in SRC requires efficient management of the supply chain and overcoming challenges such as complex conversion processes and uncertainties in biomass quality and supply. In this study, the optimisation of biomass utilisation using SRC to produce electricity is conducted considering the entire biomass supply chain. The model is developed as a combined biomass supply chain network and SRC process flowsheet and optimized in GAMS to achieve the most effective power generation while optimising the network economics. The concept of the SRC process-based approach to biomass supply network is evaluated through a demonstrative case study of a relatively small region.

**Keywords:** supply chain optimisation, mathematical modelling, biomass utilisation, steam Rankine cycle

## 1. Introduction

The depletion of fossil fuels, their negative impact on the environment and the security of energy supply have stimulated many countries to focus on more extensive use of renewable energy resources to reduce environmental burdens and achieve energy security and fuel diversification. Among renewable energy sources, biomass is becoming increasingly important, as it can be used for heat and power generation and biofuel production. Apart from biofuels, the most widely used technology for biomass utilisation is direct combustion, where the resulting high-temperature gases are typically used to generate high-pressure steam. Power generation using steam cycles such as the steam Rankine cycle (SRC) is suitable for large-scale power plants where thermal efficiencies of over 30 % can be achieved. SRC uses water as working fluid, which has the advantage of being highly available and non-toxic, but it precludes its wide range of applications, especially for low and medium grade heat sources (Abbas et al., 2020).

In many situations, biomass suitable for power generation is available as a feedstock in large quantities with low density and largely distributed production, characterised by its seasonal availability. Achieving competitive electricity generation through biomass utilization requires an efficient management of the biomass supply network, which primarily addresses biomass harvesting, transportation, storage, and utilisation. Biomass supply chain optimisation focuses on supply chain performance and configuration, component sizing and operations scheduling, usually with an objective of minimising cost (Nunes et al., 2020).

In this study a new supply network concept is proposed that considers integrated biomass supply network formulation and detailed optimization of SRC process. The objective of the study is maximising the revenue from selling heat and electricity and subtracting distance-dependent biomass transportation cost and cost of piping network to distribute heat.

## 2. Methodology

The proposed approach consists of optimizing the integrated biomass supply network and SRC process flowsheet system. First, the proposed integrated design is explained, and further mathematical formulation is briefly presented.

### 2.1. Biomass Supply Network and Steam Rankine Cycle

An integrated biomass supply network and SRC process, schematically represented in Fig. 1, consists of 3 main layers (L1-L3). The first layer (L1) represents the supply of feedstocks to the plant and accounts for the regional characteristics of each zone ( $i$ ) and biomass storage at locations  $s$ . The second layer (L2) represents the SRC plants which are located at sites  $j$ . SRC processes are formulated as a flowsheet structure consisting of two heat exchangers (boiler and condenser) and two pressure changers (turbine and pump). The formulation enables consideration of details, such as optimization of temperatures, pressures, flowrates, specific enthalpies and energy flows. Generated products by SRC plants (heat and electricity) are then distributed to the third layer (L3) at sites  $d$ . Road transport is considered as the transportation mode for biomass to SRC utilisation sites, while pipeline is used for delivery of hot water to demand sites.

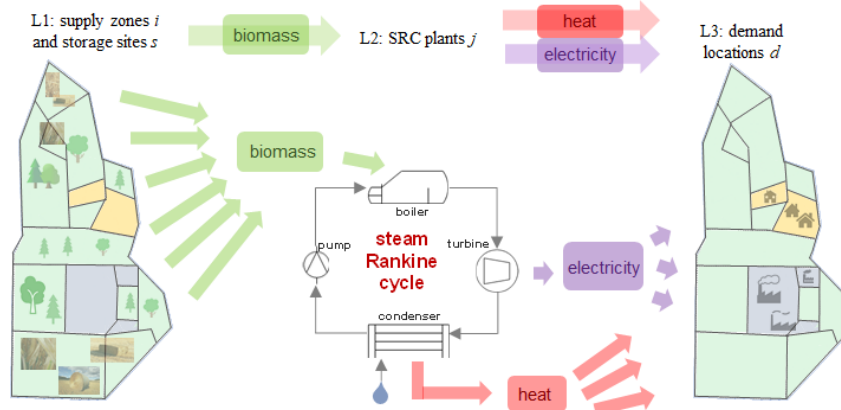

Figure 1: Schematic representation of integrated biomass supply network and SRC

### 2.2. Model Formulation

The developed model for optimization of biomass supply chain for maximal profit of sold electricity and heat produced by SRC reduced by variable transportation cost comprises material and energy balances and economic constraints (transportation cost, revenue) for the supply and demand layers, interconnections supply - process and process - demand and optimization of SRC which accounts for optimizing the operating conditions of the cycles. The approach for simultaneous consideration of supply network and process flowsheet optimization is based on the work by Kegl et al. (2021) and the approach for optimizing operating conditions in the SRC is adapted from Dokl et al. (2022).

For simplification, the main objective ( $Z$ ) is to maximize revenue obtained from SRC ( $R_{SRC,i}$ ) subtracted by transportation cost generated from the supply network ( $c_{tr}$ ) (Eq. (1)).

$$Z = \max(\sum_{j=1}^n R_{\text{SRC}_j} - c_{\text{tr}}) \quad (1)$$

Such objective is selected to identify a simple economic bound of the system (Biegler et al., 1997), while considering only such costs that the selected distances between possible connections will be minimal. Transportation cost is for simplification thus calculated only based on the distance variable costs, and accounts for factors related to return trips and tortuosity factor (Egieya et al., 2019). The obtained revenue of plant  $j$  is based on production of electricity and heat (Eq. (2)). Electricity generation in the turbine depends on the fluid flow rate ( $q_j^{\text{turb}}$ ), specific enthalpy difference ( $h_j^{\text{turb,out}} - h_j^{\text{turb,in}}$ ) and turbine efficiency ( $\eta_j^{\text{turb}}$ ), while the obtained heat in the form of hot water at the condenser outlet is described by the heat duty of the condenser ( $Q_j^{\text{cond}}$ ) reduced by the transportation heat loss ( $L_{\text{tr}}^{\text{heat}}$ ) between plant  $j$  and demand site  $d$  ( $D_{j,d}$ ).

$$R_j = (q_j^{\text{turb}} \cdot (h_j^{\text{turb,out}} - h_j^{\text{turb,in}}) \cdot \eta_j^{\text{turb}}) + (Q_j^{\text{cond}} \cdot (1 - L_{\text{tr}}^{\text{heat}})^{D_{j,d}}) \quad (2)$$

The optimized operating conditions are obtained by correlating thermophysical properties with temperature and/or pressure. Such properties are specific enthalpies of water and steam (Fig. 2), vapor liquid pressure, specific heat capacity at constant pressure and heat capacity ratio.

Figure 2: Specific enthalpy of a) water and b) steam, changing with temperature and pressure

### 3. Case Study and Results

The integrated biomass supply network – SRC flowsheet optimization model is implemented on a demonstration case study of a relatively small region. For simplification, the model assumes single time-period and the average values of parameters in a year. The map of the case study is shown in Fig. 3, with a total area of 906.6 km<sup>2</sup>. Up to 17 supply ( $i_1 - i_{17}$ ), 8 storage ( $s_1 - s_8$ ), 5 plant ( $j_1 - j_5$ ) and 5 demand locations ( $d_1 - d_5$ ) (built-up and industrial areas) could potentially be selected.

The actual areas for growing biomass in zones (forest and agricultural areas) are between 10 and 90 % of the zone areas. The yield of wood is based on MKGP (2011) and of agricultural residues from Jejičič and Verbič (2019). Only the main biomass feedstocks  $pb$  are considered, which are wood, corn stover, grain straw and oilseed straw with the yields of 3.21 t/(ha·y) for wood, 5.41 t/(ha·y) for grain straw, 5.59 t/(ha·y) for corn stover and 5.72 t/(ha·y) for oilseed straw. The distribution of area for biomass in the municipality is 87.3 % for wood, 8.6 % for grain straw, 3.9 % for corn stover and 0.2 % for oilseed straw.

For the SRC, all the characteristics of process units and streams were optimized to satisfy the given objective. The only assumptions are minimum temperature difference in condenser, which is 5 °C for all the cycles, 85 % mechanical efficiency of turbines, maximum flow rate of water in the condenser of 200 kg/s (Yıldırım et al., 2006), and temperature of water at condenser inlet (50 °C) and outlet (90 °C) (Čuček et al., 2015). The MINLP model consists of 3852 single equations, 5026 single variables, and 25 binary variables and was solved using DICOPT solver in GAMS (GAMS, 2022). The solutions are provided in around 10 s on a personal computer with an Intel® Core™ i7-10750 H CPU @ 2.60 GHz processor with 16 GB RAM. For the calculation of the revenue from sold electricity and heat, price of electricity of 222.48 €/MWh was assumed as the average day-ahead Slovenia auction trading price of November 2022 (BSP Energy Exchange, 2022) and price of heat of 101.07 €/MWh, which is a recent price for the supply of natural gas for business consumption (Energetika Ljubljana, 2022).

The results from the breakdown of optimal quantities of feedstocks selected and related transportation cost together with optimal conditions of selected SRC plants ( $j_1$ ,  $j_3$  and  $j_4$ ) are shown in Table 1. From Table 1 it can be seen that optimal biomass supply chain structure and operating conditions of SRC plant can generate the total annual revenue of 67.89 M€, of which the highest revenue is obtained from heat (29.12 M€/y) and electricity (8.53 M€/y) by SRC plant  $j_3$ .

Optimal turbine working conditions are the same for all selected SRC plants, where steam enters the turbine with temperature of 284.7 °C and pressure of 5.8 bar and passes to the condenser with temperature of 103.9 °C and pressure of 1.1 bar. Higher heat and electricity rates in plant  $j_3$  correspond to higher flows of working fluid and water in the condenser, reaching the upper limit of 200 kg/s. SRC plant  $j_4$  has for 14 M€/y lower revenue than plant  $j_3$ , while with plant  $j_1$  only 6.6 M€/y of revenue is obtained. Distance-dependent transportation cost presents 7.98 % of revenue for plant  $j_1$ , 2.2 % for plant  $j_3$ , and only 0.72 % for  $j_4$ . Fig. 4 further shows optimised supply chain superstructure, presenting relation between layers with optimal selection and connections between sites of biomass supply, storage sites, utilisation plants, and demand sites.

Three storage locations are selected for storing feedstocks, where  $s_2$  receives biomass from 8 zones,  $s_6$  from 9 zones, one of which ( $i_{16}$ ) transport biomass also to  $s_8$ . Feedstock is further transported to the selected utilisation plant  $j_1$ ,  $j_3$ , and  $j_4$ , delivering produced heat to demand sites  $d_1$ ,  $d_3$ , and  $d_4$ .

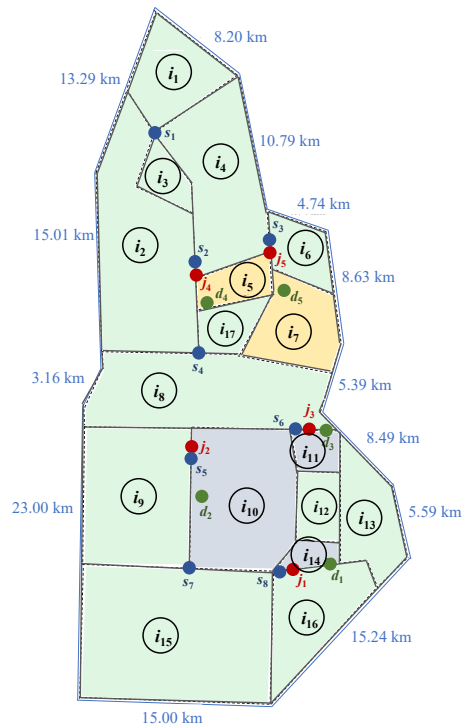

Figure 3: Map of demonstrative case study with areas of zones, storage, plant and demand sites

Table 1: Optimal values of variables for selected SRC plants

Optimal values	$j_1$	$j_3$	$j_4$
<b>Steam Rankine cycle</b>			
$Q_{\text{boiler}}$ (kW)	6879.1	38,670.9	24,420.2
$W_{\text{turbine}}$ (kW)	778.4	4375.7	2763.2

Revenue from heat (M€/y)	5.08	29.12	18.26
Revenue from electricity (M€/y)	1.52	8.53	5.39
Objective value (M€/y)	66.37		

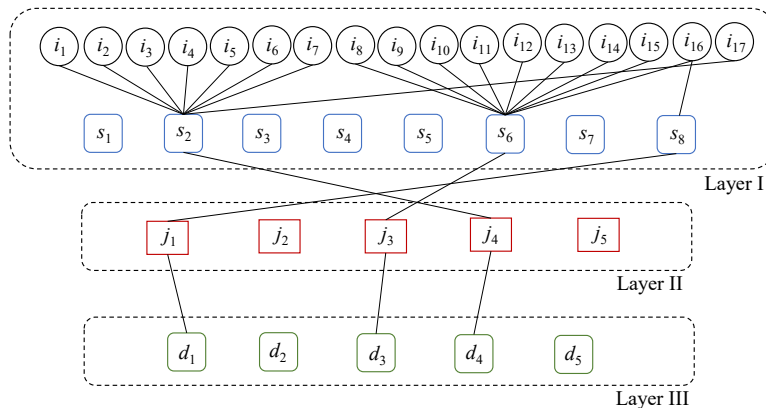

Figure 4: Biomass supply chain superstructure

Figure 5:  $T-s$  diagram for SRC at selected plants

In Fig. 5 temperature vs. entropy ( $T-s$ ) diagram for all the selected SRC plants is shown, representing energy transfer within the cycles. The lower horizontal blue line illustrates steam condensing in the condenser, which is further passed to the boiler, where its temperature is increased to 284.7 °C, extending high above saturation curve (grey dashed curve) as it is being superheated for about 126 °C. The expansion in the turbine is shown by vertical blue line, also closing the cycle by entering the condenser again.

#### 4. Conclusions and Recommendations

In this paper the integration of biomass supply network and SRC flowsheet is performed by optimising the revenue from selling electricity and heat subtracted by transportation

cost, and demonstrated on an illustrative case study of a relatively small region. The optimal structure of biomass supply network at optimal operating conditions of selected SRC plants can annually produce almost 8 MW of electricity and about 1300 t/h of hot water for district heating at supply and return temperatures of 90 and 50 °C. Optimal supply chain consists of 17 biomass supply zones, 3 storage locations, 3 SRC plants for biomass utilisation and 3 demand sites of heat consumption. In the future, a multiperiod model could be developed to account for the seasonal characteristics of biomass supply and the complete economic and environmental performance of the studied superstructure could be evaluated.

## Abstract

Process developments to achieve more efficient monoclonal antibody (mAb) production processes include cell line modifications to obtain high-performance alternatives. Cell lines with higher growth rates can exhibit higher sensitivities to variations in carbon sources in the cell culture leading to shifts in metabolic behavior. Current kinetic process models often rely on static model parameters like specific cell consumption and production coefficients. Such models can be inadequate for describing process performance in cases of shifts in cell metabolism. Further understanding of the complex biological phenomena is required to develop more robust process models. In this work, pilot-scale experimental results were obtained for a novel high-performance cell line exhibiting switches in metabolic behavior. State estimation-based methods were used to evaluate the model fit over the course of the run and to identify regions where parameter updates are required. Clustering of the underlying experimental conditions was performed to isolate the sources of variations and correlate them with the different regions of model fit. Alternative empirical formulations are accordingly proposed for the varying model parameters. This approach allows for the development of more interpretable hybrid models by using the data-driven insights to categorize and describe the underlying variations in operating parameters and their influence on cell behavior and process performance.

**Keywords:** Biopharmaceutical production, cell culture, state estimation, hierarchical density-based clustering

## 1. Introduction

The exponential rise in demand for monoclonal antibodies (mAb) over the past decade (Butler & Meneses-Acosta, 2012; Walsh, 2018) has been driving the search for innovative solutions to increase production efficiency. In addition to exploring different operation modes, e.g., continuous cultivation, and optimizing operating conditions, developments were achieved through modifying the cell lines used (Badr & Sugiyama, 2020). The newly established CHO-MK cell line is a high-performance alternative offering rapid cell growth and higher mAb productivity. This cell line is, however, sensitive to carbon source

concentrations, e.g., glucose and lactate, and could exhibit fluctuating behavior in cell metabolism. A shift from lactate production to net consumption has been observed with this cell line. Such shifts have been reported for other cell lines in literature, but the exact mechanism leading to such a switch is still unverified (Hartley et al., 2018). Understanding and manipulating these shifts is important for better process controllability and achieving higher efficiency.

Developing versatile process models to adequately describe the process operation and changes is essential to reach optimal solutions for process design, operation, and control. Kinetic models currently available for describing cell cultivation often rely on static parameters to describe cell-related factors, such as specific productivity or nutrient consumption rates. For stable cell lines, like the standard CHO-K1 cells, these models could show relatively good fit to the experimental and pilot-scale data obtained (Badr et al., 2021). In industrial or experimental applications, cells may temporarily take different metabolic pathways. The reliance on static parameters in the models often leads to discrepancies with industrial applications, especially in the case of sensitive cell lines as the CHO-MK cell line. Discrepancies can be sometimes only partial and not over the course of the entire experimental run. Okamura et al. (2022) have demonstrated the use of a hybrid modelling technique, which inserts a data-driven module to get updated parameter values to better describe shifts to lactate consumption. The input to the data-driven module included the online sensor measurements and the initial predictions of the kinetic model.

In this work, we investigate a data-driven approach to aid the development of more comprehensive and robust mechanistic models for process design and control. This work aimed to isolate the operating conditions correlated to the shifts in metabolic behavior and a change in state. The model fit was analyzed to identify regions where parameter updates are required. Data clustering of the online measurements was used to isolate separate phases of the underlying experimental conditions. The results were combined to suggest new forms for influential model parameters.

## 2. Methods

### 2.1 Experimental data

Pilot-scale experimental data were obtained from the Kobe GMP consolidated lab of the Manufacturing Technology Association of Biologics in Japan. CHO-MK 9E-1 cells were cultivated in a 50 L stirred tank in fed-batch mode for 7 days. Supplementary media feeding was started on day 2. Feeding rates were doubled on day 3 and then adjusted on the following days to maintain a glucose concentration of 3 g/L in the solution. Nutrient and metabolite concentrations were measured daily. Online measurements included dissolved oxygen, pH, temperature, pressure, solution weight, air and oxygen sparging, and agitation rate.

### 2.2 Kinetic model

The model used to describe fed-batch cultivation was based on the one presented by Badr et al. (2021) and adapted by Okamura et al. (2022). The model involves a set of mass balance equations for important system components and Monod expressions for cell growth and death as shown in Eq. (1-7).

$$\frac{d(VX_V)}{dt} = (\mu - \mu_d) VX_V \quad (1)$$

$$\frac{d(VP)}{dt} = Q_P VX_V \quad (2)$$

$$\frac{d(V[GLC])}{dt} = - \left( \frac{\mu}{Y_{X_V/glc}} + m_{glc} \right) VX_V + F_{in} C_{in} \quad (3)$$

$$\frac{d(V[LAC])}{dt} = Q_{lac} VX_V \quad (4)$$

$$\frac{d(V)}{dt} = F_{in} \quad (5)$$

$$\mu = \mu_{max} \left( \frac{[GLC]}{K_{glc} + [GLC]} \right) \left( \frac{KI_{lac}}{KI_{lac} + [LAC]} \right) \quad (6)$$

$$\mu_d = k_d \left( \frac{[LAC]}{KD_{lac} + [LAC]} \right) \left( \frac{KD_{glc}}{KD_{glc} + [GLC]} \right) \quad (7)$$

where,  $X_V$  is the viable cell density and  $V$  is the culture volume.  $F_{in}$  is the supplementary feed flows rate.  $P$ ,  $[GLC]$ , and  $[LAC]$  represent the antibody product, glucose and lactate concentrations, respectively.  $C_{in}$  is the glucose concentration in the supplementary feed streams.  $\mu$  and  $\mu_d$  are cell growth and death rates respectively, while  $\mu_{max}$  and  $k_d$  are their corresponding maximum values.  $Q_P$  is the specific productivity of mAb, while  $Q_{lac}$  is the specific productivity of lactate.  $Y_{X_V/glc}$  and  $m_{glc}$  represent specific glucose consumption for cell growth and maintenance, respectively.  $KI_{lac}$ ,  $K_{glc}$ ,  $KD_{lac}$ ,  $KD_{glc}$  are the Monod model parameters. In the previous works,  $Q_{lac}$  [ $\text{mmol cells}^{-1} \text{h}^{-1}$ ] has been treated as a constant. However, to account for shifts between lactate production and consumption,  $Q_{lac}$  should either be treated as a variable that can vary in magnitude and direction, or an additional term for lactate consumption should be added to Eq. 4.

### 2.3 Data Analysis

State estimation methods have been extensively used in the chemical industry for control applications where process models are well established (Mohd Ali et al., 2015). Observers can be used to estimate hard to measure state variables. A recent study demonstrated the application of the extended Kalman filter (EKF) with a hybrid model for monitoring and control of mammalian cell cultures with limited mechanistic understanding (Narayanan et al., 2020). In this work, we explored the use of a similar concept for the development of improved process models.

Parameter estimation was first conducted given the measured experimental values of system concentrations. Initial guesses for model parameters were provided and a one step forward solution was obtained. A solution was found to minimize the error between the model estimates and experimental values. The model fit was assessed during different regions of the experimental run. This approach allows us to isolate the regions where parameter updates are required. Further analysis of the experimental conditions enables matching the regions with required parameter updates to the underlying varying conditions thus giving a basis for the generation of modified model equations.

Hierarchical density-based clustering (HDBSCAN) was then applied to the online experimental measurements. This method was chosen due to its resilience to noise in the data and its ability to identify clusters of nonuniform densities. It also requires minimal parameter finetuning or assumptions about the number of clusters in the data. The minimum number of points per cluster was set to 50, which is low compared to the size

of the online measurements taken every minute, effectively unrestricted the number of clusters formed. The resulting clusters were compared to the different regions of varying model fit and the underlying varying experimental conditions were accordingly isolated. Experimental measurements of lactate concentrations were interpolated using the Akima spline method and were used to regress the values for  $Q_{lac}$ . Alternative formulations for  $Q_{lac}$  were then suggested as a function of the identified varying experimental conditions.

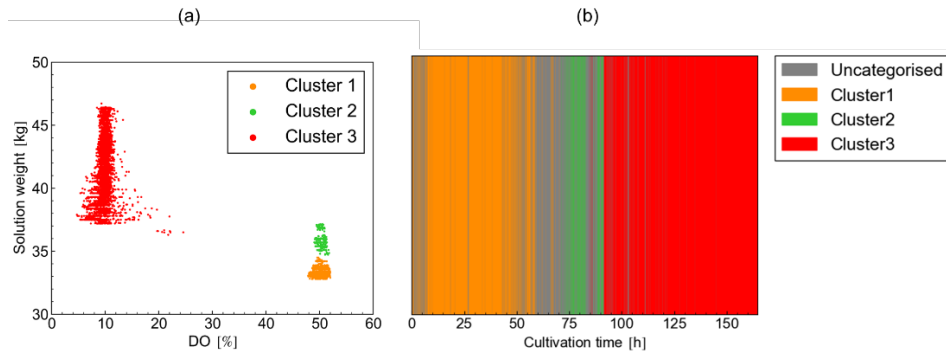

### 3. Results and discussion

**Figure 1** shows an example of the obtained results of the final one step forward simulation using the updated parameters estimated by the implemented algorithm. The figure shows three regions of different model fit to estimate lactate concentrations. Lactate was the component with the highest discrepancies between model estimations and the experimental results relative to all predicted concentrations. There were areas of good model fit observed towards the latter half of the experimental run, areas of partial fit, where model predictions were correct in direction but not in magnitude, and finally areas of poor fit, where the model failed to capture both magnitude and direction of lactate concentration development. Regions of poor fit were those where the cell shifted to net lactate consumption instead of production, this generally coincided with nutrient depletion in the solution.

The results of the clustering step for the operating conditions are shown in **Figure 2**. Three clusters were identified by the algorithm. The strongest separation of the different clusters was observed as a function of the solution weight and the dissolved oxygen (DO) levels as shown in **Figure 2(a)**. Nutrient addition during the fed-batch run leads to changes in the solution weight. The dependency on the solution weight indicates a strong role of nutrient levels in determining the different clusters. In addition, other conditions that showed an impact on cluster formation were the pH and the  $O_2$  sparging levels. **Figure 2(b)** shows a representation of the distribution of the cluster points along the course of the experimental run. The identified clusters were closely related to the different regions of model fit. As a result, it can be concluded that the identified conditions were correlated with the changes in the cell metabolic behavior, resulting in net lactate consumption.

**Figure 1.** Measured lactate concentrations in comparison to the results of the one step forward simulation using the estimated model parameters to assess the model fit.

**Figure 2.** Results of the HDBSCAN clustering. (a) solution weight plotted against dissolved oxygen, (b) the distribution of the clusters with respect to experimental run time.

Regression of the  $Q_{lac}$  values from the experimental values and Eq. 4 show that  $Q_{lac}$  is only constant in the latter regions of the experimental run (coinciding with clusters 2 and 3). Whereas in the earlier regions (cluster 1), values of  $Q_{lac}$  decreased until negative values were reached, indicating net lactate consumption. **Figure 3** shows the regressed values of  $Q_{lac}$  along the experimental run. The variations in  $Q_{lac}$  values in the earlier regions (cluster 1) showed a strong correlation with variations in the  $O_2$  sparging levels. Therefore, an empirical formula for calculating  $Q_{lac}$  in the variable region as a function of the  $O_2$  sparging rate [ $L\ min^{-1}$ ] was proposed as follows in Eq. 8. **Figure 3** shows the correspondence between the calculated and the experimentally obtained values of  $Q_{lac}$ , where an  $R^2$  value of 0.93 was obtained.

$$Q_{lac} = \frac{k_0}{k_1 + O_2 \text{ sparging rate}} + k_2 \quad (8)$$

The influence of the  $O_2$  sparging rate on the  $Q_{lac}$  must still be studied in further detail to draw more concrete mechanistic conclusions. Oxygen sparging is assumed to impact dissolved oxygen levels in the system in addition to affecting the general mixing conditions in the reactor. While the sparging rates varied rapidly in the system, DO levels remained fairly constant in the bulk levels during cluster 1 conditions (**Figure 2 (a)**). This could suggest an impact of sparging levels on local variations in nutrient, metabolite, and

**Figure 3.** Regressed values of the specific lactate productivity factor ( $Q_{lac}$ ) from the experimental data and comparison to calculated values for each of the identified clusters.

oxygen concentrations around the cell. Another aspect to be investigated is the impact of changes in pH on  $Q_{lac}$  and on the cell metabolic behavior. Lactate concentrations strongly impact pH levels, while concurrently variations in pH have been reported to influence the switch from lactate production to net consumption (Hartley et al., 2018). Further work also includes determining the role of depletion of different nutrients, e.g., glucose and glutamine, on variation of  $Q_{lac}$ . Further experimental runs are required to confirm the findings and resolve the uncertainties.

#### 4. Conclusions

This work exploits state estimation concepts to develop an understanding of model fit in cases where shifts in cell metabolic behavior result in a need for model parameter updates. Clustering of experimental conditions is used to isolate the underlying variations in experimental conditions leading to a change of cell metabolic behavior and state. This approach allows the development of more interpretable hybrid models, where the data-driven insights are used to describe correlations between experimental conditions and variations in model parameters. The derived insights in this approach can be applied to develop more flexible and representative mechanistic models which can increase the interpretability of the results and help achieve further understanding of the complex biological phenomena.

## Abstract

Pressure swing adsorption (PSA) has been widely studied for various gas separation tasks. The efficiency of PSA processes is influenced by the properties of adsorbents and the process operating conditions. As innovative adsorbents, metal-organic frameworks (MOFs) have been designed and synthesized. As special family of MOFs, anion-pillared (AP) MOFs where anion groups (e.g.,  $\text{SiF}_6^{2-}$ ,  $\text{TiF}_6^{2-}$ ,  $\text{AlF}_5^{2-}$ , etc.) are used as linkers have been proposed for the separation of light hydrocarbon. The pore size and framework topology (e.g., interpenetrated and non-interpenetrated) of AP MOFs have a dramatic impact on the adsorptive behavior. Considering the diversity of MOF chemistry and only a limited number of AP MOFs reported, a large design space is worth to be explored. In this work, a computational approach is developed to design new hypothetical AP MOFs. The objective is to find high-performance AP MOFs that can be used in PSA processes for propane/propene separation.

**Keywords:** metal-organic frameworks, anion-pillared MOF, computational material design, organic linkers, C3 separation

## 1. Introduction

Pressure swing adsorption (PSA) has been widely applied in the chemical and energy industries for gas separation. It exploits the different affinity of gaseous components to solid adsorbents at different pressures to achieve gas separation. Hence, the adsorbent properties strongly influence the separation efficiency. As well known, multiple types of porous materials can be used as adsorbents such as metal-organic frameworks (MOFs), zeolites, or porous polymers. Among them, MOFs are formed via the self-assembly of different building blocks (i.e., metal nodes and organic linkers) in different topologies. Due to the large variety of available building blocks, MOFs have a nearly infinite design space (Yao et al. 2021). In addition, MOFs have many superior properties such as large porosity, tunable pore geometry, functional pore surface, and importantly modular-ordered. Thus, it is desirable to develop high-performance MOFs that can enhance process efficiency in adsorption-based gas separation (Zhang et al., 2020).

When MOFs are used as adsorbents, four alternative separation mechanisms exist: equilibrium separation, kinetic separation, molecular sieving, and gate-opening separation. Among these, equilibrium separation is the most common method, which enables separation based on the difference of gas equilibrium loadings. So far, an increasing number of MOFs with diverse isotherm characteristics have been synthesized

by varying MOF chemistry and structure (e.g., pore geometry and topology). Given certain separation tasks, it has been found that many MOFs fail to achieve the pre-specified separation requirements, not to mention good process performance (Burns et al. 2020). To find promising MOF adsorbents efficiently, various computational screening strategies have been developed. In general, a set of MOF candidates are collected. Their adsorption and diffusion properties are computed via molecular simulations. Then, simple performance metrics (e.g., working capacity and selectivity) are calculated to rank top candidates. Although this approach can be used to screen a large pool of MOFs, using simple performance metrics cannot tell whether specific separation requirements are satisfied, particularly when tough separation specifications (e.g., purity  $\geq 99.95\%$  in  $H_2$  purification) exist. Thus, a computational methodology is developed in this work to design and screen MOFs that can best serve the process for achieving pre-specified gas separations.

Anion-pillared (AP) MOFs where anion groups (e.g.,  $SiF_6^{2-}$ ,  $TiF_6^{2-}$ ,  $AlF_5^{2-}$ , etc.) are used as linkers have been highlighted for light hydrocarbon separations. The pore sizes of AP MOFs can be fine-tuned by rationally designing their chemistry. It has been found that small changes of pore sizes can have a dramatic impact on the adsorptive behavior of AP MOFs. Moreover, AP MOFs generally have two types of cuboid networks: non-interpenetrated and interpenetrated. The non-interpenetrated network is the standard primitive cubic (i.e., *pcu*) topology, while the interpenetrated one is composed of doubly interpenetrated nets that are isostructural to the non-interpenetrated network (Lin et al. 2011). Evidently, the non-interpenetrated network can form a small pore size with a large organic linker. So far, only a limited number of AP MOFs have been reported and a large design space has not been explored yet considering the diversity of MOF chemistry. This inspired us to design new AP MOFs for efficient gas separation.

As an essential building block for polypropylene production, propene (PE) is a key olefin raw material. It is widely known that polypropylene synthesis requires high-purity propylene (over 99.5%). Thus, the removal of other hydrocarbons, especially propane (PA), from propene is one of the critical gas separation tasks in the modern chemical industry. Currently, this is achieved by the energy-intensive cryogenic distillation. As energy-efficient alternatives, adsorption-based separation methods are of great interest. In this case, the development of advanced adsorbents that can achieve low energy consumption is crucial. Thus, the objective of this work is to use the proposed methodology to design new hypothetical AP MOFs for efficient PA/PE separation.

## 2. Workflow of Anion-pillared MOF Design

Figure 1 shows the explicit workflow for computational AP MOF design. First, the reported AP MOFs are collected and decomposed to identify the feasible alternatives of metal nodes and anion pillars. Meanwhile, all the MOFs in the 2019 CoRE MOF database are deconstructed. Referring to the common characteristics found in AP MOFs, feasible organic linkers are selectively extracted. Then, based on the topology templates and the collected building blocks, we constructed hypothetical AP MOFs using ToBaCCo that are modified to generate MOFs with two types of organic linkers (i.e., anion pillars and the general organic linker). Afterwards, the single-component adsorption isotherms of hypothetical AP MOFs are predicted using grand canonical Monte Carlo (GCMC) simulations performed in RASPA. To improve the reliability, new Lennard-Jones (LJ) parameters that are suitable for AP MOFs are calibrated based on experimental isotherm data. The obtained single-component isotherms are used to fit the multi-component

isotherm models that can be directly applied in a short-cut PSA model. This model can efficiently evaluate whether the new AP MOFs are feasible to satisfy the pre-specified separation requirements. After this feasibility check, rigorous PSA optimization are performed on the feasible AP MOFs to obtain the optimal adsorbent together with optimal PSA process operating conditions.

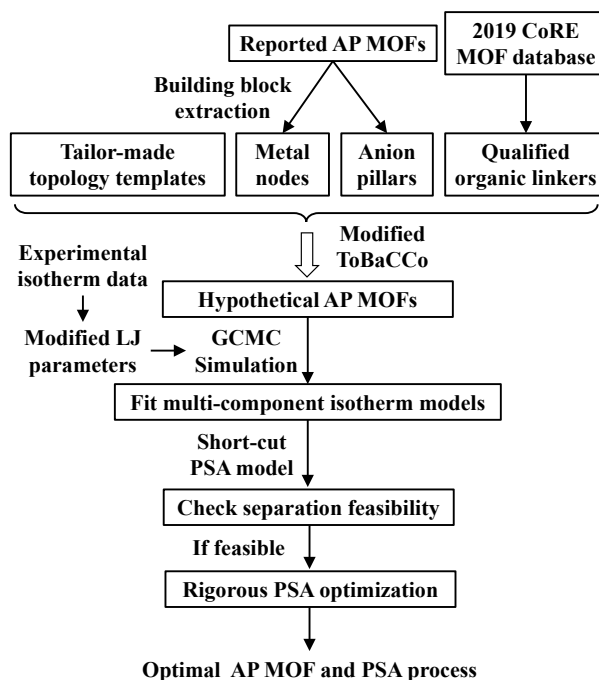

Figure 1. Workflow of computational AP MOF design.

### 3. Build Blocks Construction

AP MOFs consists of metal nodes and two types of organic linkers (i.e., anion pillars and general organic linkers serving as donor and acceptor, respectively) in certain topologies. For creating sound feasible AP MOFs, proper building blocks and topology templates have to be specified.

#### 3.1. Two topology templates

So far, AP MOFs with limited types of topologies (e.g., *pcu*, *pcu-i*, *mno*, *pto*, etc.) have been successfully synthesized. Since the non-interpenetrated *pcu* and interpenetrated *pcu-i* are the two most common topologies, only these two types are considered here. The *pcu* template can be found in the original ToBaCCo platform, while the *pcu-i* template is made using Material Studio.

#### 3.2. Sixty-four feasible organic linkers

The general organic linkers that can be used in AP MOFs are extracted from the CoRE MOFs. After removing the CoRE MOFs with structural defects, 9268 CoRE MOFs are left and 14107 organic linkers can be extracted. Then, referring to the most reported AP MOFs, it is found that the general organic linkers should be symmetric and only consist of carbon, nitrogen, and oxygen atoms (Li et al. 2022). Considering these common characteristics, 64 unique symmetric organic linkers are finally obtained.

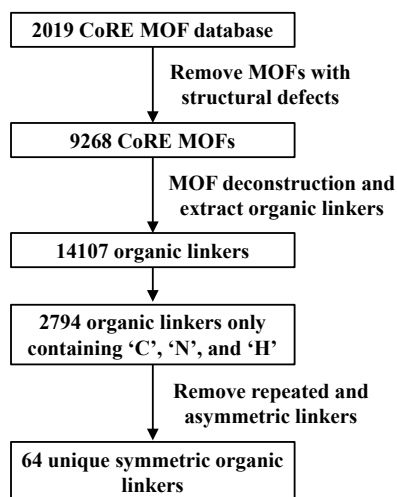

Figure 2. Procedures of extracting general organic linkers used in AP MOFs.

### 3.3. Five metal nodes and eight anion pillars

After decomposing the reported AP MOFs with *pcu* and *pcu-i* topologies, it is found that the metal nodes are simply single-metal atoms and five metal atoms are commonly involved (i.e., Zn, Fe, Cu, Co, Ni). In addition, 8 kinds of anion pillars are found including  $\text{SiF}_6^{2-}$ ,  $\text{TiF}_6^{2-}$ ,  $\text{SnF}_6^{2-}$ ,  $\text{GeF}_6^{2-}$ ,  $\text{ZrF}_6^{2-}$ ,  $\text{FeF}_5^{2-}$ ,  $\text{AlF}_5^{2-}$ , and  $\text{NbOF}_5^{2-}$ . With these, the collected AP MOFs in the form of cif files are imported into Material Studio to extract the corresponding metal nodes and anion pillars.

### 3.4. Bond lengths between building blocks

For MOF construction, building blocks are connected via single-bonds. Given the collected building blocks above, metal-fluorine bonds are formed when connecting metal nodes and anion pillars. Metal-nitrogen bonds are formed when connecting metal nodes and general organic linkers. Since each atom-atom pair has different bond length, the bond lengths between metal-nitrogen and metal-fluorine should be specified explicitly. Based on the reported AP MOFs, Table 1 lists the average bond lengths between metals and two connection atoms. These data can be directly used to adjust the sizes of the five metal nodes.

Table 1. Bond lengths between metals and connection atoms in AP MOFs.

Metal	Metal-fluorine distance (Å)	Metal-nitrogen distance (Å)
Co	2.04	2.15
Cu	2.25	2.04
Fe	1.99	2.19
Ni	1.97	2.08
Zn	2.09	2.13

## 4. Design of anion-pillared MOFs for PA/PE separation

### 4.1. ToBaCCo-based AP MOF generation and isotherm prediction

The prepared building blocks and topology templates are imported into the modified ToBaCCo to generate hypothetical AP MOFs. In this process, a series of MOF construction feasibility rules will be verified and the cell sizes will be optimized. After this, over 3000 hypothetical AP MOFs in the form of crystallographic information framework (.cif) files are obtained.

The cif files are directly used to perform GCMC simulations using the open-source software RASPA. The reliability of GCMC simulations relies on the force field parameters (i.e., LJ parameters). It is well-known that generic force fields such as DREIDING force field and Universal Force Field (UFF) are widely used in MOF screening studies. However, for AP MOFs, the PA and PE isotherms cannot be predicted accurately using those general force fields. Thus, a new set of LJ parameters should be specified based on experimental isotherm data. After careful literature review, the single-component PA and PE experimental isotherm data at 298 K of three AP MOFs (i.e., GEFIX-2-Cu-i, SIFSIX-2-Cu-i, and NbOFFIVE-i-Ni) are collected (Wang et al. 2020; Cadiau et al. 2016). On the basis of UFF, the LJ parameters of three atoms (i.e., Ni, Nb, and Ge) and two groups (i.e., CH<sub>3</sub>- and CH<sub>2</sub>- for PE) should be modified so that the predicted isotherms can match the corresponding experimental data well.

### 4.2. Process-based AP MOF screening

After specifying the new LJ parameters, the single-component PA and PE adsorption loadings at four pressure levels (i.e., 0.1, 0.5, 1, and 2 bars) and 313 K are calculated for all hypothetical AP MOFs. The obtained GCMC results are used to fit the multi-component dual-site Langmuir isotherm models for the purpose of process-based screening and optimization.

Clearly, it brings great computational burdens to perform rigorous PSA optimization for all the AP MOFs. Thus, for fast screening, a short-cut PSA model is proposed to identify whether an AP MOF can meet the pre-specified separation specifications (i.e., 99.5% PE purity and 65% PE recovery). The short-cut model is based on a one-bed, four-step PSA process that consists of pressurization, adsorption, rinsing, and desorption steps. It is assumed that the column is initially saturated with 99.95% PE at a low pressure ( $P_{low}$ ). The column goes through the pressurization step where PA/PE gases at a high pressure ( $P_{high}$ ) are fed into the bottom of the column. The PE mole fraction in the feed gas is set to 85%. The top is closed and the internal pressure gradually increases. When the column's top reaches an intermediate pressure level (i.e.,  $0.85P_{high}$ ), the top is opened and the adsorption step begins. The adsorption is stopped when the stream leaving the top is the same as the feed gas (i.e., breakthrough state). Afterwards, based on the mass balance and PE recovery, a certain amount of 99.5% PE gas is fed into the bottom for rinsing. Finally, in the desorption step, a constant low pressure ( $P_{low}$ ) is enforced at the bottom of the column where purified PE can be collected. If the collected PE stream has a purity above 99.5%, the column state at the end of desorption can presumably be equal to the initial state (i.e., 99.5% PE at the low pressure). This implies that the adsorbent can meet the pre-specified separation requirements. Otherwise, the adsorbent is deemed as infeasible one. Clearly, this short-cut model is a batch PSA process model with two variables (i.e.,  $P_{high}$  and  $P_{low}$ ). Grid search on the two variables can be easily performed for a complete feasibility check. Hence, the proposed short-cut model is applied to screen all the generated AP MOFs. It can be found that a set of potential AP MOFs can survive such as NbOFFIVE-15-Fe-i and SIFSIX-2-Co. By minimizing the energy consumption

and maximizing the productivity, finally a multi-objective rigorous PSA optimization can be performed on those feasible AP MOFs for final evaluation.

## 5. Conclusions

This work presented a computational approach to systematically design and screen hypothetical AP MOFs for efficient PA/PE separation in PSA processes. The workflow starts with extracting various building blocks from the reported AP MOFs and the CoRE MOFs. Together with two topology templates, hypothetical AP MOFs are constructed using the modified ToBaCCo. For each generated AP MOF, GCMC simulations are performed using newly calibrated LJ parameters to predict the single-component adsorption loadings of PA and PE. With the predicted loadings, multi-component DSL isotherms are fitted and used in a short-cut PSA model for fast screening. Finally, for the survived candidates, rigorous multi-objective PSA optimization are carried out in order to find the real optimal AP MOFs and the corresponding process operating conditions. Clearly, as demonstrated via the PA/PE separation example, hypothetical AP MOFs leading to better process performance can be computationally synthesized and screened. The major novelty of the present work is the use of modified computational tools and models to design optimal AP MOFs efficiently. Since AP MOFs with specific topologies have similar synthesis routes, this provides great conveniences for the subsequent experimental validation.

## Abstract

Polymer Matrix Composite (PMC) is gaining attention for its excellent modeling processability, light weight, low unit cost, and various mechanical properties by reinforcing the heat resistance and strength of plastics with fillers. However, to this day, PMC development relies on designers' intuition, and the cost of repeated testing is quite high. Therefore, in order to enhance PMC's development competitiveness, an AI model that predicts mechanical properties according to the combination and composition of constituent materials is essential. Since these mechanical properties can be grasped using the Stress-Strain curve (S-S curve) obtained from tests such as tensile, creep, and bend, the S-S curve is a kind of mechanical property evaluation index that can accurately know the mechanical properties.

However, Finite Element Method (FEM)-based simulators or Machine Learning (ML)-based predictive models that calculate S-S curve are deterministic models that provide only one S-S curve and do not have a predictive model that considers the uncertainty (variance) of PMC tensile data. Therefore, in this study, after collecting S-S curve data of PMC, Using the Probabilistic Neural Network (PNN) model, we develop a model that predicts the confidence interval along with the mean value of the tensile S-S curve of the PMC. The performance of the developed model is evaluated on the  $R^2$  basis, and it is confirmed that not only the elastic section, which is relatively easy to predict, but also the S-S curve of the plastic section can be predicted. Based on the results of future research, it is expected that this model can be used to build an AI-based PMC reverse engineering system.

**Keywords:** Polymer Matrix Composite (PMC), Mechanical behavior, Gaussian Process Regression (GPR), Probabilistic Neural Network (PNN), Feed-Forward Neural Network (FNN)

## 1. Introduction

The mechanical behavior of the material can be expressed in the S-S curve and not only the mechanical properties such as tensile strength, modulus of elasticity and maximum load are evaluated, but also the deformation from the elastic section to the plastic section. However, polymeric materials have a high uncertainty in the S-S curve due to the inherent

nonlinearity properties of the material, which shows a wide distribution. Therefore, in general, when designing polymers, the average value of the data obtained after conducting at least 10 experiments after uniform formulation and manufacturing conditions is used as the S-S curve of the material to consider 'uncertainty'.

However, if the average value of the repeated experiment is used, there is a possibility of over-estimating or under-estimating the physical properties of the composite material because it ignores the variance of the data. Prior studies that directly predicted the S-S curve, which is the result of such a PMC tensile test, [G. Chen et al. \(2021\)](#). In previous studies, the microstructure of composite materials is simulated and analyzed through Convolutional Neural Networks (CNN) models. However, the results of this study produce only one predicted S-S curve and are difficult to apply to composite materials such as PMC with a wide distribution. Therefore, as the first step in the AI-based material reverse engineering system, this study proposes a model that predicts the confidence interval of the S-S curve by reflecting the uncertainty of the PMC tensile S-S curve. First, Domain Knowledge is used to obtain information such as density, porosity, and Poisson's ratio of constituent materials to build a feature set. Next, feature engineering is performed to input a sufficient amount of information to predict the S-S curve of the PMC by the ML-based model and at the same time prevent falling into the dimensional curse. As a feature engineering technique, Feature elimination is used to secure an optimal feature set by selecting only useful features that are most involved in the performance of the model from the feature sets obtained. Using the obtained optimal feature set and tensile test data of PMC, model training is carried out, and a model is designed to predict the S-S curve of PMC using Gaussian Process Regression (GPR), a representative ML model that provides variance of regression results.

## 2. PMC Tensile Test Data

Figure. 1. Universal Testing Machine (UTM)

Matrix	Polypropylene (PP), Polycarbonate (PC), Polyamide 6 (PA6), Polyamide 6,6 (PA6,6)
Filler	Al <sub>2</sub> O <sub>3</sub> , Al <sub>2</sub> O <sub>5</sub> Si, Boron Nitride (BN), Si <sub>3</sub> N <sub>4</sub>
Matrix wt%	90 ~ 40

Figure. 2. Combination and composition of subject to tensile test

### 2.1. Data collection

A training database of an integrated model for predicting mechanical properties was established by integrating literature material information data, material information bank data, and data factory collection data. As for the tensile test data, the test was conducted with a universal testing machine as shown in Fig. 1. The material to be subjected to the tensile test was manufactured by selecting a PMC, which is widely used as a lightweight material. As shown in Fig. 2, the matrix was set to have Polypropylene (PP), Polycarbonate (PC), Polyamide 6 (PA6), Polyamide 6,6 (PA6,6) and filler were Al<sub>2</sub>O<sub>3</sub>, Al<sub>2</sub>O<sub>5</sub>Si, Boron Nitride (BN), and Si<sub>3</sub>N<sub>4</sub>, and the composition ratio of the polymer and filler was set to between 90% and 40%. According to the combination and composition set in this way, a total of 85 PMC specimens were produced and a tensile test was conducted.

As mentioned earlier, the uncertainty of the tensile test data of the PMC is high due to the high randomness of the polymer itself.

As can be seen from Fig. 3, the high dispersion of the PMC tensile test data shows different S-S curves even when manufactured and tested with the same recipe. Fig. 3 shows the tensile test data of the PMC manufactured with 40wt% PA6,6 and 60wt% Al<sub>2</sub>O<sub>3</sub>, 90wt% PC and 10wt% Al<sub>2</sub>O<sub>3</sub>. As can be seen from the figures, the tensile test data of each PMC has a high uncertainty of 7% to 24%.

Generally, when designing a PMC, the average value of physical properties obtained after performing five or more repeated experiments is determined and used as the physical properties of the polymer composite water. However, in this study, since the model design considering the uncertainty of the data is the goal, the collected S-S curve raw data was used as it is, not the S-S curve calculated as an average.

## Abstract

The profitability and sustainability of process industries are affected by the performance of each unit involved. A key measure of a unit's performance is based on whether it operates in a desired production window or whether it trips into an abnormal condition. In this contribution, we study flooding of industrial distillation columns. We aim to improve the performance of an industrial debutanizer column by designing a data-driven flooding indicator. The design of the indicator consists of three steps; (a) the data treatment, (b) a priori labeling, and (c) indicator design. The prior knowledge about flooding within the column is used to design a reference indicator. This knowledge is either unused or fully exploited during the design of the indicator. We compare various design methods and show the potential of data-driven approaches for flooding indication.

**Keywords:** Debutanizer Column, Flooding Indicator, Soft Sensor, Subset Selection

## 1. Introduction

Flooding is an undesired phenomenon in industrial distillation columns. It occurs when the liquid rises above a tray because of foaming or excessive downcomer fill-up (King, 2016). This state causes a high loss in tray separation efficiency and, hence, plant profitability. Early flooding detection is thus crucial for a profitable and sustainable plant.

Several works dealt with the problem of flooding detection. They considered correlation of the flooding effect with internal process variables, especially the pressure difference (drop) across the column (Peiravan et al., 2020) and the time derivative of the pressure drop (Pihlaja, 2008). Industrial experts use these results and combine them often with an insight into the principal triggering cause of flooding, creating a tailored solution for each column. This requires some effort that could be saved using machine learning (ML).

Several ML approaches (Mojto et al., 2021; Oeing et al., 2021; Fuentes-Cortés et al., 2022) were employed to aid decision making in industrial columns. Unsupervised ML approaches, such as *k*-means clustering (Forgy, 1965) or principal component analysis (PCA) (Pearson, 1901), consider no knowledge about the model outcome. The supervised ML techniques, e.g., subset (feature) selection (SS) (Smith, 2018) or support vector machine (SVM) (Boser et al., 1992), use knowledge on the desired outcome for training.

This paper investigates the design of data-driven flooding indicators for an industrial debutanizer. Performance of indicators designed via data-driven approaches (unsuper-

vised and supervised ML) is assessed against the reference indicator (considered as ground truth), which is designed according to the industrial experience about flooding.

## 2. Problem Statement

Flooding indication is essentially a binary classification problem. We aim to design an indicator  $\mathbf{I}$  that assigns a categorical label  $\hat{y}$  via the classification model  $f(x)$  as:

$$\hat{y} = \begin{cases} +1 \text{ (flooding)}, & \text{if } f(x) \geq 0, \\ -1 \text{ (normal operation)}, & \text{if } f(x) < 0, \end{cases} \quad (1)$$

where  $x \in \mathbb{R}^{n_p}$  represents a subset (sparse representation,  $n > n_p$ ) of all online plant measurements  $\xi \in \mathbb{R}^n$  at one time instant. We consider a linear classifier in the form:

$$f(x) = w^\top x + w_0, \quad (2)$$

where  $w \in \mathbb{R}^{n_p}$  represents a classifier normal vector and  $w_0$  is a classifier off-set.

### 2.1. Industrial Debutanizer Column

We study a debutanizer (distillation) column that is a part of the FCC unit of the refinery Slovnaft, a.s. in Bratislava, Slovakia. The column (40 trays) separates the C4/C5 fraction into the C4-fraction-rich distillate product and the C5-fraction-rich bottom product.

The available dataset involves the measurements from January 2019 to April 2021. In this study, we consider 30-minute moving average values of the available minutely data. Overall, the dataset involves 34,297 measurements. The measurements from two plant shutdowns (May – July 2019 and December 2020) are excluded.

The following 41 input variables are directly measured by online sensors at the column:

$$\xi = (vo_B, vo_{D,1-3}, vo_R, vo_{reb,h}, T_{col,1-5}, T_{B,1-2}, T_{D,1-3}, T_F, T_{reb,h,1-2}, Q_{con}, p_{col}, p_{D,1-4}, p_{df,col}, p_{con}, F_R, F_B, F_{D,1-4}, F_F, F_{reb,h,1-2}, L_{reb,1-2}, L_{con,1-3}), \quad (3)$$

where  $vo$ ,  $T$ ,  $Q$ ,  $p$ , and  $F$  are a valve opening, temperature, heat input, pressure, and flow rate, respectively. Indices B, D, F, R, col, con, reb, and df represent a bottom section, distillate section, feed section, reflux section, column section, condenser section, reboiler section, and cross-column difference, respectively. Note that exact location of sensors cannot be disclosed due to the confidentiality reasons. The input vector is extended with ratios ( $F_R/F_F$ ,  $F_B/F_F$ ,  $Q_{con}/F_F$ ) and pressure compensated temperatures ( $PCT_B$ ,  $PCT_D$ ).

The studied debutanizer column usually operates within the desired operating regime. At times, however, the operating conditions within the unit induce flooding. The envisioned low-cost solution to the flooding problem is to design a reliable indicator. The key aspect of this approach is that the indicator is not only used for monitoring the plant, but it is connected directly to the advanced process controller that can provide a fast response.

The dataset does not contain any direct indication of flooding that could be used to label the data. However, it is possible to attribute flooding occurrence to the increased values of  $p_{df,col}$ ,  $F_R$ ,  $F_{reb,h,2}$ , and  $T_{col,4}$  and decreased values of  $T_{reb,h,1}$ . We use this knowledge to design the reference indicator to provide the ground truth of the flooding for our study.

## 3. Methodology

Data-driven indicators are designed using unsupervised ( $\mathbf{I}^{Uns}$ ) and supervised ( $\mathbf{I}^{Sup}$ ) ML approaches. For training ( $\mathbf{I}^{Sup}$ -type indicator) and testing, the ground truth is provided by the aforementioned reference indicator resulting from industrial expert knowledge.

### 3.1. Indicator Design

The design procedure of the data-driven indicator consists of three sequential steps:

1. Data processing (data filtering/treatment, distribution to training/testing dataset).
2. A priori labeling of the training dataset (only applied for  $\mathbf{I}^{\text{Uns}}$ -type indicators).
3. Training of a classifier (fit the  $f(x)$  parameters on the labeled training dataset).

After the standardization of the data set (zero mean and unit variance), the aim of the data treatment (the 1<sup>st</sup> step) is to reduce the number of outliers. Due to the non-ideal (yet close normal) noise distribution within the industrial dataset, minimum covariance determinant (MCD) (Hubert and Debruyne, 2010) is applied. The outlier detection is performed using the  $F$ -distribution, retaining data with 99.9999% probability. The high probability follows from the need to eliminate only the most deviated measurements while maintaining the data representing the flooding, which can be otherwise seen as outliers.

It is optional to smoothen the dataset by filtering out the high-frequency noise that does not represent slower effects of flooding. Subsequently, as flooding is characterized by the changes of the variables, we extend the dataset (here, 46 variables) by time differences:

$$\Delta\xi_i(k) = \xi_i(k) - \xi_i(k-1), \quad \forall_i = \{1, 2, \dots, n\}, \quad (4)$$

where  $k$  is a time instant. The resulting dataset considers both, the original dataset and time differences, i.e., 92 variables. Effectively, we assign  $\xi \leftarrow (\xi, \Delta\xi)$  in this step.

The 2<sup>nd</sup> step, applied to label the data for  $\mathbf{I}^{\text{Uns}}$ -type approaches, is performed by  $k$ -means clustering (Forgy, 1965) with the elbow method to determine the optimal number of clusters. The clusters with a low cardinality but large distance between the cluster center and the dataset mean are considered to represent the debutanizer flooding.

The training phase needs to choose an appropriate indicator input space ( $\mathbb{R}^{n_p}$ ) among all the process variables and their time differences. The methods used in this study are:

1. Industrial patent by (Pihlaja, 2008), which uses  $\Delta p_{\text{df,col}}$  only (referred to as  $\mathbf{I}_{\text{pat}}$ ).
2. Industrial experience (specific to the studied debutanizer) using  $\Delta p_{\text{df,col}}$ ,  $\Delta F_R$ ,  $\Delta F_{\text{reb,h,2}}$ ,  $\Delta T_{\text{col,4}}$ , and  $\Delta T_{\text{reb,h,1}}$  (referred to as  $\mathbf{I}_{\text{ref}}$ ).
3. PCA approach (Pearson, 1901) that chooses a number principal components that explain at least 95% of variance in the dataset (referred to as  $\mathbf{I}_{\text{PCA}}$ ).
4. SS approach (Smith, 2018), which determines the best subset of inputs via cross-validation and comparison of structures with  $n_p = \{1, 2, \dots, 5\}$  (referred to as  $\mathbf{I}_{\text{SS}}$ ).

In the 3<sup>rd</sup> step, the linear classifier (see Eq. (2)) is designed according to the chosen inputs ( $x \in \mathbb{R}^{n_p}$ ). To this end, we use support vector machines (SVM) (Boser et al., 1992).

### 3.2. Performance Assessment

The outcome of an indicator can fall into four categories: true positive (TP) and false positive (FP), when flooding is indicated correctly and incorrectly, respectively, and, vice versa, true negative (TN) and false negative (FN), for indicating of normal operation. We use some well-known normalized performance criteria for the designed indicators:

$$AC = \frac{TP + TN}{TP + FP + TN + FN}, PR = \frac{TP}{TP + FP}, RC = \frac{TP}{TP + FN}, F1 = \frac{2 \times PR \times RC}{PR + RC}, \quad (5)$$

here AC (accuracy) is a measure of how often the classifier makes the correct prediction, PR (precision or correctness) is a measure of how precisely the true prediction is achieved, RC (recall or sensitivity) is a measure of how actual observations are predicted correctly. F1-score (F1) is a harmonic mean between PR and RC. In the industry, it is important to warn about the potential of flooding and thus low value of FN (high RC) is preferred.

Figure 1: Histogram of two variables from the debutanizer dataset treated by the MCD method.

Figure 2: Visualization of training and testing datasets and ground truth labels.

## 4. Results

The results of data treatment using the MCD method are shown in Fig. 1. The data values are anonymized for confidentiality reasons. Only the most deviated measurements (0.75%) are considered as outliers, and the rest of the measurements (99.25%) is retained. The dataset is further smoothed by filtering using a 10th-order low-pass Butterworth filter with a cut-off frequency of 0.028 mHz (with zero-phase distortion).

For fairness of assessment, we distribute the retained data chronologically on an alternating monthly basis into the training and testing datasets (see Fig. 2). From the entire dataset (25,775 points), 12,781 and 12,994 points are assigned to the training and testing dataset, respectively. Fig. 2 illustrates the training-testing data division together with (ground truth) labels assigned based on industrial experience with the reference indicator.

### 4.1. Training of Data-Driven Indicators

Design of the data-driven flooding indicators for the debutanizer column is conducted via MATLAB based on the methods from Section 3.1. MATLAB built-in routines for  $k$ -means clustering, PCA, and SVM are exploited. We design indicators based on unsupervised ML ( $\mathbf{I}_{pat}^{Uns}$ ,  $\mathbf{I}_{ref}^{Uns}$ ,  $\mathbf{I}_{PCA}^{Uns}$ ,  $\mathbf{I}_{SS}^{Uns}$ ) and supervised ML ( $\mathbf{I}_{pat}^{Sup}$ ,  $\mathbf{I}_{ref}^{Sup}$ ,  $\mathbf{I}_{PCA}^{Sup}$ ,  $\mathbf{I}_{SS}^{Sup}$ ). A main difference between the approaches is the use of  $k$ -means (used for  $\mathbf{I}^{Uns}$  indicators).

Table 1: The comparison of the true positives (TP), false positives (FP), true negatives (TN), false negatives (FN), accuracy (AC), precision (PR), recall (RC), and complexity (no. of input variables  $n_p$ , no. of principal components  $n_{pc}$ ) of the designed data-driven indicators on the testing dataset.

ML method	Unsupervised learning			Supervised learning				
	Structure	$\mathbf{I}_{pat}^{Uns}$	$\mathbf{I}_{ref}^{Uns}$	$\mathbf{I}_{PCA}^{Uns}$	$\mathbf{I}_{pat}^{Sup}$	$\mathbf{I}_{ref}^{Sup}$	$\mathbf{I}_{PCA}^{Sup}$	$\mathbf{I}_{SS}^{Sup}$
TP		1,784	1,704	618	1,192	2,031	1,720	2,029
FP		3,828	2,823	3,147	1,358	4	168	0
TN		7,097	8,102	7,778	9,567	10,921	10,757	10,925
FN		285	365	1,451	877	38	349	40
AC		68.3	75.5	64.6	82.8	99.7	96	99.7
PR		31.8	37.6	16.4	46.7	99.8	91.1	100
RC		86.2	82.4	29.9	57.6	98.2	83.1	98.1
F1		46.5	51.7	21.2	51.6	99	86.9	99
$n_p/n_{pc}$		1	5	17	1	5	17	2

A key to success of unsupervised ML is an appropriate data labeling. The results indicate that, unsurprisingly, the best results are obtained when the  $k$ -means clustering is performed on a dataset with reduced dimensionality (e.g., one variable for  $\mathbf{I}_{pat}^{Uns}$  indicator or seventeen principal components determined for  $\mathbf{I}_{PCA}^{Uns}$ ), with appropriate input structure. The clustering method reveals 4–5 clusters out of which 1–2 clusters are selected to represent flooding. This result suggest that merging of steps 1 and 2 mentioned in Section 3.1 is a sensible approach to successful indicator design. We can, therefore, expect PCA-based approaches to give inferior performance. We exclude  $\mathbf{I}_{SS}^{Uns}$  from the assessment as its performance would suffer from the inaccurate data labelling. Only a more advanced design method (iterating over steps 1–3 from Sec. 3.1) would construct a useful indicator.

The performance assessment of the designed indicators on the testing dataset is shown in Tab. 1, taking into account the so-called confusion matrix elements (i.e., TP, FP, TN, and FN) and performance criteria (i.e., AC, PR, RC, and F1). The complexity of designed indicators is represented by the number of principal components  $n_{pc}$  for PCA-based approach and by the number of input variables  $n_p$  for the rest of approaches. We can directly see that the supervised ML approaches outperform the unsupervised ones when we compare similar structures. The only exception appear to be the RC criterion when evaluated for  $\mathbf{I}_{pat}$  indicator. There are two reasons for this performance drop: 1. RC is given up in training for the AC and precision as the dataset is more populated with data points of normal operation; 2. the industrial data labels indicate flooding based on other variables than pressure (the sole input to  $\mathbf{I}_{pat}$  indicator) and thus  $\mathbf{I}_{pat}$  indicator falls short in terms of model (input) adequacy (some extra input variables would explain flooding better). Note that, the first reason can be remedied by a modification to SVM objective and some proper tuning, which, however, is beyond the scope of this study.

Among the  $\mathbf{I}^{Uns}$ -type approaches, it is interesting that, although the structure of the reference indicator is optimal, the highest RC criterion (low FN) is achieved by  $\mathbf{I}_{pat}^{Uns}$ . Of course, this is paid off by worse accuracy as the classifier mis-indicates flooding (high FP) more often. The PCA-based indicator appears to be the least effective (in all criteria). This is attributed to the aforementioned inappropriate labelling in high dimensions.

Unlike for the unsupervised learning approaches, the performance of the  $I_{PCA}^{Sup}$  indicator is sufficient. It also appears that the  $I_{PCA}^{Sup}$  is more efficient compared to the  $I_{pat}^{Sup}$  indicator viewed by each performance criterion. The highest efficacy among supervised learning approaches is achieved for  $I_{ref}^{Sup}$  and  $I_{SS}^{Sup}$  indicators. These approaches already consider or can find the best possible input structure. It is noteworthy that  $I_{SS}^{Sup}$  achieves the best performance (almost 100% in all performance criteria) using a very simple structure. This effectively tells that the reference structure is overly complicated (some inputs are redundant) and that it is possible to indicate flooding with data from just two sensors. It is also a very interesting result as it allows the industrial practitioners to concentrate efforts regarding sensor maintenance towards smaller subset of online sensors. Surprisingly, pressure is not among the inputs selected for the best indicator. The input structure involves reflux flow  $\Delta F_R$  and the time difference of heating medium flow in the reboiler  $\Delta F_{reb,h,2}$ , which are both part of the reference indicator structure. It is possible that the two selected flow rates are measured with better precision and that they do not involve high-frequency fluctuations as pressure measurements do. The results need further validation in an industrial setup to validate the reference indicator (ground truth).

## 5. Conclusions

This contribution is focused on the design of a data-driven flooding indicator for an industrial debutanizer column. As the ground truth, a reference indicator is used that is designed according to the industrial experience. The effectiveness of unsupervised and supervised machine learning (ML) approaches was evaluated by considering various input structures. The results showed that the unsupervised learning approach can provide sufficient flooding indicators if appropriate input variables are used. The supervised ML approaches achieved higher effectiveness compared to unsupervised ML approaches, resulting from the direct usage of reference indicator labels. The results of supervised learning approaches revealed that the most accurate estimate of the debutanizer flooding is provided by the reflux flow rate and heating medium flow in the reboiler. Future work involves design of indicators for the chosen performance criterion in a multi-objective fashion. It would also be possible to design an unsupervised approach capable of choosing the optimal indicator structure much like the structure achieved with supervised ML.

## Abstract

CO<sub>2</sub> emissions are set to rise in view of continuous growth in economic and supporting infrastructure. This means that the indispensable approach to decarbonize the economy in the medium term is through carbon capture, utilization and storage (CCUS). The main challenges in the large-scale implementation of CCUS network are costs of carbon capture, compression and transportation, energy requirements for CO<sub>2</sub> utilization and conversion, and limited market demand for end products. The development of strategic designs for such CCUS infrastructure at this scale is a non-trivial activity, which must take account of local industry specifics and development plans. A multiscale system modeling and optimization approach is developed to assess alternative CCUS processes and understand transient network behavior. The potential of CCUS in main potential markets in the United Arab Emirates such as simultaneous CO<sub>2</sub> storage with Enhanced Oil Recovery (CO<sub>2</sub>-EOR), CO<sub>2</sub> capture using microalgae and mineralization have been examined.

**Keywords:** CO<sub>2</sub> capture, Optimization, Multiscale Modeling, CCUS, techno-economic.

## 1. Introduction

The most recent Intergovernmental Panel for Climate Change (IPCC) report indicates that climate change is unequivocal and that without mitigation, average global temperatures may increase by 2-6 °C by 2100. As a result, most major economies have announced targets for reductions in GHG emissions. UAE is amongst the nations wishing to take a lead in this area and aspires for a flourishing low carbon economy. Sustainable development is a major aspect of Abu Dhabi's Vision 2030, and this is closely linked with achieving significant reductions in carbon emissions, maintaining economic growth and building a circular economy with minimum ecological footprint. Lately, the government of the UAE announced the country's net zero carbon strategic initiative in 2050. This aligns with Paris agreement signed in 2015 by 195 countries including the UAE, which aims to limit the increase in global average temperature to 1.5°C. In addition, the 2<sup>nd</sup> intended nationally determined contribution of the UAE is to reduce its greenhouse gas (GHG) emissions for the year 2030 by 23.5%, relative to the Business-As-Usual (BAU) scenario (i.e., a reduction of 70 million tons of CO<sub>2</sub> per year in 2030). These ambitious CO<sub>2</sub> reduction targets should go in line with developing technologies and markets for CO<sub>2</sub> capture, utilization and storage (CCUS) along with energy efficiency,

renewables, energy storage, and others. CCUS involves CO<sub>2</sub> capture from air or flue gas emitted from power plants and industrial sources using solvents or adsorbents, and then use it as a feedstock in an economically chemical, biological and industrial processes. There are many CO<sub>2</sub> utilization routes that has different market share, temporal storage potential, technological readiness level (TRL) and product value. The main utilization pathways at a scale (Fig. 1) are (1) chemicals; (2) building materials; (3) CO<sub>2</sub>-enhanced oil recovery (EOR); (4) soil carbon storage; (5) microalgae; and (6) fuel.

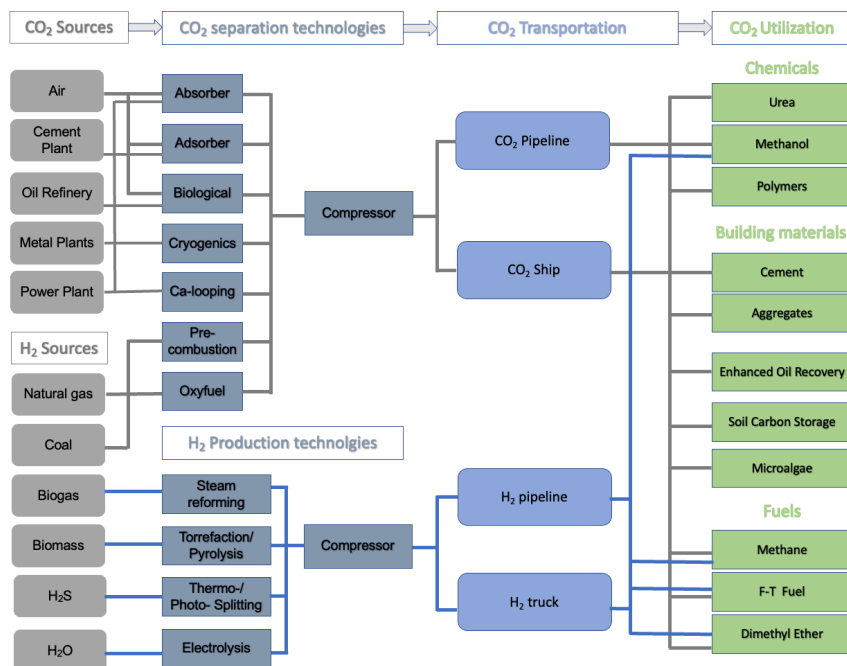

Figure 1: Superstructure of potential CCUS networks

CO<sub>2</sub> capture of around 100 kt yr<sup>-1</sup> and utilization for urea production has already been implemented commercially in the UAE. Globally, 140 Mt yr<sup>-1</sup> of CO<sub>2</sub> is used to produce 400 Mt yr<sup>-1</sup> of urea (Perez-Fortes et al., 2014). Other emerging chemical is polycarbonate polyols that will have a limited market of 10-50 Mt yr<sup>-1</sup> in 2050 (Hepburn et al., 2019). CO<sub>2</sub> fixation in waste streams from exhausted slag-based and carbon-based sorbents to produce carbonate and silicate aggregates for material construction is a promising long-term utilization route to reduce the overall ecological footprint of CCUS process. This has a large-scale potential in countries climbing the development ladder such as the UAE. One of the main anthropogenic CO<sub>2</sub> utilization route in oil exporting companies such as the UAE is CO<sub>2</sub>-Enhanced oil recovery (EOR). EOR is a tertiary approach applied to mature oil reservoirs to improve oil recovery. There are three main temporal phases in oil extraction: primary recovery, at the early stage of oil production, geologic pressure and pumps can push oil from the wellbore to the surface; secondary recovery maintains the pressure of the reservoir and improves oil productivity through injection of water or gas; tertiary recovery, which can recapture 30 to 60% of the original oil in place (OOIP). CO<sub>2</sub> injection decreases the viscosity of the remaining oil, swell it and detach it from the formation. This allows it to move freely in the reservoir reaching the production well,

while trapping CO<sub>2</sub> in the reservoir, leading to CO<sub>2</sub>-EOR and storage. Part of this CO<sub>2</sub> is produced and recycled back in the operation making it complex to quantify the potential of CO<sub>2</sub> utilization. In this work, a multiscale modeling approach based on system dynamics is demonstrated to examine the potential of combined CO<sub>2</sub>-EOR and storage. Another emerging utilization route is soil carbon storage (SCS). Understanding the carbon balance in the soil is essential to evaluate the potential of SCS. Soil stores organic carbon comprising of decaying plants, fungal, bacterial and animal matters. This also enhances the soil structure and reduces the erosion and carbon losses. CO<sub>2</sub> fixation in waste sorbents and carbon rich materials such as char can also play an important role in enhancing the carbon content and water within the soil enhancing the productivity of growing plants. An important utilization route in arid environments such as the UAE is to cultivate microalgae for simultaneous fixation of carbon dioxide (CO<sub>2</sub>) and production of high value-added products such as vitamins, antioxidants, and carotenoids for pharmaceutical use. Microalgae are organisms that are able to fix CO<sub>2</sub> with solar energy at higher rates than other plants with no need for arable land and freshwater resources — it can be cultivated using wastewater or salt water medium. Here, a multiscale model is demonstrated to examine the potential and scale of Microalgae cultivation in the UAE. Other utilization routes through recycling CO<sub>2</sub> back into different fuels (Fig. 1) involves production of green hydrogen at a reasonable price as most of the fuel cost comes from hydrogen production (i.e., >85% for methanol (Atsonios et al., 2016)). This is highly linked to the availability of renewables and cost of power. In the UAE, a low power production price was recorded at US\$0.015/kWhr. This should go in line with dispatching hydrogen economy at a scale, increasing efficiency and reducing CAPEX of electrolyzers. A price of US\$1.0/kg of hydrogen is required to deploy this pathway at a scale. It is worth noting that the fuel generated using this option will be burnt again and emits CO<sub>2</sub>, which emphasis an open carbon cycle. This might limit the impact of adoption of power to fuel technologies at a scale while looking at the impact of storage unless carbon is being captured and utilized again in a closed cycle. This work demonstrates the significance of multiscale model as a guide to examine the potential of three major utilization pathways namely CO<sub>2</sub>-EOR, microalgae and mineralization.

## **2. Multiscale modelling methodology**

This work builds upon multiscale modelling approach for CCUS system connecting models across different length and time scales (Fig. 2). At picosecond and angstrom scales, molecular dynamics simulations are performed to examine the potential of each sorbent to attract solutes within the available sites in the material. This helps in generating the missing data required to generate isotherm models for CO<sub>2</sub> capture in adsorbents. A continuum model based on partial differential and algebraic equations systems at a scale of seconds and length of meters are used to find the optimal scheduling of different adsorption steps. This helps in establishing the performance of different sorbents through capturing the relationships and trade-offs between structure-property and key performance indicators such as cost, purity, and recovery. Moving to the km scale of reservoir size and decades of EOR operations, a system dynamics model has been developed to quantify the demand of CO<sub>2</sub> for EOR, amount of CO<sub>2</sub> stored and recycled. This integrated multiscale models also applies to other utilization routes such as CO<sub>2</sub> capture using microalgae at the country level. This integrates genomic scale models based on flux balance analysis that describes the change in inter-cellular metabolites with kinetic based models that describes the interactions with extra-cellular environment. The optimal CCUS network can be obtained through Mixed Integer Linear Programming

(MILP) (Alhajaj and Shah, 2020) or Mixed Integer Non-Linear Programming (MINLP) approach.

Figure 2: Illustration of multiscale model (Reproduced from (Balogun et al., 2021) with permission of the Royal Society of Chemistry)

### 2.1. Problem definition

A multiscale model integrating models across different length and time scales have been used to find the potential of CCUS considering main markets in the UAE, namely CO<sub>2</sub>-EOR, microalgae and mineralization. The main objective was to examine the potential in meeting the 2<sup>nd</sup> national reduction target standing at 70 Mt CO<sub>2</sub> yr<sup>-1</sup>. The multiscale CCUS supply-chain network model was formulated as an MILP problem, similar to our earlier work (Alhajaj and Shah, 2020). The selection of CO<sub>2</sub> sources, main capture technologies with varying configurations, absorbents, and adsorbents in addition to microalgae, transportation modes and CO<sub>2</sub> utilization routes have been considered in this work. The model has been used to find the cost-optimal network that meets a specific CO<sub>2</sub> decarbonization target with a positive long-term environmental impact. The latter is considered through performing life cycle analysis in utilization pathways. This captures the energy requirements for synthesis and upgrading of fuels and materials in addition to the duration of CO<sub>2</sub> storage.

In this work, a multiscale model is used to obtain realistic data for the maximum storage capacity and utilization potential per year, presented as inequality constrains in the MILP problem. This has been used to capture the system dynamics of CO<sub>2</sub>-EOR enterprise. The adoption of anthropogenic CO<sub>2</sub> as a solvent to enhance oil recovery in aging reservoirs combined with CO<sub>2</sub> storage to mitigate climate change is a complex process due to the interplay of environmental, technical and market targets. A system dynamics model has been adopted to account for the complex interactions between the dynamics of oil production, climate change mitigation targets, CO<sub>2</sub> sources market, oil production targets, carbon credits, policies, and oil market subsystems (Santos et al., 2021). This has been used to obtain the yearly demand of fresh CO<sub>2</sub> and the potential of CO<sub>2</sub>-EOR storage in mitigating greenhouse gas emissions in the UAE and meeting the 2<sup>nd</sup> national reduction target.

To examine the potential of embracing biological carbon capture and utilization using microalgae at a large scale, bio-process model imbedded with genomic scale model have been used to examine the potential of biological CO<sub>2</sub> capture and utilization from 400 MW combined cycle gas turbine (Alhajaj et al., 2016). This has identified the pond size (length scale) and time scale required for deep decarbonization of flue gas using microalgae. All data obtained from the detailed analysis of utilization pathways and capture technologies are fed into the supply-chain network to obtain realistic and cost-optimal decarbonization pathways.

### 3. Preliminary Results

The results of the multiscale model have identified CO<sub>2</sub>-EOR as a major utilization and storage route in the UAE. This can mitigate 10-20% of the 2<sup>nd</sup> national reduction target of the UAE (i.e., 13.6-25.6 Mt CO<sub>2</sub> trapped in the reservoir). On contrary, microalgae CO<sub>2</sub> capture and cultivation from combined cycle power plant require a massive land with a size of Dubai Expo (i.e., >10000 hectares) to capture 75% of the flue-gas. A higher capture rate (Fig. 3) is difficult due to the high evaporation rates and emissions to atmosphere resulting from the exponential growth in number of ponds. This demonstrates the complexities in applying microalgae at a scale to mitigate climate change due to the slow process of CO<sub>2</sub> fixation. The main driver to implement microalgae projects should be targeted to small scale high-value and green products.

Figure 3: Illustration of microalgae CO<sub>2</sub> capture and utilization from large scale power plant

The results of this study have demonstrated the difficulties of implementing solo-CCUS route at a scale. Therefore, synergized adoption of CCUS with storage should be implemented to mitigate climate change. Emerging markets such as CCUS in building materials and soil carbon storage can complement large scale storage in reservoirs and reactive Basaltic rocks. Other enabling technologies such as hydrogen economy should be supported to create the mass for economies at a scale. This will help in creating new large-scale markets for CO<sub>2</sub>-Fuel, especially for aviation.

#### 4. Conclusion

Implementing large scale Carbon Capture, Utilization and Storage (CCUS) projects is required to mitigate climate change and meet national CO<sub>2</sub> reduction targets. In this work, we have developed multiscale models that has helped in examining the potential of large scale CCUS pathways such as CO<sub>2</sub>-EOR, mineralization and microalgae in the UAE. The results of this study have highlighted the potential of implementing CCUS at a large scale in the UAE with positive environmental impacts. CO<sub>2</sub>-EOR with storage can play an important role in developing CCUS infrastructure, which helps in establishing a network and economies of scale for wider adoption. Emerging markets such as mineralization, soil storage and saline aquifers can help in accelerating the rate and scale of CCUS implementation in the UAE. Microalgae and CO<sub>2</sub>-based fuels have an important market such as hard-to-abate aviation but further decarbonization strategies should be implemented to ensure larger net CO<sub>2</sub> reductions. This depends on the availability of enabling resources such as renewables, heat, green hydrogen, and storage sites. These CCUS pathways are region-specific and might not be replicated at a large scale elsewhere. There is also a need for policies and incentives to de-risk the CCUS business and liability, which will assure deep decarbonization of the society. Overall, this study has demonstrated the need for integrated tools and models across different length and time scales to capture the system dynamics using various key performance indicators such as cost and life cycle analysis. This integrated tool can guide policy makers and governments on selecting right incentives and policies that help in wider adoption of CCUS with desired social benefits.

## Abstract

Carbon nanofibers (CNF) with different morphologies and microstructures were widely used as electrode material for supercapacitors since they exhibit high electrolyte-electrode interface, flexibility, and tunable physicochemical properties. This CNFs-based electrode electrochemical performance is greatly influenced by their surface area, pore structure, and fiber diameter. No credible physical model is available that can predict the performance of supercapacitors based on the CNFs physicochemical properties. In this work, we have used a data-driven Artificial Neural Network (ANN) model to predict the performance of CNF electrode-based supercapacitors based on electrode material microstructural properties and electrochemical operational parameters. The proposed model demonstrates its feasibility in predicting specific capacitance with a correlation coefficient (R-square) value close to 0.95. A sensitivity analysis was also conducted to understand the effect of independent input parameters on a single output parameter (specific capacitance).

**Keywords:** ANN, Supercapacitor, Data-driven, Energy storage, Machine learning.

## 1. Introduction

Recent developments in supercapacitors have attracted great attention due to their superior power density and cyclic stability when compared to conventional batteries (Panda et al., 2020). The use of carbon nanomaterials, such as activated carbons, nanoparticles, nanofibers, etc., as electrode materials for supercapacitors, has been widely studied because of their high surface area, high conductivity, and low production cost (He et al. 2020; Lokhande et al. 2020; Mathis et al. 2019). Compared to other electrode materials, CNFs are unique in that they are both flexible and possess tunable surface area, porosity, and fiber diameter. These characteristics make them ideal electrode materials for flexible supercapacitors. Hence, these CNFs have been extensively studied as electrode materials for supercapacitors (Chandu et al., 2020). However, the improvement in the specific capacitance is inadequate due to charge storage at the electrode-electrolyte interface. Activation and physical etching methods were used to engineer the microstructural properties of these CNFs to enhance their electrochemical performance. The microstructural properties, micro (<2 nm) and mesopore (2nm-50nm) volumes, specific surface area (SSA), and fiber diameter greatly rely on the polymer precursor and carbonization process. In addition to these microstructural properties, supercapacitor performance depends on voltage window, scan rate, cell configuration, and electrolyte characteristics. As the performance of CNF-based supercapacitors depends on these many

parameters, there is a significant need to develop a model that correlates these parameters to the performance of the supercapacitors. It is imperative to note that the development of a model does not only assist in predicting the performance of the supercapacitor, but also in planning the experiments to achieve the desired microstructural properties for enhancing its performance. The qualitative deviation of electrochemical performance with electrode SSA, micropore, and mesopore volumes has been examined through experimental studies. However, no physical model has been developed that predicts how these parameters interact to affect electrochemical performance in a synergetic manner. Alternatively, experimental data may be used to develop a data-driven machine-learning model that addresses this problem.

In recent years, various machine learning models have been applied to determine the synergetic effects of multiple variables on the electrochemical performance of energy storage devices. Among different machine-learning models, an ANN was widely used to develop a model using complex and nonlinear data (Himanenmanen et al. 2019; Farouji et al. 2022). In a recent study, Rahimi et al., 2022, developed an ANN-based data-driven model that correlated microstructural characteristics of activated carbon electrodes, electrode synthesizing procedures, and operational conditions that affect the electrode's performance. The developed model accurately predicted the performance of activated carbon electrodes with an R-square value of 0.9. To our knowledge, there are no studies on CNF-based electrodes using data-driven machine-learning models. In this work, we have developed an ANN model to predict the performance of CNF-based electrodes using various independent input variables. Our goal is to examine the effect of input variables independently and synergistically on the prediction of specific capacitance of the CNF-based electrode.

## 2. Material and methods

### 2.1 Experimental data collection and preprocessing

The ANN model in this work was trained using seven input parameters, which include carbonization temperature ( $C_t$ ), SSA, total pore volume ( $V_t$ ), micropore volume ( $V_{mic}$ ), mesopore volume ( $V_{meso}$ ), nanofiber diameter (NFD), and voltage window (VW) and a single output parameter (Specific capacitance). Data for both input and output parameters were collected from 70 research articles reporting experimental data, each reference paper we took one single data set. The data was limited to the pristine CNFs-based electrode studies with the aqueous electrolytes and incorrect or outdated data can also impact the accuracy of the model so we considered only recent research articles data and inconsistent formatting or scaling of data can affect the model's accuracy so as a preprocessing step, all the parameters were normalized between 0 and 1. This normalization enables the ANN to learn more quickly since the output is more sensitive to changes in the input (Rafiq et al. 2001). The following function was used to normalize the data in this study:

$$X_{nor} = \frac{X - X_{min}}{X_{max} - X_{min}}$$

where  $X$  denotes the variable value and  $X_{nor}$  denotes the value of the normalized variable,  $X_{min}$  and  $X_{max}$  correspond to the minimum and maximum values of the variables, respectively.

#### 2.1.2 Artificial neural network

It is possible for an ANN to learn rather than be programmed to make predictions. The ANN consists of input parameters, output parameters, and several hidden layers. Depending on the weight ( $W_{ij}$ ) and bias ( $B_i$ ), the hidden layer will augment or cripple the received information. Herein, our goal is to use this ANN and the experimental data

collected from the literature to build a data-driven model as shown in Fig. 1 that can predict the specific capacitance performance of a CNF electrode-based supercapacitor. Our model was trained and tested using input and output data collected using the supervised machine learning method and the neural network toolbox in MATLAB 2021a. The artificial neural network consists of one hidden layer with a different number of neurons (11 to 23), a log-sigmoid activation function in a hidden layer, and a purelinear transfer function at the output layer.

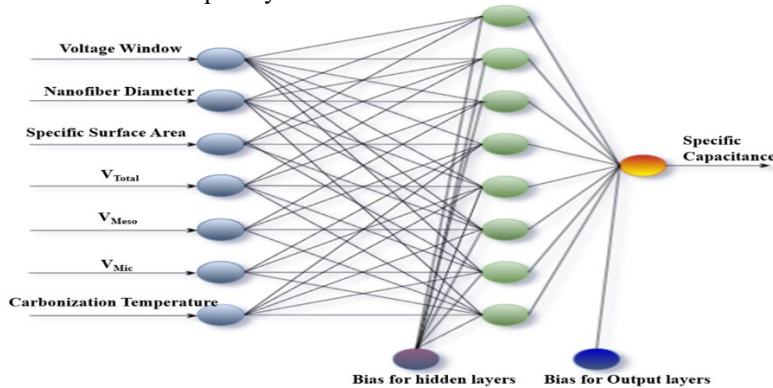

Figure 1. The neural network model of ANN used in this study.

An ANN model was trained using Levenberg–Marquardt with backpropagation of errors (LM-BP)(Willis et al.1991) Levenberg-Marquardt algorithm appears to be the fastest method for training moderate-sized feedforward neural networks (up to several hundred weights). It also has an efficient implementation in MATLAB software, because the solution of the matrix equation is a built-in function. The data was divided into three subsets of 70%, 15%, and 15% for training, testing, and validation, respectively. The schematic illustration of the dataset preparation procedures and modeling implementation is shown in Fig. 2.

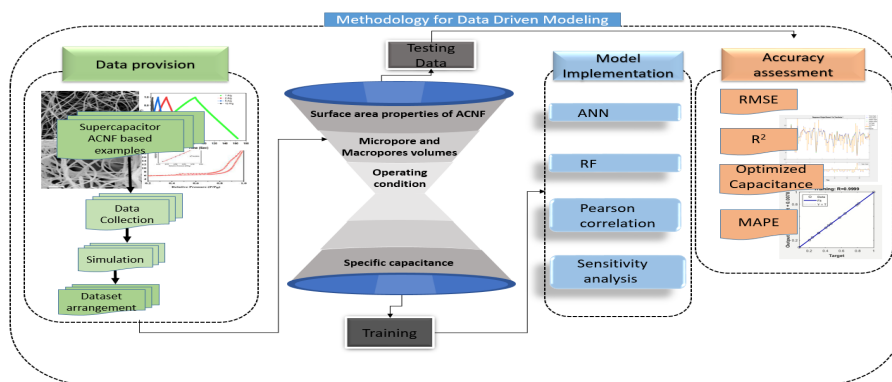

Figure 2. Schematic representation of data-driven modeling methodology

The number of neurons in an ANN model's hidden layer also significantly affects the prediction. To avoid overfitting (a high number of neurons) and offsetting (a low number of neurons), the number of neurons in the ANN model were optimized(Karsoliya, 2012). In this study, the number of neurons in hidden layers (hidden layer size) varied between 11 and 23. After the training, the performance of ANN was evaluated using the test data

set. The error of ANN is determined by the mean square error (MSE) and correlation coefficient (R-Square).

### 3. Results and Discussion

#### 3.1 Result of ANN model

The Pearson correlation coefficient (PCC) was used to investigate the linear relationship and co-occurrence of input and output parameters, as shown in Fig.3. The PCC analysis reveals the dependency of the specific capacitance (output parameter) on all the input parameters. The reliance is in the decreasing order of  $SSA > V_{meso} > V_t > V_{mic} > C_t > VW$ . NFD, an independent input variable, showed a negative correlation (-0.16) with specific capacitance in the group of seven input parameters. Due to this, linear/inverse relationships cannot be used accurately to predict capacitance.

Figure 3. Pearson correlation matrix of the seven input variables and single output variable (specific capacitance).

Table 1 summarizes the effect of hidden layer size on the performance (as MSE & R-square) of the training algorithm LM-BE. Increasing the number of neurons in the hidden layer from 11 to 19 resulted in a moderate decrease in the MSE from 0.0554 to 0.0031, and a further increase in neurons from 19 to 23 resulted in a moderate increase in the MSE to 0.006. As a result, a network with 19 neurons with least MSE value (0.0031) was used for sensitivity analysis studies. Furthermore, the network with 19 neurons demonstrated excellent correlation coefficients, with R-square values exceeding 0.95 for both training and testing achieved performance metrics are consistent across multiple training repetitions.

Table 1: Performance of ANN vs. Number of neurons in hidden layer

Hidden layer size	Training		Testing	
	MSE	R <sup>2</sup>	MSE	R <sup>2</sup>
11	0.01550	0.786	0.05540	0.918
13	0.00117	0.888	0.00700	0.921
15	0.00392	0.873	0.00310	0.967
17	0.00238	0.878	0.00835	0.910
19	0.00035	0.955	0.00286	0.955
21	0.00703	0.916	0.00160	0.854
23	0.00648	0.867	0.00200	0.866

Based on the results presented in Fig. 4, it can be concluded that substantial agreement exists between the actual and predicted values of specific capacitance during both the training and testing phases. Mostly, ANN models can be compared to other machine learning models such as Decision Trees, Random Forests, Support Vector Machines, etc., so Random Forest (RF) model is used to compare the ANN accuracy results. ANN model showed better accuracy than RF model.

Fig.4 The predicted and actual values of specific capacitance in both test and training, using the ANN.

### 3.2 Sensitivity analysis

A sensitivity analysis was conducted by selecting input parameters precisely to determine how they affect the performance of CNF-based supercapacitors. The sensitivity analysis is presented in detail in table 2. First, all input variables were considered in this analysis, and then a single input parameter was excluded from other analyses. Microstructural variables appear to have a substantial impact on the electrochemical performance of CNF-based supercapacitors. According to this analysis, specific capacitance is greatly influenced by  $V_{meso}$  and SSA, in agreement with experimental observations (Xie et al. 2020). In addition, the mean absolute percentage error (MAPE) was also used to quantify the degree of dependency. The MAPE values for the input set excluding  $V_{meso}$  and the input set excluding SSA rose to 4.1% and 4.74%, respectively. This increase in error value indicates the importance of these microstructural properties on the performance of CNF-based supercapacitors. The input set without NFD, however, showed lower sensitivity, with MAPE of 1.57.

Table 2 Sensitivity analysis of the ANN model versus independent variables.

Model Input	Input set	MAPE		
		Train	Test	Total
	All	0.56	1.10	0.58
Structural	All exclude Vmic	3.20	3.56	2.93
	All exclude Vmeso	4.63	4.20	4.10
	All exclude SSA	5.14	5.96	4.74
	All exclude Vt	2.10	2.90	2.01
	All exclude NFD	1.90	1.00	1.57
Carbonization	All exclude Ct	2.88	1.69	2.41
Operational	All exclude VW	3.12	3.39	2.84

#### 4. Conclusion

The ANN model predicts the CNF-based electrode performance accurately using microstructural properties and operational parameters as input. In addition, the proposed model with 19 neurons showed a high R-square value of 0.95 and a lower MSE value of 0.003. The results of a sensitivity analysis on seven input parameters suggested that SSA and  $V_{\text{meso}}$  have a significant impact on electrode performance. In contrast, the input parameter NFD has a relatively small effect. The developed model can be employed to design nanofiber-based electrode materials experimentally, which reduces the need for labor-intensive experimentation to optimize the microstructural properties.

## Abstract

Data dimensionality analysis or model size determination (identifying the true dimension of the underlying data variant space from experimental data) is a key step for the accurate identification of reaction networks and kinetic modeling of chemical systems. Here, several data analysis tools are compared regarding their relative performance in the identification of the model size from simulated noisy data concerning a challenging case study that presents low reaction extents. Depending on the characteristics of the data used, distinct choices of analytic methods can be suggested. The complementary application of different methods to reinforce the confidence of this analysis is also considered.

**Keywords:** Data dimension, Model size, Reaction networks, Systematic methods, Statistical approaches.

## 1. Introduction

Accurately describing chemical reaction systems, including their dynamics, generally requires using systematic frameworks and a detailed set of experimental data. Models under and over-parameterized might present unsatisfactory predictive abilities during the calibration (training) and validation (testing) phases, thus compromising their subsequent applications such as process optimization, design, and control (Bonvin et al., 2016). A common concern to modelers is to maximize the extent of the information explained by the model, while avoiding the addition of model features that can be essentially attributed to noise, thus preventing overfitting.

One crucial step during the modeling task is the identification of the underlying data variant space, whose dimensionality can be described as the model size for the system. The integration of various existing methods within a systematic methodology for chemical reaction model development has been proposed and tested (Vertis, 2022). In this context, the model structure (or the system stoichiometry) can be further identified by determining an abstract (latent) space without using any information about the system kinetics (Bonvin and Rippin, 1990). Here, we compare classical empirical methods such as the scree test (Cattell, 1966), the fractional variance analysis (Bro and Smilde, 2014), and the Kaiser test (Cliff, 1988), in addition to the parametric F-test (Malinowski, 1989) and the procedure for non-parametric cross-validation by eigenvectors (Wise and Ricker, 1991), concerning their ability to identify the “true” model size from noisy reaction data. These data represent cumulative extents corrupted with (white) noise generated from in silico experiments, simulated at different experimental conditions. This type of problem may become challenging if the concentration of some species is of the same order of

magnitude as the system noise, leading to various model identifiability issues. As an illustration example, a simulated system including 6 species and 4 reactions is considered. The results allow a comparison of the efficiencies of the methods in capturing the correct model size, and their requirements in terms of the data characteristics. These results also evidence that the choice of the best method to identify the model size depends on the data itself, especially on the characteristics of the underlying noise component.

## 2. Methods considered

The information from the Singular Value Decomposition (SVD) is very useful to determine the model size  $R$ , since it allows the data decomposition in directions ordered by decreasing variance. Thus, many tools for model size identification rely on the analysis of (squared) singular values / eigenvalues. A collection of them is briefly listed next.

### 2.1. Heuristic approaches

This section introduces three empirical (*ad hoc*) methods, available in the literature, for determining  $R$ : the scree test, the Kaiser rule, and the analysis of fractional variances.

#### 2.1.1. Scree test

The scree test assumes that the relevant information can be distinguished from random noise in terms of singular values and that the magnitude of the random noise variation seems to stabilize linearly with the number of components (Cattell, 1966). The common graphical analysis based on heuristic principles requires a visual analysis of the eigenvalues plot and the use of a given threshold.

#### 2.1.2. Kaiser rule

Kaiser's rule assumes that if a component has an eigenvalue greater than one, it explains the variation of more than one original variable (Cliff, 1988). This led to the rule of selecting all components with eigenvalues greater than one; however, recent works demonstrate this rule can be inadequate (Bro and Smilde, 2014).

#### 2.1.3. Fractional variance analysis

Another rule of thumb is to include the first  $R$  eigenvectors such that the sum of their variances (represented by eigenvalues) is up to an amount of the total, such as 95% or 99%, which can be seen as an empirical rule to match model accuracy and parsimony.

### 2.2. Statistical $F$ -test

Malinowski (1989) proposed a parametric test to determine  $R$  (within a specified significance level) based on the Fisher variances ratio obtained from pools of samples with normal distribution and i.i.d.

### 2.3. Cross-validation procedure

The goal of the method selected for cross-validation consists of finding the number of model components that leads to the best overall prediction in the testing phase, established through the minimum PRESS-CV (predicted residual error sum of squares evaluated in a cross-validating approach). The original data matrix  $\mathbf{D}[n_o \times n_s]$  is randomly sampled (without replication) into  $K$  data files of size  $[n_c \times n_s]$  and  $[n_v \times n_s]$ , respectively, with  $n_c + n_v = n_o$ . For clarification, let  $\mathbf{D}^{-k}[n_c \times n_s]$  and  $\mathbf{D}^k[n_v \times n_s]$  be the matrices of data used, respectively, for model training and testing in  $k^{\text{th}}$  iteration ( $k \in \{1, \dots, K\}$ ). Then, the SVD of  $\mathbf{D}^{-k}$  is carried out resulting in  $\mathbf{U}[n_c \times n_c]$ ,  $\mathbf{\Sigma}[n_c \times n_s]$  and  $\mathbf{V}[n_s \times n_s]$  orthogonal matrices where  $\mathbf{U}$  and  $\mathbf{V}$  contain, respectively, left and right eigenvectors of  $\mathbf{D}^{-k}$ , and  $\mathbf{\Sigma}$  is a rectangular diagonal matrix containing the singular values. This structure is then used (in an internal loop to that of  $k$ ; the counter is  $s$ ) to construct a projection matrix  $\mathbf{M}$  from  $\mathbf{V}_{R^*}[(n_s - 1) \times R]$  which, on turn, is obtained from the columns 1 to  $R$  of  $\mathbf{V}$  by stripping

the  $s^{\text{th}}$  row. For every  $s = 1, \dots, n_s$  a column vector  $\mathbf{d}_s^k [n_v \times 1]$  containing the variable  $s$  is removed from  $\mathbf{D}^k$ , resulting in a smaller matrix  $\mathbf{D}_*^k [n_v \times (n_s - 1)]$ . Afterwards, the matrix of scores for data validation, say  $\mathbf{T} [n_v \times R]$ , is then predicted by projecting  $\mathbf{D}_*^k$  onto  $\mathbf{M}$ . Finally, the variable  $s$  in  $\mathbf{D}^k$  can be estimated as a linear combination of  $\mathbf{T}$  using the excluded row vector  $\mathbf{v}_{R,s} [1 \times R]$ .

This strategy is commonly designated as *cross-validation by eigenvector* to distinguish it from classic cross-validation where the goal is estimating a model using (partial) least-squares. In contrast, in principal components models (or models from SVD of data) the left-out elements and their predicted values are not independent, resulting in a decreasing PRESS-CV with the number of components (never reaching a minimum) if the traditional (k-fold or leave-one-out) cross-validation approaches are considered (Bro et al., 2008). This result would lead to the incorrect conclusion that all components are significant, thus overestimating the optimal model size. Here, in practice, the problem is handled by predicting the missing variable from the model eigenvectors extracted from the training dataset by excluding one of the columns of the testing data set such that the expectation is maximized (Wise and Ricker, 1991).

### 3. Case study

The example considered for comparison consists of a catalytic reaction system where 6 chemical species are linked by 4 chemical reactions – the reaction network in Figure 1 (right panel). The reaction kinetics follow the Langmuir-Hinshelwood model (1) where species A, B, and C are adsorbed in the catalyst with a single active site. In this equation, for the reaction  $j = 1, \dots, 4$ ,  $k_j$  is the kinetic constant in  $\text{min}^{-1}$ ,  $C_{\text{reac}_j}$  and  $\alpha$  are, respectively, the normalized concentration and the stoichiometric number of moles of the reactant species, and  $K_s$  (inverse molar ratio units, dimensionless) and  $C_s$  (molar ratio) are, respectively, the adsorption equilibrium constant and the normalized concentration respecting the adsorbed species  $s = A, B, C$ . Both  $k$  and  $K$  parameters are temperature-dependent following the Arrhenius (2) and van't Hoff (3) equations, where  $A_0$  (in  $\text{min}^{-1}$ ) is the pre-exponential factor and  $E_a$  (in  $\text{J}\cdot\text{mol}^{-1}$ ) is activation energy of the reaction,  $R$  (in  $\text{J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$ ) is the universal gas constant,  $T$  (in K) is the experimental temperature, and,  $\Delta H_{\text{ad}}$  (in  $\text{J}\cdot\text{mol}^{-1}$ ) and  $\Delta S_{\text{ad}}$  (in  $\text{J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$ ) are the enthalpy and entropy changes of the species adsorption.

$$r_j = \frac{k_j C_{\text{reac}_j}^\alpha}{(1 + K_A C_A + K_B C_B + K_C C_C)}, \quad j = 1, \dots, 4 \quad (1)$$

$$k_j = A_{0j} \exp\left(\frac{-E_{aj}}{RT}\right), \quad j = 1, \dots, 4 \quad (2)$$

$$K_s = \exp\left(\frac{-\Delta H_{\text{ad}_s}}{RT} + \frac{\Delta S_{\text{ad}_s}}{R}\right), \quad s = A, B, C \quad (3)$$

The in-silico experiments were simulated at 50, 70, and 90 °C, respectively, lasting for 30 min with the reaction starting from pure A; thus, three data sets were produced by sampling the process every 2 min. White noise with 0.015 standard deviation was added to the entire set of concentration data. In Figure 1 the model dynamics for a single experiment is presented. As can be seen, the species E is present only in very small concentrations and is strongly affected by noise, leading to potential model identification issues.

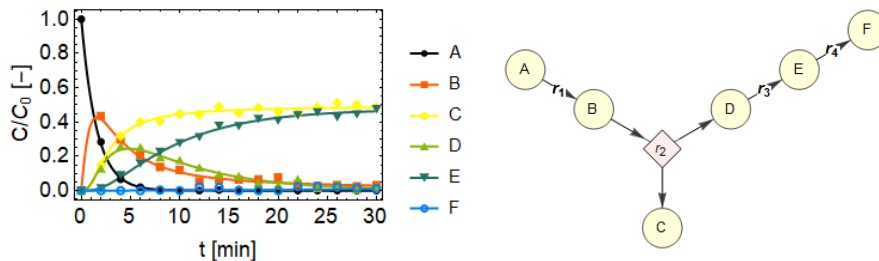

Figure 1 – Model simulation (continuous curves) and noisy experimental data (discrete points) at 70 °C, and model structure (reaction network) on the right-hand side.

The methods described in Section 2 were applied to cumulative molar changes (species extent data) to compare their performance in identifying the correct model size. Note that apart from the measurements, no additional information about the reaction system is used in this task. Also, we considered the cumulative molar changes as they allow minimizing the error in estimation of changes, compared to the estimation of derivatives. In Figure 2 the results obtained for the heuristic approaches are shown. The distribution of the logarithm of the variances in (a) does not present a clear sharp curve, leading to an inconclusive result. Plot (b) shows that the Kaiser test overestimates the model size, indicating a 5-dimensional model. Finally, the plots (c) and (d) for the fractional variance analysis indicate a model with 3 components. However, if 1% of the noise injected was used as a threshold criterion, only a single model component would be selected.

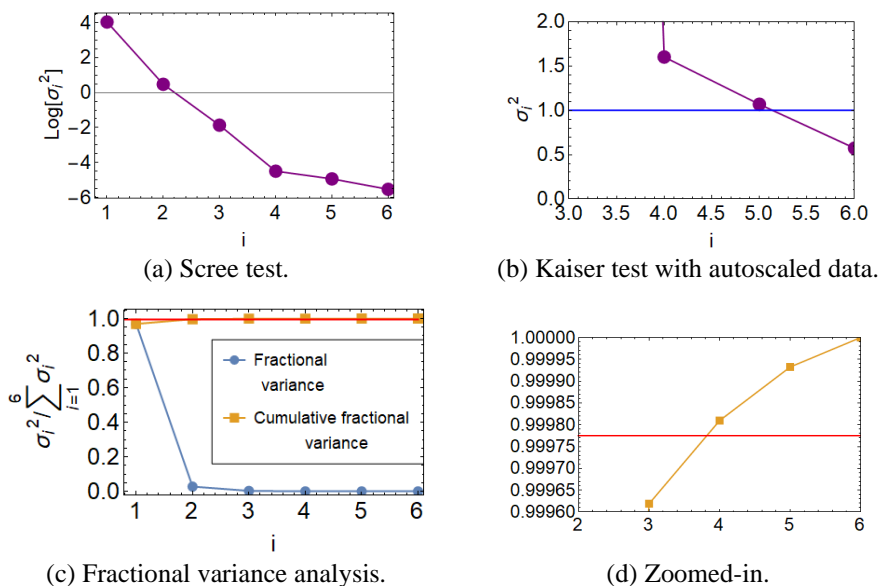

Figure 2 – Heuristic methods results based on data variance analysis.

The F-test indicates that 3 model components are statistically significant. The results are shown in Table 1 and Figure 3. The  $F$ -distribution plots indicate the respective PDF and CDF profiles for different pool sizes. The results demonstrate that  $F < F_c$  until the 2-dimensional pool size analysis (where the vertical red dashed line is located to the right of the vertical black dot-dashed line and the horizontal red dashed line is located above

the horizontal black dot-dashed line). When the 3<sup>rd</sup> lowest component is included, the opposite behavior is observed, i.e.,  $F > F_c$ . Therefore, according to these results, the 3<sup>rd</sup> model component contains structural information related to the data variability that is greater than the noise variability, and hence, it must not be discarded from the pool of noisy components.

Table 1 - F-test results.  $F_c$ : critical  $F$  value for  $\alpha = 5\%$ .  $\alpha^\ddagger$  indicates the percentage of the remain CDF function for each  $F$  observed (cutoff value if that  $F$  was considered critical).

$R$	$n_s - R$	$v(R) \times 10^5$	$v(0) \times 10^5$	$F(1, n_s - R)$	$F_c(1, n_s - R)$	$\alpha^\ddagger[\%]$	$H_0$
5	1	8.763	9.904	0.885	161.448	51.95	Failed to reject
4	2	8.856	4.568	1.939	18.513	29.84	Failed to reject
3	3	90.174	2.998	30.077	10.128	1.19	Rejected
2	4	731.095	10.560	69.234	7.709	0.11	Rejected
1	5	21021.1	55.807	376.677	6.608	0.00	Rejected

Figure 3 -  $F$ -distributions for several sizes of pools. The red dashed lines indicate  $F_c$  (x-axis) concerning  $1-\alpha = 95\%$  (y-axis). The black dot-dashed lines indicate the observed  $F$  (x-axis) and the respective  $1-\alpha^\ddagger$  (y-axis).

Figure 4 presents the PRESS-CV for the adopted cross-validation ( $k$ -fold) approach. In this plot, a flat behavior of the PRESS-CV curve can be observed between model sizes from 2 to 4, indicating that the predictive ability of the data is similar for models including 2 to 4 components. In a purely data-driven-based approach, 2 components would be selected as it allows maximizing the parsimony. However, only from the fourth dimension the PRESS-CV sharply increases, showing the presence of noise in the fifth component and consequent data overfitting. Although there is no significant improvement in the prediction with the addition of a 3<sup>rd</sup> and a 4<sup>th</sup> component to model structure, these are necessary for the complete description of the reaction system through a structure that represents the production/consumption of the entire set of observed species. Thus, from a fundamental perspective where the model needs to be able to describe the underlying phenomena, it is preferable to remain with 4 dimensions in the model, which can be seen as the most plausible model size.

Figure 4 - Cross-validation results for 5 groups of validation datasets.

#### 4. Conclusions

The correct identification of model size from experimental data is important to accurately describe the dynamics of reaction systems. Several methods can be applied, without using any additional system information (like the assumed system kinetics or stoichiometry). The choice of the method must consider the noise, the number of measurements available, the subsequent model application, and the complexity of its structure. When large datasets are considered, the PRESS-CV method tends to perform well and shows a high likelihood of correctly capturing the “true” model size, since the chance of sampling bias is small in this case. The F-test seems preferable to heuristic-based methods, since the former has some theoretical support. When chemical reactions only occur in low extents (i.e., when the signals have variances of the same magnitude as the noise variance) the identification of the “real” size of the model becomes a hard problem. Within this setup, the use of non-heuristic-based methods is advised as they are grounded on theoretically consistent approaches. The results also highlight the advantage of combining different methods to determine the data characteristic space and the complementary space (i.e., the model size and the set of variables included in model representation, and the complementary set of variables). Given the possible synergies of the metrics, the combination of methods can increase the degree of confidence in the identification of the “true” dimensionality of the underlying system. In addition, the results obtained serve as preliminary guidelines for finding new model-based experiments for identifying the real size of the model. Table 2 presents the adequacy of the methods tested (here “+++” indicates a significant preference, “++” an average preference, and “+” a lower preference) and the basic characteristics of the data sets required for its application.

Table 2 - Preference of applicability of the selected methods and respective constraints.

Preference	Method advised	Requirements for successful application
+++	Cross-validation by eigenvectors	Large datasets
++	F-test	---
+	Heuristic approaches*	Low noise content

\*When the noise content is known the fractional variance analysis is preferred.

## Abstract

Agglomeration of powders in pan granulators is a widespread production process, in many industries, e.g., agricultural and pharmaceutical. A continuous operation provides certain desired advantages over batch operation including constant throughput with constant properties of the product particles. An extended setup including a sieve mill recycle can improve the sustainability of overall process. As shown for related process, e.g., fluidized bed granulation, such a setup can exhibit interesting dynamic phenomena like sustained oscillation of the product particle properties, which must be researched in more detail to identify (un-)favorable process regimes. In this contribution, a model for fertilizer production in such a setup is presented. Simulation results indicate the potential benefits not only on increased product particle yield but also manipulation of particle properties.

**Keywords:** Population balance modeling, pan granulation, numerical solution, digital process twin, fertilizer manufacturing.

## 1. Introduction

Agglomeration is a particle formation process in which at least two particles are fused. This principle is used in many industries, e.g. fertilizer production. The properties of the formed agglomerates, e.g. size, shape and porosity, significantly affect certain end-use properties, e.g., dissolubility, processability and storeability (Bück & Tsotsas, 2016). In particular for fertilizer production and minerals processing, agglomerates are often formed in drums or pans (Litster & Ennis, 2004) in continuous operation which may provide constant throughput with constant product quality (in terms of specific agglomerate properties) during steady-state operation. Besides sophisticated experiments, mathematical modeling is also important to come to a deeper understanding and for potential development of model-based process control and intensification. In this report, focus is on population balance modelling of pan granulation which is also known under the term dish or disc granulation. The process setup is given as follows: a powder is fed constantly to an inclined rotating dish into which additional liquid binder is sprayed. Wet granules are sticking together and form larger ones. Flux from the pan does not only contain product particles but also fines and oversized particles. To improve sustainability of the process the non-product fractions can be recycled using a sieve-mill recycle. It is well-known that for size-enlargement processes like pan granulation individual

properties, like characteristic size and porosity, differ from particle to particle. As an alternative to Monte-Carlo modeling approaches, population balance modeling (PBM) (Ramkrishna & Singh, 2014) represents an established framework to model such processes. For standard monivariate PBEs, accounting mostly for characteristic particle size or volume, efficient and accurate numerical solution algorithms have been developed, see e.g. Kumar et al. (2008), Dürr & Bück (2020), and the references therein. In this contribution, a PBM for the continuous pan granulation process with sieve-mill recycle is presented based on a recently reported model for operation without recycle. The model is also extended for a mass controller to guarantee stable process operation. In different scenarios the advantage of recycling is emphasized and also the effects on the product particle characteristics in terms of size distribution is shown.

## 2. Process Model

### 2.1. Population Balance Model

Starting from the model for continuous pan agglomeration presented in Otto et al. (2021) the model equations must be adapted to account for the screen-mill-recycle. The volume density distribution function of the particles in the pan can be described with the following population balance model

$$\frac{\partial n(t,v)}{\partial t} = \dot{n}_{\text{feed}}(t,v) + \dot{n}_{\text{rec}}(t,v) - \dot{n}_{\text{out}}(t,v) + \dot{n}_{\text{agg}}(t,v)$$

Therein, the expressions on the left hand side represents the accumulation of particles in the pan while the right hand side describes contributions of the powder feed to the pan, the recycled particle stream, particles withdrawn from the pan and new particles generated by agglomeration. It is furthermore assumed that the process parameters are chosen such that particle formation via aggregation is dominant and thus additional effects from breakage of granules is negligible. In the following, all expressions on the right hand side are described in more detail.

### 2.2. Modeling of Powder Feed and Agglomeration

For the description of the powder feed to the pan the approach for the process without screen-mill-recycle presented in Otto et al. (2021) is used.

$$\dot{n}_{\text{feed}}(t,v) = N_{\text{in}}(t) \widetilde{n}_{\text{feed}}(v)$$

Here, it is assumed that the powder particle volume characteristics do not change over time and can be represented by the normalized feed powder number density function. Furthermore, denotes the time dependent feed rate.

The change in the particles NDF by formation of a new agglomerate of volume  $v$  by binary fusion of two primary particles of volumes  $u$  and  $v-u$ , respectively, is described with the following expression

$$\dot{n}_{\text{agg}}(t,v) = \frac{1}{2} \int_0^v \beta(t,u,v-u) n(t,u) n(t,v-u) \, du - \int_0^\infty \beta(t,u,v) n(t,v) n(t,u) \, du$$

Generally, the formation of new particles by agglomeration depends on multiple factors, e.g. temperature, binder composition, and particle volume. A common approach to describe such dependencies is a so-called separation approach for the agglomeration kernel function

$$\beta(t, v, u) = \beta_0(t)\beta_v(v, u)$$

with the first factor, the coalescence frequency, accounting for time-dependency due to process conditions or operating parameters and the second for volume dependency. The latter function can either be derived from micro-scale mechanistic modelling, heuristic assumptions or abstract data-driven approaches. In this manuscript, focus is on steady-state operation and thus constant process conditions can be assumed. In consequence,

$$\beta_0(t) = \beta_0 = \text{const.},$$

the so-called Kapur-Kernel is used

$$\beta_v(u, v) = \frac{(u+v)^a}{(u+v)^b}.$$

### 2.3. Modeling of Outflux Rate

The outflux rate comprises granules smaller than product range, granules in product range and also particles larger than the desired product range.

$$\dot{n}_{\text{out}} = \dot{n}_{\text{fines}} + \dot{n}_{\text{product}} + \dot{n}_{\text{over}}.$$

Assuming a sieve with two screens as presented in *Neugebauer et al. (2019)* the rates above can be modeled as

$$\begin{aligned} \dot{n}_{\text{over}} &= T_{\text{screen},1} \dot{n}_{\text{out}} \\ \dot{n}_{\text{product}} &= (1 - T_{\text{screen},1}) T_{\text{screen},2} \dot{n}_{\text{out}} \\ \dot{n}_{\text{fines}} &= (1 - T_{\text{screen},1})(1 - T_{\text{screen},2}) \dot{n}_{\text{out}}. \end{aligned}$$

With sieving functions given as

$$T_{\text{screen},i}(L) = \frac{\int_0^L \exp\left(-\frac{(\xi - L_{\text{screen},i})^2}{2\sigma_{\text{screen},i}^2}\right) d\xi}{\int_0^\infty \exp\left(-\frac{(\xi - L_{\text{screen},i})^2}{2\sigma_{\text{screen},i}^2}\right) d\xi}.$$

In contrast to the previous characterization of granules by volume, the sieving function is described in terms of characteristic particle size and thus reformulation under the assumption of spherical granule shape, i.e.,

$$v = \frac{\pi}{6} L^3$$

When then distribution function is reformulated it must be taken specific care for mass conservation in a subsequent computational implementation, i.e.,

$$n(t, v) dv = n_L(t, L) dL$$

### 2.4. Modeling of recycle rate

The recycle rate includes particles which are out of the desired product particle range with oversized particles being milled before being fed back into the pan

$$\dot{n}_{\text{rec}}(t, v) = \dot{n}_{\text{fines}}(t, v) + \dot{n}_{\text{mill}}(t, v)$$

Assuming an idealized mill, the milled particles follow a normal distribution (*Neugebauer et al., 2019*)

$$n_{L,mill}(t, L) = \frac{\int_0^L \exp\left(-\frac{(\xi - L_{mill})^2}{2\sigma_{mill}^2}\right) d\xi}{\int_0^\infty \exp\left(-\frac{(\xi - L_{mill})^2}{2\sigma_{mill}^2}\right) d\xi} n_{L,over}(t, L)$$

### 2.5. Powder feed manipulation for mass control

The extension of the process setup for the recycle requires control of the overall volume/mass of particles in the pan to guarantee a constant product stream and omit situations with too much or too few particles in the pan. Different control variables could be used to manipulate the overall mass of the pan content:

- Pan inclination,
- Angular speed of the pan,
- Recycle stream,
- Powder feed rate.

Manipulation of the first two variables are favored for the manipulation of the granule properties and for improved sustainability the goal is to use the full recycle stream in the process. Thus, manipulation of the powder feed rate is supposed to be the best option to obtain a stable mass/volume of the pan content. The change of particle mass in the pan is given as the sum of all the in- and outgoing particle fluxes

$$m_{pan} \dot{=} m_{feed} + m_{rec} - m_{out}$$

One pragmatic choice of control would be to use a two-point controller for manipulation of the feed stream. However, the mass of particles in the pan can not be assessed easily and thus an alternative strategy is proposed: The process is run without recycle at startup until steady-state conditions are obtained for a given mass stream of feed-particles  $m_{feed,nom}$ . Afterwards the recycle is added and the feed is manipulated as follows

$$m_{feed} \dot{=} m_{out} - m_{rec}$$

## 3. Results

In the following, simulation scenarios for the setup with recycle are summarized. Feed particle size distribution, separation function and agglomeration kernel parameters are the same as in the non-recycle setup presented in *Otto et al. (2021)*. All additional parameters are summarized in Table 1. Simulations were carried out in MatLab2021a. A detailed description of the simulation algorithm is found in *Otto et al. (2021)* and the references therein. In Fig. 1 – 4 results are shown for four different scenarios: operation without recycle (I), with only milled particles recycled (II), only fines recycled (III) and both recycled (IV).

It can be observed, that recycling of particles which are out of the product specification is favorable in terms increased product particle mass flow. However, the recycling rate also has a clear effect on the characteristic particle size distribution of the product fraction.

Figure 1: Scenario (I) without recycle stream: mass flows of different fractions (left) and normalized particle size distribution (right)

Figure 2: Scenario (II) recycle of milled-particles: mass flows of different fractions (left) and normalized particle size distribution (right)

Figure 3: Scenario (III) recycle of undersized particles: mass flows of different fractions (left) and normalized particle size distribution (right)

Figure 4: Scenario (IV) recycle of milled and undersized particles: mass flows of different fractions (left) and normalized particle size distribution (right)

#### 4. Summary and Outlook

In this contribution a population balance model for continuous pan granulation with sieve-mill-recycle was presented. Here, it must be mentioned that a mass controller is necessary to guarantee a stable process operation. Simulation results indicate that increased product mass flows are obtained yet also the product particle size distribution and thereby the product properties are affected. Therefore, further research is necessary on this issue as well as identification of (un-)favorable process regimes and interesting dynamic phenomena, such as sustained oscillations, e.g., by bifurcation analysis (Otto et al., 2022). Additionally, particle breakage could be taken into account requiring the adaption of the presented concepts. Moreover, the model may be used for the design of model-based sensors or controllers. Of course the previous mentioned research perspectives require model adaption to experimental data (Otto et al., 2021b; Przywara et al., 2021)

## Abstract

The synthesis of heat-integrated distillation sequences for energy-efficient separation of zeotropic multicomponent mixtures is complex due to the many interconnected design degrees of freedom. This paper explores the basis on which reliable screening can be carried out. To solve this problem, a screening algorithm has been developed using optimization of a superstructure for the sequence synthesis using shortcut models, in conjunction with a transportation algorithm for the synthesis of the heat integration arrangement. Different approaches for the inclusion of heat integration are explored and compared. Then the best few designs from this screening are evaluated using rigorous simulations. A case study for the separation of NGL is used to compare options. It has been found that separation problems of the type explored can be screened reliably using shortcut distillation models in conjunction with the synthesis of heat exchanger network designs. Unintegrated designs using thermally coupled complex columns show much better performance than the corresponding designs using simple columns. However, once heat integration is included the difference between designs using complex columns and simple columns narrows significantly.

**Keywords:** Distillation sequencing; energy efficiency; process synthesis and design; process optimization

## 1. Introduction

Distillation is by far the most widely applied separation technology but is recognized as the most energy intensive operation in the chemical industries due to its inevitable energy degradation. Therefore, to genuinely enhance the energy efficiency of the distillation system, it is necessary that all the degrees of freedom are manipulated simultaneously (Kiss and Smith, 2020), i.e. the basic separation configuration including thermally coupled complex columns, column pressures, reflux ratios, feed conditions, condenser types and heat integration arrangement. For all but the simplest separation problems an exhaustive search is infeasible. The method most often used to address larger problems is to use short-cut distillation models to screen the large number of structural options and determine the best few potential designs, followed by more detailed examination of the best few designs using rigorous simulation. However, this raises many questions regarding the screening procedure. It is not clear whether short cut distillation models have the necessary accuracy for reliable screening, and whether

heat integration must be included in the screening. Moreover, if heat integration is included, it is not clear whether the integration can be represented by the energy targets of pinch analysis, or it is necessary to use detailed heat exchanger network designs for screening. This work addresses the problem of multicomponent separation by distillation sequences, by developing an integral systematic optimization method which simultaneously synthesizes sequences, optimizes simple and complex distillation arrangements, heat integration, operating conditions, as well as closed cycle heat pump for refrigeration systems.

The fractionation of natural gas liquids (NGL) is presented here to demonstrate the developed methodology. NGL fractionation, which demands a sequence of several distillation columns, is one of the most energy-demanding processes in the oil and gas industry, producing marketable products such as ethane, propane, butanes, and heavier hydrocarbons. NGL feed is typically 2.5 million tons per year, and approximately 77 GJ per barrel of NGL feed is required, which is equivalent to 4.65 tons of CO<sub>2</sub> emissions per barrel (Manley, 1998). Several attempts based on process intensification principles have been made on the NGL fractionation process to generate more energy efficient distillation sequence design with better separation performance and lower energy use. However, these previous studies made simplifications to reduce model complexities to achieve the challenging optimization: only simple columns are taken into account (Yoo et al., 2016), column pressures are fixed, relative volatilities of the initial feed stream are used for all sequence columns (Ramapriya et al., 2018), or assume only saturated liquid or vapor-phase feed and product streams (Tamuzi et al., 2020). These simplified assumptions on key operating variables lead to loss of accuracy, and none of the previous works considered all degrees of freedom, which risks missing the promising solutions.

## 2. Problem statement

The optimization of the NGL fractionation system is motivated by the benefits of energy savings in reducing costs and CO<sub>2</sub> emissions. Its design requires many interconnected design degrees of freedom, as well as column arrangement possibilities (simple column or complex column arrangements), which lead to a challenging optimization problem. The present study solves this problem through a novel and systematic optimization approach to evaluate all the complex energy integrated NGL fractionation sequence alternatives simultaneously, eliminating simplifications on key design variables. The best sequences can be ranked based on techno-economic analysis.

## 3. Methodology and optimization approach

For a given multicomponent mixture, a superstructure is initially created that contains all possible sequences using simple columns, and then the superstructure is extended to merge any two simple columns in series to form different complex column arrangements, including side draw columns, side stripper, side rectifier, prefractionator, Petlyuk and dividing wall column, as illustrated in Figure 1 (a) (Smith, 2016). Therefore, based on the same starting defaults of each simple column sequence, the modified superstructure generates complex column sequences accordingly. Shortcut Fenske-Underwood-Gilliland models are used to design the columns in this task, which can screen the very many options and avoid dramatic computational difficulties created by nonlinear, large tray-based combinations of rigorous design formulation. The sequences screened by shortcut models are then evaluated by Aspen Plus rigorous simulations.

Figure 1 Extended superstructure for sequence synthesis (a), heat integration matrix (b) and the overall methodology flowchart (c)

Heat integration opportunities including feed preheating or precooling and column to column heat recovery are optimized with sequence synthesis and sequence design simultaneously. All heat sinks and heat sources are compiled into an incidence matrix (as shown in Figure 1 (b)) and solved by the MILP transportation method. Binary variables are introduced to make discrete decisions for each match between rows and columns of the matrix. The optimal heat exchanger network structure to minimize operating costs is determined. Liquids and gases are pressurized by pumps and multistage-compressors and depressurized by valves and turbo expanders. The separation is assumed to be sharp split.

A decomposed optimization methodology is created and illustrated by a flowchart shown in Figure 1 (c). The overall model is formed as an MINLP problem and solved by simulated annealing (SA). The shortcut distillation models equations are built into the optimizer, acting as a ‘simulation’ section to eliminate the non-linearity in the optimization. For a given mixture, the SA creates ‘moves’ in the optimization that allow for changes in the distillation structure, for example, changing two adjacent simple columns to be a complex column, and the operating variables in their permitted bounds. The values are then sent to the objective function which uses them as inputs for the simulation model. After each move, the sequences are simulated, heat exchanger network designed, and the corresponding total operating cost (TOC) is evaluated by the current column design details and then by the heat integration. The objective value is then returned to the optimizer. The operating variables can subsequently be changed by the optimizer and the process repeated until convergence. This optimization methodology can be carried out within the ColSeq software developed and available at the Centre for Process Integration, The University of Manchester (CPI Suite, 2022).

## 4. Results and discussion

The conventional configuration of the NGL fractionation uses a train of 4 simple distillation columns: deethanizer (30.98 bar), depropanizer (17.50 bar), debutanizer (5 bar) and deisobutanizer (6.50 bar) to generate 5 products (Manley, 1998; Long et al., 2018). In this work, the NGL fractionation is optimized by applying the developed optimization model to enhance its energy benefits. Multiple utilities considered for heating, cooling and refrigeration and their prices are taken from Turton et al., (2018). The corresponding details of feed and products are taken from Long et al., (2016). For heat exchangers, the minimum temperature difference between hot streams and cold streams (including utilities) is assumed to be 10 K for above ambient heat transfer, whereas for sub-ambient it is assumed to be 4 K (Kiss and Smith, 2020). The optimization is carried out using a desktop with CPU - *Intel<sup>(R)</sup> Core i7-10700 CPU 2.90 GHz* with 8 cores, and the average time resource is 16 hours.

By optimization, a total of 14 simple sequences using 4 simple columns, and the corresponding 14 complex column sequences are generated. These sequences are developed by two optimization routes for the NGL fractionation: sequences without heat integration and integrated sequences with detailed heat exchanger network design.

### 4.1. Optimization results evaluation and analysis

Firstly, the developed approach is validated demonstrating by non-heat integrated simple column sequences. Figure 2 (a) shows sequence rankings in terms of the total operating cost. The ranking top 5 sequences (Zone-I) shown in Figure 2, with relatively small differences in TOC (less than 5%), are considered as the most economically attractive sequence family identified by the screening method based on shortcut models. To evaluate the optimized sequences based on shortcut models, the short-cut design details (reflux ratio, trays, condenser temperatures and distillate rate) are extracted as the initialization parameters, and then all optimized sequences are rigorously simulated using Aspen Plus rigorous distillation models. The sequences S7, S6, S4 are the top ranked sequences identified by rigorous simulations in terms of total operating costs, which have all been preselected in the attractive families by the developed pre-screening approach. These results indicate that despite the deviation between shortcut and rigorous models, the developed fast screening method using shortcut models is validated and comparable. Compared to the conventional distillation sequence (Manley, 1998), the optimized operating conditions based on the same separation structures lead to lower column pressure for all four columns without changing the refrigerant level of the deethanizer, and lower condenser and reboiler duties with 2.37 M\$/yr TOC savings.

Figure 2 Total operating costs ranking of non-heat integrated simple column sequences (a) and heat integrated sequences (b)

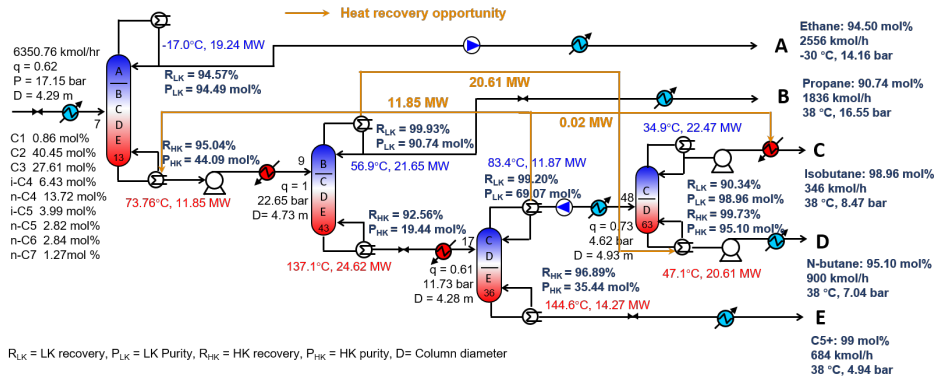

Figure 3. Design details of heat integrated simple column sequence S4

#### 4.2. Energy integrated distillation sequences

Energy intensified sequences using complex columns can bring energy savings. For the non-heat integrated sequences, introducing complex columns can achieve up to 21% operating cost savings compared with the simple column sequences. The conventional sequence (which is the same structure as the simple sequence S4 in this case) that is ranked as the most economical sequence in a simple column sequence, is ranked 11 out of 28 taking into account complex column sequences. The best sequence is now the complex sequence 6, which separates isobutane by a side rectifier, followed by two simple columns separating C2 / C3 and n-butane / C5+, with the TOC of 12.78 M\$/yr.

To achieve further energy savings, heat integration is adopted, achieved by optimizing heat exchanger network with column operating conditions simultaneously for both simple and complex sequences. Figure 2 (b) shows the overall rank of heat integrated simple and complex column sequences. The total operating cost saving brought by heat integration on the optimized non-heat integrated simple columns is up to 26%, and the operating cost saving from optimizing both heat integration and complex columns can achieve up to 38%. The top 6 sequences are considered as the most economically attractive sequences family with a relatively small operating cost difference. Further designs can be taken within this attractive families based on different requirements.

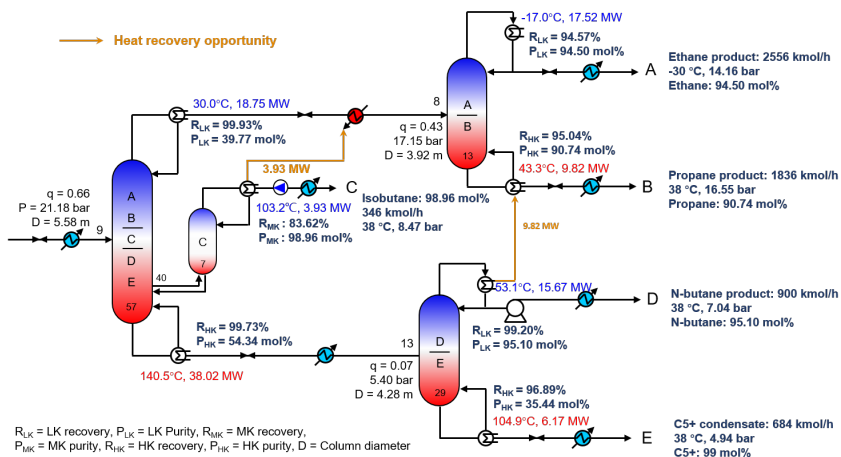

Figure 4. Design details for heat integrated complex column sequence C9

It is shown that when heat integration is adopted, the simple sequence 4 is ranked the best (with the detailed design in Figure 3), followed by the complex sequence C9 (as shown in Figure 4). Simple column sequences benefit to a larger extent from heat integration compared to complex column sequences; simple column sequences can achieve an average energy saving of 16% by introducing heat integration, but complex columns gain an average 11% energy saving by introducing heat integration. This is because complex columns could lose potential heat integration possibilities when constraining the combination of heat sinks and sources during the merging, so that the number of design degrees of freedom of complex columns decrease. The complex sequence C9 may get more benefits when taking into account capital costs due to the reduced equipment sizes. The capital cost is not considered at this stage, as capital costs may not be reflected accurately using approximate capital cost calculation methods.

## 5. Conclusions

The systematic screening approach developed in this study was successfully used for simultaneously optimizing sequence structures, accounting for all design degrees of freedom and heat integration in the distillation sequences. By optimizing the whole sequencing process, new NGL fractionation sequences have been explored and ranked techno-economically. The generated economically attractive sequences (ranked by the operating costs) are shown to be comparable with those of rigorous simulations using the Aspen Plus RadFrac model. For a given feed composition and product requirements, the ranking of the detail designed energy integrated complex sequences for NGL fractionation are listed, and the most energy efficient and economically attractive sequences family have been selected. These results demonstrate that screening of the search space of energy-efficient distillation sequences, considering synthesis and optimization of the many design degrees of freedom, is achievable with the newly proposed approach.

## Abstract

In this study, a multi-scale model is developed to address the transport of gases, ions, and electrons inside a solid oxide fuel cell. Transport phenomena and electrochemical reactions inside the active layer of anode are simulated at the nanometer scale, while the rest of cell is simulated macroscopically at a coarser resolution. The microstructure of the anode side is reconstructed using pluri-gaussian random fields and the triple phase boundary (TPB), where all the electrochemical reactions are assumed to take place, is captured from the discretized (in voxels) image of the microstructure. Therefore, this multi-scale framework offers a much finer level of description for transport phenomena and for electrochemical reactions, significantly increasing the accuracy of numerical modelling of entire solid oxide fuel cells.

**Keywords:** Solid Oxide Fuel Cell, Multi-scale model, Triple phase boundary

## 1. Introduction

Fuel cells, as an alternative power generation device, have shown tremendous potential in clean, small- and large-scale electricity generation in recent decades. Fuel cells convert the chemical energy of a fuel (typically hydrogen) into electricity through electrochemical reactions. The energy conversion (chemical to electrical) is not limited by any thermodynamic law. Theoretically they can have 100% efficiency, whereas the efficiency of e.g., coal-powered stations is limited by the first and second law of thermodynamics and the maximum efficiency attainable is the Carnot efficiency. If hydrogen is to be utilized inside a cell as fuel, the only by-products of the electrochemical reactions would be oxygen gas and water.

Solid oxide fuel cells as the name suggests use a solid ceramic compound as the electrolyte to generate clean electricity (Singh, Zappa, and Comini 2021). SOFCs are well known for their high operating temperatures, which eliminate the need for metallic catalysts. Due to the convoluted interplay between different transport phenomena and chemical/ electrochemical reactions inside the cell, which span different length scales (Grew and Chiu 2012), complex models are needed to capture their behaviour. The

electrode microstructure has a substantial effect on the overall electrochemical performance of the cell (dos Santos-Gómez et al. 2021). However, the size of an entire fuel cell is far larger than the microscopic details of the electrodes to be considered in a macroscopic model. It is not, therefore, practically possible to numerically solve the mathematical equations governing the SOFC behaviour over an entire cell while maintaining a fine degree of description of microscopic details. This issue is thoroughly discussed by Grew and Chiu (Grew and Chiu 2012). Hence, most relevant works in the literature are focused either on macroscopic descriptions [4], component-level modelling [5], or on pore-scale modelling [6] of SOFC electrodes. These classes of models make multiple assumptions about the unresolved physics of the “other” scale. To bridge the gap between these two classes of numerical models, an integrated multi-scale numerical framework has been developed in this work by enabling a macroscopic model to obtain information directly from a pore-level model.

The macroscopic model uses the finite-element approach, and its domain covers the entire cell (fuel/air channels, electrolyte, and electrodes, and interconnects). In addition, a microscopic model is developed to simultaneously solve the coupled mass, ion, and electron transport equations, and chemical/electrochemical reactions in a three-dimensional microstructure of the SOFC electrode. Microscopic simulations are only performed on small segments (patches) of the microstructure. A “patch” [7] is a small spatial computational domain extracted from a larger volume/surface of interest, in order to facilitate the efficiency of complex computations. The contribution of this work is that the developed integrated, multi-scale model can resolve the physics linked to the fine microscopic topological features of the electrode microstructure over an entire length of an electrode in a particular fuel cell. This can improve the overall performance prediction of SOFCs, which is highly dependent on both their microscopic and macroscopic features.

## 2. Methodology

In this section, the two different models that are developed to address the multiscale problem are briefly discussed. The micro model solves the gas/electron/ion transport inside the active electrochemical layer. Using Fick’s and Ohm’s laws, mass/charge conservation equations can be written as follows. Knudsen diffusivity should also be considered due to small radius of pores. It can be approximated using kinetic theory of gases.

$$\nabla(-D_{H_2}\nabla c_{H_2}) = -\frac{\rho_{TPB}J}{2F}M_{H_2} \quad (1)$$

$$\nabla(-\sigma_{el}\nabla V_{el}) = -\rho_{TPB}J \quad (2)$$

$$\nabla(-\sigma_{io}\nabla V_{io}) = \rho_{TPB}J \quad (3)$$

Here,  $c_{H_2}$ ,  $V_{el}$ ,  $V_{io}$  are the hydrogen concentration, electronic potential, and ionic potential, respectively.  $\rho_{TPB}$  is the density of the triple phase boundary and  $J$  is charge transfer rate. This rate is only non-zero at the TPB. Therefore, all three governing equations (1-3) reduce to the Laplace equation anywhere else in the domain. For the microscopic model, these equations are solved over a representative volume element of a microscopic domain with regular hexahedral mesh. Each grid element represents a pixel in the tomographic

image obtained from 3D imaging. Finite-volume method is employed to discretize equations in 3D space. Boundary conditions for micromodel consist of constant ion and electron potential at microstructure surfaces facing electrolyte and anode, respectively. Hydrogen concentration is also assumed constant at the boundary facing anode side. All other boundary conditions are zero-flux. Three coupled systems of linear equations resulting from discretizing equations 1-3 over the entire microscale domain are then solved until convergence using GMRES algorithm implemented in python.

The macroscopic model solves the mass and charge conservation equations inside an entire cell. The governing equations are the same as mentioned above. Since electrochemical reactions take place on the TPB in microscale, they cannot be resolved with the macroscale model. Instead, these reactions are modeled in the microscale model and then volume-averaged reaction rates are imported into macroscopic model as boundary conditions on the interfaces between electrolyte and porous electrodes. The charge transfer rate is assumed to follow the Butler-Volmer model.

$$J = J_0 \rho_{TPB} \left( \exp\left(\frac{2\beta F}{RT} \eta_{act}\right) - \exp\left(-\frac{2(1-\beta)F}{RT} \eta_{act}\right) \right) \quad (4)$$

Where  $J_0$  [A/m] is the lineal exchange current density taken from data provided by Prokop et al. [8].

A schematic of the macroscopic and the microscopic model and their interactions is shown in Figure 1. The macroscopic domain contains fuel/air channels, porous electrodes, and electrolyte. The microscopic model, on the other hand, is limited to the active electrochemical site between the porous anode and the electrolyte. The microstructure is generated using pluri-gaussian random fields described in [9], and the location of TPB inside the microstructure is calculated with the algorithm discussed by Vivet et al. in [10].

**Figure 1** – Schematic of the multi-scale numerical framework. The macroscopic model spans an entire cell, whereas the microscopic model only covers the electrochemical active layer between electrolyte and electrodes

The transport equations are solved until convergence both in macro and in micro models. The information that is shared between two models are the physical features of the porous media (porosity, permeability), the effective current density exiting the electrolyte layer, operating voltage, and amount of overpotentials.

Geometrical parameters of the cell and physical properties of Nickel and YSZ are taken from papers by Tseronis et al. [4], and Shearing et al. (Shearing et al. 2010).

The numerical mesh that is used for the microstructure model is essentially the same as that of the voxelized image. Since the voxelized image is the finest description available of the real porous geometry, it has been decided that no smoothing should be performed on the reconstructed image. If the reconstructed geometry is to undergo smoothing, a finer numerical mesh can be constructed, which however would not be useful as its features would have been finer than the finest level of microstructure description available.

### 3. Results and discussion

In this section, the results of the multi-scale model combining the macro- and micro-scale models are presented and discussed. For the simulations, the operating temperature of the cell is assumed to be 900 °C. The density of the triple phase boundary is measured to be  $9.456 \mu\text{m}^2$ . The variation of the ion potential and current density in the microstructure electrochemical active layer of the anode side is shown in Figure 2. The YSZ phase inside the microstructure is on the left-hand side of the figure with the TPB lines depicted on the outer surface of the YSZ phase as black lines. On the right-hand side of the figure, the variation of the current density is shown on the TPB lines. To visualize the TPB lines, it was assumed that they have an artificial thickness of two pixels on each perpendicular direction. The top interface of the microstructure in this figure is adjacent to the electrolyte and the bottom side faces towards the porous anode layer. Due to the electrochemical reaction taking place on the TPB sites, the ion potential increases from the electrolyte interface (-0.341 V) to the porous anode interface (-0.5 V). The highest charge transfer rate is on the electrolyte interface, and it gradually reduces to zero as the distance from the electrolyte increases.

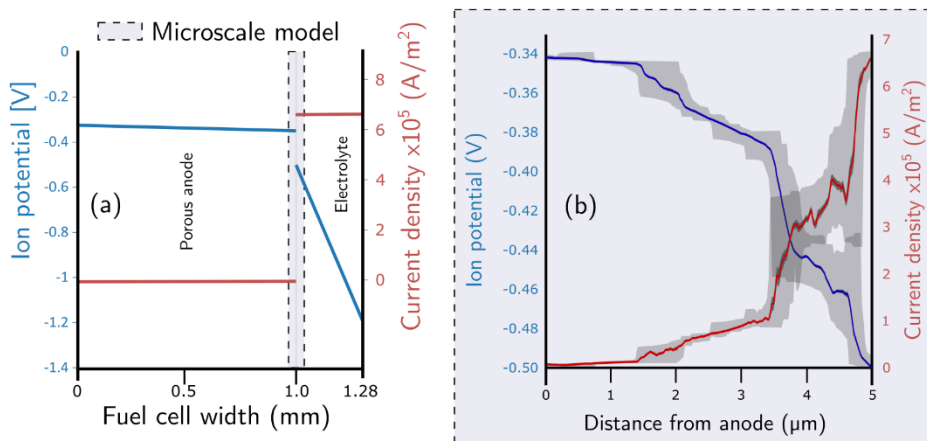

Changes in hydrogen concentration and electronic potential in the microstructure were insignificant, so they were not shown here. The micromodel is also capable of computing the local activation and concentration overpotential in the microstructure.

**Figure 2** – spatial variation of ionic potential and current density, respectively in the YSZ phase and on the TPB.

Results of the multi-scale model are illustrated in Figure 3 below. Figure 3a depicts results from the macroscopic model, which the mass and charge transport through the entire cell, whereas Figure 3b depicts the results of the microscopic model. As mentioned above, the microscopic model solves the same transport equations as of the macroscopic model, with the exception that the micro-scale model also computes the electrochemical reactions on the TPB sites. As shown below, this enables the micro-scale model to capture the rate of charge transfer locally with nanometer resolution. To demonstrate the capability of the multi-scale model, changes of ion potential and current density in the electrolyte and the porous anode are shown in figure 3a, whereas Figure 3b depicts the local variation of the same variables on the interface between electrolyte and porous anode, with much finer (nanoscale) resolution. For comparison, the size of each computational node in the macro-model is roughly 0.1 mm, whereas each computational node of the micro-model is only 25 nm. In Figure 3b, the minimum and maximum value, and the 95% confidence band of ion potential and current density in each slice of the microstructure in x direction (refer to Figure 1) is also shown.

The microscale model covers the electrochemical active layer only. Therefore, the rate of electrochemical reactions (or consequently current density, red curves in Figure 3) approaches zero when the distance from the electrolyte increases in the micromodel. The maximum current density on the electrolyte surface is then transferred to the macroscale model to simulate large-scale mass/charge transport. Potential difference across the micromodel (blue curves in Figure 3) implies the sum of activation and concentration overpotentials in the anode side. This potential difference is forced in the microscale model by macroscale simulation. As a result, until the mass and charge conservation criteria between the micro and macro domains are satisfied, there is an iterative loop between the micro and macro models. This link between micro and macro models allows macroscopic description of mass/charge transport inside a single cell while maintaining a microscopic resolution to explain electrochemical reactions at TPBs. It ultimately creates a framework to investigate the effects of microscopic features on macroscopic performance of the cell in our future studies.

**Figure 3** – Variation of ion potential and current density across the width of the fuel cell both in macro- and micro-models with different numerical resolutions. (a) macroscale model. (b) microscale model

#### 4. Conclusions

A multi-scale numerical framework has been developed to study the mass/ion/electron transport inside the entire solid oxide fuel cell, from fuel channel to air channel with the capability of resolving the nanometer scale features inside the active electrochemical layer. This can help to achieve a more accurate description of electrochemical reactions taking place on the TPB and also on the double phase boundaries in the case of mixed ionic-electronic conductors, which ultimately increases the accuracy of the numerical model for predicting the performance of the entire cell or even an entire stack of cells. The future research direction is to extend this multi-scale numerical framework to use multiple microstructures in parallel (patches) to capture the nanometric features and rate of electrochemical reactions across the length of the entire fuel cell, and even across multiple cells, significantly expanding the computational capabilities of the multi-scale model.

## Abstract

Parameter estimation is typically used as part of model development to determine the values of unknown parameters. However, depending on the model complexity the number of parameters can also vary. High complexity models have large numbers of parameters requiring more computational effort to determine them and are also prone to overfitting. Low complexity models have smaller numbers of parameters but may have reduced accuracy. Based on available experimental data cross-validation can be used to compare different complexity models and determine the most appropriate complexity (James et al., 2013). Alternatively, it is possible to look at the identifiability of parameters based on experimental data which considers the sensitivity and correlation between parameters. Both these types of methodologies can be used to reduce the complexity of models such that insensitive and/or dependent/correlated can be removed or re-estimated and an alternative set of parameters can be computed. In this work both types of methods are explored with examples. Cross-validation combined with a Least Absolute Shrinkage and Selection Operator (LASSO) regularisation method is used to reduce the complexity of linear empirical equations for predicting the performance of downdraft biomass gasification (Binns and Ayub, 2021). Sensitivity and identifiability methods utilizing the Fischer Information Matrix (FIM) are used to reduce the complexity of a nonlinear system of partial integral differential equations describing a population balance model for microalgae cultivation (Usai et al., 2022). Application of these methods allows the number of parameters to be reduced depending on the tolerance and/or accuracy required.

**Keywords:** Model reduction, Parameter estimation, Optimisation, Identifiability, LASSO.

## 1. Introduction

Model development typically starts from some knowledge derived from existing experimental data and the equations which have previously been used to model similar systems. Based on this starting point a model might be suggested which includes all known physical variables and parameters which affect the system outputs. This approach might lead to a complex model for which there are a large number of unknown parameters. For this reason model reduction and identifiability methods can be used to reduce the complexity (Baker et al., 2015). In this study we compare two different approaches for model reduction combined with parameter estimation: LASSO based regularization (James et al., 2013; Binns and Ayub, 2021) and a sensitivity and

identifiability analysis utilizing the Fischer information matrix and multi-objective optimisation to reduce correlations and improve identifiability.

## 2. Parameter estimation methods

Parameter estimation involves minimising or reducing the difference between model predictions and experimental values by changing the values of parameters in the models. This is typically achieved by minimising a least-squares type function such as equation 1 where  $y_z$  is the experimental value,  $\hat{y}_z$  is the corresponding model prediction and  $N$  is the number of data points.

$$RSS = \sum_{z=1}^N (y_z - \hat{y}_z)^2 \quad (1)$$

The number of parameters to be estimated depends on the complexity of the terms used in the models to predict  $\hat{y}_z$ .

### 2.1. Parameter elimination

Reducing the complexity of models may be possible through the elimination of certain parameters which are either insensitive or do not affect the model outputs. There are potentially three ways by which parameters can be eliminated

- Set parameter to 0
- Set parameter to 1
- Set parameter to a fixed value

In cases where a fixed value is used this is defined using existing knowledge of the system. Alternatively setting values to 0 or 1 will typically allow the model equations to be written in a simpler form.

### 2.2. LASSO regularisation

$$RSS = \sum_{z=1}^N (y_z - \hat{y}_z)^2 + \lambda \sum_{i=1}^n |\beta_i| \quad (2)$$

Regularisation is the methodology where the objective function from equation 1 is modified to include a second set of terms including the sum of the values of  $n$  parameters,  $\beta$ , multiplied by a factor,  $\lambda$ . When this function is minimised the values of parameters are also minimised and if the absolute values of  $\beta$  are used (as shown in equation 2) the effect is that a number of parameters are set equal to zero (James et al., 2013). Varying the value of  $\lambda$  will change the number of parameters set to zero. A very small  $\lambda$  value leads to the same solution obtained by minimising equation 1, a very large value  $\lambda$  will lead to a solution where all the parameters are set to zero. Additionally, this value will also affect the model accuracy, so cross-validation is required to find the most appropriate value of  $\lambda$ . In particular cross-validation involves dividing the training set into a number of sections or folds. One of the folds is selected for testing and the remainder are used for training. Sequentially repeating this for every fold will then lead to an overall cross validation mean square error. This cross validation is then repeated for every value of  $\lambda$ , being considered giving a range of different model solutions with varying accuracy and varying numbers of non-zero parameters.

### 2.3. Sensitivity and identifiability analysis

#### 2.3.1. Sensitivity based parameter reduction

As mentioned in section 2.1 a parameter might be eliminated by setting its value to either zero, one or some pre-defined fixed value. Starting from some existing full model containing possibly a very large set of parameters the change in model output ( $y$ ) resulting from and a small change in each parameter ( $P$ ) will give sensitivity values as shown in equation 3. Then sequentially considering the elimination of each parameter by setting it to some fixed value and checking if the resulting model error exceeds some specified tolerance leads to a reduction of the number of parameters.

$$S_p = \frac{dy}{dP} \quad (3)$$

#### 2.3.2. Identifiability analysis and correlations

After reducing the number of parameters either through the regularisation (as described in section 2.2) or utilizing sensitivities and a sequential removal method (as described in section 2.3.1) it is useful to consider the identifiability of the remaining parameters. Based on the available experimental data identifiability analysis asks which of those parameters can be uniquely identified. Those without a unique solution may have a range of acceptable values or it may not be possible to identify a reasonable value. Starting from the sensitivities it is possible to calculate the Fischer Information Matrix (FIM) which uses the local sensitivities around a fitted set of parameters ( $S_p$ ) together with the weighted variance ( $\hat{\Sigma}$ ).

$$FIM = \sum_{j=1}^{N_{exp}} \sum_{i=1}^{N_{sample}} \left( S_p(i, j) \right)^T \hat{\Sigma}^{-1} \left( S_p(i, j) \right) \quad (4)$$

The inverse of this FIM gives a lower bound for the covariance matrix which can be used to calculate the correlation matrix (Stoica and Ng, 1998; Baker et al., 2015). The following equations (5-8) are suggested in order to minimise correlations between parameters. From the correlation matrix ( $\rho$ ) it is possible to calculate an overall correlation coefficient as shown in equation 5. Subsequently from this correlation matrix the most highly correlated parameter (with the highest  $I_j$ ) is chosen as a pivot parameter and other parameters which are strongly correlated with this are defined by linear relations as in equation 6.

$$I_j = \sum_{i=1}^{N_{parameters}} \rho_{ij} \quad (5)$$

$$P_i = C_{ij} P_j \quad (6)$$

$$Z_1 = \min \left( \frac{y(C_{ij} P) - y(\hat{P})}{y(\hat{P})} \right)^2 \quad (7)$$

$$Z_2 = \min I_j(C_{ij}) \quad (8)$$

To reduce the magnitude of correlations present the correlation values can be optimised (subject to any bounds on the final parameter values from the model) by minimising  $Z_2$  as defined in equation 8. A second objective is given in equation 7 which is the deviation

in model output between using the original parameters and those modified by changing the correlation values. Hence, this is a multi-objective optimisation which should give a pareto curve of possible solutions. If parameters change without affecting model results this suggests they are not identifiable and can be eliminated or set to constant values.

### 3. Case studies

#### 3.1. Empirical models for biomass gasification

Biomass gasification models should predict the outlet gas composition based on a number of input variables. In particular the input biomass composition (*Ultimate analysis: %C, %H, %O, %Ash*), moisture content (*MC*), equivalence ratio (*ER*) and gasification temperature ( $T_{gas}$ ) are expected to affect the output gas composition. For the gasifier considered here additional inputs are also available including grate rotation speed (*Gr*), gas fan speed (*Fs*), Wet bulk biomass density (*bulk*) and biomass void percent (*void*).

Figure 1. Block diagram representing a biomass gasifier.

Although more complex models are possible, for example based on knowledge of reaction kinetics, in this study simpler empirical models are considered relating the inputs with the outputs through linear and quadratic expressions. In this case the experimental data of Chee (1987) is used including 34 data points with inputs and outputs defined in Table 1. This is the same case investigated by Binns and Ayub (2021) who focused on finding the minimum cross-validation error model for each output. Here we consider the ranges of solutions which can be found with varying  $\lambda$ , the accuracy and simplicity of models obtained. For this purpose we consider the modelling of  $\text{CO}_2$  volume percentage in the produced gas with a range of possible solutions shown in table 1 and figure 2. As can be seen from figure 2 and table 2 the model accuracy varies with changing value of  $\lambda$ . For lower values all eleven parameters are non-zero but the cross-validation error is highest. The lowest cross-validation error is achieved in a linear model with 7 non-zero parameters and at high values of  $\lambda$  all the parameters are zero and the model reduces to a constant value with a single fixed value.

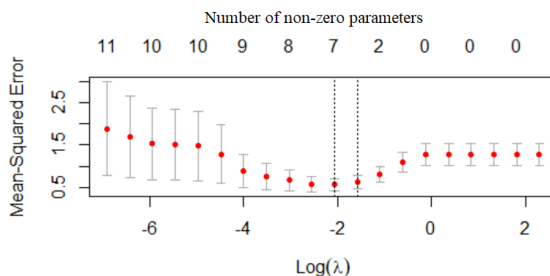

Figure 2. Cross-validation mean square error for  $\text{CO}_2$  using a linear model with varying  $\lambda$ . The number of non-zero parameters excludes a constant fixed parameter ( $\beta_0$ ).

Table 2. Parameter reduction using LASSO regularisation (Binns and Ayub, 2021)

$\lambda$ value	Cross validation error	Expression
$\lambda = 0.001$	1.8851	$CO_2(\%) = \beta_0 + \beta_1 Tgas + \beta_2 ER + \beta_3 MC + \beta_4 H + \beta_5 O + \beta_6 C + \beta_7 Ash + \beta_8 Gr + \beta_9 Fs + \beta_{10} Bulk + \beta_{11} void$
$\lambda = 0.2069$	0.6402	$CO_2(\%) = \beta_0 + \beta_2 ER + \beta_3 MC + \beta_5 O + \beta_7 Ash + \beta_8 Gr + \beta_{10} Bulk + \beta_{11} void$
$\lambda = 0.3360$	0.8053	$CO_2(\%) = \beta_0 + \beta_2 ER + \beta_3 MC$
$\lambda = 1.4384$	1.2909	$CO_2(\%) = \beta_0$

### 3.2. Population balance models for microalgae cultivation

The population balance model considered here is for the growth of the microalgae *Haematococcus pluvialis* from the model developed by Usai et al. (2022). This model describes the growth (G), birth (B), disappearance of mother cells (M) and cell lysis (D) giving the overall population balance in equation 9.

$$\frac{\partial \Psi_V}{\partial t} + G(v) = B(v) - M(v) - D(v) \quad (9)$$

where  $\Psi_V$  is the density distribution function of cells in the system.

The full model including expressions for each of the terms in equation 9 requires 34 parameters which are fitted to experimental data (Usai et al. 2022). It can be shown that applying sensitivity based parameter reduction 10 parameters can be eliminated with a tolerance of 0.05. Increasing the tolerance would allow more parameters to be eliminated (similar to the way increasing  $\lambda$  reduces the number of parameters).

Table 3. Parameter reduction using sensitivity approach (Usai et al., 2022b)

Tolerance	Parameters eliminated	Total parameters remaining
0.025	5	29
0.05	10	24
0.1	11	23

After the reduction of parameters, the sensitivity values can also be used to calculate the Fischer information matrix and subsequent covariance and correlation matrices. This identifies a number of strong correlations including existing relations between Monod kinetic parameters. If the objective function in equation 8 is minimised the magnitude of most correlations can be reduced by approximately 35%.

## 4. Discussion and conclusions

Two methods for model reduction based parameter estimation have been evaluated with two case studies and both are able to reduce complexity of the resulting models. A comparison of the two methods can be seen in table 4. The main advantage of the LASSO regularisation method is that it can start from a very complex model and directly reduce the number of parameters as part of the parameter fitting while the sensitivity and

identifiability approach generally starts from a full fitted complex model before reducing model complexity. However, the sensitivity and identifiability approach can more directly control the accuracy of the reduced model through the setting of a tolerance. It also offers more flexibility in terms of how to eliminate parameters, although possibly the LASSO regularisation could be modified so it can eliminate parameters in the same way. The main advantage of the sensitivity and identifiability methods are that they identify potential correlations between parameters and optimisation methods can be used to reduce the correlation values and potentially improve the identifiability of the model.

Table 4. Comparison of model reduction based parameter estimation methods

Issue	LASSO regularisation (Binns and Ayub, 2021)	Sensitivity and Identifiability analysis
Complex initial model	Can identify reduced models starting from a very complex model $\left( \begin{array}{l} N_{parameters} \gg N_{datapoints} \\ N_{reduced\ parameters} < N_{datapoints} \end{array} \right)$	Requires full potentially complex model with fitted parameters as starting point
Accuracy vs. simplicity control	Control using $\lambda$ factor (accuracy or model error must be calculated as an extra step)	Control using model tolerance
Parameter elimination	Set eliminated parameters to zero	Set eliminated parameters to either zero, one, or to specified values
Correlations and identifiability	Does not test for correlations. Reduces some statistical identifiability issues by reducing the number of parameters compared to the number of data points	Identifies potential correlations Can reduce correlation values to improve identifiability

## Abstract

This paper describes the development of product property models for a new hydrocracking catalyst, developed by IFPEN. The naphtha density is used as an illustrative example. A Bayesian Transfer Learning approach is used to transfer the ordinary least squares (OLS) parameters from a source dataset consisting of 3980 points from industrial units operating previous (n-1) catalyst generations to a target dataset with 96 points from pilot plant tests with the new catalyst (n). Robustness of the new model is greatly improved because information from the larger dataset is included in the new model. The Transfer Learning approach is shown to give good results and lead to a more robust model with respect to feedstock descriptors.

**Keywords:** Transfer Learning, Modelling, Hydrocracking, Bayesian Statistics

## 1. Background

Accurate and robust predictive models are essential when commercializing a new chemical process in order to design the industrial units. Models can be derived from first principles or data driven. It is not always possible to do the former, which requires knowledge of all chemical reactions involved, as well as analytical methods for detailed characterization of the feedstocks and products. In this case empirical model must be developed, which require a much larger number of experimental data points in order to achieve the required precision and accuracy. Running pilot-scale experiments is rather expensive and time-consuming, which limits the amount of data which can be obtained in practice. The estimation of physical properties for petroleum refining products is a particularly challenging subject due to the complexity of the feedstocks, which are composed of hundreds of thousands of different hydrocarbon compounds.

### 1.1. Process Description

Hydroprocessing is a crucial component of a modern petroleum refinery (Jones 2006), which is used to convert heavy fractions obtained by distillation of crude oil (i.e. Vacuum Gas Oil – VGO) into more commercially valuable middle distillate (Diesel & Jet) or naphtha fractions over a fixed-bed catalyst under hydrogen pressure of 80 – 160 bar at temperatures from 360 – 410°C. Naturally occurring nitrogen and sulfur are removed in the Hydrotreatment (HDT) section, while long-chained hydrocarbons are broken up into smaller compounds in the Hydrocracking (HCK) section(s). The HDT section is necessary because organic nitrogen is a poison to zeolitic HCK catalysts. Ammonia (NH<sub>3</sub>) and hydrogen sulfide (H<sub>2</sub>S) gasses produced in the HDT section is carried over to the

HCK section, the  $\text{NH}_3$  inhibits HCK catalyst activity. The effluent of the reactor is split into the product cuts in a fractionator. It is possible to adjust the desired conversion and yield of product streams via selection of the catalyst(s) or operating conditions, this makes hydrocracking a very versatile process. HCK produces high-quality cracking products.

Higher rates of conversion can be obtained by recycling Unconverted Oil (UCO). In a two-stage process, the UCO-recycle stream is processed in a third HCK reactor, the effluents of the two HCK sections are blended before fractionation. Only trace amounts of  $\text{NH}_3$  are present in the second HCK reactor, which therefore requires much lower temperatures to achieve the desired conversion.

In maxi-middle distillate mode, the yields of Diesel and Jet cuts are favored, while maxi-naphtha mode aims to maximize naphtha production. Consequently some, or all, of the produced Jet and Diesel cuts are also recycled in this configuration.

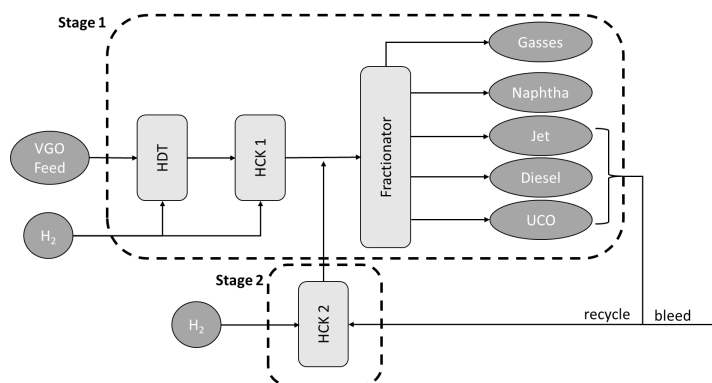

Figure 1 Schematic representation of the two-stage hydrocracking process in maxi-naphtha mode

### 1.2. Catalysts

IFPEN develops a wide range of HDT and HCK catalysts. The catalyst of generation n-1 is commercialized and used in single-stage maxi-middle distillate production and data from industrial units has been collected over the last 15 years. Catalyst of generation n has been developed for maxi-naphtha production in one- or two-stage configurations and is yet to be commercialized.

### 1.3. Product & Feedstock Properties

Petroleum feedstocks and products are complex mixtures of long-chained hydrocarbons, which can be roughly classified as paraffins (unbranched chains), iso-paraffins (branched chains), naphthenes (saturated cycles), and aromatics. The detailed characterization of VGO feedstocks, which are composed of 100,000s of individual species remains currently impossible. Petroleum cuts are characterized by Simulated Distillation (ASTM D2887), and density (spgr or  $d_{154}$ ), as well as the concentration of organic nitrogen and sulfur. Several product properties, such as RON/MON for naphtha or cold-flow properties for middle distillates are also measured – these properties are to be estimated from the macroscopic feedstock and process parameters.

The distillation curves of the products depend on the chosen cut points, which are adjusted to the requirements of each individual refinery, as well as the overlap between cuts, i.e.

efficiency of the fractionation column. The  $K_{\text{watson}}$  is a calculated feedstock descriptor, often used in petroleum refining, which combines the mean average boiling point (MeABP in °R) and specific gravity (spgr):  $K_{\text{watson}} = \text{MeABP}^{1/3} / \text{spgr}$ .

Accurate estimation of cut densities is particularly important because it is required to convert mass into volumetric flowrates, and because it is itself used as a descriptor in the models for other product properties.

## 2. Methodology

### 2.1. Bayesian Transfer Learning

The linear model for the target dataset is given below, where  $\beta_t$  is the vector of model parameters of size  $n_p$  and  $\mathbf{X}$  is the design matrix (a column filled with ones has been added to include the intercept).

$$y = \beta_t \mathbf{X} + \epsilon$$

For the transfer approach (Bouveyron 2010, Iapteff 2022, Robert 2007),  $\beta_t$  is considered to be a random variable of prior density  $\pi(\beta_t)$ . The Bayes theorem gives that the posterior of  $\beta_t$  with respect to the target observations  $\mathbf{X}_t$  and  $y_t$  is:

$$\pi(\beta_t | y_t) = \frac{\pi(\beta_t) f(y_t | \beta_t, \mathbf{X}_t)}{f(y_t | \mathbf{X}_t)}$$

An improvement of Zellner’s prior, also known as g-prior was proposed by L. Iapteff (2022), which acts on prior covariance in addition to prior distribution only:

$$\pi(\beta_t) = \mathcal{N}(\hat{\beta}_s, g \sigma_s^2 (\mathbf{X}_s^T \mathbf{X}_s)^{-1})$$

Where  $\hat{\beta}_s$  is the maximum likelihood estimator learned on only the source data. The mean of the corresponding posterior distribution is then:

$$\hat{\beta}_t = (\mathbf{X}_t^T \mathbf{X}_t + \sigma_t^2 g^{-1} \Sigma_s^{-1})^{-1} (\mathbf{X}_t^T y_t + \sigma_t^2 g^{-1} \Sigma_s^{-1} \hat{\beta}_s) \text{ with } \Sigma_s = \sigma_s^2 (\mathbf{X}_s^T \mathbf{X}_s)^{-1}$$

For large values of g the posterior mean tends to  $\hat{\beta}_s$ , for small values it tends to the prior mean ( $\hat{\beta}_t$ ). The difficulty lies in determining a suitable value for g. L. Iapteff (2022) showed that for normalized data a good estimate for the optima value of g can be defined as follows, in terms of  $\Sigma_s = \sigma_s^2 (\mathbf{X}_s^T \mathbf{X}_s)^{-1}$ :

$$g = \left( \frac{1}{n_p} \sum_{j=1}^{n_p} (\Sigma_s)_{j,j} \right)^{-1}$$

### 2.2. Feature Selection

A limited number of potential features is available due to the limitation described in 1.3. Hydrogen partial pressure and residue conversion (X370+) are retained as process descriptors. Nitrogen, Sulfur, density, and KWatson are retained as feedstock descriptors. Furthermore, the SimDis end-points (5% and 95%) were retained for both, the feedstock and naphtha cuts.

### 2.3. Data Normalization

The data is normalized according to the median for centering and interquartile range for reduction, based on the source training dataset (Iapteff 2022).

### 2.4. Process Simulation

In practice, the selected process and feedstock descriptors are always known with high confidence. The SimDis of the HCK effluent is estimated using a Continuous Lumping model and product cut SimDis is calculated using a model for fractionator efficiency (Kister 1992). The ensemble is implemented, together with the various product property correlations in a simulator developed in-house by IFPEN.

## 3. Datasets

### 3.1. Source Dataset

Follow-up data was obtained for 31 cycles from 15 industrial plants using HCK catalyst of generation n-1 in maxi-middle distillate, single stage mode, with or without recycle. A total of 3980 data points were retained for model development after expert-filtering and outlier detection (LOF), which was performed on a per-cycle basis. The entire industrial dataset was used to estimate the model parameters, a second dataset with 129 points obtained from IFPEN pilot plant tests was used for validation of the model. Performance indicators for the two datasets are shown in Table 1, the RMSE is in both cases below the acceptability criteria of  $\pm 0.005$  g/cm<sup>3</sup>.

Table 1 Indicators for source model

	<i>me</i>	<i>mae</i>	<i>rmse</i>	+/- 0.01 (%)	+/- 0.005 (%)	+/- 0.0025 (%)
<i>Train (Indus)</i>	0.0002	0.0030	0.0040	97.8	83.2	52.5
<i>Test (Pilot)</i>	0.0011	0.0034	0.0042	97.7	72.9	45.7

### 3.2. Target Dataset

The target dataset for the new catalyst contains 115 experimental points for stage 1 and 24 points for stage 2 from IFPEN pilot plant tests. Seven different feedstocks were available for testing in Stage 1, however, only two feeds were available for stage 2. The feeds were pre-treated in a separate pilot plant with HDT+HCK catalysts and tested in a single HCK reactor. This approach does not exactly reproduce the HCK 2 feeds in an actual recycle configuration but was considered sufficiently close to develop a first model. The principal weakness of this dataset is the lack in feedstock variability, whereas the feeds vary on a day-by-day basis during an industrial cycle.

#### 3.2.1. Gas-Liquid re-combination

An innovative analytical method based on recombination of gas and liquid analysis (chromatography), developed by IFPEN, was used to characterize the cuts below 175°C in terms of family (paraffins, iso-paraffins, naphthenes, and aromatics) and carbon number. Using this data, the distillation curves and densities for arbitrary naphtha cuts can be calculated. Three artificial cuts, 65-150°C, 80-150°C, and 80-175°C were thus generated, greatly increasing the number of points available for model development.

#### 3.2.2. Stage 1 – Changing the Reaction Coordinate

Residue conversion of the residue cut, with boiling points above 370°C (X370+) is used as reaction coordinate in maxi-middle distillate HCK, maxi-naphtha modem on the other hand aims to convert the middle distillate cuts. It is furthermore possible that the feed

contains significant amount of Gasoil (250-370°C), the X370+ is less meaningful in this case. The X175+ conversion is used instead. The transformation between X370+ and X370+ is essentially linear in nature.

3.2.3. Stage 2 – Changing the Model Perimeter

The model parameters for stage 1 and stage 2 are shown in Figure 1. The feedstock for stage 1 is the feed of the HDT reactor, which is known. The HDT effluent (i.e. HCK1 reactor feed) is rarely analyzed in industrial units, it is therefore not included in the model. For stage 2 pilot plant tests the HCK2 reactor feed, i.e., the 175+ cut of the blended HCK1 & HCK2 effluents is used in the model. This represents a significant deviation from the stage 1 case, as illustrated in Figure 2.

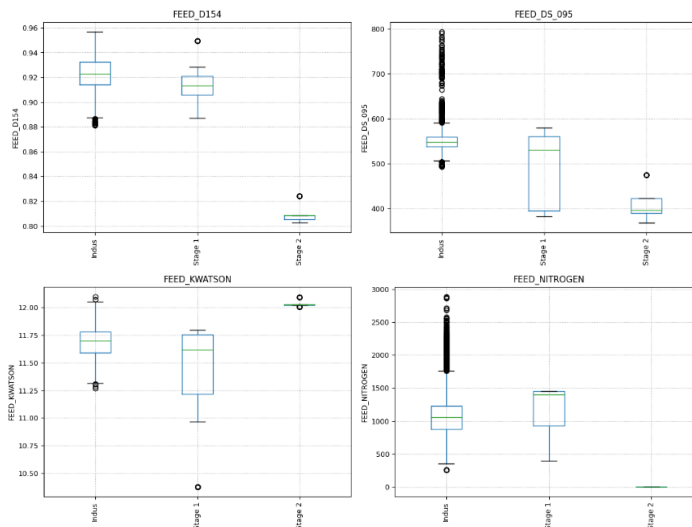

Figure 2 Feedstock characteristics in source (Indus) and target datasets for stage 1 and stage 2

4. Results & Discussion

The model indicators for Stage 1 and Stage 2 with and without transfer from the n-1 dataset are shown in Table 2 and Table 3 respectively.

Table 2 Performance indicators for Stage 1 model with and without transfer

	<i>me</i>	<i>mae</i>	<i>rmse</i>	+/- 0.01 (%)	+/- 0.005 (%)	+/- 0.0025 (%)
<i>Train without transfer</i>	-0.0008	0.0024	0.0035	97.6	86.0	68.4
<i>Test without transfer</i>	-0.0007	0.0022	0.0034	95.3	88.4	73.3
<i>Train with transfer</i>	-0.0006	0.0025	0.0037	97.9	84.5	64.4
<i>Test with transfer</i>	-0.0005	0.0025	0.0037	95.3	86.0	69.8

Table 3 Performance indicators for Stage 1 model with and without transfer

	<i>me</i>	<i>mae</i>	<i>rmse</i>	+/- 0.01 (%)	+/- 0.005 (%)	+/- 0.0025 (%)
<i>Train without transfer</i>	0.0011	0.0015	0.0019	100	100	80
<i>Test without transfer</i>	0.0007	0.0014	0.0017	100	100	90.5
<i>Train with transfer</i>	0.0011	0.0016	0.0021	100	97.3	74.7
<i>Test with transfer</i>	0.0008	0.0015	0.0019	100	100	81

For both datasets the results are well within the acceptable range of  $\pm 0.05 \text{ g/cm}^3$ . Model performance with transfer is equivalent to not using transfer learning, the values of the fitted parameter are however rather different. This suggests significant over-fitting when transfer learning is not applied.

An additional test was performed to validate the robustness of the two models. This time the pilot plant was operated in two-stage recycle mode half of the time and in single stage mode the other half. Two, previously unseen feedstocks were tested. The points were simulated using the in-house simulator (see 2.4). Figure 4 shows that the transfer modelling approach leads to more robust model. The model without transfer performs very poorly, confirming the over-fitting of the feedstock related features. The transferred model performs much better because information from the large industrial dataset is retained.

Figure 3 Parity graph for additional experimental points

## 5. Conclusion

Using transfer learning on the linear model, with an improved prior including the prior mean and covariance, was applied successfully on real-world datasets. Model robustness was shown to be improved when the target dataset is limited.

## Abstract

The increasing importance of flexible and large-scale green hydrogen production necessitates the accompanying modeling and simulation of these processes to optimize plant flexibility. State-of-the-art monolithic modeling approaches do not address the flexibility and interoperability expected from modular plants, as shown by (Mädler *et al.*, 2022). Therefore, in this work, a new approach to the modeling of modular electrolyzers is proposed. Beginning with a steady-state equation system for the individual Process Equipment Assemblies (PEAs) it is later expanded to a detailed dynamic model. Instead of a single simulation flowsheet for the entire plant, this will result in a set of Functional Mockup Unit ready PEA models which can be combined depending on the plant assembly via co-simulation. This enables the user to generate models for various configurations and test the individual PEAs as well as the composite plant more efficiently. As a first step, a simple case study is presented where two steady state sub-models are developed and connected via co-simulation.

**Keywords:** Hydrogen Electrolysis, Modular plants, Simulation

## 1. Introduction

Alkaline water electrolysis (AEL) technology has been present for a long time. Most of the work related to the modeling of these electrolysis plants considered them to be monolithic and focused on the detailed modeling of the electrolyzer or on the entire plant, including the Balance of Plant (BoP). Ulleberg, (2003) presented a detailed parametric model that acts as a baseline for most of the works that followed. The closest work in alkaline electrolysis towards a modular design is done by Brée *et al.*, (2020), where the author defines the electrolysis model as a collection of individual half-cells which could be coupled to form the entire electrolyzer. But this doesn't account for the BoP.

As per VDI 2776 a modular plant is defined as an aggregation of individual process engineering assemblies (PEAs) that offers high flexibility and interoperability within the modules. Oppelt *et al.*, (2015) is one of the earlier works that point towards the use of simulation in the life cycle of a modular plant and describes the future scenarios involving model reuse and co-simulation. A design basis for such plants and their realization on a mini plant, pilot scale, and production scale is discussed by Eilermann *et al.*, (2018). This is clarified by Mädler, Viedt, *et al.*, (2022) in detail, explaining the requirements needed for a digital twin and elaborates the role of modeling and simulation in developing digital twins.

With the eventual goal of developing a digital twin, we try to contextualize this in the case of an alkaline water electrolysis plant, which could be modeled and simulated, taking into account the modular nature of the plant and propose a workflow that could be used for the modeling of different modular electrolysis assemblies. In the first section, the basic principles and functioning of the alkaline water electrolyzers is introduced along with an overview of the modular concept and how this is made part of the simulation process. In the next section a case study and its results are presented where the proposed workflow is applied to a couple of submodels. The paper ends with a conclusion pointing towards the next steps in the workflow.

## 2. Theory

Large scale and sustainable production of green hydrogen is gaining more and more importance and water electrolysis is one of the major technologies to achieve this goal. In project eModule of the hydrogen lead-project H<sub>2</sub>Giga, the focus is on developing modularized electrolysis plants that could be readily assembled and operated to achieve a high degree of flexibility and scaling up. Among the existing technologies, alkaline water electrolysis is the most mature and has been widely used commercially (Brée *et al.*, 2020). Water, being a stable compound, requires a lot of energy for its splitting. With electrolysis, this requires a high potential. In the case of alkaline water electrolysis, this is accomplished with the aid of an alkaline compound. This lowers the potential required for the breakup of water into hydronium and hydroxide ions. In the presence of an electric current hydrogen is produced at the cathode and oxygen is collected from the anode. Typically 20-40% KOH or NaOH solutions are used for electrolysis, and this is depicted in the below figure along with the reactions that occur during electrolysis (Shiva Kumar & Himabindu, 2019).

Figure 1: Alkaline Electrolysis (Shiva Kumar & Himabindu, 2019)

For increased flexibility and faster planning, modular approach to design and construction of electrolyzer-plants is assumed (Radatz *et al.*, 2019). With the modular approach, there will be a set of submodels that would have the functional properties corresponding to the individual and independent PEAs. A PEA or process engineering assembly consist of

process units that are largely independent, self-sufficient, and can perform a particular process step. It could include single or multiple functional equipment assemblies. These sub-models are brought together in a co-simulation framework where the various sub-models could be coupled together based on the required configuration. The individual PEAs could interact and communicate with each other exchanging information. The assembled model could later be simulated to obtain the overall simulation model of the plant. An overall process flow diagram for the alkaline electrolyzer along with the individual PEAs is shown in Figure 2.

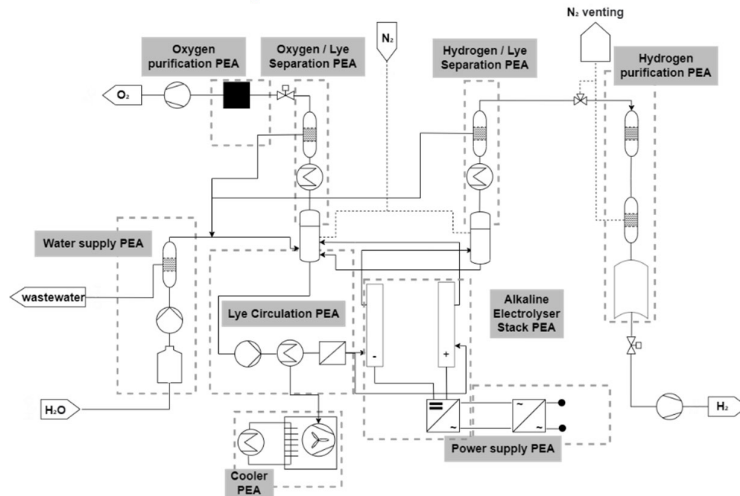

Figure 2: Process flow diagram for the AEL with individual PEAs, Courtesy of the VDMA Power-to-X for Applications platform (Beisswenger & Erdmann, 2022)

Compared to a continuous plant, where these are designated as individual units, here the distinction is made based on the function served. The PEAs present are:

1. Water supply – The function of this PEA is to supply water for the electrolyzer that meets the required specifications.
2. Lye circulation – This PEA assembly mixes the individual lye streams and makes up water, pressurizes the lye stream to the set pressure, heats it to the required temperature specification, and distributes the lye to the Electrolyzer.
3. AEL stack (Electrolyzer) – The water electrolysis occurs here generating hydrogen at the cathode and oxygen at the anode.
4. Cooler – Excess heat from the electrolyzer is removed
5. Power supply – Rectifier arrangement that supplies the necessary power for the electrolyzer
6. Hydrogen Separation - Separates the hydrogen from the gas-liquid lye stream coming from the electrolyzer PEA, cools the outgoing gas to room temperature, and eliminates any fine droplets present in the gas stream.
7. Oxygen separation – Similar to the hydrogen separator, oxygen is separated.
8. Hydrogen purification – removes any oxygen in the stream dries the stream and compress it to the required specification
9. Oxygen purification – Since oxygen is not considered further, this is sent to a combustion chamber and disposed of

Following the iterative modeling process described in Mädler *et al.*, (2021), the first step involves the creation of a simple model. Such a process provides a baseline model for comparison, easier debugging, and testing and, results in models with different levels of complexity. After gathering the necessary preliminary information like the flow diagrams, functional process description, etc. a sub model for each PEA is developed. Since the eModule project consists of several types of electrolyzer modules, individual PEAs are developed in such a way that they can be reused and integrated across multiple electrolyzer technologies with minimal modifications. To do this, each component is developed as an object with its characteristics that can be replicated and reused. They are converted into Functional Mock-up Units (FMU), assembled, and simulated. These steady state models would be used to check the basic performance of the electrolyzer assembly, and it also serve as a baseline with which the results of the more complicated configurations could be compared. In the final step, various tests are performed for the quality of the model (Viedt *et al.*, 2022).

In the second stage, the simple model is extended to include control strategies. Necessary modifications in the individual PEAs as well as the necessary control loops are made during this step. This stage allows for the modular automation of the PEAs. Again, the PEAs are assembled, simulated, and tested. In the final step, the equation system is expanded. If needed, additional equations and correlations for various parameters are supplemented including those for physical properties, thus resulting in a final detailed model that closely resemble a physical plant. Again, the control loops are tested, and the co-simulation is made. The approach is illustrated in the following diagram.

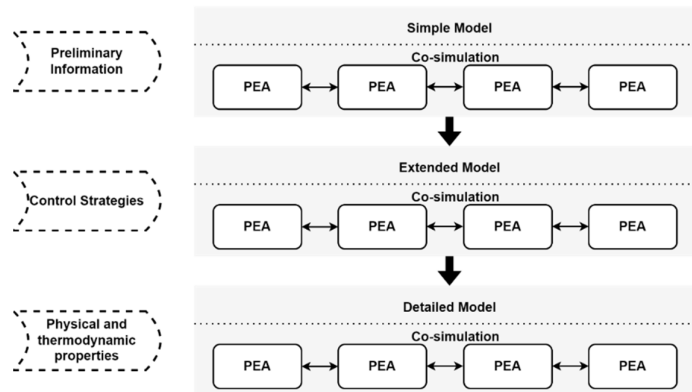

Figure 3: Workflow for Model Development

### 3. Case study

This is demonstrated by developing a co-simulation model for the PEA of a simple AEL sub-model and combining this with a lye separation sub model. In general, the starting point is a simple steady-state model for each individual PEA. In this phase the goal of the modeling process is to develop a minimal model that could be connected with other PEAs while outputting verified results with a certain degree of accuracy. For developing the initial model for AEL, the model equations presented by Ulleberg (2003) are used. This is a highly parametric model that has been experimentally validated. The main assumptions for this simple steady state model are:

- a. KOH is readily ionized, and water is replenished sufficiently to ignore the effect of OH- accumulation.
- b. All gases are in ideal condition and hydrogen is freely transported across the membrane (there is no resistance due to bubble formation, diffusion, etc.).
- c. A constant Faraday efficiency of 0.86 is assumed and excess heat is transferred to the cooler

For the cooler, the water inlet temperature is assumed constant at 20°C and exits at 30°C and the cooler is considered as an ideal heat exchanger with no pressure drop across it. Also, the physical properties are considered constant within each PEA. The individual PEAs were developed and after verifying them, they were exported as FMUs and simulated. Further details and the simulation models are provided as a GitHub repository (Rajan Gopa, 2022). Thus, totally independent submodels were successfully combined. Input conditions from Sánchez *et al.*, (2020) were used to validate results. For the simulation, 896 kg/h lye flow, Temperature, and pressure at 75 ° C and 7 bar and an electric power supply of 10 kW were used. The results from the co-simulation are:

Results	eModule model	Reference
Oxygen flow - cathode, kg/h	1.45	1.37
Hydrogen flow - anode, kg/h	0.18 (2.05 Nm <sup>3</sup> /h)	0.17
Temperature increase of Lye, °C	1.6	2.2
Current density, A/cm <sup>2</sup>	0.4721	0.42
Heat to cooler, W	1500	2392.8
Cooling water, kg/h	-	130

Table 1: Results of the simple model simulation and comparison to Sánchez *et al.* (2020)

The simple model adhered well to the steady state results from Sánchez *et al.*, (2020). The oxygen and hydrogen production are similar and the increase in value could be attributed to the higher current density for the co-simulation model. Only the excess heat that goes to the cooler is comparatively lower than that in the cited work. This could be due to the use of constant values for the physical properties and the underlying assumptions. This is also evident from the difference in the lye temperature increase. Cooling water consumption for this operating point was also obtained but this could not be validated with the referenced work. But the obtained value does correspond to a heat duty in the range of 1500 W. As mentioned before, the overall goal of the simple model is not to produce exact results but to provide a valid and reliable baseline that could be compared to, which the above results justify.

#### 4. Conclusion

In this work, modular workflow to the modeling and simulation of electrolyzers is discussed, and a simple model is implemented for two PEAs of the alkaline electrolyzer plant. These two sub-models are then exported as FMUs and simulated. The results from the co-simulation are compared to a similar work, thus validating this approach. Through this use case the viability of this method is demonstrated. Following this, the other PEAs will be modeled using the same approach to later simulate the entire electrolyzer plant. The deviation in the excess heat could either be due to the simplicity of the model or the

absence of any physical property data. This will be incorporated in the detailed models including their individual control strategies so that the final plant configuration could be selected from a combination of these PEAs and various test scenarios could be validated. Different scenarios involving the numbering up and interoperability of different electrolyzers from multiple stakeholders will be tested. To validate the proposed approach for the modular simulation models, the results from one of the co-simulation models will be compared to those obtained from a demonstrator plant.

## Abstract

To limit the global CO<sub>2</sub> emissions, installation of renewables is expected to increase significantly. This would require storage of renewable energy, possibly using an energy carrier such as hydrogen, methane, ammonia, etc. Reversible Solid Oxide Cell (rSOC) is a high temperature modern technology that can be operated in fuel cell or electrolysis mode. The Solid Oxide Electrolysis (SOEC) can be used to convert renewable electricity into hydrogen or carbon-based fuels (Power-to-Fuel). Conversely, Solid Oxide Fuel Cell (SOFC) has high overall efficiency for generating electricity from hydrocarbon fuels (Fuel-to-Power). The SOFC/SOEC technology is underdevelopment and being tested at several hundred kW scales. Generally, there are two different systems, SOFC and its balance of plant (BOP) system; SOE and methanation with their BOP system. The main challenge of rSOC system is to make both systems (SOFC and SOEC) highly integrated. Hence, it must utilize the maximum heat from heat sources and supply maximum heat to heat sinks. In this study, SOFC with oxy-combustion system and its reverse mode (SOEC) with methanation system have been optimized by minimizing the energy requirement and number of heat exchangers for individual system. The heat exchanger network synthesis problem is mixed integer linear programming problem, and it has been implemented in AMPL. For each heat exchanger (i.e., pair of streams), we have computed the heat exchanger area. This study evaluates the operating-flexibility of the shared HEN for rSOC-reformer/methanation system. The results show that heat exchangers can be shared between SOFC and SOEC modes, by manipulating the stream connections.

## 1. Introduction

Today, the world's global primary energy supply is still heavily dependent on fossil fuels (up to 84.3% in 2019 [1]). It is well known that burning fossil fuels heavily contributes to climate change through the release of green-house gases (GHG) [2]. Furthermore, fossil fuels have a big impact on human health [3]. With the critical situation regarding climate change, there is a need to decarbonize economical activities with mitigation that occurs through different alternatives.

The scientific community is exploring several viable alternatives to replace the use of fossil fuels with renewables. However, variability, intermittency and storage are the main challenges for the renewable energy usage. Therefore, significant efforts have been invested on the development of efficient energy conversion technologies. Solid oxide fuel cell (SOFC) has attracted huge scientific attentions in the recent years. It is a modern and efficient power production technology that can reduce user's dependency on electricity-

grid. SOFC system can generate electricity using liquid [4] or gaseous fuels [5]. It can easily be adjusted for different industry power plant scales. Moreover, SOFC operates at high temperature (600 °C), and it cogenerates high-quality heat or steam, which can be used as a heat source within the system. As maximum fuel utilization for SOFC is around 85%, a burner is required for the combustion of unconverted fuels. The burner provides additional heat to the SOFC system, at the same time, it generates more CO<sub>2</sub>.

In order to meet “net zero” emission target for greenhouse gases in 2050, it is essential to introduce Carbon Capture and Storage (CCS) technology that can retrieve most of the produced CO<sub>2</sub> from emission intensive activities and store it permanently in nature (e.g., underground), leading to an almost carbon neutral activity. The stored CO<sub>2</sub> can also be used in methanation process, to convert H<sub>2</sub> into methane. In SOFC system, it is possible to perform oxy-combustion, by using stoichiometric amount of O<sub>2</sub> inside a catalytic burner. At the outlet of burner, CO<sub>2</sub> and H<sub>2</sub>O at high temperature are the only two products. After water condensation, CO<sub>2</sub> can be separated from the mixture automatically.

A reversible SOFC system or solid oxide electrolyzer cell (SOEC) has attracted huge attention for H<sub>2</sub> and fuel production. H<sub>2</sub> and O<sub>2</sub> are produced on the cathodic and anodic side of SOEC, respectively. H<sub>2</sub> can be stored and used in SOFC to produce electricity, whereas O<sub>2</sub> can also be stored and used in catalytic burner. SOEC with methanation is an alternative way of methane production, where excess renewable electricity is converted into methane. SOEC can be considered as a low-cost alternative to address the gap between hydrocarbon fuel/hydrogen supply and demand [6]. The reversibility of the solid oxide cells (rSOC) manages the variability of electrical grids by transforming and storing power through H<sub>2</sub>/methane when there is a surplus of electrical power or by generating electrical power through H<sub>2</sub>/methane when there is demand. A general system layout has been provided in

Figure 1.

For economic reasons, both systems shall share most of the components, and they should easily be switched. The heat exchange network (HEN) synthesis is very challenging for integrated rSOC system, due to two different operation mode of the system [7]. State of the art of HEN synthesis methodologies have been published over the past few decades, and sequential approach is commonly used [8][9]. In this study, a shared HEN has been designed and optimized for 10 kW SOFC system and 30 kW SOEC system.

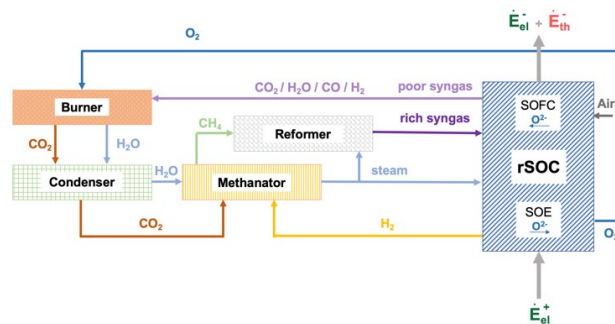

Figure 1. Global rSOC system layout

## 2. System and methodology description

### 2.1 SOFC with oxy-combustion

The fuel cell mode is operated when electricity demand cannot be fulfilled by the solar panels. In the fuel cell nominal mode, a mixture of methane and steam is fed into a reformer to convert part of it into syngas ( $H_2 + CO$ ). The resulting flow is then fed into the anode side of the fuel cell, where rest of the reforming takes place.  $H_2$  and  $CO$  are consumed inside the fuel cell, and steam and  $CO_2$  rich syngas comes out of fuel cell. On the cathode side, air is fed to supply oxygen, and oxygen depleted air is released into environment. The unconverted  $H_2$  and  $CO$  from fuel cell are combusted using air or pure oxygen. The oxygen combustion ensures absence of  $N_2$  in the exhaust gases, and recovery of product  $CO_2$  that can be used in SOEC/methanation,  $O_2$  has been assumed to be purchased from the market, but this configuration would allow to store and use oxygen produced from electrolyzer mode.

## 2.2 SOEC with methanation

Electrolyzer mode is operated when excess electricity has to be stored as methane. The excess electricity is fed into the electrolyzer, as well as steam on the cathode side. The cathode side outlet contains  $H_2$  and excess/unreacted steam. On the anode side, an air sweep is typically used to carry product  $O_2$ . Alternately,  $O_2$  can be used as sweep, and product  $O_2$  can be stored for further usage.  $H_2$  and  $CO_2$  are consumed inside the methanator to produce methane.

## 2.3 Heat exchanger network synthesis

The goal of the heat exchanger network synthesis formulation is to define process streams, objective function, heat balance equations, inequalities and potential constraints which will allow to obtain optimal amounts of hot and cold utility, the pairs of process streams which will exchange heat. Here, only essential details are presented, and detailed methodologies can be found in the literature [9].

- Overall stream heat balance

$$(T_i^i - T_i^o) \cdot Cp_i = \sum_{k \in ST} \sum_{j \in CS} Q_{ijk} + Q_{CUI} \quad i \in HS; \quad (T_j^o - T_j^i) \cdot Cp_j = \sum_{k \in ST} \sum_{j \in HS} Q_{ijk} + Q_{HUj} \quad j \in CS \quad (1)$$

- No splitting (avoid splitting of hot stream  $i$  and cold stream  $j$ )

$$\sum_{i \in HS} z_{ijk} \leq 1 \quad j \in CS, k \in ST; \quad \sum_{j \in CS} z_{ijk} \leq 1 \quad i \in HS, k \in ST \quad (2)$$

- Forbidden matches (avoid heat exchange between hot stream  $i$  and cold stream  $j$ )

$$z_{ijk} \leq 0 \quad k \in ST; \quad z_{CUI} \leq 0; \quad z_{HUj} \leq 0 \quad (3)$$

- Required matches (in the case of a required match, there are two options: data of heat exchange is removed from the streams input data, following constraints are activated)

$$\sum_{k \in ST} Q_{ijk} - Q_{min,ij} \geq 0; \quad Q_{CUI} - Q_{min,CUI} \geq 0; \quad Q_{HUj} - Q_{min,HUj} \geq 0 \quad (4)$$

- Restricted matches (the match is allowed but, in the case, where it exist the heat exchanged is subject to an upper bound)

$$\sum_{k \in ST} Q_{ijk} - Q_{max,ij} \leq 0; \quad Q_{CUI} - Q_{max,CUI} \leq 0; \quad Q_{HUj} - Q_{max,HUj} \leq 0 \quad (5)$$

- Objective functions: There are different options for the objective function. This study uses minimum heat requirement and minimum number of heat exchangers as objective functions.

$$\min \left( \sum_{i \in HS} Q_{CUI} + \sum_{i \in HS} Q_{HUj} \right); \quad \min \left( \sum_{i \in HS} \sum_{j \in CS} \sum_{k \in ST} z_{ijk} + \sum_{i \in HS} z_{CUI} + \sum_{j \in CS} z_{HUj} \right) \quad (6)$$

The HEN synthesis problem is mixed integer linear programming (MILP) problem, and it has been implemented in AMPL and solved by CPLEX solver. Cooling water (5 to 15 °C) is used as cold utility. Hot air is used as hot utility (800 to 1000 °C).

#### 2.4 Heat exchangers area estimation

In the first step, log-mean temperature difference is calculated. This study uses following values of overall heat transfer coefficients ( $U$ ,  $W/m^2/K$ ): 50 (air to air), 80 (gas to gas) and 160 (gas to water). The heat exchanger areas are computed using heat balance equation.

### 3. An integrated heat exchanger system design

Typical heat exchanger network of SOFC system has been studied in the previous literature [7]. SOFC system layout with HEN is shown in Figure 2. There are three heaters (H1, H2, H3) and four coolers (C1, C3, C4, C5). In order to improve the practical feasibility of HEN, HEN synthesis has been studied with some constraints. The evaporation of water occurs with direct injection of fuel in H1, therefore, the fuel and water streams are combined together, as shown in Figure 2. In practice, progressive water injection reduces heat requirement at constant temperature while providing a smooth temperature enthalpy profile. This aids in system heat integration. Moreover, in the previous studies, hot air has been used/split, to heat exchange with several streams. In reality, this design brings plant layout complexity, and it will also bring challenges in heat exchanger design, to avoid the potential leakage and explosion. Therefore, in this study, cold air heater (H3) has been restricted to perform heat exchange with hot air cooler (C3).

For SOFC system, the objective functions values for minimum energy requirement and number of heat exchangers are 2.01 kW (cold utility) and six, respectively. As expected, the exhaust gases from burner are used as the only heating source. The outlet stream from burner has been used to heat exchange with the stream before stack (C1-H2), and then it provides heat to the pre-reformer, finally, it passes through H1, to provide the heat for water heating, evaporation and superheating. The heat exchangers design specifications have been presented in Table 1 and Figure 4. There are mainly five heat exchangers: HEX 1, 2, 3, 4 and 5. HEX3 has the largest heat exchange area, where air flow rate is adjusted to balance the heat within the stack (exothermic reaction).

In SOEC system with methanator, the burner will be bypassed, as it is not necessary to burn part of cathode-off gas to provide heat to the system, and it decreases the energy efficiency.  $H_2$  produced from cathode side is pressurized and injected in methanator. Moreover, unlike SOFC exothermic operation mode, SOEC has an endothermic operating mode normally, therefore, additional electrical heating is required. For SOEC system, the objective functions values for minimum energy requirement and number of heat exchangers are 2.97 kW (hot and cold utilities) and six, respectively.

As shown in Figure 3, there are two heaters (H1', H3') and five coolers (C1', C2', C3', C4', C5'). Water flows through methanator as the first heat exchange step. Here, 10% heat loss has been assumed in methanator according to the experiment data. In the following step, steam exchanges heat with SOEC cathode off-gas (HEX6). The cathode off-gas is pressurized to 15 bar, and the temperature increases to 890 °C (maximum material resistance temperature). Finally, steam is heated up to 754 °C inside HEX7. Electrical heaters are used, to heat up anode inlet air from 760 to 800 °C, and steam from 754 to 800 °C. As shown in Table 1 and Figure 4, there are mainly five heat exchangers. Similar as SOFC system, the biggest heat exchanger is air to air heat exchanger (9.42 m<sup>2</sup>).

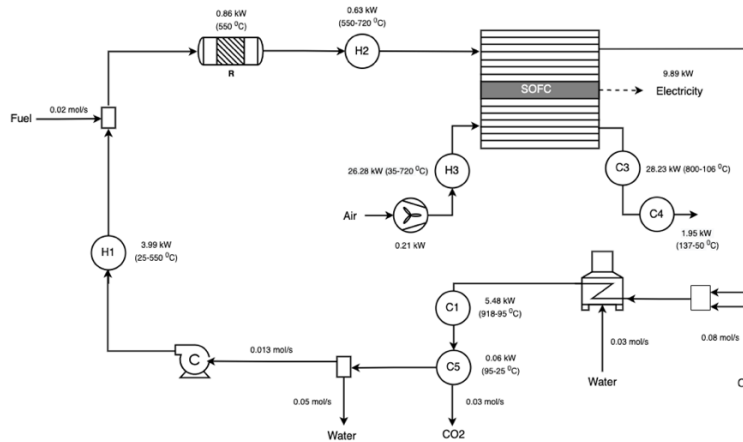

Figure 2. SOFC system with HEN design

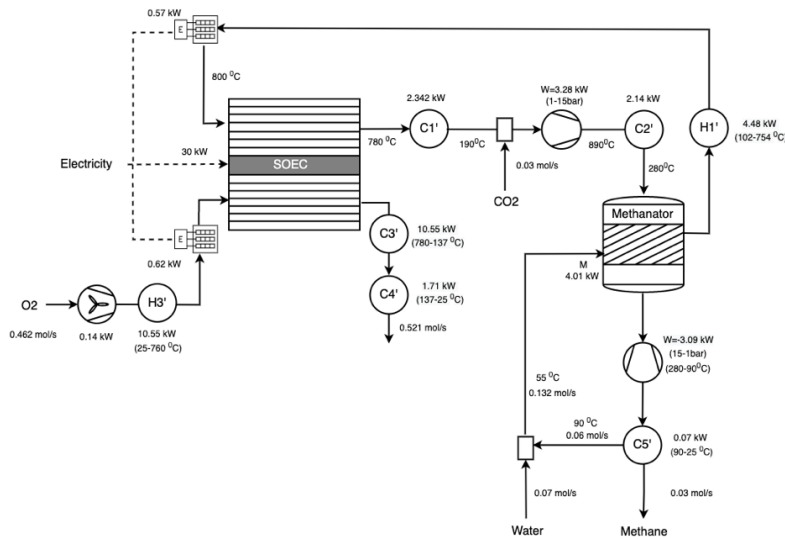

Figure 3. SOEC system with HEN design

By comparing duty and HEX area of two systems, HEX1, HEX2, HEX3, HEX4 and HEX5 from SOFC system can be reused as HEX6, HEX7, HEX9, HEX8 and HEX10 in SOEC system. As a conclusion, five shared heat exchangers are possible in rSOC system.

#### 4. Conclusion

This study presents a shared HEN design for rSOC system, comprising five heat exchangers, reformer and methanator. After studying heat integration, five heat exchangers can be shared. Air to air heat exchanger has largest heat exchanger area. The heat exchangers can be reused by adjusting pipelines connections. Moreover, methanator in SOEC system, has also been considered as the heat exchanger, this can be achieved by using adiabatic methanator, it benefits in waste heat usage and temperature maintainence. Additional electricity is required in electrical heaters and other components. Performing multi-period optimization for two systems simultaneously will be done in future work.

# Multi-objective optimisation of the algae *Arthrospira platensis* under uncertainty: a Pareto ellipsoids approach

Wannes Mores, Satyajeet S. Bhonsale, Filip Logist, Jan F.M. Van Impe\*

*BioTeC+*, KU Leuven, Gebroeders De Smetstraat 1, Gent 9000, Belgium

\* [jan.vanimpe@kuleuven.be](mailto:jan.vanimpe@kuleuven.be)

## Abstract

Multi-objective optimisation allows a decision maker to evaluate trade-offs between objectives by supplying a set of optimal solutions, for example to find the balance between process performance and sustainability in process design. Accurate prediction of these objectives and, more importantly, safe operating conditions are needed. Thus, we need to account for uncertainty within the model. The Pareto ellipsoids approach ensures efficient use of computation while visualising the effect of parametric uncertainty. The novel Pareto ellipsoids-based algorithm is applied to the algae *Arthrospira platensis* and determines optimal light conditions for both biomass and product yield. Uncertain parameters are selected to investigate propagation of uncertainty from both the light intensity model and the Droop model. Finally, the obtained Pareto ellipsoids' accuracy is verified using a Monte Carlo approach.

**Keywords:** Multi-objective optimisation, Parametric uncertainty, Droop model

## 1. Introduction

Multi-objective dynamic optimisation is an important tool for (bio-)process design and operation (Logist et al., 2010). It allows a decision maker (DM) to evaluate different criteria, which are often of a conflicting nature. A typical example of this is the trade-off between an efficient, low-cost process and a high throughput process. To evaluate this trade-off, model-based multi-objective optimisation is often used. Here, a set of optimal solutions is generated, known as the Pareto front. With this set, a DM can decide where the point of operation lies. Pareto fronts can be generated with vectorisation (Bhaskar et al., 2000) and scalarisation approaches (Das and Dennis, 1998).

Model-based optimisation is a useful tool if the model represents the real process well. However, uncertainty on model parameters propagate through the model and influence the performance of the process. This not only leads to sub-optimal performance but can also cause critical errors in the process. Incorporating the effect of parametric uncertainty is important for safe and effective process design and operation (Vallerio et al., 2015).

Incorporating uncertainty into the optimisation is done in two ways. Robust optimisation accounts for the worst-case scenario and is a very conservative approach. Stochastic optimisation uses information on the distribution of the uncertainty and defines confidence on model outputs. Incorporating uncertainty into stochastic optimisation can be done in different ways, an overview is given in Nimmegeers et al. (2016).

In this work, stochastic methods are used to incorporate uncertainty. These methods lead to a significant increase in computational expense, it is therefore important to use

computationally efficient stochastic approaches and generate only significant Pareto points. Hashem et al. (2017) developed the D&C algorithm that finds relevant regions of the Pareto front with user-specified filter settings. In this work, the idea behind D&C is expanded by using information obtained from stochastic optimisation approaches. The uncertainty on model parameters will influence the performance regarding the objectives. In the case that the uncertainty on the objective is Gaussian, this can be shown by drawing ellipsoids around the Pareto points. These Pareto ellipsoids are then used to determine the significance of a Pareto point and aid in the spread of points on the Pareto front.

This novel Pareto ellipsoids-based optimisation algorithm is applied to the production of C-Phycocyanin through *Arthrospira platensis*. C-Phycocyanin is commonly used as a natural colorant in the food and cosmetic industry, reducing the need for synthetic colorants with possible toxic effects (Martelli et al., 2014). The use of *Arthrospira platensis* for production is promising as it yields high C-Phycocyanin concentration in cells (Xie et al., 2015). Del Rio Chanona et al. (2015) developed advanced dynamic models for this production process using experimental data from both batch and fed-batch processes. For this process, it was shown that light intensity plays a big role in C-Phycocyanin production. Higher light intensities promote biomass production but inhibit and even decrease intracellular C-Phycocyanin content. The substrate concentration promotes biomass growth but also suppresses C-Phycocyanin accumulation. In this work, a Droop model is used to determine optimal light conditions and substrate level for the trade-off between biomass production and C-Phycocyanin yield.

## 2. Methodology

In this section, the methodology for multi-objective optimisation under uncertainty is presented. The concept of Pareto ellipsoids is introduced, which is used to define a novel significance criterion in a Pareto ellipsoids-based algorithm. These methods are applied to the Droop model for *Arthrospira platensis*, described in the final part of this section.

### 2.1. Multi-objective dynamic optimisation

A multi-objective optimisation problem can generally be formulated as:

$$\min \mathbf{J} \quad (1)$$

subject to

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), \mathbf{p}, t) \quad (2)$$

$$\mathbf{c}(\mathbf{x}(t), \mathbf{u}(t), \mathbf{p}, t) \leq 0 \quad (3)$$

Here,  $\mathbf{J}$  is the vector of objective functions to be evaluated,  $\mathbf{x}$  is the state vector,  $\mathbf{f}$  is the vector of state equations and  $\mathbf{c}$  is the constraint vector. The vector  $\mathbf{p}$  contains all the model parameters, including the uncertain parameters. It is assumed that the distribution is known for the uncertain parameters.

The propagation of this uncertainty is quantified using the sigma points method (Julier et al., 1996). This method relies on selecting sample points within the uncertainty distribution, which are propagated to the outputs of the model and combined to obtain the expected value  $E$  and variance  $V$  of model outputs. Other methodologies for uncertainty propagation exist, an overview is presented in Nimmegeers et al. (2016). The solutions of the multi-objective optimisation problem are obtained through the nominal boundary intersection (NBI) method, presented in Das and Dennis (1998).

### 2.2. Pareto ellipsoids

The uncertainty on the objective functions is used to define the concept of Pareto ellipsoids. If normally distributed uncertainty on the objective functions is assumed, the

uncertainty can be visualised using an ellipsoid. The center of the ellipsoid is the expected value  $E$ , and the radii can be defined using the covariance matrix  $\Sigma$  as follows:

$$(x - E[J])^T \Sigma_J (x - E[J]) = c_\alpha^2 \quad (4)$$

Where  $c_\alpha^2$  is the upper  $\alpha$ th percentile of a  $\chi^2$  distribution. The value of  $\alpha$  determines the level of confidence that the objective value is inside the ellipsoid.

### 2.3. Pareto ellipsoids significance criterion

Regions of the Pareto front with high uncertainty levels on objective performance are usually undesirable. A novel significance criterion is used to include this effect in the *a priori* smart filter. The Pareto ellipsoids criterion can be defined as follows:

A Pareto point is considered insignificant if the Pareto point falls within the Pareto ellipsoid of a neighboring Pareto point or if one of its neighboring Pareto points falls within the Pareto ellipsoid of the Pareto point.

For two Pareto points  $P1$  and  $P2$ , this can be checked by evaluating 2 inequalities:

$$(E[J_{P1}] - E[J_{P2}])^T \Sigma_J (E[J_{P1}] - E[J_{P2}]) \leq c_\alpha^2 \quad (5)$$

$$(E[J_{P2}] - E[J_{P1}])^T \Sigma_J (E[J_{P2}] - E[J_{P1}]) \leq c_\alpha^2 \quad (6)$$

### 2.4. Pareto ellipsoids-based algorithm

The underlying concept of the D&C algorithm with the information criterion from Hashem et al. (2017) can be extended with this novel criterion to reduce points in regions of high uncertainty. The information criterion settings are specified with  $\sigma_{low}^2, \sigma_{high}^2$ . The ellipsoid criterion is added when evaluating the information criterion. This requires the expected values and covariances of the objective functions, in this work obtained using the sigma points method. The ellipsoid criterion setting is specified using  $\alpha$ .

---

#### Algorithm 1 Pareto ellipsoid-based algorithm

---

**Input:** Specify  $\alpha, \sigma_{low}^2, \sigma_{high}^2$   
**Output:** Pareto (ellipsoid) set with adaptive resolution  $S$ .  
**Step 1:** Initialise solution set  $S = \{\}$ .  
**Step 2:** Construct weight cell  $C_{in}$  corresponding with the boundaries of the Pareto set  
**Step 3:** Initialise the weight cell  $C_w$ :  $C_w = C_{in}$   
**Step 4:** Start the recursive function for weight distribution  
**for**  $i = 1: n_w$  ( $n_w =$  number of entries in  $C_w$ )  
    **if**  $C_w \in \text{CHIM}$  **do**  
        Solve an NBI subproblem using  $C_w[i]$  to obtain Pareto point  $P_i$   
        Compute  $E[J_{P_i}]$  and  $V[J_{P_i}]$  (using sigma points)  
    **end for**  
**Step 5:** Construct a Pareto cell  $C_p = [P_1, \dots, P_{n_{Pareto}}]$ , with  $n_{Pareto} \leq n_w$   
**If** information criterion and Pareto ellipsoid criterion not activated **do**  
    Add  $C_p$  to  $S$   
    Divide: Construct daughter cells  $C_{d1}, \dots, C_{dn_w}$   
    Repeat **Step 4** with  $C_w = C_d \in \{C_{d1}, \dots, C_{dn_w}\}$   
**else Conquer:** Exit recursive call and stop exploring current segment.  
**Step 6:** Produce  $S$  when all recursive calls are ended  
**End**

---

### 2.5. Model description

The model used for optimisation is the Droop model for *Arthrospira platensis*. Droop models use intracellular quota to represent the nutrient storage inside the cell. In total, the model considers 4 states: biomass concentration  $c_X$ , nitrogen concentration  $c_N$ , intracellular normalised nitrogen quota  $c_q$ , and intracellular Phycocyanin quota  $c_{qc}$ . The model also incorporates the Aiba model, where illumination affects the phycocyanin production constant and specific growth rate. For brevity, the model equations are not included, a detailed description can be found in del Rio Chanona et al. (2015).

The light intensity throughout the reactor is determined using the Lambert-Beer law.

$$I(z) = I_0[\exp(-(\tau \cdot X + K_a) \cdot z) + \exp(-(\tau \cdot X + K_a) \cdot (L - z))] \quad (7)$$

Where  $I_0$  is the incident light intensity,  $\tau$  the cell absorption coefficient,  $K_a$  the bubble reflection coefficient, and  $z$  the distance from the light source. In this study, the photobioreactor is lit from both sides and has width  $L$ .

The light intensity plays a big role in the C-Phycocyanin production process as it promotes biomass growth and inhibits C-Phycocyanin production. To evaluate optimal lighting conditions for the process, two objectives are considered. These are maximisation of biomass growth ( $J_1$ ) and maximisation of C-Phycocyanin yield ( $J_2$ ). The control input for the optimisation is the incident light intensity  $I_0$ , and contributes to the contradicting aspect of the two objective functions as described previously. As optimisation is usually done by minimisation, the objective functions are negative resulting in maximisation.

$$J_1 = -c_{X,f} \quad (8)$$

$$J_2 = -\frac{c_{qcX,f}}{c_{N,0}} \quad (9)$$

Constraints are imposed on the model, which include minimal product return, a lower and upper bound on initial substrate concentration, and the initial state of  $c_X$ . The constraints are found in equations (9-11) The two parameters considered uncertain are chosen from both the Droop model equations and the nested Aiba model. These are the cell absorption coefficient  $\tau$  and the cell specific decay rate  $u_d$ . Both parameters are assumed to have a normally distributed uncertainty with a standard deviation of 10% of their nominal value.

$$c_X(0) = 0.1 \frac{g}{L} \quad (10)$$

$$c_N(0) \geq 1000 \frac{L}{mg} \quad (11)$$

$$c_{qcX}(f) \geq 100 \frac{mg}{L} \quad (12)$$

## 3. Results

The pareto ellipsoids-based algorithm is implemented in the POMODORO toolbox (Bhonsale et al., 2018), available at <https://cit.kuleuven.be/biotec/software/pomodoro>. It is a python-based toolkit for solving multi-objective optimal control problems. For optimisation, an  $\alpha$  of 70% is chosen, which means that the ellipsoids should have a 70% confidence that the true objective value lies within its boundaries. The settings for the information criterion  $\sigma_{low}^2, \sigma_{high}^2$  are chosen to be 0.001.

### 3.1. Pareto ellipsoids set

The multi-objective optimisation study results in a set of Pareto ellipsoids shown in Figure 1. Looking at the control profiles for the anchor points and a chosen trade-off solution, an early spike in light intensity is beneficial for initial biomass growth. Retaining the high light intensity results in efficient biomass production and limits the C-Phycocyanin production, which is seen in the maximised biomass control profile. The spike in control

profile is later for the maximised yield, which is explained through the fact that light intensity decreases the intracellular C-Phycocyanin content, and a later spike means less loss of product. The starting nitrate concentration is also lower for maximised yield. High nitrate concentrations suppress intracellular phycocyanin accumulation but promote biomass growth. The trade-off solution shows a mix of the two anchor points.

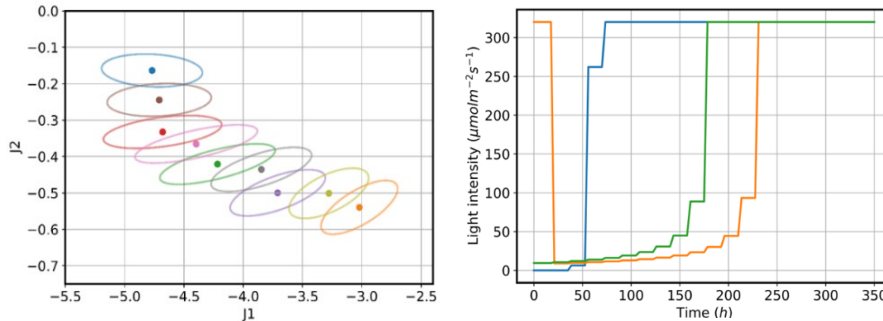

Figure 1: overview of the Pareto ellipsoids set (left) and selected control profiles (right)

Overall, the front of Pareto ellipsoids has relatively constant shape of ellipsoids. There is an increase in uncertainty in the middle of the trade-off zone between the anchor points. When minimising  $J_1$ , the ellipsoid seems relatively aligned with the objective axes, when moving towards minimising  $J_2$ , the ellipsoids have more rotation. Using this visualisation of uncertainty, a DM can improve his awareness of the uncertainty's effect and make a better decision regarding expected process performance and safety of operation.

Figure 2: visualisation of objective values using Monte Carlo for both anchor points

### 3.2. Pareto ellipsoids verification

Monte Carlo simulation is used to verify the accuracy of ellipsoids. 1000 samples from the uncertain parameters' distribution are evaluated and shown in Figure 2. As the setting for the Pareto-ellipsoids based algorithm was set to  $\alpha = 70\%$ , the expectation is that 70% of all Monte Carlo iterations are within the boundary of the ellipsoid (green points).

Table 1: Sigma points accuracy through Monte Carlo simulation

Ellipsoid:	1	2	3	4	5	6	7	8	9
$\sigma_{J_1}^2$	97.6%	101.6%	100.2%	99.4%	101.9%	97.9%	98.0%	97.7%	97.9%
$\sigma_{J_2}^2$	98.2%	97.8%	97.2%	96.8%	96.4%	95.6%	96.1%	95.5%	96.0%
$\text{Cov}(J_1, J_2)$	103.7%	101.3%	99.7%	98.8%	108.7%	95.7%	94.9%	95.6%	95.8%
% green points	70.3%	69.3%	69.3%	70.1%	69.4%	68.8%	68.4%	68.5%	69.0%

Additionally, the covariance matrix obtained through sigma points can be compared to the covariance matrix from the Monte Carlo dataset to determine its accuracy. An overview of the covariance matrix accuracy is found in Table 1. Figure 2 shows the ellipsoid, which is using sigma points, and the Monte Carlo iterations as points.

Overall, the ellipsoids are very accurate. All ellipsoids contain between 68 – 71% of Monte Carlo iterations, which is very close to the desired 70%. The shape of the Monte Carlo dataset also seems to resemble the ellipsoid's shape. The covariance accuracy shows that the variance of objective 2 is underapproximated by around 3 – 4%. A more in-depth analysis is done for a range of different case studies in Mores et al. (2023).

#### 4. Conclusion

In this work, a novel Pareto ellipsoids-based algorithm for multi-objective optimisation is presented and applied to a case study of C-Phycocyanin production through *Arthrospira platensis*. The algorithm provides only relevant points, as defined by the user through settings  $\sigma_{low}^2$ ,  $\sigma_{high}^2$  and  $\alpha$ . This ensures efficient calculation of the Pareto set, which is important when implementing uncertainty propagation techniques. The Droop model as presented in del Rio Chanona et al. (2015) is used and two parameters are considered uncertain. Application of the novel algorithm results in a set of Pareto ellipsoids, which show how the uncertainty will propagate to the performance of the process. Early increase in light intensity is used to promote biomass growth, while delaying it leads to a more efficient C-Phycocyanin production. The ellipsoids' accuracy is evaluated using a Monte Carlo approach and shows that they represent the uncertainty accurately, allowing a DM to make a more informed decision on how to design and operate the process.

## Abstract

Li-ion batteries are a widely used electrochemical energy storage device. But, catastrophic failure via thermal runaway leads to great flammability and toxicity hazards. As such, there is a need to better understand the thermal runaway process. In doing so, reducing its occurrence and improving predictions of its hazards. To achieve this, we aim to develop a more detailed model of thermal runaway. This is based on fundamental reaction theory. Micro-kinetic modelling techniques are applied to predict the kinetic evolution of the reacting systems on a mechanistic level, based on a detailed analysis of the elementary reaction steps. Using this methodology, we simulate the thermal decomposition of dimethyl carbonate, as a model electrolyte solvent, and predict the product species present in the off-gas. We also investigate the impact of the temperature on the composition of the off-gas and the lower flammability limit. This demonstrates a method for predictive hazard assessments of Li-ion battery failure. For the DMC case study, we show that the LFL increases with increasing the operating temperature due to the large proportion of CO<sub>2</sub> generated. This effectively makes the off-gas safer in terms of explosion hazards. Further work will extend this methodology to construct the reaction systems for a complete Li-ion cell.

**Keywords:** Reaction network analysis, Hazard prediction, Dimethyl carbonate, Lower explosion limit, Thermal decomposition

## 1. Introduction

Li-ion batteries (LIBs) have been extensively adopted as energy storage devices. Hence, the safety of LIBs is of great importance. This is because under adverse conditions LIBs can undergo thermal runaway (TR) (Wang *et al.*, 2012) that occurs when the Li-ion cell's component materials exothermically decompose. This leads to an exponential increase in heat generation and cell temperature. Further, the decomposition process leads to the generation of a complex vapour-gas mixture including electrolyte vapours, as well as flammable, toxic, and poisonous gases (Fernandes *et al.*, 2018). The most notable toxic gas is HF. While CO<sub>2</sub> is not poisonous and can cause suffocation in large enough quantities. Flammable gasses also have the potential to cause explosions. LIBs are increasingly used in EVs, and domestic and commercial stationary energy storage. As a result, these hazards are present to more people and methods to improve LIB safety are essential.

To help achieve this goal LIB researchers and developers need to improve their ability to predict the complexities of TR. TR modelling has been used to predict thermal hazards of cells, some including flammability behaviour (Zhang *et al.*, 2022a). However, studies on the flammability of the off-gas are based on a given gas composition determined from experimental studies. This is because typical TR models that simulate the decomposition of the battery materials do not provide a detailed description of the reaction products (for example, Bugryniec *et al.*, 2020). Micro-kinetic modelling can overcome this limitation by including all reactants, e.g. Li-ion cell components, and all possible products, e.g. off-gasses (Bugryniec *et al.*, 2022) in the reaction network as well as each possible elementary step and reaction intermediate. Further, the kinetic parameters of these detailed models are typically estimated based on a solid theoretical basis and no a priori assumptions on the rate-determining steps are needed (Hermes *et al.*, 2019).

An important parameter to quantify the combustion risk is the lower flammability limit (LFL), or the lower explosion limit (LEL) (Ludwig, E., 1991). The LFL is the threshold percentage of gas that is required to be present in the air for it to ignite/explode. Below this threshold, the fuel conditions are too lean for combustion. Complimentary to this is the upper flammability limit (UFL) which indicates the highest fraction of flammable gas at which a flammable mixture is formed. In this work, we focus on the LFL as it is the start of the flammability hazard. The LFL can be determined experimentally or theoretically by the Le Chatelier formula which is discussed in detail in Section 2. The error calculating the LFL by Le Chatelier's formula is relatively small (<7%) (Li *et al.*, 2019). As such it is a widely accepted method in engineering applications.

The LFL has been calculated for the off-gas generated when experimentally abusing Li-ion cells. This can range from 4% to 50% depending on SOC and chemistry. Typically, the higher values of LFL relate to a higher fractional amount of CO<sub>2</sub> being generated (Chen *et al.*, 2020, Li *et al.*, 2019, Zhang *et al.*, 2022b). The LFLs of electrolyte solvents have also been reported. For dimethyl carbonate, diethyl carbonate and ethyl methyl carbonate the LFL are 3.2%-4.2%, 1.4%-1.6%, and 2.1% respectively (Henriksen *et al.*, 2019, IPCS INCHEM, 2000, IPCS INCHEM, 2005). However, the LFL of the off-gas from solvent decomposition has not been calculated, nor has the LFL of Li-ion cell off-gas been predicted. To the authors' knowledge, this is the first work on the prediction of the off-gas flammability behaviour on the topic of LIB safety.

Considering this, we aim to develop a TR model that predicts the generation and composition of LIB off-gas by applying micro-kinetic modelling methodologies. From this, the flammability (LFL) of the gas composition is assessed. In this work, we focus on one subcomponent of the cell, the electrolyte solvent dimethyl carbonate (DMC). For this component, we construct a reaction model in MATLAB® to simulate the generation of gas species under heating. With this, predictions are made on the gas composition during different stages of TR, from which changes in flammability hazard (i.e. LFL) are assessed.

## 2. Methodology

As stated previously, this work focuses on the reaction network for DMC thermal decomposition in an inert atmosphere. The reaction network applied is presented in Figure 1, reproduced from Fernandes *et al.*, 2019. The reaction network consists of 16 forward reactions and 12 species. The arrows in Figure 1 indicate the reactions proceeding in the forward direction. However, each elementary step included in the network was considered to be reversible. Within this, there are 3 possible pathways leading to the

decomposition of DMC: The direct decomposition of DMC to dimethyl ether, and the reaction of DMC with water or hydrogen.

Figure 1. Reaction network for DMC thermal decomposition.

The micro-kinetic model consists of a system of 12 ordinary differential equations (ODEs) describing the change in concentration over time of the 12 species included in the mechanism. Each ODE is expressed as the algebraic sum of all relevant reaction rates ( $R_i$ ) corresponding to a given reaction step.  $R_i$  is governed by an Arrhenius equation of the form  $R_i = A_i e^{-E_{a,i}/RT} \prod_j C_j$ . In which  $A_i$  is the frequency factor,  $E_{a,i}$  is the activation energy,  $R$  is the gas constant,  $T$  is the temperature and  $C_j$  is the species concentration. The kinetic parameters of each rate-determining step are determined from transition state theory. The thermochemistry (of the reaction species, complexes, and transition state structures) was determined using density functional theory (DFT). This was carried out in Gaussian (Gaussian 16, 2019) with the method and basis set combination of B3LYP/6-311++G(d,p). The solution to the system of ODES is computed in MATLAB® (MATLAB, 2021).

The initial reactant system is assumed to be a mixture of only DMC and water with concentrations of 11.87 mole/L and 1.30E-3 mole/L, respectively. This is in line with the typical water content of commercially available DMC. The time-varying simulation assumes a constant linear temperature increase of 1°C/min, starting from 20°C and ending at 800°C. This is to approximate the common LIB abuse tests of adiabatic calorimetry. The predicted decomposition species are then used to calculate the temperature dependant LFL of the off gas.

As  $\text{CO}_2$  is expected to develop, the off-gas mixture can be considered dilute. The LFL for a dilute mixture,  $\text{LFL}_M$  (see Eq. 1), is calculated using the extended Le Chatelier's formula (Schroeder, 2016). The  $\text{LFL}_M$  is determined from the  $\text{LFL}'_i$ , the modified LFL of each species accounting for the diluting species, i.e.  $\text{CO}_2$ , (see Eq. 2). In which the  $\text{LFL}'_M$  is the LFL of only the flammable gas mixture (see Eq. 3). Further,  $a_i$  and  $B_k$  are the molar fraction of flammable gas  $i$  and molar fraction of inert gas  $k$ , respectively.  $\bar{K}$  is the average value of the nitrogen equivalency  $K_k$ , of the inert gases weighted according to their molar fractions. For pure  $\text{CO}_2$   $\bar{K} = 1.5$ .

$$LFL_M = \frac{100}{\sum_i^n \frac{a_i}{LFL'_i}} \quad (1)$$

$$LFL'_i = \frac{100 - LFL'_M - \left( (1 - \bar{K}) \frac{\sum_{p=1}^k B_k}{\sum_{i=1}^n a_i} \times LFL'_M \right)}{100 - LFL'_M} \times LFL_i \quad (2)$$

$$LFL'_M = \frac{100}{\sum_i^n \frac{a_i}{LFL_i}} \quad (3)$$

### 3. Results and Discussion

The predicted decomposition of DMC and generation of the off-gas species, along with the calculated LFL of the off-gas is presented in Figure 2. Only 8 species are presented in Figure 2 as the concentrations of the other 4 species ( $\text{H}_2\text{O}$ ,  $\text{OH-C(=O)OCH}_3$ ,  $\text{CH}_3\text{OC(=O)H}$ , and  $\text{HCOH}$ ) included in the reaction network do not reach a significant value. This is due to the low concentration of water in the initial solution which prevents  $\text{OH-C(=O)OCH}_3$  from being generated in high concentrations. On the other hand,  $\text{CH}_3\text{OC(=O)H}$  is not observed in high concentrations due to the number of favourable decomposition paths that this species can decompose by.

From Figure 2 it can be seen that DMC begins to decompose at  $450^\circ\text{C}$ . At this initial stage, DMC leads to  $\text{CH}_3\text{OCH}_3$  and  $\text{CO}_2$  generation only. At approximately  $550^\circ\text{C}$   $\text{CH}_3\text{OCH}_3$  starts to decompose leading to  $\text{CH}_4$  and  $\text{CH}_2\text{O}$  generation. At even greater temperatures,  $650^\circ\text{C}$ ,  $\text{CH}_2\text{O}$  decomposes to  $\text{H}_2$  and  $\text{CO}$ . At  $800^\circ\text{C}$  the gas produced predominantly consists of  $\text{CO}_2$  and  $\text{CH}_4$ , with  $\text{H}_2$  and  $\text{CO}$  in low quantities.

The  $LFL_M$  is calculated only considering the major species present. The LFLs of these individual species,  $LFL_i$ , are presented in Table 1. It can be seen from Figure 2 that  $LFL_M$  increases compared to the  $LFL_{\text{DMC}}$  as decomposition progresses. This is mainly driven by the diluting effect of  $\text{CO}_2$ . As even in the early stages of decomposition when  $\text{CH}_3\text{OCH}_3$  is present with a lower LFL than DMC the  $LFL_M$  still rises. This indicates that the greatest flammability risk when cell venting occurs (at  $\sim 200^\circ\text{C}$ ) would be from the solvent vapour (whilst not considering the electrode decomposition reactions). Further, we can see that generation of  $\text{CO}_2$  has a beneficial effect of increasing the  $LFL_M$ . However, a large quantity of  $\text{CO}_2$  presents a significant suffocation hazard.

Figure 2. DMC decomposition and predicted off-gas species with calculated LFL of the mixture.

Table 1. LFL of major species present in the off-gas.

Species	LFL (%)	Source
DMC	4.20	(IPCS INCHEM, 2005)
CH <sub>3</sub> OCH <sub>3</sub>	3.35	(Zlochower, 2012)
CO <sub>2</sub>	n/a	(Chen et al., 2020)
CH <sub>3</sub> OH	6.00	(PubChem, Methanol)
H <sub>2</sub>	4.00	(Chen et al., 2020)
CH <sub>4</sub>	5.00	(Chen et al., 2020)
CH <sub>2</sub> O	7.00	(PubChem, Formaldehyde)
CO	12.50	(Chen et al., 2020)

#### 4. Conclusion

This work proves that micro-kinetic modelling can predict gas generation during LIB TR. We have shown the flammability risk can be evaluated using the extended Le Chatelier's formula. In doing so, the LFL of the off-gas is calculated. A large amount of CO<sub>2</sub> increases the LFL of the off-gas. This reduces the flammability hazard but increases the suffocation hazard. The composition of off-gas varies over the temperature range studied.

This work will be extended to full Li-ion cell systems to be practical for LIB developers. Including all electrolyte and electrode materials. Also, this method can be extended to calculate the ignition energy and the heat of reaction of the off-gas. Providing further predictive capabilities for risk assessment of LIB energy storage systems.

## Abstract

A carbon cycle model based method is proposed for performance evaluation of carbon offset projects that compensate industrial emissions. As a case study, carbon cycle impact assessment was conducted for five representative approaches to carbon neutrality. The result indicates that fossil to biomass fuel switching is doomed to a high concentration of atmospheric carbon dioxide and large scale deforestation, and that reduction of emissions is more effective than extension of sequestration from an environmental point of view. Finally, from a social point of view, optimization of carbon offset networks in terms of both carbon cycle dynamics and carbon market economics is suggested as future work.

**Keywords:** carbon neutrality, net zero emissions, carbon offset, carbon credit, carbon cycle impact assessment

## 1. Introduction

Carbon neutrality is an arithmetic concept that can be achieved by net zero emissions, which only guarantees a steady state for the carbon cycle (Manousiouthakis and Choi, 2021). If emissions and absorptions are equally large, the steady state concentration of carbon dioxide in the atmosphere can still be high even though carbon neutrality is attained. A typical example is harvested plant biomass, which inherently owes a huge carbon debt (Choi and Manousiouthakis, 2020) when combusted, and thus cannot be a proper alternative to fossil fuels (Manousiouthakis and Choi, 2021). Furthermore, emissions can be overcompensated by carbon offsets (Kotchen, 2009) such as renewable energy and energy efficiency projects that only indirectly reduce emissions. Therefore, carbon cycle impact assessment is necessary when a carbon offset project is considered as an approach to carbon neutrality.

Chemical plant industries, mostly carbon based, are on the way to carbon neutrality, reducing emissions by carbon capture and utilization (CCU), carbon capture and storage (CCS), and by growing and processing of biomass (Gabrielli et al., 2020), and earning or purchasing carbon credits (Blaufelder et al., 2021) that can be obtained by carrying out or investing in carbon offset projects such as forestry, renewable energy, energy conservation, and conversion of waste to energy (EIC, 2020). Among these projects, forestry is essential, because it directly controls atmospheric carbon dioxide. Forests should be protected because deforestation is equivalent to carbon emissions (Photopoulos, 2017), and one to one reforestation cannot fully recover the initial state of atmospheric carbon dioxide as long as deforestation continues (Choi and Manousiouthakis, 2020). Besides, as an alternative to forestry, direct air capture (DAC) is receiving attention (Chatelain, 2022) with skepticism on its efficiency (Day, 2021).

Carbon offsetting is criticized, especially strongly by environmentalists, because it does not directly reduce emissions (Ghussain, 2020). This issue could be moderated by corrective evaluation of carbon credits, reflecting the fact that less emissions are better than more sequestration. Therefore, carbon cycle impact assessment is suggested for emissions trading system (ETS) also. In this work, a model is proposed as shown in Fig. 1, as a tool for performance evaluation of carbon offset projects. The solid arrows represent main active flows involved in carbon cycle and carbon offsetting. The dashed arrows represent flows that are much less dynamic than the others. The model indicates that the total amount of carbon credits, i.e., allowances of carbon emissions, should be limited to the total capacity of sequestration by forests in order to achieve net zero emissions. Furthermore, the prices of carbon credits should be sufficiently high in order to drive the industry to substantially reduce emissions (Opanda, 2022).

## 2. Proposed Method

### 2.1. Modeling of Carbon Cycle

Carbon cycle impact assessment is required in order to rigorously evaluate carbon offset projects in terms of contribution to climate change mitigation. Proposed carbon cycle model equations are as follows:

$$\dot{C}_a = f_{rp}(C_p) + f_{rs}(C_s) - f_p(C_a, C_p, A_v) - f_a(C_a, C_{so}) + r_v + q(t) \tag{1}$$

$$\dot{C}_p = f_p(C_a, C_p, A_v) - f_{rp}(C_p) - f_l(C_p) - h(t) \tag{2}$$

$$\dot{C}_s = f_l(C_p) - f_{rs}(C_s) - f_t(C_s) \tag{3}$$

$$\dot{C}_{so} = f_a(C_a, C_{so}) + f_t(C_s) + f_{up}(C_{do}) - f_{dw}(C_{so}) \tag{4}$$

$$\dot{C}_{do} = f_{dw}(C_{so}) - f_{up}(C_{do}) - f_s(C_{do}) \tag{5}$$

$$\dot{C}_r = f_s(C_{do}) - r_v \tag{6}$$

$$\dot{A}_v = \left[ \int_0^t s(t - \tau) \dot{g}(\tau) d\tau - h(t) \right] \frac{A_v}{C_p} \tag{7}$$

where

Figure 1. Carbon cycle and emissions trading system.

- $C_a$  = mass of carbon in the atmosphere, PgC  
 $C_p$  = mass of carbon in plants, PgC  
 $C_s$  = mass of carbon in soils, PgC  
 $C_{so}$  = mass of carbon in the surface ocean, PgC  
 $C_{do}$  = mass of carbon in the deep ocean, PgC  
 $C_r$  = mass of carbon in rocks, PgC  
 $A_v$  = normalized vegetated land area  
 $f_p$  = rate of photosynthesis, PgC/y  
 $f_{rp}$  = rate of plant respiration, PgC/y  
 $f_l$  = rate of litterfall, PgC/y  
 $f_{rs}$  = rate of soil respiration, PgC/y  
 $f_t$  = rate of transfer from soils to the surface ocean by the river flow, PgC/y  
 $f_a$  = net rate of absorption to the surface ocean, PgC/y  
 $f_{up}$  = rate of upwelling from the deep ocean, PgC/y  
 $f_{dw}$  = rate of down-welling from the surface ocean, PgC/y  
 $f_s$  = rate of sedimentation to the crust, PgC/y  
 $r_v$  = rate of volcano emission, 0.1 PgC/y  
 $q$  = rate of carbon emissions by fuel combustion, PgC/y  
 $h$  = rate of plant harvesting, PgC/y  
 $s$  = target rate of biomass production by planting seedlings, PgC/y  
 $g$  = normalized tree mass growth function,  $g(0) = 0$ ,  $g(\infty) = 1$

The unit PgC represents  $10^{15}$  grams of carbon, which is equivalent to GtC. The initial conditions at present are as follows:

$$\begin{aligned}
 C_a(0) &\approx 1.5C_a^\circ, C_p(0) \approx C_p^\circ, C_s(0) \approx C_s^\circ, C_{so}(0) \approx 1.02C_{so}^\circ, C_{do}(0) \approx C_{do}^\circ, \\
 C_r(0) &\approx C_r^\circ, A_v(0) \approx 0.75
 \end{aligned}$$

where the parameters with degree symbols represent reference values estimated for the time right before the industrial revolution. Detailed expressions of the functions in the above equations and model validation are referred to Choi and Manousiouthakis (2022).

## 2.2. Simulation of Carbon Offset Networks

Simultaneous implementation of multiple carbon offset projects can be viewed as a carbon offset network. The resulting rate of carbon emissions can be calculated as follows:

$$q(t) = \sum_{i=0}^n q_i(t) \tag{8}$$

where  $q_i < 0$  represents the reduced rate of emissions by the  $i$ -th project, which should be close to the annually earned carbon credit if properly evaluated. Rates of plant harvesting and planting seedlings can be calculated in the same way as follows:

$$h(t) = \sum_{i=0}^n h_i(t) \tag{9}$$

$$s(t) = \sum_{i=0}^n s_i(t) \tag{10}$$

Let us assume that harvested plant biomass is partially combusted as a fuel, and the rest is stored as a product. Then, carbon neutrality is achieved at  $t = t^*$  if the following condition is satisfied:

$$q(t) = h(t), t \geq t^* \tag{11}$$

Therefore, the above three functions  $q$ ,  $h$ , and  $s$  compose design variables for a carbon offset network to be optimized subject to the following constraints:

$$C_a \leq C_a^* \tag{12}$$

$$A_v \leq A_v^* \tag{13}$$

where  $C_a^*$  is set by the maximum allowable increase in the global temperature, and  $A_v^*$  by the maximum available land area for forestry.

### 3. Case Study

#### 3.1. Approaches to Carbon Neutrality

Consider a hypothetical task of achieving carbon neutrality in 25 years with initial emissions of 10 PgC/y, which approximately corresponds to the current situation. Five approaches are summarized in Table 1, and six cases are defined as follows:

Case 0. Fossil fuels

As a base case, it is assumed that fossil fuels are used as ever.

$$q(t) = 10, h(t) = s(t) = 0 \tag{14}$$

Case 1. Fossil to biomass with reforestation

Fossil fuels are gradually replaced by harvested plant biomass with 1:1 reforestation.

$$q(t) = 10, h(t) = s(t) = \begin{cases} 0.4t, & 0 \leq t < 25 \\ 10, & t \geq 25 \end{cases} \tag{15}$$

Case 2. Fossil to biomass with afforestation

Fossil fuels are gradually replaced by harvested plant biomass with 1:1 afforestation.

$$q(t) = 10, h(t) = \begin{cases} 0.4t, & 0 \leq t < 25 \\ 10, & t \geq 25 \end{cases}, s(t) = 10 \tag{16}$$

Table 1. Changes in design variables for different approaches to carbon neutrality

Case	Approach to carbon neutrality	Changes in design variables
1	Fossil to biomass with reforestation	
2	Fossil to biomass with afforestation	
3	Extension of sequestration	

4	Reduction of emissions	
5	Half reduction and half afforestation	

Case 3. Extension of sequestration

Fossil fuels are used while sequestration is extended by 1:1 afforestation.

$$q(t) = 10, h(t) = \begin{cases} 0, & 0 \leq t < 25 \\ 10, & t \geq 25 \end{cases}, s(t) = 10 \quad (17)$$

Case 4. Reduction of emissions

Fossil fuels are gradually replaced by non-carbon based energy.

$$q(t) = \begin{cases} 10 - 0.4t, & 0 \leq t < 25 \\ 0, & t \geq 25 \end{cases}, h(t) = s(t) = 0 \quad (18)$$

Case 5. Half reduction and half afforestation

Fossil fuels are gradually reduced to half, and sequestered by 1:1 afforestation.

$$q(t) = \begin{cases} 10 - 0.2t, & 0 \leq t < 25 \\ 5, & t \geq 25 \end{cases}, h(t) = \begin{cases} 0, & 0 \leq t < 25 \\ 5, & t \geq 25 \end{cases}, s(t) = 5 \quad (19)$$

3.2. Performance Evaluation

Carbon cycle impact assessment was carried out for the above six cases. The results are as shown in Fig. 2. Cases 1 and 2 indicate that fossil to biomass fuel switching is an improper approach to carbon neutrality because of huge carbon debts, i.e., the initial atmospheric carbon dioxide that exceeds that of fossil fuels, and large loss of forests. Cases 3 and 4 show that extension of sequestration cannot replace reduction of emissions in effect. Case 5 is a compromise between cases 3 and 4, which is considered to be a feasible approach whose impacts on the carbon cycle are acceptable.

Figure 2. Predicted carbon cycle impacts of different approaches to carbon neutrality.

#### 4. Conclusions

The result of case study shows that net zero emissions can result in various levels of concentration of carbon dioxide in the atmosphere. Therefore, it is suggested that the concept of carbon neutrality should be more conservatively redefined in view of dynamic effects, and the credits for carbon offset projects should be more rigorously revaluated based on carbon cycle impact assessment. Then, the proposed method is expected to be able to contribute to optimal design of carbon offset networks in terms of not only carbon cycle dynamics, but also carbon market economics, for process systems to achieve net zero emissions within a given period of time.

## Abstract

Mass transfer of oxygen is investigated in this work using a pilot-scale bubble column unit with a two-fluid nozzle for aeration. First-principles models for the bubble column unit are identified by utilizing concepts in artificial intelligence (AI) and machine learning (ML), and applying the same to experimental data. By combining process knowledge with data-driven modeling, we discovered interpretable models for oxygen transport phenomena in bubble columns. By virtue of obtaining symbolic models, it is possible to perform post-hoc analyses on the same in order to gain physical insights into the mechanisms occurring in the system -- a convenience lost when using black-box models such as neural networks. This provides valuable understanding which can be applied when modeling more complex systems such as fermentation processes.

**Keywords:** Artificial intelligence; Machine Learning; Hybrid AI; Interpretable models; Mechanistic modeling

## 1. Introduction

With the advent of improved computing power, and the ability to generate and handle copious amounts of data, artificial intelligence (AI) has yielded successes in the domains of computer vision, game-playing, recommender systems, among other applications. It must be noted however, that such domains do not have guiding mathematical equations that determine their existence. In stark contrast, physicochemical phenomena, are governed by constitutive equations and conservation laws, among other functional relationships (Venkatasubramanian 2019). Further, knowledge about these phenomena is known in many cases, and can be leveraged to better describe the same. Consequently, when attempting to derive mathematical models of such systems using data-driven tools, it is imperative that one utilize any prior knowledge available about the system, and incorporate the same into the conventional data-driven modeling framework (Chakraborty et al. 2022). This hybrid approach results in simpler, more interpretable models, and can yield models that can provide mechanistic insights about the system.

The majority of industrial fermentation processes are aerobic i.e. they require oxygen to be supplied for the microbial metabolic processes to take place. Oxygen is supplied through aeration, in which air is bubbled through the fermentation broth, facilitating a mass transfer of oxygen from the bulk gas phase through the gas-liquid interface to the bulk liquid phase (Doran 2013). Typically modeling of the oxygen transfer in fermentation processes is based on the difference between the dissolved oxygen concentration at saturation and the dissolved oxygen concentration in the fermentation

broth as driving force, an overall liquid-phase mass transfer coefficient, and the surface area of the gas-liquid interface. Experimentally it is difficult to separate the overall liquid-phase mass transfer coefficient from the surface area of the gas-liquid interface, therefore these two terms are generally combined to a volumetric mass transfer coefficient, which can be determined through methods such as the sulphite oxidation technique and gassing-out techniques (Stanbury et al. 1995). Prediction of the volumetric mass transfer coefficient has typically relied on empirical correlations, while theoretical correlations have been introduced using Higbie's penetration theory and Kolmogoroff's theory of isotropic turbulence (Kawase et al. 1992).

In this work, we attempt to obtain an interpretable model of a bubble column aeration system. The data used for modeling has been experimentally generated under 6 different conditions. We propose a hierarchical modeling approach by broadly classifying the same into 2 operating regimes - with, and without addition of salt (here,  $\text{MgSO}_4$ ). This enables us to obtain high fidelity models accounting for the nonidealities that are manifested as a result of (or lack thereof) salt addition. In the remainder of the manuscript, we describe the bubble column aeration system in Section 2, and briefly mention the model discovery engine used to obtain the models in Section 3. We then discuss the results when compared to purely first-principles models, in Section 4. Finally, we conclude our findings and, highlight potential future directions to investigate.

## 2. Problem Description

The experimental set-up consists of a main column, a recycle loop for circulating liquid in the system, a compressed air supply, and a  $\text{H}_2\text{O}_2$  solution storage tank (Figure 1). Aeration in the bubble column is introduced using a two-fluid nozzle, in which air and recycled liquid are premixed before entering the column. The recycle flow in the system is enforced using a centrifugal pump, and a  $\text{H}_2\text{O}_2$  solution is fed to the system either in the bottom of the column, in the top of the column, or through the aeration nozzle using a variable speed dosing pump. Online sensor measurements are accessible through a Supervisory Control And Data Acquisition (SCADA) system and stored in a central data base. Online sensor measurements in the system includes: flow sensors for liquid recirculation ( $FI_1$ ) and compressed air ( $FI_2$ ), dissolved oxygen sensors at bottom ( $AI_1$ ) and top ( $AI_2$ ) of the column, temperature sensor ( $TI_1$ ), conductivity sensor ( $CT_1$ ), level sensor ( $LI_1$ ), and weight measurements of the  $\text{H}_2\text{O}_2$  solution storage tank ( $WT_1$ ). The system is used to investigate oxygen mass transfer and the influence of air flow, liquid recycle flow, and salts on the mass transfer. The hydrogenperoxide-catalase method is employed in the system, in which  $\text{H}_2\text{O}_2$  is decomposed to water and oxygen in the presence of an enzyme (Eq. 1).

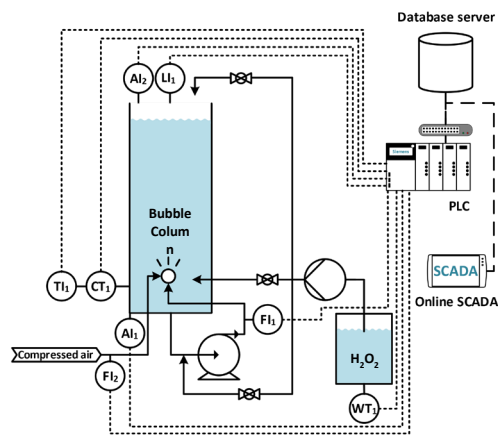

Figure 1 Experimental bubble column set-up with live measurements accessible through SCADA system.

The oxygen liberated in reaction (Eq. 1) will be dissolved in the liquid phase, effectively making the solution supersaturated. The oxygen transfer is thus going to be from the liquid phase to the gas phase. A model for the oxygen transfer in the bubble column is given in (Eq. 2) assuming that the conversion through reaction (Eq. 1) is instantaneous, irreversible, and that the column is ideally mixed.

$$\frac{dO}{dt} = \frac{r}{2} - K_L a(O - O^*) \tag{2}$$

In which  $O$  is the dissolved oxygen concentration,  $O^*$  is the dissolved oxygen concentration at saturation,  $K_L$  is the overall liquid-phase mass transfer coefficient, and  $a$  is the surface area of the gas/liquid interface.  $r = c_{H_2O_2}m/V$  is the rate of added  $H_2O_2$  per column volume,  $c_{H_2O_2}$  is the concentration of  $H_2O_2$ ,  $m$  is the volumetric flowrate of  $H_2O_2$ , and  $V$  is the volume of the column. Integrating (Eq. 2) from  $t_0$  to  $t$  using  $O(t_0) = O_0$  yields the analytical solution (Eq. 3).

$$O = O^* + \frac{c_{H_2O_2}}{2K_L aV}m - \frac{c_{H_2O_2}}{2K_L aV}me^{-K_L a(t-t_0)} - O^*e^{-K_L a(t-t_0)} + O_0e^{-K_L a(t-t_0)} \tag{3}$$

In the system, the mass transfer coefficient and the surface area of the gas/liquid interface is a function of the liquid recirculation flowrate ( $F_1$ ), the air flowrate ( $F_2$ ), and the presence of salts in the liquid. A total of six experimental runs were performed for the system using the experimental conditions given in Table (1).

Table 1 Experimental conditions used for the bubble column system

Experiment	$F_1$ (l/min)	$F_2$ (l/min)	Salt
1	0	300	None
2	0	600	None
3	100	300	None
4	100	600	None
5	0	300	MgSO <sub>4</sub>
6	100	300	MgSO <sub>4</sub>

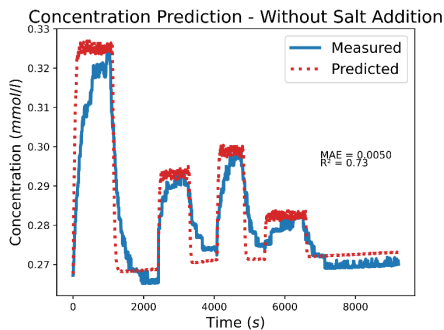

Figure 2 Model predictions using analytic model and measured oxygen concentrations for experiments in which no MgSO<sub>4</sub> was added.

Figure 3 Model predictions using analytic model and measured oxygen concentrations for experiments in which MgSO<sub>4</sub> was present in the system.

By performing a post-hoc analysis of the data from the six experiments, steady-state  $K_L a$  values can be determined and introduced as a constant in (Eq. 3) to model the dissolved oxygen concentration for each of the six experiments.

Predictions of the experiments using the analytic model reveals that the full system dynamics are not captured in the deterministic model (Figure 2 and 3). This suggests that some of the assumptions in the deterministic model should be relaxed to account for the unmodelled phenomena. However, deriving a deterministic expression for the unmodelled phenomena is a challenge, as it includes complicated enzyme kinetics and mixing phenomena dependent on the configuration and geometry of the bubble column. Due to the complicated nature of the unmodelled phenomena in the system, it is considered to be unknown in this work.

### 3. Methods

The data obtained from the pilot-plant is used to discover interpretable models that bear some resemblance to the analytical solution, whilst also being able to account for the nonidealities in the system. A genetic algorithm-based approach - titled *AI-DARWIN* (Chakraborty et al. 2020, 2021) - was used for the same. This approach takes a list of permitted tractable function transformations for each of the inputs, and extends the concept of genetic algorithm (Koza 1995) to mathematical models, in an attempt to explore the possible search space of different possible models. The advantage of such an approach is that it searches through the space of potential models with only the user-permitted function transformations. This allows one to curb the complexity of the models obtained, and allows for inclusion of prior knowledge into the modeling exercise.

The bubble column is a complex dynamical system with a multitude of disparate operating regimes. Consequently, a hierarchical modeling approach was used due to the low variation in the experimental conditions. Two different models were determined: one for the system without  $\text{MgSO}_4$ , and one for the system containing  $\text{MgSO}_4$ .

### 4. Results

The models discovered using *AI-DARWIN* (Table 2 and 3) contain several features that are either a direct analogue, or are similar to features used in the analytic solution (Eq. 3).

Table 2 Models predicting oxygen concentration discovered using *AI-DARWIN* with standardized features

$\text{MgSO}_4$	<i>AI-DARWIN</i> output	Fitness (MAE and $R^2$ )
No	$O = \beta_0 + (\beta_1(-t)^2 + \beta_2 F_1 + \beta_3 F_2)m$ $+ \beta_4 m e^{-t} + \beta_5 (O^*)^2 e^{-t} + \beta_6 (-t)O^*$ $+ \beta_7 (-t)(O^*)^2 + \beta_8 F_2 O^* + \beta_9 F_2^2 (O^*)^2$ $+ \beta_{10} e^{-2t} + \beta_{11} e^{-t}$	0.0016 ( $R^2 = 0.97$ )
Yes	$O = \beta_0 + (\beta_1 m (O^*)^2 + \beta_2 m)m$ $+ \left( \frac{\beta_3 (-t)}{O^*} + \beta_4 (-t)^2 + \frac{\beta_5 (-t)^3}{O^*} \right) O^*$ $+ \beta_6 F_1 e^{F_1} + \beta_7 O^* + \beta_8 (O^*)^2 F_2^2$ $+ \beta_9 (O^*)^2 (-t)^2 + \beta_{10} e^{-t} + \beta_{11} e^m$	0.0011 ( $R^2 = 0.98$ )

Terms containing the features  $m$  and  $e^{-t}$  are found in all models, while the Taylor series expansion  $(-t + (-t)^2 + (-t)^3)$  is found as a feature in the model for experiments with  $\text{MgSO}_4$  discovered using *AI-DARWIN*. The intercept ( $\beta_0$ ) is approximately the same

as the initial value of  $O^*$  for both the discovered models. Additional terms correlating the features  $F_1$  and  $F_2$  to the output  $O$  appear in the discovered models, a correlation handled in the analytic solution by the  $K_L a$  values determined from post-hoc analysis. The extra terms found in the discovered models are accounting for the unknown phenomena in the bubble column.

Using the discovered models for predicting the concentration of dissolved oxygen in the bubble column it is found that the dynamic behavior in the system is significantly better represented compared to the analytic solution, as indicated by the improved fitness (Figure 4 and 5). The improved performance of the discovered models indicates that the unknown phenomena is successfully accounted for in the six different experiments in the bubble column system.

Table 2 Parameters for models predicting oxygen concentration discovered using *AI-DARWIN* with standardized features

MgSO <sub>4</sub>	No	Yes
$\beta_0$	0.26	0.29
$\beta_1$	-0.014	-0.000
$\beta_2$	-0.002	-0.004
$\beta_3$	-0.003	0.013
$\beta_4$	0.005	0.004
$\beta_5$	-0.015	-0.003
$\beta_6$	-0.004	-0.000
$\beta_7$	0.021	-0.009
$\beta_8$	-0.003	0.000
$\beta_9$	0.016	-0.001
$\beta_{10}$	-0.003	-0.003
$\beta_{11}$	0.017	0.003

Table 3 Features in deterministic model and selected features from the models discovered using *AI-DARWIN*

Model	Feature				
Deterministic	$O^*$	$m$	$me^{-(t-t_0)}$	$O^*e^{-(t-t_0)}$	$O_0e^{-(t-t_0)}$
<i>AI-DARWIN</i> w/o. MgSO <sub>4</sub>	$\beta_0$	$m$	$me^{-t}$	$(O^*)^2e^{-t}$	-
<i>AI-DARWIN</i> w. MgSO <sub>4</sub>	$\beta_0$	$m$	-	$O^*(-t + (-t)^2 + (-t)^3)$	-

Figure 4 Predicted and measured oxygen concentrations for experiments 1, 2, 3, and 4 in which no MgSO<sub>4</sub> was added.

Figure 5 Predicted and measured oxygen concentrations for experiments 5 and 6 in which MgSO<sub>4</sub> was present in the system.

An interesting observation is the inclusion of certain terms which exist in the analytical solution, in the models predicted by *AI-DARWIN*. While some complex nonlinear parameterized features are represented through a Taylor Series expansion, other novel terms are included to account for nonidealities in the system. We encounter the interaction effects of the different input variables which yield more complex function

transformations, but result in better predictability. While it would be the desired goal to be able to decouple the effects of the ideal conditions as expressed by the analytical solution, and the nonidealities which are accounted for by virtue of the additional terms, it remains an ongoing challenge in the interpretability of ML models in the sciences and engineering.

## 5. Conclusion

A step forward in the direction of creating a digital-twin for a complex bubble column system has been made, by virtue of an interpretable modeling approach. Such a technique relied on the use of *a priori* knowledge of the system's dynamics, and was able to account for the analytical solution obtained from first-principles. Such a data-driven approach combined with first-principles permits interpretability, which is not possible in purely black-box models (Chakraborty et al. 2022). Due to the high cost of performing experiments, varied set of conditions for some input variables ( $F_1$  and  $F_2$ ) have not been considered in this work (at most 2 conditions were considered). Future steps include sampling of the data at different operating conditions using appropriate experimental design techniques. Incorporating this into the overall modeling framework can help us obtain more reliable and robust models. Certain key underlying assumptions of the first-principles-based modeling approach include the instantaneity of Reaction 1 and the bubble column being well-mixed -- both of which do not seem to hold upon performing the experiments. As a result, the  $K_L a$  values have been assumed to be constant at given conditions when modeling using first-principles. It would be worthwhile to explore the possible function form of the mass transfer coefficient under different operating regimes.

## Abstract

In this work, a systematic framework was developed and implemented to optimize large scale processes, through a particular case study. In this process, 32 operating and design variables were found, which can be subject to modification using an optimization process. The identification of high impact variables was carried out through a sensitivity analysis using the method of standardized regression coefficients, together with the Latin hypercube method. Once these variables were identified, the optimization of the process was carried out for the maximization of profits together with the minimization of the operating costs using only the most important identified variables. The solution of the process model was done using Aspen Plus and the optimization was performed using the technique of genetic algorithms, which is available in MATLAB. The results illustrated that was possible to increase the profit by 5.02 % and decrease the energy cost 4.6 %. The framework allowed to reduce the computational time 34.2 % compared when all the manipulating variables were used in the optimization task.

**Keywords:** Latin hypercube method, sensitivity analysis, phytosterols production.

## 1. 1. Introduction

The development of new products and their manufacturing processes have demanded innovative manners to solve those challenges (Pistikopoulos et al., 2021). Process optimization has been employed as a paramount strategy to improve the performance in the development of new products and processes, through the introduction of new optimization strategies, advanced methods, combinations of computer-aided tools, etc.

Process optimization most of the time has been categorized as time consuming task, especially when metaheuristic methods are employed, such as genetic algorithms. The implementation of optimization in large and new processes could rise the complexity in the solution, since the number of variables to optimize could be large increasing the time to obtain the optimal solutions (Katok et al., 2021). In a previous work, Ponce-Rocha et al. (2022) proposed a rigorous process design optimization under uncertainty combining Aspen Plus-Matlab, using genetic algorithms (GA) obtaining remarkable results, and showing the functionality of the combination of the computer-aided tools. GA method uses a set of initial solutions (initial populations), randomly selected from the feasible solution space. The fitness function is evaluated for each solution, and the solutions are consequently ranked. Then, the population evolves through several operations, such as reproduction, crossover, and mutation to optimize the fitness function and obtain the final optimal solution. The process is repeated until some criteria are satisfied. This evolutionary algorithm is preferred to classical optimization approaches because it can handle the nonlinear, nonconvex, and nonsmooth optimization problem of the component sizing for the hybrid system (Katok et al., 2021); the nonconvexity of the problem makes it difficult for classical optimization methods to obtain a global optimum. On the other hand, GA globally searches the domain of possible solutions for an optimal solution. Therefore, the objective of this work is to present a systematic framework to optimize large processes, decreasing optimization time, maximizing profits, and decreasing operating costs, where the first step is the identification of the most significant variables of the process, followed by optimization using GA to find the best values of these variables using the combination of Aspen Plus and Matlab. The employed case study was the production of phytosterols and biodiesel from crude vegetable oils.

## 2. Methodology

The framework includes three main sections applied to one case study of relevant interest.

### 2.1. Case study

The production of phytosterols ( $\beta$ -sitosterol and stigmasterol), glycerol and clean biodiesel from crude vegetable oils was taken as a case study. The integrated process consists of two main sections as illustrated in Figure 1: A) Phytosterols production: the separation of triglycerides from phytosterols, phyto-glucoside compounds and fatty acids (FFA) is performed employing supercritical extraction using  $\text{CO}_2$  and a mixture of  $\text{CO}_2$  –  $\text{CH}_3\text{OH}$  as supercritical fluids and vacuum distillation processes. B) Biodiesel production: this is performed using a reactive distillation column to carry out the transesterification reactions of triglycerides to produce clean biodiesel and glycerol, followed by two distillation columns. It is possible to identify diverse important designs and operating variables in the process.

### 2.2. Generation of the process diagram in Aspen Plus and the connection with MATLAB.

Firstly, the process flow diagram is generated using a process simulator, in this case Aspen Plus can be used as simulation environment. Then, the connection between MATLAB® and Aspen plus® can be made using COM technology, which allows making the bridge between these two computer-aided tools. For the case study mentioned above, 32 variables were identified for case A-B and for case A only 13 variables were distinguished.

### 2.3. Sensitivity analysis.

As second step, a sensitivity analysis is performed where the Latin hypercube method can be used to obtain different possible scenarios and analysis the functionality of certain

variables using a Monte Carlo approach. One advantage of the Latin hypercube method is that guarantees that each of these components is represented in a completely stratified way (*i.e.*, the population is separated into exclusive segments). For sensitivity analysis, a random sampling of 1,000 samples were generated, which are subject to a 5 % variation for upper and lower limits. Then, the identification of the most significant variables of the system was performed using the standardized regression coefficient method.

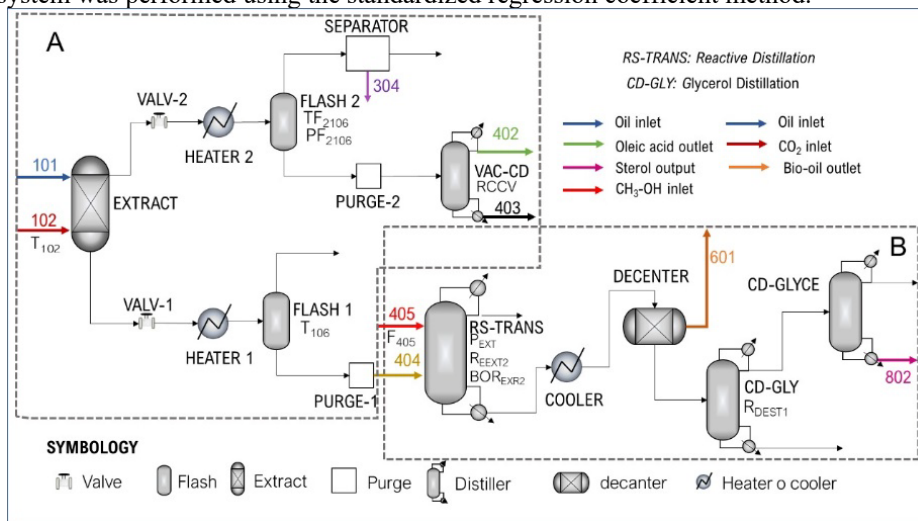

Figure 1. Flowsheet for the production process of phytosterols and biodiesel from palm oil.

#### 2.4. Optimization using multi-objective genetic algorithms.

The identified variables in the sensitivity analysis were used as decisions variables for the optimization step to improve the performance of the process. The optimization was carried out using the Genetic Algorithm Toolbox included in MATLAB. In a previous work Ponce-Rocha et al. (2022) found that the best working condition for genetic algorithms in MATLAB together with Aspen Plus was having a population of 100 and generations of 50.

### 3. Results

The framework was evaluated using the production of phytosterols and the process to produce phytosterols and biodiesel.

#### 3.1. Case study A: phytosterols production

The identifiability analysis largely depends on the interpretation of the sensitivity function of parameters and variables with respect to model outputs, usually corresponding to the measured variables such as operating costs or gross profit. The sensitivity analysis allowed to identify 6 variables with the highest impact in the operating cost, gross profit and net earnings. Table 1 illustrates the identified variables. For this case the confidence factor was 0.95-0.99 %. Figure 2 shows the significant variables for the operating cost, gross profit and the net earnings defined as the difference between the gross profit and operating costs. The results show that 3 model variables were especially important for the 3 output variables, 1 variable is significant for 2 output variables and 1 variable is important for the operating cost; the identified operating and design variables were employed in the optimization step.

Figure 2. Variable significance ranking (only the first 7 highest ranking variables are shown) for case A model outputs based on the sensitivity measure of gross profit, operating costs and, net earnings.

Table 1. Results of Sensitivity analysis for case study A

Variable	Gross profit, %	Operating costs, %	Net earnings, %
F <sub>102</sub>	0.93	<b>11.6</b>	8.4
T <sub>102</sub>	<b>91.9</b>	1.0	<b>56.9</b>
T <sub>106</sub>	0.17	<b>79.8</b>	<b>61.9</b>
TF <sub>2106</sub>	1.72	<b>35.3</b>	<b>28.5</b>
RC <sub>CV</sub>	1.28	<b>34.5</b>	<b>27.6</b>
P <sub>102</sub>	<b>2.8</b>	0.5	1.6

### 3.2. Case study A-B: phytosterols and biodiesel production.

Figure 3 shows the identified variables with high impact in the output variables for process A-B. Table 2 illustrates the variables with high impact in the operating costs, gross profit and the net earnings (defined above) and, the percentage of relevance in process A-B.

Figure 3. Variable significance ranking (only the first 7 highest ranking variables are shown) for case A-B model outputs based on the sensitivity measure of gross profit, operating costs and, net earnings.

Table 2. Results of sensitivity analysis for case study A-B

Variable	Gross profit, %	Operating cost, %	Net earnings, %
T <sub>102</sub>	<b>67.3</b>	0.14	0.41
F <sub>405</sub>	<b>57.2</b>	<b>79.9</b>	<b>79.8</b>
REXT <sub>2</sub>	<b>13.1</b>	<b>15.1</b>	<b>15.1</b>
BOR <sub>EXR2</sub>	4.4	<b>16.2</b>	<b>16.3</b>
P <sub>EXT</sub>	<b>25.2</b>	7.0	7.1
R <sub>Dest1</sub>	0.98	<b>53.9</b>	<b>53.9</b>

### 3.3. Results of the optimization for case study A

Once sensitivity measures have identified the significant variables in the process, the following step is to find out the optimal operating conditions with the aim of reducing the operating costs and increasing the net profit of the system. The variables related and identified with the gross profit were the temperature and pressure in the stream 102 (T<sub>102</sub>, P<sub>102</sub>, respectively); for the operating costs, the flowrate for stream 102 (F<sub>102</sub>), temperature of the flash unit 1 (T<sub>106</sub>), temperature for flash 2 (TF<sub>2106</sub>), reflux ratio (RC<sub>CV</sub>) were related and identified; a finally for the net earnings, the variables identified for the operating costs were also selected adding the temperature of the stream 102 (T<sub>102</sub>). The purple diamond (right and lower side of the plot) illustrates the value of the objective function for the base

case scenario (without optimization). The light blue triangles show the values of the objective function when the most important variables identified with the operating costs in the sensitivity analysis step, (see red and bold values in Table 1) were used as manipulated variables in the optimization task, the results showed a reduction of operating costs of about 4.5 % with respect to the base case, and a small increase in gross profit (about 3.4 %) as illustrated by the star with the same color. Similar case was observed when the optimization was performed using the significant variables for gross profits (see red and bold values in Table 1), here it was possible to see an increase of 4.3 % gross profit and only 3.0 % of reduction in the operating costs as illustrated by green star. In the case of net earnings, a considerable increase in profits was obtained (4.3 %) and a reduction of 4.6 % in operating costs was reached compared to the base case scenario as it is illustrated by the blue star. In the case of the optimization tasks using all the available manipulated variables (11 variables), it resulted in an increase of 3.7 % in the profit and a reduction of 2.1 % in the operating costs (see red star in Figure 4).

Figure 4. Pareto front to determine the optimal design case A.

### 3.4. Results of the optimization for case study A-B.

The results of case study A-B are shown in the Pareto front illustrated in Figure 5. The highest improvement was found when the identified variables using the net earnings (see red and bold values in Table 2) were used in the optimization step; the energy cost decreased by 4.4 % and the profit increased 5.02 % compared with base case scenario (purple diamond and blue star, respectively in Figure 5). When the optimization was performed using the 32 manipulated variables of the process A-B, an increase in profit of 3.02 % and a decrease in operating costs of 3.87 % (illustrated with the red star) were found compared with the base case scenario. The optimization results for the variables selected to reduce energy costs (see color red values in Table 2) provided good results because the reduction in operating costs was 4.2 %, but the increase in the profits was only 0.27 % (see light blue star). A similar case was observed when the variables with higher impact for the gross profit (see color red values in Table 2), where it was possible to increase 4.6 % the gross profit and decrease the energy consumption by 0.47 % (see green star).

Figure 5. Pareto front to determine the optimal design case A-B.

During the optimization of the 32 variables, the optimization time was 10.56 hours, while the optimization time using only the variable identified in the sensitivity analysis was 6.95 hours, that is, the computational time was reduced 34.2 %, in addition with better results.

#### 4. Conclusion

A framework for a more efficient optimization task was developed. The sensitivity analysis revealed that based on the objectives (operating costs, gross profit and net earnings) only a few variables had an impact in the magnitude of the sensitivity measure. It was possible to observe that the identified variables were the most important in the optimization problem, allowing to reduce computing time and improving the optimal results. The sensitivity analysis generated for the variables provided an accurate picture in the selection of high impact variables with respect to the objective established for each process section and, this can be clearly seen in the optimization results for both case studies. The results also showed that was possible to find a better alternative design and operation of the plant in comparison to the base case scenario.

# Effect of coalescence models on the prediction of the separation of dispersed oil-water pipe flows

Nikola Evripidou,<sup>a</sup> Federico Galvanin,<sup>a</sup> Panagiota Angeli,<sup>a</sup>

<sup>a</sup> *Department of Chemical Engineering, University College London, London WC1E 7JE, UK*

## Abstract

The effect of coalescence models on the prediction of the separation of dispersed oil-water pipe flows was assessed using a one-dimensional mechanistic model. The mechanistic model predicts the formation and evolution of four characteristic layers along the pipe: a pure water layer at the bottom, a flotation/sedimentation layer, a dense-packed zone, and a pure oil layer on the top. It was shown that the film drainage coalescence model by Jeelani and Hartland (1994) that considers interfacial mobility produces good predictions at low mixture velocity, but it depends on the flowrate. The asymmetric film drainage coalescence model by Henschke et al. (2002) is independent of the mixture velocity and the dispersed-phase fraction, and produces reasonable predictions. There was small deviation between the model outputs in the presence of the four characteristic layers, but further investigation of the regions where a single dense-packed layer persists is required.

**Keywords:** coalescence; liquid-liquid; dispersion; separation; modelling

## 1. Introduction

Liquid-liquid pipe flows are common in the petroleum industry. Deepwater and marginal fields with lower volumes of reserve entail new development challenges, while heavy oils and mature wells require water flooding to enhance production. Increased volumes of water in the pipelines affect the flow, as they can alter the spatial configuration of the two immiscible phases. Considering the high cost associated with oil extraction and separation, as well as the increased demands for further offshore drilling, ensuring a successful and economical flow of oil-water mixtures is essential in optimising transportation and downstream separation of the extracted oil. Additionally, subsea separation facilities are used to reduce the cost and space requirements of remote deepwater operations. The oil-water flows in pipes are often in the dispersed pattern. Models that can predict flow pattern transitions in unstable dispersed pipe flows are essential during both design and operation of industrial facilities.

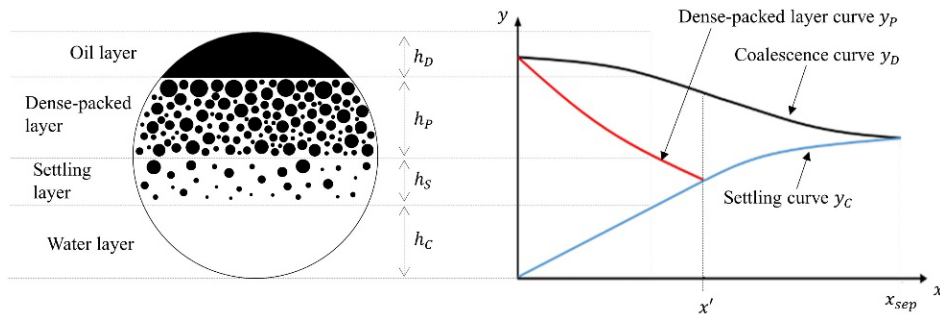

Henschke et al. (2002) developed a mechanistic model that predicts the evolution of heights of the characteristic layers that develop in separating batch dispersions as well as the average drop size. The model uses coalescence time correlations based on asymmetrical film drainage between the drops. Pereyra et al. (2013) attempted to extend Henschke's model to one-dimensional pipe flows by changing the time scale to a length scale. Evripidou et al. (2019) further modified the model to account for hindered settling of drops in dense dispersions. Another coalescence model was proposed by Jeelani and Hartland (1994) and is based on the interfacial mobility. In this work, we use the mechanistic model as presented in Evripidou et al. (2019). We consider both the

*asymmetric film drainage coalescence model* by Henschke et al. (2002) and the *interfacial mobility film drainage coalescence model* by Jeelani and Hartland (1994), to assess their ability to predict the formation and evolution of the characteristic layers in a pipe, for different oil-in-water dispersed flows.

## 2. Model description

Four characteristic layers may emerge in a separating dispersed pipe flow. In an oil-in-water dispersion, these are a pure water layer at the bottom, a settling layer (SL), a dense-packed layer (DPL), and a pure oil layer at the top. Figure 1 shows schematically these layers. The thickness of each layer depends on the drop settling (flotation/sedimentation) rate and the coalescence rate of drops, with their homophase. The drop size may also change through drop-drop coalescence.

**Figure 1: Diagram of the cross-sectional area of the pipe for an oil-in-water dispersion and diagram of the evolution of the characteristic layers.**

The mechanistic model is applicable to liquid-liquid pipe flows where the separation is primarily gravity-driven. A constant mixture velocity,  $u_M$ , is assumed for both phases – this allows velocity profiles to be ignored, which means that there is no exchange of momentum between layers. For the dispersed layers, monodisperse drop distributions are assumed for simplification, while interfacial tension is considered constant. Lastly, drop break-up and turbulence effects are neglected. In what follows, the model equations associated with coalescence are briefly discussed.

### 2.1. Coalescence analysis

#### 2.1.1. Drop-interface coalescence

Accumulation of drops near the top of the pipe results in coalescence and the formation of a pure oil layer of thickness  $h_D$ . Assuming a monodispersed DPL with drops of diameter  $d_{p,I}$ ,

$$\frac{dh_D}{dx} = \frac{2\varphi_I d_{p,I}}{3\tau_I u_M}, \quad (1)$$

where  $\tau_I$  is the drop-interface coalescence time. The oil fraction at the interface  $\varphi_I$  is taken as approximately equal to 1.

#### 2.1.2. Drop-drop coalescence

Drop-drop coalescence is considered only in the DPL. Assuming that in each step, all drops within the DPL are of equal size,  $d_{p,I}$ ,

$$\frac{d(d_{p,I})}{dx} = \frac{d_{p,I}}{6\tau_C u_M}. \quad (2)$$

where  $\tau_C$  is the drop-drop coalescence time.

### 2.1.3. Coalescence time

Two coalescence models are considered. These are outlined in table 1.  $d_{p,0}$  is the drop size at the inlet,  $\mu$  is viscosity,  $\rho$  is density,  $\sigma$  is the interfacial tension whereas the subscripts C and D refer to the continuous and dispersed phases respectively;  $g$  is the gravitational constant.

**Table 1: Coalescence models**

<i>Asymmetric film drainage model</i>	<i>Interfacial mobility film drainage model</i>
Drop-interface coalescence time: $\tau_I = \frac{(6\pi)^{\frac{7}{6}} \mu_C r_a^{\frac{7}{3}}}{4\sigma^{\frac{5}{6}} H^{\frac{1}{6}} r_{F,I} r_V^*} \quad (3)$	Drop-interface coalescence time: $\tau_I = \frac{\tau_{I,0} d_{p,I}}{h_P} \quad (9)$
Drop-drop coalescence time: $\tau_C = \frac{(6\pi)^{\frac{7}{6}} \mu_C r_a^{\frac{7}{3}}}{4\sigma^{\frac{5}{6}} H^{\frac{1}{6}} r_{F,C} r_V^*} \quad (4)$	Drop-drop coalescence time: $\tau_{I,0} = \frac{3\pi\mu_C r^4}{4(1+2m)F\delta_r^2} \quad (10)$
Drop-drop contact radius: $r_{F,C} = 0.3025 d_{p,I} \sqrt{1 - \frac{4.7}{La+4.7}} \quad (5)$	Modified coalescence equation: $\frac{dh_D}{dx} = \frac{2\phi_I h_P}{3\tau_{I,0} u_M} \quad (11)$
Drop-interface contact radius: $r_{F,I} = \sqrt{3} r_{F,C} \quad (6)$	Drop-interface film radius: $r = d_{p,0}^2 \sqrt{\frac{ \rho_C - \rho_D  g}{12\sigma}} \quad (12)$
Channel contour radius: $r_a = 0.5 d_{p,I} \left( 1 - \sqrt{1 - \frac{4.7}{La+4.7}} \right) \quad (7)$	Force due to gravity: $F = \frac{\pi d_{p,0}^3  \rho_C - \rho_D  g}{6} \quad (13)$
Modified Laplace number: $La = \left( \frac{ \rho_C - \rho_D  g}{\sigma} \right)^{0.6} h_P^{0.2} d_{p,I} \quad (8)$	Critical film thickness: $\delta_r = 0.267 \left( \frac{\pi r^4 H^2}{6\sigma F} \right)^{\frac{1}{7}} \quad (14)$

The left column of table 1 shows the *asymmetric film drainage coalescence model*, which depends on the deformation of the drops. Deformation increases with dense packed layer thickness below the drop considered. Two unknown parameters are present in this model: the Hamaker coefficient,  $H$ , and the asymmetry parameter,  $r_V^*$ .  $H$  is set to  $10^{-20}$  N m as proposed by Henschke et al. (2002) for all systems.  $r_V^*$  is system specific and can be obtained experimentally.

The right column of table 1 presents the *interfacial mobility film drainage coalescence model*. This coalescence model does not depend on drop size. Instead, the model allows equation (1) to be simplified into equation (11) through the use of equation (9), making  $h_D$  independent of  $d_{p,I}$ . The fitted parameter  $m$  is the interface mobility, i.e. the sum of the mobilities due to induced circulation in the adjacent phases and the interfacial tension gradient and is characteristic of each system. When  $m = 0$  the velocity at the interfaces on both sides of the draining film is 0, and the surfaces are deemed immobile; when  $m = 1.5$  the velocity at one of the interfaces is 0 while the velocity gradient at the other surface is 0. Under these conditions, film drainage, and thus the rate of coalescence, is extremely slow. Other values of  $m$  are also possible and correspond to different surface velocities and velocity gradients. Values of  $m$  larger than 1.5 correspond to more mobile interfaces.

### 3. Results and discussion

#### 3.1. Experimental methods

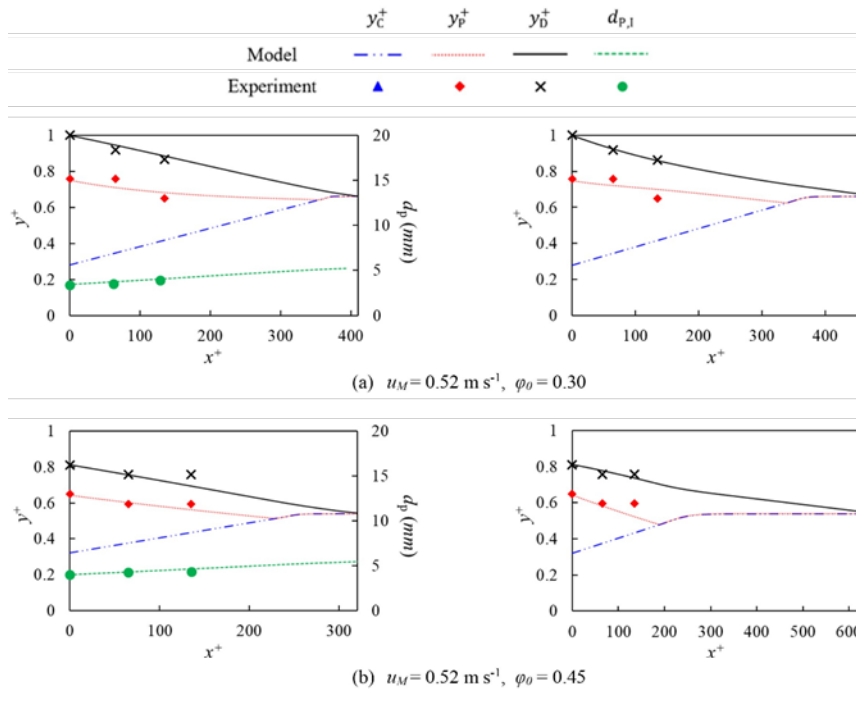

The experimental data used to assess the performance of this model were obtained by Voulgaropoulos (2018) in a two-phase liquid-liquid flow facility discussed in detail in Voulgaropoulos et al. (2016). In the experiments tap water and oil ( $828 \text{ kg m}^{-3}$ ,  $5.5 \text{ mPa s}$ ) were used as test fluids. The test section comprised of transparent acrylic pipes with an internal diameter of  $37 \text{ mm}$  and overall length of around  $8 \text{ m}$ . Partial dispersions of oil in water were generated at the inlet of the test section using a multi-nozzle mixer. High-speed imaging was employed at three locations along the spanwise dimension of the pipe to enable the identification of the flow patterns. A dual-conductance probe was implemented to measure the local volume fractions and the drop size distributions of the dispersions. Measurements were taken every  $2 \text{ mm}$ , spanning the whole pipe diameter.

#### 3.2. Results and discussion

Three case studies were investigated (c.f. Table 2). For each case, we solved the mechanistic model twice, implementing a different coalescence model each time, using gPROMS ModelBuilder at intervals of  $0.1 \text{ m}$  pipe length.  $C_h$  was taken as  $0.01$  as suggested by Evripidou et al. (2019) and  $r_V^*$  was set to  $0.007$  as suggested by Pereyra et al. (2013).  $m$  was fitted to experimental data obtained at  $u_M = 0.52 \text{ m s}^{-1}$  and was found to be  $360$ . The resulting flow profiles were nondimensionalized using the pipe diameter and are presented in Figures 2 and 3.

**Table 2: Inlet conditions of the experiments**

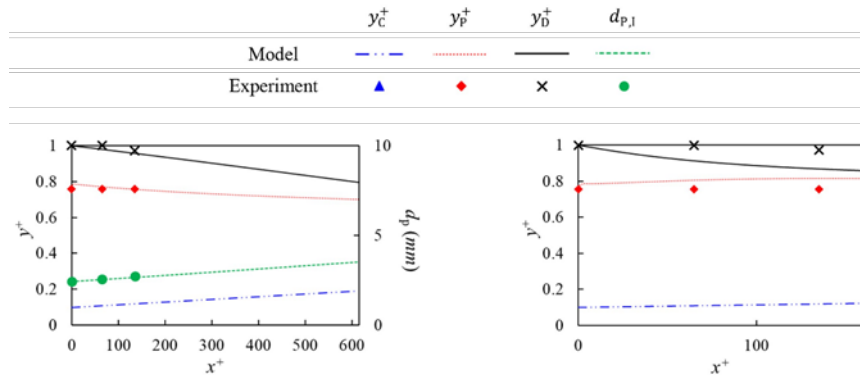

$u_M \text{ (m s}^{-1}\text{)}$	$\varphi_0$
<b>0.52</b>	0.30
	0.45
<b>1.04</b>	0.60

**Figure 2: Model predictions of the asymmetrical film drainage coalescence model (left) and the interfacial mobility film drainage coalescence model (right) for  $u_M = 0.52 \text{ m s}^{-1}$ .**

Figure 2 shows the two case studies at  $u_M = 0.52 \text{ m s}^{-1}$  and  $\varphi = 0.30$  and  $0.45$ . The two mixtures separate in a similar fashion and both coalescence models predict the separation with reasonable accuracy. The rate of drop-settling is large enough to deplete the SL first. On the contrary, the DPL persists throughout the pipe and coalescence controls the rate of separation.

Although both coalescence models show reasonable agreement with experimental data, the *interfacial mobility film drainage model*, where the coalescence rate is a function of the DPL thickness shows a better fit to the experiments. Despite that, the SL is depleted at similar axial lengths for both cases with deviations of 13% or less in  $x'^+$  between the predictions of the two models. The predictions of the interfacial mobility film drainage model for the total separation length are consistently larger than the predictions of the asymmetric film drainage model. Specifically, for the case with oil fraction of 0.30, the interfacial mobility film drainage model predicts an  $x_{sep}^+$  of 455, while the prediction of the asymmetric film drainage model is 9% less at 412. This difference is even larger for the case of oil fraction of 0.45. For this case, the asymmetric film drainage model predicts a separation length of 320, while the other coalescence model predicts  $x_{sep}^+ = 624$ , a value that is almost twice as large. The above observations suggest that the models behave in a similar manner at the pipe locations where all four characteristic layers are present, and any major deviations between the two arise past the point of depletion of the SL (i.e. at lengths  $x > x'$ ).

**Figure 3: Model predictions of the asymmetrical film drainage coalescence model (left) and the interfacial mobility film drainage coalescence model (right) for  $u_M = 1.04 \text{ m s}^{-1}$  and  $\varphi_0 = 0.60$ .**

Figure 3 presents the results obtained at a mixture velocity of  $1.04 \text{ m s}^{-1}$  and oil fraction of 0.60. The deviations in the predictions of the two models for this case study are significant. The coalescence model by Henschke et al. (2002) produces reasonable results with deviations of 2% or less to experimental measurements. On the other hand, the *interfacial mobility film drainage model* significantly overestimates the coalescence rate of drops with their homophase. As a result, the oil layer acquires a large thickness at the beginning of the pipe. This suggests that the mixture velocity may affect interfacial mobility and that  $m$  should be fitted for each mixture velocity.

Nevertheless, both models predict depletion of the DPL, which, according to Evripidou et al. (2022), occurs once the thickness of the DPL becomes smaller than the drop diameter along the interface. At this point, settling becomes the limiting separation mechanism and controls the rate of separation. Predictions of the complete flow profile

up to the point of total separation are not possible with the current model, as it is only applicable to regions where a DPL is present and coalescence controls the rate of separation.

#### 4. Conclusions

The paper presents a comparison between two coalescence models that can be used in mechanistic models of separating dispersed pipe flows. At the low mixture velocity, both coalescence models capture the drop-interface coalescence adequately. The *interfacial mobility film drainage model* shows better agreement with experimental data, hence may be preferred over the *asymmetric film drainage coalescence model*. The two models result in similar predictions for the length of depletion of the settling layer (SL), but the *interfacial mobility film drainage model* predicts significantly larger separation lengths  $x_{sep}$ . Hence, for the low mixture velocity, we concluded that the models behave similarly in pipe locations where all four layers are present, and any major deviations between the two models occur at pipe lengths greater than  $x'$  for which we have no experimental data. Therefore, further experimental studies, especially in the region  $x > x'$ , are needed to provide the necessary information to differentiate between the two coalescence models.

At the high mixture velocity, the *asymmetric film drainage coalescence model* shows good agreement with the experimental data. The *interfacial mobility film drainage model*, however, significantly overpredicts the rate of drop-interface coalescence. The observations suggests that the interfacial mobility coefficient  $m$  varies with  $u_M$ , but not with oil fraction  $\varphi$ . To the contrary,  $r_V^*$  is specific to the oil-water system but independent to both  $u_M$  and  $\varphi$ , hence the *asymmetric film drainage model* may be preferred for cases with variable flowrates. Nevertheless, both coalescence models predict the depletion of the DPL at the high mixture velocity. To account for the depletion of the DPL a different approach must be used such as that described in Evripidou et al. (2022).

## Abstract

Machine learning techniques for building surrogate models typically generate single-output expressions. However, Chemical Engineering processes are naturally multi-output, with several of the outputs depending on the same physico-chemical phenomena. This work is an extension of our previous work on Symbolic Regression aimed to learn interpretable models from data that reflect the shared physico-chemical phenomena as common bases in the derived expressions. To do so, we consider two multi-output algorithms: one based on multi-output linear squares regression, and the other one on an islands model. As case studies, we use real historical data from a C3/C4 splitter from an oil refinery. The results from the proposed multi-output algorithms are compared to those from the previous single-output algorithm and a multi-output Gaussian Process implementation. We conclude that both multi output strategies are competitive, and in some cases better, than the single-output one although within the same order of magnitude in the error in the validation set. In all cases the multi-output algorithms perform better than Gaussian Process.

**Keywords:** machine learning, surrogate modeling, symbolic regression, interpretable models, multi-output regression.

## 1. Introduction

Machine learning techniques for learning models from data are increasingly receiving attention within the Chemical Engineering community. As examples, the work of Eagle and Sahinidis (2022), developed a symbolic regression (SR) algorithm to obtain surrogate models for equations of state; and the work of Chakraborty et al. (2021), considers a machine learning technique to obtain interpretable models based on genetic feature extraction. Our own previous work in Ferreira et al., 2022a, also addresses the problem of learning an explicit interpretable model from data without a priori definition of the functional bases. The techniques used in all these examples are single output, meaning that if one wishes to derive expressions for multiple outputs, the algorithms must be repeatedly executed.

However, for many Chemical Engineering applications it is highly desirable to be able to learn models that result in common (interpretable) terms for those outputs that are known to depend on common phenomena. In Ferreira et al., 2022b, we proposed two multi output

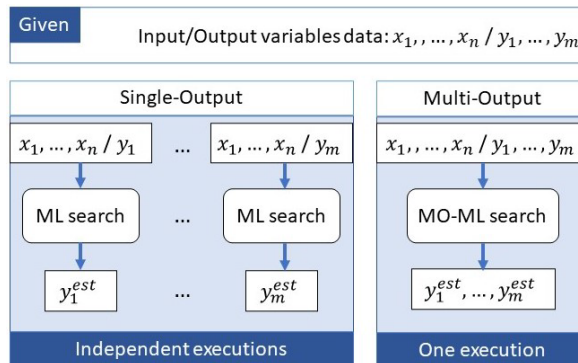

Figure 1 – Scheme of generation of surrogate models for several outputs with the same input data. Left: single-output algorithm executes to learn one model at a time. Right: the multi-output strategy learns all the models in the same run.

algorithms and tested them using benchmark functions or made-up data stemming from reaction engineering problems. In this work, we extend our previous contributions to learn multi-output interpretable models from real data from a distillation column that operates in an oil refinery. Specifically, we consider the data for the C3/C4 splitter in Ferreira et al. (2022a) and apply the two multi-output algorithms. The results from these, are compared with those from the previous single-output algorithm and a multi-output Gaussian Process implementation.

## 2. Algorithms

Figure 1 shows a scheme of the approaches considered in this work. On the left, we include the strategy used by most ML methods to solve multi-output surrogate modeling. This is, for each input-output dataset (represented by several vectors  $x$ , and one of the vectors  $y$ ), an individual execution is performed for each  $y_j$  to learn a model that relates it to the  $x$  variables. We named this strategy as the Single-Output (SO) approach. On the right, we consider the multi-output (MO) approaches where models for all  $y$  are learned in the same execution. Figure 2 shows the specific algorithms used in this work. In all cases, KP refers to the iterative algorithm that solves SR problems from input-output data. KP searches for models that are linear combinations of nonlinear expressions. These nonlinear expressions are the functional bases  $f_i^j$  that are created and modified by operations of Genetic Programming, and the coefficients  $\beta_i^j$  are calculated by Ordinary Least Squares (OLS). The details about KP have been published in Ferreira et al. (2022a). The first multi-output strategy,  $\text{MO}_{\text{MLR}}$ , performs a multi-output linear regression based on OLS in the step of calculation of the coefficients. This change forces term sharing between the  $y_j$  models at each iteration. The second multi-output strategy,  $\text{MO}_{\text{IM}}$ , is based on the islands model for parallelization of evolutionary algorithms.  $\text{MO}_{\text{IM}}$  alternates independent search steps with migration steps. In the independent search steps, each output variable  $y_j$  is learned as a SO strategy; in the migration step the functional bases of each output variable (that were searched in the independent executions) are shared with the others output variables. Thus, in the next independent search step, each independent search for  $y_j$  starts with all the functional bases of the other  $y$ . It is important to note that contrary to the other multi-output strategy,  $\text{MO}_{\text{IM}}$  does not force the final expressions of the models to all have the same functional bases but enhances the probability of that happening. More details on the MO algorithms can be found in Ferreira et al. (2022b).

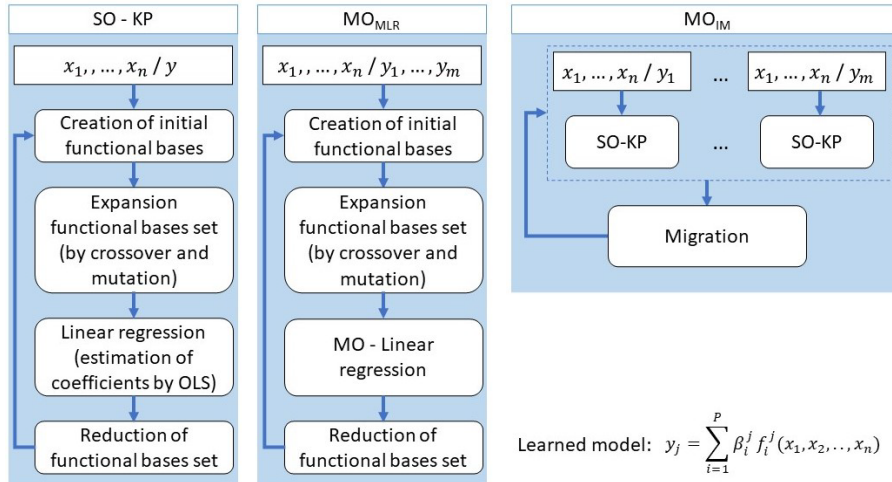

Figure 2 – Scheme of algorithms used in this work.

### 3. Case studies

As mentioned earlier, we applied the MO algorithms to the C3/C4 oil refinery splitter in Ferreira et al. (2022a). In such splitter, the inlet stream is mainly composed of C3 and C4 hydrocarbons, while other hydrocarbons with 1, 2, 5 and 6 carbons, as well as H<sub>2</sub> and H<sub>2</sub>S are the main minor components. The system is continuously monitored through eight online sensors that measure the feed, reboiler, head and distillate temperatures; the reflux, bottoms and distillate flows; and the bottom’s pressure. These 8 variables are the input variables to the models, i.e.  $x = [T_{feed}, F_{reflux}, F_{bottoms}, F_{distil}, T_{reb}, T_{head}, T_{distil}, P_{bottom}]$ .

The quality of the outlet streams is monitored through laboratory experiments (chromatography) that determine the composition of 19 species with daily or bi-daily frequency. As case studies we evaluate the development of models in two instances. One to obtain the models of the volumetric fraction of C4s in the distillate and the volumetric fraction of C3s in the bottoms (reboiler)  $y_{case-1} = [C4_{distillate}, C3_{reboiler}]$ . These fractions evaluate the quality of the outlet streams and depend on the temperature and pressure of the distillate/reboiler; we do not expect the expressions for the outlets to share these terms. In the second case study, we are interested in developing models for the volumetric fractions of the seven C4 hydrocarbons in the distillate  $y_{case-2} = [1,3\text{-butadiene}, 1\text{-butene}, \text{cis-2-butene}, \text{isobutane}, \text{isobutene}, \text{n-butane}, \text{trans-2-butene}]$ . This is the case where we expect the output variables to share many terms.

To compare the three algorithms (SO-KP, MO<sub>MLR</sub> and MO<sub>IM</sub>), we followed the statistical procedure in Alba and Luque (2005). This is, first, one hundred independent executions were performed for each algorithm; then, the Friedman test was used as an omnibus test to compare the RMSE distributions over validation sets. Finally, a pairwise Wilcoxon signed test to the RMSE distributions was performed in those cases in which differences among the distributions were found through the Friedman test. All the statistical tests were performed with a confidence level of 99%.

Figure 3 – Absolute differences of the estimation and data point by the best model with  $MO_{IM}$  and GP, over validation set.

## 4. Numerical results and discussion

### 4.1. Case study 1

Based on Friedman test we found that for  $y_1$  there is statistical difference between the distributions of the RMSE of the models obtained with the three algorithms ( $p_{value} = 4.81 \cdot 10^{-12}$ ), and for  $y_2$  there is not statistical difference ( $p_{value} = 0.0105$ ), with a median of RMSE between 0.062 and 0.067.

From the Wilcoxon signed rank test for  $y_1$ , we found that there is no statistical difference between the error's distributions of the models obtained by  $MO_{IM}$  and  $MO_{MRL}$  ( $p_{value} = 0.033$ ), whereas the models obtained by SO-KP had an overall lower median for RMSE ( $p_{value} = 2.51 \cdot 10^{-9}$  for  $MO_{IM}$  and SO-KP and  $p_{value} = 2.35 \cdot 10^{-7}$  for  $MO_{MRL}$  and SO-KP). The RMSEs are: 0.051, 0.056 and 0.057, respectively for SO-KP,  $MO_{MRL}$  and  $MO_{IM}$ .

Figure 3 presents the absolute difference between estimation and data over the validation set, for the second output variable by the best model obtained by  $MO_{IM}$ , and the one obtained using the multi-output Gaussian Process algorithm (GP, implemented in the *scikit-learn* package). From the figure, we can see that all estimations obtained with the KP-based algorithm are better than the ones obtained with GP. This is reinforced by the value of RMSE of the model obtained by GP: 0.088. It is worth commenting that all the values presented in these figures were normalized to preserve data confidentiality.

Table 1 shows the best model for each output variable obtained with each KP-based algorithm. It can be seen that the models obtained with  $MO_{IM}$  correctly capture the dependence of  $y_1$  on  $T_{head}$  and  $T_{distil}$ , and of  $y_2$  on  $T_{reb}$  and  $P_{bottom}$ . On the other hand, those obtained with SO-KP include almost all inlet variables in the mathematical expression. Thus, despite its slightly largest RMSE, we consider the  $MO_{IM}$  model to be superior.

### 4.2. Case study 2

In this case, based on Friedman test, we found that for  $y_1$  there is no statistical difference between the distributions of the RMSE of the models obtained with the three algorithms. For the rest of the output variables there exists statistical difference.

Table 1 – The best learned models for the second output variable with SO-KP, MO<sub>IM</sub> and MO<sub>MLR</sub> algorithms. The coefficients are presented as Greek letters in order to preserve confidentiality.

y <sub>1</sub>	SO-KP	$\beta_1^1 \frac{F_{reflux}^2}{(F_{reflux} + P_{bottom})T_{head}} + \beta_2^1 \frac{F_{reflux}F_{distil}}{T_{head}P_{bottom}} +$ $\beta_3^1 \frac{T_{reb}}{T_{head}P_{bottom}} + \beta_4^1 \frac{F_{reflux}T_{distil}}{T_{head}P_{bottom}} + \beta_5^1 \frac{F_{reflux}^2}{P_{bottom}} +$ $\beta_6^1 F_{reflux} + \beta_7^1 F_{bottoms} + \beta_8^1 F_{distil} + \beta_9^1 T_{feed} + \beta_{10}^1 T_{head} +$ $\beta_{11}^1 T_{feed}(F_{bottoms} + F_{distil}) + \beta_{12}^1 T_{distil} +$ $\beta_{13}^1 \left( \frac{T_{head}}{T_{reb}} \right)^{\left[ (P_{bottom} - F_{distil}) \frac{F_{reflux} - F_{bottoms}}{T_{distil} - P_{bottom}} \right]} +$ $\beta_{12}^1 (F_{bottoms} + F_{distil})F_{distil}$
	MO <sub>IM</sub>	$\gamma_1^1 F_{distil} + \gamma_2^1 P_{bottom} + \gamma_3^1 F_{reflux} + \gamma_4^1 T_{distil} + \gamma_5^1 T_{feed} +$ $\gamma_6^1 T_{reb} + \gamma_7^1 F_{reflux}F_{distil} + \gamma_8^1 F_{reflux}T_{feed} +$ $\gamma_9^1 (F_{reflux}^2 - T_{head} T_{distil}) + \gamma_{10}^1 T_{reb}T_{head}$
	MO <sub>MLR</sub>	$\delta_1^1 P_{bottom} + \delta_2^1 T_{head} + \delta_3^1 F_{distil} + \delta_4^1 F_{reflux} + \delta_5^1 T_{feed} +$ $\delta_6^1 F_{reflux}^2 + \delta_7^1 F_{reflux}T_{reb} + \delta_8^1 T_{reb} + \delta_9^1 \frac{T_{feed}F_{bottoms}T_{reb}}{T_{distil}}$
y <sub>2</sub>	SO-KP	$\beta_1^2 \left( \frac{F_{reflux} - F_{bottoms}}{F_{distil} + T_{reb}} \right) + \beta_2^2 F_{bottoms} + \beta_3^2 F_{reflux} +$ $\beta_4^2 F_{bottoms} + \beta_5^2 P_{bottom} + \beta_6^2 \frac{F_{bottoms} - F_{reflux}}{2F_{distil} - T_{distil}} + \beta_7^2 T_{reb} +$ $\beta_8^2 F_{distil}$
	MO <sub>IM</sub>	$\gamma_1^2 \frac{F_{bottoms}}{T_{reb}} + \gamma_2^2 F_{reflux} + \gamma_3^2 F_{bottoms} + \gamma_4^2 P_{bottom} + \gamma_5^2 T_{reb} +$ $\gamma_6^2 P_{bottom}^2 + \gamma_7^2 F_{reflux}T_{reb} + \gamma_8^2 F_{reflux}F_{distil}$
	MO <sub>MLR</sub>	$\delta_1^2 \left( \frac{T_{feed}}{F_{reflux} - T_{reb}} - \frac{P_{bottom}}{T_{head}} \right) + \frac{\delta_2^2 F_{distil}}{F_{reflux} - T_{reb}} +$ $\frac{\delta_3^2 P_{bottom}}{T_{feed}} + \delta_4^2 F_{reflux} + \delta_5^2 F_{bottoms} + \delta_6^2 P_{bottom} +$ $\delta_7^2 T_{reb} + \delta_8^2 T_{head} + \delta_9^2 (F_{reflux} - T_{feed})F_{bottoms}T_{distil} +$ $\delta_{10}^2 (F_{bottoms} - F_{reflux})T_{reb}$

For output variables y<sub>2</sub> to y<sub>7</sub>, the Wilcoxon signed rank test showed that there is not statistical difference for three output variables, MO<sub>IM</sub> has lower median RMSE than SO-KP for two output variables, and SO-KP lower than MO<sub>IM</sub>. in one case. Comparing SO-KP with MO<sub>MLR</sub>, SO-KP median RMSEs were lower than MO<sub>MLR</sub> in two cases. Finally, comparing MO<sub>MRL</sub> and MO<sub>IM</sub>, there was no statistical difference in two cases, MO<sub>IM</sub> had lower RMSEs in three cases, and MO<sub>MRL</sub> lower than MO<sub>IM</sub>, in one case.

Then, the models obtained by multi-output algorithms generally perform better in terms of RMSEs. MO models also showed better performance in terms of term sharing which is coherent with the fact that in this case, output variables are strongly related, and the multi-output learning is enriched by incorporation of data from all variables.

## 5. Conclusions

In this paper we tested the performance of two multi output (MO) strategies to learn an interpretable models (symbolic regression) where the bases functions were learned via genetic programming and the coefficients via least squares regression. The first MO strategy,  $MO_{MLR}$ , is based on the use of a multi-output linear regression instead of a single-output linear regression. The second algorithm,  $MO_{IM}$ , is based on the islands model for parallelization of evolutionary algorithms, in which steps of independent search alternate migration steps where the best functional bases are exchanged. The models obtained by the multi-output algorithms were compared with the single-output executions for each output variable, and a multi-output Gaussian Process algorithm.

Data from a real C3/C4 splitter from an oil refinery was used in the case studies. We considered a first case where the output variables were weakly related by the physico-chemical phenomena, and a second case, where the output variables were strongly related. We showed that in the first case study, the island based multi-output strategy  $MO_{IM}$  was able to identify the variables that were relevant for each output variable model, although having a slightly worse performance in terms of RMSE (in the validation set). In the second case study, multi-output strategies performed better than the single-output one, although within the same order of magnitude in RMSE. The three algorithms performed better than the multi output Gaussian Process one.

## Abstract

As an application of advanced analytics (AA) in supply chains (SCs), to model supply chain resilience (SCR) of transactions, logistics, operations, etc., of such complex representation of networks, we propose a supervised machine learning approach as a predictive analytics decision regression modelling framework that uses a coefficient setup MIQP (mixed-integer quadratic programming) technique. This can determine optimisable surrogate models to correlate independent X variables (e.g., resistance and recovery of the SC resilience) to the dependent Y variable SCR considering a dynamic behaviour of the SC with lag- and dead-time. A novel methodology to quantify SCR, based on a tree of continuous x and binary y variables of resistance (avoidance and containment) and recovery (stabilisation and return), considers ad hoc relationships of x and y to be part of the SCR predictions in the machine learning MIQP identification method. Such SCR algebraic or analytical formulas obtained in this constrained decision regression approach (a type of predictive analytics) can be used in optimisation and control problems of prescriptive and detective analytics types of AA. The proposed model is applied in an oil and gas case pertaining to liquid natural gas (LNG) and its leaks known as boil-off gas (BOG). The vapors generated by the leaks or venting of BOG in the LNG supply chain reduces the SCR of this commodity. There are losses of materials, environmental impacts, reduction in the calorific value of the LNG to be re-gasified, potential safety issues, to name a few. This research aims to introduce a methodology to model and predict SCR in a general way (by a new design as example), but particularly, covers the digital transformation implementations that can potentially lead to an enhanced resilience in the supply chain of LNG towards the desired level of digital supply chain resilience (DSCR).

**Keywords:** supply chain, resilience, advanced analytics, surrogate modelling.

## 1. Introduction

Making determinations on complex design, operation, and control of today's industry may count on recent capabilities of advanced analytics (AA) that is widespread in machine learning techniques and big data novelties and applications. Particularly, supply chain and logistics organisations operate in a data-rich environment, managing huge amount of data about customers' demands, offerings of suppliers, previous and current orders, satisfaction levels and reviews, shipment movements, locations of containers, temperature, humidity, among others. Hence, many supply chain organisations have put data analytics at the top of their strategic priorities. This is driving interest in smart analytics techniques designed to help diagnose operational issues, optimise network

planning, and predict future scenarios. As a branch of the so-called smart manufacturing, AA can consider multiple scopes, scales, scenarios, and layers to model and solve decision-making problems as found in the engineering management and decision science literature. It moves from the mature or old-fashion descriptive analytics of past activities to the needed cognitive analytics with self-learning and adaptive structures in both manufacturing systems and supply chains (Menezes et al., 2019a).

The proposed SCR modelling in this work uses a methodology that considers a MIP-based machine learning modeling approach with the objective of identifying the causation and correlation among (1) two parent inputs (resistance and recovery) and (2) their four child inputs (avoidance and containment, and stabilisation and return) of the SCR from Melnyk et al. (2014) as seen in Figure 1. This can guide directions in the investments on new design and digital transformation building blocks for improvement of the liquid natural gas (LNG) supply chain resilience that is impacted by the boil-off gas (BOG) losses during the shipping and its adjacent areas (upstream and downstream).

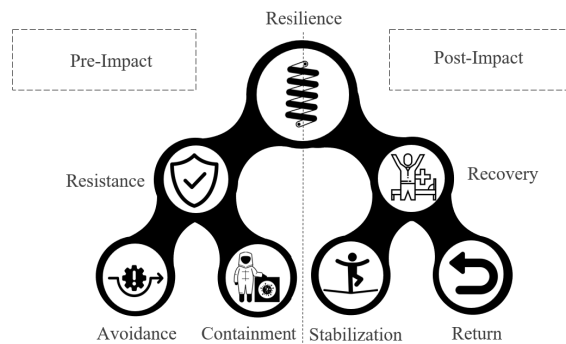

Figure 1: Tree of supply chain resilience (adapted from Melnyk et al., 2014).

## 2. Boil-off gas in the LNG supply chain

To be stocked and transported in the liquid state, natural gas (NG) requires very low temperatures, therefore it is very susceptible to heat invasion and other driven-forces and starts to boiling at  $-162\text{ }^{\circ}\text{C}$ . This vaporised LNG represents a substantial energy waste with a negative impact in economics, climate warming, and operational hazard. Henceforth, the LNG losses throughout the supply chain requires to be controlled and managed in the most efficient manner, avoiding the losses of BOG or containing it, if LNG boils. Also, if it is lost, measures to recovery the commodity to its initial product condition in terms of its properties and specifications (after the liquefaction plant).

Figure 2 illustrates potential deployment of internet-of-things (IoT), automated decision-making and controls, artificial intelligence (AI), etc., elements of the Industry 4.0 age on LNG vessels and their associated facilities. Besides the use of technology (more operational related) to increase SCR, other types of investments are related to changes in design, by changes in grassroots projects or retrofit of current assets. Among these investments, there are (1) new vessels propelled by LNG, (2) retrofit in current vessels to install liquefaction systems to liquefy the BOG; and (3) different storage tank inside the vessels considering the two main LNG vessel types, the MOSS and membrane. In the latter, as example, the membrane design is more resilient and advantageous due to many reasons, but mainly by its robust insulation, as it contains an amalgamation of multiple

layers of carefully selected materials that is split into two membranes (a primary and a secondary) that spans across almost one meter distance between the ship's inner hull and the LNG cargo.

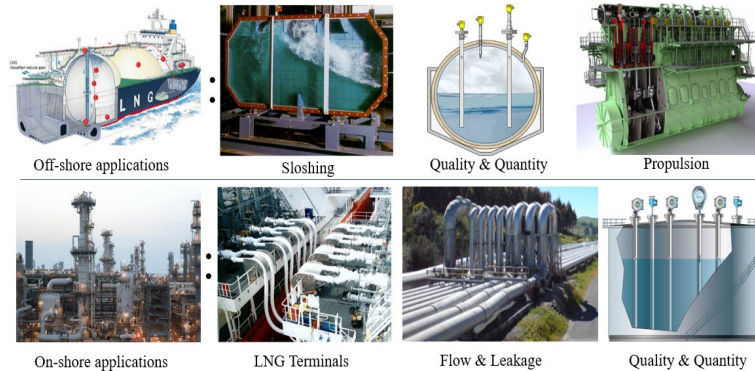

Figure 2: Potential investments to increase supply chain resilience.

### 3. LNG supply chain resilience stages

In the following, a detailed description of examples of resistance and recovery stages related to the BOG losses in the LNG supply chain is given.

#### 1) Resistance Stage

In the avoidance stage, supply chain resilience (SCR) can be associated to the supply chain vulnerability (SCV) for the BOG generation driven-forces. Some SCVs are the (a) fluctuation in the ambient temperature and tank pressure, and (b) sloshing (LNG fluid excessive movement and friction with its internal reservoir surfaces), which is influenced by excessive rolling of the ship during voyage. Besides, by augmenting the insulation between the ambient and the stored LNG layer in LNG ships is under constant development, and it is one of the main reasons the old MOSS type vessels are now progressively replaced with the new membrane type vessel. However, insulation enhancement is extensive work and requires excessive out of operations periods and expensive drydock repairs.

In the same context, controlling the tank pressure is a critical factor to avoid BOG generation, and this could be established with any sort of sensing-calculating-actuating (SCA) capability to proactively regulate the tank pressure (Menezes et al., 2019b). Moreover, route optimisation is an efficient methodology to main the ship voyage smooth and hence significantly reduce the time-period of the friction between the LNG and its tank surfaces, eventually reducing the BOG generation. Such an enhancement can be achieved via deploying artificial intelligence (AI) and big data (BD) enablers with the objective of calculating maritime records about waves, currents, and winds, among others to find optimised routes. From work experience, ship arriving late due to taking longer voyage route could have better economics compared to a ship that charted a shorter route but through rough waves that generated excessive BOG.

In the containment stage, the objective is to explore methodologies to contain and utilise the generated BOG within the LNG ship eco-system instead of losing it to the atmosphere.

Such enhancement can be via deploying re-liquefaction plants onboard the ship, which receive the generated BOG, re-liquefy it, and eventually direct it to the LNG storage tank. This non-I4.0 enhancement requires excessive time out of operations and drydock repairs due to the extensive pipe work involved. Another enhancement in this stage is directing the generated BOG towards the propulsion system of the ship, however limited percentage of LNG ships worldwide have this capability. Currently, there are two types of two stroke engines that deliver this flexible dual-fuel propulsion, that are MEGI (M-type, Electronically Controlled, Gas Injection), and XDF (low pressure 2-stroke engine). Most of the newly built LNG ships are either MEGI or XDF; however, despite some major marine engine manufacturers are starting to offer retrofitting ships solutions, this option may not be economically viable (Man Energy Solutions, 2022).

2) *Recovery Stage*: in this stage and its sub-stages of stabilisation and return, the objective is to achieve stabilisation and return post the generation of BOG, where it is not attainable to avoid, nor contain it. An envisaged enhancement in this stage is to deploy AI solutions with the objective to optimise receiving terminals pumps operation algorithms in a manner that assist in the recovery process. Similarly, another enhancement is injecting ethylene ( $\text{CH}_2=\text{CH}_2$ ) in the receiving terminals to enhance the calorific value and heat content of the delivered LNG during its re-gasification stage and injection in pipelines.

The aforementioned discussion is summarised in Table 1.

Table 1: BOG resilience tree.

Avoidance (On the ship), potential I4.0 enabler and desired function		
Tank temperature	Operational (I4.0)	Deploy
	Design (Retrofit)	Install enhanced insulation around the tank
Tank pressure	Operational (I4.0)	Deploy S-C-A to keep the pressure in the tank regulated
Optimise route	Operational (I4.0)	Deploy AI and BD to calculate maritime records about waves, currents, and winds, etc., and find optimised routes
Containment (On the ship), Potential I4.0 enabler and desired function		
Propulsion	Design (Grassroots)	Generated BOG fuelling propulsion systems
Re-liquefaction	Design (Retrofit)	Re-liquefy the BOG
Stabilisation (At receiving terminal), Potential I4.0 enabler and desired function		
Pumping at receiving terminals	Operational (I4.0)	Deploy AI to optimise operation of the pumps in receiving terminal (KBC, 2021)
Return (At the receiving terminal), Potential I4.0 enabler and desired function		
Injecting ethylene ( $\text{CH}_2=\text{CH}_2$ )	Operational	Inject ethane in the re-gasification stage in the receiving terminal to correct the calorific value and heat content of LNG

From the operational and design related projects as seen in Table 1, with I4.0 content or not, a plot can be sketched for the proposed resilience domains (resistance and recovery) that are function of the investments. This is shown in Figure 3, where two planes are highlighted to exemplify SCR investments more related to design and those with focus on operational investments (supposedly less expensive, but not such efficient in comparison with the design expenditures.

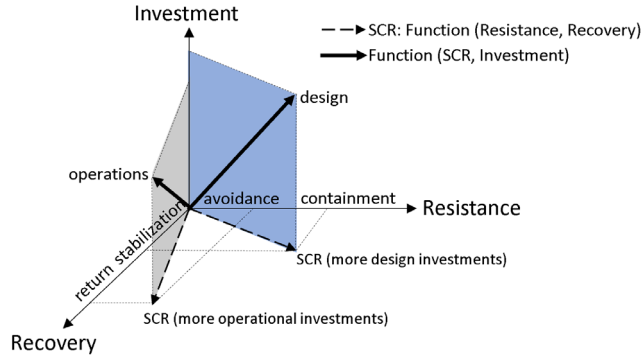

Figure 3. SCR investments in design and operations.

#### 4. Methodology and results

This research proposes a modeling approach for the supply chain resilience (SCR) concerning the BOG generation in the LNG supply chain by evaluating SCR in two distinct stages as shown in Figure 1: resistance and recovery, and their consequential sub-stages of: avoidance and containment (for resistance) and stabilisation and return (for recovery). The surrogates are built to represent dependent variables of interest  $Y$ , such as the SCR. Independent-dependent variations correlate as  $Y_i = f(X_j)$ . The input variables considered to form the surrogates represent the BOG resilience tree as in Table 1. When building surrogate models, it is important to consider some important aspects concerning the required data for training and testing, functional form of the surrogates and proper evaluation to verify their performance. A simplified framework methodology proposed by Franzoi et al. (2021a), as shown in Figure 4.

Figure 3: Framework for the surrogate model building strategy.

1) *Surrogate Model Building*: To model the SCR, bilinear surrogate models can be used, as shown in Equation (1) to calculate the dependent variable  $Y_i$  (see Franzoi et al., 2020).

$$Y_i = I_i + \sum_{j \in DV} b_{ij} X_j + \sum_{j \in IV} \sum_{k \in IV} c_{ijk} X_j X_k \quad \forall i \in DV, j \leq k, k \leq n \quad (1)$$

In which  $I_i$  is the intercept of each point  $i$  within dependent variables (DV), and  $b_{ij}$  and  $c_{ijk}$ , are the coefficients to be determined or estimated during the building process of the surrogate model by evaluating the accuracy of the input-output data to achieve the target of minimising the prediction error for each independent variable point (IV). This optimisation target is presented in Eq.(2) for minimising the least-squares error (LSE).

$$\text{Minimize} \sum_{p=1}^{n_{training}} (y_{ip} - Y_{ip})^2 \quad (2)$$

In which  $y_{ip}$  is the actual calculated using a simulation of the for the variable  $i$  at each point  $p$  within the training data set  $n_{training}$ , whereas  $Y_{ip}$  represents the calculated values using the surrogate model estimated coefficients for each independent variable  $i$  at each point  $p$ .

The dataset to construct the surrogate model is determined by concatenating the operational and design investments from Table 1. As example, if no installation of more efficient temperature insulation by using membrane technology instead of MOSS (independent variable  $X_2$ ), it is expected to have losses of the calorific value  $Y$  due to the no perfect control of the temperature (independent variable  $X_1$ ). The SCR modelling in this case is considered investment projects (operational- or design-related) that would avoid and contain the BOG or, if in the case of recovery, those measure that would stabilise or recovery to the initial stage of the calorific value  $Y$  in the beginning of the supply chain, from liquefaction plants to receiving terminals. Equation (3) is the surrogate for the calorific value  $Y$ . Cases of application of this method can be found in chemical engineering for applications on cutpoint optimization (Franzoi et al., 2020).and reactor systems where an adaptive sampling algorithm can converge to parameters of the surrogate formulas for ranged spaces (Franzoi et al., 2021b).

$$\begin{aligned}
 Y_{CV} = & -10X_1 - 5.1X_2 - 3.2X_3 - 10X_4 - 10X_5 + 7.4X_7 - 9.2X_1X_2 + 10X_1X_3 \\
 & - 10X_1X_4 - 10X_2X_3 + 10X_2X_4 + 7.3X_2X_7 - 10X_3X_4 + 10X_3X_5 \\
 & + 10X_3X_6 + 10X_3X_7 - 10X_4X_5 - 10X_4X_6 - 1.4X_4X_7 + 5.5X_5X_7
 \end{aligned} \quad (3)$$

## 5. Conclusion

The main purpose of this paper is to build surrogate models that can effectively determine digital supply chain resilience in considering the boil-off gas in the LNG supply chain. The surrogates can be built to represent the resistance and recovery measures to be managed in the proposed modeling. Considering the generic SCR modeling using MIP-based machine learning for the parent and child components as in the Figure 1 tree (parent: resistance and recovery, children: resistance, recovery, containment, stabilisation), a more complex combination will be proposed for the second-order or cross-product of the components. It will cover the following aspects of the CSR in the LNG supply chain such as (1) physical elements of the LNG shipping: pressure, temperature, BOG losses, etc., and (2) trustworthiness levels of the IoT considering communication, timeliness, etc.

## Abstract

The current socio-economic and environmental concerns envisage entities to make sustainable investments and improvements. However, sustainable investment selection in a given industry might not be straightforward from the several technological alternatives available. Several methodologies exist to help in the alternatives assessment and help in the decision-making activity. GREENSCOPE (Ruiz-Mercado et al., 2012), used in this work, calculates 139 normalised sustainability indicators from four different classes: efficiency, environment, energy, and economy. Analysing such indicators for investment alternatives is a complex multi-objective decision-making process (MODM) for which many methodologies exist. GREENSCOPE suggests using the Additive Utility Method (AUM) (Smith & Ruiz-Mercado, 2014), which might have some limitations in identifying different alternatives. An alternative method is implemented in this work, the Analytic Hierarchy Process (AHP) (Saaty, 1978). Both methods were tested and tweaked, originating AHPmod and AUMmod. These were applied to three case studies.

**Keywords:** Sustainability, decision-making, multi-objective, sustainability indicators

## 1. Introduction

The newest IPCC report, released on April the 4th, 2022, focuses on the mitigation of climate change, calling for an improvement in sustainable development and an increase in efficiency (WGIII IPCC, 2022). Therefore, decision-making must take into consideration, not just economic sustainability but environmental sustainability as well. UN sustainable goals is a set of internationally recognized goals that call for sustainable development (UN General Assembly, 2015). The main challenge when evaluating the sustainability of a given project is the assessment of the environmental impacts since they might have a different importance in different regions. For a

region frequently affected by droughts, local industry's water consumption and efficiency might be of higher priority in the agenda against CO<sub>2</sub> emissions mitigation. Therefore, the decision-making process should always consider the socio-economic impacts (Ruiz-Mercado et al., 2012).

GREENSCOPE (GRNS) is a life cycle assessment methodology focused on gate-to-gate analysis that uses a total of 139 indicators. They are spread (not evenly) across 4 metrics: Mass Efficiency, Environment, Energy and Economy.

$$\%G = \frac{|x_i - x_{i,worst}|}{|x_{i,best} - x_{i,worst}|} \quad (1)$$

The normalization technique used on the GRNS methodology implies an indicator score between 0 % and 100 % (max-min normalisation). It makes for a straightforward interpretation of the results, with the user always aiming for a score as close to 100% as possible. Even though the maximum and minimum values assumed by the methodology for the normalisation step might have some degree of uncertainty and subjectivity, it is considered a well-based methodology. Despite the representation for the scores make for eye-appealing graphs, as per Figure 1, it is not easy to quantify the improvement from alternative to alternative.

Figure 1 - Graphical representation of acetaldehyde case study GRNS scores.

This work's main goal is to establish a decision-making process based on the indicators calculated using GRNS. Even though the representation of the scores

in spider-like graphs (Figure 1) intends to help the decision-maker by showing that a given alternative with scores closer to the outside boundaries is better than other not as close, a quantification method is also needed.

Smith et al. (2013) use marginal rates of substitution (MRS) to determine the relative importance of any indicator, compared to the others, and AUM to decide upon the best alternative. However, the decision-making process is based on a limited number of indicators that are selected subjectively.

In this work, 2 different methods are implemented, AUM and AHP, together with 2 new variations of these methods. An analysis of the results obtained with each method is performed to decide on which is more suited to this type of multi-objective decision-making (MODM) problems.

## **2. Methodology**

In this section, MODM methodologies, such as AUM and AHP, are applied to GRNS indicators, to decide what is the best alternative for each case study.

### **2.1. Additive Utility Method (AUM)**

GRNS uses a scoring between 0 % and 100 % for each indicator, which may lead to accept that a higher sum of scores indicates the best alternative. However, the increase in one indicator score can come at the expense of another (Smith & Ruiz-Mercado, 2014). AUM is a method that uses the summation of indicator scores combined with MRS.

MRS uses the derivative of one indicator to another, with which it is possible to create an interaction matrix with size  $n$  (where  $n$  is the number of indicators considered for the analysis). From this matrix, one column, to be used as reference indicator, is selected and multiplied by the indicator scoring obtained from GRNS. The resulting vector values are summated, and a final value is obtained. This procedure, using the same interaction matrix from MRS, is repeated for each alternative. Comparison between alternatives is made using the calculated single scores for each alternative.

### **2.2. Analytic Hierarchy Process (AHP)**

AHP, a well-known Multi-Criteria Decision Making (MCDM) method (Saaty, 1994), proposes a systematic methodology to compare multiple possible choices structuring a problem in three parts: goal, possible solutions (alternatives), and criteria (indicators). To determine the best possible solution, one must assign priorities to the various criteria being considered. It can be different for any given problem; Saaty proposes a scale of relative importance from 1 to 9. Using this relative importance is possible to establish a

pairwise comparison matrix  $A$ , which is a  $n \times n$  reciprocal matrix (where  $n$  is the number of indicators taken into consideration).

For each indicator a matrix  $M$  must be calculated, which is a  $m \times m$  matrix (where  $m$  is the number of alternatives considered). And, like matrix  $A$ , it is a reciprocal matrix that is obtained by dividing the scores of every indicator by each other.

Vectors  $P$  and  $p$  (obtained from the geometric mean and normalisation of matrices  $A$  and  $M$ ) are then rearranged in a table, where their values are multiplied and summed to obtain a final score, see eq. (2).

$$Priority = \sum_{i=1}^n P''(i) \times p''_k(i) \quad (2)$$

### **2.3. Additive Utility Method modified (AUMmod)**

Since the AUM method uses a reference indicator arbitrarily chosen, whose selection may be arguable, a modified version that considers all the indicators is herein proposed. This method consists in using the vector  $P''$ , originated from the interaction matrix  $A$  on the AHP method, to balance the scores from GRNS, allowing for a single score.

### **2.4. Analytic Hierarchy Process modified (AHPmod)**

A proposed modification to the AHP method is also presented. An interaction matrix for every alternative with the values of every indicator was calculated, and the same mathematical steps of matrix line geometric mean and normalisation were applied. These two vectors,  $P''$  and new  $p$  are to be multiplied and summed, with the highest value being the best performing alternative.

### **2.5. Implementation**

The four methods previously outlined were implemented using MATLAB. A code was written to obtain the indicators scoring from the GRNS file and make the calculations. The implementation of AUM was straightforward since it had already been used for GRNS indicator scoring comparison.

For the AHP and AHPmod methods implementation, a systematic methodology to overcome the subjective score selection (1-9) was carried out. Therefore, matrix  $A$  was generated not based on the relative difference attributed by the user, but based on the delta calculated through the difference between maximum and minimum possible indicator values, that corresponds to the denominator of eq. (1).

The indicators used in every method were determined via a set of restrictions outlined to ensure calculations feasibility, since MRS uses delta divisions, which cannot be zero. The set of restrictions imposed on the indicator selection are defined in Table 1, as stages.

Table 1. Indicator selection, elimination stages with description.

Stage	Description
0	139 GRNS indicators
1	Remove $\nabla_i < 0.01$
2	Remove $\%G_i < 0.01$
3	Remove $P_i'' < 0.01$
4	Remove $P_i'' = \infty$
5	Remove $p_i'' = \infty$

In stages 4 and 5, the elimination of infinite values on the  $P''$  and  $p_i''$  vectors, is essential for the implementation of AHP and AUM methods. Stage 6 ensures that the same set of indicators is used on every alternative evaluation.

Finally, to facilitate the interpretation, a ranking was attributed to the scenarios evaluated, so if a scenario has a better final score than any other, it is ranked as the best alternative in a scale from 1<sup>st</sup> to 4<sup>th</sup>.

### 3. Case study

To carry out a sustainability analysis, there must be a reference scenario upon which the comparison can take place; otherwise, the score obtained can't be interpreted. In the context of the present work, 3 case studies were evaluated, for which 4 different scenarios were created. Since decision-making can only take place if there is more than one alternative to choose from, in Table 2 is possible to find a quick overlook of scenarios for the different case studies.

Table 2. Case studies and its scenarios.

Scenario	Description		
	Biodiesel plant	Acetaldehyde plant	Propylene Glycol plant
V0	Base scenario	Base scenario	Base scenario
V1	Lower price of feed streams	Energy integration (EI)	Energy integration (EI)
V2	Lower price of product streams	Recirculation, no EI	Recirculation, no EI
V3	Lower energy consumption (EI)	Recirculation with EI	Recirculation with EI

### 3.1. Biodiesel plant

The biodiesel plant was used as case study in GRNS (Ruiz-Mercado et al., 2013). Since the model for this case study was not available, modifications to the original biodiesel demonstration file (V0) were made, as follows: a decrease of 10 % in raw materials cost (V1), a 10 % reduction in products value (V2) and decrease of 10 % in energy consumption (V3). These scenarios were created to better understand the decision-making process based on the indicators calculated.

### 3.2. Acetaldehyde and propylene glycol plant

Acetaldehyde production is a very well-known academic case study, and so is the propylene glycol. These cases are particularly suited for a sustainability analysis since the assessment outcomes can be clearly validated. As for the biodiesel plant, several alternatives were created: base case scenario with no energy integration or material recirculation (V0), energy integration and no material recirculation (V1), recirculation without energy integration (V2) and material recirculation with energy integration (V3). The V3 alternative is expected to be more sustainable, with higher sustainable scores across the GRNS indicators.

## 4. Results

The methods previously described (see paragraphs 2.1 to 2.4) were applied to the GRNS scores obtained for every alternative of the case studies. Since the results obtained through the implementation of the MODM methods are not comparable and have very different orders of magnitude, the results obtained are presented in ranking order in Table 3.

Table 3. Rankings obtained to the alternatives of the case studies.

<b>Biodiesel plant case study</b>
-----------------------------------

	Expected	AUM	AUMmod	AHP	AHPmod
V0	3	4	4	2	<b>3</b>
V1	1	3	3	<b>1</b>	<b>1</b>
V2	4	1	1	3	<b>4</b>
V3	2	<b>2</b>	<b>2</b>	4	<b>2</b>
<b>Acetaldehyde plant case study</b>					
V0	4	4	4	2	3
V1	3	1	1	1	4
V2	2	<b>2</b>	<b>2</b>	3	<b>2</b>
V3	1	3	3	4	<b>1</b>
<b>Propylene glycol plant case study</b>					
V0	4	2	2	2	3
V1	3	1	1	1	2
V2	2	3	3	3	4
V3	1	4	4	4	<b>1</b>

From Table 3 the pattern set by not having material recirculation (V0 and V1) could not be identified by AHP, AUM and AUMmod methods as the worst alternatives. Moreover, those methods also failed in identifying the best and worst performing alternatives.

The AHPmod method ranked the alternatives in the expected order. In the biodiesel case, the ranking corresponds to the expected ranking set. For the acetaldehyde case, two main groups without material recirculation (V0 and V1) are identified as the worst performing alternatives, and ranked 3 and 4, respectively. The order in which V0 and V1 were ranked is not unexpected since energy integration represents capital investment increase, that should be carefully analyzed and justified. It can have a rippling effect across many sustainability indicators. V4 was considered the best-performing one, as expected, since it considers material recirculation and energy integration.

However, in the propylene glycol case, only the best-expected alternative was ranked as anticipated (using the AHPmod). This represents a good accuracy in

the AHPmod method for the best-performing cases, even though it can miss rank other alternatives that do not have a very different scoring.

### 5. Conclusion and future work

Decision-making using sustainability indicators can be a very subjective process. Many methodologies use weights that are determined subjectively to decide on the best and worst-performing alternatives. The work developed and presented in this paper shows that it is possible to use MODM methods to help in sustainability analysis. The proposed methods remove the need for weights and can, with a certain degree of uncertainty, identify a pattern of increasing sustainability. Even though AHP and AUM were not the best performing MODM methods, those are the base for the AHPmod method presented and proposed for further validation. Future work will use TOPSIS method for additional validation of the techniques presented, sensibility analysis of the indicator eliminations steps and Pareto analysis of the vector  $P''$  generated in the MRS reciprocal matrix.

## Abstract

The process industries are increasingly electrifying their processes in order to reduce the carbon footprint by the use of “green” electric power. However, the supply of power from renewable sources and the prices of electric energy are volatile which creates an opportunity and a challenge. On the one hand, the volatility of the price creates an opportunity to reduce cost and at the same time reduce the CO<sub>2</sub>-footprint as the price and the availability of power from renewables are strongly correlated. On the other hand, the plants must be flexible enough to adapt to the price levels and the operational strategy must become more dynamic. This paper investigates the flexible operation of a continuous tubular reactor for the hydrothermal synthesis of zeolites with the goal to determine the economically optimal operating trajectory in the presence of parametric model-plant mismatch. The robust dynamic optimization strategy is presented and the benefits over the usage of the nominal model are evaluated.

**Keywords:** Demand response, Dynamic optimization, Robust optimization, Process Intensification, Continuous crystallization

## 1. Introduction

The industrial sector accounts for 38 % of the total global energy consumption. Therefore, besides increasing the energy efficiency of the production processes, a change of the primary energy sources from fossil to renewable sources in the industrial sector has to take place. In the chemical industry, the direct electrification of processes is one of the main contributors to this transition. The supply of electric power is fluctuating due to the increasing share of renewable power, while there is a (up to now mostly) steady demand for electric energy from the industrial sector. The synchronization of supply and demand via price signals is referred to as Demand Side Management or Demand Response. This adaptation has multiple benefits. The production company is able to use electric energy in periods of lower prices and therefore has an economic benefit. The grid operator on the other hand profits because supply and demand are balanced better. As a result, the share of fluctuating sources in the grid can be increased, while maintaining grid stability. So overall also the CO<sub>2</sub>-footprint is reduced. The procurement of electrical energy by large consumers is usually realized by longer-term contracts (e.g. time of use tariffs) and by the participation in different power markets, such as the day-ahead spot market the intraday market and the frequency reserves. The time procurement horizons of these markets range from the next day on the day-ahead spot market to 15 minutes before consumption on the intraday market to 30 seconds on the frequency reserves.

Demand Side Management strategies are frequently formulated as Mixed Integer Linear Problems (Zhang and Pinto, 2022, Dalle Ave et al., 2019), where the dynamics of the processes are reduced to minimum up and down times or ramp constraints on the change of the production levels, neglecting the real dynamics of the processes. However, for slow processes and fast load changes, these formulations are too coarse and dynamic models of the behavior of the plants have to be included. This has been investigated by several authors for a variety of examples, e.g. Air Separation Units (Pattison et al., 2016) and a continuous zeolite production plant (Semrau et al., 2022). The economic and environmental advantages of demand side management for the zeolite plant were investigated in detail in Semrau and Engell (2023), assuming a perfect plant model. In this work, the effect of stochastic parameter uncertainties on the optimal day-ahead commitment of the electric energy demand is studied. First, the plant and the optimization problem are described. Then the robust dynamic optimization problem is presented and the results are shown for historic data for the prices of electric energy. Finally, the difference to the usage of a nominal model is quantified.

## 2. Problem statement

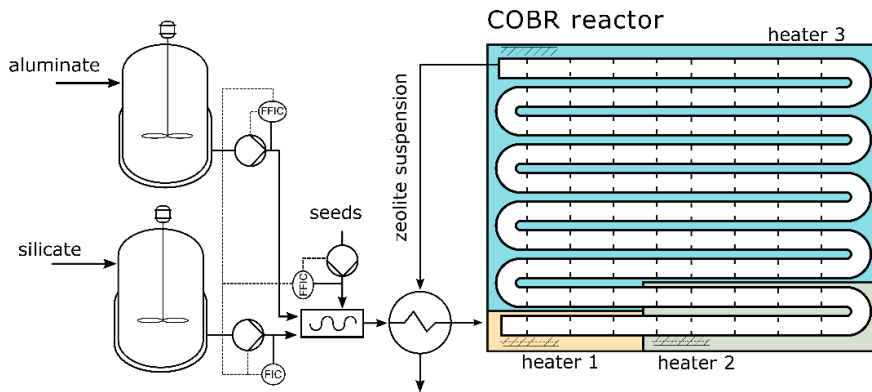

Figure 1: Scheme of the continuous zeolite production process

The process for the continuous production of NaX zeolites is shown in Figure 1. The silicate and the aluminate suspensions are mixed along with seed crystals and fed into the tubular reactor. The reactor is equipped with three heaters along the reactor. In the continuous oscillatory baffled reactor, the amorphous solids are converted to the desired crystalline zeolites. This takes place at elevated temperatures. The outlet stream is used to preheat the entering stream. The inputs of the system are the total flowrate and the heat duty of the three heaters. The zeolite crystal content in the outflow should be higher than 98%. The reaction temperature is limited to 403.5 K, due to the formation of side products. The production process is described in detail in Ramirez Mendoza et al. (2020). The reactor is modelled by the axial dispersion partial differential equation with reaction terms for the dissolution of the amorphous solid and the nucleation and growth of the zeolite particles. To solve the population balance of the zeolite particle formation, the method of moments is used. A general notation of the model is given by (1) with the states  $x$ , the inputs  $u$ , and the parameters  $p$ .

$$\dot{x} = f(x, u, p) \quad (1)$$

### 2.1.1. Parametric uncertainty

Models are only simplified description of the plant behavior. Especially, the nucleation and growth of the crystalline particles is a highly complex, stochastic process. Therefore, the prediction of the plant behavior is prone to errors. In this work, a parametric stochastic deviation from the nominal model prediction is assumed, which can be described by a stochastic differential equation (2) with a linear time invariant matrices  $A$ ,  $a$ ,  $B$  and the Wiener process  $dW$ . The evolution of mean value  $\bar{p}$  and the covariance matrix  $P$  can be described the differential equations (3),(4). The nucleation rate and the heat transfer coefficient of the preheater are assumed to be stochastic. The deterministic description of the system is replaced by a stochastic one.

$$dp(t) = (A p(t) + a)dt + BdW \quad (2)$$

$$\dot{P} = AP + PA^T + BB^T \quad (3)$$

$$\dot{\bar{p}}(t) = A\bar{p}(t) + a \quad (4)$$

$$d \begin{pmatrix} x \\ p \end{pmatrix} = \begin{pmatrix} f(x, u, p) \\ Ap + a \end{pmatrix} dt + \begin{pmatrix} 0 \\ B \end{pmatrix} dW \quad (5)$$

### 2.1.2. Economic cost structure

In the considered case, the energy costs and the revenue are considered. Therefore, the costs can be described by the normalized usage of electric energy multiplied by the normalized price  $\gamma(t)$  subtracted by the relative throughput.

$$\phi(t) = \gamma(t) \frac{\sum_j^3 \dot{Q}_j}{\sum_j^3 \dot{Q}_{j,ref}} - \frac{F}{F_{ref}} \quad (6)$$

## 3. Method

In the following, the dynamic optimal schedule based on the day-ahead and the intraday electric energy price markets in the presence of stochastic parametric model-plant mismatch is presented.

### 3.1. The Unscented Transform

The Unscented Transform (Julier 2002) approximates the propagation of a multivariate Gaussian distribution  $\mathcal{N}(m, \Sigma)$  of dimension  $N$  through a nonlinear function  $g(m)$  with individual samples  $m$ , the sigma points. The expected value of the function  $g(m)$  can be approximated by a weighted sum of the sigma points. The individual weights  $w_i$  are chosen, such that the corresponding moments of the distribution are accurate to the third order.

$$m \sim \mathcal{N}(\bar{m}, \Sigma) \quad (7)$$

$$m_i = \bar{m} \pm \sqrt{(N+1)\Sigma_i} \quad (8)$$

$$\mathbb{E}(g(m)) \approx \sum_{i=0}^{2N} w_i g(m_i) \quad (9)$$

### 3.2. Robust dynamic optimization

The optimization problem under uncertainty is formulated in (10). The stage cost is the expected cost of electric energy. For the robustification of the solution, the constraints are satisfied for all sigma points. Similar approaches were used by e.g. Vallerio et.al.(2016). The optimization variables are the extended state vector  $X(t)$ , which consists of the states  $x_i$  for the corresponding sigma points  $p_i$ , and the input trajectory  $u(t)$  which is the same for all sigma points. The terminal cost is introduced to reduce the terminal sell-off effect, it consists of a linear term with  $\lambda_{ss}^{*,T}$  being the Lagrange multiplier at the optimal steady state (Zanon and Faulwasser, 2018). To further reduce the sell-off effect, the optimization problem is solved on two horizons, of which the second one is discarded, similar to model predictive control approaches. The constraints of the optimization are the dynamic model and the bounds on the process variables and the product quality, which need to be satisfied for all sigma points. Furthermore, the mean production is ensured.

$$\min_{x, u, E} \int_0^{t_f} \mathbb{E}(\phi(t)) dt + \lambda_{ss}^{*,T} X(t_f) \quad (6a)$$

$$s. t.: \dot{x} = f(x_i, u, p_i) \quad \forall i \in (0, 2N) \quad (6b)$$

$$x_i(0) = x_{0,i} \quad \forall i \in (0, 2N) \quad (6d)$$

$$0 \geq h(x_i, u, p_i) \quad \forall i \in (0, 2N) \quad (6e)$$

$$0.98 \leq X_i(t) \quad \forall i \in (0, 2N) \quad (6f)$$

$$F_{fix} = \frac{1}{t_{k+1} - t_k} \int_{t_k}^{t_{k+1}} F(t) dt \quad \forall k \in [0, 1] \quad \forall i \in (0, 2N) \quad (6g)$$

Time is discretized with the OCFE method using Radau polynomials of a second order. The optimization problem is implemented CasADi and solved with the NLP solver IPOPT. The length of the first horizon is chosen to be 24 h, the length of the second horizon is 12 h. The resulting nonlinear optimization problem has around 320.000 variables and is solved within 12h.

## 4. Results

For the selection of the sigma points, the mean and the covariance of the parameters are the steady state solution of the equation (2), (3). The resulting mean value of the parameter, is one, parameter covariance matrix is given by

$$P_{ss} = \text{diag}([65.53, 4.08]) 10^{-6}. \quad (7)$$

The tuning parameter of the Unscented Transform was chosen such that the isoprobability curve on which the Sigma Points lie, covers 95% of the distribution. The electric energy price trajectory for the day-ahead electric energy price is data from the EPEX Spot market from the 13.01.2020.

The results of the optimization are shown in Figure 2 for the nominal optimization, in which only the mean is considered and the robust optimization. The normalized electric energy price is shown in the bottom plot. The resulting optimal trajectories for the temperature (T) and crystallinity (X) at the outlet for the different sigma points.

Additionally, the throughput (F) and the heating powers for individual the heaters ( $\dot{Q}_j$ ) are displayed. The energy usage is shifted in both cases to the low energy price period, while the constraints are satisfied for all sigma points. It is clearly observable, that the inputs vary in a smaller range, and the height of input movement is smaller.

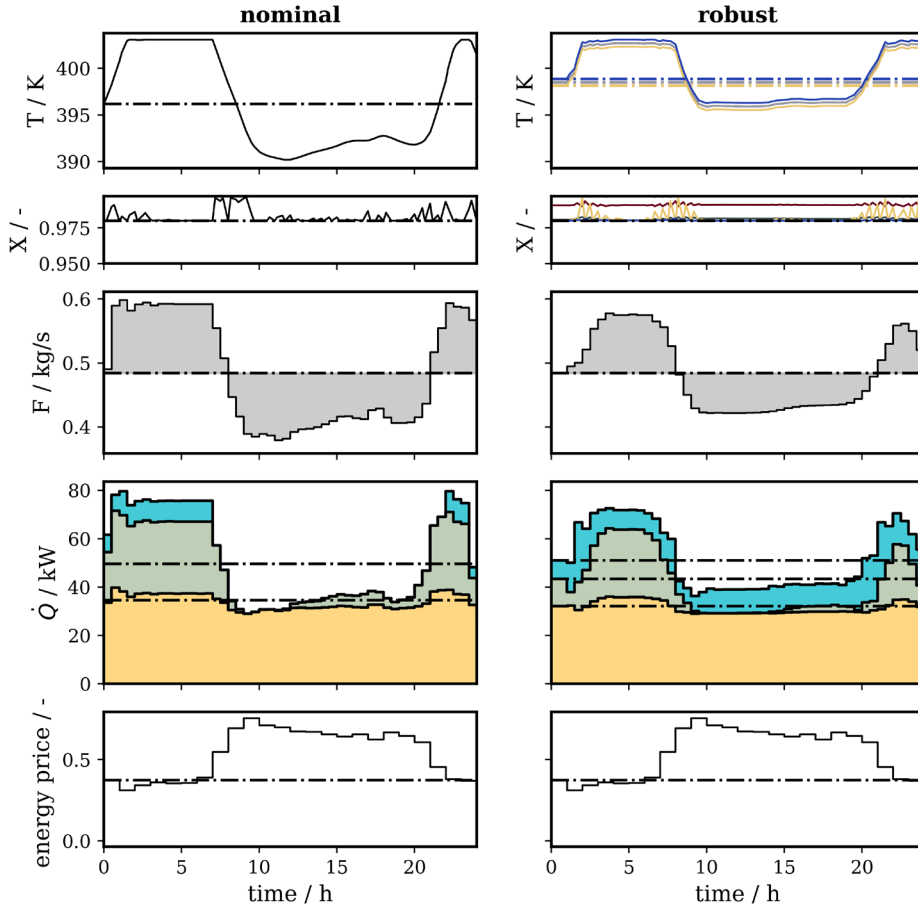

Figure 2: Optimal dynamic operation with energy price data for 13.01.2020 as the result of the robust optimization

Figure 3: Application of the robust optimal trajectory to the stochastic system

To test the validity of the calculated solution the stochastic differential equation of the model (5) is numerically solved for 20 different realization of the noise the results are shown in Figure 3. In which, the outlet temperature, the crystallinity and the two varying parameters are shown. The grey lines represent the solution of the stochastic differential equation for different realizations, the constraints are marked in red and the considered sigma points in black lines. The robust optimal operation of the process limits the constraint violation to 3.67% instead of 33.26% in the nominal case. However, the economic energy cost savings decrease from 9.29% using the nominal trajectory to 4.13% for the robust optimization.

## 5. Conclusion

This work presents the extension of a moving horizon day-ahead optimization for the flexible usage of electric energy based on the day-ahead market by the inclusion of stochastic parametric model-plant mismatch. The problem statement and the robust optimization problem are introduced. The optimization problem is solved for a one-day operation using past energy price data. The benefit of using the optimization under uncertainty is demonstrated for multiple realization of the stochastic model description, demonstrating an improvement of the robustness with a negative impact on the calculated cost. Further work will address the estimator design to identify the model parameters and robust economic NMPC to be able to reduce the performance loss, while maintaining the robustness of the solution. Furthermore, the application of two stage stochastic programs will be exploited to optimally choose the energy purchase on the different markets.

## Abstract

In the process of milk production, dairy farmers are confronted with the management of their herd. Indeed, when a group of cattle is in the lactation phase, several genetic and phenotypic factors can impact the milk production (W. L. Weigel, 2017). That way, good herd management can increase production, lower costs, and at the same time reduce the carbon emissions. In this sense, one of the pillars of a good herd management is the renewal rate of the cows (voluntary culling). However, optimize the decision to cull cow is very important. For example, culling a cow with a good milk production potential or keeping a cow in the herd with a non-satisfactory production is not economically profitable. Regarding this, the objective of this work was to process the database of the experimental farm of the UniLaSalle polytechnic institute and try to understand, using machine learning models, the phenotypic and genetic parameters that played an important role in the longevity of cattle cow.

**Keywords:** cow culling; milk production; ai-based decision tool; machine learning; optimization

## 1. Introduction

The current global scenario is very unstable and uncertain. In particular, the tensions created by the war in Ukraine, the energy crisis, and the environmental crisis, among other implications, create for instance a pression on the price of raw materials. An important input for dairy cows is soybean, see in the Figure 1 the price evolution (from 208,51 US\$/ metric ton at the end of 2002 to 561,79 US\$ / metric ton at the end of 2022 or an increase of 169% in 10 years)

**Figure 1: U.S. Dollars per metric ton of soybeans in the last 10 years. Source: <https://fred.stlouisfed.org/series/PSOYBUSDQ> (International Monetary Fund)**

In this context, dairy farms face multiple challenges while remaining efficient and competitive. The trivial way to increase milk production on a farm would be to increase the size of the dairy herd. However, this approach will lead to economic and environmental consequences. In that sense, with the advancement of technology and genetic improvement of the herds, the trend observed in the field is the opposite: the number of dairy cattle decreases and productivity increases, as illustrated in Figure 2 (from 2009 to 2020 a 5,40% decrease in the number of cows and a 14,75% increase in milk production in France)

**Figure 2: Milk production per year from 2009 to 2020 vs number of cows in France. Source: CNIEL, Agreste. (a: Number of dairy cows and their yield, b: millions of cows and c: liters of milk per year)**

Knowing that the trend is to reduce the number of cattle and increase production, mastering herd management becomes very important. We should mention 3 aspects of herd management. First, if we keep productive cattle with good genetic and phenotypic parameters, the production tends to increase. Secondly, if we detect the least productive cattle, and the causes of this weak production, we can act to correct these malfunctions and reduce the costs of breeding. Finally, reduce the number of cows and keep the same production yield reduces the environmental impact and the economic. Accord to with (Lengagne, 2019) the average renewal rate of the herds is around 34% and the objective according to the Regional Chamber of Agriculture in 2022 (French Government) is to be less than 25%.

Milk production depends on several phenotypic and genetic factors. Phenotypic parameters are subject to external interferences (stochastic events) caused, as for example, by breeding conditions. For instance, diseases, artificial inseminations, or milk quality yields. These parameters can be explained, and they are influenced, by genetic indexes. In the sense that, the observations of reality are the expressions of the genetic indexes. Precisely, these genetic indexes tell us about the performance of the cows. On the field, the interactions experienced by animals in the environment will contribute positively or negatively to the milk production and it can disturb the veracity of these genetic variables.

On the other hand, with the advancement of data collection, processing and modeling, the use of phenotypic and genetic parameters is widely used to understand the milk production process (Weigel, 2017 and M. Lopez-Suarez et al, 2018). In that sense, our objective is to understand the longevity of a dairy cow. With genetic and phenotypic data can we explain the factors that have contributed, positively and negatively, in the longevity of a dairy cow?

## 2. The environment and the database

### 2.1. UniLaSalle's experimental farm

At UniLaSalle, a French engineering school in agriculture, based in Beauvais, northern region of France, "La Ferme du Bois" is an experimental farm used by the professors and the engineers-students to develop their projects. The farm is functional and productive to deserve the school's community.

### 2.2. The database

We have built up a database from our experimental farm with phenotypic data (milk production data, calving data, diseases data etc.) and genetic data (milk indexes, health index etc). See Figure 3. The phenotypic parameters are collected on the farm and referred in the database either by a farm employee or automatically by the milk robot. Genetic parameters are collected directly from the cattle by an external company and after referred it in the database.

*Example of variables in the database*

532 cows	calving_calving_interval
	diseases and diseases_types
	artificial_inseminations
	milk_protein_rate
	milk_fat_rate
	milk_production_rate
	number_of_calves
	longevity
	milk_production_index
	milk_quality_index
	general_synthesis_index

**Figure 3: some variables in the database.**

An important part of this work was cleaning up and extracting exploitable datasets for training machine learning models. In total we have 532 cattle already culled in the database, however if we would have, for instance, utilize 10 variables to evaluate their impact on the longevity we need enough culled cattle information to have a model.

## 3. Methodology and models

In a first step, we have processed this database to verify the veracity of some genetic indexes and its influence in the phenotypic parameters. Secondly, we applied some machine learning models to understand the longevity of already reformed cattle referenced in the database.

For this, we used a python environment, in form of Jupyter Notebook, on Google Colab and we used the basic libraries for manipulation and visualization of tabular data (Pandas, Numpy, Seaborn and Matplotlib). For the predictions we used the models available in Scikit-Learn library (Boyu.Ji, 2022).

### 3.1. Genetic index phenotypic performance

Initially, we have looked for the veracity of some genetic indexes by making a comparison with the collected phenotypic data. In general, we have noticed 3 different instances between the indexes and the phenotypic parameters that we can exemplify with these 3 examples (see figure 4): The milk index (genetic) is 53% correlated with the milk production (phenotypic). Then the milk index (genetic) is 61% correlated with the first lactation milk production (phenotypic). Finally, the butter index is 84% correlated with the butter index of the first lactation (Gabriel M. Dallago et al., 2022).

**Figure 4: (a) milk\_production correlated 53% with the milk\_index (b) milk\_index correlated 61% with the milk production in the first calving (c) butter\_index correlated with 84% the butter\_index in the first lactation**

### 3.2. Machine Learning

We have deployed several supervised machine learning models, essentially linear regression, XGBoost and random forest to predict a phenotypic variable: longevity (A.Essl, 1998). For that, we standardized data by

$$\tilde{x} = \frac{x - \bar{x}}{\sigma}$$

where  $\bar{x}$  is the average of each variable and  $\sigma$  the standard deviation. To train our models we also used a 5-cross-validation test with parameters specific to each model. The data in each model was divided in 70% train et 30% test and the metric utilized to compare and to estimate the precision of the model was the  $R^2$ -metric. Regardless, we have also looked for the feature-importance of the of each prediction because it is important to understand the variables influence the longevity. In fact, initially all variables were considered and after some models were tested, we selected only the most pertinent variables with the objective of optimizing the models.

#### 4. Results

In some senses, we have succeeded in explaining the longevity of a dairy cow with the genetic and phenotypic data was available. The Figure 5 below shows a visual example of the prediction of one of the trained models. The example shows predictions for the longevity of at least 60 cattle. It means that the dataset used initially had 200 cows with enough information for the selected variables (more than 30 variables). Thus, the model was trained with 140 cows (70% training) and was tested with 60 cows (30% test) as shown in the Figure 5.

Figure 5: Random Forrest results: blue predicted values and red reality values

Figure 6: feature importance of the random forest model

In the figure 6 we can see that the age at first calving, the average of the duration of the lactation and the number of artificial inseminations are the most impacting variables concerning longevity. These factors must be evaluated and corrected by the cattle farmer.

#### 5. Discussion and outlook

In terms of improvement, a major difficulty in this work was the data preparation and processing phases. The database has an important number of missing values for several variables. In this case, we reduced the quantity of cows to have more information about

them in the models. Then, expanding our database is extremely important for the future. In addition, predicting longevity is important, but also linking milk production in the model is interesting. For instance, the following synthetic variable can be modeled by the parameters in our database.

$$\frac{m \times 300 \times (l - c_{age})}{l \times 365}$$

where  $m$  is the average of the dairy milk production,  $l$  is the longevity and  $c_{age}$  is the age at first calving. The value 300 is explained by the rest that the cow had after each calving, around two months.

Another axis of improvement is to find a way to use the information from the feature importance to help the cow farmers. It means, not only to have an estimate of the longevity of his cattle, but also what the breeder can act to improve the parameters impacting the longevity. Finally, training a clustering model to classify the cattle to be culled or not is also intended (Esther van der Heide, 2020).

The authors would like to mention that this work was carried out by the first author in the context of his master's thesis.

# Analyzing the Large-Scale Supply of Low-Carbon Hydrogen in Germany

Paul Sizaire<sup>a</sup>, Emre Gençer<sup>a</sup>

<sup>a</sup>*MIT Energy Initiative, Massachusetts Institute of Technology, 400 Main Street, Cambridge, MA 02142, USA*

## Abstract

The increasing political momentum advocating for decarbonization efforts, in Europe and elsewhere, has led many governments to unveil national hydrogen strategies. Hydrogen is viewed as a potential enabler of deep decarbonization, notably in hard to abate sectors such as the industry. A linear programming model was developed to assess the procurement of low carbon hydrogen in Germany, a large industrial consumer.

Results show that decarbonizing the current industrial demand (55 TWh/yr) with domestic electrolytic hydrogen would result in a levelized cost of hydrogen totaling ~\$5kg/H<sub>2</sub>, requiring 22 GW of electrolyzer, 30 GW of solar and 15 GW of wind, highlighting the requirement to import. Retrofitting natural gas derived production will likely result in a carbon intensity exceeding low carbon requirements unless emissions from the natural gas supply chain are adequately addressed, engendering significant additional investments. Imports from neighboring countries such as Norway can significantly reduce costs and meet carbon intensity requirements if sourced correctly, leveraging the relatively short distance between countries using an undersea pipeline.

This model highlights the likely importance of imports in decarbonizing hydrogen procurement in Germany to address high costs of domestic electrolytic production and high carbon intensity of retrofitted natural gas derived production.

**Keywords:** hydrogen, supply chain, electrolyzer, linear programming, Germany

## 1. Introduction

Despite the ratification of the Paris agreement by 189 countries in 2015, carbon emissions have remained fairly constant and above 30 Gt per year (IEA, 2021). This has incited calls for further action, which resulted in several countries pledging to attain carbon neutrality by mid-century. An advocated decarbonization pathway promotes the reduction of carbon emissions from electricity generation and the electrification of several end-uses that currently rely on a variety of incumbent fuels. However, electrification may be impaired by feasibility or cost-effectiveness issues in several applications, notably in the industry sector. Among alternatives, a portfolio of low-carbon fuels such as hydrogen and biofuels are considered. Hydrogen's versatility is deemed to make it suitable to various end-uses such as industrial processes, long-haul transport, or renewable energy storage. This has incited several countries worldwide to release national hydrogen strategies, which highlights the potential future role of hydrogen in the decarbonization effort.

In Europe, the current largest consumer of hydrogen is Germany. It almost entirely consumes it in the chemical industry, predominantly for refining, followed by ammonia and methanol production. Germany produces most of its hydrogen, relying very little on imports, with an annual output reaching ~55 TWh. This production is dominated by a

single process – Steam Methane Reforming (SMR), which uses natural gas as a fuel, across 44 plants in the country. The predominance of hydrogen production from SMR is associated with substantial carbon emissions - this process emits  $\sim 10$  tCO<sub>2</sub>/tH<sub>2</sub> (IEA, 2019). To date, Germany possesses less than 200 MW of electrolytic capacity. To comply with the amendment to the Climate Change Act stating a net-zero target by 2045 (Bundestag, 2021), Germany has produced a national hydrogen strategy. The government only considers electrolytic hydrogen produced from renewable electricity to be sustainable in the long term. The strategy focuses on demand applications that are close to commercial viability and those which cannot be decarbonized in other ways, citing the steel and chemical industries. It expects 90-110 TWh of hydrogen demand in 2030. Setting a target of 5 GW of electrolyzers in 2030 aiming to produce 14 TWh of hydrogen using 20 TWh of renewable electricity, Germany is aware that this will not be sufficient to meet the entire demand. As such, Germany views imports as crucial.

The ambitious targets are likely to face several challenges. Current global electrolytic capacity is dwarfed by the sheer scale of envisioned deployment - reaching Germany's target corresponds to a 75% compound annual growth rate until 2030. Electrolytic hydrogen may be expensive in the short- to medium- term which may impair competitiveness in the industrial sector, current incumbent of hydrogen demand. Furthermore, this production requires low-carbon electricity to provide low-carbon hydrogen, triggering an extensive addition of renewable energy in the German electricity grid, which is currently characterized by a relatively large carbon intensity. The creation of a holistic supply chain will also require transmission pipelines and large-scale storage.

To provide insights regarding the least cost scenario for a developed hydrogen supply chain while addressing the various concerns aforementioned, an optimization model has been developed. Using a linear approach, a multi-nodal system representing Germany's regions optimizes for electricity generation, hydrogen generation, transmission, and storage. Hydrogen produced in Norway sent through a pipeline is evaluated as a method of import. Several power generation, hydrogen production, and storage options are considered. This model aims to provide insights regarding the development of a hydrogen supply chain realistically, by implementing several objectives laid out in the German hydrogen strategy.

## 2. Methodology & Case Study

### 2.1. Overview

The model presented in this report is a multi-nodal system that seeks to optimize for a hydrogen supply chain comprising power and hydrogen production, transmission, and storage. It is developed from a macroeconomic modeler's perspective, thus optimizing for social welfare by minimizing the overall costs. A perfect foresight is adopted using power generation data, which will be described subsequently.

Each node in the system represents a region of Germany. Within all nodes, capacities of renewable generation from solar and wind, electrolyzers, Auto Thermal Reforming (ATR) and SMR plants, and hydrogen and electricity storage are optimized for. Power generation is assumed to be wholly used for powering electrolyzers and compressors for hydrogen storage and transmission. A portion of the electricity that cannot be used is therefore curtailed, not sent into the grid. Most of the infrastructure considered in this analysis is greenfield. The cost of electricity omits any taxes, according to the stated

objective that will see the EEG surcharge non-applicable to electrolyzers (The Federal Government, 2020). The relative share of wind and solar resources to install is optimized for depending on the regions in which this production is located.

Transmission is optimized for both electricity and hydrogen. This model also performs a life cycle analysis, which is accounted for in the objective function via a carbon tax. It includes emissions for all infrastructure installed, which is assumed to linearly scale with increasing capacity. It notably includes carbon emissions not captured by CCS from ATR and SMR. Hydrogen storage is assumed to be provided by salt caverns. The technical potential of salt caverns has been evaluated and reported in several studies (Michalski et al., 2017; Welder et al., 2018). Hydrogen demand is assumed to come exclusively from industrial applications – as such, demand is considered to be flat throughout the year. Regional demand reflects their current relative hydrogen consumption.

## 2.2. Objective Function, Variables & Constraints

The objective function aims to minimize the annualized costs of the system, which comprises capital and operational expenditures of assets, fuel, and emissions costs. A set of electrical production infrastructure is denoted  $P_e$  and comprises solar PV, wind turbines, inverters, and electrical storage (Li-Ion batteries). Another set of hydrogen production/storage infrastructure is denoted  $P_h$  and comprises electrolyzers, ATR plants, storage and compressors, while  $P_{ng}$  contains SMR plants only. A set  $T$  denotes transmission, encompassing electrical cables as well as domestic and international hydrogen transmission. Finally, set  $E$  corresponds to electrolyzers, solar, and wind, while  $C$  includes SMR, ATR, and Norwegian hydrogen.  $Cap$  denotes the capacity of the assets,  $DF$  is a detour factor,  $AF$  is an annualized factor, and  $RCC$  is the retrofit cost. The resulting objective function is composed of several cost components, laid out below:

Capacity:	$CC = \sum_{p_e \in P_e} CapEx_{p_e} \times (AF_{p_e} + OpEx_{p_e}) \times \sum_{n \in N} Cap_{p_e, n} + \sum_{p_h \in P_h} CapEx_{p_h} \times (AF_{p_h} + OpEx_{p_h}) \times \sum_{n \in N} Cap_{p_h, n} + \sum_{t \in T} CapEx_t \times (AF_t + OpEx_t) \times \sum_{n_{in} \in N} \sum_{n_{out} \in N} Cap_{t, n_{in}, n_{out}} * DF_{n_{in}, n_{out}}$	(1)
Retrofit:	$RC = \sum_{p_{ng} \in P_{ng}} RCC_{p_{ng}} \times AF_{p_{ng}} \times \sum_{n \in N} Cap_{p_{ng}, n}$	(2)
Fuel Cost:	$FC = Production_{ng} * Cost_{ng} + Production_{Norway} h_2 \times Cost_{Norway} h_2$	(3)
Em. Costs:	$EC = \sum_{e \in E} Emissions_e \times Cap_e + \sum_{c \in C} Emissions_c \times Production_c$	(4)
<b>Objective:</b>	$OF = CC + RC + FC + EC$	(5)

The variables in the model relate to the capacities of all technologies, electricity flows, hydrogen flows, and hydrogen and electricity storage levels. The capacities are optimized for every node, while all other variables are additionally optimized hourly, enabling great insights into the temporal operation of the various flows within the supply chain. Three main constraints dictate the hourly production of electricity, associated flows, and electrolytic production ( $CF_{n,h}$  = hourly capacity factor at node  $n$  and time  $h$ ,  $F$  = flow,  $H$  = hours in a year,  $EE$  = electrolyzer efficiency):

Production:	$Gen_{elec, n, h} = Capacity_{wind, n} \times CF_{wind, n, h} + Capacity_{solar, n} \times CF_{solar, n, h} \quad \forall n \in N, h \in H$	(6)
flows:	$Gen_{elec, n, h} = F_{el \rightarrow etlz, n, h} + F_{el \rightarrow curtail, n, h} + F_{el \rightarrow storage, n, h} + \sum_{n_{out} \in N} F_{el \rightarrow transmission, n_{in}, n_{out}, h} \quad \forall n \in N, h \in H$	(7)
Electrolyzer:	$Gen_{n_2, n, h} = (F_{el \rightarrow etlz, n, h} + F_{el \rightarrow storage \rightarrow etlz, n, h} + \sum_{n_{in} \in N} F_{el \rightarrow transmission, n_{in}, n_{out}, h}) \times EE \quad \forall n \in N, h \in H$	(8)

Resulting electricity and hydrogen flows are subsequently used to model the operation of the supply chain, such as the compression, transmission, storage, and so on. They also set

the required capacity variables with a variation of the constraint  $flow_{n,h} \leq capacity_n \forall n \in N, h \in H$ .

### 2.3. Case Study

The system analyzed in this report is Germany, in which 12 regions are considered and modelled as nodes. The focus of this analysis consists of short- to medium-term decarbonization of hydrogen production – as such, most costs are not projections but current values. Similarly, demand was assumed to equal the current demand of 55 TWh/yr, kept instead of the projected 100 TWh/yr due to large uncertainties. This demand was spread across regions according to the industrial hubs using data from Welder et al. (2018). The cost parameters of the model consist of the CapEx, OpEx, and lifetime of all assets considered, gathered from public sources. Emission values were also obtained from publicly available sources. Hourly renewable production data for wind and solar were gathered from the RE-Europe dataset, which provides granular hourly capacity factors for both technologies (Jensen and Pinson, 2017). Finally, a land eligibility analysis was performed to define thresholds for solar, wind, and salt caverns availability regionally.

An initial scenario considered a theoretical edge case in which all production is ensured with domestic electrolyzers, to illustrate the potential required infrastructure deployment and the associated costs entailed. Another more realistic scenario caps the electrolytic production to 14 TWh/yr (as per the German strategy target for 2030), while the remainder of the production comes from either new ATR plants or retrofitted SMR plants. A final scenario allows imports to occur between Norway and Germany.

## 3. Results

### 3.1. First Scenario: Self-Sufficiency with Electrolytic Hydrogen Only

In this situation, all hydrogen production stems from electrolyzers. The resulting supply chain as well as the LOCH<sub>2</sub> are illustrated in Figure 1. The resulting LCOH<sub>2</sub> is 5.12 €/kgH<sub>2</sub>. The required renewable energy/electrolyzer capacity oversize ratio is ~2, resulting in a total of 11% of electricity curtailed. Total electrolytic capacity reaches 22 GW, which is more than twice as much as what Germany plans to build by 2040. By 2021, installed solar capacity totaled 58 GW and wind capacity reached 64 GW in Germany (IRENA, 2022). Such a system would therefore monopolize a significant portion of renewable capacity. This edge case highlights the requirement to either import or continue producing domestically using other processes.

Hydrogen transmission accounts for less than 1% of the total costs. While hydrogen storage negligibly participates in the levelized cost, the required capacity is significant. The technical potential, evaluated at ~200 TWh for Germany, heavily relies on assumptions – actual potential might be closer to the order of magnitude of the optimum capacity. The cost of storage is also notably complicated to quantify and bears significant uncertainties. Since the deployment of such assets is unlikely in the short-term, storage may have to be performed by tanks, which would drive up the levelized cost.

### 3.2. Addition of Natural Gas Derived Hydrogen with New Plants and Retrofits

A further self-sufficiency scenario was run with a cap on electrolytic hydrogen production set to 14 TWh/yr. The remainder of the demand, or 41 TWh/yr, is fulfilled by natural gas derived hydrogen production. Two cases were considered: all fossil production came from new ATR plants, or all fossil production came from SMR retrofits.

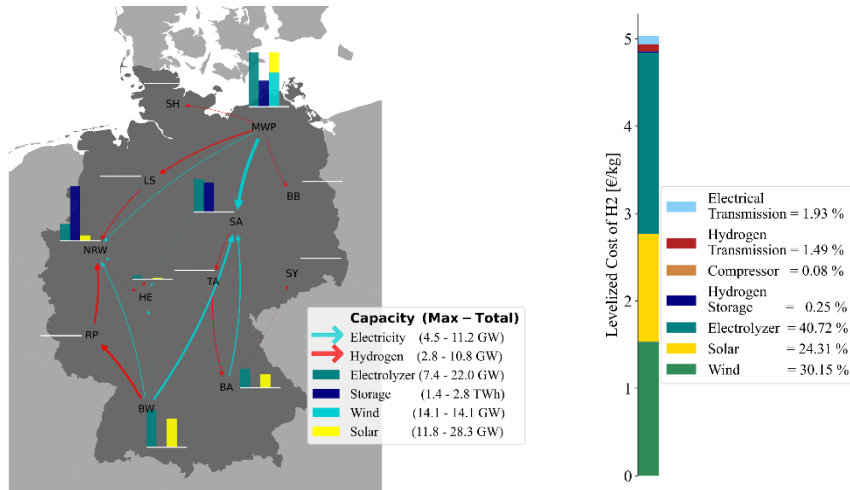

Figure 1: Supply chain required if Germany were to produce all its hydrogen with electrolyzers. “Max” represents maximum capacity between two regions (for electricity and hydrogen transmission) and within a region (for all other technologies), and “Total” represents overall capacity.

The resulting carbon intensities are laid out in the following table:

Table 1: Emission intensity for ATR (91% capture) and SMR (85%)

	ATR [kgCO <sub>2,eq</sub> /kgH <sub>2</sub> ]	SMR [kgCO <sub>2,eq</sub> /kgH <sub>2</sub> ]
Process (91% capture for ATR, 85% capture for SMR)	0.62	1.38
Indirect upstream (compression, transport infrastructure and flaring)	1.79	2.99
Electricity	1.44	1.77
Leaks and venting, production and transmission	1.35	2.25
<b>Total</b>	<b>5.20</b>	<b>8.38</b>
<b>Emissions per Year</b>	<b>6.39 MtCO<sub>2</sub>/yr</b>	<b>10.31 MtCO<sub>2</sub>/yr</b>

This assumes 9 gCO<sub>2,eq</sub>/MJ of natural gas for indirect upstream emissions (Bauer et al., 2021), 400 gCO<sub>2,eq</sub>/kWh intensity from the electricity grid, 1.5% methane leakage rate along the supply chain, a natural gas pipeline length of ~2000 km, and a 100 year global warming potential for methane. In contrast, electrolytic hydrogen has a carbon intensity of 0.8 kgCO<sub>2</sub>/kgH<sub>2</sub>. While direct emissions from the process are greatly reduced (down from ~10 kgCO<sub>2</sub>/kgH<sub>2</sub>), these results highlight the need to adequately reduce upstream emissions both from the natural gas supply chain as well as from the electricity.

### 3.3. Addition of Norwegian Hydrogen

This scenario considers imports of Norwegian hydrogen. This import is considered exogenously – hydrogen is assumed to be available at a constant rate and for a certain price (2€/khH<sub>2</sub>). Once again, electrolytic production is capped at 14 TWh/yr, implying 41 TWh/yr of imports. Imports occur through an undersea pipeline. The results show that a pipeline with a 4.7 GW capacity is required, dispatching hydrogen at a constant flow rate. An equal total capacity of domestic pipelines (~10.5 GW) is required in this scenario as would be in the 100% electrolysis case. Storage requirements are greatly decreased, highlighting the benefits of a steady source of hydrogen as opposed to an intermittent production.

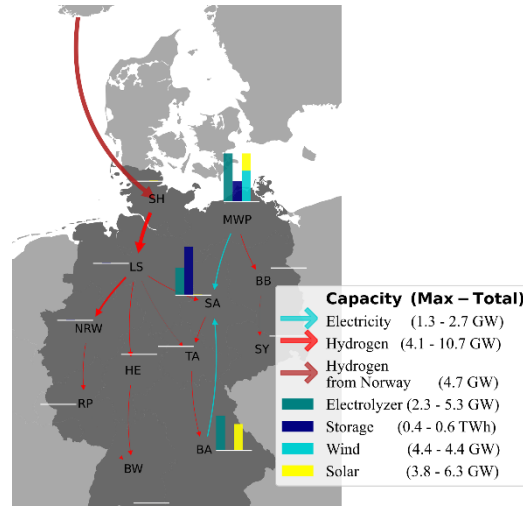

Figure 2: Hydrogen supply chain with 41 TWh/yr of imports from Norway.

Even though the levelized cost of electrolytic remains close to 5 €/kgH<sub>2</sub>, sourcing cheaper hydrogen from imports would in this case reduce the average levelized cost to 3.1 €/kgH<sub>2</sub>.

#### 4. Conclusion

This paper demonstrated that reaching hydrogen production self-sufficiency in a decarbonization context would face several limitations: cost hurdles, capacity limitation, both for electrolyzers and renewable technologies, and scale of natural gas plant retrofit required. Imports are therefore likely to become central to decarbonize procurement and should be further evaluated.

## Abstract

An equilibrium analysis of the reaction system for the synthesis of methanol based on CO<sub>2</sub> & CO hydrogenation and Water-Gas Shift reaction was performed to define the conditions under which the reaction system favours methanol production. The results were compared with a sensitivity analysis in a simplified Tubular Packed Bed Reactor (TPBR) with commercial Cu/Zn/Al<sub>2</sub>O<sub>3</sub> catalytic bed. As a result, the highest feedstock conversion to methanol at equilibrium was found with increasing pressure, decreasing temperature, and setting the initial H<sub>2</sub>/CO<sub>2</sub> ratio to 2.55. The reactor model showed similar behaviour in pressure and H<sub>2</sub>/CO<sub>2</sub> inlet ratio but differed in the temperature effect on feedstock conversion to methanol. Differences between equilibrium analysis and final reactor conversions are briefly discussed.

**Keywords:** CO<sub>2</sub> hydrogenation, Equilibrium analysis, Tubular packed bed reactor (TPBR) simulation, Sensitivity analysis.

## 1. Introduction

Methanol is an important commodity commonly used in the chemical industry to produce diverse value-added chemicals. According to the analysis made by Sonthalia (2021), this molecule is the basis for synthesizing diverse important compounds such as alcohols, dimethyl ether (DME), formaldehyde, methyl tertiary butyl ether (MTBE), acetic acid, and methyl formate among others. This molecule is not only used not only as a feedstock but also as a fuel in internal combustion engines with great environmental advantages since it can be produced more easily from renewable energies than commonly used fuels (Verhelst et al., 2019). In the work made by Khojasteh-Salkuyeh (2021) are established some used methanol production pathways in the industry such as natural gas conventional reforming, dry-reforming, tri-reforming or direct carbon dioxide hydrogenation. Among them, implementing direct CO<sub>2</sub> hydrogenation can carry out some advantages compared with natural gas reforming (widely used production method), like providing a more controlled reaction process due to a lower temperature in the reaction and a favourable environmental analysis of net CO<sub>2</sub> emissions when using green H<sub>2</sub>. The direct CO<sub>2</sub> hydrogenation to methanol is a reaction system highly dependent on equilibrium conditions, thus, this study aims to state the implication of temperature, pressure, and inlet feedstock ratio on the methanol production from an equilibrium approach with actualized data and relate these results with a sensitivity analysis in a simplified tubular packed bed reactor (TPBR).

## 2. Model Formulation

### 2.1 Model for species concentration at equilibrium

The carbon dioxide hydrogenation to methanol is an exothermic reaction system  $\Delta H_r = -49.4 \text{ kJ/mol}$ . Defined by Graaf (1986) as:

Reaction	Name	Abbreviature	$\Delta H_{t@298K}$
$\text{CO} + 2\text{H}_2 \leftrightarrow \text{CH}_3\text{OH}$	CO Hydrogenation	$r_1$	-90.5 kJ/mol
$\text{CO}_2 + \text{H}_2 \leftrightarrow \text{CO} + \text{H}_2\text{O}$	Water Gas Shift (WGS)	$r_2$	41.1 kJ/mol
$\text{CO}_2 + 3\text{H}_2 \leftrightarrow \text{CH}_3\text{OH} + \text{H}_2\text{O}$	CO <sub>2</sub> Hydrogenation	$r_3$	-49.4 kJ/mol

Table 1 – Reaction system for the synthesis of methanol from carbon dioxide.

The molar fraction of a component in a gas system when the equilibrium is reached  $(y_i)_{eq}$  depends on the equilibrium constants  $(K_{eq,j})$ , the pressure (P) and temperature (T) according to the implicit relation in eq.1.

$$0 = K_{\phi,j}(T, P, y_i(\epsilon_j))_{eq} \cdot K_{y,j}(y_i(\epsilon_j))_{eq} \cdot P^{\alpha_j} - K_{eq,j}(T) \quad \text{eq.1}$$

The equilibrium constants can be calculated with a polynomial temperature-dependent expression as presented in eq.2, the constants for this equation were taken from Graaf (2016).

$$\ln K_{eq,j}(T) = (1/RT) \cdot (a_1 + a_2T + a_3T^2 + a_4T^3 + a_5T^4 + a_6T^5 + a_7T \ln T)_j \quad \text{eq.2}$$

The non-ideal behavior of gas species was corrected by calculating the fugacity coefficients  $(\hat{\phi}_i)$  from the modified Soave-Redlich-Kwong equation of state (SRK-EoS) proposed by Van Bennekom (2012) and replacing these values in eq.3.  $K_{y,j}$  was calculated with eq.4.

$$K_{\phi,j} = \prod_{i=1}^n (\hat{\phi}_i(T, P, y_i(\epsilon_j))_{eq})^{\alpha_{ij}} \quad \text{eq.3}$$

$$K_{y,j} = \prod_{i=1}^n (y_i(\epsilon_j))_{eq}^{\alpha_{ij}} \quad \text{eq.4}$$

Note that the composition is expressed as a function of the reaction extent  $y_i(\epsilon_j)$  and this is useful to avoid extra degrees of freedom since each variation in species concentration follows a stoichiometric relation. Eq.5-6.

$$y_i(\epsilon_j) = \frac{n_{i0} + \sum_{j=1}^k \alpha_{ij} \epsilon_j}{n_T} \quad \text{eq.5}$$

$$n_T(\epsilon_j) = n_0 + \sum_{i=1}^n \sum_{j=1}^k \alpha_{ij} \epsilon_j \quad \text{eq.6}$$

Finally, by finding reaction extents values that make true the equality of eq.1, is possible to calculate the equilibrium compositions of each specie when temperature, pressure, and initial compositions changes.

## 2.2 Model for the tubular packed bed reactor

It is important to highlight that all variables affecting the concentration at equilibrium in eq.1  $(T, P, y_i)$  can only be manipulated indirectly by affecting conveniently the reactor design variables and input conditions. To compare this ideal equilibrium approach to a more accurate analysis, it was proposed a simplified model for a tubular packed bed reactor (TPBR) and the mathematical model is summarized in Table 2.

<b>Mass Balance</b>	$\frac{dF_i}{dW} = r'_i = \sum_{j=1}^2 c_{ij} \cdot r'_j$	eq.7
<b>Energy Balance</b>	$\frac{dT_R}{dW} = \frac{UA_s(T_j - T_R) + \sum_{j=1}^2 -\Delta H_j \cdot r_j}{F_{tot} \cdot C_{p,m}}$	eq.8
	Co-Current Jacket Configuration $\frac{dT_j}{dW} = \frac{UA(T_R - T_j)}{\dot{m}_c C_p}$	eq.9
	Counter-Current Jacket Configuration $\frac{dT_j}{dW} = \frac{-UA(T_R - T_j)}{\dot{m}_j C_{pj}}$	eq.10
<b>Momentum Balance</b>	$\frac{dP_R}{dW} = -\frac{G}{\rho_g g_c D_p} \left( \frac{1-e}{e^3} \right) \left[ \frac{150(1-e)\mu}{D_p} + 1.75G \right] * \frac{1}{(1-e)A_c \rho_c n_t}$	eq.11

Table 2 – Mathematical model for a Tubular Packed Bed Reactor.

## 2.4 Model for properties estimation

The properties of the gas mixture (gas density, volumetric flow, heat capacity and viscosity) were calculated or estimated under ideal conditions considering the temperature and

pressure in which the reactor simulation was developed (175°C - 255 °C and 25 bar – 60 bar respectively).

### 2.5 Kinetic model

The kinetic model was taken from Graaf (1988) and is summarized in Table 3. This kinetic model is based on widely used Cu/Zn/Al<sub>2</sub>O<sub>3</sub> catalysts. This kinetic study implies no mass diffusion limitations inside the catalyst particle and no mass transfer limitation in the solid-gas interface.

$r_1$	=	$k_1 b_{CO} \cdot \frac{\left( P_{CO} P_{H_2}^{3/2} - \frac{P_{CH_3OH}}{P_{H_2}^{1/2} K_1} \right)}{\left( 1 + b_{CO} P_{CO} + b_{CO_2} P_{CO_2} \right) \cdot \left( P_{H_2}^{1/2} + b_{H_2O} / b_{H_2}^{1/2} P_{H_2O} \right)}$	eq.12
$r_2$	=	$k_2 b_{CO_2} \cdot \frac{P_{CO_2} P_{H_2} - P_{CO} P_{H_2O} / K_2}{\left( 1 + b_{CO} P_{CO} + b_{CO_2} P_{CO_2} \right) \cdot \left( P_{H_2}^{1/2} + b_{H_2O} / b_{H_2}^{1/2} P_{H_2O} \right)}$	eq.13
$r_3$	=	$k_3 b_{CO_2} \cdot \frac{\left( P_{CO} P_{H_2}^{3/2} - \frac{P_{CH_3OH} P_{H_2O}}{P_{H_2}^{3/2} K_3} \right)}{\left( 1 + b_{CO} P_{CO} + b_{CO_2} P_{CO_2} \right) \cdot \left( P_{H_2}^{1/2} + b_{H_2O} / b_{H_2}^{1/2} P_{H_2O} \right)}$	eq.14

Table 3 – Kinetic model of the reaction system for CO<sub>2</sub> hydrogenation to methanol.

### 3. Computational and simulation aspects

For solving the reaction extents that make true the equilibrium relation in eq.1, it was used a trust-region algorithm with finite central numerical evaluation provided by Matlab integrated function *fsolve*. In this numerical process is present a high instability since  $K_{\phi,j}(T, P, \epsilon_j)$  and  $K_{\gamma,j}(\epsilon_j)$  (eq.3-4) are defined by a product operator, and it is necessary to rearrange these equations to avoid singularities in the numerical evaluation. The reactor model was simulated with the Matlab function *ode45* and the optimization of both equilibrium and reactor was performed by *fmincon* Matlab function.

The variable to evaluate the effect of inlet conditions (temperature, pressure, and initial H<sub>2</sub>/CO<sub>2</sub> ratio) on methanol concentration when equilibrium is reached was the feedstock conversion to methanol ( $X_C$ ). The meaning of this response variable is the total conversion of hydrogen and carbon dioxide to methanol when the equilibrium is reached compared to the stoichiometric quantities (eq.15).

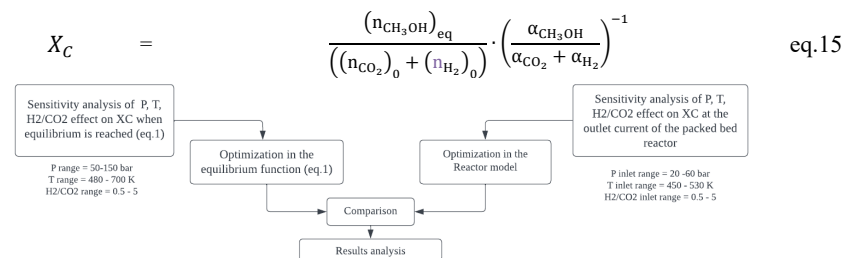

Figure 1 – General diagram to compare the effect of inlet temperature, pressure and H<sub>2</sub>/CO<sub>2</sub> on both current and equilibrium.

## 4. Results

### 4.1 Sensitivity analysis and optimization of feedstock conversion at equilibrium

The temperature and pressure effect on  $X_C$  were evaluated according to values in Table 4. As a result, it was evidenced a higher conversion of carbon dioxide and hydrogen to methanol at lower temperatures and higher pressures (Figure 2a). When evaluating the inlet H<sub>2</sub>/CO<sub>2</sub> ratio effect on  $X_C$ , it was evidenced a maximum value of feedstock conversion to methanol in a H<sub>2</sub>/CO<sub>2</sub> ratio equal to 2.55 (Figure 2b).

Constrained variables	Evaluation range		Optimal Values
	Min	Max	
Temperature	480 K	700 K	480 K
Pressure	50 bar	150 bar	150 bar
H <sub>2</sub> /CO <sub>2</sub> ratio	0.5	5	2.55
			$X_c = 0.79$

Table 4 – Optimal temperature, pressure and H<sub>2</sub>/CO<sub>2</sub> ratio to maximize feedstock conversion to methanol at equilibrium in the constrained numerical optimization of eq.1.

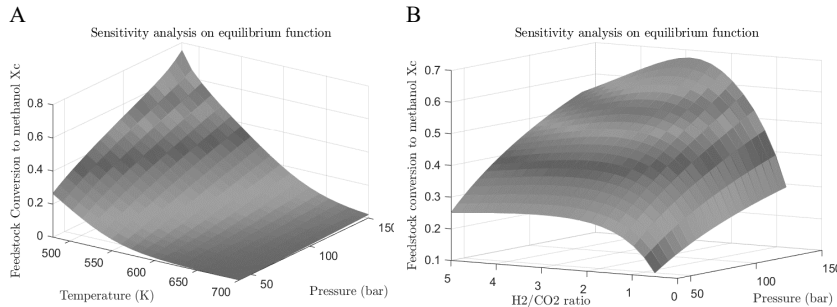

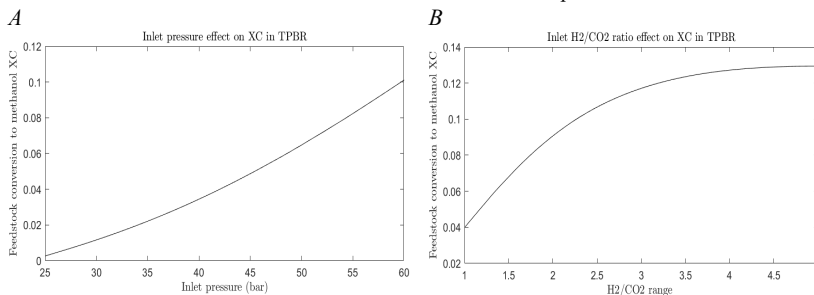

Figure 2 – Temperature, pressure and initial H<sub>2</sub>/CO<sub>2</sub> effect on feedstock conversion to methanol. a) T and P effect on  $X_c$ . b) P and inlet H<sub>2</sub>/CO<sub>2</sub> ratio effect on  $X_c$ .

#### 4.2 Sensitivity analysis and optimization of feedstock conversion in the TPBR

Only were evaluated temperature, pressure, and inlet H<sub>2</sub>/CO<sub>2</sub> effect, and other reactor-related variables was considered as parameters. When the sensitivity analysis was performed in the reactor model it was found a similar effect of inlet pressure and H<sub>2</sub>/CO<sub>2</sub> ratio on  $X_c$  as in equilibrium function (Figure 3a-b) but different in the temperature analysis (Figure 3c). An increment of the inlet temperature of feedstock current or in the liquid at the different jacket configurations increased  $X_c$  until limit value in which the trend was reversed and finally followed the same tendency as in equilibrium analysis. Note that the equilibrium is not reached in the TPBR at the end of the process and the temperature and pressure ranges differs in both equilibrium and reactor sensitivity analysis; this is why all values of  $X_c$  in the reactor model are lower than the direct analysis of the equilibrium expression (see Figure 3d). The optimization constrains of the TPBR are in Table 5.

	Evaluation range			Optimal Values
	Min	Max		
Temperature	Feedstock	480 K	530 K	508 K
	Jacket - Countercurrent	480 K	530 K	530 K
	Jacket - Co-current	480 K	530 K	530 K
Pressure	20 bar	60 bar		60 bar
H <sub>2</sub> /CO <sub>2</sub> ratio	0.5	5		4
				$X_c = 0.165$

Table 5 – Optimal temperature, pressure and H<sub>2</sub>/CO<sub>2</sub> ratio to maximize feedstock conversion to methanol at the outlet of the TPBR in the constrained numerical optimization of EDO in Table 2.

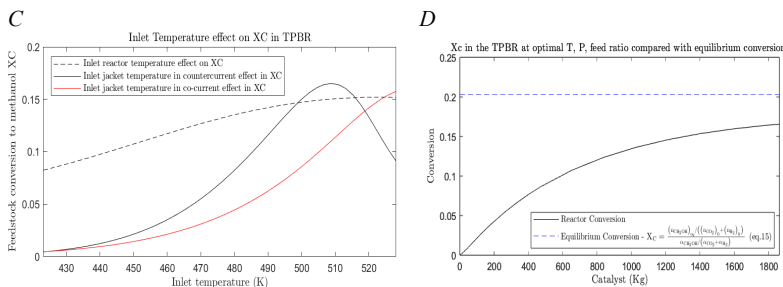

Figure 3 – a) Effect of inlet pressure on  $X_C$  in the TPBR. b) Effect of inlet  $H_2/CO_2$  on  $X_C$  the TPBR. c) Effect of inlet temperature (Inlet species temperature vs inlet Jacket temperature) on  $X_C$  in the TPBR. d) Direct comparison of equilibrium analysis and de conversions achievable in the proposed TPBR.

## 5. Comparison and brief results discussion

### 5.1 Temperature

Temperature affects mainly the equilibrium constants ( $K_{eq,j}$ ) and the fugacity coefficients of the components in the mixture ( $\hat{\phi}_i$ ). The evaluation of eq.1 in Figure 2a shows that lower temperatures favor methanol synthesis. As higher the temperature, higher the methanol oxidation to carbon dioxide and higher the production of undesirable products like CO and  $H_2O$  (WGS reaction). When the temperature was evaluated in the TPBR, the tendency was different, among others, because the activation energies in Graaf (1988) kinetic model. For instance, in Figure 4 the reaction rate of methanol is favored with temperature despite the different tendency in equilibrium sensitivity analysis. Then, it is necessary to optimize temperature to be high enough to reach a good react rate and be low enough to achieve good feedstock conversion to methanol. Finally, the optimal inlet temperature is different depending on the heat dissipation system properties throughout the catalytic bed weight. In the proposed model, the countercurrent configuration reached a higher feedstock conversion to methanol faster than co-current configuration.

### 5.2 Pressure and $H_2/CO_2$ ratio

The equilibrium composition of methanol increases with pressure (Figure 2, 3a). Pressure is directly related with concentration of moles in the gas phase and the species activity. When the  $H_2/CO_2$  ratio effect is analyzed (Figure 2b), the feedstock conversion to methanol reaches a maximum value when inlet feedstock ratio is 2.55. This value represents an optimal feedstock input and is a quantity close to the stoichiometric relation in the reaction.

## 6. Conclusions & further recommendations

As lower the values of temperature and higher the pressure in the gas-phase system, the feedstock conversion to methanol increases, but the temperature should be enough to promote the methanol reaction rate to achieve considerable feedstock conversion in the reactor geometry. When temperature raises, the system shifts towards carbon monoxide and water production. For a constrained optimization of equilibrium expression, the optimal values of temperature, pressure and  $H_2/CO_2$  ratio values were 480 K, 150 bar and 2.55 respectively. The temperature control in the TPBR model depends on the jacket fluid configuration and the characteristics of the heat dissipation system. For this specific set of conditions, it was found a jacket liquid temperature in countercurrent to maximize  $X_C$  of 508K, an inlet pressure of 60 bar and inlet  $H_2/CO_2$  ratio of 4. Also, is secure to affirm that

Figure 4 – Temperature and pressure effect on methanol reaction rate in Graaf (1988) kinetic model at the inlet conditions of the TPBR reactor.

an increase of the pressure is an excellent form to increase feedstock conversion to methanol due to its positive effect in both equilibrium expression and TPBR model analysis. The most substantial differences between the analysis of the equilibrium expression and the reactor model may lie in the fact that this reactor model is limited and cannot reach a closer conversion to equilibrium concentrations with the specified reactor design parameters. Another limitation is the small range of temperatures and pressures over which the reactor model is valid. Further analysis should robust the reactor model and compare all the temperatures and pressures ranges in the reactor with the equilibrium expression. But, with the basis relations founded in this simple reactor model is possible to understand the fundamentals of the reaction behavior and design more complex reactor models.

## 7. Notation table

$T_R$	Reactor Temperature (K)	$U$	Global Heat Transfer coefficient ( $J/m^2sK$ )
$T_j$	Jacket Temperature (K)	$A_s$	Heat Transfer Area ( $m^2/kgCat$ )
$P_R$	Reactor pressure (bar)	$\widehat{\Phi}_i$	Fugacity coefficient of the components in mixture (bar)
$F$	Total molar flow (mol/s)	$y_i$	Molar fraction in gas phase (-)
$F_i$	Species molar flow (mol/s)	$\epsilon_j$	Reaction extent
$H_2/CO_2$	Inlet Hydrogen vs Carbon dioxide relation (-)	$P, T$	Pressure (bar) – Temperature (K) for equilibrium function analysis.
$\rho_g$	Gas mixture density ( $kg/m^3$ )	$\alpha_{ij}$	Stoichiometric coefficients
$\mu_g$	Gas mixture viscosity ( $Pa \cdot s$ )	$\bar{\alpha}_j$	Sum of stoichiometric coefficients for $j$ reaction.
$G_g$	Gas mass Flux density ( $kg \cdot m^{-2} \cdot s^{-1}$ )	$K_\Phi$	Equilibrium constant based in fugacity coefficients
$C_{p_g}$	Molar gas mixture heat capacity ( $J/molK$ )	$K_y$	Equilibrium constant based on molar fractions
$C_{p_j}$	Molar Jacket liquid heat capacity ( $J/molK$ )	$K_p^0$	Equilibrium constant based in partial pressures
$e$	Catalyst void fraction (-)	$X_c$	Feedstock conversion to methanol (-)
$\rho_{cat}$	Catalyst density ( $kg_{cat}/m^3$ )	$\Delta H_{r,j}^0$	Enthalpy change of formation ( $J/mol$ )
$D_p$	Particle diameter (m)	$r'$	Reaction rate per weight of catalyst ( $mol/skg_{cat}$ )
$n_t$	Tubes number (-)	Subscripts	
$D_t$	Tubes diameter (m)	$i$	Refers to species $n = \{1,2,3,4,5\}$
$A_c$	Tube cross-sectional area ( $m^2$ )	$j$	Refers to reactions $k = \{1, 2, 3\}$
$g_c$	Conversion factor (SI=1)	$0$	Refers Initial state
$b$	Adsorption constant	$eq$	Refers to equilibrium

## Abstract

In Crystal Structure Prediction, transferable force-fields (FF) offer an efficient means to construct cheap surrogates of more accurate models. FF development, however, demands large volumes of high-quality reference data which are scarce in experimental databases. In this work, we use periodic DFT-D generated reference data to parameterize a FF apt for predicting properties of crystals in which molecules interact via hydrogen-bonds. Tang-Toennies damping is applied to the underlying Buckingham potential, and several fitting schemes are tested. Our FF achieves good agreement with the energy and geometry training data, for structures with and without hydrogen-bonds. When applied to a validation set, the quality of property predictions are largely preserved, evidence of FF transferability. Testing the popular FIT FF on our data fails to achieve the same accuracy, likely since it was derived from different reference data and lacks the damping function.

**Keywords:** Crystal Structure Prediction, Transferable Force-field, Parameter Estimation

## 1. Introduction

Many industrial process intermediates and commercial products exist in crystalline form. To predict the physicochemical properties of such materials requires knowledge of the three-dimensional arrangement of molecules within their crystal lattice. This, however, is complicated by the fact that most molecular crystals can exist in geometries other than their thermodynamically most stable form (Cruz-Cabeza *et al.*, 2015). Failure to identify these metastable polymorphs can have severe financial, legal, and social repercussions (Bučar *et al.*, 2015), especially since the interconversion to a more stable form is spontaneous yet highly unpredictable if the metastable form is kinetically trapped.

The central goal of Crystal Structure Prediction (CSP) is thus to characterize the structure and thermodynamic stability of all putative crystal forms from a description of only molecular connectivity (Pantelides *et al.*, 2014). Most CSP methodologies seek to accomplish this by minimizing the crystal static lattice-energy ( $U_{\text{latt}}$ ) relative to its geometry at 0 K and 0 Pa (Bowskill, 2021). By minimizing an ample number of crystalline geometries, an adequate survey of the crystal structure landscape may be achieved. Energetically low-lying minima, within 10 kJ/mol of the global minimum (Nyman & Day, 2015), are then regarded as potentially observable experimental forms.

The validity of any CSP study is thus dependent on both the breadth of the search and the accuracy of the energy model used. Hybrid energy models which use a combination of

*ab initio* calculations and empirical force-fields (FFs) offer a good balance between accuracy and computational cost. Whilst the *ab initio* components of these models have been studied extensively, the accompanying empirical FFs have not. Transferable FFs like FIT (Coombes *et al.*, 1996) and W99rev (Pyzer-Knapp *et al.*, 2016) are widely used despite deficiencies in the estimation of FF parameters (Gatsiou *et al.*, 2018). For instance, reliance on experimental heat of sublimation ( $\Delta H_{\text{sub}}$ ) data to provide “experimental” values of  $U_{\text{latt}}$  limits FF validity for two reasons. First, the relationship used to derive  $U_{\text{latt}}$  from  $\Delta H_{\text{sub}}$  is approximate. Second, experimental  $\Delta H_{\text{sub}}$  values are scarce, resulting in FF parameters biased towards geometry prediction. Finally, both FFs mentioned were derived using multipole (MP) descriptions of electrostatics. This may invalidate their use in the initial stages of CSP, with point-charge (PC) electrostatics.

In the larger context of CSP, dispersion-corrected periodic density-functional theory (DFT-D) is regarded as the gold-standard of accuracy (Brandenburg & Grimme, 2016) and is usually applied at end of CSP studies to refine results obtained with cheaper models. In the spirit of a blind CSP study, it is thus more sensible to design hybrid models that act as surrogates for the DFT-D landscape since the true experimental landscape remains unknown. For these reasons, in this work, we seek to develop a robust FF compatible with PC electrostatics, fit to high-quality DFT-D generated reference data. Details of the energy model and fitting procedure are described in Section 2. In Section 3, the performance of the newly parameterized FF is then explored.

## 2. Methodology

### 2.1. Lattice-Energy Model

Within our energy model,  $U_{\text{latt}}$  comprises intra- and intermolecular contributions,

$$U_{\text{latt}}(\mathbf{X}, \mathbf{p}) = \Delta U_{\text{intra}}(\mathbf{X}) + U_{\text{inter}}(\mathbf{X}, \mathbf{p}) = \Delta U_{\text{intra}}(\mathbf{X}) + U_{\text{elec}}(\mathbf{X}) + U_{\text{FF}}(\mathbf{X}, \mathbf{p}), \quad (1)$$

where  $\mathbf{X}$  is the vector describing the crystal geometry (cell lengths and angles, and atomic positions).  $U_{\text{latt}}$  contains the energy cost of distorting a molecule’s conformation relative to its gas-phase conformation ( $\Delta U_{\text{intra}}$ ), and stabilizing packing forces ( $U_{\text{inter}}$ ).  $U_{\text{inter}}$  comprises intermolecular charge-charge interactions ( $U_{\text{elec}}$ ), electron-correlation, and exchange-repulsion. The latter two effects are described by the pairwise summation of interactions between atoms  $i$  and  $j$  separated by distance  $r_{ij}$ , interacting via a Buckingham potential (BHP) with model parameters  $\mathbf{p} = \{A_{ij}, B_{ij}, C_{ij}\}$ ,

$$U_{\text{FF}}(\mathbf{X}, \mathbf{p}) = \sum_i \sum_j A_{ij} \cdot \exp\left(-\frac{r_{ij}}{B_{ij}}\right) - f_6(\beta_{ij}, r_{ij}) \cdot \frac{C_{ij}}{r_{ij}^6}, \quad (2)$$

$$f_6(\beta_{ij}, r_{ij}) = 1 - \left[ \sum_{k=0}^6 \frac{(\beta_{ij} \cdot r_{ij})^k}{k!} \right] \cdot \exp(-\beta_{ij} \cdot r_{ij}) \quad \text{where } \beta_{ij} = \frac{1}{B_{ij}}. \quad (3)$$

In its native form ( $f_6 = 1$ ) the BHP potential exhibits unphysical short-range attractions. When  $A_{ij}/B_{ij}$  is small and/or  $C_{ij}$  is large, this unphysical region extends to longer ranges and eventually the potential can become fully attractive. To mitigate this occurring in highly attractive hydrogen-bond (HB) interactions, the Tang-Toennies (Tang & Toennies, 1984) damping function ( $f_6$ ) is applied within our potential. Its damping factor ( $\beta_{ij}$ ) is correlated to the  $B_{ij}$  repulsion term to avoid overfitting. Finally,  $U_{\text{elec}}$  and  $\Delta U_{\text{intra}}$  are determined from *ab initio* calculations performed on the isolated molecules of interest, while the  $\mathbf{p}$  in  $U_{\text{FF}}$  are found empirically by fitting to crystal data. As a result,  $U_{\text{FF}}$  absorbs systematic errors from the *ab initio* components of the model (Pantelides *et al.*, 2014). For instance, the inductive effects molecules exert on each other in the crystal lattice are neglected by isolated molecule calculations and must be captured by  $U_{\text{FF}}$ .

## 2.2. Reference Data

DFT-D reference data are generated in the Vienna Ab initio Simulation Package (VASP v5.4.4, Kresse & Joubert, 1999) using the Tao-Perdew-Staroverov-Scuseria (Tao *et al.*, 2003) functional with D3 dispersion-correction (Grimme *et al.*, 2010). Experimental structures from the Cambridge Structural Database are first relaxed to obtain reference geometries. A single-point calculation is done on isolated molecule  $m$  at its crystalline conformation to obtain its monomer energy ( $U_{\text{iso},m}$ ). Using the number of molecules in the unit cell ( $Z$ ) and asymmetric unit cell ( $Z'$ ), the reference energy ( $U_{\text{inter,ref}}$ ) is found from

$$U_{\text{inter,ref}} = \frac{U_{\text{total,vasp}}}{Z} - \frac{\sum_{m=1}^{Z'} U_{\text{iso},m}}{Z'}. \quad (4)$$

The training set comprises 313 non-HB (NHB) crystals and 132 HB crystals, while an additional 28 structures (12 NHB and 16 HB) are used in the validation set. More details about the computational methods and training structures are described in Bowskill (2021).

## 2.3. Parameter Estimation Algorithm

The parameter estimation is conducted using CrystalEstimator (v1.4) as described in Bowskill (2021). During the parameter estimation, the following problem is solved,

$$\min_{\mathbf{p}} \frac{1}{2} \sum_{i=1}^{N_c} \left\{ \sum_{j=1}^{N_{X,i}} \frac{\omega_g [X_{ij}^{\text{ref}} - X_{ij}^*(\mathbf{p})]^2}{N_{X,i} \cdot [X_{ij}^{\text{ref}}]^2} + \sum_{j=1}^{N_{R,i}} \frac{\omega_g [R_{ij}^{\text{ref}} - R_{ij}^*(\mathbf{p})]^2}{3(N_{R,i} - 1)} + \frac{\omega_e [U_{\text{inter},i}^{\text{ref}} - U_{\text{inter},i}^*(\mathbf{p})]^2}{[U_{\text{inter},i}^{\text{ref}}]^2} \right\}, \quad (5)$$

where  $X_{ij}$  is the  $j^{\text{th}}$  lattice cell parameter (lengths and angles) for crystal  $i$ ,  $R_{ij}$  its  $j^{\text{th}}$  atomic fractional coordinate, and  $U_{\text{inter},i}$  its intermolecular energy respectively. The number of crystals is  $N_c$ , and the dimensions of  $X_i$  and  $R_i$  are crystal-specific ( $N_{X,i}$  and  $N_{R,i}$ ).  $\omega_g$  and  $\omega_e$  are the respective weights for the geometry and energy residuals. The superscripts ‘ref’ and ‘\*’ respectively indicate the reference values and the values calculated by minimizing  $U_{\text{latt}}$  at a given  $\mathbf{p}$ . The parameter estimation is thus a bilevel optimization since at each trial  $\mathbf{p}$ , all reference crystals must have their  $U_{\text{latt}}$  minimized first. In this minimization, molecules are kept rigid at their reference conformation ( $\Delta U_{\text{intra}} = 0$ ,  $U_{\text{latt}} = U_{\text{inter}}$ ) and  $U_{\text{elec}}$  is calculated from PCs derived in Gaussian09 using the HLYGAt scheme with the PBE0 functional and 6-311G(d,p) basis set. Due to the multiplicity of local minima on the  $\mathbf{p}$ -solution landscape, multi-start initialization using low-discrepancy Sobol’ sequences is used to generate the initial  $\mathbf{p}$  vectors. The Sobol’ point which yields the best objective function value (OF) is taken to be the final solution. At the solution, we evaluate the RMSD<sub>15</sub> value between optimized and reference structures, determined with the Cambridge Crystallographic Data Centre’s COMPACK tool (distance and angle tolerances are set to 0.4 and 40°), and deviations in  $U_{\text{inter}}$  ( $dU = U_{\text{inter}}^* - U_{\text{inter}}^{\text{ref}}$ ).

## 2.4. Lattice-Energy Model

To select a suitable number of parameters which capture the underlying physics without overfitting, several fitting schemes are tested. We opt to parameterize all heteroatomic interactions ( $i \neq j$ ) rather than using combining rules. Analysis of our training set and experimental crystal structures (Gavezzotti & Filippini, 1994) indicates that Hs bonded to O ( $H_o$ ) and N ( $H_n$ ) exhibit distinct HB geometries, hence we distinguish the two. It was previously asserted that polarized Hs would be stripped of electron density and exhibit no dispersive attractions ( $C_{ij} = 0$  for  $i = H_{o/n}$ ) (Pyzer-Knapp *et al.*, 2016). In practice, other parts of the model may not fully capture the HB effects and require the FF to compensate, hence, we test setting  $C_{H_o \text{ or } H_n/j} = 0$  and varying  $C_{H_o \text{ or } H_n/j}$ . Finally,  $A_{ij}$  and  $B_{ij}$  are highly correlated, thus it is common to fix  $B_{ij}$  and fit only  $A_{ij}$  and  $C_{ij}$ .  $B_{ij}$  were initially fixed to the FIT FF values, but subsequently some  $B_{H_o \text{ or } H_n/j}$  were also allowed to vary.

Table 1: Performance of each FF in describing the training set. Only FF1, FF2, and FF3 are damped. The average RMSD<sub>15</sub>, average  $dU$ , and average absolute  $dU$  ( $|dU|$ ) are presented for the entire training set (NHB+HB), NHB, and HB crystals. The number of structures which failed to give a valid RMSD<sub>15</sub> are given in parenthesis. Parameters are obtained either by combining rules (CR), varied in the optimization (VR), or fixed (FX).

FF	$i \neq j$	$B_{ij}$	$C_{ij}$	OF	Data	RMSD <sub>15</sub> (Å)	$dU$ (kJ/mol)	$ dU $ (kJ/mol)

### 3. Results

Three FFs are obtained using the fitting schemes described in Section 2. Their performance in describing the training set is compared against the FIT FF in Table 1. In some structures, failure to match 15 molecules results in no RMSD<sub>15</sub> being generated.

Over the training set, all three newly parameterized FFs present with similarly small errors in average  $dU$  ( $< 5$  kJ/mol) and  $|dU|$  ( $< 10$  kJ/mol). In a previous work which used the same training set (Bowskill, 2021), the average  $dU$  and  $|dU|$  of the HB structures were 22.31 kJ/mol and 22.48 kJ/mol respectively, indicating that the new FFs exhibit a marked reduction in the energy errors for these structures. In the previous work, energy data for the HB structures was omitted due to numerical issues associated with the optimization. The inclusion of the damping function in this work appears to have mitigated these problems. However, to match the HB energies well, the geometry predictions worsen significantly, particularly for the HB structures. Using FF1 and FF2, not only do the average RMSD<sub>15</sub> values for HB structures increase over the previous work (0.238 Å), but more critically, some structures fail to produce any RMSD<sub>15</sub> values at all.

This tradeoff between energy and geometry may be explained as follows. In FF1, fixing  $C_{ij} = 0$  for the H<sub>o/n</sub> interactions prevents these interactions from contributing to the deficit in  $U_{\text{inter}}$ . The only recourse is for the optimizer to set  $A_{ij}$  in these interactions to 0 (or close to 0), allowing greater short-range charge-charge interactions and other atoms to interact deeper within their energy-wells, at the expense of the fidelity to geometry. Allowing non-zero  $C_{ij}$  within FF2 does somewhat alleviate this issue, but there remain some interactions (e.g., O/H<sub>o</sub>) where  $A_{ij} = 0$ , resulting in fully attractive potentials. The absence of repulsive walls in FF1 and FF2 (Figure 1, left) permit unnaturally close contact distances that prevent the assessment of RMSD<sub>15</sub> and cast doubt on the transferability of these FFs. In contrast, by allowing some of the  $B_{ij}$  involving H<sub>o/n</sub> to vary (FF3), we attain potentials which *all* have repulsive walls. As the only ‘physically sensible’ FF, the transferability of FF3 is tested on an independent validation set. Overall, the performance of FF3 does not deteriorate radically from the training set (Table 2), with a similar quality of energy prediction. While the average RMSD<sub>15</sub> for HB structures increases, it is still within a cutoff that most CSP practitioners would consider acceptable ( $< 0.5$  Å).

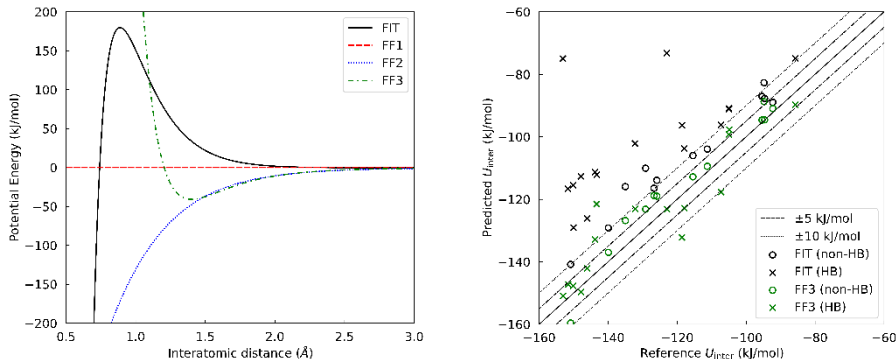

Figure 1: (Left) Comparison of the H/O potential for the four FFs. (Right) Parity plot of the validation set  $U_{inter}$ , comparing the performance using the FIT FF and FF3.

As mentioned before, the goal of modern CSP FFs is to act as proxies for the DFT-D landscape. To further benchmark our FFs, we compare against the FIT FF. Within both the training and validation set, whilst the FIT FF offers good geometry predictions, energies are substantially underbound, especially for HB structures. We note FIT is being used well beyond the data to which it was parameterized. Correcting from their  $\Delta H_{sub}$  to our DFT-D  $U_{inter,ref}$  is approximately given by  $-\Delta H_{sub} = U_{inter} + \Delta U_{intra} + 2RT$ . In deriving FIT, it was assumed that  $\Delta U_{intra} \approx 0$ , while our VASP calculations predict  $\Delta U_{intra}$  as large as 20 kJ/mol in HB structures even with small conformational changes. Moreover, our  $U_{inter,ref}$  are effectively at 0 K, while the room-temperature data used in FIT would result in a positive  $2RT$ , but this was ignored in the original fitting. Overall, the FIT reference energies underpredict the DFT-D  $U_{inter,ref}$ , explaining the large, positive average  $dU$  observed when applying FIT here. This is also apparent when one considers the shape of the potentials (Figure 1, left): FF3 has deeper energy-wells and shorter-range repulsive walls, while FIT has a repulsive wall at distances exceeding the typical HB lengths (O-H $\cdots$ O distances  $\approx 1.6$ -1.9 Å, Gavezzotti & Filippini, 1994), and shallower energy-wells.

#### 4. Conclusion

Electronic-structure methods like DFT-D offer our ‘best guess’ of the polymorphic landscape and are used in the final stages of a CSP study. With this in mind, we construct hybrid energy models to emulate the DFT-D landscape as opposed to the (unknown) experimental landscape. In parameterizing a FF using DFT-D generated training data, commonly used model-simplifications were found to yield unphysical results. By altering the functional form of the FF and avoiding setting model parameters to arbitrary values,

Table 2: Performance of FF3 and FIT in describing the validation set. The average  $RMSD_{15}$ , average  $dU$ , and average absolute  $dU$  ( $|dU|$ ) are presented for the full dataset, NHB, and HB crystals. All structures gave valid  $RMSD_{15}$  with both FFs. The change in each metric from the training set is given in parenthesis for FF3.

FF	Data	$RMSD_{15}$ (Å)	$dU$ (kJ/mol)	$ dU $ (kJ/mol)
FIT	NHB+HB	0.2811	20.8127	20.8127
	NHB	0.2097	10.7082	10.7082
	HB	0.3346	28.3911	28.3911
FF3	NHB+HB	0.2380 (+0.0177)	1.6665 (+1.3777)	6.3550 (+2.2946)
	NHB	0.1549 (-0.0580)	2.9774 (+2.8044)	4.4317 (+1.0027)
	HB	0.3003 (+0.0626)	0.6833 (+0.1198)	7.7975 (+2.2402)

we were able to obtain a FF that makes physical sense and is effective in describing crystal properties. In both the training and validation sets, our new FF has an average  $|dU| < 10$  kJ/mol, well within the threshold for identifying putative structures. Conversely, a FF like FIT that was parameterized to experimental data is unsuited to predict the DFT-D landscape. Ultimately, using computationally generated reference data will allow us to circumvent the limitations of scarce experimental data and explore new avenues in CSP FF development, such as the expansion of atom-typing.

## Abstract

Taking uncertainty into account is crucial when making strategic decisions. To guard against the risk of adverse scenarios, traditional optimisation techniques incorporate uncertainty based on prior knowledge on its distribution. In this paper, we show how, based on limited historical data, we can generate from a low-dimensional space the underlying structure of uncertainty. To this end, we first exploit the correlation between the sources of uncertainty through a principal component analysis (PCA) to reduce dimensionality. Next, we perform clustering to reveal the typical uncertainty patterns, and finally we generate polyhedral uncertainty sets based on a kernel density estimation (KDE) of marginal probability functions.

**Keywords:** Polyhedral Uncertainty Set, Robust Optimisation (RO), PCA, Kernel density estimation (KDE), Dimensionality Reduction, Data scarcity.

## 1. Introduction

Optimisation under uncertainty aims to find optimal solutions given uncertain outcomes. This is typically done through methods like chance-constrained optimisation, robust optimisation, or stochastic optimisation, which require prior knowledge of an uncertainty set or probability distribution. Robust optimisation (RO) is for instance a suitable method in situations where insufficient historical data is available to accurately estimate distributions (Roald et al., 2023). In this method, the solution hedges against a range of possible realisations called uncertainty set with emphasis on the worst-case to guarantee feasibility of the policy derived. The definition of such uncertainty set is crucial: the larger it is, the less informative it becomes and the more conservative is the solution, which could render it impractical (Ben-Tal et al., 2009).

We mention here some methods and their limitation that have been recently proposed in the literature to generate uncertainty sets. First, Bianchi et al. (2018) employ statistical hypothesis tests to derive uncertainty sets' sizes. Nonetheless, these tests become impractical in cases of data scarcity. In Shang et al. (2017); Ning and You (2018), a single polyhedral uncertainty set (PUS) is obtained using respectively kernel learning (support vector clustering) or a principal component analysis (PCA) coupled with kernel smoothing. However, this assumes continuous data and cannot handle uncertainty formed as a collection of independent states. To circumvent this limitation, Ning and You (2017, 2019) define the uncertainty set as the union of PUS, which are generated using a Dirichlet process mixture model. However, the latent uncertainty used to generate the PUSs is of same dimension as the original uncertainty, leading to computational intractability for high dimensional uncertainty sets when used in RO (Ben-Tal et al. 2009).

There is consequently the need for a method that generates polyhedral uncertainty sets in the case of data sparsity where uncertainty is highly dimensional and consists of independent sets of realisations; this is the objective of the present paper.

The rest of this paper is structured as follows: In Section 2, we present the method which derives polyhedral uncertainty sets from a low-dimensional space based on historical data. We then show in Section 3 how it can be applied to the energy data in the United Kingdom. In Section 4 a discussion of the key findings is presented and finally in Section 5 conclusions on the main contributions of this work are drawn.

## 2. Method for deriving polyhedral uncertainty sets

To motivate the importance of building polyhedral uncertainty sets, we consider the following scenario-based linear adaptive robust optimisation (ARO) problem, which is recurrently used to formulate energy problems (e.g. unit commitment):

$$\underset{\mathbf{x}}{\text{minimise}} \mathbf{c}^T \mathbf{x} + \sum_{k \in \mathcal{K}} p_k \left( \max_{\mathbf{v}_k \in \mathcal{V}_k} \min_{\mathbf{y}_k} \mathbf{b}_k^T \mathbf{y}_k \right) \quad (1a)$$

$$\text{such that } \mathbf{A}\mathbf{x} \leq \mathbf{d} \text{ and } \forall k \in \mathcal{K}: \mathbf{h}_k - \mathbf{T}_k \mathbf{x} - \mathbf{M}_k \mathbf{v}_k \leq \mathbf{W}_k \mathbf{y}_k \quad (1b)$$

where  $\mathbf{x}$  and  $\mathbf{y}_k$  with  $k \in \mathcal{K}$  are respectively the first and second stage variables,  $\mathcal{K}$  is the set of distinct operation conditions/scenarios,  $\mathcal{V}_k$  is the uncertainty set associated to the uncertain parameters for scenario  $k \in \mathcal{K}$ , and  $p_k$  is its weight (or probability of occurrence). Such problem can be solved either in a monolithic fashion or by using variants of Benders' decomposition. If each set  $\mathcal{V}_k$  is a polyhedral uncertainty set, then each set can be expressed as linear constraints, which facilitates the resolution of the ARO problem by exploiting the dual formulation associated to a linear program (Birge and Louveaux, 2011). We now show how to derive these PUSs  $\mathcal{V}_k$  based on limited historical data and how to generate them from lower dimensional spaces. The method is here illustrated for energy uncertainty data but is not restricted to such application.

Let  $n \in \mathbb{N}$  be the number of uncertain attributes (e.g. electricity demand, temperature). Let  $\mathbf{v}^{(i)} \in \mathbb{R}^{24n}$ ,  $i \in \llbracket 1, m \rrbracket$ , be  $m$  historical data points, where the vector  $\mathbf{v}^{(i)}$  contains the standardised daily profiles (hourly values) of all attributes on a given day  $i \in \llbracket 1, m \rrbracket$ . We assume that the data is standardised in the sense that the sample mean and standard deviation of each component over all  $m$  data points is respectively 0 and 1. This allows for attributing an even weight to any uncertain component. Given a data point  $\mathbf{v}^{(i)} \in \mathbb{R}^{24n}$ , let  $\mathbf{V}^{(i)} \in \mathbb{R}^{n \times 24}$  be the matrix with the daily profiles of each attribute on its rows.

As an initial step, based a correlation analysis, we define a set  $\mathcal{A}$  of disjoint groups of attributes such that the data inside a group is strongly correlated while being weakly correlated with any other group. We then assume that these groups of attributes are independent and separately generate a polyhedral uncertainty set for each one of them. The (weak) correlation between the groups will partly be reinstated on a later stage when defining the scenarios. For any group of attributes  $a \in \mathcal{A}$ , we denote by  $\mathbf{v}_a^{(i)} \in \mathbb{R}^{24n_a}$  the data related to the  $n_a$  attributes associated to  $a$  for a day  $i \in \llbracket 1, m \rrbracket$ .

The following steps allow for deriving a PUS based on a lower dimensional space for each group  $a \in \mathcal{A}$ : First, we perform a principal component analysis (PCA) and express the data in the PCA basis: this allows for finding the directions along which the data has greatest variance. Mathematically, there exists an orthogonal matrix  $\mathbf{P}_a \in \mathbb{R}^{24n_a \times 24n_a}$

such that, any data point  $\mathbf{v}_a^{(i)}$ ,  $i \in \llbracket 1, m \rrbracket$ , expressed in the original basis can be expressed in the PCA basis using the linear transformation:  $\mathbf{w}_a^{(i)} = \mathbf{P}_a \mathbf{v}_a^{(i)}$ . As  $\mathbf{P}_a$  is orthogonal, the linear transformation from the PCA basis to the original basis is given by  $\mathbf{v}_a^{(i)} = \mathbf{P}_a^T \mathbf{w}_a^{(i)}$ . Given the data in the PCA basis, we perform dimensionality reduction by retaining only the first  $r_a$  components that explain the most the variability inside the data. As the data is strongly correlated inside any group  $a \in \mathcal{A}$ , we expect to have  $r_a \ll 24n_a$ . Let  $\bar{\mathbf{w}}_a^{(i)} \in \mathbb{R}^{r_a}$  denote the data points in the truncated PCA basis, where only the first  $r_a$  components are kept.

To define the typical operational conditions associated to a group  $a \in \mathcal{A}$  of attributes, we perform clustering (e.g. K-means) on the data points expressed in the truncated PCA basis. Clustering in the PCA basis rather than in the original basis allows to give relatively more importance to the directions explaining the most the variance and obtain more meaningful clusters (Ding and He, 2004). We denote by  $\mathcal{K}_a$  the set of clusters related to  $a \in \mathcal{A}$ , call each cluster  $k_a \in \mathcal{K}_a$  a *group-scenario* and define its probability of occurrence  $p_{k_a}$  as the proportion of data points attributed to this cluster.

We now follow a similar approach as Ning and You (2018) to construct a polyhedral uncertainty set for each group-scenario  $k_a \in \mathcal{K}_a$ . To this end, we estimate the marginal probability density function  $\hat{f}_{a,k_a,r}$ ,  $r \in \llbracket 1, r_a \rrbracket$ , along each truncated principal component direction (with a kernel smoothing method such as KDE for instance (Chen, 2017)). We denote by  $\hat{F}_{a,k_a,r}$  the associated cdf, and by  $\hat{F}_{a,k_a,r}^{-1}$  the associated quantile function. We now define the PUS related to the group of attributes  $a \in \mathcal{A}$  and the cluster  $k_a \in \mathcal{K}_a$ , which we call a *group-scenario PUS*, as follows:

$$\bar{\mathbf{w}}_{a,k_a}^{pol} := \left\{ \bar{\mathbf{w}} \in \mathbb{R}^{r_a} \left\{ \begin{array}{l} \mathbf{0} \leq \mathbf{z}^-, \mathbf{z}^+ \leq \mathbf{1} \\ \mathbf{1}^T (\mathbf{z}^- + \mathbf{z}^+) \leq \Phi_{a,k_a} \\ \forall i, j \in \llbracket 1, s_{a,k_a} \rrbracket: z_i^- + z_i^+ + z_j^- + z_j^+ \leq \Psi_{a,k_a} \\ \boldsymbol{\xi}_{a,k_a}^{lb} = [\hat{F}_{a,1,k_a}^{-1}(\alpha_{a,k_a}), \dots, \hat{F}_{a,r_a,k_a}^{-1}(\alpha_{a,k_a})]^T \\ \boldsymbol{\xi}_{a,k_a}^{ub} = [\hat{F}_{a,1,k_a}^{-1}(1 - \alpha_{a,k_a}), \dots, \hat{F}_{a,r_a,k_a}^{-1}(1 - \alpha_{a,k_a})]^T \\ \boldsymbol{\lambda} = \frac{1}{2} (\mathbf{z}^+ - \mathbf{z}^- + \mathbf{1}) \\ \bar{\mathbf{w}} = \boldsymbol{\xi}_{a,k_a}^{lb} \circ (\mathbf{1} - \boldsymbol{\lambda}) + \boldsymbol{\xi}_{a,k_a}^{ub} \circ \boldsymbol{\lambda} \end{array} \right. \right\} \quad (2)$$

where  $\mathbf{0}$  and  $\mathbf{1}$  are vectors of respectively zeros and ones of size  $r_a$ , where  $\circ$  defines the Hadamard product, and where vectors inequalities must be understood componentwise. This set is similar to the budgeted uncertainty set proposed by (Bertsimas and Sim, 2004), which enables to control the degree of conservatism: the larger the volume of the PUS, the more conservative is the resulting robust Optimisation Problem (1). The uncertainty set is parametrised by  $\alpha_{a,k_a}$ ,  $\Phi_{a,k_a}$  and  $\Psi_{a,k_a}$ . First,  $\alpha_{a,k_a}$  is used to exclude both tails of the marginal pdf along each principal component axis. Then,  $\Phi_{a,k_a}$  limits the cumulative dispersion from the nominal value along all retained PCA axes. Finally, the parameter  $\Psi_{a,k_a}$  additionally limits the pairwise dispersion along the first  $s_{a,k_a}$  PCA components. This parameter is important to further exclude unlikely data points from the uncertainty that would otherwise not be cut with the general budget constraint parametrised by  $\Phi_{a,k_a}$ .

We have so far generated a PUS for each group-scenario  $k_a \in \mathcal{K}_a$  for each  $a \in \mathcal{A}$ . Let  $\mathcal{K}^\times := \times_{a \in \mathcal{A}} \mathcal{K}_a$  denote the Cartesian product of the sets of group-scenarios. The probability  $\hat{p}_k$  associated to  $k \in \mathcal{K}^\times$  is estimated as the proportion of the data points such that the uncertainty part related to  $a$  is attributed to cluster  $k_a$  for all  $a \in \mathcal{A}$ . To take into

account the weak correlation between groups of attributes (so far assumed to be independent), we retain only the most probable combinations of group-scenarios  $k := \{k_a \in \mathcal{K}_a, a \in \mathcal{A}\} \in \mathcal{K}^\times$ , keeping those with associated probability greater than a threshold probability  $\tilde{p}$ . The more conservative we desire to be, the greater the acceptance probability threshold  $\tilde{p}$  should be. The set of scenarios  $\mathcal{K}$  is then constituted of the combinations in  $\mathcal{K}^\times$  satisfying the probability threshold  $\tilde{p}$ . The probability of occurrence  $p_k$  of each scenario  $k \in \mathcal{K}$  used in (1a) is then defined as the scaled probability when the scenarios that do not satisfy the acceptance threshold are excluded, *i.e.*  $p_k = \hat{p}_k / \sum_{k \in \mathcal{K}} \hat{p}_k$ . Finally, the PUS in the original basis related to a scenario  $k = \{k_a \in \mathcal{K}_a, a \in \mathcal{A}\} \in \mathcal{K}$  is then defined as follows:

$$\mathcal{V}_k := \left\{ \mathbf{v} \in \mathbb{R}^{24n} \mid \forall a \in \mathcal{A}: \begin{cases} \bar{\mathbf{w}}_a \in \bar{\mathcal{W}}_{a,k_a}^{pol} \\ \mathbf{v}_a = \mathbf{P}_a^T \begin{bmatrix} \bar{\mathbf{w}}_a \\ \mathbf{0}_{n_a-r_a} \end{bmatrix} \end{cases} \right\} \quad (3)$$

where  $\mathbf{0}_{n_a-r_a}$  is a vector of zeros of size  $n_a - r_a$ . The reduction in dimension appears clearly: the uncertain part  $\mathbf{v}_a \in \mathbb{R}^{24n_a}$  related to  $a \in \mathcal{A}$  is generated from elements of  $\bar{\mathcal{W}}_{a,k_a}^{pol}$ , which is in the lower-dimensional space  $\mathbb{R}^{r_a}$ .

In some applications (e.g. unit commitment), we are interested in taking into account the uncertainty over several days. Given the succession of  $N$  daily scenarios  $k_{1 \rightarrow N} := (k_1, \dots, k_N) \in \mathcal{K} \times \dots \times \mathcal{K}$ , we can define an associated PUS based on the definition of  $\mathcal{V}_k$  in (3) as follows:

$$\mathcal{V}_{k_{1 \rightarrow N}} := \left\{ \mathbf{v} \in \mathbb{R}^{24nN} \mid \begin{cases} \mathbf{v} = [\mathbf{v}_1, \dots, \mathbf{v}_N] \\ \forall i \in \llbracket 1, N \rrbracket: \mathbf{v}_i \in \mathcal{V}_{k_i} \\ \forall i \in \llbracket 1, N-1 \rrbracket: |(\mathbf{V}_{i+1}[:,1] - \mathbf{V}_i[:,24]) - \boldsymbol{\mu}_\Delta| \circ \frac{1}{\boldsymbol{\sigma}_\Delta} \leq c \end{cases} \right\} \quad (4)$$

where  $1/\boldsymbol{\sigma}_\Delta$  must be understood componentwise, where  $\mathbf{V}_i \in \mathbb{R}^{n \times 24}$  is the matrix representation of  $\mathbf{v}_i$ , and where  $\boldsymbol{\mu}_\Delta$  and  $\boldsymbol{\sigma}_\Delta$  are vectors in  $\mathbb{R}^n$  that correspond respectively to the sample mean and standard deviation of the step size between successive profiles for all  $n$  attributes. The third constraint in (4) enforces continuity between the daily profiles by limiting the step size with the parameter  $c > 0$ .

### 3. Case study: uncertainty related to energy data in the UK

We apply the method presented in the previous section to derive uncertainty sets for quantifiable sources of uncertainty related to power generation based on historical data for the UK in 2015. This includes national electricity demand, as well as regional data on gas demand, temperature, solar availability, offshore and onshore wind availability (we refer to the paper Charitopoulos et al. (2022) for more details). Each data

Figure 1: Correlation between all the attributes

point corresponds to the collection of hourly daily profiles of the different attributes. The size of the uncertainty space is therefore high dimensional, which motivates the need for a reduction technique to generate uncertainty sets. Based on the correlation plot (see Figure 1), three groups of attributes have strong intra-correlation and weak inter-

correlation: *seasonal* data (electricity/gas demand and temperature), *solar* data and *wind* data (off/onshore wind), i.e.  $\mathcal{A} = \{\textit{seasonal}, \textit{solar}, \textit{wind}\}$ .

Figure 3 illustrates for each month the proportions of days that are allocated to each cluster (4 clusters are generated for each group of attributes  $a \in \mathcal{A}$ ). The correlation between the solar and seasonality data is clearly apparent: the simultaneous occurrence of the blue wind cluster with the red solar cluster is for instance highly improbable. Now, if we focus on the clustering from April to October, we observe that the clusters proportions in the wind data are roughly the same for each month. This translates the idea that the seasonal data and wind data are independent for this period of the year. As a consequence of these observations, we do not define the scenarios as the Cartesian product of group-scenarios since all combinations are not as probable. Figure 2 depicts how the number of scenarios retained varies with the acceptance threshold  $\tilde{p}$ . It seems that adopting a probability threshold of  $\tilde{p} = 3\%$ , which results in keeping 14 scenarios, is in line with the trade-off between accuracy and computational tractability: a higher value would lead to too few scenarios (6 or less), while a lower value would lead to too many scenarios and therefore would not allow for the pruning of the least likely realisations.

Figure 2: Number of scenarios given the probability threshold  $\tilde{p}$

Figure 3: Proportion of days allocated to each cluster for all groups of attributes

Finally, Figure 4 depicts data generated with (3) for the parameters values:  $a = \textit{seasonal}$ ,  $k_a = \textit{blue}$ ,  $r_a = 24$ ,  $\alpha_{a,k_a} = 5\%$ ,  $\Phi_{a,k_a} = 5$ ,  $s_{a,k_a} = 24$  and  $\Psi_{a,k_a} = 1.5$ . We observe that the daily outliers in the historical data are ignored and, as desired, that the synthetic realisations are similar to the 90% of cases around the median. The size reduction is as follows:  $n_a = 40$  attributes are associated with the group  $a = \textit{seasonal}$ , which implies that the seasonal data is of size  $24n_a = 960$  and is generated on the basis of  $r_a = 24$  PCA components; this corresponds to a size reduction factor of 40. Figure 5 depicts realisations generated with (4) for the seasonal group of attributes for the succession of five days, where  $k_{1 \rightarrow 5} = \{\textit{blue}, \textit{blue}, \textit{orange}, \textit{orange}, \textit{orange}\}$  and where the continuity constraint parameter is equal to  $c = 2.5$ .

Figure 4: Comparison of historical and synthetic realisations for the blue cluster.

Figure 5: Synthetic realisations for  $k_{1 \rightarrow 5} = \{\text{blue, blue, orange, orange, orange}\}$ .

## 4. Results and discussion

We first point out why we did not start by clustering the data and then, for each cluster, generate a PUS, as it would implicitly take into account the (weak) correlation between attributes and avoid generating clusters based on a correlation analysis. The answer lies in two main points: Firstly, the scarcity of data. Indeed, in the case study, if we were to generate the 14 scenarios by clustering over the 365 historical data points, then each of them would have on average 26 data points. In contrast, in the method presented in this paper, only 4 clusters are generated per group of attributes. The quantiles of each cluster are then derived on the basis of around 90 data points. The PUS derived with our method are thus less subject to statistical estimate errors. Secondly, establishing groups of uncorrelated attributes allows for associating to each one of them a uncertainty dispersion budget  $\Phi_{a,k_a}$ . In this way, we do not constrain the realisations of independent attributes together.

## 5. Concluding remarks

In conclusion, the advantages of our method are the following: First, it considerably reduces the size of the original uncertainty set as it can be expressed as a linear transformation of a truncated basis using PCA. Secondly, the PUS generated are statistically meaningful and can exploit the possibly independence of uncertain attributes. Thirdly, it generates consistent uncertainty daily profiles for which the continuity from hour to hour is guaranteed. Finally, it derives polyhedral uncertainty sets that can then be used in a robust optimisation (RO) type of problem.

**Reproducibility:** All the graphs of this article can be reproduced with the code made available on [GitHub](#), where we have also shared the 2015 UK energy uncertainty dataset.

## Abstract

A novel integrated continuous filter-drying carousel unit has as an enabling technology to handle filtration and drying of crystallization slurries within an end-to-end continuous pharmaceutical manufacturing train. However, due to the complexity of available contactless moisture sensing technologies, the challenges lie in developing an online monitoring system, which can accurately predict and control moisture content of the crystal product. In this work, we develop a hybrid monitoring framework to enhance the operation of this continuous filtration-drying unit by incorporating a knowledge-driven process model implemented in the object-oriented modeling platform, PharmaPy. The model is iteratively recalibrated from online measurements using a moving horizon state estimation methodology. The digital twin is shown to effectively track the offline measured moisture content. The integrated quality-by-control (QbC) framework achieves a substantial increase in process productivity and product quality.

## 1. Introduction

Integrated filtration-drying has become an important emerging technology for continuous drug purification to produce high-purity small molecule oral drugs. [1] These steps serve as vital operations to achieve purity requirements of the final drug product [2]. Hence, process intensification (PI) of the filtration technology has attracted increased attention in the pharmaceutical sector due to its potential to achieve the critical quality attributes (CQAs) and target purity with improved economic and environmental outcomes [3]. The semi-continuous filtration carousel (CFC) has become a crucial technology by adopting separated small-scale batch process within continuous manufacturing (CM) mode. However, the CFC process is highly nonlinear due to; 1) the dynamic operation of the filtration-drying batch steps; 2) the uncertainty in the model parameters of these steps, and 3) the occurrence of unmodeled disturbances in the system, e.g., drifting critical process parameters (CPPs) due to fouling phenomena.

To overcome the challenges posed by input variability and model parametric uncertainty, quality-by-design (QbD) initiatives have been developed in the last years by the US Food and Drug Administration (FDA). QbD seeks to define the viable operating region within which the process can be operated while meeting target CQAs for given sets of critical material attributes (CMAs) and CPPs. With the increasing availability of process

analytical tools (PAT) and digital design tools, QbD has been used in various open-loop studies that create and use process digital twins to optimize process metrics (CQAs, costs, waste generation) with CPPs as decision variables [4]. For the pharmaceutical isolation step, crystal properties and final product impurities of regulated materials are the main CQAs. Since impurities remaining in the solid at the end of the drying step will be directed to the downstream process, failure to reach the drug's targeted purity will lead to off-spec products under the stringent regulatory requirements imposed on the CQAs [5]. To improve the estimation and monitoring of the CQAs, it is critical to incorporate the decision-making framework developed from the design space (DS) into the closed-loop control of the product quality to achieve a higher level of assurance.

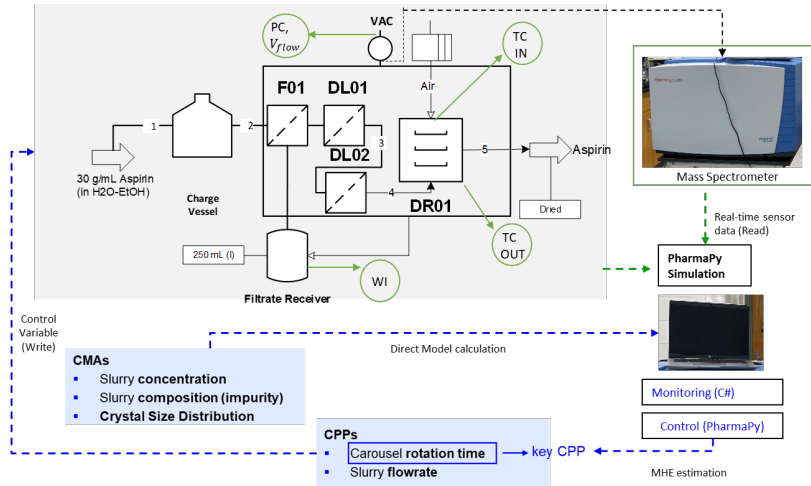

In this work, we develop a digital twin of the physical CFC system, which combines knowledge-driven model predictions calculated from dynamic flowsheet simulations with actual data retrieved in real-time from sensor measurements. The flowsheet model is simulated in the Python-based, object-oriented modeling platform PharmaPy [6]. The PharmaPy simulator is a first-principles model of the process, which includes dynamic mass, energy, and momentum balances for the multi-phase component system [7]. A moving horizon estimation (MHE) framework that relies on state estimation of average moisture content of active pharmaceutical ingredients (API) filtration cakes is applied to the flowsheet which simulates the pharmaceutical filtration-drying step of a real continuous drug substance isolation operation in CFC. This paper describes how the resulting digital twin accurately predicts the main CQAs, namely, cake moisture content (MC) and improves productivity, while minimizing plant-model mismatch.

## 2. Digital Twin Development on the Continuous Filtration Carousel (CFC)

### 2.1. Continuous CFC platform and Real-time Data Communication

In this study, we incorporate a prototype version of carousel designed and manufactured from the Alconbury Weston Ltd (UK) as a platform for performing continuous solid liquid separation of crystal slurries. The flowsheet of the process installed at Purdue University CryPTSys lab is shown in Fig 1. The main body of the carousel consists of 5 different stations in which the material goes through one of the filtration and drying steps. The slurry with API crystals is intermittently introduced into a charge vessel and transferred to the first station where filtration step occurs driven by the pressure gradient developed across the cake and filter mesh. Filtration is automatically followed by a deliquoring step (DL01-DL02) in station 3. Finally, the remaining mother liquor inside the cake is reduced by introducing a hot stream of air at DR01 (4<sup>th</sup> station). After the given rotation time, the final dried product is ejected from the system by a mechanical piston in 5<sup>th</sup> station.

Real-time data acquisition is enabled via OPC (OLE (Object Linking and Embedding) for Process Control) protocol, using the existing CFC process sensors and a mass spectrometer. A vacuum pump connected to the filtrate receiver creates a pressure gradient at the bottom of the processing stations, and pressure sensor (PC) measures the pressure drop in the system. Moreover, a flow sensor measures the flowrate of the gas coming from the DR01. The thermocouples (TCIN, TCOU) measure the temperature of the inlet and outlet of gas streams of the drying port respectively. A weighing scale, WI, monitors the mass of the filtrate collected in the filtrate receiver and a mass spectrometer is used to determine the composition of the drying gas. The data acquisition is implemented in the programmable logic control (PLC) of the unit by read/write functions and fed as the inputs to the PharmaPy simulator, which calculates the residual moisture content of the final dry product, acting as a soft sensor.

**Fig 1.** Schematic of CFC flowsheet and sensor network for a continuous purification process

## 2.2. Hybrid State Estimation Framework

A hybrid state estimation approach is presented to account for the plant-model mismatch under process disturbances. The purpose of the methodology is developing an online monitoring framework, which accurately captures the measurements from the physical sensor, hence it is used to construct controllers to control the MCs of the dry product by adapting cycle duration ( $t_{dry}$ ). First, the model calculates the process outputs by solving the mechanistic equations given real-time input information (Eq. 2). A moving horizon estimation (MHE) approach iterates this to solve optimization problem by adapting model parameters to the fluctuations of the CFC system (Eq. 1).

$$\min_{\theta_p} J(t, x, y, u, \theta_p) \quad (1)$$

$$s. t. \quad \dot{x} = PharmaPy(x, u, \theta_p), \quad x_0 = x(t_0) \quad (2)$$

$$y = h(x, u, \theta_p) + v \quad (3)$$

$$\theta_p^{lb} < \theta_p < \theta_p^{ub} \quad (4)$$

The variable  $J$  is an estimation function to determine the state disturbances,  $x = [T_{node}, x_{liq}, y_{gas}]$  is the state matrix comprised of vectors of the dynamic gas temperature, the species composition of the liquid phase, and the species composition of the gas phase from the drying port,  $y = [T_{out}^T, \sum_{i=0}^k \frac{dy_{gas}(t_i)}{dt}]$  is the measurement vector,  $u = [t_{dry}]$  is the process input,  $\theta_p = [S_{var}, k_y, h_T]$  is the vector of model parameters,  $PharmaPy$  represents the vector function of the dynamic state equations,  $h$  is the vector function of the measurement equations,  $v$  is measurement noise vector,  $k$  is the sampling instance within a cycle window.

To compensate for the performance degradation from the presence of process uncertainties, the digital twin process model should be continuously updated using the new measurements obtained at each batch cycle ( $k$ ). Here, the online state estimation framework is depicted in Fig 2. A MHE is exploited for state estimation in which the state variables are estimated by solving two consecutive optimization problems. First, the

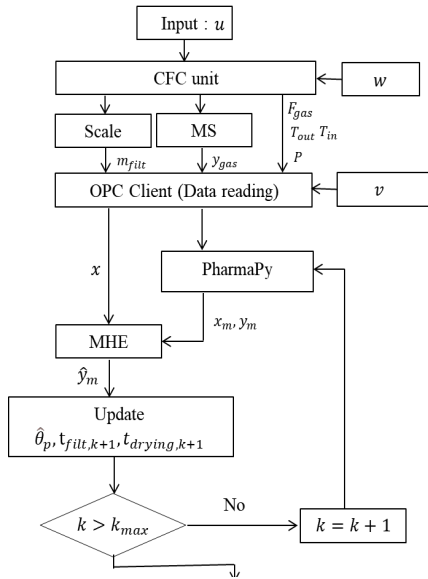

Fig 2. Block diagram of the framework

maximizing the correlation is to inform the model with an intermediate saturation value after the final deliquoring step based on different drying rate period MS data. The output of the decision variable is utilized to reinitialize the initial saturation of the deliquored

$$\min_{h_T, k_y} J = \sum_{t_i=(k-1)N_{past}}^{kN_{past}} (y_{t_i} - \hat{y}_{t_i})^T W_E (y_{t_i} - \hat{y}_{t_i}) \quad (6)$$

cake on the second problem (Eq. 6), and the problem is sequentially solved.

### 3. Result and Discussion

#### 3.1. Case study: CFC experiment on Aspirin-H<sub>2</sub>O/EtOH slurry

The monitoring framework is tested on a continuous purification process of Aspirin from solvent mixture of water-ethanol under the presence of disturbances, e.g., uncertain model parameters and control variables. The performance on the final MC prediction is examined by comparing with off-line measured MC of dry product from each batch cycle via a gravimetric method.

Fig 3 demonstrates the trajectory tracking control of the monitoring framework on the outlet temperature of the drying gas and 1<sup>st</sup> derivative of ethanol composition read from the MS (a) by adapting a set of uncertain model parameters per every cycle window (b). The soft sensor on MC of the dry product is validated against the off-line measured MC as shown in Fig 3-c. Overall, the soft sensor performs well in terms of following the trend of the measurements throughout the whole cycle.

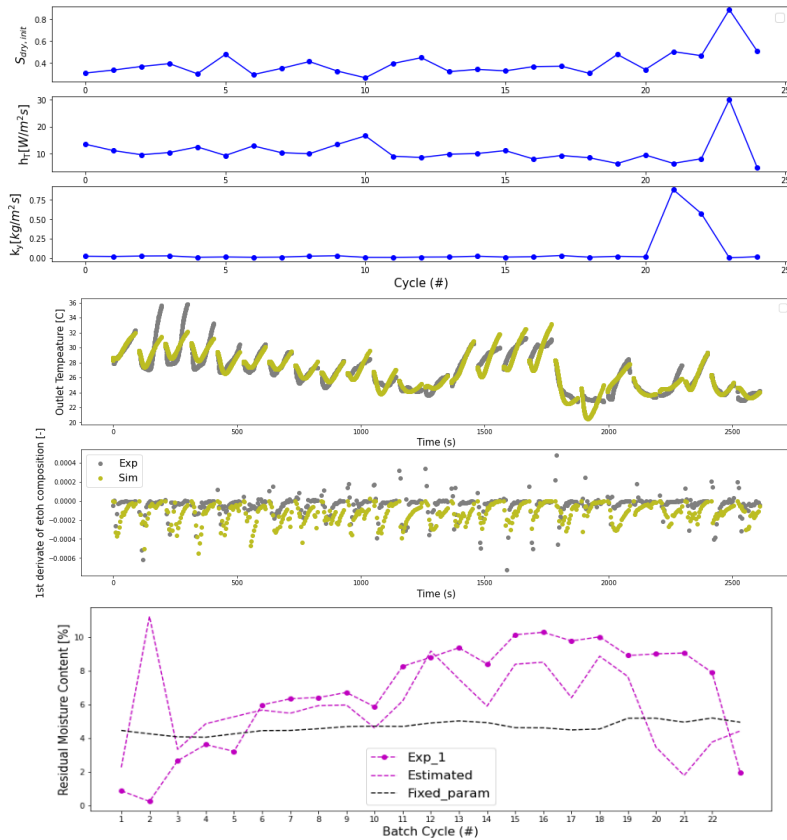

Moreover, the adaptive model parameter enables accurate capture of the relative performances of the subsequent drying batch compared to the fixed parameter model and shows good comparability to the offline measured residual MC. This proves our hybrid monitoring system allows the informative and efficient solution of state estimation problems to be real-time feasible within an online optimization framework.

distance between simulated  $f_{sim,t_i}$  and measured  $f_{p,t_i}$  gas composition is minimized by varying  $S_{var}$  (cake saturation after deliquoring) over a respective batch time frame (Eq. 5) from the best fitting line on the parity plot at  $i^{th}$  sampling point within the estimation horizon ( $N_{past}$ ) of the  $k^{th}$  cycle window.

$$\min_{S_{var}} J = \sum_{t_i=(k-1)N_{past}}^{kN_{past}} f_{p,t_i} - f_{sim,t_i} \quad (5)$$

Next, heat and mass transfer coefficients ( $h_T, k_y$ ) are estimated by solving Eq. 6.

The variable  $W$  is the weighting matrix,  $y$  is vector of measurements and  $\hat{y}$  is vector of predicted measurement. The first optimization problem (Eq. 5) is first solved to maximize the correlation of the dynamic trend of the EtOH composition in the gas phase. The purpose of

**Fig 3.** Result on online state estimation; top (a): decision variables from the problem; middle (b): comparison between prediction and measurement variables; bottom (c): comparison of moisture content (MC) from the model and measurement

The monitoring framework is further coupled with a proportional-integral (PI) controller to update the control variables ( $t_{drying}$ ) based on the differences of the MC between prediction and the target MC (5%) (Eq. 8).

$$u(t) = u_{bias} + K_c e_i(t) + \frac{K_c}{\tau_I} \sum_{i=1}^k e_i(t) \Delta t \quad (7)$$

$$e_i(t) = \widehat{MC}_{est}(t_i) - MC_{target}, \quad MC_{target} = 5 \%$$

The initial  $t_{drying}$  of 60 s is chosen for the base control variables ( $u_{bias}$ ). The response of the control system to attain the target moisture content and resulting residual MC measurement is depicted in Fig 4. With initial cycle time, the batches produced in Cycle 1-2 was above 20% which do not meet the desired quality. The controller increases the cycle time to allow a longer operation based on the abnormal MC on the Cycle 3 and we see the MC to be regulated under the target MC. The controller starts decreasing  $t_{drying}$  by reducing the excessive operation duration, which is not needed anymore as batches produced in Cycle 3-14 are maintained either below or slightly above the target MC, hence effectively increasing the throughput. At Cycle 16, however, controller again increases the cycle time as the residual MC shows a consistent increment of its value due to the fouling of the process and simulator predicts that the CQA does not meet the quality threshold.

**Fig 4.** Controller responses and resulting measured MC of the dried product from experimentation

#### 4. Conclusions

A digital twin is developed and tested for the continuous filtration and drying operation of Aspirin and shown to produce sufficiently accurate estimates of the residual MC of the dried crystals with fluctuation in absolute errors within 4%. The estimated outputs are fed to a PI controller that adjusts MC and throughput of the dried product by manipulating drying cycle time. The result showcases a successful application of a real-time hybrid monitoring framework that offers the advantages of both knowledge-driven process modeling and optimization that rely on real-time data acquisition and analysis of the continuous filtration and drying process.

## Abstract

Modeling and optimization of fed-batch reactors with several multi-step reaction pathways is challenging due to the nonlinear dynamic system behavior and large number of kinetic parameters. We showcase the model-based optimization of an industrial (20 m<sup>3</sup>) fed-batch reactor by using our open-source dynamic optimization software DyOS. First, we build a detailed mechanistic model of the fed-batch reactor. Second, we conduct parameter estimation of the mechanistic model with 25 states and 44 fitting parameters using historic time-series industrial production data. Third, we perform dynamic multi-stage optimization and identify optimal feeding profiles for the operation, targeting improvements in economic profit over the established experience-based production routine. We demonstrate substantial economic improvement: The optimized production recipe can save up to 10% of raw material at the same yield of main product. Our findings underline the strong capabilities of model-based process optimization and its application to industrial challenges in process design and operation.

**Keywords:** Dynamic process optimization, Fed-batch reactor, Industrial application, Reaction optimization.

## 1. Introduction

The determination of feeding strategies is of paramount importance in the design and control of fed-batch reactors. Finding optimal feeding strategies is typically based on the dynamic optimization of a reactor model. However, modeling reaction processes with several multi-step reaction pathways can be challenging due to nonlinear system behavior that needs to be expressed by many equations and parameters, and a lack of mechanistic knowledge about the considered reaction, e.g., reaction kinetics and corresponding parameters. When experimental data of the reactor is available, kinetic parameters can be estimated using dynamic optimization. Subsequently, dynamic optimization can be employed for determining optimal feeding profiles with respect to a defined objective, e.g., reaction yield, product quality, and economic targets. Dynamic optimization of fed-batch reactors has been performed successfully for several applications including the production of (bio-)polymers (Zavala et al, 2005; Lopez et al., 2010, Jung et al. 2015), yeast (Hjersted & Henson, 2006) and drugs (Banga et al., 2005). We have also recently optimized fed-batch reactors for microgel (Jung et al., 2019) and polymer (Faust et al.

2021) production. To this end, we have employed our dynamic optimization software DyOS (Caspari et al., 2019), which is an open-source framework for the optimization of large-scale differential algebraic equation (DAE) systems.

Herein, we use DyOS for the optimization of feeding strategies for a fed-batch reactor of industrial scale. Specifically, we conduct three steps with the overall goal to identify optimal feeding strategies: (i) mechanistic modeling of the fed-batch reactor with the reaction kinetics, (ii) estimation of kinetic reaction and heat transfer parameters, and (iii) dynamic multi-stage optimization of raw material feeding profiles. In the first step, we develop together with the plant operators a mechanistic reactor model in the Modelica modeling language (Modelica, 2022). The parameter estimation in the second step includes the collection of historic industrial production data of the currently established experienced-based feeding profiles that we then use to fit model parameters with DyOS. In the third step, we start from the established feeding profiles and apply DyOS to identify economically optimized feeding strategies. Our in-silico results suggest that the optimized feeding strategies can lead to substantial economic improvements and savings in raw materials.

Due to confidentiality reasons, we cannot provide detailed insights on the model, the corresponding data, and the literature sources we used to collect information about the considered reaction process. We thus focus on the methodological approach of using dynamic optimization for fitting model parameters and optimizing feeding profiles. In the following, we schematically describe the considered fed-batch reactor, explain the three steps (i – iii) in detail, and present the modeling and optimization results.

## 2. Fed-Batch Reactor Model Development

We consider an industrial stirred-tank fed-batch reactor producing one main product in a multi-step reaction. The reactor has a volume of 20 m<sup>3</sup>. A schematic illustration of the reactor is shown in Figure 1. The inputs to the reactor are composed of four raw materials (RM1, RM2, RM3, RM4), water (H<sub>2</sub>O), and a catalyst (CAT). All input components are fed in liquid form, either in pure species or in aqueous solutions. RM2, H<sub>2</sub>O, and CAT are filled into the reactor before the reactions start. When RM1 and RM3 are introduced to the reactor, several multi-step reactions involving multiple intermediate products (IPs) are initiated. RM1 and RM3 are dynamically fed during the reaction process and can be used to influence the reaction rates. The production goal is the main product (MP). Additionally, several undesired byproducts (BPs) occur in the reaction competing with the MP production. The reactor temperature during operation is controlled with cooling water (CW) that flows through the cooling jacket of the reactor and enters with ambient temperature. To stop the reaction process an inhibitor (RM4) is fed to the reactor. After feeding RM4, the species concentrations remain approximately constant and the reactor can be drained.

Figure 1. Schematic illustration of fed-batch reactor with input, output, and cooling water flows.

### 2.1. Mechanistic Modeling

We develop a dynamic model of the reactor and reaction system. The model includes 25 differential equations with 44 fitting parameters corresponding to the mass balance with the reaction kinetics and to the energy balance. The reaction kinetics involve 21 reactions for which reaction constants are calculated using the Arrhenius equation, i.e., two parameters in the form of the pre-exponential factor and the activation energy. Note that 3 side reactions have the same rate constant such that the reaction kinetics effectively have 38 fitting parameters in total. The energy balance accounts for the enthalpy of reactions, enthalpy flows, and cooling heat transfer rate affecting the temperature of the reaction mixture. Five reaction enthalpy parameters need to be estimated as several side reactions are modeled by the same enthalpy parameter. For the cooling, the heat transfer coefficient represents another fitting parameter, whereas we calculate the heat exchange surface and the cooling-water hold up based on the reactor geometry. For all other model parameters, e.g., as part of density and heat capacity correlations, we use standard values from the literature. In addition, we neglect other energy flows, e.g., heat loss over the reactor surface. Next to the differential equations, several algebraic equations, e.g., for pH, density, heat capacity, and yield calculation, are part of the model.

For modeling the dynamic input streams, we discretize the feed flows of RM1, RM3, RM4, and CW in one-minute intervals. Since RM2, H<sub>2</sub>O, and CAT are loaded to the reactor without any main reactions occurring, we use the respective total amount loaded to the reactor as initial values.

### 2.2. Implementation

We implement the reactor model in the modeling language Modelica (Modelica, 2022). Further, we apply our dynamic optimization framework DyOS (Caspari et al., 2019) with integrator NIXE (Hannemann et al., 2010) and NLP solver SNOPT (Gill et al., 2005). We use the Python interface of DyOS to implement and run the case study in Python. We use a Microsoft Windows Server with an Intel(R) Xeon(R) E5-2630 v2 processor running at 2.6 GHz and 128 GB RAM; simulating the model with given parameters took ca. 2 sec.

## 3. Parameter estimation

The model constitutes overall 44 fitting parameters that we initialize by data obtained from laboratory experiments and literature. However, as the simulation results when using these parametric values did not match the measured temperature profiles and final concentrations available from historical reactor data, we performed parameter estimation. To this end, we measured concentrations of some main components and the reactor temperature profile for one fed-batch run. In Figure 2, the feeding strategy for this run for (a) RM1, RM3, RM4, and (b) CW is illustrated. Subsequently, we used this experimental data for fitting the parameters of the model.

Figure 2. Feeding profiles of one fed-batch run for (a) RM1, RM3, RM4 and (b) CW.

In the parameter estimation process, we utilized DyOS to fit the 44 model parameters with the objective to minimize the mean squared error (MSE) of the model deviation to

the measured time-series of the concentration profiles and the reactor temperature profile. We solve the optimization problem using direct single shooting with optimality and feasibility tolerances of  $10^{-3}$ . We apply absolute and relative integrator tolerances of  $10^{-4}$ . Figure 3 shows the simulation results with the initial and fitted parameters in comparison to the experimental data for the temperature profile and the concentration profiles of the MP and RM2. In contrast to the initial model, the results from the fitted model match the temperature profile with slight deviations. The fitted model also predicts the concentration measurements of MP and RM2 with high accuracy. We stress that due to the large model size and large number of parameters, we did not perform a parameter identifiability study. Other parameter values might also yield a good fit but were not explored since we find a sufficient match of the experimental data using the fitted model.

Figure 3. Comparison of the experimental results from batch run used for fitting with the simulation results obtained with the initial and the fitted model: Temperature (left) and concentrations for RM2 (middle) and MP (right).

For validation of the fitted model parameters, we conducted another experimental run of the industrial reactor at similar conditions. Figure 4 illustrates the temperature profiles and concentration measurements against the simulation results of the fitted model. We observe that the model matches the profiles closely. Some deviations regarding the MP concentration are, however, noticeable.

Figure 4. Comparison of the experimental results from validation batch run with the simulation results obtained with the fitted model: Temperature (left) and concentrations for RM2 (middle) and MP (right).

We also tested the model for other batch runs for which historical data on the temperature profile and the end concentrations but not all initial conditions, e.g., temperatures and impurities of raw material feed flows, was available. Here, we also observe a generally good match of the fitted model results and the experimental data, but also find some deviations, especially in the concentrations of some byproducts. We attribute the deviations to uncertainty factors in the initial conditions including BP impurities in the feed flows, limitations of the mechanistic model in capturing all characteristics of the multi-step reaction, and presumably slight overfitting of the parameters. In comparison to the initial model, the parameter fitting improves the prediction accuracy.

Overall, we conclude that the fitted model correctly captures the trends of temperature profiles and concentration measurements. In the next step, we will thus use the model with the fitted parameters for optimization of the feed profiles.

#### 4. Dynamic optimization of the reactor feeding profiles

In the optimization of the feeding profiles, we aim at identifying changes in the currently established feeding strategy to produce the same amount of MP while using fewer raw materials per batch. As a starting point for the optimization, we herein consider the feeding profiles from the fed-batch run for which we collected concentration measurements and fitted the model parameters. The objective of the optimization is to decrease the total costs of RM1 and RM3 fed to the reactor, which we formulate as

$$\begin{aligned}
 & \min_{\dot{m}_i(t)} \quad m_{RM1} \cdot c_{RM1} + m_{RM3} \cdot c_{RM3} \\
 & \text{s. t.} \quad m_{MP,cur}(t_{end}) \leq m_{MP}(t_{end}), \\
 & \quad T_{R,min} \leq T_R \leq T_{R,max}, \\
 & \quad V_{L,min} \leq V_L \leq V_{L,max}, \\
 & \quad 0 \leq \dot{m}_i(t) \leq \dot{m}_{i,max}, \\
 & \quad c_{BP,j} \leq c_{BP,j,max}, \\
 & \quad i \in \{RM1, RM3, CW\}, j \in BPs,
 \end{aligned} \tag{1}$$

where  $c_{RM1}$  and  $c_{RM3}$  are cost factors and the mass flows,  $\dot{m}_i(t)$ , of the raw materials RM1 and RM3 and the CW are the control variables, i.e., degrees of freedom. To enforce a minimal MP production, we add a constraint for the final produced amount of MP,  $m_{MP}(t_{end})$ , to at least matching the currently established strategy (cur),  $m_{MP,cur}(t_{end})$ . We consider additional constraints that include limits on the reactor temperature,  $T_R$ , the reactor level  $V_L$ , the mass flows,  $\dot{m}_i(t)$ , and concentrations of BPs,  $c_{BP,j}$ . The upper and lower limits on the reactor temperature and level arise from safety considerations, the upper limits on the mass flows are based on plant equipment limits, and the upper limit on the BPs' concentrations results from process downstream quality limits. Furthermore, the process control system only allows for a maximum number of four step changes in the mass flow of RM1 which we formulated as a multi-stage problem with free stage duration. For solving the optimization problem (Eq. 1), we apply DyOS with the same integrator and optimizer settings as for parameter estimation (cf. Section 3).

Figure 5: Optimized vs. currently established feeding strategy for RM1, RM3, and CW.

Figure 5 illustrates the currently established (dashed line) and optimized (full line) feed. According to the optimization results, RM1 should be fed in three steps with different flow rates instead one constant rate. The optimized RM3 feed is at a higher rate from the start of the batch and is then reduced almost linearly instead of in three steps. The cooling water feed is also at the maximum possible rate and changes only slightly compared to the established routine; specifically, the reactor is cooled longer. With the optimized feeding strategy, we find the produced MP amount being at the lower bound, i.e., matching the MP amount produced with the established feed profiles, which is expected as it is enforced by a constraint in the problem formulation. At the same time, the amounts of RM1 and RM3 can be reduced by 6% and 17%, respectively. This corresponds to about 10% cost savings as the same MP amount is produced by using less raw material. The main reasons for the reduced amount of required raw materials are higher main product

yield, less byproduct production, and less overfeeding of RM3. We are currently working on the experimental validation of these results.

## 5. Conclusions

We present the dynamic modeling and optimization of an industrial 20 m<sup>3</sup> fed-batch reactor. We first develop a mechanistic reactor model and then collect experimental data on the reaction process and perform parameter estimation using our in-house dynamic optimization software DyOS. Based on the developed model, we apply DyOS to identify promising feeding strategies for which the model suggests improved reaction yield and higher economic profit by 10 %. The experimental validation of the identified feeding strategies is planned as the next step with the overall goal to establish a new feeding routine for the industrial operation of the reactor.

Future work could include further model validation and potentially improvements of the model, e.g., by collecting additional experimental data that can be used for parameter fitting. Next to model refinements, more fine-grained feed profiles could be investigated to incentivize changes to the current process control system limitations. Furthermore, the presented method could be transferred to other processes with fed-batch reactors.

## Abstract

This paper describes optimization studies of a large-scale fixed bed reactor model using Aspen Adsorption cycle simulations. The model uses Lewatit® VP OC 1065 amine-functionalized adsorbents and temperature vacuum swing adsorption (TVSA) cycles to capture CO<sub>2</sub> from the ambient air. Building a comprehensive direct air capture (DAC) model to optimize process design and cost is crucial to assess the feasibility of DAC technologies and therefore, a novel surrogate-based derivative free global optimization algorithm, referred to as SCR is implemented to evaluate a large-scale DAC system. Lastly, in order to achieve zero emissions and assess the viability of deploying large-scale DAC systems, assessments involving emission factors of various energy sources in different countries' electricity energy grid systems are studied. The optimization study showed a reduction in capture cost by 45% compared to the base case.

**Keywords:** Direct air capture, TVSA, process modelling, surrogate-based optimization

## 1. Introduction

Negative emission technologies (NETs) with a cumulative CO<sub>2</sub> capture of 450 to 1000 Gt are necessary to meet the strict 1.5 °C temperature increase target between 2010 and 2100 (Rogelj et al., 2015). One of the potential NETs is Direct Air Capture (DAC), and the likelihood of technological progress could significantly reduce DAC's energy usage, making it a practical long-term mitigation strategy (Realmonte et al., 2020). DAC was first proposed by Lackner and coauthors in 1999 to reduce climate change and the captured CO<sub>2</sub> may be used in various ways, including enhanced oil recovery, construction materials, and production of goods like chemicals, fuels, cement, etc. The CO<sub>2</sub> can also be permanently stored in deep geological formations (IEA, 2022).

Negative emission technologies (NETs) with a cumulative CO<sub>2</sub> capture of 450 to 1000 Gt are necessary to meet the strict 1.5 °C temperature increase target between 2010 and 2100 (Rogelj et al., 2015). One of the potential NETs is Direct Air Capture (DAC), and the likelihood of technological progress could significantly reduce DAC's energy usage, making it a practical long-term mitigation strategy (Realmonte et al., 2020). DAC was first proposed by Lackner and coauthors in 1999 to reduce climate change and the captured CO<sub>2</sub> may be used in various ways, including enhanced oil recovery, construction materials, and production of goods like chemicals, fuels, cement, etc. The CO<sub>2</sub> can also be permanently stored in deep geological formations (IEA, 2022).

There are several DAC techniques, including membrane, chemical, and electro-swing adsorption (ESA) methods (IEA, 2022, Voskian and Hatton, 2019, Fujikawa et al., 2021). The chemical methods can be further classified as a liquid solvent and solid sorbent

techniques which are the furthest technologies in development. In the case of the liquid solvent approach, an aqueous KOH solution is used as the capture medium and a calcium caustic loop is used as the recovery mechanism at high temperatures between 300-900°C (Keith et al., 2018). Solid sorbents technologies usually employ amine groups on the internal surface of the sorbent to react with CO<sub>2</sub> from the ambient air at low pressure, followed by regeneration at medium temperature of 80 – 120°C (McQueen et al., 2021). There are 18 operating DAC plants that capture almost 0.01 MtCO<sub>2</sub> annually according to the IEA report (2022) however, the majority of current DAC plants operate on a small scale for testing and demonstration purposes. Also, few studies for DAC have been conducted on process scales (Schellevis et al., 2021). Therefore, in order to address the aforementioned gaps, this paper presents a large-scale fixed bed reactor system of Kim and Léonard (2022), to capture CO<sub>2</sub> from ambient air via Temperature Vacuum Swing Adsorption (TVSA) using Lewatit® VP OC 1065 amine-functionalized adsorbents. Moreover, important operating parameters impacting the energy and cost of DAC systems are identified and CO<sub>2</sub> capture cost is optimized via SCR algorithm. Lastly, the viability of deploying DAC systems based on various electricity grid systems in different countries is explored to achieve net zero emissions.

## 2. Modelling

A large-scale one-dimensional fixed bed reactor model for gas adsorption (at 400 ppm CO<sub>2</sub>) presented in the work of Kim and Léonard (2022b) is studied further to find feasible operating conditions under TVSA cyclic operation (adsorption, evacuation, desorption and cooling). The large-scale model was scaled up in the aforementioned work from a kg-scale DAC model where this small-scaled model was validated with experimental results presented in the works of Bos et al. (2019) and Yu et al. (2017). The validations of equilibrium loadings of CO<sub>2</sub> onto the solid sorbent, breakthrough curves and model assumptions are presented in Kim and Léonard (2022a&b).

## 3. Optimization Methodology

In this work, the DAC unit is being optimized using a recently published optimization algorithm called SCR which was presented by Zaryab et. al. (2022). SCR is a surrogate - based derivative free optimization algorithm; this algorithm was chosen because the simulation model of DAC has a very high computational cost, but the use of a surrogate model helps reduce it. SCR considers the DAC simulation code as a black box function and creates Kriging-based surrogate models of this function and its constraints. SCR then finds the region where the global minimum of this surrogate model lies and then calls the black box function within this region to look for the optimum. Using this optimization strategy helps to greatly reduce the number of functional evaluations required to reach the optimum thus saving significant time. For the optimization a total of five optimization variables have been selected, these include: the adsorption time ( $t_{ads}$ ), depressurization time ( $t_{eva}$ ), desorption time ( $t_{des}$ ), cooling time ( $t_{cool}$ ) and the vacuum pressure ( $P_L$ ). In the case of the desorption temperature ( $T_{des}$ ), Aspen Adsorption model was not robust enough to allow  $T_{des}$  to be a part of the optimization variables within the time limitation and therefore, two optimization runs were carried out at two fixed desorption temperatures ( $T_{des}$ ) of 352.15 K and 360.15 K. The goal of the optimization is to minimize the specific cost of the DAC unit (€/ton<sub>CO2</sub>). The constraints of the optimization are that the recovery should be greater than 90% and the purity should be greater than 85%.

## 4. Results and Discussions

### 4.1. Optimization of large-scale DAC systems

A benchmark study of Climeworks Hinwil plant (Climeworks, 2017) capturing 2460 kg/day with 18 DAC units was selected in the work of Kim and Léonard (2022b), where a single large-scale DAC unit model was developed. This model could capture 127 kg of CO<sub>2</sub> per day via 4 cycles and this led to a total capture of 2286 kg/day using 18 DAC units which is similar to the Climeworks Hinwil plant's capture scale. Based on this result, a CO<sub>2</sub> capture cost of 620.7 €/tonCO<sub>2</sub> was reported in the aforementioned work. In the current paper, the DAC costs of Kim and Léonard (2022b) are re-evaluated with updated equipment and utility costs (case A) and then optimized using SCR algorithm of Zaryab et al. (2022) at two  $T_{des}$  of 352.15 K (case B) and 360.15 K (case C). Case A's revised capture cost was found to be 552.78 €/tonCO<sub>2</sub> and then TVSA step times ( $t_{ads}$ ,  $t_{eva}$ ,  $t_{de}$ ,  $t_{cool}$ ) and  $P_{vac}$  were optimized in the cases B and C using SCR by minimizing the capture cost (€/tonCO<sub>2</sub>). Variables before and after optimization are presented in Table 1 below.

**Table 1.** Summary of variables before and after optimization

	Before optimization		After optimization	
	Case A	Case B	Case C	
$T_{des}$ [K]	352.15	352.15	360.15	
$P_{vac}$ [bar]	0.33	0.37	0.46	
$t_{ads}$ [s]	6500	6467	6664	
$t_{eva}$ [s]	30	72	56	
$t_{des}$ [s]	6700	7539	5561	
$t_{cool}$ [s]	6300	1535	1000	
Captured CO <sub>2</sub> per cycle [kg/cycle]	31.66	34.57	34.75	
Capture cost [€, 2021/tonCO <sub>2</sub> ]	552.78	367.23	301.35	

It was found in both cases B and C that  $t_{cool}$  has been shortened significantly. Before optimization, the adsorption bed temperature was allowed to cool down to ambient temperature while in the optimized cases, due to the shortened cooling time, the bed temperature is not fully cooled down to its initial temperature. However, as air is fed into the bed during the adsorption step, the bed rapidly cools down to its initial state. This may seem highly ideal but the temperature profile of the simulation can be further refined through experimental data to validate the cooling steps. Based on the simulation results, the drastic decrease in cooling time allows more cycles to be achieved per day (grey line) and this allows more CO<sub>2</sub> to be captured which reduces capture cost per ton of CO<sub>2</sub> (orange line) for Case B and C as depicted in Figure 1.

**Figure 1.** Purity and recovery of the system with capture cost and number of daily cycles

The purity of the different cases stayed around 97% while recoveries of case B increased to 99% from 90% (case A). This is due to an increase in desorption time in case B which allows improved utilization of the adsorption bed. Case C shows desorption at a higher temperature of 360.15 K with longer  $t_{ads}$  (6664 s) and the shortest  $t_{des}$  of 5561 s among cases. Although the recovery may be slightly lower (97%) than case B (99%), this indicates that it is more advantageous to operate at a higher  $T_{des}$  as even at a shorter desorption time, a large recovery per cycle can be achieved.

Specific energy duties of the cases are also calculated and presented in Figure 2 with the annualized CAPEX and OPEX. The electrical energy includes feed (air) compression, vacuum compression of purge streams and air blowers (in hatched column graph sections) while the thermal energy comprises the heat of reaction of  $\text{CO}_2/\text{H}_2\text{O}$ , sensible and latent heat of purge streams as well as sensible heat of sorbents and reactors (in solid column graph sections). Note that water adsorption isotherm is not included in this study and therefore, a theoretical heat of reaction of  $\text{H}_2\text{O}$  (the energy required for  $\text{H}_2\text{O}$  desorption) is calculated using the vaporization enthalpy (Veneman et al., 2015).

**Figure 2.** Specific energy duties (column graphs) with annualized costs (line graphs)

There are small changes in specific energy duties in the case of A and B (before and after optimization at 352.15 K respectively). For the optimized results at 360.15 K (case C), due to its higher  $T_{des}$ , there is an increase in sensible heat of sorbent/reactor but operating at higher  $T_{des}$  is beneficial since this reduces compression duties and sensible/latent heat of purge streams (less steam is required) which makes the overall specific energy duty to decrease. Climeworks process needs between 1.8 and 2.6 MJ/kg of electrical energy and between 5.4 and 11.9 MJ/kg of thermal energy (Deutz and Bardow, 2021), where the minimum value represents the target value for the future and the maximum value depicts the energy requirements at present. For all cases, the thermal energy is in the agreement with the reported range in literature while the electrical energies including air blowing obtained in this study are in the same magnitude but higher in both cases B and C. However, in case C, an electrical duty of 3.76 MJ/kg was estimated which is 31% higher than the upper boundary from the literature. More detailed optimization can be performed to further reduce the electrical duties.

In terms of economics, the annualized CAPEX throughout the cases showed a small change since the dimensions of the columns and the air feed flow rates are kept constant. However, due to the increase in the number of cycles per day in cases B and C, higher operating costs are expected. Nevertheless, the capture costs after the optimization showed a reduction of 33.6% and 45.5% for case B and C respectively as compared to case A since more  $\text{CO}_2$  can be captured with a small increase in costs.

#### 4.2. Achieving net-zero emission with DAC

As it is known, the energy source for DAC systems is a key factor in achieving negative emissions and, low-cost and low-carbon resources are crucial to obtain this goal of the DAC process. To point out this issue, the assessment of integrating different renewable resources into DAC systems has been suggested in the literature (Zolfaghari et al., 2022). Moreover, using currently available electricity sources for DAC is considered the most cost-effective approach for this technology (Hanna et al., 2021). One way to decrease the amount of emitted CO<sub>2</sub> by the DAC process itself is the utilization of electricity not only for electrical equipment (e.g. fans and pumps) but also for heat generation. Therefore, in this section, the total energy requirement, which is acquired through the optimization of the DAC model, is used to calculate the amount of CO<sub>2</sub> produced from DAC operations. The energy mix of electricity grids presented in Figure 3 (Global change data lab, 2022) and the emission factor of different sources from Bruckner et al. (2014) are used to assess the possibility of achieving negative emission in the case of a fully electrified DAC process.

Figure 3. Share of energy sources in electricity production of different countries.

As it is depicted in Figure 4, due to the lower CO<sub>2</sub> emission from electricity grid systems in countries with a higher share of renewables or nuclear energy, the usage of grid electricity for DAC is effective to achieve negative emissions in countries like Norway, Sweden and France, producing about 0.15-0.3 kg<sub>emitted,CO2</sub>/kg<sub>captured,CO2</sub>. On the other hand, the application of grid electricity for carbon removal from ambient air in countries that have a higher share of fossil fuels in power productions (e.g. China, India, and the USA) results in producing more carbon dioxide than captured. Nevertheless, to be able to compare DAC processes with other capture technologies and minimize the side effects of these systems, a detailed Life Cycle Assessment (LCA) is essential.

Figure 4. The amount of produced CO<sub>2</sub> through DAC process.

### 5. Conclusion and perspectives

In this paper, a large-scale DAC model of Kim and Léonard (2022b) is studied. The capture cost (€,2021/tonCO<sub>2</sub>) of DAC systems was minimized by varying cyclic operating parameters (adsorption time, evacuation time, desorption time, cooling time and vacuum pressure) and using the SCR algorithm of Zaryab et. al. (2022) at two fixed

desorption temperatures of 352.15 K and 360.15 K. The optimized results showed that there are desirable step times which can yield a higher capture rate and there is a significant reduction in the cooling time (assuming ideal cooling profiles) allowing more CO<sub>2</sub> to be captured per day, increasing its performance. In terms of the specific energy duties and CAPEX of the systems, small changes were observed before and after the optimization but larger operating costs were observed due to more cycles per day. The increase in the number of cycles per day and the higher cyclic capture rate [kg/cycle] however greatly decreased the capture cost by 33.6% and 45.5% for optimized case B and C respectively. The thermal energy duties of the considered cases agree with Climeworks' benchmark unit. The higher desorption temperature reduces electrical duties but further studies involving different bed configurations, dimensions, different sorbents and air/purge flows are required to further reduce the electrical (as well as thermal) energies of the current model. In next steps, more robust optimization studies including desorption temperature, steam flow rates and cooling cost would be needed.

Also, a location for implementing a fully electrified DAC system is important in achieving net-zero emissions since depending on the country's electricity grid systems, the same DAC system may or may not be a negative emission option. However, a detailed LCA is required to obtain more insights into the relevance and potential deployment of DAC technology. Lastly, the co-adsorption of CO<sub>2</sub> and H<sub>2</sub>O, not considered in the present study, can be included to fully assess the impacts of humidity on the performances of DAC units. Overall, this study shows a complex model with a high computational cost can benefit from SCR algorithm which is a surrogate-based derivative free optimization method. The results from the optimization also suggest the potential for DAC improvement as well as its promising potential as a negative emission technology.

# Simulation of biodiesel production from algae

Suresh Kumar Jayaraman,

*AVEVA Group Plc, Lake Forest, California 92630, United States of America*

## Abstract

Increasing oil demand and depletion of fossil fuel acts as a motivator for alternate fuel research. Biofuels, derived from renewable resources, have the potential to replace their petroleum counterparts, providing a domestic, and carbon-neutral fuel. This study analyzes a large-scale alga dewatering technique and production of biodiesel from algae oil. The dewatering stage extracts algae from water with liquefied propane or butane, which is part of a refrigeration process, is found to be cost effective compared to other dewatering methods. Dry algae are processed into algal oil, and the oil is then trans esterified to Fatty Acid Methyl Ester (FAME), a common biodiesel. The glycerol byproduct is converted to methanol, a more profitable product. This article involves developing a detailed steady state simulation of production of biodiesel from algal oil using first principles unit-op models and rigorous thermodynamics on a next generation commercial simulation tool, AVEVA Process Simulation.

**Keywords:** dewatering, algae oil, biodiesel, process simulation

## 1 Introduction

Biofuels, derived from renewable resources, have the potential to replace their petroleum counterparts, providing a domestic, and carbon-neutral fuel. Common sources of biofuel include sunflower, safflower, canola, soy, and corn. In order to address the issue of food crops being used for fuel production, researchers have turned their focus to non-food resources like algae<sup>1</sup>. Algae are ubiquitous photosynthetic organisms, ranging from single-celled forms to complex multicellular colonies<sup>2</sup>. Algae require sunlight, carbon dioxide, and nutrients like nitrates and phosphates to grow.

The major four processing steps in the production of biofuels are cultivation, Dewatering, Algae extraction, and Biodiesel production. Nutrients are the most cost-involving requirements of algae growth, so optimizing the nutrients requirement can reduce the associated production cost<sup>3</sup>. Out of various algae species, members of the marine green algae such as *Nannochloropsis* are the best species for biodiesel production, because of high lipid content and biomass productivity<sup>4</sup>. The fully grown concentration of algae in an aqueous culture medium is usually 0.1 w/w%, and this concentration is enhanced up to 20 w/w% through a traditional method like drying using heat or electricity<sup>5</sup>. Given the high latent heat of water, algae dewatering by evaporation is an energy intense process<sup>6</sup>, alternative approaches are necessary to improve the energy efficiency of algae dewatering process. Mechanical disruption techniques and hexane extraction are often used to extract algae oil from algae biomass<sup>7</sup>. The algae oil is mostly composed of triglycerides, which is converted

to biodiesel by the transesterification reaction<sup>8</sup>. This paper proposes a novel dewatering technique using propane as solvent, as part of a plant-wide refrigeration system.

## 2 Process Simulation

Process simulations are used to assess the commercial feasibilities of the proposed processes. The Next generation process simulation software, AVEVA™ Process Simulation developed by AVEVA, is used in this work. Microalgae consists of carbohydrates, proteins, and lipids. Here, algae are assumed to be of 50 % lipids, 25 % proteins, 25 % carbohydrates. Glucose is used to model carbohydrates, and poly lysine is used to model protein, and both are simulated as solid components. For simplicity just triolein ( $C_{57}H_{104}O_6$ ) is used to represent lipid content of the algae in the simulation of dewatering process<sup>2</sup>. Triolein (glycerol esterified with a free fatty acid called oleic acid commonly found in various oil sources) is used to represent triglycerides and Methyl Oleate (MOLEATE) is used to represent FAME. All the components are added from DIPPR (Design Institute for Physical Properties) data bank. Non-Random Two-Liquid (NRTL) and Ideal Gas Law thermodynamic properties are used in this simulation. Missing thermodynamic properties are entered manually in the fluid.

## 3 Algae-dewatering process:

Algae-dewatering has been identified as one of the bottlenecks limiting the overall energy efficiency of algal biofuel technology<sup>9</sup>, which currently inhibits the large-scale processing of algae into useable products. Centrifuges are usually used to concentrate the algae and remove lipids, but this processing step is energy intensive and is currently an area of significant research. Algae biomass production rates can vary based on the species chosen, cultivation technique, nutrients, and pond conditions. It is suggested that algal biomass production of  $30 \text{ g m}^{-2} \text{ d}^{-1}$  ( $109.6 \text{ t ha}^{-1} \text{ y}^{-1}$ ) is possible<sup>10</sup>. The cultivation land of 1,500 acres, wet algae flowrate of 760,000 Kg/hr, and 1 w/w % of algae concentration is assumed in the simulation. Figure 1 shows the algae-dewatering process using liquid propane to reduce the moisture content from 99 % to 0.02%. This process stands out because a chemical manufacturer (such as fertilizer plant) generates waste (such as N,  $\text{CO}_2$  and heat) and needs refrigeration. The proposed propane extraction idea uses the dewatering energy to supplement the plant refrigeration need and integrating the algae production with the plant converts waste to needed raw material. The condenser is used in the process to cool the compressed propane gas to liquid propane. Since propane and water are immiscible, they can be separated by decanting. Then propane is separated from algae biomass using flash separators

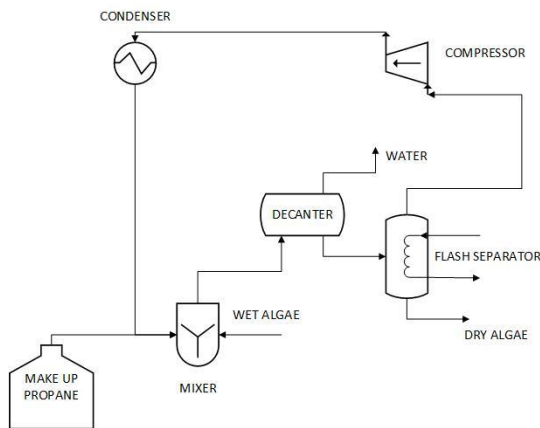

Figure 1: Algae dewatering process

and recycled to the fresh feed. The water from the decanter can be recycled back to the pond, thereby minimizing the wastage of water. In this process the water is removed, not by heating or drying but by a much less energy intensive process. The dried algae from this process are sent to an extraction unit to extract algae oil. The propane is evaporated in the flash separator, leaving the algal paste to be removed mechanically. The gaseous propane is compressed, constituting a refrigeration cycle, thereby supplementing an energy need for an adjacent plant. Butane can be used as an alternative solvent choice in the dewatering process. Though Coefficient of performance (COP) of butane is better than propane, the process economics suggest that propane dewatering technique would be a cost-effective way to dewater algae. However, the interaction of algae with propane, and ways to remove algal paste from the separator remain unknown.

#### 4 Algae Oil Extraction Process:

After dewatering, the algae biomass undergoes a pre-treatment process to enhance the efficiency of lipid extraction process. The pre-treatment is either performed in a single step or multiple steps. If pre-treatment is not performed, the algae biomass concentrate is directly processed for lipid extraction. The algae biomass concentrate is either exposed to a cell disruption technique or dried and then milled into fine powders<sup>11</sup>. The pre-treated algae (disrupted concentrate or dried powder) is then exposed to an eluting extraction solvent which extracts the lipids out of the cellular matrixes<sup>11</sup>. Due to limited data on oil extraction process, a simple conversion model is used in this simulation study to convert 50% of the dry algae to algae oil/lipid. Under nutrient stress during the cultivation stage, the increase in total lipid primarily consists of triglycerides<sup>12 13</sup>.

#### 5 Biodiesel Production Process:

Component information and thermodynamic models are set up and the process steady-state simulation is simulated in a next generation simulation tool, AVEVA Process Simulation. Process flowsheet of production of biodiesel is shown in Figure 2. The oil content of algae is assumed to be 50% in the simulation. The Biodiesel production process in this work consists of following sections:

##### 5.1 Transesterification reactions

The most common way to produce biodiesel is by stepwise transesterification, which is a catalyzed chemical reaction between algae oil and an alcohol to yield fatty acid alkyl esters (biodiesel) and glycerol as shown below.

When triglycerides react with alcohol (e.g., methanol), the three fatty acid chains are released from the glycerol skeleton and combine with the alcohol to yield fatty acid alkyl esters<sup>10</sup> and glycerol as a by-product. Methanol is the most commonly used alcohol and Transesterification

reactions can be alkali-catalyzed, acid-catalyzed, or enzyme-catalyzed<sup>10</sup>. Based on several studies in the literature<sup>10, 14</sup>, the transesterification reaction is carried out at a temperature about 60°C and a 6:1 molar ratio of methanol to algae oil is fed to the Plugflow reactor, which helps in shifting the equilibrium to the product side. The reaction submodel is developed to define the reaction kinetics of the transesterification reactions<sup>15</sup>. Fresh make up methanol, recycled methanol, and sodium hydroxide with a concentration of 1.0 wt% of the algae oil are mixed prior to being pumped into stoichiometric reactor by a pump. For the study, 97% conversion of triglycerides in transesterification reaction is assumed in the reactor.

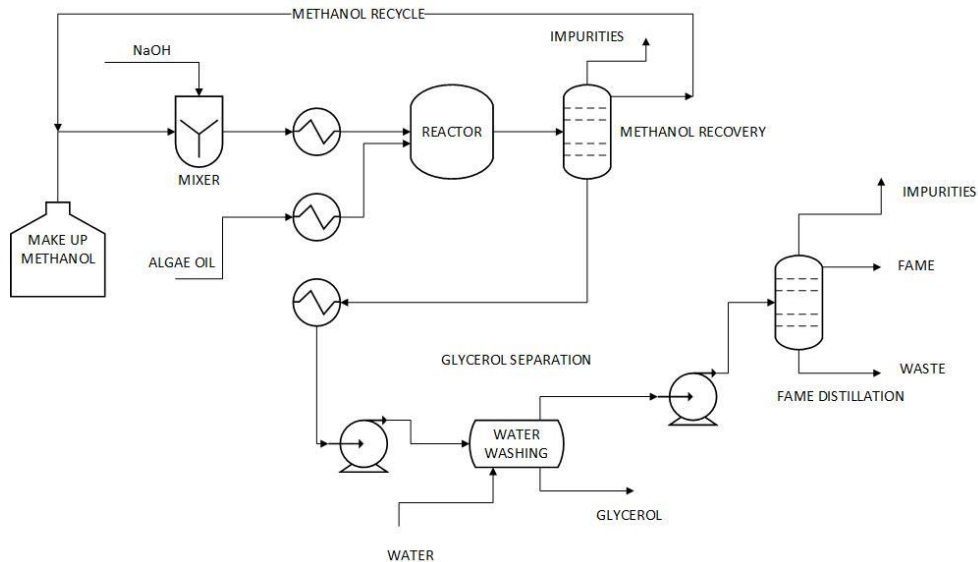

Figure 2: Biodiesel production process

### 5.2 Methanol recovery

The distillation column used for MeOH recovery has four theoretical stages, a reflux ratio of 2, total condenser, and kettle reboiler for a good separation of methanol from other components. Pressure in the range of 20 kPa is used to maintain the temperature of bottom stream under 150°C. Methanol is collected in the distillate stream with a purity of 96%. Methanol from distillate stream is recycled to the fresh make up methanol and then fed to the stoichiometric reactor. Bottom stream is sent to decanter to separate glycerol and FAME. Carbon-dioxide and oxygen are removed as impurities in this section.

### 5.3 FAME and glycerol separation

FAME is separated from glycerol, methanol and catalyst using a water washing column in this study. The FAME is separated from glycerol, methanol, and catalyst by adding 110 kg/hr water. The unreacted triglycerides, methanol and water in the top stream are less than 6 % and glycerol is collected in the bottom stream. Feed water amount is determined by performing the sensitivity analysis to achieve complete separation between FAME and glycerol.

#### 5.4 FAME purification

Biodiesel purity of 99.65% is required to meet ASTM D 6751 of biodiesel specification <sup>22a</sup>. To obtain a final biodiesel product adhering to specifications, FAME distillation column with four theoretical stages, a reflux ratio of 1, total condenser, and kettle reboiler is used. Distillation column is operated under vacuum to keep temperatures low to avoid degradation of the FAME. Methanol, water, and unreacted oil are collected in the column overhead using a total condenser. FAME is obtained as distillate with the purity of 99.8 %.

#### 5.5 Methanol production from glycerol

For every 9 kg of biodiesel produced, about 1 kg of a crude glycerol is formed as a by-product. The crude natural glycerol could be converted to a useful chemical, to increase the profitability of the biodiesel production plant. Glycerol can be converted to methanol, which can be used as fresh make up solvent to the transesterification reaction. Glycerol is converted to methanol and CO<sub>2</sub> as shown below

Glycerol from the water washing column is sent to the conversion reactor along with water, and 99% of glycerol is assumed to be converted to methanol and CO<sub>2</sub>. The reaction takes place at 470 °C and 5 MPa to produce methanol and CO<sub>2</sub>. Separation of methanol

and CO<sub>2</sub> is done in a distillation column with 5 theoretical stages and a reflux ratio of 1.5. Pure CO<sub>2</sub> is collected as a distillate, containing 99% of the total CO<sub>2</sub> and pure methanol is collected as a bottom product, containing 95% of the total methanol. Combining this process along with the biodiesel

production, methanol can be used as fresh make up solvent for the transesterification reaction and CO<sub>2</sub> can be used as a nutrient for the growth of algae.

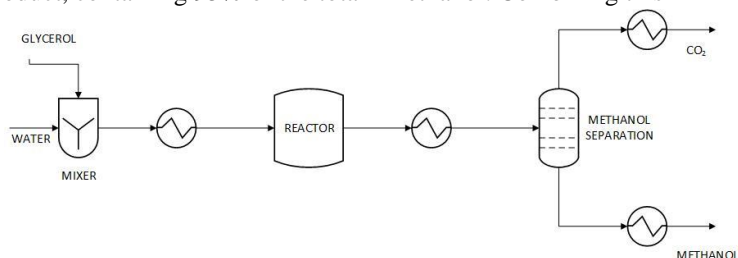

Figure 3: Methanol production process

## 6 Conclusion:

In this work, a new dewatering technique using propane is discussed and simulated using AVEVA Process Simulation. This work simulated a biodiesel production plant using the simulation tool to produce 33000 tons of biodiesel per year, with algae species of 50% oil content. The results show that the production unit is profitable only with 50% and 70% oil content, suggesting that the choice of algae species plays a vital role in the production of biodiesel. Algae species with 70% oil content is not achievable, so this work concludes that

the production plant is profitable with algae species of 50% oil content. So future research should focus on cultivation and pond construction to make this biodiesel production more profitable. Since the production of glycerol exceeds the world demand, the byproduct glycerol is converted to methanol and CO<sub>2</sub>, which can be used as make up solvents and nutrients for algae respectively. However, the present study shows that the biodiesel can be produced at a reasonable cost, thereby making algae a potential source for biofuels.

## Abstract

With the digitalization of industry and further development of computational methods, different ways to control and optimize production processes are possible. Depending on which automation level (i.e. process, field or control level) is chosen for optimization, a variety of operator decision support systems exists. Using the example of water and wastewater industry this contribution explores existing optimization methods: high-fidelity first-principle, data-driven and linear dynamic black-box models. All described solutions can connect online to distributed control systems, but use case, engineering and deployment differ significantly for each of these applications.

**Keywords:** process simulation, optimization, model-predictive control

## 1. Introduction

Saving resources, securing sustainable supply, lowering maintenance and increasing market volatility are some of many challenges that the water industry is facing. A variety of model-based methods for process optimization exists to advice on optimal operating setpoints in an increasingly complex environment while meeting internal and external constraints. The following methods are described below in more details:

- Process level: high-fidelity first-principles models, optimization problem can be formulated in an arbitrary way, additional value provided by e.g. soft sensors, steady state or dynamic optimization for a specified time horizon (gPROMS & gDAP example: reverse osmosis desalination plant)
- Field level: Data-driven models, optimization problem is predefined: minimize switching operations or energy costs for a time horizon of 24 h. (SIWA Optim example: drinking water supply network)
- Control level: linear dynamic black-box models, dynamic optimization problem is essentially to minimize future deviations from specified setpoints in a specified prediction horizon for any multivariable feedback control problem (PCS 7 embedded MPC (Model Predictive Control) Example: wastewater treatment plant).

## 2. Real-time optimization based on first principles model

First principles models rely on fundamental laws of physics, chemistry and biology. The knowledge captured in these models is used since a long time for offline simulation and optimization. Using such models for online applications is a fairly new use case.

### 2.1. General Application Use Case

The provision of desalinated water by reverse osmosis is an energy intensive task. Due to the high osmotic pressure of seawater, significant energy is required to generate water of

a certain quality (salt content). The energy consumption of the process is influenced by various decisions operators take based on process experience. To support operators' decisions, real-time optimization (RTO) based on first principles models is explored. In RTO, the optimum values of setpoints for underlying controllers are re-calculated periodically (e.g., every hour or every day). These repetitive calculations involve solving a constrained steady-state optimization problem. Therefore, a steady-state process model, a performance index (e.g., energy consumption) and constraints are required.

## 2.2. Process Model

The process model of the reverse osmosis section of a desalination plant was developed in gPROMS PROCESS using the library for membranes including a detailed description of the mass transfer (see [1.]). The model also includes dynamics like the gradually increasing fouling layer on the membranes. Overall, in gPROMS a differential-algebraic system of equations (DAE) is created, which can be used for a variety of use cases: simulation, global system analysis, soft-sensing and optimization.

### 2.2.1. Optimization problem

The optimization problem was configured within gPROMS PROCESS itself. A major advantage of a first principles model in the context of optimization is the flexibility to define an optimization problem: any calculated variable can be chosen as objective function, e.g., summation of all energy consumers. Similarly, all assigned variables can be decision variables and constraints can be specified according to process requirements. gPROMS also allows the use of discrete decision variables leading to mixed-integer optimization problems. Finally, constraints like product quality can be configured based on all calculated variables. The time horizon can be set-up as steady-state or dynamic.

### 2.2.2. Engineering Workflow

The engineering workflow of an RTO application from a first principles model follows four steps: 1. Development of a model based on design data like tank size, pump curves, membrane specifics etc. 2. Model validation based on historical process data to determine unknown parameters like mass transfer coefficients or fouling functions. 3. The calibrated model are then used to determine optimal operating points offline. 4. If the robustness of the model is proven, the optimization task can be transferred into an online application.

### 2.2.3. Deployment for Online Operation

For the online deployment the gPROMS digital application platform gDAP is used. The core component is the computational module required for the optimization based on the offline optimization task. Additionally, online connections are configured like e.g., OPC-UA, SQL Server, Historian. Measurement data coming from the real world like flowrates, pressure, quality measurements are validated before using in the computational module. Optimization results are then validated as well before sending them back to the real world.

### 2.2.4. Example from Water Industry

A high-fidelity process model including a detailed model of the membranes used for the separation of retentate (high salt loading) and permeate (lower salt content) with a detailed description of the mass transfer incl. fouling function depending on the load is developed in gPROMS PROCESS [1.]. This model was used for offline optimization studies to determine the optimization potential in typical operation conditions, as described by [1.]. As objective function, the energy consumption of a defined time horizon is chosen. As decision variables the following assigned variables are chosen: split fraction between 2<sup>nd</sup> stage and product tank, setpoints for the flowrate of the booster pumps in the 1<sup>st</sup> stage and setpoints for the flowrate of the high-pressure pump. As constraints, salt content in the permeate and overall production capacity are considered. Based on the offline

optimization study, a significant potential for energy savings is determined. The developed set up is ready for online deployment with the dedicated framework gDAP.

### **3. Demand driven Optimization**

The economic operation of pumps is one of the biggest challenges in the operation of water networks due to different energy tariffs and the increasing number of renewable energies. Since pumps are the largest energy consumer in the network they should be operated in a smooth and efficient way. This is a special use case of RTO, that can be solved by a Siemens software SIWA Optim dedicated to this optimization task.

#### *3.1. General Application Use Case*

The goal of RTO for drinking water networks is calculating a schedule for the most efficient pump operation, ensuring water supply at all times, taking all important parameters such as tank level, energy prices, consumer demands or pump availabilities into consideration. SIWA Optim assists in daily operation by continuously calculating schedules in individually set time intervals or supporting maintenance and operation planning with manually started what-if scenarios and calculations [2.].

#### *3.2. Process Model*

The water network is modeled in a flowsheet with realistic tank sizes and linearized pump models describing the relationship between transported volumes and required energy in the given environment. Model parameters are derived from process data. The simulation uses a linear, flow-based model (in contrast to a hydraulic model that consider pressure calculation). Besides filling of tanks, no other dynamic effects are described in the model.

##### *3.2.1. Optimization problem*

The optimization problem is solved by a Mixed Integer Linear Program Solver (MILP). It can be executed in a manual or cyclic way. In a manual mode it is possible to change the parameters and study the system in more detail, mainly for operation or maintenance purpose. Cyclic calculations are running autonomously in the background in a defined time interval between 1-24 h. Pump status and tank levels are updated before every cyclic optimization. Short intervals between the optimizations can increase operation safety since unexpected events like damaged pumps or low tank levels can be recognized sooner and taken into consideration for the next pump schedule. The calculated pump schedule can also be sent back to the DCS where a dedicated function block is receiving it and transfers the flow setpoints per station or pump to the control unit of the pump group.

##### *3.2.2. Engineering Workflow*

The water network is modeled as a flow based, abstract distribution network. It includes consumer forecast demands, water suppliers feeding fixed quantities of water or providing water in a specific range. Tanks with minimum and maximum level restrictions, pumping stations with limited allowed combinatorics of pumps as well as energy suppliers which calculate the working price for the specific stations and limit power consumption are also included into the model.

This data is used to calculate an optimal schedule for the upcoming 24 hours. Data like pump status and current tank level can be imported from the control system via an OPC UA connection, which allows reading independently of control system provider. The model is fine-tuned by validating the results with the real plant data.

##### *3.2.3. Deployment*

The application is running in Linux dockers within a virtual machine hosted by Hyper-V Manager. The user interface is accessible via Google Chrome. The network engineering for the application is done in an MS Visio based engineering tool.

## 4. DCS embedded Model Predictive Control (MPC)

An optimization problem for a dynamic process model on a finite time horizon, where the performance index includes deviations of model output variables from specified setpoints (or ranges) can be classified as an MPC problem, if it is solved repeatedly in a fixed sample time and the time horizon is shifted accordingly (“moving horizon”).

### 4.1. General Application Use Case

The general use case is multivariable feedback control, namely model predictive control. In some cases, the aim is to reduce the demand for manual operator interactions and increase the degree of automation. In most cases the goal is to optimize process operation with respect to resource consumption, throughput or yield. This is achieved in two steps: 1. Reduce variances of process variables by improved feedback control. 2. This allows to push process operation towards constraints without the risk to violate them. Constraint pushing means to exploit the full potential of the process. As an example from water industry, aeration control in a waste water treatment plant will be described.

### 4.2. Process Model

All MPC algorithms exploit the IMC principle (Internal Model Control [3.]): a dynamic process model is not only used for offline controller design but constitutes an integral part of the online control algorithm, where it is used to predict future process behavior along a specified finite prediction horizon. Most industrial applications of MPC rely on linear dynamic process models that are identified from active experiments (like step testing) in the plant. The typical models are multivariable FIR (Finite Impulse Response) or FSR (Finite Step Response) models as they allow simulation of model response with minimal computing effort. Nonlinear MPC is out of the scope here but described elsewhere [4.].

#### 4.2.1. Optimization problem

The second central idea of MPC is to formulate the feedback control problem as an optimization problem: minimize the squared sum of “control deviations” and other “costs” of control like MV (Manipulated Variables) moves over a finite time horizon. The specific formulation of the objective function for optimization offers many degrees of freedom for controller design. Control deviations are differences between predicted process outputs and future setpoints. Different controlled variables (CVs) can be assigned weights in the performance index to reflect their relative importance to process operation. Move penalties for manipulated variables in the objective function restrict controller moves to be more or less aggressive. Hard constraints like MV limits and soft constraints for model output variables are considered in the optimization problem. The time horizon for optimization is user-defined and in typical applications set for a few hours. Special version of Quadratic Programming solvers are applied inside linear MPC algorithms.

#### 4.2.2. Engineering Workflow

Linear MPC models are typically not derived from first principles but from process data. Active experiments in the plant like step tests around the typical plant operating point are required to create process data with a sufficient information content on process dynamics. From such data, the linear dynamic process model is created automatically, using one of the existing MPC software packages. Simulations of process model are compared to real process data to verify model quality. Definition of optimization problem reduces to specification of MPC design parameters like priority of controlled variables and move penalties for manipulated variables. Offline simulations of closed MPC control loop with linear dynamic process model inside MPC software allow fine-tuning of parameters.

#### 4.2.3. Deployment for Online Operation

There are two deployment types of MPC in context of DCS in process industry: 1. deployment on a Windows PC interfaced to DCS via OPC. 2. DCS embedded MPC, where the online control algorithm is a function block similar to a PID controller. This is currently only available from two DCS vendors: Emerson DeltaV and Simatic PCS 7.

#### 4.2.4. Example from Water Industry

An aeration control in a wastewater treatment plant is reviewed: [5.], [6.]. Closed-loop control of the biological operations in the activated sludge tank is a big challenge for sewage treatment plant automation, because aeration is the most sensitive and energy-consuming part of the WWTP.  $O_2$ -concentration in aeration tank is controlled by PID controllers which manipulate air blower speed. However, the decisive KPIs for water cleaning performance are  $NH_4$  and  $NO_x$  outlet concentrations. Instead of leaving those KPIs to the plant operator, closed loop feedback control by MPC can be established. Manipulated variables of MPC are setpoints for existing PID controllers for recirculation rate and  $O_2$ -concentration. Fluctuations in WWTP feed (feed rate and pollution load) are a challenge for aeration control. Thus, they are included as measurable disturbance variables in the MPC concept, improving prediction quality and providing better compensation of the disturbances effects on  $NH_4$  and  $NO_x$  concentration. WWTP plant operation by MPC assures the fulfillment of the legal specifications for purified wastewater. Test runs in a large WWTP operated by Hansewasser in Germany confirm that energy savings of 3-10% compared to manual operation with constant  $O_2$ -setpoint and heuristic reflux can be achieved.

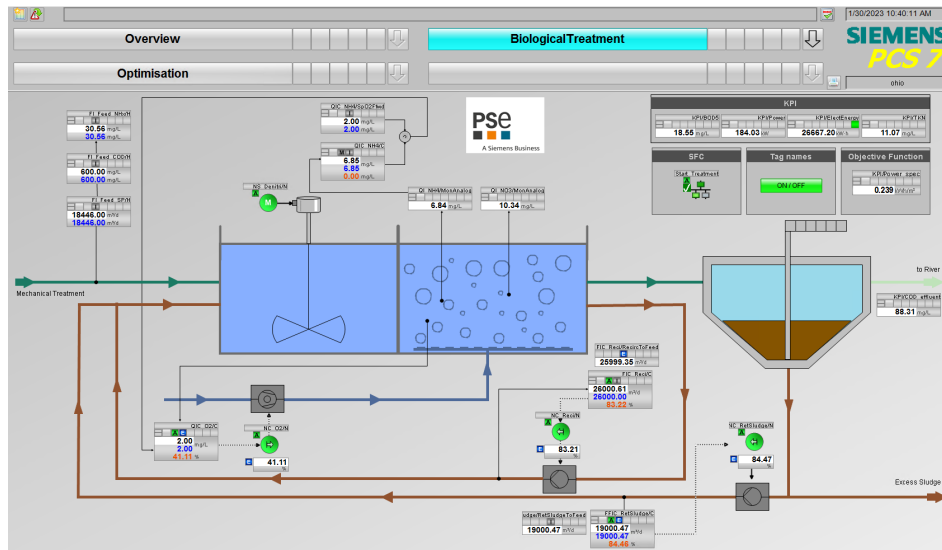

Figure 1: Simatic PCS 7 Unit template for aeration control in wastewater treatment plant [7.]

## 5. Conclusion

If a dedicated software solution for a given optimization problem (like SIWA Optim) is available in context of existing automation hardware and software architecture of a process plant, it is always recommended to exploit this offering. Otherwise, a very general approach like RTO can be applied. In some cases the term “optimization” in requirement specifications is not used in the narrow sense of mathematics. It has to be carefully

checked if there is actually a feedback control problem in the plant, or rather potential for RTO. The typical cycle time for feedback control in process plants is seconds or minutes, whereas steady state RTO is calculated daily or hourly. In general, apply feedback control if target values (or target ranges) for the most important process variables are known and can be used as setpoints for MPC. Apply RTO if the focus is not on stabilizing plant operation at specified setpoints, but rather driving the plant in a desired direction of optimization, e.g. minimize energy consumption. The decision support workflow is shown in Figure 2. It is recommended to discuss it with the experts, to consider all factors.

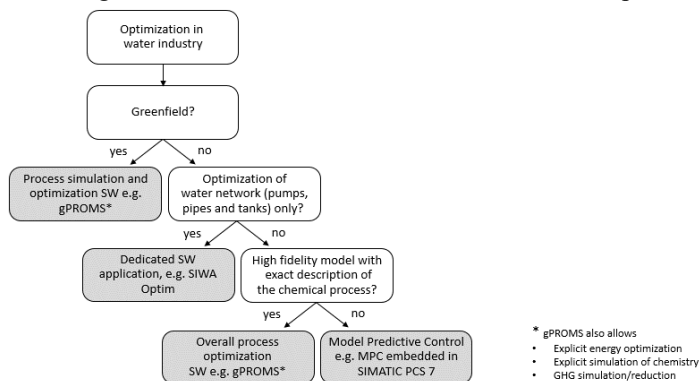

Figure 2: Decision support workflow for optimization in the water industry.

## Abstract

The present work studies fixed bed methanation reactor for the upgrading of biogas, which is expected to provide chemical energy storage for non-programmable sources. The dynamics of such systems can exhibit complex behaviors, that could make the numerical solution computationally expensive. In this work the influence of both the inlet temperature and the recycle ratio on the reactor dynamics are studied employing an empirically based reduced-order model allowing a significant reduction of computational time. Moreover, an assessment of the accuracy of the proposed reduced-order model enables its use within real-time control applications, or in speeding up the resolution of time-consuming optimization.

**Keywords:** reduced models, POD, methanation, step response, Power-to-Methane.

## 1. Introduction

Numerical simulation of high-fidelity models of complex systems can take hours or even days. Some applications, such as parametric studies or optimization, often require thousands of those simulations, and for this reason, overall CPU time rapidly increases. Anyhow, simulations enable to optimize process parameters, to reduce costs, or maximize the productivity of the studied process (Bizon and Continillo, 2021) without the need for time-consuming and expensive experimental work but, most importantly, permit to predict unwanted behaviors and adopt adequate control strategies (Bareschino et al., 2022). In this work, the studied process is related to sustainable energy conversion and reduction of CO<sub>2</sub> emissions, which are challenges that cannot be procrastinated any further, in line with the core principles of the European Green Deal and Power-to-Gas concept. Particularly, the production of biofuels as green energy resources is very promising (Mancusi et al., 2021). Among biofuels, biogas from the anaerobic digestion of organic waste stands out as an attractive way to reduce landfilling and to produce energy. However, the CH<sub>4</sub> content in biogas usually never reaches values above 70%, so it needs to be purified (removal of trace components) and improved (removal of CO<sub>2</sub>) before it can be used. One of the most widely studied upgrading processes involves the methanation of CO<sub>2</sub> (Bareschino et al., 2021). Recently, modeling studies on the methanation process have addressed specific aspects such as the dynamical characterization of methanation reactors (Zimmermann et al., 2022). In this work, the

simulations of a dynamical system that describes the methanation of biogas in an adiabatic fixed-bed reactor with a nickel-based catalyst and a recycle loop are conducted by applying classical proper orthogonal decomposition (POD) for the model-order reduction. This methodology enables the use of the previously derived robust numerical model (Bareschino et al., 2022) for more computationally intensive applications. POD is a popular model reduction technique that, combined with Gal rkin projection, is widely applied in the field of chemical engineering and many other fields, to alleviate the computational expense required for the solution of very high-dimensional systems (Sahyoun and Djouadi, 2013). Both methanation (Bremer et al., 2017) and fixed-bed reactors with recycle have been simulated successfully with this methodology (Bizon and Continillo, 2012).

To understand if the proposed POD/Gal rkin-based reduced-order model (ROM) can correctly predict the dynamics of the methanation reactor, in this work a step response analysis is performed in a region of the space of the parameters where periodic solutions are encountered, and in its vicinity. Temperature oscillations inside the reactor must generally be avoided, as they can lead to permanent deactivation of the catalyst. Outlet concentration variations are also generally inconvenient. The ROM developed here can be useful if incorporated into the design of a control system.

## 2. Mathematical model and computational methods

### 2.1. Mathematical model of an adiabatic fixed bed reactor for biogas upgrading

The methanation reactor investigated is a fixed-bed adiabatic reactor with mass recycle. The catalyst considered is a nickel-based catalyst and the kinetic model employed is the one proposed by Xu and Froment (1989). The chosen model is one-dimensional pseudo-homogeneous with axial dispersion (R nsch et al., 2016). Gas recycle is necessary to keep the temperature inside the reactor within an acceptable limit, determined by catalyst deactivation and carbon formation. The model is mathematically formalized in species and heat balances, Eq.(1) and (2) respectively.

$$\varepsilon_g \frac{\partial c_i}{\partial t} = D_{ax} \frac{\partial^2 c_i}{\partial z^2} - u_{sg} \frac{\partial c_i}{\partial z} - (1 - \varepsilon_g) \rho_c r_i \quad (1)$$

$$\left( \varepsilon_g \rho_g c_{pg} + (1 - \varepsilon_g) c_{pc} \right) \frac{\partial T}{\partial t} = \lambda_{eff} \frac{\partial^2 T}{\partial z^2} - u_{sg} \rho_g c_{pg} \frac{\partial T}{\partial z} - \rho_c \sum_{j=1}^3 \Delta H_{R_j} R_j \quad (2)$$

where  $z$  is the axial position along the reactor,  $\varepsilon_g$  represents the bed porosity,  $c$  ( $\text{kmol} \cdot \text{m}^{-3}$ ) the gas concentration,  $\rho_c$  ( $\text{kg} \cdot \text{m}^{-3}$ ) the packed-bed density, and  $r_i$  ( $\text{kmol} \cdot \text{kgcat}^{-1} \cdot \text{s}^{-1}$ ) the rate of consumption or formation of the  $i^{\text{th}}$  species ( $i = \text{CH}_4, \text{CO}, \text{CO}_2, \text{H}_2, \text{H}_2\text{O}$ ); the latter is determined by summing up the reaction rates of that species in all the reactions,  $R_j$  (Xu and Froment, 1989) according to the stoichiometric coefficient, as follows:

$$r_i = \sum_{j=1}^3 \nu_{i,j} R_j . \quad (3)$$

The boundary conditions are:

$$c_i(0, t) = c_{i,in}(t); \quad T(0, t) = T_{in} \quad (4)$$

where

$$c_{i,in}(0, t) = \frac{c_{i,0}}{1 + R} + R \frac{c_{i,out}(t)}{1 + R} \quad (5)$$

In Eq.(5)  $R$  represents the recycle ratio. To solve the above system of partial differential equations, the method of lines was initially employed: spatial derivatives were approximated using finite differences over a uniform grid of 200 discrete nodes, yielding a system of 1200 ordinary differential equations (ODE) that was solved with MATLAB ode15s, a solver for stiff ODEs. To simplify the description of the reduction method, and to efficiently code the system of ODEs in MATLAB, the following matrix notation is employed:

$$\frac{d}{dt}\mathbf{c}_i = \mathbf{A}_c \mathbf{c}_i + \mathbf{B}_c \mathbf{c}_i \odot \mathbf{u} + \mathbf{F}_c(\mathbf{c}_i, \mathbf{T}) \quad (6)$$

$$\frac{d}{dt}\mathbf{T} = (\mathbf{A}_T \mathbf{T} + \mathbf{B}_T \mathbf{T} \odot \mathbf{u}) \odot \frac{1}{\varepsilon_g \rho_g(\mathbf{c}_i, \mathbf{T}) c_{pg} + \rho_c c_{pc} (1 - \varepsilon_g)} + \mathbf{F}_T(\mathbf{c}_i, \mathbf{T}) \quad (7)$$

where  $\mathbf{A}$  and  $\mathbf{B}$  are the coefficient matrices discretizing spatial derivatives which include also the terms resulting from the outlet boundary conditions, whereas the nonlinear functions  $\mathbf{F}_c$  and  $\mathbf{F}_T$  incorporate the inlet boundary conditions (Eq. (4) and Eq. (5)). The discretized system above is hereafter referred to as the full-order model (FOM).

### 2.2. Reduced order model formulation.

The POD method allows to extract a set of empirical basis functions from observations originating from experiments or numerical simulation (Holmes et al. 1996). The observations, often referred to as snapshots, are collected in the snapshots matrix  $\mathbf{Y}$ . The choice of the most relevant snapshots is often driven by the knowledge of the spatiotemporal complexity of the system and its variability when changing key parameters of the model. In this work, the most straightforward strategy (uniform sampling) is employed (Bizon et al., 2012). After collecting the snapshots, the POD basis is determined by solving the eigenvalue problem:

$$\mathbf{C}\Phi = \Lambda\Phi \quad (8)$$

In Eq. (8)  $\mathbf{C}$  is the autocorrelation matrix defined as  $\mathbf{Y}\mathbf{Y}^T/M$ , where  $M$  is the number of observations used for the construction of the basis, while  $\Phi$  and  $\Lambda$  are, respectively, the matrix containing basis functions and the relevant eigenvalues. The magnitude of each eigenvalue indicates the contribution of the corresponding POD mode to the ‘‘information’’ content of the original data. Using the POD basis, the generic state variable vector  $\mathbf{y}$  can be expressed in truncated form as:

$$\mathbf{y} \approx \tilde{\mathbf{y}} = \sum_{k=1}^K \phi_k x_k = \Phi_K \mathbf{x}_K \quad (9)$$

where  $K \leq N$  is the dimension of the reduced model, and  $\Phi_K \in \mathbf{R}^{N \times K}$  is a matrix composed of the first  $K$  columns of matrix  $\Phi$ . In Eq. (9), the unknowns are the  $K$  time-dependent coefficients  $\mathbf{x}_K$ . They can be determined by resolving the following ROM obtained after substitution of Eq. (9) into Eq. (6)-(7), followed by Gal erkin projection onto  $\Phi_K$ :

$$\frac{d}{dt}\mathbf{x}_K = \Phi_K^T \mathbf{A} \Phi_K \mathbf{x}_K + \Phi_K^T \mathbf{B} \Phi_K \mathbf{x}_K \odot \mathbf{u} + \Phi_K^T \mathbf{F}(\Phi_K \mathbf{x}_K) \quad (10)$$

The state variables vector has been divided into six sets of variables, associated with the species concentrations and temperature. Each one of these sets has been reduced with its own POD basis.

## 3. Results and discussion

The values of the main operating conditions and parameters characterizing the reactor geometry used in both FOM and ROM simulations are reported in Table 1. Fig. 1 reports

a schematic of the system (a) and the grid of parameters explored (b). Before starting the construction and validation of the reduced-order model, several simulations of FOM were performed for the different values of the three parameters analyzed in this work, namely:  $T_{in}$  – the inlet temperature assumed to calculate the steady state,  $\Delta T_{in}$  – the amplitude of the step forcing, and  $R$  – the value of the recycle ratio used for both steady-state and step response calculations.

Table 1. Main model parameters

Parameter	Value	Parameter	Value
$L_r$ [m]	7	$d_r$ [m]	1.2
$P$ [atm]	20	$\rho_c$ [ $\text{kg}\cdot\text{m}^{-3}$ ]	2350
$c_c$ [ $\text{J}\cdot\text{kg}^{-1}\cdot\text{K}^{-1}$ ]	1107	$y_{\text{CH}_4,in}$	0.271
$Q_{in}$ [ $\text{Nm}^3\cdot\text{s}^{-1}$ ]	1	$y_{\text{CO}_2,in}$	0.146
$D_{ax}$ [ $\text{m}^2\cdot\text{s}^{-1}$ ]	$10^{-2}$	$y_{\text{H}_2,in}$	0.583

Figure 1. Scheme of methanation reactor (a) and values of the parameters used in simulations performed with the FOM (b). The two darker dots correspond to the set of parameter values employed in the construction of the ROM.

The simulations were conducted in two steps: first, the steady state (ss) solution is determined for different values of  $T_{in}$  and  $R$ ; then, a step change  $\Delta T_{in}$  of the inlet temperature is introduced, and the response of the reactor is simulated. Different values of  $\Delta T_{in}$  are considered. The whole set of FOM simulations performed is represented inside the space of the studied parameters (Fig. 1b). The snapshots matrix is built with the spatial profiles of the step response of the FOM simulations, sampled uniformly in time. To build the snapshots matrix, different sampling strategies in the parameter space have been evaluated, but only the one that has given the best results in terms of ROM accuracy is reported in this work. Particularly, the snapshots matrix is built using only two FOM step response solutions. Those solutions were obtained for the values of the parameters highlighted in Fig. 1b, that is  $T_{in} = [295.3, 323]$  °C,  $\Delta T_{in} = 10$  °C, and  $R = 1.6$ . After computing the set of basis functions, the truncation order was set to  $K = 35$  for each state variable. Temperature time series and spatial profiles obtained using FOM and ROM are shown in Fig. 2(a) and (b), respectively. Before the inlet temperature step change, the system was simulated only using FOM, once the step change is imposed both FOM and ROM solutions are determined and reported in Figs. (2). This is because the ROM was built to reproduce only the step response of the system. As an interesting case study, to assess the ROM accuracy, an inlet temperature step change was applied to the operating conditions for which the oscillatory regime (or) was encountered. The parameters used in

the simulation are  $T_{in}=306\text{ }^{\circ}\text{C}$  and  $R=1.4$ . As reported in a previous study (Bareschino et al., 2022), this set of parameters is inside a region of periodic regimes. To avoid these undesired behaviors, the inlet temperature can be reduced, for instance, by  $10\text{ }^{\circ}\text{C}$ . Forcing the system with a step of  $\Delta T_{in}=-10\text{ }^{\circ}\text{C}$  results in a steady-state solution. As can be seen from the overlapping curves shown in Fig. 2a, the ROM predicts even the steepest transient oscillations quite accurately.

Figure 2. Time series (a) of the outlet temperature as computed with FOM before the step forcing (in the legend, or: oscillatory regime), and with both FOM and ROM after the step forcing (in the legend, sr: step response); (b) spatial profile of the temperature at different time instants confirming the accuracy of the ROM solution inside the reactor.

The choice of using only 35 POD modes was made to achieve a sufficient reduction of CPU time and to maintain suitable accuracy of the obtained ROM. The resulting ROM has 210 degrees of freedom, which is one order of magnitude lower than the corresponding FOM. The simulation of the step response toward a stable steady state is less computationally expensive, and in this case, the speed up (the ratio of CPU time of ROM simulation over FOM simulation) of the analyzed ROM is 15. For the chosen approximation, the computed relative root mean squared error (RMSE) between FOM and ROM (calculated for the solutions described in Fig. 2) is of the order of  $10^{-3}$  with a maximum value of the error in correspondence of the peak value of  $T$  (at 3130 s) of  $1.9 \cdot 10^{-2}$  and a steady state error of  $6.5 \cdot 10^{-5}$ . Although the ROM was built without taking into account periodic regime solutions, it can predict such regimes accurately.

Figure 3. Time series as computed with FOM before the step forcing (in the legend, ss: steady state), and with both FOM and ROM after the step forcing – after the vertical line – (a); and phase space to highlight the accuracy of the ROM predicting the oscillatory regime (b).

This is demonstrated in Fig. 3: as it can be seen, if the system is forced to go from a stable steady state (ss) regime towards an oscillatory regime, the ROM correctly predicts periodic oscillations. The parameter values used in the simulation are  $T_{in}=300.7$ ,  $R=1.6$ ,  $\Delta T_{in}=10$  °C. In Fig. 3b, to highlight the accuracy of the ROM, the limit cycle obtained using both models are reported. In this case, the simulation is more expensive in terms of CPU time both for FOM and ROM because the solution is characterized by steep gradients that slow the convergence of the employed stiff-stable solver. In this case, the ROM achieves a speed up of 5 with a computed RMSE of  $4 \cdot 10^{-3}$ .

## Conclusions

The simulation of the complex system that describes the methanation of biogas in a fixed bed reactor with mass recycle has been conducted by means of a purposely developed efficient reduced-order model, and its application is critically discussed. For the case analyzed in this study, it has been shown that sufficiently reliable POD basis can be extracted using two solutions obtained from FOM simulations. Despite the nonlinearities, which might have made ROM perform worse due to the need of recomputing the nonlinear terms in the FOM space at each step, the chosen approach resulted in a significant reduction in calculation time, with speedup between 5 and 15 for periodic and stationary regimes, respectively. The dimension of the system has been reduced by one order of magnitude, preserving accuracy both of stationary and periodic solutions. Having assessed the performance of the proposed ROM, a more efficient optimization or a real-time control application can be developed. A considerably larger benefit in terms of reduction of CPU time is expected if the methodology is applied to reduce more complex models such as those considering the radial distribution of temperature and concentration.

*\*edenmar@auburn.edu*

## Abstract

Sustainable and cost-effective capacity expansion in chemical process industries is essential. In this work, a systematic capacity expansion procedure is developed based on reactor intensification, which can help reliably formulate the expansion horizon and investment plans to be determined from a large solution space. Using the developed approach, the case study showed the impact of ethylene oxide reactor intensification on various capacity expansion modes. With a base case of 100 kton/yr, the Brownfield process is the cheapest capacity expansion option up to 112 kton/yr. Subsequently, the retrofitted mode yielded a minimum cost until a capacity of 157 kton/yr, and above that, we would need green field capacity expansion. On the other hand, in terms of utility carbon emission, Greenfield was the lowest carbon producer among the investment alternatives.

**Keywords:** Process Intensification; Capacity expansion; Greenfield process; Brownfield process; Process Retrofitting

## 1. Introduction

Widespread use of modern amenities by human society requires continued expansion of the capacity of the chemical process industry. As the commodity industry contributes about 32% of US emissions stemming from energy usage (Brueske *et al.*, 2015), the question remains: What are the most cost-effective and sustainable ways to expand the capacity of chemical processes? In this regard, various process intensification technologies might play a pivotal role in sustainable capacity expansions. Process intensification can provide innovative approaches to process and equipment design, which can bring significant benefits in process efficiency and lower capital and operating expenses (Demirel *et al.*, 2019).

New reactor intensification technologies have shown significant advancement, such as enhanced heat transfer reactors (Sheng *et al.*, 2011; Rye *et al.*, 2017). Reactor intensification has a profound impact on downstream separation and as such the overall process. We analyzed the keywords of 1800 research journal papers highlighting “Process Intensification”. A high number of journal papers indicate significant interest in process intensification and their distribution in various fields is shown in Figure 1 by the size of the circle representing the relative research concentration in each field. That also emphasizes the need for considering separation process and capability upon reactor intensification.

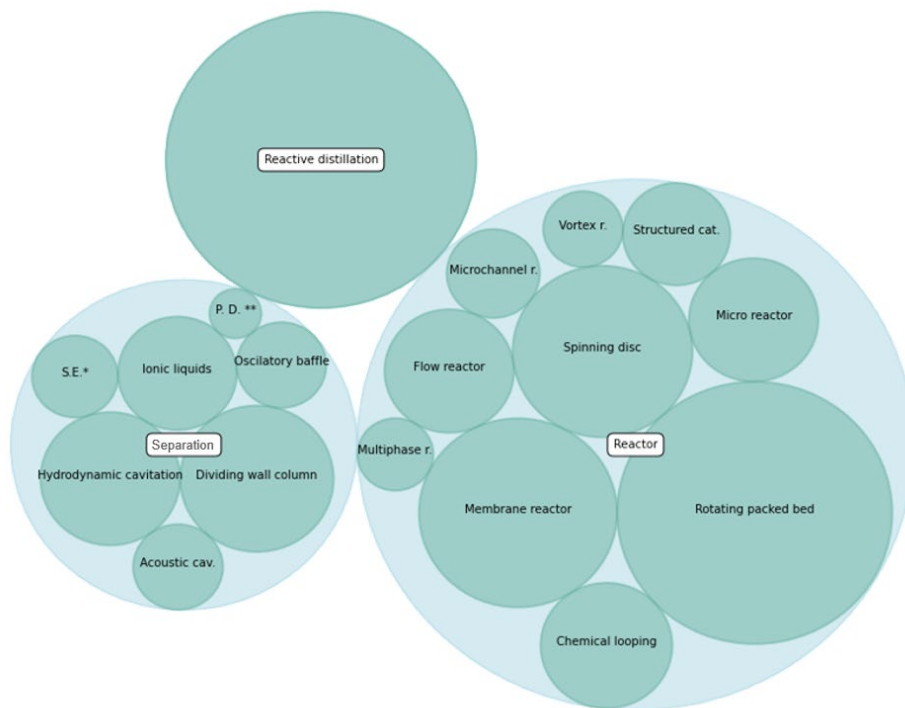

Figure 1. Research areas within Process Intensification (\*Supercritical extraction; \*\*Precipitation disk; r.: reactors.)

Traditional ways of capacity expansion mostly hinge on ultimately building new plants (Greenfield). Increasing the capacity of existing plants (Brownfield) through retrofitting sometimes occurs without effectively considering alternative technologies. We have shown the potential capacity expansion option advantages in Figure 2. First, it can be assumed that potential process intensification options can be readily applied to the green field mode in all parts of the process as we are building the process plant from the ground up. For retrofit, the process intensification options can only be applied to a particular (smaller) section of the plant that we are retrofitting, as we might be using rest of the existing process flowsheet and equipment configuration. For Brownfield, assuming no retrofitting is done in this mode, the scope of process intensification gets reduced even further. It is also evident that for Greenfield the execution time and capital investment might be higher than the Brownfield and retrofitted processes.

It is important to find a suitable intensification technology candidate which can capture the effects of the different capacity expansion modes that we have discussed. Most of the intensification technologies might only affect certain unit operations rather than the overall process. Among the intensification technologies discussed, reactor intensification may have a profound impact on both feed conditioning and downstream separations. Micro fibrous Entrapped Catalyst (MFEC), a reactor intensification technique, can be an ideal candidate in this case (Cheng *et al.*, 2022). MFEC is a microfibrinous metal mesh of either Nickel, steel, or Copper. Moreover, MFEC can remove the reaction heats fast from the catalyst-filled tubes through a conductive heat transfer mechanism instead of

traditional convective heat transfer. Moreover, the smaller particles used in MFEC-based reactors, in comparison to larger particles (>1mm) in the traditional packed bed reactor, provide better control of the reactor temperature and thus quench the heat. MFEC has the potential to reduce the intra-particle and inter-particle transport resistances considerably. All these properties of MFEC are advantageous and affect the downstream process and overall capacity expansion plans.

## 2. Methodology

This section expands on cost calculation methodologies that we discussed in our previous work for a different capacity expansion scenario (Mukta *et al.*, 2022). In this work we are applying the methodology to reactor intensification by Microfibrous Entrapped Catalyst (MFEC), which is a highly conductive catalyst support that intensifies reactors through conductive rather than convective heat transport and large surface area. This technology is an ideal candidate to test our methodology for the impact of reactor intensification on various capacity expansion modes as MFEC intensified reactors have the advantage of positively impacting reaction rates, mass transfer, and heat transfer inside the reactor. This can significantly affect the downstream separation process i.e. capacity expansion plan.

### 2.1. Capacity Expansion Options

Greenfield cost calculation followed the conventional process plant installation procedure. Different formulations considering the lack of land development requirements, module cost, and utility requirements should be considered for Brownfield and retrofitting cases.

Table 1: Capacity expansion options

<b>Greenfield</b>	<b>Retrofit 1</b>	<b>Retrofit 2</b>	<b>Brownfield</b>
A new plant on a newly developed land	Replacing reactor or other equipment	Replacing reactor	Replacing the catalyst in the existing reactor with MFEC
Capital cost calculations based on grass root equipment cost	Capital cost calculations based on modular equipment cost		
New utility systems	Existing utility systems and new utility systems can be installed	Existing utility systems	

### 2.2. Systematic Procedure for Capacity Expansion

It is important to utilize existing infrastructure from both economic and sustainability perspectives. A capacity expansion plan in process industries considering existing facility utilization entails large number of decisions. Identification of the optimum capacity expansion may require significant computational resources. A systematic procedure is necessary to improve the tractability of this potentially large problem. That is why in addition to traditional Greenfield, we analyzed and compared process feasibility and economic performance of other viable capacity expansion modes such as Brownfield and retrofitted processes. The developed systematic procedure is illustrated in Figure 2, where a step-by-step approach is used to selectively reduce the solution space as we expand the

capacity of process plants. First, we determine process flowsheet alternatives of green field mode upon reactor intensification using ProCAFD (Tula *et al.*, 2019). Subsequently, the Brownfield alternative is analyzed to see if equipment configurations can be optimized further to achieve capacity expansion. Next, the retrofitted process is analyzed as it has a significantly higher number of decision variables/constraints compared to the Greenfield and Brownfield options.

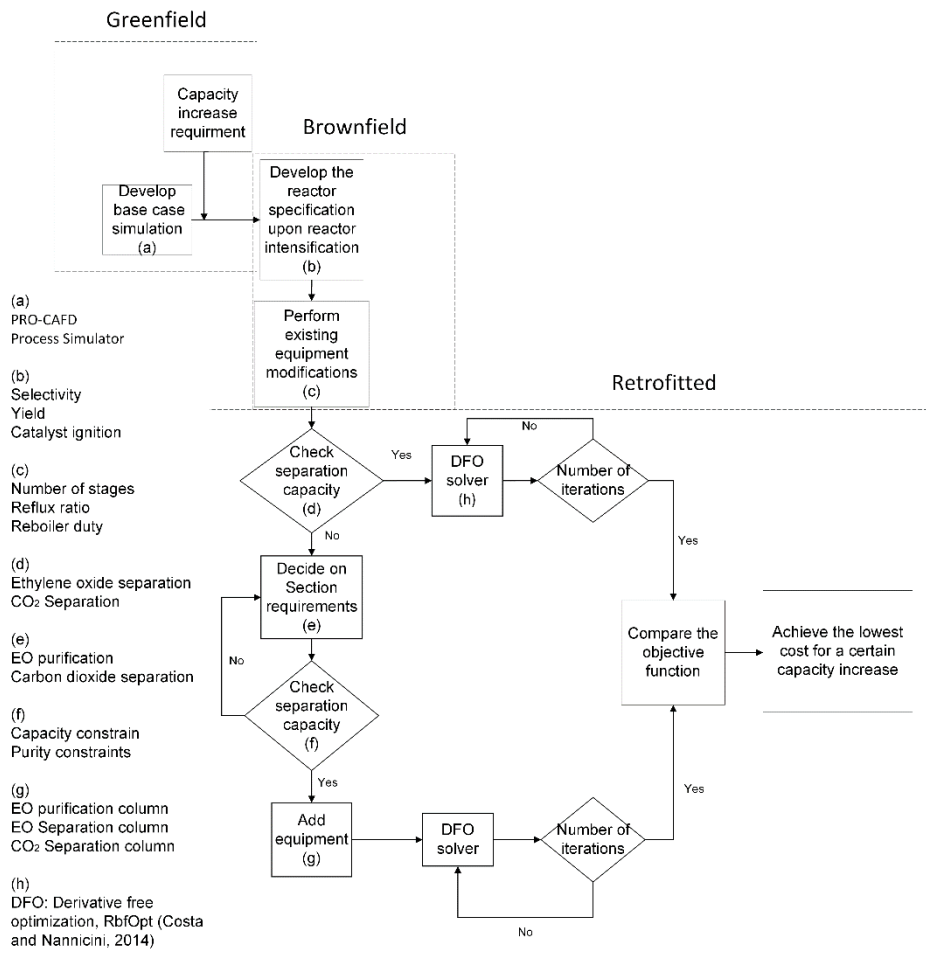

Figure 2. Flowchart showing capacity expansion procedure.

### 3. Case Study

A baseline simulation model of the conventional Ethylene oxide (EO) process has been developed using Aspen Plus<sup>TM</sup> and was described in our previous work (Mukta *et al.*, 2020). Next, standard coefficient-based costing equations were used to calculate capital and operating costs. Then the cost was annualized to form our objective function for the derivative-free optimization algorithm.

Brownfield process achieved the highest cost reduction, but above 112 kton/yr, the separation capacity was insufficient to handle excess reactor capacity. So the framework suggests the next favorable process is the retrofitted process. The retrofitted process-1 achieved a considerable decrease in production cost, but above 130 kton/yr, production costs increased dramatically with additional columns for ethylene oxide separation. Greenfield process expansion becomes cost-effective only after 160 kton/yr. The Greenfield process achieved the lowest carbon emission. The retrofitted process had a moderate increase in carbon emissions. The Brownfield process showed significant increase in carbon emissions upon an increase in capacity as the separation column operates at a higher capacity than it was designed for thus resulting in suboptimal conditions. It can be seen from the utility carbon emission graph that the Greenfield mode produces the minimum utility carbon among all capacity expansion scenarios that we checked. Carbon emission due to construction was not considered for the new equipment for retrofitted process or Greenfield, which might affect the overall carbon emissions of the process plant.

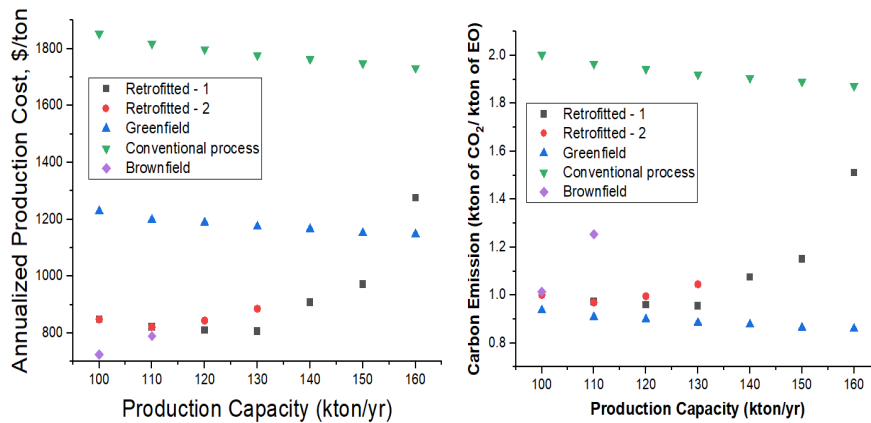

Figure 3: Techno-economic capacity expansion results and associated utility carbon emission.

Figure 4: Various capacity expansion modes regions.

## Conclusion

A systematic procedure of capacity expansion upon reactor intensification for ethylene oxide production has been developed that might be applicable to other chemical processes. The Brownfield process is found to be the cheapest capacity expansion option up to 112 kton/yr. Subsequently, the Retrofitted mode yielded a minimum cost until 157 kton/yr capacity, and above that, we would need Greenfield expansion. But in terms of utility carbon emission, Greenfield was the lowest carbon producer among the investment alternatives.

## Abstract

The reliance of the petrochemical industry on fossil-based sources will need to be reduced by the introduction of Alternative carbon sources (ACS). Introducing ACS in a petrochemical cluster will require existing processes to be modified or replaced, potentially affecting other chemical processes within the cluster due to existing material and energy interconnections. Therefore, it is important to understand the current level of interconnections, functioning, and performance of the petrochemical cluster before introducing ACS. In this work, a representative cluster model based on the petrochemical cluster of the Port of Rotterdam was developed and considered as a case study. This model was analyzed using complex network analysis and environmental and technical key performance indicators. The selected key performance indicators (KPIs) provide insight into the performance of a petrochemical cluster, while the network properties give an understanding of the exchange of material and energy in an industrial cluster.

**Keywords:** petrochemical cluster, key performance indicators, complex network properties, material transition, alternative carbon sources

## 1. Introduction

The petrochemical industry is reliant on fossil-based sources as an energy and carbon source, and therefore it will have to transition to alternative carbon sources to reach the CO<sub>2</sub> reduction goals. The use of new carbon feedstocks (CO<sub>2</sub>, biomass, waste) will require the modification or removal of existing chemical processes. Given the high level of interconnections in existing industrial clusters, these changes are likely to impact existing material and energy connections between processes and among companies in petrochemical clusters. Before these impacts can be assessed, it is needed first to evaluate the complexity and interdependency of petrochemical clusters in terms of material and energy connections and quantify their performance so they can be used as a point of departure.

Network analysis is a method used to study complex systems such as industrial clusters. It allows the interdependencies of processes or companies within a cluster to be assessed by quantifying the exchange of material, energy, or knowledge between processes and or companies. Prior studies (Domenech and Davies, 2011; Song et al., 2018) focused on the occurrence of a link between processes and companies, and assumed that each link is equally important. However, processes are diverse, not only in terms of products but also

in terms of production capacities, and the magnitude of their incoming and outgoing materials and energy flows will also vary as a result. Therefore, it is important that the relative importance of the interconnections is identified and included in the analysis.

In addition to understanding the interdependencies of processes within a petrochemical cluster, additional metrics are required to determine the environmental and technical performance of a petrochemical cluster. Key performance indicators (KPIs) that have been used to assess the performance of industrial clusters are, for instance, CO<sub>2</sub> emissions (Yu et al., 2015) and energy consumption (Sokka et al., 2011).

In this work, a new framework for assessing the complex network properties and performance of a petrochemical cluster is presented. The framework was applied to a case study based on the petrochemical cluster in the Port of Rotterdam (PoR).

## 2. Petrochemical Cluster Model Framework

The methodological framework used to characterize and evaluate the performance of the representative petrochemical cluster (RPC) is presented in Figure 1. The first step is to select the petrochemical processes and utility units that are part of the RPC. For instance, processes producing chemical building blocks (CBBs), intermediate chemicals (ICs), and end-of-value chain chemicals (EVCs) were selected based on the PoR cluster. Additionally, utility production processes that provide the required steam, electricity, and auxiliary chemicals for the chemical processes need to be selected.

In the next step, detailed process models based on publicly available data were built for each selected chemical and utility generation process using Aspen Plus. Each process model was modeled according to the production capacity and process technology of its counterpart in the PoR cluster. These process models provided detailed material and energy balances for each process and utility generation unit. Furthermore, the bare equipment costs and land footprint were determined for each process using Aspen Process Economics Analyzer.

In the third step, the material and energy connections between the processes in the RPC were mapped. This was done by collecting the results of the models and publicly available data on infrastructure and connections of the PoR and using it to match the material and energy requirements within the processes in the RPC. The resulting mapping of exchanges contains all connections between the processes within the cluster and the processes' connections to the outside world. For example, natural gas imported into the cluster, wastewater sent to wastewater treatment plants, and emissions emitted to the environment.

Next, detailed material and energy stream data from the Aspen Plus process models is automatically extracted using an in-house developed Python module. The material and

Figure 1: Methodological framework for modeling and assessing a petrochemical cluster

energy data is used to construct a complex network representation in Python using Py3plex (Škrlj et al., 2019). This complex network representation uses graph theory to describe the petrochemical cluster, where the material and energy connections are represented as links, and the chemical and utility generation processes are depicted as nodes. In this work, we developed a multiplex graph of the cluster, where each layer represents a different type of interaction between the nodes. For instance, the first layer represents all the material interactions, and the second layer depicts all the energy exchanges between processes. The only type of interlayer connections are with the counterpart of each node present in the other layers.

Py3plex is based on the complex network analysis Python module NetworkX by Hagberg et al. (2008), thereby allowing the complex network of the graph to be calculated. The number of connections a node has  $k_i$ , also known as the degree of node  $i$ , was determined by:

$$k_i = \sum_{j \in N} a_{ij} \quad (1)$$

where  $N$  is the number of nodes, and  $a_{ij}$  is zero if there is no direct link between nodes  $i$  and  $j$  and one if there is. Alternatively, the degree centrality  $C_{D,i}$  was calculated by:

$$C_{D,i} = \frac{\sum_{j \in N} a_{ij}}{N-1} \quad (2)$$

The degree centrality only considers whether a connection between processes is present, and the magnitude of the material or energy exchange is not considered in its calculation. It determines the importance of a process in the petrochemical cluster by considering the number of connections it has to other processes in the cluster. To consider the magnitude of the material or energy exchange, the strength of a node  $s_i$  was calculated by:

$$s_i = \sum_{j \in N} w_{ij} \quad (3)$$

where  $w_{ij}$  is the weight of the link between nodes  $i$  and  $j$ . For instance, in the context of the transformation of petrochemical clusters, the mass of carbon in a link could be considered to calculate the weight of a link as it allows the most important nodes in terms of carbon flows between processes to be identified.

The final step consisted of determining the environmental and technical performance of a petrochemical cluster. The graph representation and list of connections were used to calculate the key performance indicators carbon efficiency, CO<sub>2</sub> emissions, and total energy usage within the boundaries of the cluster. The carbon efficiency  $\eta_{Carbon}$  of the cluster is calculated by:

$$\eta_{Carbon} = \frac{\sum m_{Carbon,p}^{Product}}{\sum m_{Carbon,f}^{Feed}} \quad (4)$$

where  $m_{Carbon,p}^{Product}$  is the mass of carbon present in stream  $p$  leaving the petrochemical cluster, while  $m_{Carbon,f}^{Feed}$  is the total mass of carbon present in the material feed stream  $f$  entering the cluster. The total CO<sub>2</sub> emissions of the petrochemical cluster are determined by the mass of CO<sub>2</sub> present in the streams being emitted to the environment:

$$m_{CO_2} = \sum_{i=1}^{N_{streams}} m_{i,CO_2}^{Environment} \quad (5)$$

Where,  $m_{i,CO_2}^{Environment}$  is the mass flow rate of CO<sub>2</sub> in stream  $i$  emitted to the environment, and  $N_{streams}$  is the total amount of streams emitted to the environment.

As described before, the framework presented was implemented using an RPC based on the PoR cluster, and the results of its implementation are discussed in the next section.

### 3. Results and Discussion

Nine utility generation processes and 33 petrochemical processes producing 52 chemicals were selected and modeled in Aspen Plus. Based on these models, a complete mapping of all the material and energy streams of the cluster was created and used to construct a complex network representation of the petrochemical cluster. A two-layer multiplex graph was created containing 49 nodes, where the first layer represented the material exchanges and contained 64 links, while the second layer represented the exchange of energy and contained 48 links. In figure 2, a multiplex graph representation of a small section of the cluster consisting of four chemical processes and three utility generation units is shown.

Figure 2: Multiplex graph representation.

The degree centrality and strength of the nodes of the material layer are presented in Table 1. It shows that the EDC/VCM plant and the SMR plant are the most interconnected processes of the cluster, followed by the aromatics and olefins plants. The EDC/VCM plant is part of the chlorine sub-cluster, which contains many interconnections. The SMR plant supplies H<sub>2</sub>, which is used as auxiliary material in the production of several chemicals, while the aromatics and olefins plant produce the CBBs that are either directly or indirectly used by the other processes within the cluster. Therefore a high level of interconnectivity is expected for these processes. When considering the strength of the nodes, the aromatics plant appears as the most critical process in terms of carbon flows, followed by the ethylbenzene (EB) and olefins plants, respectively.

Table 1: Degree centrality and strength of the most interconnected processes on the material layer

Process	Degree centrality	Process	Strength (ktonne of carbon per year)
Ethylene dichloride/Vinyl chloride monomer (EDC/VCM)	0,19	Aromatics	1757,19
SMR	0,19	Ethylbenzene (EB)	1430,39
Olefins	0,17	Olefins	1110,50
Aromatics	0,17	Propylene oxide/Tert-butyl alcohol (PO/TBA)	978,34
Chlorine	0,13	Propylene oxide/Styrene monomer (PO/SM)	866,78

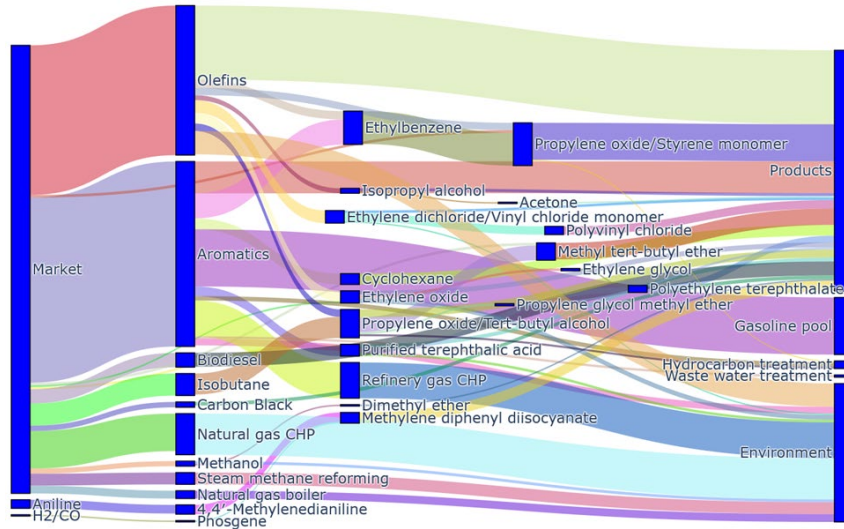

Figure 3: Sankey diagram of all the carbon mass flows in the petrochemical cluster.

In terms of performance, carbon mass flows of the petrochemical cluster are shown in a Sankey diagram in Figure 3. In this diagram, all the chemical processes, the mass flows of carbon between the processes in the cluster, and the carbon flows from and to the outside world are shown. The market represents any material flows being imported into the cluster, while the products represent all material being exported out of the cluster, and the environment represents any CO<sub>2</sub> directly being emitted to the environment. The petrochemical cluster has an overall carbon efficiency of 58.5%. Nearly all the fossil-based carbon feedstock imported into the cluster is sent to the aromatics and olefins plants, with 44.3% and 35.9% of the carbon feedstock, respectively. These plants transform the carbon feedstock into CBB, and these are distributed across the different value chains that make up the cluster. Therefore, replacing these fossil-based processes with alternative carbon source processes such as CO<sub>2</sub>, biomass, or waste will most likely have the most significant impact on the transformation of the petrochemical industry. Additionally, not all chemicals produced by the olefins plant and the aromatics plants are used by the downstream chemical processes in the petrochemical cluster and instead exported out of the cluster. Compared to the strength of the nodes, the importance of the olefins and aromatics is more clearly defined in the Sankey diagram. This is due to the

Figure 4: Pie chart of the CO<sub>2</sub> emissions of the chemical and utility generation processes in the cluster in ktonne of CO<sub>2</sub> per year.

manner the strength of a node is calculated, with only links between processes inside the cluster being considered and not the stream entering or leaving the cluster.

In this case study, the petrochemical cluster emits 11.647 Ktonne of CO<sub>2</sub> every year. The distribution of direct CO<sub>2</sub> emission for all chemical and utility processes emitting at least 25 ktonne per year is shown in Figure 4. A major part of all CO<sub>2</sub> emissions in the cluster is from the utility units that provide the required steam, electricity, and auxiliary chemicals by the chemical processes. The olefins plant has the highest direct CO<sub>2</sub> emissions, as it burns byproducts to provide the heat required for the process. However, new alternative carbon source processes could result in a shift of CO<sub>2</sub> from inside the cluster to outside the cluster. Therefore, an LCA cradle-to-gate approach should be implemented. This will be investigated in further research.

#### 4. Conclusions

The transformation of a petrochemical cluster to more sustainable carbon sources can impact the exchange of material and energy between processes and the performance of the cluster. Thus, network properties and performance indicators are required to assess the current petrochemical cluster and future configurations. In this work, a framework was presented for modeling a petrochemical cluster from the bottom up based on the cluster in the Port of Rotterdam. This model was analyzed using complex network analysis and environmental and technical key performance indicators. In future work, the network properties and performance of a modified cluster, including alternative carbon source processes, will be compared with the benchmark developed in this work, allowing the potential impacts of the transformation of petrochemical cluster to be identified.

# Quality assessment of partial models for co-simulation of modular electrolysis plants

Isabell Viedt<sup>a</sup>, Kumar Rajan Gopa<sup>a</sup>, Jonathan Mädler<sup>a</sup>, Leon Urbas<sup>a,b</sup>

<sup>a</sup>*TU Dresden, Process Systems Engineering Group, 01069 Dresden, Germany*

<sup>b</sup>*TU Dresden, Chair of Process Control System, 01069 Dresden, Germany*

## Abstract

Co-simulation of modular process plants combines partial models for each Process Equipment Assembly (PEA) from different manufacturers. Considering the manufacturer's intellectual property (IP), the co-simulation of the partial models must be realized via a standardized interface using Functional Mock-up Units (FMU). This approach also requires a flexible approach to model quality assessment. In this paper, a workflow for the quality assurance of modularized simulations models for co-simulation is presented via the example of a modular electrolysis plant. The first step is an analysis of the required partial models to derive requirement specifications, the resulting quality models, and the test specifications. These specifications lay the groundwork for the test implementation for the modular electrolysis plant. This use case addresses eighteen partial models of varying modeling depth, including models provided solely as a FMU.

**Keywords:** Model Quality Assurance, Modular Process Plants, Modular Electrolysis.

## 1. Introduction

Modular process plants according to VDI 2776 consist of individual Process Equipment Assemblies (PEA) from different manufacturers (VDI, 2020). With these PEAs envisioned to be equipped with simulations models and a digital twin (Mädler et al., 2022), the simulation of the entire modular process plants must also combine partial models from the individual manufacturers which are potentially confidential. Integrated into varying composite models, co-simulation of different plant configurations can not only be used to determine the best plant setup, but also to test out different scale-up scenarios. As most manufacturers are assumed to be reluctant to share their internal model structure because of IP concerns (Mädler et al., 2022), the co-simulation of the partial models must be realized via a standardized interface, the Functional Mock-up Interface (FMI), using Functional Mock-up Units (FMUs).

Since green hydrogen production will play an important role in the decarbonization of the process industry, scale-up of the hydrogen production is necessary (Buttler & Spliethoff, 2018; IEA, 2021). One approach is the transfer of the concepts from VDI 2776 to electrolysis plants (VDI, 2020). Simulation models will be vital in the testing of the necessary scale-up concepts. In this paper, the workflow for quality assurance of simulations models for co-simulation for modular hydrogen production is presented. The case study consists of eighteen partial models of varying modeling depth and approach, including models provided solely as a FMU. The models are implemented in MATLAB/Simulink and tested via the test-driven modeling workflow.

The remainder of this paper is structured as follows. Section 2 introduces current methods for quality assessment and the methodology for model quality assurance approach

regarding modular plants. In section 3 the case study for the quality assurance of a modular electrolysis plant is presented. The first step is an analysis of the required partial models to derive the requirement specifications, the resulting quality models, and the test specifications. With this, necessary quality factors and criteria such as interoperability, flexibility, and security are discussed as well as functional suitability and reliability. These specifications lay the groundwork for the test implementation and modeling of the electrolysis sample plant. Section 4 provides a conclusion and further research potential.

## 2. Methodology for model quality assurance

### 2.1. Quality assessment of simulation models

In literature, different strategies for the quality assessment of simulation models exist (Murray-Smith, 2015). The most widely known and used strategies are the methods for verification and validation (V&V) by Balci and Sargent (Sargent & Balci, 2017). Although they provide a wide spectrum of assessment methods, the main focus remains on the models' accuracy. Within the meta analysis of Sargent and Balci (2017) it was found that many simulation studies do not consequently apply V&V methods or even disregard them altogether. Mädler et al. (2021) and Viedt et al. (2022) discuss the applicability of quality assurance methods from software development to simulation models. For this approach, quality assessment strategies from software development such as test-driven development and quality models to define quality features in form of FCM (factor–criteria–metrics) models are applied to ensure test-driven modeling.

### 2.2. Quality assurance methodology for modular process plant simulation models

With the increasing importance of model-based approaches for plant optimization and scaling concepts, the quality of simulation models also gains importance. Especially for large-scale co-simulations, where partial models from different manufacturers are combined to form a process simulation of the entire modular plant, quality aspects for the interaction of those models must be considered more directly (Viedt et al., 2022). To ensure high quality co-simulation, quality assurance moves into focus. Thus, quality needs to be a driving factor for the implementation of the models. A shift from 'tagged-on' quality assessment to a quality driven-modeling approach is necessary.

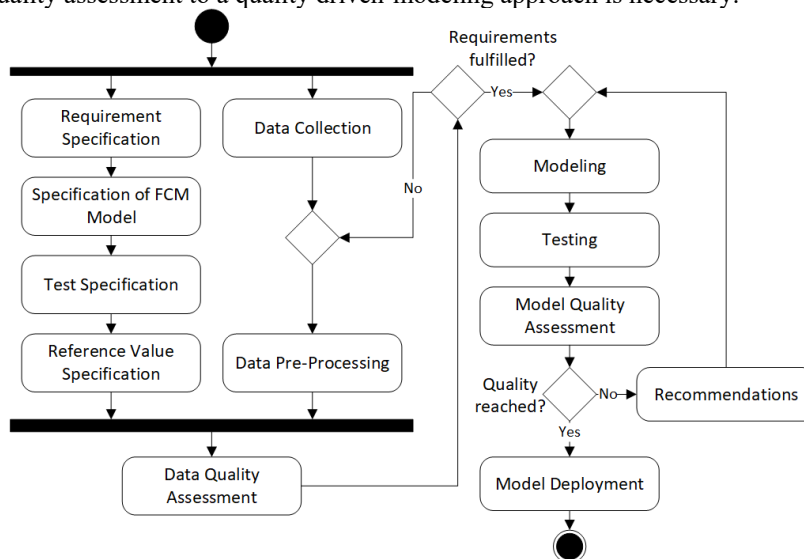

Figure 1: Quality assurance workflow for simulation models

As a result, the pre-definition of requirements, quality features, and tests prior to the start of the actual modeling is of paramount importance. With this, the authors propose a workflow for the quality assurance of simulation models which is shown in Figure 1. The workflow for model quality assurance considers two distinct quality iteration loop: data quality assurance and model quality assurance. Data quality assurance will be necessary in almost all modeling cases. This is because even if data is not used during the actual implementation of the model for a data-driven modeling approach, it will at least be utilized for model validation as well as for parameter identification (Mädler et al., 2022).

### 3. Case study modular electrolysis plant

#### 3.1. Modular electrolysis sample plant

In the research project eModule, standardized plant concepts consisting of PEAs were developed for all three major electrolysis technologies: alkaline electrolysis (AEL), proton exchange membrane electrolysis (PEMEL) and high-temperature electrolysis (HTEL) (Buttler & Spliethoff, 2018). Fig. 2 shows the exemplary flowsheet for the AEL.

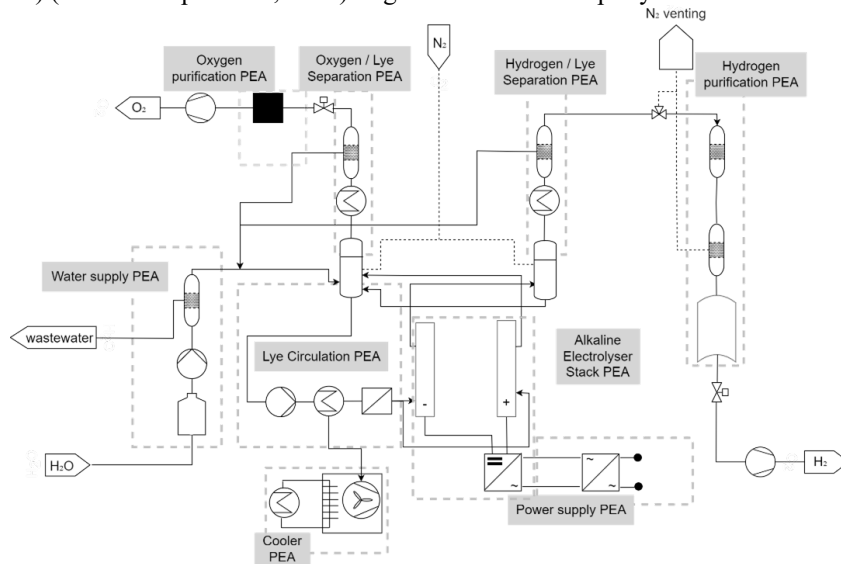

Figure 2: Flowsheet for the AEL - Courtesy of the VDMA Power-to-X for Applications platform (Beisswenger and Erdmann, 2022).

#### 3.2. Partial models and requirements definition

The first step in the test-driven modeling workflow is the specification of the model goal and scope. For the modular electrolysis plant shown in Fig. 2 for the AEL, eight independent partial models were defined: water supply, cooler, lye circulation, AEL stack, oxygen/lye separation, hydrogen/lye separation, oxygen purification and hydrogen purification. In accordance with the project scope, the power supply was not implemented as an individual partial model. For all three considered technologies, AEL, PEMEL, and HTEL, eighteen partial models are defined as necessary according to the requirements specification. This specification defines the necessary functions e.g. interfaces, components, and control functions of each individual model as well as the required modeling depth and approach e.g. a data-driven approach. Once the requirement specification for a model is derived from the modeling and simulation goal, a corresponding FCM model is derived to structure the quality features of the models.

Every metric is allocated a tag that is later used to assign the necessary test specification during the test execution. This tag consists of the tag for the partial model, e.g. WS for water supply or H2LS for the hydrogen/lye separation, and the tag for the specific metric in the FCM model. An excerpt is shown in Table 1.

Table 1: Excerpt of the FCM model for the water supply partial model.

Factor	Criterion	Metric	Tag
Functional Suitability	Functional Correctness	Target conductivity	WS-F1C1M1
	Functional Appropriateness	Degradation rate	WS-F1C2M1
		Conversion efficiency	WS-F1C2M2
	Functional Completeness	Implemented components	WS-F1C3M1
Implemented control functions		WS-F1C3M2	
Reliability	Fault Tolerance	Fault injection tolerance	WS-F2C1M1
Compatibility	Interoperability	Interface standard adherence	WS-F3C1M1

### 3.3. Test specification

The next step in the test-driven modeling workflow is the test specification which also includes the corresponding reference values for the tests. These test specifications are compiled from the aggregated information from the requirements specification, process flow diagram (PFD), the piping and instrumentation diagram (P&ID), the formalized process description, and manufacturer information. Test specification in an early model development phase allows a more comprehensive testing approach, which also makes it easier to detect missing information at an earlier development stage. An excerpt of an exemplary test specification for the AEL stack model is shown in Table 2.

Table 2: Excerpt of an exemplary test specification for the AEL stack partial model.

Tag	Test
AEL-F1C1M1	If the AEL is supplied with power, H <sub>2</sub> O is converted into H <sub>2</sub> and O <sub>2</sub> .
AEL-F1C2M2	If the AEL is not supplied with power, H <sub>2</sub> O is not converted into H <sub>2</sub> and O <sub>2</sub> .
AEL-F3C1M1	The model must adhere to the FMI standard.

### 3.4. Modeling and FMU preparation

In the modeling step the pre-defined partial models are implemented in the chosen modeling environment, here MATLAB/Simulink 2022b. In Fig. 3 the model for the hydrogen/lye separation is shown in a first iteration. In the next step, FMUs must be created for all implemented models. The corresponding FMUs will have the same inlets and outlets as the non-FMU model shown in Fig. 3.

Figure 3: Partial model for the hydrogen/lye separation for AEL.

To enable co-simulation at a later stage, the model and system configurations, which describe the connections between the individual FMUs and the system structure as a whole, must be created. These configurations are compiled from the aggregated information from the requirements specification, block flow diagram (BFD), process flow diagram (PFD), piping and instrumentation diagram (P&ID), and manufacturer information.

### 3.5. Testing and model quality assessment

Once the first modeling iteration step is concluded, the models are tested against the requirements specification and the test specification. For this case study, the tests are implemented and automated via the Simulink Test Manager for both the models implemented in MATLAB/Simulink and the provided FMUs. Since the FMUs represent the partial models provided by the different PEA manufacturers, the internal structure and modeling approach is not known. Therefore, to ensure trust in them, the testing of these partial models must be even more rigorous with more tests and a higher test coverage.

Figure 4: Excerpt of the test results for water supply (left) and hydrogen/lye separation (right).

For the modular electrolysis case study all partial models are tested against their test specification and the requirements specification. Figure 4 shows an excerpt of these test results for the tests tagged WS-F1C1M1 for the water supply and H2LS-F1C1M2 for the hydrogen/lye separation. Both partial models reach the required quality for the two shown metrics of target conductivity and target hydrogen production and can therefore be deployed for the intended purpose. If a partial model does not reach the desired quality, as per the quality assurance workflow (cf. Table 1) another modeling iteration must follow to adjust the model to improve quality. One example of this is the behavior of the hydrogen/lye separation model. In the first modeling iteration, the hydrogen purity metric, H2LS-F1C1M1, did not meet the specification. A corresponding recommendation was the adjustment of the assumptions for vapor pressure and gas solubility. The requirements specification and the FCM model also include further quality factors such as compatibility and efficiency, which are only tested qualitatively. For co-simulation in particular, quality features which do not describe the explicit model behavior are of paramount importance as runtime efficiency and model compatibility will enable successful execution.

## 4. Conclusion and outlook

With this case study it was shown that the presented quality assurance workflow allows for an easy integration of additional requirements and tests to cover multiple modular plant configurations while enabling test-driven modeling and co-simulation. Especially for a large number of models, this approach allows for a test-driven and structured

assurance process which enables better result tracking. Since the partial models are compiled into a co-simulation framework, quality features outside of the models behavior must also be considered to assure successful model interaction. One future challenge will be the rigorous assessment of FMUs and composite FMUs. Since the person conducting quality assurance is not the model builder, acceptable quality of the individual models does not automatically lead to sufficient quality of the composite models if the modeling approach etc. is not known. Therefore, there is a need for an exchange of context information between manufacturer and operator of the co-simulation to ensure compatibility in addition to standard adherence like the modeling goal and some information about the modeling approach (Mädler et al., 2022).

Another challenge for the quality assurance of the co-simulation and the model process will be the definition and creation of the co-simulation configuration. As of now, the model assurance workflow does not include the quality assessment of the configurations content besides standard adherence itself.

## Abstract

An unstructured mechanistic model is proposed to describe the industrial-scale production of Fusidic Acid in fed-batch cultivations. The model accounts for differences in dead and viable biomass and the effect of the primary carbon source and oxygen on cell growth and production. The model parameter is calibrated, and performance is tested using experimental data obtained from an operating industrial production in Denmark. The model predicted the main product concentration with a relative mean error of 7%. These successful implementations open up opportunities for soft sensor implementations for key state variables but also set a good foundation for further model extensions, such as hybrid modeling.

**Keywords:** Fermentation, Process Modelling, Pharmaceuticals

## 1. Introduction

Industrial microbiology has been one of the most common methods for the mass reproduction of antibiotics since the widescale production of penicillin. In a very similar sense, Fusidic Acid is a secondary metabolite that is commercially produced using a filamentous microorganism. At the same time, there is extensive literature on the modeling of penicillin production with varying degrees of complexity (Goldrick et al. 2015), but there is no published research on the mechanistic modeling of the Fucidin process. The bioprocess industry has seen rapid advancements toward digitalization. This has led to increasing interest in industrial applications of digital twins. These technologies require good-quality process models to act as the foundation. Mechanistic models are the gold standard as they incorporate current knowledge into a first principles mathematical description of the system of interest (Gernaey et al. 2010). While more challenging to develop, these model types are notably beneficial for application in the fermentation industry since they can be better extrapolated to new scenarios than machine learning algorithms and artificial intelligence.

A mechanistic model describes the dynamic behavior of a system with a series of mathematical formulas, typically ordinary differential equations (ODEs). These models are based on prior knowledge of the system phenomena like mass, energy, and moment balances.

The mechanistic model of Bajpai and Reuss (Bajpai and Reuss 1980) is a good starting point when designing a model structure for a poorly researched organism. It's unstructured, has low complexity, few parameters, and can be calibrated based on

experimentally measured growth profiles. Furthermore, it was made to model the secondary metabolites of a filamentous organism and showed excellent agreement with experimental data. Extensions and changes will be proposed based on observed phenomena on industrial and lab scales to improve predictive qualities and applications. This study aims to design and evaluate a mechanistic model to quantitatively describe the behavior of an industrial-scale Fusidic Acid process. To this end, a mechanistic model structure is inspired by unstructured penicillin models with extensions or modifications to account for observable phenomena in the production setting and during lab experiments performed at LEO Pharma A/S. Data from industrial-scale fed-batch fermentation is collected to calibrate and validate model parameters and structure.

## 2. Materials and Methods

A model is developed to describe a filamentous fermentation fed-batch process operated at LEO Pharma A/S. The traditional fed-batch equation is utilized for the overall concentration balance with an extension to account for the effects of evaporation.

$$\frac{dC_i}{dt} = q_i + \frac{E}{M}C_i + \frac{F_{feed}}{M}(C_{i,f} - C_i) + k_l a_i(C_i^* - C_i)$$

Where the first term  $q_i$  denotes the biochemical kinetic rate of component  $i$ , the second term accounts for increased concentration due to mass loss from water evaporation and offgas balance, where  $E$  describes the broth mass change due to evaporation and offgas balance  $E = F_{evap} + F_{OUR} - F_{CER}$ . It is assumed that all relevant components are nonvolatile and thus are not present in the offgas. The third term describes the dilution due to feed where  $F_{feed}$  is the feed rate,  $M$  is the broth weight, and  $C_{i,f}$  is the concentration of component  $i$  in the feed. The final term describes the mass transfer of component  $i$  from the gas phase to the liquid phase, where  $k_l a_i$  is the mass transfer coefficient of component  $i$  and  $C_i^*$  is the equilibrium solubility of component  $i$ . For simplifications, it is assumed that  $k_l a$  is 0 for all components except oxygen.

As the model is unstructured, it is assumed that all the biochemical kinetics can be explained with a specific growth rate term, which can be either positive, indicating growth/production, or negative, indicating consumption.

$$\mathbf{q} = \boldsymbol{\mu}X$$

Where  $X$  is the concentration of viable biomass and  $\boldsymbol{\mu}$  is a vector containing the specific rates of each species calculated with an unstructured model equation structure. Note that  $X$  is viable biomass and not the total dry weight, which accounts for the accumulation of cell debris and precipitated main product.

$$X_{TDW} = X + X_D + P_{precipitated}$$

The Contois model kinetics is utilized for growth due to the excellent agreement with experimental data for multiple microbial systems (Alqahtani et al. 2015). The overall system of equations describing the biochemical model of the main components are

$$\mu_X = \mu_{X,max} \frac{S}{K_{SX}X + S} \frac{DO}{K_{OX}X + DO} \left( 1 - \exp\left(\frac{-t}{t_{lag}}\right) \right) - k_d$$

$$\mu_P = \mu_{P,max} \frac{S}{K_{SP}X + S}$$

$$\mu_S = \frac{\mu_X}{Y_{SX}} + \frac{\mu_P}{Y_{SP}} + m_S \frac{S}{K_{SS}X + S}$$

The changes in broth mass are modelled by considering all components entering and leaving the fermenter

$$\frac{dM}{dt} = F_{feed} - F_{evap} + F_{OUR} - F_{CER}$$

Feedrate and offgas measurements are available. To estimate the evaporation, we consider the amount of water vapors in the process air and offgas.

$$F_{evap} = Q_{air} \left( \frac{\phi_{out} p_{H_2O,out}^*}{RT_{out}} - \frac{\phi_{in} p_{H_2O,in}^*}{RT_{in}} \right)$$

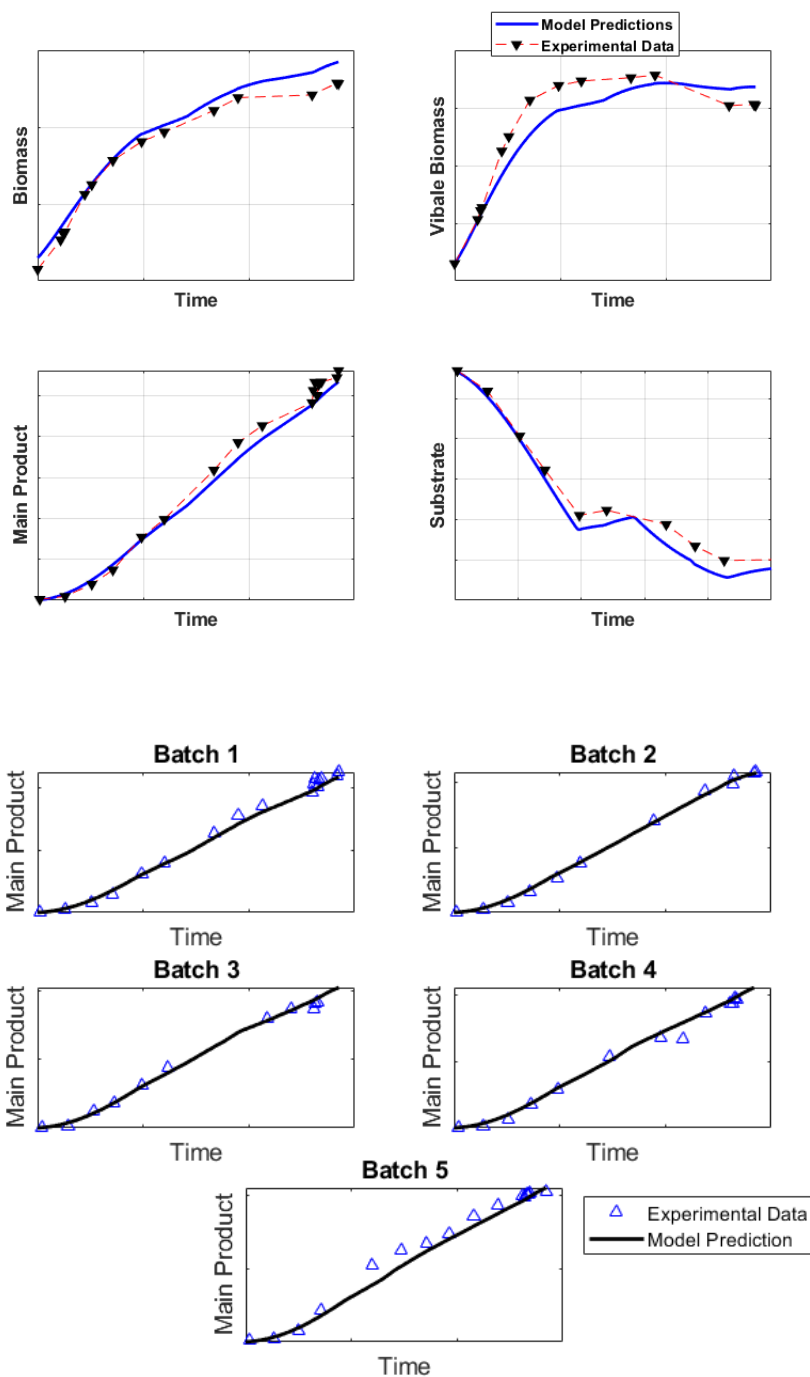

Where  $\phi$  is the relative humidity and  $p_{H_2O}^*$  is the saturation pressure of water in the air. Relative humidity of process air is available from batch measurements, and it is assumed that the offgas is fully saturated with water, i.e.,  $\phi_{out} = 1$ . The saturation pressure of water can be estimated using a steam table or the Antoine equation.

The model equation structure is implemented into MATLAB R2021B and solved using the stiff solver *ode15s*. Measured online data for Dissolved Oxygen (*DO*), pH and offgas  $F_{OUR}$  and  $F_{CER}$  are used as inputs when model is calibrated. The model contains 11 growth parameters that need to be estimated, no previous nominal values exist for the fungus and are all estimated simultaneously using *lsqnonlin* function in MATLAB.

### 3. Results

Experimental data collected from sampling industrial production are used for parameter estimation. An initial fit for the validation batch can be seen in Figure 1. The prior estimation showed a generally satisfactory fit with experimental data and can accurately

describe the concentration profiles of viable biomass and main product. It also captured the concentration of the primary carbon source reasonably.

However, for engineering purposes, we are primarily interested in the main product concentration, which is the main economic driver of the entire process. Therefore, the comparison of measured and simulated growth profiles of all sampled batches is shown in Figure 2. The overall fit to the main product considering all experimental values is depicted in figure 3 with an overall prediction error of 6.6%. This Model shows excellent fits for the main product.

Model quality was assessed with the root mean sum of squared errors (RMSSE) but is reported here as a scaled percentage deviation from the experimental measured mean value to preserve confidentiality of process scales of industrial sponsor.

$$RMSSE(\%) = 100 * \frac{\sqrt{\frac{1}{n} \sum_{i=1}^N (y_{meas,i} - y_{pred,i})^2}}{\bar{y}}$$

Process Variable	RMSSE (%)	R <sup>2</sup>
Total Dry Weight	12.75	0.98
Viable Biomass	12.99	0.91
Main Product	6.60	0.99
Substrate	19.52	0.98

Initial parameter estimation shows that the Model has the most trouble predicting main carbon source concentrations. If all measurements are included, there is an error of approximately 20%. It’s hypothesized that the complex media blend gives rise to multiple available carbon sources. At the same time, the Model focuses only on a singular primary carbon source. This may lead to different consumption rates depending on the variation

in the initial media blending. Both biomass measurements show a similar error of approximately 13% which is considered a good fit. Similarly, with the substrate predictions, it may be possible to improve fits by considering the effects of potential alternative carbon sources, but this is a highly complicated data collection and modeling process. One of the main drawbacks of using the current iteration for batch planning or as the basis for digital twins is that the model cannot run as an independent simulation. This is because the model relies on Oxygen Uptake and Carbon Evolution data to estimate evaporation accurately. Without this information, any optimization that relies on model outputs will probably underestimate final product concentrations while overestimating the current broth weight. In the current state, the mechanistic model uses batch measurements to calculate estimates of key process variables that describe the batch states that are not observable meaning it has potential applications in soft-sensor technology.

#### 4. Conclusions

A mechanistic model structure was proposed to describe an antibiotic production process of a novel filamentous fungi strain. The model can be used to simulate growth profiles on an industrial scale. It can simulate biomass growth, main product synthesis, and substrate uptake. Due to the lack of sophisticated hardware sensor technology, these key process variables are not commonly measured online. The predictions are supported by readily available online measurements such as offgas mass spectrometry to evaluate carbon evolution and oxygen uptake. Future work will use this model as a foundation for integrating machine learning techniques to expand the model capabilities to obtain readily available predictions of the missing key state variables that went unexplained in this work. We also wish to study the model's reliability in the framework of good modeling practices (Sin *et al.* 2009) by statistically analyzing the effects of uncertainty of the model structure and parameters.

## Abstract

In this paper, we combine the multiparametric programming approach proposed in Pistikopoulos et al., 2002 for quadratic Model Predictive Control (mp-QP/MPC) problems, with the solution strategy proposed in Narciso et al. 2022 for mp-QP problems. The problem statements in these two contributions are fully compatible, and we show firstly how they can be combined to deliver critical regions and the corresponding control laws of MPC problems in the offline stage. Then, a new online architecture is proposed for the calculation of optimal control actions. To this end we explore the convenient solution structure presented in Narciso et al. 2022 with the specific aim to calculate them as fast as possible via parallel processing, and where a restricted collection of critical regions is kept and continuously updated in time.

**Keywords:** Multiparametric programming, Quadratic Programming, Model Predictive Control.

## 1. Introduction

Model Predictive Control (MPC) enables an optimization-based approach to control problems, whereby a cost function driving the system's states to a predefined set point and a set of operational constraints are defined (Pistikopoulos et al. 2020). As the size of MPC problems increase, so does the total time required to solve them. This is particularly critical when the total times required to solve MPC problems exceed the required response times, which renders the optimization-based route ineffective at best (Pappas et al. 2020).

Multiparametric programming (mp) has been shown to mitigate this limitation (Pistikopoulos et al., 2002): the expensive optimization calculations are moved to the *offline* stage, where a collection of explicit critical regions and matching control laws are obtained, and thus requiring a set of inexpensive function evaluations during the *online* calculation of the optimal control actions. The drawback of mp is that as MPC problems grow very large, so do the corresponding explicit solutions, which in turn generally slow down the calculation of optimal controls in the online stage.

Several strategies have been proposed to deliver faster online calculations for MPC problems (Pappas et al. 2020). In this work, we focus on the class of mp-QP/MPC (quadratic programming) problems presented in Pistikopoulos et al., 2002, and use the mp-QP algorithm presented Narciso et al. 2022 to deliver critical regions and control laws in compact form during the offline stage. We explore this convenient solution structure and propose a new architecture for the fast calculation of controls during the online stage.

## 2. Offline calculation of optimal control laws

We consider the following class of QP/MPC problems, where the state, output, and control vectors are denoted as  $x \in \mathbb{R}^n$ ,  $y \in \mathbb{R}^p$  and  $u \in \mathbb{R}^m$  (Pistikopoulos et al., 2002):

$$\begin{aligned}
 \min_U \quad & x'_{t+N_y|t} P x_{t+N_y|t} + \sum_{k=0}^{N_y-1} [x'_{t+k|t} Q x_{t+k|t} + u'_{t+k} R u_{t+k}] \\
 \text{s. t.} \quad & y_{\min} \leq y_{t+k|t} \leq y_{\max}, k = 1, \dots, N_c \\
 & u_{\min} \leq u_{t+k|t} \leq u_{\max}, k = 1, \dots, N_c \\
 & x_{t|t} = x(t) \\
 & x_{t+k+1|t} = A x_{t+k|t} + B u_{t+k}, k \geq 0 \\
 & y_{t+k|t} = C x_{t+k|t}, k \geq 0 \\
 & u_{t+k|t} = K x_{t+k|t}, N_u \leq k \leq N_y
 \end{aligned} \tag{Eq. 1}$$

where  $U = [u'_t, u'_{t+1}, \dots, u'_{t+N_u-1}]' \in \mathbb{R}^s$ , with  $s = mN_u$ .  $P = P' \geq 0$ ,  $Q = Q' \geq 0$  and  $R \geq 0$  are constant cost matrices.  $A$ ,  $B$  and  $C$  are constant matrices defining the state-space model, and subscripts min and max denote the lower and upper bounds, respectively, on  $y$  and  $u$ .  $K$  is a constant feedback gain matrix, and  $N_y \geq N_u$ . Using  $x_{t+k|t} = A^k x(t) + \sum_{j=0}^{k-1} A^j B u_{t+k-1-j}$ , an equivalent QP/MPC is defined:

$$\begin{aligned}
 \min_U \quad & 1/2 U' H U + x(t)' F U + 1/2 x(t)' Y x(t) \\
 \text{s. t.} \quad & G U \leq W + E x(t)
 \end{aligned} \tag{Eq. 2}$$

where  $H \geq 0$ , and all additional matrices are obtained from Equation 1 and  $x_{t+k|t} = A^k x(t) + \sum_{j=0}^{k-1} A^j B u_{t+k-1-j}$ . Using the variable transform,  $\gamma = U + H^{-1} F' x(t)$ , and defining the allowable space of state variables (space of independent parameters), a mp-QP/MPC problem is obtained accordingly:

$$\begin{aligned}
 \min_{\gamma} \quad & 1/2 \gamma' Q \gamma \\
 \text{s. t.} \quad & G \gamma \leq W + S x(t) \\
 & P_A x(t) \leq P_b
 \end{aligned} \tag{Eq. 3}$$

where  $\gamma \in \mathbb{R}^s$  and  $S = E + G H^{-1} F'$ . Multiple routes are available to solve Eq. 3, namely via the explicit calculation of critical regions of the state space and the corresponding control laws (Pappas et al. 2020). In this work we consider the solution strategy for mp-QP problems presented in Narciso et al. 2022, where a final recast step is required. Note that a new transformed vector of parameters  $z = S x(t)$  is defined, and no bounds are enforced on the corresponding space of parameters  $Z$ :

$$\begin{aligned} \min_{\gamma} \quad & 1/2 \gamma' Q \gamma \\ \text{s. t.} \quad & G\gamma \leq W + z \end{aligned} \quad (\text{Eq. 4})$$

In this convenient format, it is possible to deliver the map of all critical regions (Eq. 5) and the corresponding optimal control laws (Eq. 6) in compact form for all active sets, as follows:

$$z = z^* + V_i^z \left( (\alpha^{full} - \alpha) l \right) + V_a^z(\alpha l), \alpha \in \{0,1\}, l \geq 0 \quad (\text{Eq. 5})$$

$$\gamma^{opt} = \gamma^* + V^\gamma(\alpha l) \quad (\text{Eq. 6})$$

where  $\alpha$  is the binary active set vector of Eq. 4 with size  $q = (p + m)N_c$ , and such that 0/1 denote inactive/active constraints, respectively.  $\alpha^{full}$  denotes the full active ( $\alpha^{full} = [1, \dots, 1]'$ ). Optimizers are denoted as  $\gamma^{opt}$ , and  $l$  is a non-negative multiplier vector of size  $q$ . All vectors ( $z^*$ ,  $\gamma^*$ ) and matrices ( $V_i^z$ ,  $V_a^z$ ,  $V^\gamma$ ) in Eqs 5 and 6 are obtained from the Karush-Kuhn-Tucker (KKT) conditions on all the  $q$  single-constraint active sets.

An algorithm and discussion on the significance of these vectors/matrices is presented in Narciso et al. 2022. For any given active set  $\alpha$ , it suffices to set it directly in Eqs. 5 and 6 to obtain the corresponding critical region in the transformed parameter space and optimal control law, respectively; the explicit calculation of critical regions may also optionally be enabled, where  $V_{\{\alpha\}}^z$  includes the relevant column vectors from  $V_i^z$  and  $V_a^z$  for any  $\alpha$ :

$$z = z^* + V_{\{\alpha\}}^z l, l \geq 0 \quad (\text{Eq. 7})$$

### 3. Online calculation of optimal control actions

To obtain the optimal control actions for any  $x(t)$ , 4 steps are required:

- 1) Compute  $z^{input} = Sx(t)$ ;
- 2) Solve Eq. 5 for  $z = z^{input}$  to obtain  $(\alpha, l)$ ;
- 3) Compute  $\gamma^{opt}$  from Eq. 6;
- 4) Compute the first set of control actions ( $u_t$ ) from  $U = \gamma^{opt} - H^{-1}F'x(t)$ .

Steps 1, 3 and 4 are inexpensive matrix/vector operations. Step 2, on the other hand, is a less trivial problem: when solving Eq. 5 for a given  $z$ , such statement defines in fact a Linear Complementarity Problem (LCP) (Murty and Yu, 2010). Using one of the state-of-the-art LCP solvers is the obvious choice for this step, but in fact the convenient structure of Eq. 5 enables other alternative routes for its solution in the context of mp-QP/MPC, namely via: (i) the explicit calculation of critical regions/control laws (as is in fact the common practice in the field), or (ii) recast Eq. 5 as an NLP or MILP problem.

All routes above are equivalent with respect to the solutions obtained from them. In a control context, however, not only are we concerned with finding the optimal control actions, but also to deliver them as fast as possible to avoid any undesirable delays and the consequent loss of control efficiency (Pistikopoulos et al. 2020). We propose the following procedure to calculate  $(\alpha, l)$  via step 2 as depicted in Figure 1.

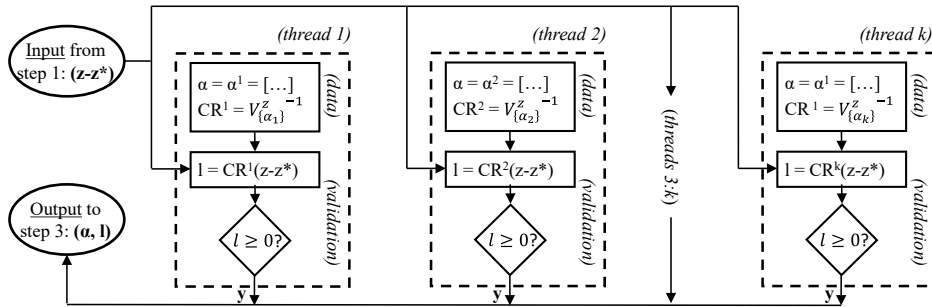

Figure 1: Online calculation of  $(\alpha, l)$  via parallel processing of all critical regions.

From Eq. 7, critical regions are obtained for all  $k \leq 2^q$  relevant active sets of Eq. 4 as  $V_{\{\alpha\}}^z^{-1}$ , which we refer to as the critical region *identifier* for  $\alpha$ . In this convenient solution format, it suffices to compute  $l = V_{\{\alpha\}}^z^{-1}(z - z^*)$ , and check which critical region satisfies  $l \geq 0$ , to identify  $\alpha$  for any given  $z = z^{input}$ . Since all identifiers are tested in *parallel* in Figure 1, this amounts in fact (and in theory) to a very fast calculation of  $(\alpha, l)$ .

In MPC problems containing many constraints, the scheme depicted in Figure 1 may become prohibitive, since the online controller requires that up to a total of  $2^q$  threads are created to store and process all active sets. A modified architecture is proposed where  $k \ll 2^q$ ; this avoids the large memory/processing requirements, while preserving the speed and effectiveness of the online controller. This architecture is shown below:

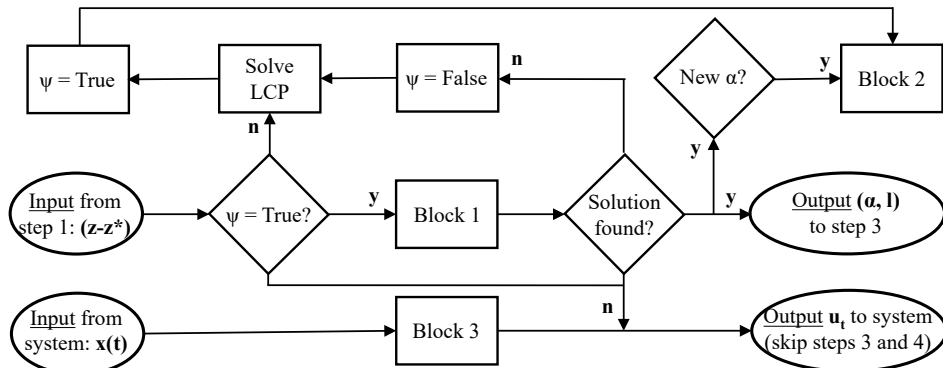

Figure 2: Online control architecture (step 2).

The middle row of tasks in Figure 2 captures the *nominal* mode of operation, where the pair  $(\alpha, l)$  is calculated via Block 1: it shares the architecture depicted in Figure 1, but where a much smaller number of *candidate* active sets and their identifiers are kept in memory (details below). Whenever a new  $\alpha$  is found between consecutive sampling times, an update of the  $k$  threads is executed in Block 2 to ensure the candidate active sets and their identifiers remain relevant as the vector of states is steered towards the set-point.  $\psi$  is a Boolean variable providing information if the current set of identifiers kept in memory are up to date and managing the calculation of controls accordingly.

Since only a small fraction of all active sets is kept in memory, it is possible that the matching active set for a given  $x(t)$  is not found for a particular  $t = t$ . In this case, a *remedy* control action is implemented via Block 3, using a conventional feedback controller (e.g. PID). When this occurs, Block 1 becomes unavailable until the optimal solution is obtained, which requires the solution of a more expensive LCP problem.

The structure of active sets and their identifiers kept in the  $k$  threads are as follows. As a minimum, a single thread must be defined: if an active set  $\alpha$  is the optimal solution at  $t = t$ , the unique defined thread includes  $\alpha$  and the matching identifier at  $t = t + 1$ . Using a single thread/active set, however, would most likely frequently trigger solving the LCP problem and using the feedback controller, as it is expected that the optimal active set does not remain constant. To strengthen the predictive capability of Block 1, additional threads are defined: this includes all active sets matching  $\alpha$ , except for up to  $r$  coordinates, where  $r$  is a design parameter. The total number of threads is given by the number of combinations  $C(q, 0) + C(q, 1) + \dots + C(q, r) = k$ , where  $k \geq 1$  (when  $r = 1$ ) and  $k \leq 2^q$  (when  $r = q$ ). When a new  $\alpha$  is found, Block 2 updates the full set of active sets in all threads, taking  $\alpha$  as a reference and updating selectively their coordinates:

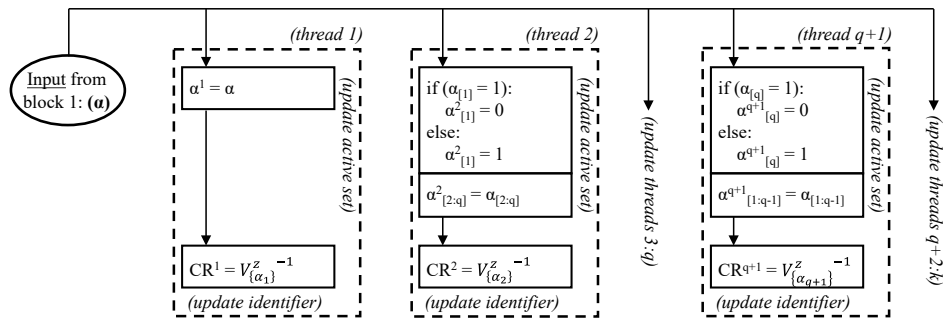

Figure 3: Threads' update of in step 2 (Block 2).

Parameter  $r$  defines a *compromise* between the computational complexity (number of active sets and identifiers kept in memory) and the predictive capability of Block 1. In stable systems, it is expected that the vector of states undergoes a smooth trajectory, and where the optimal active set frequently remains constant between consecutive times, or where a restricted number of constraints change status. Therefore, a careful tuning of  $r$  facilitates an efficient route for step 2, with a minimal fraction of time spent on solving LCPs. The most frequent or nominal control tasks are highlighted below:

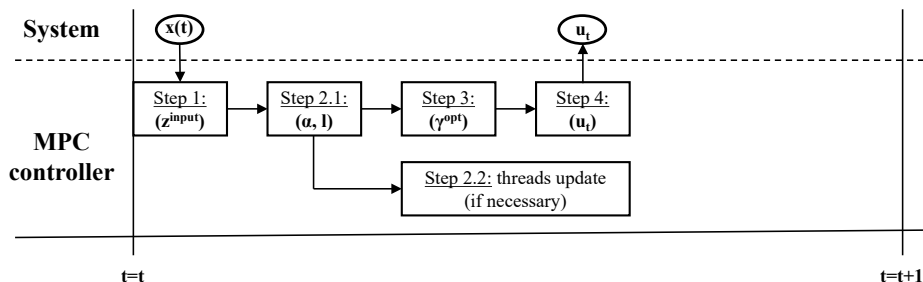

Figure 4: Control tasks in the nominal operation mode for any given  $t = t$ .

Steps 1-4 are all executed in sequence. Step 2 is broken down in two stages where steps 2.1 and 2.2 correspond to Blocks 1 and 2, respectively. Note that the threads update via step 2.2 is launched in parallel (when necessary) with steps 3 and 4 to speed up this task.

#### 4. Discussion and future work

We have shown in Section 2 that combining the mp-QP/MPC problem formulation in Pistikopoulos et al. 2002 with the mp-QP solution strategy in Narciso et al. 2022 is a trivial task, to deliver critical regions and control laws in compact form.

While this is a significant gain from the offline perspective, even more important is the ability to calculate optimal control actions very fast. With this goal in mind, a new architecture for online calculations was proposed. It makes use of the convenient structure of Eq. 5, to keep a restricted collection of active sets and their critical region identifiers. Parallel computing is used to compute the optimal control actions from the states vector via a sequence of inexpensive matrix/vector multiplications.

Several improvements to this architecture have been identified for future work, and which we discuss briefly here. Firstly, we remark that this architecture includes no provisions to deal with infeasible solutions: failing to obtain a solution from Block 1 is not necessarily a result of the identifiers stored in memory not being sufficient, but simply because no feasible solution exists for the MPC problem with a given  $x(t)$ . Additionally, to the explicit calculation of identifiers, the framework in Narciso et al. 2022 also allows the calculation of infeasible regions, which can be used for a more efficient control strategy.

A maximum of  $2^q$  critical region identifiers may be obtained from Eq. 5 since the parameter space ( $Z$ ) for  $x(t)$  is defined unbounded. This choice is made for the generality of the solution obtained in Narciso et al. 2022. In the present context, where the explicit identifiers are kept in memory, an additional check of  $Z$  may simplify the online control problem: checking for instance which constraints are always inactive or pre-calculating subspaces in  $Z$  where a constraint can be active reduces the online complexity.

More broadly, this research aims at implementing the fastest online strategy for MPC problems. Additional developments on the solution of LCPs in this specific context is of great significance. Two LCP solvers are currently under development for this class of problem. An assessment of the performance of all the viable routes on computing control actions for MPC problems of varying sizes is a key research objective. It is expected that this work can facilitate establishing several guidelines for practical applications.

## Abstract

Biomass resources can play an important role in the energy transition, being a dynamic feedstock that can be transformed either into solid, liquid or gaseous fuels. Biomass gasification is a versatile way to convert waste into energy. In this work, the modeling and simulation of two different gasification processes using wood and black liquor as feedstock are performed using Aspen Plus®. The surrogate models for these biomass-based gasification systems are generated considering different techniques (e.g. artificial neural networks, random forest, and Gaussian process regression) using an Active Learning Artificial Intelligence approach. These techniques are compared in terms of their capabilities for predicting the thermodynamic behavior of the gasification systems for the different biomass resources. As a result, the surrogate models developed were able to estimate the process design and operating conditions, and the Gaussian process regression outperformed the artificial neural networks and random forest techniques. The generated models could be helpful to be further used for replacing the simulation systems in other applications, such as multi-objective optimization, at expense of lower computational requirements.

**Keywords:** Surrogate models, Biomass, Gasification, Artificial intelligence.

## 1. Introduction

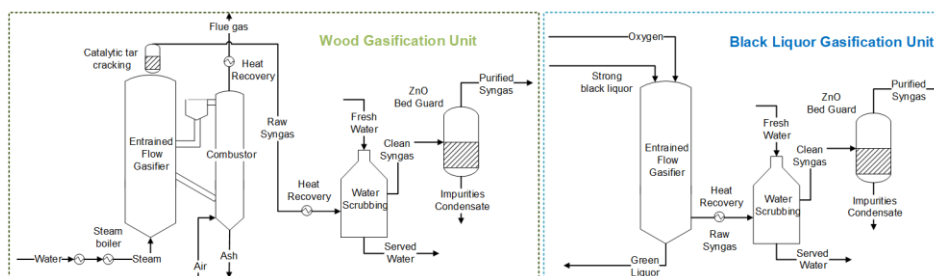

The gasification process poses modeling complexities involving several stages that occur simultaneously, such as drying process, and pyrolysis, gasification and combustion reactions. These reactions are highly endothermic and the energy balance becomes a function of the combustion and the reduction steps. In addition, the production rate, composition and properties of the syngas produced strongly vary according to the biomass properties, the gasification agent used (type and flow), the equivalence ratio, the type of reactor used (fixed bed, fluidized bed or indirect gasifier), the operating conditions (temperature, pressure, residence time) and the downstream processes considered for gas cleaning and conditioning. Numerous models have been reported, aiming at understanding and describing the behavior of such systems, using commercial simulation software. However, if integrating these complex processes into industrial systems and

performing optimization on the system level, the direct simulation approach entails high computational expenses. Surrogate models emerge as a robust solution that may help accelerate the convergence of the optimization problem (Granacher et al., 2021). This work proposes the generation of surrogate models for two gasification systems, considering wood and black liquor as feedstock, using different regression techniques applying the Active Learning Artificial Intelligence (ALAI) approach (Granacher et al., 2021). The models are compared to demonstrate their capability in predicting the processes behavior.

## 2. Methodology

### 2.1. Modeling and simulation of the gasification systems

Figure 1 illustrates the wood and black liquor gasification setups based on (Domingos et al., 2022, Flórez-Orrego et al., 2019). The simulations are performed in the Aspen Plus® software (Aspentech, 2015), using the Peng-Robinson EoS with Boston-Mathias modifications as thermodynamic model.

**Figure 1.** Wood and black liquor gasification systems.

The ultimate mass-based wood composition is set to 48.2% C, 5.8% H, 45% O, 0.2% N, 0.02% S and 0.8% ashes, whereas the mass-based proximate analysis is considered as 10% moisture (after drying), 16.4% fixed carbon, 82.8% volatiles, and ash in balance (Telmo et al., 2010). The Battelle Columbus Laboratory (BCL) indirect gasifier operating at atmospheric pressure and using steam as gasification medium is used for modeling the wood gasification system shown in Fig. 1. This system avoids the dilution with nitrogen of the syngas produced, as the combustion and gasification processes occur in a separate double column system (Kinchin, 2009). After the produced syngas leaves the gasifier, a thermal catalytic cracking of the produced tar is performed.

The black liquor ultimate composition (mass) is set as 29.86% C, 3.27% H, 29.05% O, 0.1% N, 4.09% S, 0.90% Cl and 32.73% ashes, whereas proximate analysis (mass) is considered as 15% moisture (after drying), 10.21% fixed carbon, 57.06% volatiles, and ash in balance. The pressurized entrained flow high temperature black liquor gasification (PEHT-BLG) available in the market as Chemrec® gasifier (Consonni et al., 2009) is used for modeling the black liquor gasification system. This technology has the advantage of including tar-free and uniform temperature gasification at turbulent conditions which results in a high conversion efficiency and high reaction rate. In the gasification step, the carbonaceous materials in the BL are converted into syngas rich in CO, H<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub> using oxygen as agent, while a smelt containing mainly Na<sub>2</sub>CO<sub>3</sub> and Na<sub>2</sub>S is formed in the bottom when a quench cooler separates the regenerated salts that will form the green liquor (Darmawan et al., 2017).

In both systems, a fraction of the char produced in the pyrolysis step is combusted to supply the heat required by the endothermic drying, pyrolysis and reduction reactions.

After the produced syngas leaves the gasifier, it is cooled down and scrubbed with water, in order to remove the impurities that may affect the downstream equipment.

### 2.2. Surrogate model design

The algorithm used to generate and test the surrogate models considering the ALAI approach (Granacher et al., 2021) is presented in Fig. 2. The simulation systems developed in Aspen Plus® (Aspentech, 2015) are used to retrieve the dataset comprising simulation inputs and outputs, taking into account the decision variables selected. The quasi-random Latin-Hypercube sampling (McKay et al., 1979) algorithm is applied for sampling the design space  $D$ . The dataset is then used to generate and train the surrogate models, where the uncertainty with which a prediction is made is quantified. The active learning is responsible for continuously enriching the database, and new data points are selected from a pool of unlabeled data based on the predicted uncertainty. This strategy results in a fast improvement of the surrogates' quality. When the desired quality is met following the defined performance metrics, the surrogate model is saved (Granacher et al., 2021).

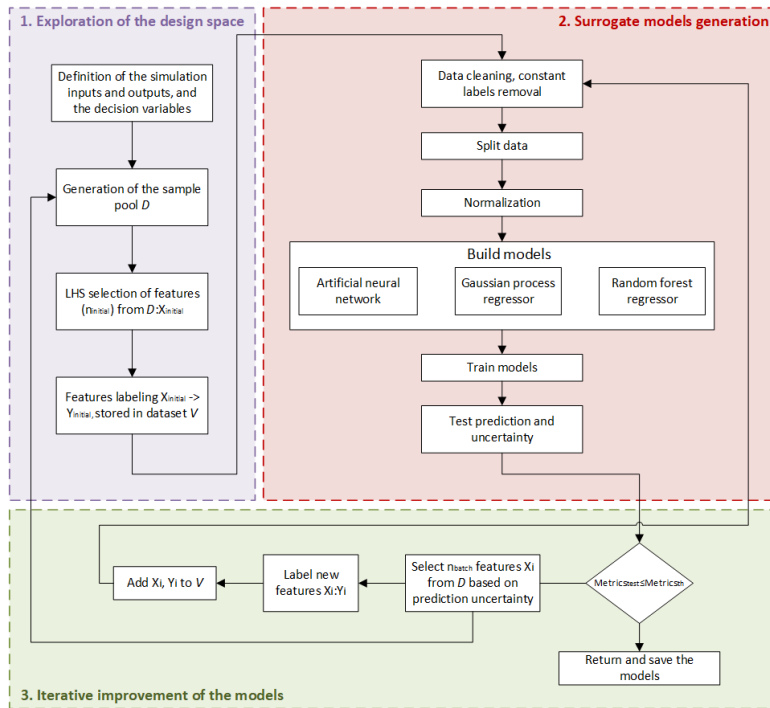

Figure 2. Algorithm for generation of the surrogate models, adapted from (Granacher et al., 2021).

In this work, three regression techniques, namely Gaussian process regression, Artificial neural networks (ANN) and Random Forest regression, are assessed and compared to generate surrogate models for the wood and black liquor gasification systems. In brief, the Gaussian process regression is a nonparametric, Bayesian approach to regression that makes predictions with uncertainty (Rasmussen and Williams, 2006). This method calculates the probability distribution over all admissible functions that fit the data instead of returning only exact predictions for each. The ANN is inspired by the biological nervous system and it consists of several layers connected by neurons that perform the input data transformations aiming to obtain the required outputs (Silva et al., 2016).

Finally, Random Forest regression is a supervised learning algorithm that combines predictions from multiple algorithms to make a more accurate prediction compared to a single model (Breiman, 2001).

For each gasification system, three parameters were chosen to be varied based on the operating conditions reported in the literature for these setups (Larsson et al., 2006, Puig-Arnabat et al., 2012). The parameters and their respective range are reported in Table 1. All the important simulation inputs, outputs, and operating conditions were set to be extracted to compose the dataset for building the surrogate modes.

**Table 1.** Operating conditions varied for wood and black liquor gasification systems.

Wood gasification		Black liquor gasification	
Parameter	Range	Parameter	Range
Gasification temperature (°C)	[760,960]	Gasification temperature (°C)	[900,1100]
Air preheating (°C)	[300,500]	Gasification pressure (bar)	[25,32]
Steam-to-biomass ratio	[0.75±30%]	Oxygen-to-fuel ratio	[0.2,0.5]

In order to measure the quality of the surrogate model, a random set of additional points is generated for testing. The new simulation points are compared against the surrogate model's response using error-based performance metrics. The mean squared error (MSE) (Eq.1) measures the average squared difference between the estimated values coming from the response of the surrogate models and the actual simulation value.

$$MSE = \frac{\sum_{i=1}^n (x_{simul,i} - x_{surr,i})^2}{n} \quad (1)$$

where  $x_{simul,i}$  is the simulation output and  $x_{surr,i}$  is the surrogate response for each parameter  $i$ , and  $n$  is the number of points in the data set. In order to facilitate the comparison between the dataset with different scales, the simulation data is normalized.

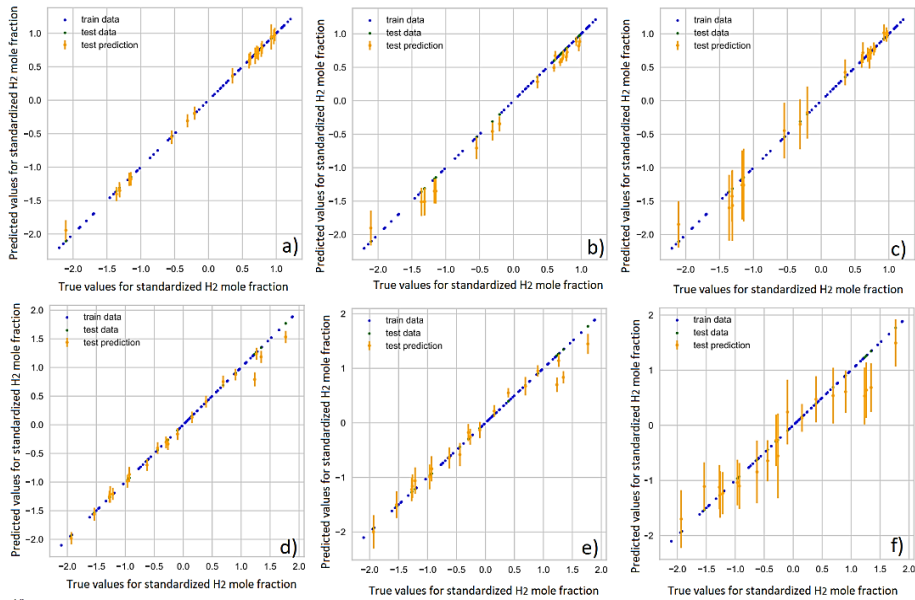

### 3. Results and discussion

Table 2 presents the mean squared errors in absolute dimensions for the surrogate models generated considering the three regression techniques. It can be seen that the Gaussian Process regression outperformed the artificial neural networks and the random forest approaches, since it presented the lowest MSE.

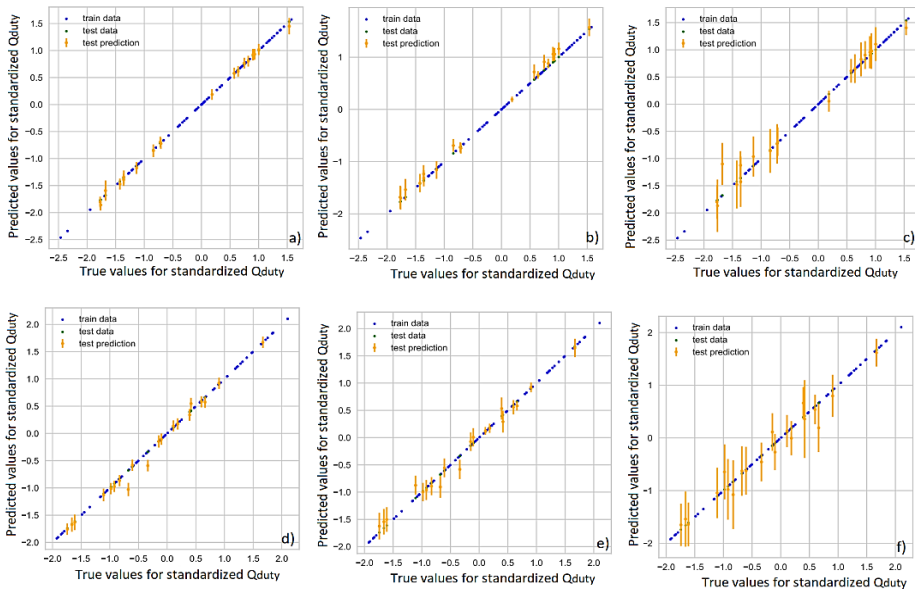

**Table 2.** Mean squared error (MSE<sub>test</sub>) considering 100 data points, absolute dimensions.

Regression model	MSE <sub>test</sub> - wood gasification	MSE <sub>test</sub> - black liquor gasification
Gaussian Process regression	0.02459	0.01498
ANN	0.02696	0.06296
Random forest	0.03061	0.05464

In Fig. 3, the predictions are displayed against the true values, with their respective uncertainty (see the orange bars in Fig. 3), for the hydrogen mole fraction in the purified syngas stream for the two gasification systems. The results demonstrate that the Gaussian process regression technique resulted in lower uncertainty, related to the prediction capability of the surrogate model considering the syngas composition. The same behavior was observed for the prediction of the heat exchanger duty related to the 'Raw Syngas' stream compared to the true values retrieved from the simulation (see Fig. 4).

**Figure 3.** Test predictions and uncertainty considering 100 data points for hydrogen mole fraction in the syngas from wood gasification using a) Gaussian regression, b) ANN, c) random forest, and from black liquor gasification using d) Gaussian regression, e) ANN, f) random forest.

**Figure 4.** Test predictions and uncertainty considering 100 data points for the heat recovery heat exchanger in the ‘Raw Syngas’ stream for wood gasification using a) Gaussian regression, b) ANN, c) random forest, and for black liquor gasification using d) Gaussian regression, e) ANN, f) random forest.

The comparison between the predictions of the surrogate models against the simulation results were also performed for the other components of the streams as well as all other process design and operating conditions. The results pointed towards a good capability of

the surrogate models in predicting the process design and operating conditions for the studied gasification systems.

#### 4. Conclusion

In this work, three regression techniques were compared to generate surrogate models applying the ALAI approach for wood and black liquor gasification systems simulated in the Aspen Plus software. The Gaussian process regression outperformed the artificial neural networks and random forest techniques for both analyzed processes, achieving lower mean squared error and associated uncertainties. Overall, the surrogate models were able to accurately predict the thermodynamic performance and the high nonlinear behavior associated to both gasification systems. Additionally, the derived surrogate models are computationally less expensive and can be further used to explore the tradeoffs between conflicting objectives, such as operating costs and syngas composition.

## Abstract

In this work, we address the global optimization of process surrogates using Bayesian symbolic regression and deterministic global optimization algorithms. In contrast to other surrogates of process models that are hard to (globally) optimize, e.g., artificial neural networks or Gaussian processes, symbolic regression leads to a closed-form mathematical expression describing the observed data that can subsequently be globally optimized using off-the-shelf deterministic solvers. After providing an introductory example, we show the capabilities of our approach in the optimization of a methanol production plant. We further discuss the model accuracy, CPU times for model building and optimization, and outline the advantages and limitations of the proposed strategy.

**Keywords:** Global optimization, Symbolic Regression, Surrogate Modelling.

## 1. Introduction

Optimizing process flowsheets is a challenging problem in Process Systems Engineering, for which several approaches have been proposed to date. Process optimization often relies on mechanistic models based on first principles (Haydary, 2019) and closed-form expressions that enable the direct application of deterministic optimization algorithms, including global optimization methods. However, building such first principles is a challenging task, potentially leading to convergence issues during their optimization. Alternatively, when there is limited knowledge about the process, data-driven models can be the method of choice to build a mathematical expression that can be used for optimization purposes. Specifically, state-of-the-art machine learning algorithms (i.e., neural networks or support vector machines) can be applied to build a data-driven process model. However, optimizing classical machine learning models to global optimality is not trivial due to their intrinsic complexity and nonlinearities (Mitsos et al., 2009; Schweidtmann and Mitsos, 2019). Recently, symbolic regression algorithms have emerged to build algebraic models from data without assuming any specific structure (Cozad et al., 2014; Guimerà et al., 2020). This work explores the use of symbolic regression to build analytical surrogates of process flowsheets that can then be optimized with state-of-the-art global optimization (GO) algorithms. A priori assumptions about the mathematical structure of the model are avoided, and well-established global optimization algorithms are applied to the algebraic surrogate without the need for tailored strategies. Notably, after building a well-fitting analytical model using Bayesian symbolic regression, BARON (Sahinidis, 1996) is used to identify its global optimum. We deploy the proposed approach in an introductory example. Additionally, we then

demonstrate the performance of the approach with a complex flowsheet of an industrial process.

## 2. Methodology

### 2.1. Problem Statement

In this work, we consider a given process in steady state and a set of input variables  $x_i$ , with  $i \in I$  being the set of dependent variables, i.e., degrees of freedom, of the flowsheet. A target objective is defined by  $f(x)$ , which can be, for example, the total cost of a plant or the conversion of a reactor. In the first step, a suitable surrogate model  $F(x)$  that approximates the studied process target  $f(x)$  appropriately is identified. Second, a model-based global optimization is performed to find the global optimum  $x^*$ , as follows:

$$\begin{aligned}
 F^* &= \min_x F(x) \\
 \text{s. t. } \quad &g_n(x) \leq 0, \forall n \in N \\
 &h_m(x) = 0, \forall m \in M \\
 &\underline{x} \leq x \leq \bar{x} \\
 &x \in \mathbb{R}^{|I|}
 \end{aligned} \tag{1}$$

Where  $F^*$  corresponds to the model-based optimum of the process approximation  $F(x)$ , and  $g_n(x)$  and  $h_m(x)$  represent inequality and equality constraints, respectively. Herein, we aim to identify an accurate surrogate model without assuming a pre-defined model structure. In addition, we apply state-of-the-art deterministic GO solvers to model (1). Due to the sake of simplicity, the purpose of this work is a proof-of-concept, rather than a performance comparison.

### 2.2. Model Building

We seek to identify an accurate surrogate process model  $F(x)$  that maps the input data  $x$  to the corresponding objectives  $f(x)$ . In addition, to apply deterministic optimization approaches,  $F(x)$  is required to be in an algebraic form. To this end, in this work, we use the algorithm developed by Guimerà et al. (2020), the Bayesian machine scientist (BMS). It implements symbolic regression that uses a Markov chain Monte Carlo (MCMC) approach to explore the space  $E$  of closed-form mathematical expressions  $z_e, e \in E$ . During this explorative search, the algorithm minimizes the description length  $\mathcal{L}(z_e)$ , which can be approximated by the Bayesian Information Criterion (BIC) and an initial prior knowledge about a given expression  $z_e$ , where Bayesian learning is incorporated:

$$\mathcal{L}(z_e) \approx \frac{BIC(z_e)}{2} - \log(p(z_e)) \tag{2}$$

For simplicity, only the approximation of the description length is given here. For a detailed derivation, the reader is referred to the original work by Guimerà et al. (2020).

#### 2.2.1. Model-Based Global Optimization

With the obtained algebraic surrogate model  $F(x)$  at hand, the model-based optimization problem in (1) can be solved to identify the optimal decision variables values  $x^*$ , providing the best value of the surrogate  $F^* = F(x^*)$  and which can be evaluated in the original process model as  $f^* = f(x^*)$ . This observed response  $f^*$  can finally be compared

to the model-based optimum  $F^*$  to measure the mismatch between the surrogate and the process model in the optimum of the surrogate  $x^*$ .

### 3. Case Studies

#### 3.1. Software Implementation

The calculations were carried out on an AMD Ryzen 5 3600 CPU (introductory example) and on an Intel®Core™ i7-8700 CPU (methanol production plant), both with 16 GB of RAM. Python v3.9 (introductory example) and v3.8 (methanol production plant) were used to implement the algorithm. The flowsheet was simulated in Aspen HYSYS v11. Python and HYSYS were connected through a COM interface. The algorithm provided by Guimerà et al. (2020) was used to train the BMS. The obtained algebraic expression was implemented using the General Algebraic Modeling System (GAMS Software GmbH, 2022) v40.2 and optimized using BARON 20.4 (Sahinidis, 1996).

#### 3.2. Introductory Example

We illustrate the approach using first a simple two-dimensional unconstrained global optimization problem, the Rosenbrock function (Rosenbrock, 1960):

$$f(x) = (x_1 - a)^2 + b(x_2 - x_1^2)^2 \tag{3}$$

There are two dependent variables  $x_1$  and  $x_2$ , and two parameters  $a$  and  $b$ . For the subsequent illustrations, parameters  $a$  and  $b$  are chosen to be 1 and 10, respectively. A graphical representation of the resulting contour plot bound to  $\underline{x} = [-2, -1]$  and  $\bar{x} = [2, 3]$ , is given in Figure 1.

Figure 1: Contour of the Rosenbrock function. The color gradient refers to the value of  $f(x)$ . The contour levels are indicated by the black lines with the corresponding values of  $f(x)$ .

To evaluate  $f(x)$  according to (3), 225 equally distant data points were generated within the bounds. The global optimum (minimization) is given by  $f^* = 0$  at  $x^* = [1, 1]$ . The obtained samples ( $N = 225$ ) were randomly split into training ( $N_{tr} = 157$ ) and test set ( $N_{te} = 68$ ). Details of the BMS training are shown in Table 1.

### 3.3. Methanol Production Plant

A methanol (MeOH) production plant model is investigated next (Figure 2), which was adapted from Vázquez and Guillén-Gosálbez (2021). The feed consists of carbon dioxide and hydrogen, whose pressure and temperature are adjusted to the desired conditions before being sent to a plug-flow reactor. The reactor outlet is sent through two flash drums and into a distillation column. Methanol is collected in the distillate, while water is the main product at the bottom. The vapor streams of the flash drums are partly recycled (from the first flash) and purged (from both drums). For a detailed description, the reader is referred to the work by Vázquez and Guillén-Gosálbez (2021).

Figure 2: Simplified schematic representation of the MeOH plant under study adapted from Vázquez and Guillén-Gosálbez (2021), with the decision variables highlighted in green.

The degrees of freedom  $x = [T, P, \eta, V, F, \zeta]$  to be optimized (in green in Figure 2) consist of the reaction temperature ( $T$ ), the reaction pressure ( $P$ ), the purge ratio of the splitter ( $\eta$ ), the reactor volume ( $V$ ), the hydrogen flow rate ( $F$ ), and the reflux ratio of the distillation column ( $\zeta$ ). The objective is to minimize the unitary cost ( $UC$ ) of methanol. The carbon dioxide inlet flow is fixed. Vázquez and Guillén-Gosálbez (2021) provide the exact calculation of  $UC$  and a more detailed description of the simulation.

To determine the optimum heat exchanger network (HEN), and, therefore, the cost of the HEN, the mixed-integer nonlinear programming model developed by Yee and Grossmann (1990) (SYNHEAT) is solved for each sampling point. The obtained samples ( $N = 1000$ ) were randomly split into training ( $N_{tr} = 800$ ) and test set ( $N_{te} = 200$ ). The bounds indicated in Table 1 were used to generate these samples. The applied settings and hyperparameters for the BMS training are shown in Table 1.

Table 1: The chosen BMS hyperparameters (MCMC steps and allowed operations) are given, whereas otherwise, the default settings chosen by the authors (Guimerà et al., 2020) were applied. Lastly, used relative optimality gap  $\epsilon_R$  of BARON is indicated for both examples.

Case Study	BMS MCMC steps	Allowed Operations	Optimizer Settings
Rosenbrock	$5 \cdot 10^3$	$\exp(x), \log(x), x^2, x^3, \sqrt{x}$ ,	$\epsilon_R = 0$
Methanol	$20 \cdot 10^3$	$+, -, \div, x^a$ , and $ x $ .	

## 4. Results and Discussion

### 4.1. Introductory Example

A summary of the results is given in Table 2. The BMS could identify the true equation, given by the following expression:

$$F(x) = (x_1 - \theta_1)^2 + \theta_2(x_2 - x_1^2)^2 \tag{4}$$

The simultaneously identified parameters were found to be  $\theta = [10, 1]$ . The model training required 788 s. These results can also be visually compared by considering the true contour plot in Figure 1, and the predictions given in Figure 3 (b).

Figure 3: (a) The training data (dark dots) is shown together with the model predictions (colored surface). The identified optimum is depicted as a red dot. (b) The contour of the BMS model predictions. The identified model-based global optimum  $F^*$  is again shown as a red dot.

Figure 3 (a) provides the training data together with the model predictions, where Figure 3 (b) represents the obtained contour plot of the model predictions. Optimizing the equation in GAMS leads to the optimum solution given by  $F^* = 0$  with  $x^* = [1, 1]$ . The optimization with BARON was carried out in 0.2 s. Implementing  $x^*$  into  $f(x)$  results in  $f^* = 0$ , which is also the true global optimum of the Rosenbrock function.

Table 2: Training and optimization results summary for the introductory example. The CPU times for training and optimization (minimization) are shown together with the calculated root mean squared error (RMSE) for the training and testing set. In addition, the obtained optimum  $x^*$  with the corresponding solution  $F^*$  is shown. Lastly, the process output  $f^*$  is shown for the corresponding optimum  $x^*$ .

CPU Training	RMSE	CPU Optimization	$x^*$	$F^*$	$f^*$
788 s	0 [-] (Train) 0 [-] (Test)	0.2 s	$x_1 = 1$ [-] $x_2 = 1$ [-]	0	0

#### 4.2. Methanol Production Plant

The goal of this six-dimensional case study is to minimize the unitary cost, which is a nonlinear programming problem (NLP). After training the BMS, an algebraic model could be obtained and then optimized in GAMS. The training and optimization steps took 40\*600 s and 1 s, respectively. Inserting the identified model-based optimum  $x^*$  into HYSYS again led to an optimum solution  $f^* = 0.73$  \$/kg, which was very close to the prediction made with the algebraic surrogate at its optimum of  $F^* = 0.72$  \$/kg. The training time of the BMS is substantial (>10 hours), yet this allows for a fast and easy optimization. However, more advanced symbolic regression algorithms could reduce the

computational time of the training phase. Moreover, an additional advantage of having an algebraic surrogate expression at hand is that it could be used for calculations that need to solve optimization models iteratively, such as in multi-objective optimization or in real-time optimization, since the optimization step is greatly simplified using the algebraic surrogate.

## 5. Conclusions

In this work, we explored the use of algebraic surrogate process models constructed using symbolic regression. Accurate process models were built using symbolic regression based on Bayesian learning and then solved in GAMS using an off-the-shelf global optimization algorithm (BARON). We showed the capabilities of the approach in two examples. The high computational training times for symbolic regression still represent a computational bottleneck, yet they might be reduced with the future emergence of faster regression algorithms. Moreover, analytical surrogate process models could be used to simplify the calculations in applications requiring solving multiple optimization problems iteratively.

## Abstract

In extractive distillation (ED), a suitable solvent is added to increase the relative volatility of azeotropic or close-boiling mixtures, thereby facilitating the separation. The viability and efficiency of this separation are largely dependent on the selection of solvent. In this work, solvents are optimally designed to improve the performance of ED processes by a molecular property targeting method. Specifically, optimal solvents are identified by directly targeting desirable molecular properties obtained from process optimization. First, data-driven process models are established to estimate key performance indicators of the ED process with the most important process-relevant physical properties of the solvents. Based on the established models, multi-objective optimization is then performed to maximize the product purity while minimizing energy cost, through which optimal molecular properties are obtained. Hypothetical target molecules featuring the desirable properties are thereby generated. Subsequently, several real solvents that approximate the optimal property profiles of the hypothetical molecules are selected from a large solvent database. In a final assessment step, the performance of these real solvent candidates is evaluated via detailed process simulations. The proposed molecular-property-targeting solvent design methodology is demonstrated by the separation of 1-butene and 1,3-butadiene. For this separation task, three real solvents are finally identified, allowing for a higher product purity and lower energy consumption compared to the benchmark solvent n-methyl-2-pyrrolidone (NMP).

**Keywords:** solvent design, artificial neural network, data-driven modeling, continuous molecular targeting, extractive distillation

## 1. Introduction

Extractive distillation (ED) processes enable the separation of azeotropic or close-boiling mixtures, where a suitable solvent is introduced to increase the relative volatility of the mixture (Gerbaud et al., 2019). The viability and efficiency of this separation largely depends on the selection of the solvent. In the past, most solvents used in chemical industries were primarily chosen based on chemical knowledge and have not been systematically designed (Chemmanattuvalappil, 2020). They may not be the real optimal candidates to meet the separation requirements. Therefore, discovering better alternatives to replace current solvents following a systematic solvent screening or design strategy can improve the performance of the ED processes.

Computer-aided molecular design (CAMD) provides a promising route to systematically design solvents fulfilling a set of target molecular attributes or process performance indicators (Gani, 2004). Taking the advantages of modern molecular property models and process models, CAMD methods have been extensively used to design solvents for various applications such as absorption (Burger et al., 2015; Zhang et al., 2021; Zhou et al., 2021), extraction (Song et al., 2018; Ten et al., 2021), and reaction (Struebing et al., 2013; Zhou et al., 2015; Zhou et al., 2016). So far, the most commonly used approach for representing molecular structures in CAMD is the decomposition into functional groups (Marrero & Gani, 2001). By this method, solvents are represented by discrete variables (e.g., the number of molecular building blocks) which are optimized under certain molecular structural constraints. To circumvent discrete molecular decisions in CAMD, Bardow et al. (2010) proposed a continuous-molecular-targeting (CoMT) approach by considering a continuous molecular structure space in terms of molecular property-related parameters. The optimal CAMD solution is then used to identify existing molecules, the properties of which approximate the optimal parameter values best. The CoMT approach has been applied to design solvents for CO<sub>2</sub> absorption (Stavrou et al., 2014) and working fluids for the organic Rankine cycle (Schilling et al., 2017).

In this contribution, the CoMT approach is adopted for the optimal design of solvents in ED processes. To achieve higher product purity and lower energy consumption, solvents are designed by directly targeting desirable solvent properties obtained from process optimization. First, data-driven process models are established to estimate key performance indicators of the ED process from the most important process-relevant physical properties of the solvent. Subsequently, solvent design is performed in two steps, namely molecular property targeting and molecular mapping. In the first step, the optimal molecular parameters are obtained by model-based optimization. Thereby, hypothetical target molecules featuring the desirable molecular properties are generated. In the subsequent step, real solvents that approximate the optimal property profiles of the hypothetical molecules are selected from a large solvent database. Finally, the performance of these solvent candidates is evaluated via detailed process simulations. The proposed molecular-property-targeting solvent design methodology is illustrated using an industrially relevant case, i.e., the separation of the close-boiling mixture 1-butene/1,3-butadiene (C<sub>4</sub>H<sub>8</sub>/C<sub>4</sub>H<sub>6</sub>).

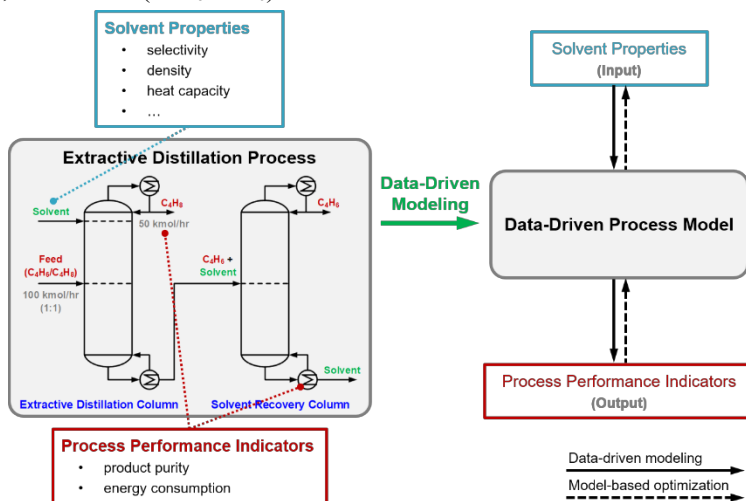

Figure 1. Data-driven modeling for the ED process.

## 2. Data-Driven Process Modeling

Process models are required to guide the design of solvents that meet the separation requirements. In a data-driven manner, process models are built where solvents described by molecular properties are directly linked to their corresponding process performance (Figure 1). Such models can direct the design of solvents by identifying the optimal values of molecular properties to maximize the process performance. We perform the solvent design under the operating conditions pre-determined by process optimization using *n*-methyl-2-pyrrolidone (NMP) as the solvent. Thus, the present work can be considered as the search for potentially better alternatives (e.g., showing lower energy consumption in extractive distillation) to replace the industrially used solvent NMP.

The dataset for data-driven modeling contains input-output pairs for 126 solvents. The inputs are five process-relevant physical properties of the solvent, including selectivity of 1-butene/1,3-butadiene at the infinite dilution condition, molecular weight, density, molar heat capacity, and viscosity. The outputs are the key performance indicators of the ED column, including product purity ( $C_4H_8$  purity in the distillate) and energy consumption (described by the reboiler heat duty for simplicity). The dataset is generated through rigorous process simulation in Aspen Plus based on the UNIFAC thermodynamic model. It is randomly split into two sets, i.e., a training set (80%) for model development and a test set (20%) for model evaluation. Feature scaling is adopted to standardize the model input.

Feedforward neural network (FNN), the most straightforward type of artificial neural networks, is used to build the data-driven process model using PyTorch (Paszke et al., 2019). To constrain model complexity and reduce overfitting, the FNN has up to two hidden layers with a maximum of four neurons in each layer during the hyperparameter optimization. Different types of non-linear activation functions are considered.

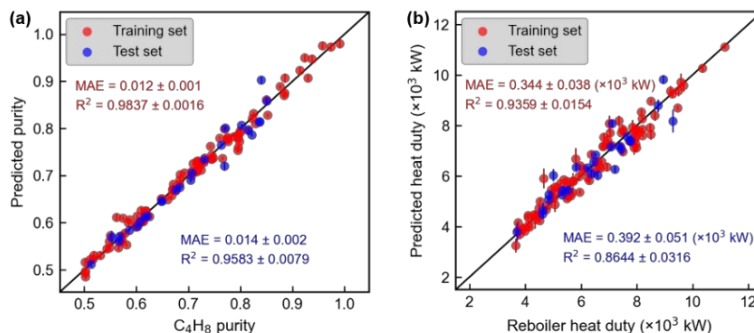

Figure 2. Performance of the data-driven models in predicting (a)  $C_4H_8$  purity and (b) reboiler heat duty. The corresponding process performance for each solvent is predicted using five models derived from the five-fold cross-validation, and the point and error bar show the average and standard deviation of these predictions, respectively.

After identifying the optimal FNN configurations (hyperparameters) using five-fold cross-validation, the models are evaluated on the training and test sets. As they present satisfactory accuracy in the prediction of  $C_4H_8$  purity and heat duty (Figure 2), the data-driven models are subsequently used for solvent design.

## 3. Molecular Property Targeting

Based on the data-driven models, a multi-objective optimization problem aiming at maximizing the  $C_4H_8$  purity, while minimizing the heat duty is formulated as follows:

$$\begin{aligned} & \min_{x \in X} (1 - f_1(x), f_2(x)) \\ \text{s.t.} \quad & X_i^L \leq X_i \leq X_i^U \\ & X_i \in \mathbb{R} \end{aligned}$$

where  $f_1(x)$  and  $f_2(x)$  are the data-driven models for the estimation of  $C_4H_8$  purity and reboiler heat duty, respectively.  $X$  is the molecular property space, in which each variable is standardized individually.  $L$  and  $U$  denotes the lower and upper bounds. Box constraints are set on each variable based on the corresponding minimum and maximum values from the dataset.

The multi-objective optimization problem is solved using a genetic algorithm implemented in Pymoo (Blank & Deb, 2020). It converges in 100 generations, obtaining a set of Pareto-optimal solutions (i.e., hypothetical target solvent molecules). The hypothetical molecules are considered to be the optimal solutions found in the design space closest to the ideal point. Figure 3 depicts the objective function values for the hypothetical target molecules featuring optimal molecular properties.

Figure 3. Multi-objective optimization visualized in the space of objective functions. Standardization is applied to the heat duty (objective function 2) in the optimization so that the magnitudes of two objective functions are comparable.

#### 4. Molecular Mapping

The industrially used solvent NMP is set as the benchmark for comparison. Our target is to find better solvents that allow for a higher  $C_4H_8$  purity and a lower heat duty under the given operating conditions. Figure 4a shows the estimated process performance for hypothetical molecules (in gray) and benchmark solvent NMP (in green). The hypothetical molecules are closer to the ideal point than NMP, demonstrating the success of the molecular property targeting step.

In the molecular mapping step, the hypothetical target molecules obtained by molecular property targeting are mapped into real solvents. The molecular mapping is performed by searching a large database consisting of 1,259 real solvents. A preliminary criterion to find the real solvents closest to the hypothetical target molecules is based on the Euclidean distance in the molecular property space. Thereby, optimal real solvents that approximate the optimal property values are identified.

Nineteen solvent candidates are obtained from the molecular mapping. Their estimated process performance is also presented in Figure 4a. It is observed that two solvent candidates are closer to the ideal point than the hypothetical molecules. Therefore, they could in principle show better process performance than the hypothetical molecules.

A detailed simulation of the ED process on the 19 solvent candidates proves that 16 of them are technically viable to achieve the separation of  $C_4H_8/C_4H_6$ . Among them, nine

solvents present both a lower heat duty and a lower  $C_4H_8$  purity compared to NMP under the same operating conditions. Besides, three solvents, methyl cyanoacetate, glutaronitrile, and 1,4-dicyano-2-butene (blue dots in the green area of Figure 4b), are better alternatives to the benchmark solvent NMP, because they allow for a higher product purity and lower energy consumption under the specified operating conditions. Moreover, their process performance can be further improved by performing rigorous process optimization.

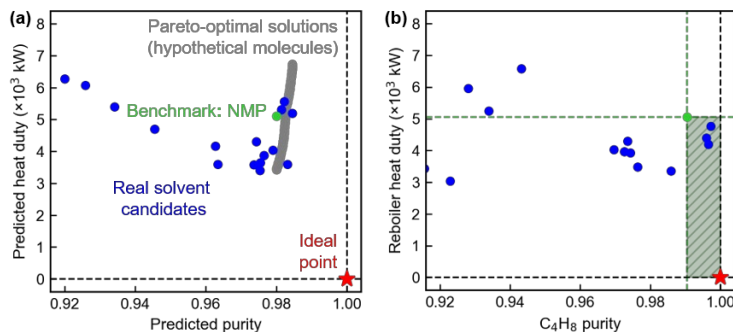

Figure 4. (a) Process performance estimated by the data-driven models for hypothetical molecules, NMP, and real solvent candidates identified by molecular mapping. (b) Process performance evaluated via rigorous simulation of the ED process. Vertical and horizontal lines in green represent the  $C_4H_8$  purity and heat duty of the benchmark process.

For the three solvent candidates, their molecular properties and corresponding process performance are summarized in Table 1. These solvent candidates have similar molecular properties (except viscosity) to the benchmark solvent NMP. A correlation analysis performed on the dataset indicates that a solvent with a higher selectivity at infinite dilution could lead to a higher  $C_4H_8$  purity. This can also be inferred from Table 1. All the three solvents have higher selectivity and higher  $C_4H_8$  purity than NMP. Therefore, the infinite dilution selectivity of the solvent may have played a vital role in designing solvents for a better separation of  $C_4H_8$  and  $C_4H_6$ .

Table 1. Molecular properties and the corresponding process performance of the solvents.

Solvent	NMP	Methyl cyanoacetate	Glutaronitrile	1,4-Dicyano-2-butene
CAS number	872-50-4	105-34-0	544-13-8	18715-38-3
Molecular formula	$C_5H_9NO$	$C_4H_5NO_2$	$C_5H_6N_2$	$C_6H_6N_2$
Selectivity at infinite dilution	1.642	1.753	1.666	1.689
Molecular weight (g/mol)	99.13	99.09	94.12	106.13
Density ( $kg/m^3$ )	1027	1117	983	1002
Molar heat capacity (J/mol·K)	161.7	192.5	191.0	200.9
Viscosity (cP)	1.89	2.82	6.17	7.13
$C_4H_8$ purity	0.9904	0.9965	0.9960	0.9972
Reboiler heat duty (kW)	5059	4198	4394	4761

## 5. Conclusion

This work presents a molecular property targeting approach for the design of solvents in ED processes. Based on data-driven process models, optimal molecular properties are obtained, thereby generating a set of hypothetical target molecules. Nineteen real solvent candidates are identified from a large solvent database by molecular mapping. Their performance on the separation of 1-butene and 1,3-butadiene is evaluated via detailed

process simulations. It turns out that three solvents allow for higher product purity and lower energy consumption under the given operating conditions, compared to the benchmark solvent NMP. Further process optimization is necessary to find the optimal ED process for these solvent candidates respectively. Future work will also account for the integrated design of the solvent and the ED process incorporating the molecular property targeting approach, where environmental, health, and safety impacts of solvents can be considered.

## Abstract

In this article we propose a novel screening approach for the development of new nanomaterials (NM) which are safe(r)-by-design. An integral part of our approach involves the use of recently proposed notation standards and extensions, which facilitate the representation and processing of data related to NMs. In particular, we utilize a general extendable representation for NMs which is built in line with InChI extensions for NMs. This representation enables us to link the composition, structure, and experimental conditions of a NM to its toxicity profile, using descriptor information obtained from available datasets. The processed data are then complemented with predictions from QSAR models and fed to a Bayesian-based procedure to assess the safety of new NM designs. This comprehensive approach can be used to build a local screening tool to search for less hazardous NM configurations.

**Keywords:** nanomaterial, toxicity, safe-by-design, Bayesian, nanoinformatics.

## 1. Introduction

During the last few decades, nanotechnology and nanomaterial (NM) applications have emerged as key enabling technologies for the global industry, since the unique properties of NMs and nano-enabled products allow for a very wide range of applications with significant potential. The risks of engineered nanomaterials (ENM) are largely unknown, however their size and composition make them inherently threatening to the human health and the environment. In effect, WHO (2017) published precautionary guidelines for their handling and use, and OECD developed appropriate Test Guidelines to identify, assess and manage potential emerging risks related to NMs throughout the development chain (OECD, 2020) towards a Safe(r) Innovation Approach (Shandilya et al., 2020).

Early identification, assessment and management of the potential health, safety and environmental risks related to ENMs throughout their life-cycle is extremely important. Risk assessment of ENMs is challenging because of the diversity in their physical and chemical composition, their surface functionalization and structural properties, and the variety of alternative configurations. Significant public and private investment over the past decades enabled the development of advanced experimental methods for generation of extensive nanotoxicity data, and supported the development of informatics tools for data management / processing and for the prediction of physicochemical, exposure and (eco)toxicological properties of novel NMs to enable in silico risk assessment (Marcoulaki et al., 2021). Among these, the NanoInformaTIX H2020 project develops a database comprising the significant amounts of available data, and a set of tools for modeling materials, exposure and dose-response. These tools will become available on a user-friendly web-based platform for ENM risk management, to support sustainable manufacturing of ENM-based products.

The development of optimization tools for designing ENMs with defined properties is a very new research field. Preliminary works applied Generative Adversarial Networks (GAN) to optimize functionality (So and Rho, 2019; Kim et al., 2020). This work proposes an incremental procedure to develop a screening framework for safe-by-design ENMs. We start from novel representation schemes, build extensions to improve the data analysis potential, propose an assessment procedure using similarity functions built on top of the representation. All these finally enable the generation and assessment of an ensemble of alternative ENM designs, starting from a given ENM design.

## 2. Representation methodology

In a recent work we proposed a general, extendable representation for NMs from the point of view of computational applications and we set qualifications for a computational-friendly representation (Blekos et al., 2022). Our proposal was in line with the recently proposed InChI for NMs (Lynch et al., 2020) and its realization greatly facilitates similarity assessments between components which, in turn, is a crucial part of calculating NM affinities. Our work identified key challenges for a computational-friendly NM representation and proposed strategies to address them. Through the resulting representation qualifications, we created a proposal of 5 extensions for the InChI for NMs that aimed to address the identified challenges.

These extensions enable the computationally-friendly representation of important and commonly found features of NMs. They are designed to facilitate standardization, curation, and comparison of data on NMs. This can help improve the sharing and management of data on NMs, and can assist researchers in identifying potential safety concerns and making informed decisions about the use of these materials. The extensions are: a) an extension to describe distributions, which can be applied anywhere a real number needs to be represented; b) an extension to describe shapes; c) an extension for the representation of mixtures and interfaces using logical operators that apply to other layers already defined, building on the mixture-InChI; d) an extension for structured comments that allows for consistent and uniform capturing of auxiliary information and facilitates database curation; and e) an extension for the definition of macros and shortcuts that allows for the creation of reusable, parametrizable, and human-readable components.

## 3. Data preprocessing

The representation and extensions described in Section 2 provide a consistent and comprehensive framework for describing and analyzing the properties of NMs. In particular, the proposed extensions for distributions and shape/morphology, provide new capabilities for data-driven tools, and enables safety assessment, which is crucial for the design of materials with improved safety profiles.

### 3.1. Data preprocessing

Starting from a given dataset, the proposed screening framework uses a bottom-up and a top-down stage to generate two outputs that will be fed to the next stages. The two data preprocessing stages are to be conducted simultaneously and they are complementary, as shown in Figure 1 and described below.

In the *top-down stage*, we access available NM databases to obtain descriptors that provide information about the composition, structure, and other characteristics of NMs. Descriptor information is taken from available datasets, linking composition, structure and experimental conditions information to the NM toxicity profile. These descriptors can be further analyzed and encoded through QSAR and/or other similar models, to explore the properties of NMs and identify safety and toxicity profiles.

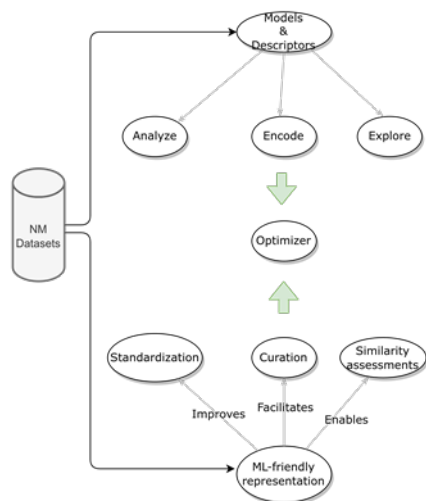

Figure 1: Two stage data preprocessing

In the *bottom-up stage*, we convert the NM data into the computational-friendly representation outlined in Section 2. The representation and the proposed extensions provide a comprehensive and consistent framework for describing and analyzing the properties of NMs, including their chemical composition, morphology, and interactions with biological systems. This allows the more detailed and accurate evaluation of the comparative properties (e.g. toxicity) of NMs.

Additionally, the proposed extensions to the representation, such as the ability to describe probability distribution functions (pdfs) and bypass categorical shape descriptors, provide new capabilities for analyzing and improving the safety of NMs. For example, the extension for describing distributions can be used to better characterize

the distribution of particles within a NM, which can have important implications for its safety and toxicity. Similarly, the extension for bypassing categorical shape descriptors allows for more flexible and comprehensive analysis of the toxicity of the NMs, which can be useful for identifying novel materials with improved safety profiles.

### 3.2. Similarity and toxicity matrices

In the next stage, the outputs of data preprocessing are used to create a matrix of toxicity values, with each toxicity model providing a separate value for each NM (Figure 2). We can additionally conduct similarity assessments based on the proposed representation model. This provides information on the similarity between different NMs, based e.g. on their chemical composition, structure, zeta potential and other characteristics etc. (Figure 3). The obtained information is used to create a matrix of similarity values for each NM and each axis of comparison (Figure 4).

## 4. Bayesian-based screening

The toxicity and similarity matrices of Section 3 are utilized as input data to create and train a Bayesian network (BN). The BN is a probabilistic graphical model that represents the conditional dependencies between different variables in a system, such as the likelihood of a given NM being toxic given its similarity to other NMs. Once the BN is obtained, it can be used to perform probabilistic inference and assess the toxicity of NMs options which are not included in the dataset.

As shown in Figure 4, the BN constitutes the core function of a local search procedure towards less toxic NMs. Note that, in principle we can consider functionality as an additional objective. Otherwise, we assume that small changes to the design descriptors are unlikely to significantly affect the functionality of the NM.

The search starts from an existing NM with known safety characteristics and the desired functionality for a particular application. A local search is performed in the vicinity of similar designs, to identify design options featuring lower toxicity. The search uses the similarity functions and the Bayesian network, to alter the NM descriptors and evaluate the new toxicity, respectively. Iterative application of this procedure on the new NMs, progressively generates design alternatives with the desired safety profile.

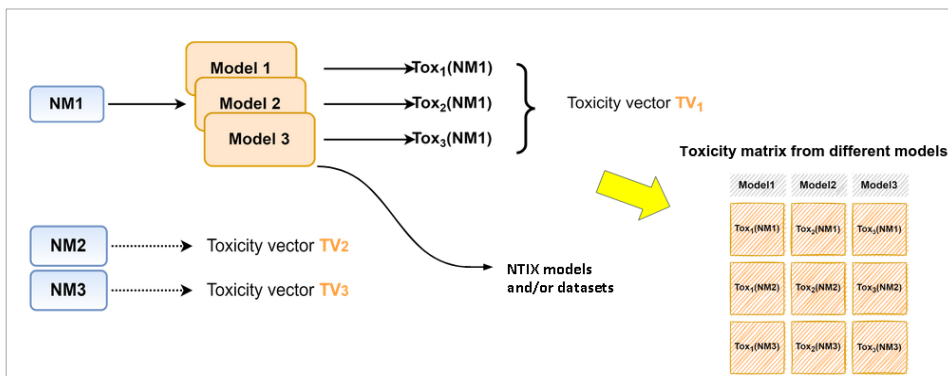

Figure 2: Toxicity matrix using externally available QSAR models

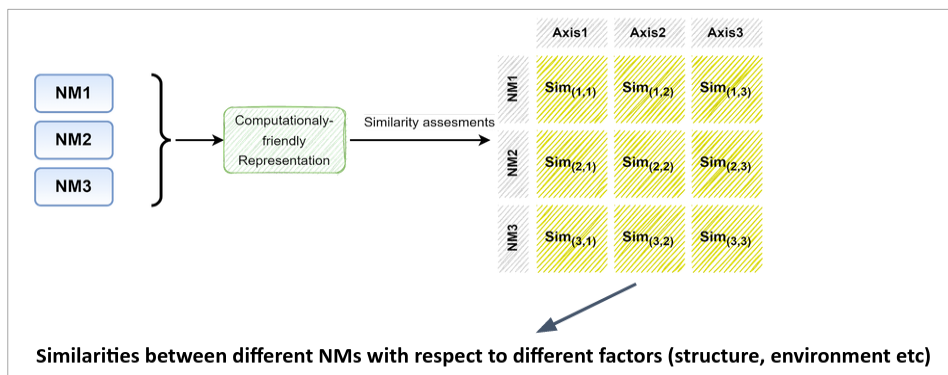

Figure 3: Results of similarity calculations for different pdfs of the NM major diameter

Similarities between different NMs with respect to different factors (structure, environment etc)

Figure 4: Similarity matrix obtained from the computational-friendly representation

Figure 5: Bayesian-based screening using the Toxicity and Similarity matrices as inputs.

The success of the proposed framework relies heavily on the availability, the accuracy and the range of descriptor information to generate reliable inputs for the BN. The data can come from relevant datasets and/or from QSAR predictions as described in section 2.

QSAR models allow for cost-effective and efficient assessment of the potential risks of NMs without the need for extensive in vivo experiments (Huang et al., 2021). Latest trends use machine learning (ML) algorithms to augment or develop QSARs (Furxhi et al., 2020; Balraadjsing et al., 2022; Singh et al., 2020). There are however many challenges in the development and use of these models for nano-toxicity predictions. A major challenge is the limited number of experimental data, making it difficult to train models that require large and diverse datasets to achieve acceptable prediction accuracy. There is also need to connect and harmonize different data sets, for example by using read across and other methods of filling data gaps. Finally, the complexity and diversity of NMs hinder the identification of the most relevant structural and/or physicochemical properties that affect their toxicity. The above can lead to the development of ML models that have low predictive power and/or a limited domain of applicability. On a different perspective, all the predictive toxicology models should be validated in a manner that is acceptable to regulatory agencies. This requires the development of transparent and reproducible validation procedures, to ensure that these models are suited to support regulatory decision-making in the field of nanotoxicity (Winkler, 2020).

To avoid these concerns, we are currently implementing a simplified version of the proposed framework, relying only on an extended and well curated dataset. This version will soon be integrated on the NanoInformaTIX project platform. Advanced QSARs are also under development in NanoInformaTIX and will be available on the platform, along with data sources and other models to enable risk assessment and property predictions. These will enable to fully implement the proposed SbD framework in the future.

## **5. Discussion and conclusions**

The physical, chemical and biological behavior of the materials at nanoscale is very different from their conventional behavior at macroscale, due to a major shift in the dominant phenomena. This creates enormous opportunities towards novel advanced solutions in a wide range of application areas. It also raises concerns on possible risks on the human health and safety and the environment, during the entire life cycle of ENMs and nano-enabled products.

The above concerns need to be taken into account ex-ante, during the early stages of material development, under the safe-by-design (SbD) principles. This work proposes a framework for SbD, using a **general and extendable representation for NMs** suitable for computational applications, and a **data-driven assessment method using Bayesian networks**. These are herein the **essential components for the systematic and efficient screening for new NM designs with improved safety profiles**.

The representation is based on the InChI for NMs, and facilitates the comparison of NM components, which is crucial for calculating NM affinities. A set of extensions to NM InChI aim to address key challenges in computational-friendly NM representation, including the ability to describe statistical distributions and bypass categorical shape descriptors typically used to describe NMs (Blekos et al., 2022). Note that, the authors are part of the NM InChI Working Group and many aspects of these extensions will be included in the proposal for a new InChI standard (InChI Trust, 2022).

The screening framework proposed here depends on the availability of many and reliable data and appropriate QSAR models to fill gaps in nanotoxicity predictions. The platform developed under the NanoInformaTIX H2020 project will contain a variety of

suitable models integrated into workflows for human and environmental risk assessment, providing the perfect playground to evaluate the proposed approach. A simplified version of the proposed framework, without dependency on predictions from external models, will soon be available at the NanoInformaTIX platform.

The proposed framework has the potential to be used in other or extended applications, including the design of new NMs with improved sustainability and functionality profiles. By taking into account these additional factors, we can better formulate the NM design problem and consider a variety of NMs, their production processes and applications.

## Abstract

Calcium-looping (CaL) is a promising cyclic process for CO<sub>2</sub> capture based on the reversible chemical reaction between CaO-based adsorbents and CO<sub>2</sub> to form CaCO<sub>3</sub>. Currently, the main CaL challenge is the decay of the adsorbents carrying capacity with increasing number of cycles of calcination-carbonation due to the particles sintering and pores blockage.

In this work, different types of CaO-based adsorbents are investigated in a cyclic laboratory scale CaL unit for CO<sub>2</sub> capture using a real flue gas from a cement plant and a synthetic gas mixture, both with same CO<sub>2</sub> content.

An artificial neural network (ANN) model is developed to predict the adsorbents' deactivation along the cycles, based on their composition and on the type of gas used. A good agreement between the experimental and predicted values was obtained, demonstrating that ANN can be successfully used to predict the adsorbents' deactivation based on the materials composition and type of gas.

**Keywords:** Calcium looping, CaO-based adsorbents, CaO deactivation, neural networks.

## 1. Introduction

The calcium looping (CaL) process is a promising CO<sub>2</sub> capture technology for industrial plants, based on the reversible chemical reaction between CaO and CO<sub>2</sub> to form CaCO<sub>3</sub>, which has received great attention in recent years. CaL process is based on the cyclic calcination-carbonation of CaO-based adsorbents, usually natural limestones (CaCO<sub>3</sub>), to capture CO<sub>2</sub> from a flue gas. The adsorbents can be reused for several cycles, but their CO<sub>2</sub> carrying capacity decreases along the cycles due to the particles sintering and pores blockage (Abreu et al. 2020; Teixeira et al., 2020). CaL is currently a potential sustainable option for emissions' reduction in the cement industry because the purged deactivated CaO-based materials can be conveniently reused and integrated in the clinker production.

Despite the synergy between the CaL process and the cement production plants, the decay of the adsorbents' CO<sub>2</sub> carrying capacity is a problem that needs to be tackled for improving the operation and efficiency of the CaL process. A fresh adsorbent make-up stream may be used to maintain the adsorbent activity and the desired CO<sub>2</sub> capture level. The degree of deactivation of each type of adsorbent material depends, among other factors, on its chemical composition as well as on the flue gas composition, and it may be assessed in the laboratory through a sequence of several calcination-carbonation cycles. A tool to predict the deactivation along the cycles is thus urgent and valuable for the CaL process at industrial scale, as it would avoid the laboratory testing burden and it would also allow the estimation of the flowrate of a purge stream of the deactivated CaO-based adsorbent, as well as a make-up stream of the fresh adsorbent.

CaO-based adsorbents are usually non expensive materials such as natural geological or waste-based materials precursors. In this work, the use of different samples of both types of CaO-based materials in a cyclic laboratory scale CaL unit for CO<sub>2</sub> capture (Marques et al., 2022) is investigated, using a real flue gas from a cement plant and a synthetic gas mixture, both with the same CO<sub>2</sub> content.

An artificial neural network (ANN) is developed to obtain a model that predicts the adsorbents' deactivation along the cycles, based on their composition and on the type of gas used.

## 2. Methodology

### 2.1. Adsorbent deactivation data

The data reported by Marques et al. (2022) for six different samples of Ca-adsorbents comprising four natural limestones (LA, LB, LC, and LD) and two waste marble powders (WMA, and WMB), was used in this work. The oxide content of the adsorbents is shown in Table 1. The samples were tested in a fluidized bed reactor using two different gases for the carbonation step, a real flue gas (FG) from a cement plant chimney (pressurized to a bottle) and a synthetic gas (SG) mixture of nitrogen and air, that replicates a real carbonation atmosphere, both with 15 % of CO<sub>2</sub>. The calcination was always performed with a SG mixture (70 % CO<sub>2</sub> balanced in air) to replicate realistic calcination conditions. The chemical composition of the gases and a simplified diagram of the experimental set-up may be found in Marques et al. (2022).

The deactivation of the adsorbent was evaluated using the amount of CO<sub>2</sub> captured by unit mass of adsorbent as indicator, the carrying capacity (CC), over ten cycles of calcination and carbonation. The characterization of the gases used, and the experimental procedure details are given by Marques et al. (2022) and will not be reproduced here.

Table 1. Adsorbents chemical composition (wt. %, adapted from Marques et al. (2022))

	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	Fe <sub>2</sub> O <sub>3</sub>	CaO	MgO	K <sub>2</sub> O
LA	9.00	3.69	1.72	45.52	0.99	0.72
LB	14.78	3.94	1.80	40.57	2.02	0.92
LC	0.49	0.26	0.11	54.90	0.46	0.06
LD	2.31	0.85	0.60	45.89	0.78	0.12

WMA	0.60	0.02	0.05	55.33	0.25	0.02
WMB	3.38	0.60	0.28	52.22	0.79	0.30

A set of 120 experimental results is available. After a careful analysis of the data, two points were considered as outliers and removed from the data set, resulting in a total of 118 points available for training, testing and validation of the ANN.

## 2.2. Model development

This work aims at developing an ANN to correlate the adsorbent characteristics and its working conditions with the capacity of capturing CO<sub>2</sub>. Eight inputs were selected for the ANN: adsorbent oxide composition (SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, CaO, MgO, and K<sub>2</sub>O), number of the cycle, and type of gas used. The output of the ANN is the carrying capacity.

A feedforward backpropagation neural network model using Levenberg-Marquardt backpropagation and a hyperbolic tangent sigmoid activation function were used. The data was divided for training (70 %), testing (15 %), and validation (15 %) using interleaved indices, with the same sets being used to train, test, and validate each network. As there are no fixed rules for the selection of the ANN size and configuration, a preliminary analysis was performed to identify the simplest architecture giving adequate results. Different ANN architectures were created, by varying the number of neurons and hidden layers. The number of internal layers tested was 1 and 2, with the number of neurons varying between 4 and 20 for layer 1, and between 1 and 3 for layer 2.

The different architectures were tested using MATLAB Deep Learning Toolbox. To increase the probabilities of achieving better performance the model was trained 500 times for each architecture, and the performance evaluated using mean squared error (MSE) as criteria. The best performing case for each architecture was then used to evaluate the influence of the number of neurons and layers in ANN performance, while also checking for an adequate description of the process. The criteria used to select the final ANN architecture was the minimization of the number of layers and neurons, while having a low value of MSE and providing a proper description of the process.

Statistical parameters were calculated to assess ANN model predictions, and included the coefficient of correlation (R) and the fitting error ( $e_i$  (%)) for each data point  $i$ , defined as:

$$e_i = \frac{(y_i^p - y_i)}{y_i} 100 \quad (1)$$

where  $y_i^p$  is the value predicted by the ANN model and  $y_i$  the experimental value.

## 3. Results and discussion

### 3.1. ANN architecture

Several tests were made to identify the proper architecture to be used, varying the number of layers, and the number of neurons in each layer. Although different results were obtained depending on the conditions used to train the ANN, as the number of times the network is trained, or the sets used for each task, for example, only a small improvement was obtained when using two layers instead of one. Furthermore, no significative improvement was observed in the performance indicator (MSE) when the number of neurons is increased over a certain number.

As an illustrative example, Figure 1 depicts the variation of the minimum value of MSE obtained for each ANN architecture, with a varying number of neurons and internal

layers. The small improvements observed, particularly for more than nine neurons, indicate that a simpler ANN, with only one layer, can still provide adequate results, while requiring a minimum number of parameters to be estimated. In view of this, an architecture with only one layer and nine neurons was selected for this problem, resulting in an ANN with eight inputs, nine neurons and one output (8:9:1).

Figure 1. Mean squared error for different ANN architecture and number of hidden neurons in the first layer (the legend indicates the number of neurons in the second layer).

### 3.2. ANN performance

Figure 2 shows the fitting performance for the three subsets used, individually and for all the data used, for the architecture 8:9:1. An overall good behavior is observed, with R values greater than 0.99 for all the cases. The histogram in Figure 3 shows a normal distribution, with most of the estimated points having a deviation lower than 0.34. The calculated overall deviations are comprised in the interval  $[-3.2, 2.8]$  and the error ( $e_i$ ) in the interval  $[-18, 14]$  %.

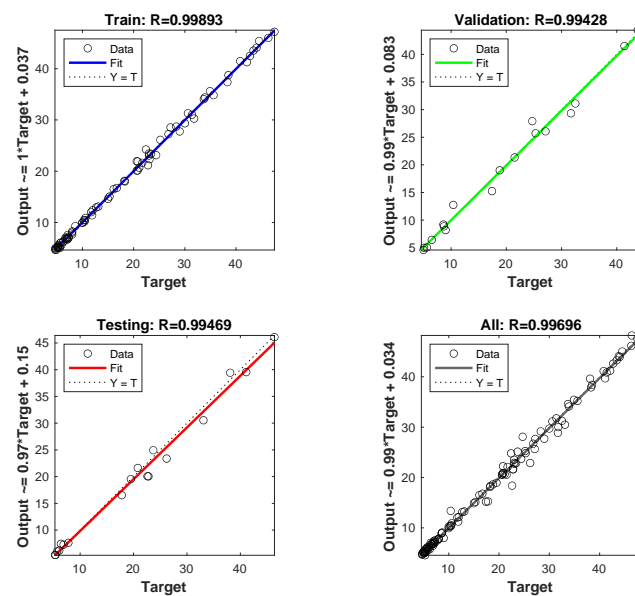

Figure 2. Fitting performance for the sets used.

Figure 3. Histogram of error obtained in fitting.

Figure 4 and Figure 5 depict the evolution of the adsorbents carrying capacity along the carbonation-calcination cycles. As expected, a decay over the cycles is observed, which is justified by adsorbent particles sintering and pores blockage. It is also observed that each adsorbent has different initial and final carrying capacities, and deactivation profile depending on the adsorbent composition and type of gas used.

The figures show a good agreement between the target measured values ( $y$ ) and the predicted values ( $y^p$ ) for most of the cases, with no apparent signs of overfitting. Some of the major discrepancies observed may be justified by the inclusion of some experimental data that would be considered as outliers, in a stricter data validation process.

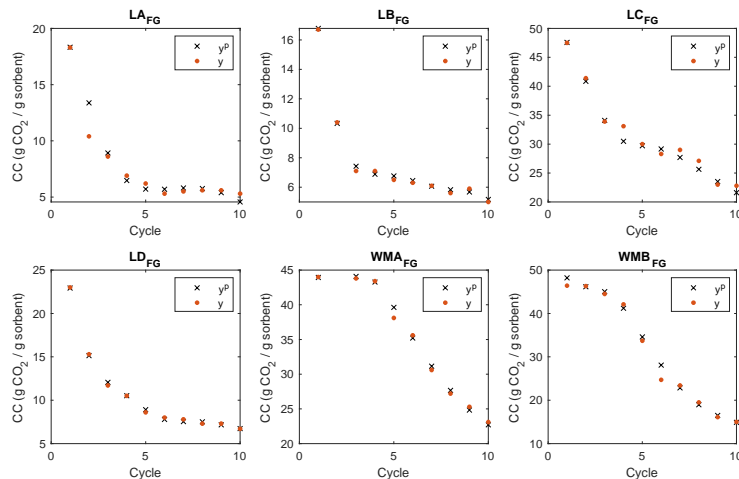

Figure 4. Experimental ( $y$ ) and predicted ( $y^p$ ) carrying capacity (CC) for each sorbent as a function of the number of cycles using real flue gas.

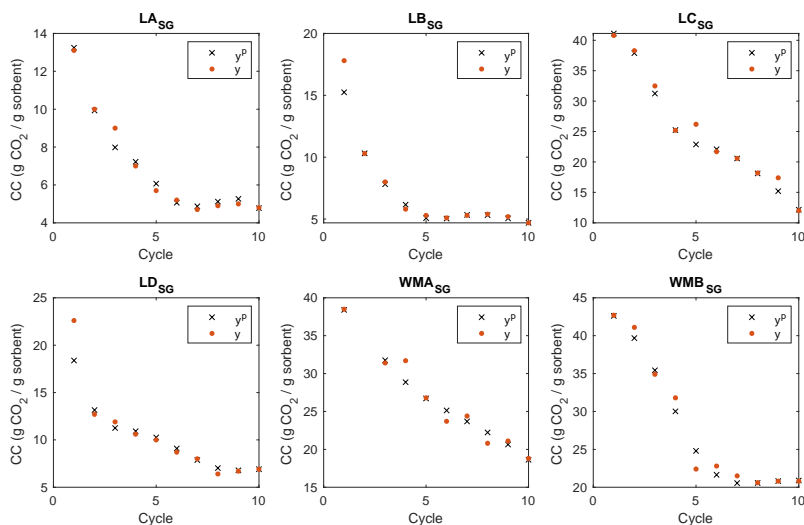

Figure 5. Experimental ( $y$ ) and predicted ( $y^p$ ) carrying capacity (CC) for each sorbent as a function of the number of cycles using synthetic gas.

#### 4. Conclusions

An ANN was developed to predict CaO-based adsorbents deactivation along the Ca-looping cycles. A study on the architecture of the ANN was performed, with no significant improvements observed above a minimum of nine neurons, even when more complex configurations were used. A good agreement between the experimental and the predicted values of the adsorbents' CO<sub>2</sub> carrying capacity was obtained for the tested materials, demonstrating that the ANN is sensible to the input variables, and can differentiate among samples composition, type of gas used, and number of cycles applied to each sorbent. The ANN model developed is a powerful tool, that can now be used to assist the selection of new adsorbents by predicting the behavior over several cycles. It may also provide useful information for models used in process design, optimization, and operation. Future work will investigate how extra information supplied to the ANN affects performance.

## Abstract

In the upcoming decades, the integration of renewable energies into our continuous process routes, by producing and processing green hydrogen, is of paramount importance to combat climate change. To include green hydrogen in conventional process routes large hydrogen storages or dynamic process control strategies for hydrogen processing are needed. In this work a dynamic process control strategy for a Power-to-Ammonia (PtA) value chain is studied. A PtA process plant and respective process control strategies to adjust the plant load are conceptualized. To study the feasibility, a Haber-Bosch reactor system is modeled and implemented in MATLAB 2022b. Simulation case studies are carried out to emulate load changes. The simulation shows that the conceptualized process enables an intermittent production of ammonia based on green hydrogen. Further studies with more detailed models and refined process control strategies are planned for a detailed analysis to optimize the efficiency and flexibility of the production.

**Keywords:** Power-to-X, Power-to-Ammonia, Requirements Analysis, Dynamic Simulation, Renewable Energies

## 1. Introduction

The integration of renewable energies, like wind energy or photovoltaics, into our existing chemical production lines is necessary to combat climate change and reduce our economic dependency on fossil resources (IEA, 2021). Power-to-X (PtX) technologies offer the possibility to integrate fluctuating energy into our value chains, by producing and processing green hydrogen. To integrate intermittent energy in conventional production lines large electricity storages or large hydrogen storages are necessary to decouple the subsystems. Since both electrical storage and hydrogen storage are expensive and exhibit increasing losses over time, flexible PtX value chains through dynamic process control is a promising approach towards integrating renewable energies in the chemical industry (Moradi, 2019). The aim of this work is to elaborate a plant and control concept for the dynamic control of a PtX value chain. The implementation and simulation of the developed concepts will be used to study whether the PtX value chain can adapt to the load changes of sustainable energy sources without large-scale electricity or large-scale intermediate hydrogen storage. Chapter 2 will shortly describe the methodology used in this work. The developed requirements, concepts and simulation will be specified in chapter 3. The conclusion of the work can be found in chapter 4.

## 2. Methodology

The plant and process control concept are developed for a selected PtX use case, namely Power-to-Ammonia (PtA), based on the available literature and a preceding requirements analysis. The concept primarily includes conventional applications to study the possibility to use established technologies for PtX value chains. Subsequently, simplified concepts are implemented and simulated in MATLAB 2022b. In this work, the focus is on the simulation of a Haber-Bosch reactor system. Necessary parameters for the reactors are taken from Khademi et al. (2017) to create models for dynamic tubular Haber-Bosch reactors. The resulting PDE system of the reactors models are discretized to derive an ODE system and are solved using the ode23t solver.

Case studies are simulated in which different load change rates are simulated and the dynamic response of the reactor system is considered. The simulation results, such as temperature and concentration profiles and molar flow rates, are validated by those from literature, but due to missing data, validation with real plant data is omitted. The time-dependent temperature and concentration profiles under load variations are evaluated to assess whether dynamic operation is feasible with the input of sustainable energy. The focus here is on whether the plant concept can maintain the permitted operating parameters even under fluctuating input conditions and different load change rates. In later iterations the complete PtA value chain with added electrolyzers, a small-scale intermediate hydrogen tank and auxiliary components shall be modeled and simulated. The determined range of load change rates can subsequently be used in the dynamic PtA value chain.

## 3. Methodology

Since PtX technologies include a wide range of production routes a specific value chain must be chosen. Ammonia production accounts for about three-quarters of the hydrogen consumption in chemical production lines (IEA, 2021). Therefore, the Power-to-Ammonia (PtA) value chain is chosen as an example to conceptualize and evaluate the flexible operation of PtX technologies through dynamic process control.

### 3.1. Use-case for main energy source, secondary energy source and plant location

The process plant design and process control strategies have to fit the chosen use-case of the PtA value chain. In the first step a use-case is defined, considering the main energy source, a potential secondary energy source and the location of the plant.

Wind energy is chosen as the main energy source, since it is the most widely used energy source for PtX applications and offers a high number of nominal operational hours with 1400-5000 h/a (Chehade, 2019). A grid connection is chosen as a secondary energy source. This enables the use of a stand-by operation, which is necessary for safe and economical operation with fluctuating energy supply without large electricity or hydrogen storage. The grid connection makes the use of a stand-by operation during times of low wind energy availability possible. The main disadvantage is that this can lead to the use of electricity from fossil resources to maintain the stand-by operation.

Finally, the process plant location is chosen to be next to the energy provider. While a positioning next to ammonia consumers or existing ammonia production facilities offer advantages like existing infrastructure, ammonia is far more suitable for long distance transport than hydrogen (IEA, 2021).

### 3.2. Plant requirements for a dynamic Power-to-Ammonia value chain

The plant, especially the electrolyzer, must be able to adjust to the load gradient of a wind turbine in order to respond to incoming energy fluctuations. It must have a large partial

load range in which the plant can be safely operated efficiently and economically. To minimize the potential use of fossil fuels, the energy consumption in stand-by operation should be as low as possible. The generated heat should be integrated in the plant. The CAPEX should be kept as low as possible, as this is a significant cost factor for the ammonia produced in small- and medium-scale plants (Chehade, 2021). The hydrogen tank necessary to act as a buffer for the different system dynamics should be as small as possible to reduce CAPEX and storage losses.

### 3.3. Process control requirements for a dynamic Power-to-Ammonia chain

The operating conditions have to be kept within the permitted value range to prevent the degradation of plant equipment and catalyst materials. The maximum warm start-up time for minimal operation of the ammonia synthesis should be less than 1 hour. If the available energy falls below minimal load, the plant transitions to stand-by operation automatically and holds the operating conditions with inert gas. The stand-by operation can be upheld for a maximum of 20 hours. Energy forecast data is used to decide, whether the plant will be kept in stand-by operation or is shut down.

### 3.4. Concept of the Power-to-Ammonia value chain using dynamic process control

The PtA plant and their respective process control strategies for the developed use-case are conceptualized, modeled and simulated. The goal is to study the plant and the respective process control concept in terms of flexibility and efficiency.

#### 3.4.1. The Power-to-Ammonia plant concept

In simplified form, the plant concept consists of a technology selection for a water electrolysis, a nitrogen recovery and a reactor concept for the Haber-Bosch synthesis for ammonia production. The concept for the process control strategies consists of strategies to hold the operating conditions in the permitted value ranges as well as strategies to change the plant load during operation.

Figure 1: Simplified process flow diagram of the PtA plant concept

The Polymer Membrane Electrolysis (PEMEL) was chosen for the hydrogen production. The advantage of the PEMEL is the flexibility of the plant operation. Both the cold start with 10–15 min and the warm start with <10 s allow the PEMEL to start up quickly. A heating curve of 0.3–1 K/min can be achieved (Buttler, 2018; Hermesmann, 2021). PEMEL systems achieve load gradients of 10–90 %/s with load flexibility of 0–160 % if the power electronics are also designed for it (Grigoriev, 2020; Milanzi, 2018; IEA, 2019). Likewise, PEMELs are more compact than other electrolysis systems for the same hydrogen output (Buttler, 2018). On the other hand, the PEM has higher requirements for

water purity and is also more expensive to procure (1390 – 2320 €/kWel) than an alkaline electrolysis (AEL) with a procurement price of 620 – 1200 €/kWel (Buttler, 2018; Hermesmann, 2021).

For nitrogen production a pressure swing adsorption is used. A minimum load range of 30 %, fast start-up behavior and efficient dynamic operation makes the compact PSA attractive for operating small- and medium-scale PtA systems (Bañares Alcántara; 2015). The ammonia synthesis takes place within a reactor cascade of three tubular reactors with interstage cooling. The Haber-Bosch process is catalyzed through an iron based catalyst. While a ruthenium based catalyst is better suited for a dynamic process due to the lower operating pressure and temperature, an iron based catalyst is chosen due to the lower cost (Chehade, 2021).

### 3.4.2. The Power-to-Ammonia dynamic process control concept

The process control focuses on the control strategy for the reactor load, because the reactors are the production speed determining components. Nitrogen production is not considered in detail and a constant nitrogen supply is assumed.

The electrolyzers are started up within 10 minutes and begin to feed the produced hydrogen into the buffer tank. Temperature in the reactor system is continuously ramped up with 20 K/h to the operating conditions of about 400 °C and the reactor is pressurized to 250 bar while the electrolyzers are starting up and already producing. The produced hydrogen is temporarily stored in the buffer tank until the operating conditions of the ammonia synthesis with 690 K reactor inlet temperature and 286 bar reactor inlet pressure are reached. The load of the Haber-Bosch reactors is controlled by adjusting the hydrogen input, since hydrogen production accounts for about 85 – 95 % of the total energy consumption (Khademi, 2017). With the assumed constant nitrogen supply a feedforward control system is used, which controls the hydrogen input to the reactor system based on the available power, the fill level of the hydrogen buffer tank and the hydrogen content in the recirculation. Adjusting the stoichiometry of the reaction to the load change through hydrogen input has been established as the most efficient method to control the Haber Bosch reaction (Khademi, 2017). The nominal ramp-up rate of the hydrogen input is set to 50 % of nominal load per hour (Viedt, 2022). The reactor pressure is maintained by the recycle compressor. In stand-by operation the temperature is maintained by the heating element upstream of the reactor.

### 3.5. Simulation of the Power-to-Ammonia value chain

The concept is modeled and simulated in MATLAB 2022b. Due to the fast dynamics of the PEM electrolysis, the electrolyzer models are simplified by assuming constant material parameters and quasi-stationary conditions in the cells, while neglecting the influence of water vaporization, gas cross-permeation and the heat capacity of the membrane and electrodes. The reactors are modeled as dynamic tubular flow reactors. Assuming constant material parameters, the one-dimensional material and energy balances of the adiabatic reactors result in:

$$\frac{dc_i}{dt} = v \frac{dc_i}{dz} + c_i \frac{dv}{dz} + R_i \quad (1)$$

*for i = H<sub>2</sub>, N<sub>2</sub>, NH<sub>3</sub>*

$$\frac{dc_{Ar}}{dt} = v \frac{dc_{Ar}}{dz} + c_{Ar} \frac{dv}{dz} \quad (2)$$

$$\frac{dT_R}{dt} = v \frac{dT_R}{dz} + T_R \frac{dv}{dz} + \frac{r(-\Delta h_R)}{\rho c_p} \quad (3)$$

The reactors are discretized in equidistant  $z$ -locations to convert the PDE system into an ODE system. A simplified convergence study shows that the temporal behavior changes negligibly with a number above 40 equidistant discretization points. The load change rate is varied from 50 500 % per hour to study the influence of the load change rate on the dynamic operation of the Haber-Bosch reactors.

### 3.5.1. Simulation results

The simulation of the reactor system provides results for the temperature and concentration curves in the Haber-Bosch reactors. For model validation, the local concentration and temperature profiles of the steady-state operating points were compared with the steady-state simulation of different Haber Bosch reactor systems by Khademi et al. (2017). The continuous operation delivers satisfactory results in this respect. The dynamic response of temperature and concentrations is difficult to compare with other literature sources due to low availability of data and different design and model assumptions. However, due to the simplifying assumptions, it is expected, that the simulated plant has a significantly faster dynamic response than real plants or more complex simulations. Figure 2 shows the temperature curve and ammonia concentration curve for 50, 200 and 500 % load change rate per hour of the first reactor during transition from zero load to nominal load.

Figure 2: Temperature profile and ammonia concentration profile of the first reactor during transition from nominal load to minimal load with 50, 200 and 500 %/h load change rate

It can be seen, that the maximum reactor temperature slightly increases with increasing load change rate. At load change rates above 200 % per hour the temperature peak in the reactor exceeds the allowed maximum operation temperature of 805 K.

#### 4. Conclusion

In summary, the operation of conventional Haber-Bosch reactors for PtA value chains can be done with load change rates of up to 200 % of nominal load per hour. This information will be used in further simulations of the entire plant and the dynamic control strategies to enable the integration of sustainable energy sources into chemical production chains even without large-scale energy storage or intermediate hydrogen storage. The simplified simulation study showed that the dynamic operation of Haber-Bosch reactors is possible without exceeding or falling below the permitted temperature range. The simulation study is thus only applicable for a limited value range. The assumptions of adiabatic operation and the neglect of loss terms and thermal masses in the plant simulation provide faster simulated system dynamics than reality and need to be included in more advanced simulations. Complex models must be created and real plant data must be used for simulation validation to provide a more reliable simulation.

Another important aspect is the choice of concept. The choice of an iron-based catalyst for ammonia synthesis represents the conventional technology well, but is not well suited for dynamic operation, due to the high operating temperature and pressure required. The potential use of new catalyst and reactor systems, such as ruthenium-based catalysts and adsorption reactors would increase the usability of the plant concept for dynamic operation, however at the cost of an increased CAPEX and a more complex control system.

## Abstract

This paper addresses the optimization of crude oil operations scheduling in a marine-access refinery, considering uncertainty in the arrival date of the ships that supply the crudes. Furthermore, we evaluate the performance of a two-stage stochastic mixed-integer nonlinear programming (MINLP) model based on continuous-time representation. For this purpose, we calculate the Expected Value of Perfect Information (EVPI) and the Value of the Stochastic Solution (VSS), which allow us to assess and compare the solution of the stochastic model against solutions obtained from deterministic models. Finally, we consider the Conditional Value-at-Risk (CVaR) measure as the objective function and evaluate the solutions obtained for different risk levels.

**Keywords:** Stochastic optimization; Continuous-time representation; Crude oil scheduling; Expected Value of Perfect Information; Conditional Value-at-Risk.

## 1. Introduction

In this paper, the problem under study is the optimization of crude oil operations scheduling in a refinery with marine access. In addition, we address two different topics related by means of stochastic programming.

First, we evaluate the solution obtained from a two-stage stochastic MINLP model based on continuous-time representation by comparing it with the one obtained from a deterministic model. We are interested in finding out if the deterministic solution is close to the stochastic optimum or, on the contrary, if it is worth using stochastic optimization in spite of the increase in computational effort. Another question that arises is how much we are willing to pay to obtain more information about the uncertainties. To answer these inquiries, there are two measures: the value of the stochastic solution (VSS) and the expected value of perfect information (EVPI), which are explained throughout the article. Second, we analyze the result of including risk management, that is, the effect of deviations from average values on the quality of the solution. For this purpose, we employ

the Conditional Value-at-Risk (CVaR) measure as the objective function and evaluate the solutions obtained for different risk levels.

The rest of the paper is structured as follows. The definition of the problem is given in Section 2. The mathematical formulation is described in Section 3. The concepts EVPI and VSS are defined in Section 4. The risk management method is described in Section 5. The solution strategy is mentioned in Section 6. Then, problem instances and computational results are reported in Section 7. Finally, conclusions are drawn in Section 8.

## 2. Problem definition

As stated before, we tackle the optimization of crude oil operations scheduling in a refinery, which is supplied with crude oil by ships. Before beginning with the description of the problem, it is convenient to clarify the meaning of "crude operations" and "operations scheduling".

The term "crude operations" refers to the operations involved in the supply, storage, and processing of crude oil. Then, when we talk about operations scheduling, we refer to the process of allocating resources to operations and sequencing their execution to comply with the production plan.

Considering these definitions, we can determine that the optimization of crude operations scheduling consists of deciding the best way to operate the terminal-refinery system, considering the management of the arrival and unloading of vessels, crude oil inventory in tanks, and loading of CDUs. Moreover, in this case, the crude oil supply availability is subject to uncertainty due to the impact of weather conditions on ship arrival dates.

Figure 1 shows a typical scheme of a refinery with a marine terminal. The crude oil is received through this terminal and stored in the refinery tanks; these two areas (terminal and tanks) are connected by a pipeline. Then, from the stored crude, the feed blends are formed, which must meet certain quality specifications. Finally, the blends obtained are loaded into the crude distillation units (CDUs) through a mixing pipeline system.

In this article, we address the problem by means of a two-stage stochastic programming with recourse model (Birge & Louveaux, 2011). In these types of models, we must define two kinds of decision variables: first-stage variables ("here and now") which have to be implemented now and affect all future decisions, and second-stage variables that would be implemented later on when more information about the process becomes available (recourse, "wait and see" variables).

For this case, the first-stage variables are: allocation of tanks to CDUs, total volumes transferred to CDUs, and start-time, end-time, and duration of slots. With respect to the second-stage ones, the following were defined: variables related to the activities carried out at the marine terminal, inventory level in tanks, and amount of each type of crude oil

transferred from tanks to CDUs. Finally, the uncertainty in the supply is represented by a discrete set of scenarios that contemplate different arrival dates.

### 3. Model formulation

We use the model developed in (García-Verdier et al., 2022), which consists of a two-stage stochastic MINLP model with continuous-time representation. In this model, the first and second-stage variables are solved jointly, i.e., the deterministic equivalent program is solved. In order not to exceed the allowed page limit, we do not show the complete mathematical formulation.

A relevant feature of this model is that the precedence between ships does not depend on the order of the elements of the set “Vessels” (Cerdá et al., 2015), nor is there a pre-assignment of slots for each ship (Reddy et al., 2004). For this case, it has been implemented the concept of predefined precedence, which consists in considering the set of slots preordered, and then, the optimization algorithm is in charge of assigning each ship to some of those slots (Gómez Palacín, 2020; Palacín et al., 2019).

#### 3.1. Objective function

To define the objective function, the cost associated with each scenario is calculated by using (1). The first summation comprises the costs due to the difference between processed volume and required demand in each CDU and constitutes the first-stage cost. The second summation involves the costs due to demurrage and departure tardiness of vessels and represents the second-stage cost.

$$z e_e = \sum_u (COP_u * op_u + CSP_u * sp_u) + \sum_b (CDMG_b * dm g_{b,e} + CTDN_b * tdn_{b,e}) \quad \forall e \in E \quad (1)$$

Where,

$COP_u$  = cost due to positive difference between processed volume and required demand by a CDU.

$CSP_u$  = cost due to negative difference between processed volume and required demand by a CDU.

$CDMG_b$  = demurrage or sea waiting cost.

$CTDN_b$  = departure tardiness cost.

$op_u$  = positive difference between processed volume and required demand by CDU u.

$sp_u$  = negative difference between processed volume and required demand by CDU u.

$dm g_{b,e}$  = demurrage of vessel b under scenario e.

$tdn_{b,e}$  = departure tardiness of vessel b under scenario e.

Finally, the objective function consists of minimizing the cost associated with the first stage and the expected cost of the second stage, considering all scenarios (2). The parameter  $\pi_e$  represents the probability of occurrence of scenario e.

$$MIN \sum_e \pi_e * z e_e \quad (2)$$

### 4. Assessment of the stochastic solution

As mentioned above, one of the objectives of the paper is to evaluate whether two-stage stochastic programming offers any advantage over simpler deterministic approaches. To this end, (Birge & Louveaux, 2011) proposed the value of the stochastic solution (VSS)

and the expected value of perfect information (EVPI) but before defining both measures it is necessary to explain some concepts.

First, the two-stage stochastic programming model is known as the recourse problem (RP), and its solution as the here-and-now solution. Second, the expected value (EV) problem corresponds to the model obtained by substituting all random variables by their expected values, and the EEV value refers to the expected result of fixing the first-stage variables according to the solution of the EV problem. Finally, if we have perfect information, we can apply the optimal solution corresponding to each scenario. Then, the expected long-term cost, known as the "wait and see" (WS) solution, will be equal to the sum of the costs of each scenario weighted by their probabilities of occurrence. In summary, the WS value represents the expected long-term cost of using the optimal solution for each scenario.

Once these concepts are established, we continue with the definition of the value of the stochastic solution (VSS) and the expected value of perfect information (EVPI). The VSS (3) quantifies the improvement obtained in the objective function when considering the randomness of the uncertainty (RP), versus its weighted average (EEV). The EVPI (4) measures the maximum amount that the decision maker would be willing to pay in exchange for complete and accurate information about the future, i.e., for perfect information.

$$VSS = EEV - RP \quad (3)$$

$$EVPI = RP - WS \quad (4)$$

## 5. Risk management

The approach described above does not evaluate the risk associated with the objective function, i.e., it is risk-neutral. The purpose of this approach is to minimize the expected value in the long run without considering the probability distribution of the objective function. However, it is often important to consider this distribution to reduce the risk that the solution obtained takes extreme values in the most unfavorable scenarios. For this purpose, there are two popular risk measures, Value-at-Risk (VaR) and Conditional Value-at-Risk (CVaR). On the one hand, VaR at confidence level  $1-\alpha$  determines the minimum value  $\omega^*$  such that the probability of the objective function taking a value less than  $\omega^*$  is greater than  $1-\alpha$ . On the other hand, CVaR at confidence level  $1-\alpha$  represents the average value of the tail of the distribution, above  $VaR_{1-\alpha}$ . The latter is more useful in optimization problems since it is simple to calculate, and is convex.

The stochastic programming model is reformulated by incorporating constraints (5) and (6), where  $\phi_e$  is an auxiliary variable to evaluate CVaR and the scalar  $\alpha$  corresponds to the CVaR significance level.

$$ze_e - var \leq \phi_e \quad \forall e \in E \quad (5)$$

$$cvar = var + (1/\alpha) * \left( \sum_e \pi_e * \phi_e \right) \quad (6)$$

Finally, the new objective function (7) minimizes CVaR for a given confidence level.

$$MIN \quad cvar \quad (7)$$

## 6. Solution strategy

The stochastic programming problem is solved from its deterministic equivalent, following a solution strategy. The solution strategy for the two-stage stochastic MINLP model consists of two steps. A more detailed description of the strategy is given in (García-Verdier et al., 2022).

### 7. Results

In this section, the resolution of an example is carried out. It consists of a 120-hour scheduling horizon, 5 storage tanks, 2 crude distillation units, and 5 classes of crude characterized by a single property. The arrival of 2 ships is expected. The arrival dates and probabilities for each scenario are detailed in Table 1. The expected departure date is 12 hours after the arrival. The demand for CDU 1 is 100,000 m<sup>3</sup> and for CDU 2 is 65,000 m<sup>3</sup>. The example has been solved using GAMS 39.2.1 software, OsiGurobi for MILPs, and CONOPT 4.19 for NLPs on a computer with Intel Core i7-10510U 2.30 GHz processor and 16 GB RAM.

Table 1. Arrival times and probabilities.

Scenarios	Probabilities	Arrival time (h)	
		Ship 1	Ship 2
1	0.01	10	40
2	0.05	50	40
3	0.01	90	40
4	0.18	10	70
5	0.5	50	70
6	0.18	90	70
7	0.01	10	100
8	0.05	50	100
9	0.01	90	100

#### 7.1. EVPI and VSS

The values obtained for RP, EEV, and WS are shown in Table 2. The RP problem involves 9,345 continuous variables, 1,272 binary variables, and 19,700 constraints; it was solved in 51.58 seconds. In addition, EVPI and VSS values are presented in the same table to analyze the effect of considering uncertainty. Figure 2 (a) compares the costs of each scenario for both the two-stage stochastic programming model and the deterministic EV model.

Table 2. Expected costs associated with proposed models, and values of EVPI and VSS.

RP	WS	EEV	EVPI	VSS
(x10 <sup>3</sup> €)				
24.42	0.74	74.79	23.68	50.37

(a) Two-stage and EV

(b) Risk-neutral, CVaR<sub>0.6</sub>, and CVaR<sub>0.99</sub>

Figure 2. Cost of scenarios.

## 7.2. CVaR

The results obtained for the two-stage stochastic programming model with risk management are shown below. Table 3 shows the VaR and CVaR values at confidence level 0.99 and 0.6. In addition, the expected costs and resolution time for both cases, including the risk-neutral approach, are shown. Figure 2 (b) compares the costs of each scenario in each of the previously mentioned approaches.

Table 3. VaR and CVaR values with confidence levels of 99% and 60%.

$1-\alpha$	VaR $_{1-\alpha}$ ( $\times 10^3 \text{€}$ )	CVaR $_{1-\alpha}$ ( $\times 10^3 \text{€}$ )	Expected cost ( $\times 10^3 \text{€}$ )	Time (s)
0.99	81.56	81.56	81.28	93.67
0.6	30	39.38	33.69	131.06
Risk-neutral (RP)	NA	NA	24.42	51.58

## 8. Conclusions

If we have access to perfect information, the RP solution will improve, and we would be willing to pay up to 23.68 k€.

The VSS indicates that it is worth using the two-stage stochastic optimization since the expected cost, when using the mean values of the uncertain parameters, increases by 50.37 k€.

Based on Figure 2 (a), we can see that, although there are some scenarios where the EV solution is better than the RP solution, the performance of the RP solution is superior. There are scenarios where the EV solution incurs very high costs (e1, e4, and e7). Therefore, it is preferable to apply the RP solution.

Finally, when including risk in the two-stage stochastic model, it is observed that the expected cost increases with increasing risk aversion. However, from Figure 2 (b) we notice that the solutions obtained by considering risk are more "stable" than the risk-neutral solution. Specifically, in scenario 2, the cost of the risk-neutral solution is twice the cost of CVaR at confidence level 0.99.

## Abstract

It is estimated that 2000 Mt/y of Municipal Solid Waste (MSW) are currently produced worldwide. A strategy for disposing of the non-recyclable fraction of MSW through chemical recycling based on thermal treatments is proposed, leading to the conversion of waste into high-value chemicals. A first-principles suite for the dynamic modeling of thermal conversion processes has been developed to reliably predict the product distribution starting from several types of waste. The GasDS suite models pyrolysis, gas-solid interactions, and gas-phase reactions by dividing the domain into finite volumes, with the possibility to choose among different fluid-dynamic configurations for a given unit. A case study based on a steam-moderated oxy-gasification of sewage-sludge-derived hydrochar is presented in this work. Detailed results showing the syngas productivity and the H<sub>2</sub>/CO molar ratio as functions of the Equivalence Ratio (ER) and the Oxygen content of the gasifying medium (O<sub>2</sub> mol%) are provided.

**Keywords:** Circularity, First-principles, GasDS, Municipal Solid Waste, Sewage Sludge

## 1. Introduction

Solid waste management is a crucial aspect of every socio-economic system worldwide. The option of conventional recycling is crucial, since it is the one that allows to accelerate the transition towards a circular economy in which waste is transformed back into a new product. In the last years, the topic of chemical recycling has been growing in importance, since it allows to valorize the non-recyclable fraction of waste which would be otherwise incinerated and/or landfilled. Chemical recycling has been shown to have a great potential in reducing CO<sub>2</sub> emissions from the treatment of residual municipal solid waste compared with incineration, especially when the electric grid has a high percentage of renewables (Voss et al., 2021). Some chemical recycling routes start from biological processes and are then followed by appropriate chemical syntheses, such as the production of biofuels from organic-waste-derived biogas (Fedeli et al., 2022; Negri et al., 2022a). Other pathways may start from the thermal degradation of solid waste and then lead to the

synthesis of biofuels and biosolvents. Some examples of said processes are based on air-based gasification (Prifti et al., 2021a), and oxy-gasification (Negri et al., 2022b; Prifti et al., 2021b). Chemical recycling processes based on thermal degradation of solid matter need a proper description of this reactive step. The most common approach typically involves a thermodynamic analysis, which has several limitations since it cannot analyze in detail complex phenomena such as chemical kinetics, intra-particle and inter-particle mass and heat transfer. Moreover, it cannot analyze the feasibility of the start-up policies proposed for the unit. This work shows an innovative approach to this problem that exploits the GasDS package, a generalized first-principle suite for the dynamic modeling of gas-solid reactive systems, already validated for biomasses (Ranzi et al., 2014), and coal (Corbetta et al., 2015). The structure of the suite is shown in its entirety, along with a case study that shows a detailed analysis of a gasification chamber working with sewage-sludge-derived hydrochar, thus opening the possibility for design and optimization of innovative thermochemical recycling processes.

## 2. Methods

### 2.1. Waste Characterization

The GasDS suite includes a rich and expandable database. Lignin, cellulose, and hemicellulose can be used to describe organic wastes, while several types of coal and tar can be used to describe char-like substances. These species are characterized in detail inside the GasDS database, which contains basic thermochemistry data and properties related to mass and energy transfer. Any general waste can be expressed as a linear combination of said species to perform a simulation. Higher precision can be obtained by entering new tailored species in the database. For example, this is the case for plastic waste, where it is advisable to add entries related to pure polymers like PE, PP, PS, which are the main components of the solid matrix. This paper analyzes the gasification of hydrochar, a waste obtained from the hydrothermal carbonization of sewage sludge. It is possible to express the composition of hydrochar as a linear combination of two types of coal, given its similarity with this substance (Knötig et al., 2021). The sample is almost a perfect linear combination of the species named COAL1 and COAL3, but it is necessary to add a dummy species to close the atomic balance on carbon and hydrogen, here represented by methane and named GCH4. Of course, this provides accurate results only if the final amount of the dummy species is relatively small on a dry-and-ash-free basis like in this case, as shown in Figure 1.

**Figure 1.** Visual representation of the linear combination for the characterization of hydrochar

### 2.2. Detailed Kinetic and Mass/Energy Transfer Modeling

The kinetic model implemented in the GasDS suite describes the pyrolysis of the solid matrix, heterogeneous gas-solid interactions, and secondary gas-phase reactions. Pyrolysis models from the literature are already implemented for biomass (Ranzi et al., 2008) and coal (Vascellari et al., 2015), and it is possible to add new reaction sets with the aim of analyzing different type of feedstocks. For example, one may include models relative to the most common polymers (PE, PP, PS, etc.) to describe the pyrolysis of plastic waste (Kaminsky et al., 2004). Gas-solid heterogeneous interactions make use of kinetic models related to the gasification and combustion of char generated by the previous pyrolysis step (Groeneveld and van Swaaij, 1980). The heterogeneous gas-solid system is modeled in detail for what concerns intra-particle mass and energy transfer taking place in parallel with the reactions. The migration of the generated gaseous species to the homogeneous gas phase is modeled by considering appropriate inter-particle transport phenomena. Finally, the homogeneous gas phase is modeled with a detailed kinetic scheme that describes the secondary gas-phase reactions occurring in said environment (Ranzi et al., 2012). The multi-scale approach used to model the reactive system is based on two crucial assumptions: both the solid particle and the reaction environment are discretized into a finite number of volumes, which are then modeled by employing zero-dimensional dynamic mass and energy balances relative to the  $i^{\text{th}}$  component and the  $j^{\text{th}}$  sector. The equations are shown in Table 1 (Corbetta et al., 2015; Ranzi et al., 2014).

**Table 1.** Balance equations used in the GasDS suite (Corbetta et al., 2015; Ranzi et al., 2014)

EQUATION	DESCRIPTION	(#)
$\frac{dm_{j,i}}{dt} = V_j R_{j,i}$	Mass balance of the solid phase	(1)
$\frac{dm_{j,i}}{dt} = J_{j-1,i} S_{j-1} - J_{j,i} S_j + V_j R_{j,i}$	Mass balance of the gas phase in the solid particle	(2)
$\frac{d \sum_{i=1}^{NCP} m_{j,i} h_{j,i}}{dt} = J C_{j-1} S_{j-1} - J C_j S_j + S_{j-1} \sum_{i=1}^{NCG} J_{j-1,i} h_{j-1,i} - S_j \sum_{i=1}^{NCG} J_{j,i} h_{j,i} + V_j H R_j$	Energy balance of the solid particle	(3)
$J_{j,i} = -D_{j,i}^{eff} MW_i \left. \frac{dc_{j,i}}{dr} \right _{r_j} - \frac{D_{a,j} dP_j}{\mu_j} \left. \frac{dP_j}{dr} \right _{r_j} c_{j,i} MW_i$	Diffusive mass and heat flux in the particle	(4)
$J C_j = -k_j^{eff} \left. \frac{dT_j}{dr} \right _{r_j}$	Heat flux in the particle by conduction	(5)
$\frac{dg_i}{dt} = G_{in,i} - G_{out,i} + J_{N,i} S_N \eta + V_R R_{g,i}$	Gas-phase mass balance for the reactor	(6)
$\frac{d \sum_{i=1}^{NCG} g_i h_{g,i}}{dt} = \sum_{i=1}^{NCG} G_{in,i} h_{g,in,i} - \sum_{i=1}^{NCG} G_{out,i} h_{g,i} + \sum_{i=1}^{NCG} J_{N,i} h_{N,i} S_N \eta + h_{ext} (T_N - T^{bulk}) S_N \eta + V_R H R_g$	Gas-phase energy balance for the reactor	(7)

The discretization of the domain makes the GasDS suite extremely flexible and adaptable to several system configurations. Dividing the particle in sectors is useful to describe thermally thick particles, which are defined as those having a significant temperature gradient between the core and the surface, a situation that may show up whenever the

particle cannot be reduced to a small enough size (Ranzi et al., 2014). The discretization of the reaction chamber allows to describe a lot of reactor morphologies. A single reaction volume can be used to describe fluidized-bed systems, in which the approximation of perfect mixing typically holds. More than one volume may be used to describe fixed/moving bed configurations, both in co-current and counter-current. The gasification chamber modeled in this work is a fixed-bed, countercurrent, cylindrical gasifier that processes 100 kg/h of hydrochar by using a binary H<sub>2</sub>O/O<sub>2</sub> mixture as gasifying agent. The unit is shown in Figure 2 and the following specifications are implemented:

- Reactor height/diameter: 2 m / 1 m
- Temperature of gasification agent at start-up/steady-state: 930°C / 230°C
- Particle average diameter: 0.01 m
- Number of discrete volumes for the analysis of the solid particles/gasifier: 2/3

**Figure 2.** Simplified scheme of the gasification chamber modeled in GasDS

### 3. Results and Discussion

The system described beforehand still has two degrees of freedom that will be the pivots of the detailed analysis. The first one is the *Equivalence Ratio* (ER), which is here defined as per equation 8, with  $ER < 1$  for fuel-lean mixtures, and  $ER > 1$  for fuel-rich ones.

$$ER = \frac{O_2|_{REAL}}{O_2|_{STOICH}} \quad (8)$$

The second degree of freedom of the system is the oxygen content of the binary gasifying mixture, which is here expressed on a molar basis. It is thus possible to evaluate the behavior of the gasification chamber in a two-dimensional domain identified by these two independent variables. Figure 3 shows the first KPIs of the analysis, the syngas productivity on the left (accounting only for CO and H<sub>2</sub>), and the H<sub>2</sub>/CO molar ratio on the right. The productivity shows an optimal value of ER for any given O<sub>2</sub> mol%, with a monotonically increasing behaviour as the Oxygen content increases. Looking at the H<sub>2</sub>/CO ratio, the value remains relatively constant with respect to ER at a given O<sub>2</sub> mol%, and the curve is monotonically decreasing as the Oxygen content increases. Discovering this kind of behaviour is crucial for a proper optimization of the operating conditions of the gasifier. For example, if the user aims at producing an hydrogen-rich molecule such as methanol and/or dimethyl ether starting from this syngas, it will be necessary to find

an operating point which is a trade-off between productivity and  $H_2/CO$  ratio, which have opposite behaviour with respect to the Oxygen content of the gasifying mixture (Negri et al., 2022b). Moreover, the GasDS suite allows to highlight deviations from engineering “best practices”, which is a typical situation when dealing with unconventional feedstocks such as solid waste. Specifically, the gasification of carbonaceous material typically uses an ER of around 0.30 – 0.33 as rule of thumb for optimal operations (Jangsawang et al., 2015); however, this study highlights that the maximum syngas productivity is systematically achieved for higher values of ER, around 0.35 – 0.45. Finally, GasDS shows an interesting behaviour of the gasifier for low values of ER, which would be lost in a thermodynamic analysis. For these extremely fuel-lean mixtures, the system cannot start-up properly with the procedure described in the previous paragraph. The system is too fuel-poor to sustain the reaction environment during the switch from the hot gasifying agent used for starting-up the chamber, to the colder steady-state current. Trying to operate the unit in this region would bring the system to a premature shut-down.

**Figure 3.** Syngas productivity in kmol/h (left) and  $H_2/CO$  molar ratio (right)

#### 4. Conclusions

A generalized first-principles suite for the dynamic modeling of thermal treatments of carbonaceous feedstocks has been introduced. The steps of a GasDS simulation have been shown in detail, starting from the characterization of the raw material to be processed, continuing with the balance equations that make up the core of the suite, and finishing with the set-up of a case study based on a steam-moderated oxy-gasification of hydrochar. The results include a detailed analysis of the syngas productivity and the  $H_2/CO$  ratio, which are fundamental KPIs for the steps following the thermal degradation. These parameters are shown as a function of the Equivalence Ratio (ER) and the oxygen content of the gasifying agent ( $O_2$  mol%). The GasDS suite allows to understand functional dependencies between the analyzed variables, deviations from engineering “best practices” shown by the system due to the unconventional feedstock, and even unfeasible operating conditions which would lead to a premature shut-down of the system. Thus, the suite can be used to model and optimize thermo-chemical waste recycling processes.

## Abstract

The present work intends to contribute to the supply chain design and planning, by addressing the technological learning due to non-mature technologies at biorefineries. The methodological approach combines optimization with discrete-event simulation, assessing its investment risk through the Conditional Value at Risk. Through the optimization model, the optimal strategic variables for the biomass supply chain under deterministic conditions are obtained. In contrast, the simulation model allows to analyze the technological uncertainty supported by the learning curve concept to evaluate the technologies' performance. The results highlight the advantage of exploring this combined approach to consider variability parameters for strategic and tactical solutions and the particular influence of technological learning in supply chain design and planning.

**Keywords:** Learning curves, Discrete-event simulation, Biomass, Supply chain design.

## 1. Introduction

Most decisions related to the design and planning of supply chains take place in an increasingly dynamic environment where variability is present at multiple decisional levels. The impact of uncertainty in decision-making has long been recognized, although modelling and solution approaches still call for improvements. For example, the complexity of strategic decisions is greatly influenced by the uncertainty on availability, quality, product demand, and process operations. Moreover, considering technological process parameters represent an additional challenge in their design and planning to ensure long-term financial viability. The general learning curve concept can be set to model the uncertain technological performance in adopting new technology. The mathematical relation reflects the technical and economic progress of the technology as users gain experience with time (Weiss et al., 2010). It is assumed that the learning factor can be translated into the technological conversion of the main process (e.g. the transesterification conversion factor from biomass to biodiesel), which becomes an uncertain parameter. In this study, we propose the development of an approach capable of modelling the impact of an expected technological development based on the learning curve concept. The approach is applied to the design and planning of integrated biorefineries supply chains. Integrated biorefineries are a promising alternative to bioenergy and biomaterials production, becoming an emerging industry where the technology performance involving biomass conversion at an industrial scale has yet to be

fully known. Therefore, the design and planning of integrated biorefineries involve a significant degree of uncertainty associated with the low maturity of technological learning, with correlated influence in the processing capacity and bioproducts availability or demand. In this scope of multilevel decision-support, discrete-event simulation (DES) can provide a useful approach to model uncertainty and evaluate a solution for the supply chain under different scenarios of the network.

The Portuguese case of a biomass supply chain is used as a real case study to illustrate the application of the proposed methodology. By combining optimization-based simulation, a detailed DES model allows to incorporate of the dynamics and uncertain conditions in the supply chain structure, evaluating a solution with the optimal number of integrated biorefineries, their location, capacities, and technology, while considering the assessment of their financial viability using Conditional Value-at-Risk (CVaR).

## 2. Methodology

The problem scope consists of assessing the biomass-to-biofuels supply chain design and planning through measuring the financial risk, with particular relevance to the technological uncertainty at integrated biorefineries. The learning curve is introduced to model the process conversion efficiency and its impact on the overall supply chain decisions. The methodology proposes an evaluation approach combining an optimization model which generates an initial deterministic solution, then simulated under the conditions of a detailed DES model with variable technological learning. Considering this overall perspective based on strategic long-term investment, the Conditional Value at Risk (CVaR) is used as a risk measure to evaluate the likelihood that a specific loss will exceed a certain value at risk. The hybridization of optimization with simulation excels in the advantages of having an analytical model that formulates a solution under ideal conditions, with a more precise simulation model that mimics how the system reacts under realistic outcomes and hard-to-model constraints (Figueira et al., 2014). The approach allows to explore alternative network solutions with reduced computational hindrance by accounting for the variability provided by uncertain operational parameters.

### 2.1. Supply chain simulation-optimization modeling

The approach combines an optimization model and a simulation model. A Mixed Integer Linear Programming model, based on Paulo et al. (2015), is implemented in GAMS to consider the supply chain superstructure with all possible locations of biomass sources (with the corresponding availability per type), biorefineries (set of available technologies and capacities), demand centers and transportation modes with the distances between all points. The objective is to minimize supply chain total cost, given by Eq.1, identifying the number, location, technology, and capacity of biorefineries to install, with the corresponding amounts produced and demand centers to serve, as well as the amount of biomass type collected at each source and transportation flows.

$$\min Total Cost = \sum (Biomass Cost + Fixed/Variable Operating Cost at Biorefiner + Transportation Costs + Annualized Investment Cost) \quad (1)$$

The DES model aims to represent the real-world environment (as is the Portuguese case) to evaluate the optimized solution under variable conditions. Through the SIMIO platform, the model computes multiple output scenario statistics involving the occurrence of events (e.g. a new bioproduct order) using probability distributions of parameters. The main library of objects available in the SIMIO software is used, which, in general, considers model entities (e.g., products) processed at servers (e.g., biorefinery), and then departs from the system. Suitable to the case level of detail, the focus is set on the impact

of the technological learning curve in the design capacity of the facilities to accommodate an expected increase in bioproduct demand. For simplification, the availability of biomass is considered non-limiting. Additional uncertainty in overall cost and prices forecast are introduced as sources of variability, being considered 1000 replications to guarantee statistical significance. The interaction of the two models aim to evaluate a supply chain configuration with a risk measure of the techno-economic investment viability. To account for the time value of money, the simulation model computes the net present value (NPV) of cashflow operations (Eq.2), for  $n$  time periods and  $CF_k$  as the annualized value of cashflows at time period  $k$  with  $i$  discount rate.

$$NPV = \sum_{k=0}^n \frac{CF_k}{(1+i)^k} \quad (2)$$

### 2.2. Learning Curves and Technological Conversion Efficiency

Empirical assessments can demonstrate that costs decrease with the gain of experience from the use of a particular technology, which usually translates in a performance improvement of the production process. There are different types of learning curves: the one-factor learning curve represents learning by accumulated production; the two-factor formulates learning by doing and by searching effects; and other multi-factor learning curves are explained by other factors. Although a detailed characterization of the learning process seems appealing, multiple factors are often difficult to quantify, therefore the one-factor learning curve is chosen for the development of the present work. Mapping the integrated biorefineries and the information on their specifications allow to find the trend of the process conversion efficiency for a given biomass-to-biofuel technology. And by defining these equations, it is possible to calculate values of conversion that reflects the learning-by-doing performance of each technology over the time horizon, which is expected to stabilize once reached a plateau (Weiss et al., 2010). The learning curve effect on costs can be generalized as a power law function given by (Eq.3), with  $CC_{cum}$  the unit cost of production in monetary units,  $CP$  the cumulated production amounts, and  $CC_{ref}$  and  $CP_{ref}$  the initial conditions at an arbitrary starting point.

$$CC_{cum} = CC_{ref} \left( \frac{CP}{CP_{ref}} \right)^{-\varepsilon} \quad (3)$$

The factor  $(CP/CP_{ref})^{-\varepsilon}$  represents the decrease ratio in the unit cost of production, with  $\varepsilon$  the learning coefficient related to the technology. Considering the conversion efficiency  $\mu$  as the ratio of the amount of bioproduct by the amount of biomass feedstock  $CB$  used to process it, the equation can be rewritten as (Eq.4).

$$CC_{cum} = CC_{ref} \left( \frac{\mu \cdot CB}{\mu_{ref} \cdot CB_{ref}} \right)^{-\varepsilon} \quad (4)$$

From (Eq.4), the relationship between the technological conversion efficiency and the learning-by-doing performance can be obtained. As higher the values of conversion, higher the accumulated production quantities obtained from the same feedstock, and therefore, lower unit production costs.

### 2.3. Financial risk assessment

Attracting investment to the biomass-based industry represents a substantial challenge, whereas making the supply chain efficient under uncertain technological process parameters increases the impact in its design and planning to assure a long-term viability. The assessment of uncertainty appeals for risk management studies and the research

community has been demonstrated their importance. The CVaR is a widely used risk metric to quantify the tail risk, where conclusions can be drawn to either downside losses or upside gains for an industrial investment, as demonstrated by Vieira et al. (2021). Given a discretized probability distribution function of NPV values, CVaR measures the weighted average outcome of far-edge tail events beyond the VaR for a specified confidence level ( $\alpha$ ). The VaR for downside losses is set as the outcome value for the  $(1-\alpha)$ -quantile of the distribution. The CVaR is given in (Eq.5), multiplying the probability of scenario  $s$  occurrence  $\Pi_s$  by the positive variable  $\delta_s$  calculated in (Eq.6), which measures the positive difference between the VaR and the NPV of each shortfall scenarios.

$$CVaR = VaR - \frac{1}{1-\alpha} \sum_s \Pi_s \delta_s \quad (5)$$

$$\delta_s = VaR - NPV_s, \delta_s \geq 0 \quad (6)$$

### 3. Case Study and Results

The described methodology has been applied to an illustrative case study of biomass supply chain of bioethanol and biodiesel production in Portugal. Supply chain characteristics and data considered in this study is summarized on Fig.1, considering two technologies – fermentation for bioethanol and transesterification for biodiesel.

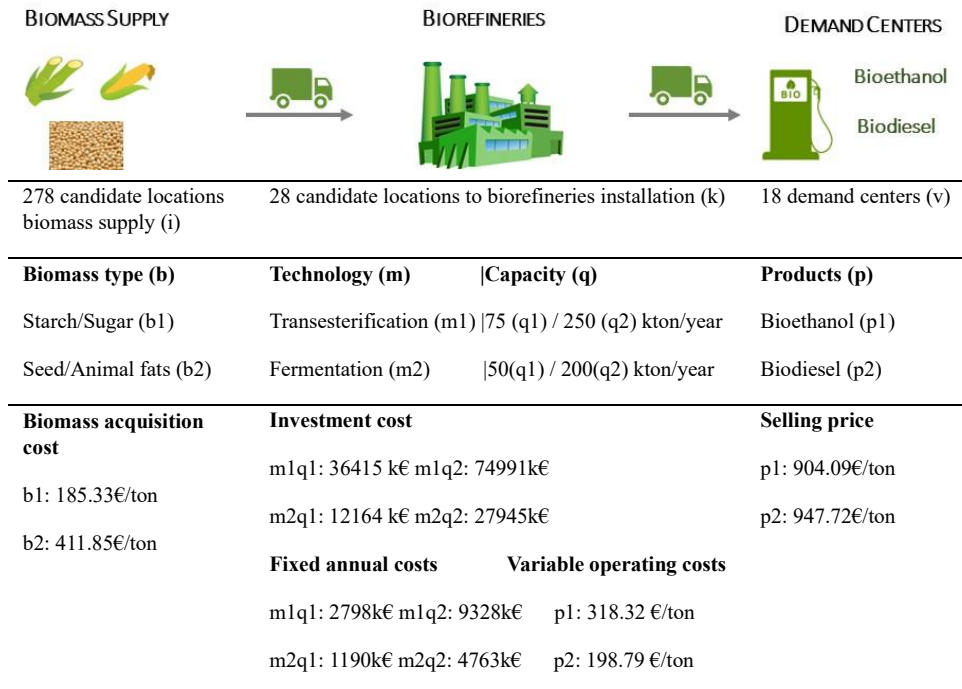

Figure 1. Case study data

The initial solution provided by the optimization model defines the supply chain superstructure, identifying 4 biorefineries to install. Lisboa, Pombal and Vila Real are the selected locations to install biorefineries using fermentation technology, with a processing capacity of 250 000 tons and 75 000 tons of bioethanol, respectively.

Santarém is selected to install a transesterification biorefinery of 50 000 tons of production capacity for biodiesel. The optimal solution also defines the biomass flows from each collecting point to each biorefinery, as well as the product flows to each demand center. This information is used to compile the simulation model details. With regard to the learning curve integration, it is considered that the two technologies selected have dissimilar characteristics in its learning-by-doing progress. From the work by Seabra (2021) based on real data, the equations used to calculate the decreasing costs for each level  $n$  of accumulated production for the fermentation ( $m1$ ) and transesterification ( $m2$ ) processes were, respectively (Eq.7) and (Eq.8).

$$CC_{n\ m1} = 534.43 (CP_{n\ m1}/10000)^{-0.3219} \tag{7}$$

$$CC_{n\ m2} = 282.10 (CP_{n\ m2}/10000)^{-0.1520} \tag{8}$$

The derived conversion efficiency trends are translated by (Eq.9) and (Eq.10), whereas the values pondered for the first time period were set as  $\mu_{fermentation}=25.58\%$  and  $\mu_{transesterification}=27.51\%$ .

$$\mu_{fermentation} = 0.055(t - 1) + 0.2558 \quad \forall t > 1 \tag{9}$$

$$\mu_{transesterification} = 0.035(t - 1) + 0.2751 \quad \forall t > 1 \tag{10}$$

It should be noted that the biomass conversion efficiency progress is expected to stabilize, which the study by Sharew et al. (2022) suggested the interval [46%-56%] for these technologies, so it is assumed a plateau value of 51%. This is added to the characteristic of each corresponding biorefinery in the model, which computes the statistical simulation for a time horizon of  $n=10$  years, and the NPV considering the defined parameters distributions, such as cost and price variability, with a discount factor  $i$  of 10%. Assuming the scenario where the transition to biofuels is fostered, the increase in the demand follows a uniform distribution between 2-4%. The results displayed in Fig. 2 demonstrates the output simulation replications, represented by a probability distribution, which enable the calculation of the CVaR by discretizing the scenarios under the VaR for a confidence level of 95% (13,6.10<sup>6</sup>€). The value of CVaR means that the proposed supply chain configuration and scenario conditions guarantees at least a NPV of 12,1.10<sup>6</sup>€ with a 95% of probability.

Figure 2 – Risk evaluation results: NPV VaR and CVaR representation

With Fig. 3 it is possible to analyze the learning curve effect in the increase of overall capacity of the biorefineries, as well as its utilized capacity while accommodating the demand increase. For example, Lisboa and Vila Real show a higher utilization of its installed capacity, while the remaining recommend to evaluate an alternative scenario of a reduced capacity or network configuration. Likewise, sensitivity analysis to learning curve progress can be simulated, for example the CVaR obtained, for a 95% confidence level, with an increase of 0,5% in the learning rate (faster learning) rises to 20,1.10<sup>6</sup>€, while a decrease of 0,5% (slower learning) generates a probable downside loss of 3,9.10<sup>6</sup>€.

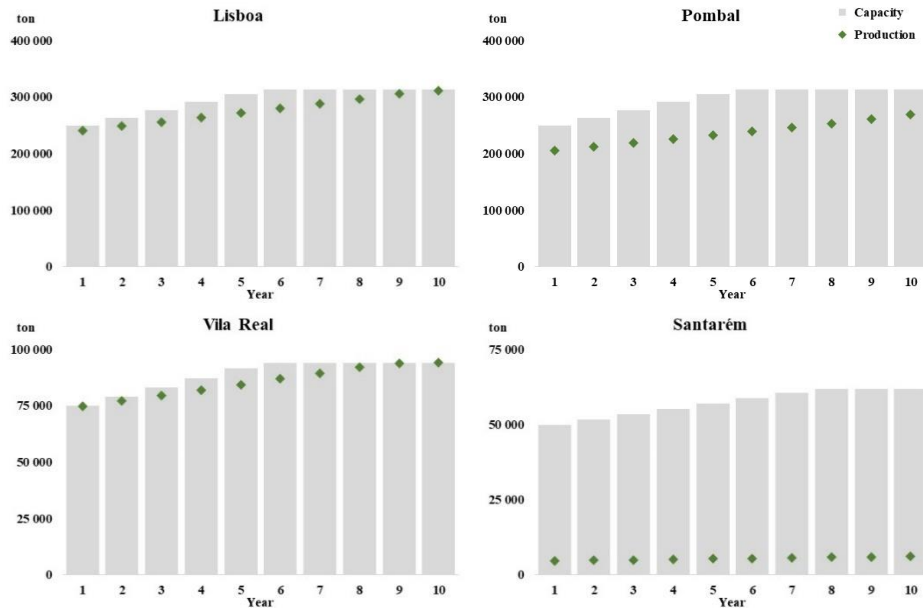

Figure 3 – Biorefineries installed capacity (bars) and production (dots) by year

#### 4. Conclusions

This work explores the effect of learning-by-doing in non-mature technologies over the biomass supply chain performance. The methodology measures the investor risk by combining simulation and optimization techniques, allowing to explore an optimal-based solution through the simulation of variable dynamic conditions, parameters distributions, and technological learning conversion. By using CVaR to measure NPV as an investment risk, the decision maker is able to have more robust information on its viability, as well as to evaluate alternative scenarios. The results demonstrate the impact of different learning rates and uphold the simulation of alternative configurations to the supply chain design, pursuing the assessment of the multiple uncertainty factors affecting these decisions.

## Abstract

Natural gas is stored as Liquefied Natural Gas (LNG) under cryogenic conditions in a storage tank. The tank is highly insulated; nevertheless, there is heat ingress from the surrounding, causing the generation of boil-off-gas (BOG). BOG generation over-pressurizes the tank and can lead to tank failure, so proper BOG management is critical to plant safety. This paper seeks to develop a data-driven model for a real industrial LNG terminal. Modeling was performed on historical real-time LNG data using different machine learning algorithms - Linear regression, Random Forest, and XGBoost. The performance of algorithms is analyzed based on  $R^2$ , Mean-Absolute-Error (MAE %), and Root-mean-square error (RMSE %) values. The critical input features are calculated based on the Shapley additive explanation method (SHAP value); less important features were removed to decrease the model complexity. Our studies show that Random Forest outperforms the other two algorithms in terms of accuracy. The developed model can help plant operators make decisions quickly with better confidence.

**Keywords:** Data-driven modeling, Liquefied Natural Gas, Boil-Off-Gas, BOG management, Machine learning.

## 1. Introduction

Natural gas (NG) is considered one of the cleanest fossil fuels, with a variety of end-uses, including fertilizer production, power generation, along with industrial and residential heating. With the global annual consumption of NG being 4.04 Tm<sup>3</sup> (Statistical Review of World Energy, 2021), it is likely to become the second most widely used fossil fuel by 2035. It is globally traded in its liquefied form (LNG) via specialized carriers that transport LNG from suppliers to receiving terminals, where it is unloaded into storage tanks. Storing LNG under cryogenic conditions enables safe, convenient, and cost-effective distribution. However, continuous heat ingress from the surrounding environment causes the vaporization of LNG, known as boil-off gas (BOG). When LNG of two different densities is stored in the same storage tank, rather than forming a homogeneously mixed liquid, it can result in stratification. This is because when the different layers are mixed, a significant amount of BOG is generated due to interface disruptions, and the tank pressure builds up. This heterogeneous mixing phenomenon is termed rollover. In this work, the broad objective is to prevent or alleviate the adverse consequences of rollover.

Rollover is a common problem across storage units in LNG supplier facilities, FSRUs, LNG carriers, and regasification terminals, with a higher frequency of occurrence at the latter (Energy report, 2018). Rollover can have catastrophic repercussions; for example, the incidents at La Spezia (Italy, 1971) and Partington (the UK, 1993) are prominent examples of how BOG generation due to rollover can have devastating impacts on the regasification terminal, causing significant economic losses. According to the GIIGNL 2019, more than 24 rollover incidents have been reported over the last 60 years. Such events are continuously increasing due to the ever-increasing use and trade of LNG. The amount of BOG generation during a rollover is enormous; nevertheless, the mechanism is, until now, not fully understood. Therefore, it is essential to develop a model to predict the rate of BOG generation in the LNG regasification terminal.

The basics of rollover and the rate of BOG generation have been the subject of several studies. These have a theoretical, experimental, or numerical foundation. Theoretical studies concentrated on how many intermediate stages were assumed to better comprehend rollover events, such as two-stage (Heestand, 1983), three-stage (Koyama, 2007), and four-stage (Li, 2015). Experimental studies focused on the effects of LNG composition, initial concentration difference (Munakata, 1994), visual observations of boundary layers, and formation and decomposition of evolved LNG layers (Bates, 1997). Numerical studies involved computations based on different geometries, modes, and angles of LNG filling (Hubert, 2019; Saleem, 2020) that can include initial conditions and boundary conditions (Zakaria, 2017), interface instability (Wei, 2018), among other factors. However, all of them are computationally expensive and difficult to model. Making industrial decisions based on these models during critical situations is difficult. We aim to address this issue in the current work. In this paper, we develop a data-driven model based on collected historical data to predict the rate of BOG generation in an LNG tank in a regasification terminal. The modelling was performed by using a simple linear model (Linear regression (LR)) as well as more complex nonlinear models (Random Forest (RF) and XGBoost). Further, the performance of all three models is analyzed to select the best model. Finally, the model is used to perform various case studies based on industrial problem scenarios.

## **2. Process description**

In the LNG regasification terminal, LNG is imported through ships and unloaded into the highly insulated storage tank. This stored LNG is continuously supplied to the customers, and whenever the tank level reaches the minimum value, a new ship arrives for fresh LNG unloading. The LNG in the tank is stored nearly at its saturation temperature under atmospheric pressure. The continuous heat ingress from the surroundings to the tanks and pipeline increases the temperature of LNG. Due to this, LNG evaporates and forms BOG, which leads to pressure build-up in the tank. For the safety of the tank and regasification terminal, the generated BOG is continuously removed from the tank through a compressor. The generated BOG contains nearly 99% methane, which has the highest calorific value, and its removal reduces the overall calorific value of LNG. The BOG can be managed in various ways within the plant, such as (1) directly supplied to the customer, (2) recondensed back to the tank, and (3) flared in of the plant. These methods are either not economically suitable or permissible due to environmental concerns. So, it is crucial to understand the behavior and BOG generation rate under various conditions and operate the plant so as to reduce BOG formation. A data-driven model is developed for this purpose.

### *2.1. Data collection*

Industries continuously monitor the pressure inside the tank and accordingly estimate the BOG generation. For process control and operations, various other variables like temperature and density of LNG, tank vapor pressure, LNG level, compressors operation, and LNG outflow are also continuously monitored. These data are continuously monitored and saved on an hourly basis between two consecutive LNG ship unloading.

This research aims to predict the rate of BOG generation under various conditions and under the influence of various parameters. Thus, an accurate relationship has to be established between the input and output variables. The model input variables are LNG level ( $x_1$ ), LNG density at the top ( $x_2$ ), LNG density at the bottom ( $x_3$ ), LNG temperature at the top ( $x_4$ ), LNG temperature at the bottom ( $x_5$ ), vapor pressure ( $x_6$ ), LNG outlet flowrate ( $x_7$ ) and operation mode of two compressors ( $x_8$  and  $x_9$ ). The model output variable is the rate of generation of BOG ( $y$ ) in the LNG storage tank.

In our work, we have used historical real-time data of all the input and output variables collected over nearly one month (934 datasets) for model development. These data are collected every second but saved at every hour interval (sampling time) for future study purposes. The data consists of various missing values and outliers, so proper data pre-processing is necessary. In our case, as the number of missing values (1.60%) and outliers (0.96 %) are small, we removed those samples from the datasets. The whole dataset of every month is segregated into different segments based on the mode of operation in the regasification terminal. The first mode considered is the unloading operation, where LNG is unloaded from an LNG ship to the storage tank. The second mode is normal operations when there is no input to the tank, but LNG is sent to the regasification process, and the gas is sent-out to customers. In this paper, we consider the latter, i.e., the normal operations mode. The data from normal operations is split into training and testing data sets in the ratio of 4:1. The training datasets are used to develop various models based on different machine learning algorithms.

## **3. Results and discussion**

The approach considered to establish a relationship between input and output features includes (1) data collection, (2) data pre-processing, (3) designing a model, (4) training with suitable algorithms, and (5) model validation. Initially, the nine input features mentioned above were used to design the model without considering the effect of time (i.e., a steady-state model was developed). We start from the simple LR model and then compare its performance against two nonlinear models – RF and XGBoost. The model's performance was further enhanced by removing outliers. Finally, a complete comparison of all three models with and without outliers is considered in the analysis, and results are reported accordingly in the results and discussion section.

### *3.1. Linear Regression*

In this section, the model is trained using multivariate linear regression, and the results are analyzed. The model was initially trained by considering the outliers and then checked the performance based on both training and testing datasets. The results clearly show that the presence of outliers in the training and testing datasets decreases the model's accuracy. The accuracy of the model was further improved by removing outliers from both training (0.64 %) and testing (0.32 %) datasets. The performance of both results is compared by calculating the R-Square value ( $R^2$ ), Mean-Absolute-Error (MAE %), and Root-mean-square error (RMSE %). After removing the outliers, the  $R^2$  value improved from 0.84 to

0.95 in training and from 0.82 to 0.96 in the testing datasets. Similarly, MAE (%) enhanced from 3.66% to 2.21% in training and 4.23% to 2.29% in testing datasets, and RMSE (%) improved from 5.5% to 3% in training and 6.3% to 2.9% in testing datasets. The mode of compressor operation, tank pressure, bottom layer temperature and LNG level are considered as important variables in the linear regression modelling.

In order to improve accuracy, two nonlinear machine learning algorithms Random Forest (RF) and XGBoost were also studied.

### 3.2. Random Forest

In this section, the model is trained and tested based on Random Forest (nonlinear algorithm). The value of  $R^2$  remains 0.99 in both cases in training datasets, while it increases from 0.88 to 0.99 in testing datasets. Similarly, the value of MAE (%) and RMSE (%) remain the same at 0.49% and 1.23% with the training datasets, while it improves from 1.29% to 0.65% and 5.03% to 1.02% in testing datasets, respectively. The model indicates mode of compressor operation, LNG level and LNG density plays crucial role in the generation of BOG in the storage tank.

### 3.3. XGBoost

The performance of XGBoost algorithm is also good but lesser than the RF algorithm. The value of  $R^2$  remains 0.98, which is unchanged with or without considering the outliers in training datasets, while it improves from 0.88 to 0.99 in testing datasets. Similarly, the MAE (%) and RMSE (%) value remains the same at 1.15% and 1.83% in training datasets, while it improves from 1.68% to 1% and 5.82% to 1.32% in the testing dataset, respectively. This algorithm suggested mode of compressor operation, LNG level, LNG outflow and LNG temperature are important input variables.

**Table 1.** Comparison of the performance of LR, RF and XGBoost, based on  $R^2$ , RMSE (%) and MAE (%)

Models		$R^2$		RMSE (%)		MAE (%)	
		Training datasets	Testing datasets	Training datasets	Testing datasets	Training datasets	Testing datasets
Linear regression	With outliers	0.84	0.82	5.50	6.30	3.66	4.23
	Without outliers	0.95	0.96	3.00	2.90	2.21	2.29
Random Forest	With outliers	0.99	0.88	1.23	5.03	0.49	1.29
	Without outliers	0.99	0.99	1.23	1.02	0.49	0.65
XGBoost	With outliers	0.98	0.88	1.83	5.82	1.15	1.68
	Without outliers	0.98	0.99	1.83	1.32	1.15	1.00

The comparison of all three models revealed that the mode of compressor operation has a significant impact on the rate of BOG generation. The compressor operation at lower capacity increases vapor pressure inside the tank, resulting in a lower rate of BOG generation. Another important variable suggested by the models are LNG level in the

tank. The LNG level provides direct information about the volume of LNG in the storage tank. Thus, higher volume results more generation of BOG.

### 3.4. Performance of models

The performance of the three models (LR, RF and XGBoost) are compared on training and testing data sets with and without considering the outliers. The performance of the Linear regression model is the least as compared to the other two nonlinear models. Among the two nonlinear models, the RF has better performance than XGBoost. The performance of all three models can easily be visualized in Fig. 1 and table 1 based on  $R^2$ , MAE and RMSE values.

### 3.5. Sensitivity analysis

The sensitivity analysis of the model helps to calculate the contribution of each individual feature in the output features. Initially, all the measurable input features (9 features) are used for modelling, but it may be possible that the model is independent of some of the input features. These extra independent features increase the complexity of the model and are responsible for both overfit and increased simulation time for large datasets. To avoid these possibilities, a sensitivity analysis was performed and analyzed the features really crucial for the modelling by using Shapley additive explanation method (SHAP value). By considering all nine input features, the SHAP value is calculated and reported in Fig. 2. (a). The lowest SHAP value input features have to be removed, and checked the performance of the model. Similarly, one by one, input features have to be removed and reviewed the performance of the model until a significant decline is observed.

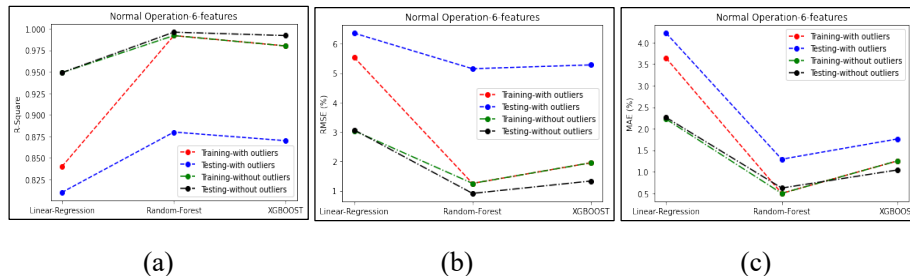

Fig. 1. Comparison of the performance of LR, RF and XGBoost with 6 input features, based on (a)  $R^2$ , (b) RMSE (%) and (c) MAE (%) with and without considering the outliers in both training and testing dataset

Fig. 2. Comparison of the mean (SHAP) value by considering (a) 9 input features, and (b) 6 input features in the model

In this modelling, we would not have observed a significant change in the model's performance after removing the three lowest SHAP value (Fig. 2 (b)) input features (top-temperature, bottom-temperature and LNG flowrate). Thus, six input features have to be considered in the model and the performance reported in Fig. 1 (a), (b), and (c).

#### 4. Conclusions

A data-driven model is used to predict the rate of boil-off-gas (BOR) generation during normal operation in an industrial LNG storage tank based on different linear and nonlinear machine learning (ML) algorithms. The three different ML algorithms (Linear regression, Random Forest and XGBOOST) are used to model the data by considering nine input features and checking the accuracy of the model. The performance of all three algorithms is analyzed based on  $R^2$ , MAE (%) and RMSE (%) values. Out of all three algorithms, the performance of Random Forest is considered to be the best, with  $R^2$  value of 0.99 in training datasets with and without outliers. The performance of  $R^2$  in testing datasets improve from 0.88 with outliers to 0.99 without outliers.

Further, sensitivity analysis is performed using the SHAP value method to find the important input features for the model. The input features with lesser SHAP values are removed one by one from the model and again checked the performance of the model. After removing top layer temperature, bottom layer temperature and LNG outlet flow rate, the performance of the model remains almost the same in both the training and testing datasets. This analysis indicates that the remaining six input features – compressor operation of 1 and 2, level of LNG, bottom LNG density, top LNG density and tank vapor pressure – play the most important role in BOG generation in the industrial LNG storage tank. Specifically, the mode of compressor operation and the LNG level are the most significant features. While the resulting model has good overall performance, it has several limitations. The dynamic behavior of the system, i.e., the temporal dimension is not considered in this model. The model also does not cover other operating modes such as LNG unloading, compressor maintenance, and special events like rollover. These will be addressed in our future work. Also, other input features like the effect of ambient temperature, and dimensions of the LNG tank would be incorporated into the model.

# Synthesis of process configurations and solvent blend for CO<sub>2</sub> capture from CCGT power plants

Nahyan Arshad,<sup>a,b</sup> Ahmed Al Hajaj,<sup>a,b</sup>

<sup>a</sup>*Department of Chemical Engineering, Khalifa University of Science and Technology, Abu Dhabi, UAE*

## Abstract

Post-combustion CO<sub>2</sub> capture (PCCC) from flue gas of power plants is a promising route to mitigate the climate change in the near term. However, high energy consumption remains the major challenge of MEA based PCCC process. This study aims to investigate the potential of a hybrid approach by replacing MEA with an energy efficient MDEA/PZ blend and applying process configurations to have the maximum reduction in the regeneration energy. Rigorous rate-based model of a MDEA/PZ based PCCC process integrated with a 750 MW CCGT power plant was developed in Aspen Plus. In addition, the study examined the synergistic effects of combining three process configurations in a single flowsheet on the regeneration energy. The energy analysis results show that AIC+RSS+LVC is the energy-optimal combination as it provides the lowest regeneration energy (2.12 GJ/t<sub>CO2</sub>). However, considering the significant electricity consumption by the lean vapor compressor, the equivalent energy results highlight that AIC+RSS+IHS is the optimum combination as it results in lowest equivalent energy (0.985 GJ/t<sub>CO2</sub>) corresponding to an overall energy saving of 8.96%.

**Keywords:** Post-combustion CO<sub>2</sub> capture; MDEA/PZ; Process configurations; Energy savings

## 1. Introduction

The significant use of fossil fuels for energy generation has resulted in high concentration of CO<sub>2</sub> in the atmosphere which primarily contributes to the global climate change. Combined Cycle Gas Turbine (CCGT) power plants are rapidly adopted worldwide for energy generation compared to coal power plants due to higher energy efficiency, lower CO<sub>2</sub> emissions rate and flexible power output; hence, they can be used in conjunction with variable renewable energy sources (Cheng et al.,2022). One of the key pathways to minimize the anthropogenic CO<sub>2</sub> emissions in the short term is Post Combustion CO<sub>2</sub> Capture (PCCC) using amines due to its technological maturity and large-scale availability. Monoethanolamine (MEA) is the benchmark solvent in PCCC applications due to its low cost, low volatility, low viscosity, and high absorption kinetics at low CO<sub>2</sub> concentrations as in the case of flue gases from power plants. In the recent years, research experts have proposed various solvents with optimal properties for CO<sub>2</sub> capture such as ammonia, ionic liquids, deep eutectic solvents and water lean solvents. However, the commercial applications of these solvents are still immature and require further testing to evaluate their techno-economic feasibility at industrial scale (Li et al.,2016). One of the major limitations of MEA based PCCC process is the significant thermal energy requirement for CO<sub>2</sub> desorption which accounts for majority of the energy consumption

and operational costs of the process (Li et al.,2016). Other limitations of MEA include high corrosion and degradation which increases the solvent makeup costs.

The two practical ways of reducing this high energy demand are the development of energy efficient solvents and synthesis of process configurations. Methyldiethanolamine (MDEA) is a potential solvent to replace MEA as it has attractive properties for CO<sub>2</sub> capture such as higher CO<sub>2</sub> absorption capacity, lower regeneration energy and degradation rate compared to MEA (Ibrahim et al.,2014). The major drawback of MDEA is the low CO<sub>2</sub> absorption rate which increases the capital costs associated with height of the absorber column. This limitation of MDEA can be improved by blending it with an absorption kinetics promoter. Among the amine family, Piperazine (PZ) has the highest CO<sub>2</sub> reaction kinetics as it rapidly forms carbamates with CO<sub>2</sub>; hence it can be considered as an efficient absorption kinetics promoter in tertiary amines such as MDEA (Ibrahim et al.,2014). The experimental study by Bishnoi and Rochelle showed the absorption rate of MDEA/PZ blend is comparatively higher than MDEA/MEA and MDEA/DEA blends (2002). Khan et al. (2020) evaluated the CO<sub>2</sub> absorption rate and regeneration energy of MDEA/PZ at varying concentrations of PZ. The Aspen Plus results of the study revealed that the optimum concentration ratio of MDEA/PZ is 30/20 wt%. The other approach to reduce the high energy demand is process configurations which are modifications in PCC plants to reduce the parasitic energy consumption of the capture process. The configurations evaluated in this paper include Absorber Inter Cooling (AIC), Rich Solvent Preheating (RSP), Rich Solvent Split (RSS), Rich Solvent Flash (RSF), Lean Vapor Compression (LVC), Rich Vapor Compression (RVC) and Inter Heated Stripper (IHS).

Majority of the studies on process configurations were based on MEA and very few studies have examined the potential of MDEA/PZ and configurations on the energy requirement of PCCC process. Therefore, this paper focuses on a combined approach of replacing MEA with MDEA/PZ blend and applying process configurations to maximize the reduction in the regeneration energy. In addition, previous work on process configurations have considered few individual configurations and single combination of three configurations due to convergence challenges. Hence, there is a need to examine several individual configurations and multiple combinations of three configurations in a single flowsheet to demonstrate the cumulative effect of combining three configurations on the regeneration energy of MDEA/PZ process. This work aims to evaluate the performance of seven process configurations and their combinations on the regeneration energy of MDEA/PZ based PCCC process integrated with a 750 MW CCGT power plant. Rate-based model was developed followed by a detailed energy analysis to identify the optimum combination interms of overall energy savings.

## **2. Methodology**

### *2.1 Baseline CO<sub>2</sub> Capture Process*

A conventional CO<sub>2</sub> capture process is shown below in Fig 1. The hot flue gas (106°C) composed of 74.32% N<sub>2</sub>, 12.09% O<sub>2</sub>, 8.67% H<sub>2</sub>O, 4.04% CO<sub>2</sub> and 0.88% Ar from a 750 MW CCGT power plant was pre-cooled to 40°C in a direct contact cooling (DCC) column. The cooled flue gas then enters the bottom of the absorber column with lean solvent fed from top of the absorber to allow efficient chemical absorption of CO<sub>2</sub> from flue gas into lean solvent. The capture rate is set at 90% after which the lean flue gas leaves from top of absorber to a waterwash unit to condense any escaped solvent vapor. The rich solvent from absorber is preheated in a Lean Rich Heat Exchanger (LRHX) followed by the desorption of CO<sub>2</sub> at elevated temperatures in a stripper column. The hot lean solvent

from the reboiler is pre-cooled in the LRHX after which it is recycled back to the top of absorber. The desorbed CO<sub>2</sub> is cooled in an overhead condenser and sent to a compression train which compresses the CO<sub>2</sub> product to 152 bars for storage purposes.

Figure 1: Conventional CO<sub>2</sub> Capture Process

### 2.2 Thermodynamic and Rate Based Model

The process model for the MDEA/PZ based CO<sub>2</sub> capture was developed in Aspen Plus V10 software. The liquid properties of the ionic species were computed by the Electrolyte Non Random Two Liquid (ENRTL) method while the vapor properties of the species were computed using Redlich Kwong (RK) Equation of State. The equilibrium and kinetic reactions of the MDEA-PZ-CO<sub>2</sub>-H<sub>2</sub>O system were the same as in the inbuilt MDEA/PZ CO<sub>2</sub> capture model in Aspen Plus.

The absorber and stripper columns were modeled using the rate-based modeling as it considers mass transfer resistance between phases and reaction kinetics assuming equilibrium only at the fluid interface. Hence, rate based modeling provide more reliable results for column design compared to equilibrium based modeling. The initial data for rate-based modeling such as packing specifications, film resistance, mass and heat transfer correlation methods, etc was obtained from the work of Li et al. (2016).

### 2.3 Equivalent Energy

Equivalent energy is a standard KPI which unifies the thermal and electrical energy consumptions to make a reasonable comparison of overall energy consumption of conventional process with process configurations such as LVC and RVC consuming additional electrical energy. The equation to determine equivalent energy is shown below where the first part represents the equivalent electrical penalty of thermal energy while the second part represents the electrical energy consumed by compressors and pumps in the process.

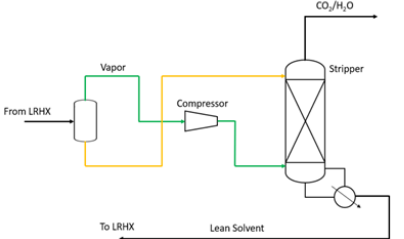

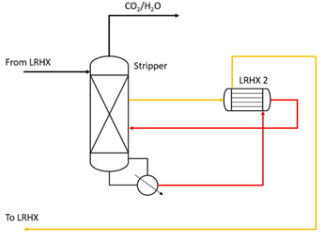

$$E_{eq} = 0.75Q_{reb} \left( \frac{T_{reb} + 10K - T_{sink}}{T_{reb} + 10K} \right) + E_{elec}$$

### 2.4 Process Configurations

The descriptions and schematics of process configurations evaluated in this study are summarized in Table 1:

Table 1: Description and Schematics of Process Configurations

Configuration	Description	Schematic
Absorber Inter Cooling	Extraction and cooling of a portion of semi-rich solvent to enhance the driving force for CO <sub>2</sub> absorption	
Rich Solvent Preheating	Additional heating of the preheated rich solvent after LRHX to lower the amount of energy required to heat the solvent	
Rich Solvent Split	Splitting of rich solvent into cold stream which enters from top of stripper and heated stream which enters from middle to allow pre-stripping of CO <sub>2</sub> from hot vapors	
Rich Solvent Flash	Flashing of the heated rich solvent after which vapor is sent to overhead condenser to reduce the heat required for CO <sub>2</sub> desorption	
Lean Vapor Compression	Flashing of the lean solvent followed by the compression and reinjection of vapor into stripper to minimize steam requirement in the reboiler	

<p>Rich Vapor Compression</p>	<p>Flashing of the rich solvent followed by the compression and reinjection of vapor into stripper to lower reboiler's steam demand</p>	
<p>Inter Heated Stripper</p>	<p>Withdrawing and heating of semi-lean solvent using heat from hot lean solvent from reboiler to reduce sensible heat required in the stripper</p>	

### 3. Results and Discussion

The summary of regeneration energy, equivalent energy and percentage energy savings for the individual and combined process configurations are presented below in Table 2:

Table 2: Summary of Energy Analysis Results

Configuration	Regeneration Energy (GJ/tCO <sub>2</sub> )	Equivalent Energy (GJ/tCO <sub>2</sub> )	% Savings in Energy
Base Case	2.87	1.082	-
AIC	2.58	1.046	3.33
RSP	2.97	1.102	-1.85
RSS	2.76	1.070	1.12
RSF	2.87	1.083	-0.10
LVC	2.38	1.053	2.68
RVC	3.02	1.135	-4.90
IHS	2.72	1.058	2.22
AIC+RSS+LVC	2.12	0.996	7.95
AIC+RSS+IHS	2.30	0.985	8.96
AIC+IHS+LVC	2.18	1.002	7.40
RSS+IHS+LVC	2.22	1.011	6.56

#### 3.1 Discussion of energy analysis results

The results presented in the above table demonstrate that AIC provided the highest savings in equivalent energy (3.33%) as it enhances the absorption capacity of MDEA/PZ blend, thus reducing the regeneration energy. RSP provided negative energy savings (-1.85%) due to consideration of additional heat consumption by the preheater in the overall energy analysis. The integration of waste heat from flue gas cooling process for the rich

MDEA/PZ preheating process is not possible due to significant difference in specific heat capacities of flue gas and rich MDEA/PZ. RSS resulted in an energy savings of 1.12% as there is less pre-stripping of CO<sub>2</sub> by hot vapors from heated fraction of amine, hence having less impact on the driving force for CO<sub>2</sub> desorption. RSF had negligible energy savings (0.10%) as the reduction in regeneration energy was almost equivalent to an increase in the sensible heat demand in the stripper due to flashing the heated rich solvent. LVC and RVC have similar mechanisms; however, the results demonstrate that LVC provided positive energy savings (2.68%) while RVC resulted in negative energy savings (-4.90%). This is because the electrical energy consumption by rich amine compressor and pump is relatively higher than the thermal energy reduction by RVC. IHS provided an energy savings of 2.22% as the heating of semi lean solvent elevates the temperature of the stripper which enhances the CO<sub>2</sub> desorption kinetics, thus lowering the overall energy requirement.

Various combinations of three configurations were proposed, so the advantages of each configuration can be combined to have the maximum reduction in the regeneration energy. The energy analysis results show that all combinations resulted in positive energy savings with AIC+RSS+LVC providing the lowest regeneration energy (2.12 GJ/t<sub>CO2</sub>). However, LVC consumes substantial amount of electrical energy which reflects in the equivalent energy results concluding that AIC+RSS+IHS as the optimal combination in terms of overall energy savings (8.96%). In comparison to MEA base case (1.202 GJ/t<sub>CO2</sub>) present in the literature, the hybrid case (MDEA/PZ and AIC+RSS+IHS) provides 18.2% savings in the equivalent energy.

#### 4. Conclusion and Future Work

This study investigated the performance of seven process configurations and their combinations applied to MDEA/PZ based PCC process attached with 750 MW CCGT power plant. In addition, the study demonstrated that combining three configurations showed higher energy savings than individual configurations due to combined advantages of each configuration. The results of the energy analysis conclude that AIC+RSS+IHS is the optimum combination based on the equivalent energy savings. The future work should include a detailed techno-economic analysis to gain deeper insights on the tradeoffs between energy savings and higher capture costs of different configurations in order to identify optimum combination in terms of energy and cost savings.

# PREDICTION OF BIOMEDICAL WASTE GENERATION IN SANITARY EMERGENCIES FOR URBAN REGIONS USING MULTIVARIATE RECURRENT NEURAL NETWORKS

Nicolas Galvan-Alvarez<sup>a</sup>, David Rojas-Casadiago<sup>a</sup>, Viatcheslav Kafarov<sup>a</sup>,  
David Romo-Bucheli<sup>a</sup>

<sup>a</sup> *Universidad Industrial de Santander, Bucaramanga, Santander, Colombia.*

## Abstract

Biomedical waste (BMW) generation is severely affected by generalized sanitary emergencies such as epidemics, as shown recently during the COVID-19 pandemic. These sanitary emergencies often increase plastic use in personal protection items, single-use plastics, and other healthcare elements. This increase might surpass the capacity of the waste management mechanism of a specific region, leading to a potential increase in its population health risks. Predicting the trends of BMW generation is not straightforward because it depends on several variables associated with the local health system and the health emergency status. However, a substantial amount of work has been done in epidemics modelling. Our main hypothesis is that BMW generation is strongly associated with sanitary emergencies dynamics. We propose a simulation framework that uses historical data from an ongoing sanitary emergency to build a model that can predict BMW generation trends in urban regions of developing countries.

**Keywords:** Biomedical waste, Simulation, Epidemics, Neural networks, Developing countries.

## 1. Introduction

Biomedical waste (BMW) is defined as any waste produced during the diagnosis, treatment, or immunization of human or animal research activities or in the production or testing of biological or in health camps. Recently disposal of BMW has become a major problem all over the world due to the influence of health emergencies such as epidemics on the generation of this type of waste. Specifically, the COVID-19 pandemic has exacerbated the problem of BMW management in several regions around the world. For instance, the world health organization (WHO) estimates that between March 2020 and November 2021, approximately 87,000 tons were purchased and are presumed to have ended up as waste (WHO, 2022). Also, according to press releases in March 2021, the generation of medical waste (infectious and non-infectious) increased significantly (+370%) in Hubei Province, with a high proportion of plastics. Additionally, from January 20 to March 31, 2020, accumulated medical waste across China was estimated at 207 kt, and in Wuhan medical waste increased from a normal level of 40 tons per day (t/d) to a peak of 240 t/d, exceeding the maximum incineration capacity in that city of 49 t/d (Klemeš, 2020). The purpose of this work is to develop a prediction model to estimate

the amount of BMW during different scenarios associated with sanitary emergencies, such as the COVID-19 pandemic. The main motivation of this type of simulation models would be to inform the government institutions in the selection of strategies for BMW management and avoid potential health risks.

## 2. Related Work

Several strategies have been used to simulate waste generation and treatment. Kannangara et al. carried out a simulation study for waste management. The purpose was to develop models for accurate prediction of municipal solid waste generation and diversion from demographic and socioeconomic variables (Kannangara, 2018). Additionally, in May 2021, an article was published by Vu et al. in which machine learning models are used for modelling municipal solid waste disposal rates during COVID-19 (Vu, 2021). On the other hand, Yu et al. proposed a reverse logistics network strategy to address the drastic increase in healthcare waste generation during the pandemic (Yu, 2020). This reverse logistics network aims to optimize decisions to establish temporary waste management facilities and transportation strategies at different stages. Similarly, in 2022 Chowdhury et al. carried out a simulation study by calculating the amount of waste generated per patient. A full estimate of the healthcare waste generated from March 2020 to May 2021, during the COVID-19 pandemic in the period, depended on whether the patient is infected, isolated, deceased, ICU or in quarantine (Chowdhury, 2022). The main contribution of this work is the development of a simulation strategy aiming to predict the amount of BMW in a specific geographical region based on epidemics variables. The simulation integrates a “Susceptible Exposed Infectious Recovered Deceased” (SEIR-D) compartmental model and a multivariate RNN (LSTM) model. The integrated strategy leverages the SEIRD model, broadly known in epidemics modelling, to analyze different sanitary emergency scenarios (pessimistic, neutral, and optimistic). The SEIR-D model generates synthetic data associated with the number of cases and deaths. These variables are then fed to the LSTM to simulate BMW generation rates. The simulation tool allows to study the influence of the sanitary emergency dynamics and its environmental impact.

## 3. Data Collection

### 3.1. India's COVID-19 dynamics and India Biomedical Waste Dataset

For this study, a dataset was constructed with daily values of BMW generation for five states of India. Monthly reports available from the central pollution control board (CPCB) of India's ministry of environment, forest, and climate change, with measurements of BMW during COVID-19 emergency (from June 2020 to December 2021) were retrieved (CPCB, 2022). For the COVID-19 dynamics, we added daily data on infected and deceased individuals for each of the states and territorial unions of India. The data used come from daily worldwide reports from the COVID-19 Data Repository by the Center for Systems Science and Engineering (CSSE) at Johns Hopkins University (Dong, 2020). Additionally, data associated with changes in residential mobility, workplaces, and public transportation from Google's Local Mobility reports were also included (Google, 2021).

### 3.2. COVID-19 Colombian Dataset and AMB Biomedical Waste Dataset

Data on COVID-19 cases and deaths in Bucaramanga Metropolitan Area (AMB in Spanish), were extracted from a dataset designed by the Colombian government, which includes COVID-19 cases and deaths for each municipality in Colombia. On the other hand, BMW data was obtained from a waste collection company in AMB. Moreover, data associated with changes in residential mobility, workplaces, and public transportation from Google's Local Mobility reports on COVID-19 were also included (Google, 2021).

### 4. Methods

The simulation model consists of two integrated components: a health emergency dynamic modelling component (COVID-19) and a BMW generation estimation component (Figure 1a).

Figure 1. Left (a): Schematic of the model. Upper right (b): Inputs and outputs of the XGBoost model. Predictions for x days consider only the input variables of these x days. Down right (c): Inputs and outputs of the LSTM model. The network previous state is used to make a new prediction.

#### 4.1. XGBoost Model

For the BMW estimation component, the XGBoost algorithm (Figure 1b) was implemented. The model is fed with variables such as confirmed COVID-19 cases and deaths per day, and mobility indices (residential, workplaces and transit stations). The task is to predict the BMW. It should be clarified that the model predicts data for the same day on which it is predicted, i.e., the data of the 5 variables mentioned for a certain day are entered, and the amount of BMW is predicted for that same day.

#### 4.2. Multivariate LSTM Model

Subsequently, to develop a much more complete model, a recurrent neural network (RNN) was implemented for the prediction of such BMW, which is a type of neural network that is naturally adapted to the processing of time series data and other sequential data. To predict biomedical residuals based on COVID and mobility variables, a type of RNN called “Long short-term memory” (LSTM) was used (Figure 2). Introduced by Cho et al. in 2014, LSTM aims to solve the leakage gradient problem that comes with a standard recurrent neural network (Cho, 2014).

Figure 2. Structure of the LSTM cell (Adapted from Matlab, 2023).

Similar to the XGBoost model, the LSTM (Figure 1c) is fed with variables such as confirmed cases, deaths per day, and some mobility indices calculated during the pandemic (residential, workplaces, and transit stations). The model aims to predict BMW in a specific time window. However, the main difference with respect to the XGBoost is that it takes 7 days of input as a reference for the initialization of the model, and from then on it is fed back with the data it is predicting. This behavior is more convenient, since it allows us to make longer predictions with a smaller amount of data.

Several LSTM models for each region were trained with data from: new COVID-19 cases and deaths, mobility indexes, and amount of BMW from June 11st 2020 to June 29th, 2021. First, data is normalized by the region population. Then a windowing

process is performed, which consists of dividing the data into windows of 7 days. The LSTM model is trained to predict the amount of BMW on the 8th day.

#### 4.3. Epidemics Model (SEIR-D)

For the dynamics component (COVID-19) a SEIR-D compartmental epidemiological model was implemented, which is applied for the mathematical modelling of infectious diseases and allows dividing the individuals of a population  $N$  into five compartments: Susceptible (S), Exposed (E), Infected (I), Recovered (R) and Deceased (D), which are governed by the following set of ordinary differential equations:

$$\begin{aligned} \frac{dS}{dt} &= -\frac{\beta SI}{N} & \frac{dE}{dt} &= \frac{\beta SI}{N} - \sigma E & \frac{dD}{dt} &= \mu I \\ \frac{dI}{dt} &= \sigma E - \gamma I - \mu I & \frac{dR}{dt} &= \gamma I & N &= S + E + I + R + D \end{aligned}$$

Equation 2.

Where  $\beta$  is the rate at which infected individuals interact with other infected individuals,  $\sigma$  is the estimated incubation period of the disease,  $\gamma$  is the duration of illness or recovery rate,  $\mu$  is the mortality rate due to the disease, and  $R_0$  is the transmission of the disease or basic reproduction number. Considering the variability in the trends and the different COVID-19 dynamics, pessimistic, neutral, and optimistic scenarios were proposed based on historical data from the AMB. The parameters for each of the scenarios were defined by optimizing the least squares of the residual data between the initial simulations and the historical data depending on whether there was a high number of cases (pessimistic scenario), a medium number of cases (neutral scenario), or a low number of cases (optimistic scenario). Table 1 shows the optimized parameters for each scenario.

Table 1. Parameters defined for the scenarios.

Scenario	$R_0$	$\beta$	$\sigma$	$\gamma$	$\mu$
Optimistic	1.4	0.121	0.001	0.083	2.21E-10
Neutral	1.99	0.173	0.002	0.043	1.39E-04
Pessimistic	1.07	6.755	0.815	6.274	-2.28E-04

#### 4.4. Performance metrics for predictive models

The mean squared error (MSE) was used to evaluate the models. MSE represents the mean squared difference between the estimated values and the true value, and can be expressed as  $MSE = \frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2$ , where  $x_i$  are the estimated values, and  $y_i$  are the actual values of the corresponding vectors.

## 5. Results

This section will explain the results by analyzing the predictive capability of the LSTM model and subsequently integrating it with the full model.

### 5.1. Results of multivariate predictive models

When evaluating the prediction of BMW in the AMB, the XGBoost obtained a mean square error of 0.2551 for the 3 months predicted, obtaining the results presented in Figure 2a. As can be seen, the performance of this model is poor, which may be since in this prediction period there is a drop in BMW never seen before in the training window. On the other hand, Table 3 shows the results of the LSTM model based on its MSE. For the study, 5 states of India whose population numbers are similar to the AMB were taken. As can be seen, the best and worst performing region was Nagaland and the AMB respectively. The associated error for the Nagaland state is extremely low because in the predicted period its BMW and COVID variables remained somewhat constant

(probably related to bad BMW data collection). On the other hand, the main cause of the poor results in the AMB region is that the model has not seen such a steep drop in the amount of BMW during the training phase, so it is very difficult to predict.

Table 2. MSE results for the LSTM Model.

Region	window-size		
	7	14	28
Puducherry	0.025368	0.140410	0.152633
Goa	0.030012	0.025989	0.007791
Manipur	0.018458	0.012636	0.016037
Nagaland	5.403496E-05	8.69878E-06	2.12439E-07
Mizoram	0.001639	0.000436	0.000371

More specifically, the results obtained in the AMB case study are presented in Figure 2b, obtaining a mean square error of 0.1186 tons on average for the 3 months predicted, using the model with a 7-day window.

Figure 3. Right (a): LSTM model results for the AMB. Left (b): XGBoost model results for the AMB.

### 5.2. SEIR-D integrated model

Figure 4. Left (a): SEIR-D model predictions for confirmed COVID-19 deaths in the AMB. Right (b): Results of the LSTM model for simulating BMW generation for the three COVID-19 scenarios in the AMB.

Once the parameters of Table 1 were defined, predictions were made with the SEIR-D model, and the results collected (Figure 3a). The pessimistic scenario has a peak of infected persons in September 2021. The cases, and deaths of the neutral scenario increase over time, and both variables remain constant for the optimistic scenario. The cases and deaths predicted by the SEIR-D model were used as input for the LSTM network (Figure 1c), and for the mobility indicators the actual data was used. Figure 3b shows the predictions for the proposed scenarios: the pessimistic scenario produces the highest amount of BMW at the peak of COVID cases in September 2021. The neutral scenario has the second largest BMW increase. Finally, for the optimistic scenario, the output is fairly constant and has the lowest amount of BMW. The simulation results are difficult to evaluate, but the general tendency of each scenario is coherent. Additionally, it is important to note that the closest scenario to the actual COVID19 data (optimistic scenario), also obtained the smallest error in terms of BMW generation (Table 3).

Table 3. MSE results for the simulated scenarios in the integrated model.

Scenario	COVID-19 cases	BMW
Pessimistic	67513.363322	1.516234
Neutral	29823.396586	0.700147
Optimistic	<b>1013.564280</b>	<b>0.172478</b>

## 6. Conclusions

In this work, a widely used epidemic model for modelling the transmission of diseases (SEIR-D) was successfully developed as an initial stage to simulate the process of plastic BMW generation. The SEIR-D model simulates different scenarios (pessimistic, neutral, and optimistic) for the development of a health emergency. The output of the SEIR-D compartmental model is then fed to multivariate recurrent models that can estimate BMW generation rates that are consistent with historical values observed in a specific geographic region. Simulation results demonstrate that the recurrent neural networks successfully capture the characteristics associated with the healthcare system of a particular location during a health emergency. We have integrated data from different domains (i.e, epidemiological (number of cases and deaths) and mobility indexes (based on Google mobility report)) to estimate the biomedical waste generation via a recurrent neural network. The model trained on historical data, could be useful afterwards to simulate different developing scenarios for sanitary emergencies. The simulation outputs are consistent with expected tendencies, showing that non-linear recurrent models using multimodal information might become an important modelling approach for complex scenarios.

## Abstract

High-Fidelity (HF) simulations are essential in quantitative analysis and decision making in engineering. In cases where explicit equations and/or derivatives are unavailable, or in the form of intractable nonlinear formulations, simulation-based optimization methods are used. We recently proposed a data-driven equivalent of spatial branch-and-bound that constructs underestimators of high-fidelity simulation data. Within this framework, low-fidelity surrogate data can also be used to inform underestimators. In this work, we utilize the recent advances in hybrid multifidelity surrogate modeling techniques to improve the validity of our underestimators, which leads to better bounds and incumbent optima with lower sampling requirements. Specifically, we show that by modeling the error between the high-fidelity and low-fidelity data, the surrogates learn more about the underlying function with less sampling requirements.

**Keywords:** Data-driven Optimization, Branch-and-bound, Convex underestimators, Multifidelity surrogate models, neural networks, support vector regression, hybrid modeling.

## 1. Introduction

In many engineering fields, it is desirable to simulate complex processes and use these quantifications of system performance for decision-making. Many such cases exist for chemical engineers, including molecular simulations, flowsheet simulations, computational fluid dynamic models, agent-based models, and more. These models are referred to as High-Fidelity (HF) simulations. But often these HF function evaluations are computationally expensive, and this implies that the number of function evaluations is limited by cost or time. Adding to this difficulty, in most cases, the objective functions and the constraints are only available as black-box evaluation function outputs (Fisher, Watson et al. 2020, van de Berg, Savage et al. 2022, Zhai and Boukouvala 2022). As a result, optimization of such systems becomes increasingly prohibitive. The absence of information on the system calls in for derivative-free optimization (DFO) or simulation-based optimization techniques. DFO techniques can be broadly classified into Sampling-based and Model-based methods. Numerous algorithms have been proposed in the recent years (Rios and Sahinidis 2013) for both cases. Sampling-based methods rely on comparing the function values directly and utilize this information to further sample adaptively. On the other hand, Model-based methods rely on constructing Machine Learning (ML) surrogate models as approximations of HF simulations with the aim to expedite the optimization process (Kim and Boukouvala 2020, Li, Dong et al. 2021). A disadvantage of using sampling-based methods is that they require too many samples to

infer the optimum solution, while in surrogate model-based approaches, constructing an accurate surrogate can be challenging and computationally expensive. A solution that we have recently proposed combines advantages of both the methods in the form of a data-driven equivalent of the spatial branch-and-bound algorithm (DDSBB) (Zhai and Boukouvala 2022). The key idea of DDSBB is based on constructing convex underestimators of simulated data. A schematic of spatial branch-and-bound and its data-driven equivalent are shown in Figure 1.

These underestimators serve as relaxations and are convex, so they can be efficiently optimized, circumventing the task of directly optimizing nonconvex fitted surrogates. Samples drawn from the HF simulation serve as upper bounds (UB) of the global optimum and the minimum of the convex underestimator serve as lower bounds (LB). The search space is then progressively partitioned by using branching, node selection and pruning rules and adaptively sampling in the non-pruned subspaces. To build underestimators, using  $N$  samples, the underlying formulation is shown in Equation 1.

$$\begin{aligned}
 & \min_{\mathbf{a}, \mathbf{b}, c} \sum_i^N (f(\mathbf{x}_i) - f_{lb}(\mathbf{x}_i)) \\
 & \text{s.t. } f(\mathbf{x}_i) - f_{lb}(\mathbf{x}_i) \geq 0 \quad \forall i = 1 \text{ to } N \\
 & f_{lb}(\mathbf{x}_i) = \mathbf{a}\mathbf{x}_i^2 + \mathbf{b}\mathbf{x}_i + c \quad \forall i = 1 \text{ to } N \\
 & \mathbf{a} \geq 0, \quad \mathbf{a}, \mathbf{b} \in \mathbb{R}^D, \quad c \in \mathbb{R}
 \end{aligned} \tag{1}$$

In contrast to the conventional sample-based and surrogate-based approaches, DDSBB employs some of the positive aspects of both. Like the sample-based approaches, it adaptively samples in the search space and uses this information to improve the bounding of the original function, by constructing the relaxations and pruning the subspaces that are not promising. It also utilizes surrogates to construct Low fidelity (LF) data but does not directly optimize the surrogates or rely on a single surrogate prediction. This LF data can be utilized along with the HF data to build the convex relaxations. In our recent work (Zhai and Boukouvala 2022), we have shown that by jointly using LF and HF data (multifidelity MF), we can optimize a higher fraction of benchmark problems

While the MF approach employed in DDSBB showed promising performance, a fraction of benchmark studies was still not optimized given limits on sampling requirements. In this current work, we improve the performance of our framework by incorporating more advanced hybrid multifidelity modeling techniques. Specifically, using the same amount of HF data as before, we attempt to learn more about our underlying black-box problem by modeling the error between the HF and LF data. The hypothesis is that this will overall improve our underestimators, and consequently the overall efficiency of the DDSBB

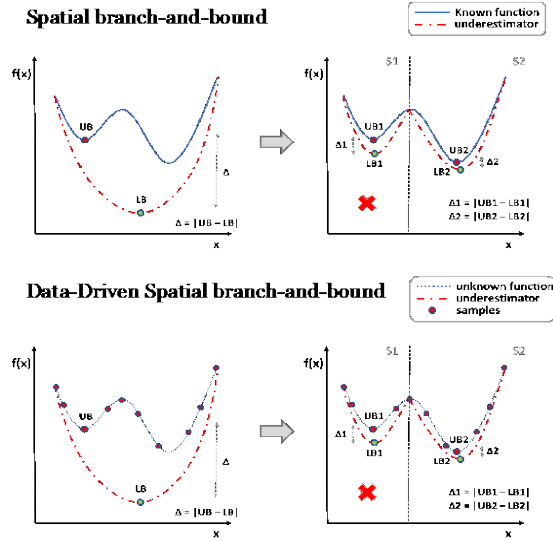

Figure 1: Deterministic Spatial Branch-and-Bound, and Data-Driven Spatial Branch-and-Bound, and the process of branching and bounding in both variants

approach, without increasing sampling requirements. Recent studies show that there is an increasing amount of focus in constructing surrogate models that combine data with different fidelity (Meng and Karniadakis 2020, Bradley, Kim et al. 2022). These Multifidelity Surrogate Models (MFSMs) exploit the relation between LF data and HF data. In this study we integrate these MFSMs into the DDSBB architecture and quantify their performance by benchmarking the method on 2-10 dimensional black-box optimization problems.

## 2. Overview and explored methods

### 2.1.1. Multifidelity approach in DDSBB

The overview of DDSBB is shown in Figure 2. Initially, an input design is generated in the variable search domain by employing Latin Hypercube Sampling (LHS) to generate HF samples. This HF samples are then used for constructing quadratic underestimators by employing the formulation shown in Equation (1). This is shown in the figure using a solid red line. Subsequently, a set of branching, node selection and pruning rules are used to adaptively add samples in the non-pruned subspaces until convergence. Alternatively, as shown in red dotted line, if the MF approach is selected, these HF samples are used to generate LF surrogate models and LF samples. These LF samples are then used along with the HF samples to construct the underestimators. Currently, DDSBB has the capability to use Support Vector Regression (SVR), Neural Networks (NN) and Gaussian Process Regression (GPR) as the surrogate options. For the rest of the study, we utilize SVR as the surrogate option.

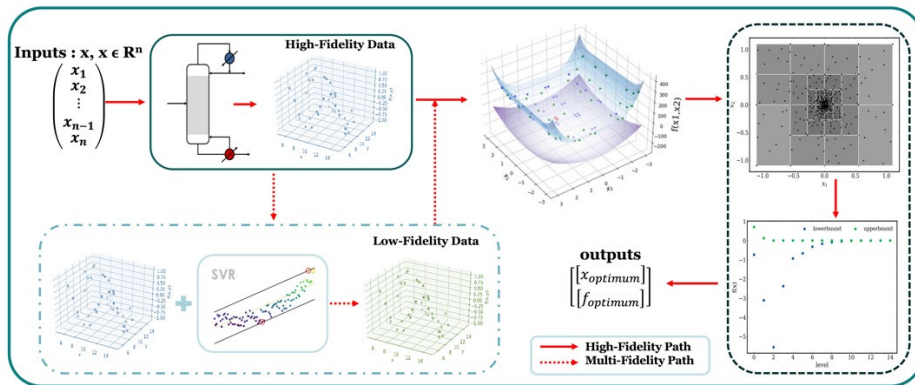

Figure 2: Overview of DDSBB. High-fidelity approach is shown in solid red line and multi-fidelity approach is shown in dotted red line.

### 2.1.2. Multifidelity Surrogate models to improve LF data

There is an inherent trade-off between the number of HF samples that are used to construct LF surrogates, and the accuracy of the constructed surrogates. Also, adding the LF samples makes the convex underestimators more conservative with respect to bounding the function. We have found that in certain cases this leads to improving their validity, and as a result it leads to locating the global optimum of challenging benchmarks (Zhai and Boukouvala 2022). At the same time, LF surrogate predictions can make the underestimators overly conservative, thus leading to large sampling requirements for convergence. In this work, our hypothesis is that, MFSMs can be used to improve the accuracy of the LF data, which leads to improvement in underestimator validity. A

widely used correlation to build MFSMs is:  $y_H = \rho(x)y_L + \delta(x)$  where  $y_L, y_H$  represent the low and high-fidelity data respectively,  $\rho(x)$  is multiplicative correlation surrogate and  $\delta(x)$  is the additive surrogate. In a more general way, we can re-write it as  $y_H = F(x, y_L)$ . To establish a correlation between the HF and LF data, one would need a HF and a LF model to generate that data (Meng and Karniadakis 2020, Bradley, Kim et al. 2022). In case an LF model is available, it can be directly used. In cases where the LF model is not available, we propose a framework (Workflow 1) shown below to create a LF model using a fraction of available data.

---

### Workflow 1: Constructing MFSMs

---

Let the data set  $[\mathbf{x}_{HF}, \mathbf{y}_{HF}]_{tot}$  represent the complete HF data.

Generate a training set data  $[\mathbf{x}_{HF}, \mathbf{y}_{HF}] = 75\%[\mathbf{x}_{HF}, \mathbf{y}_{HF}]_{tot}$

Set  $\mathbf{x}_{HF} \leftarrow input$  and  $\mathbf{y}_{HF} \leftarrow output$ ,

While termination criteria **not true**:

TRAIN SVR

$$\text{Calculate } MSE_{SVR} = \frac{1}{N_{LF}} \sum_{i=1}^{N_{LF}} (|y_{LF} - y_{HF}|^2) + \beta_1 \|\phi_{SVR}\|_2$$

Tune SVR parameters

Generate LF dataset  $[\mathbf{x}_{HF}, \mathbf{y}_{LF}]_{tot}$  using HF input  $[\mathbf{x}_{HF}]_{tot}$

Utilize the correlation  $y_H = F(x, y_L)$  to model error between LF and HF outputs  $[y_{LF}]_{tot}$  and  $[y_{HF}]_{tot}$  respectively using a NN

Set  $[\mathbf{x}_{HF}, \mathbf{y}_{LF}]_{tot} \leftarrow input$  and  $\mathbf{y}_{HF} \leftarrow output$ ,

While termination criteria **not true**:

TRAIN NN

$$\text{Calculate } MSE_{NN} = \frac{1}{N_{HF}} \sum_{i=1}^{N_{HF}} (|y_{LF}^* - y_{HF}|^2) + \beta_2 \|\phi_{NN}\|_2$$

Tune NN parameters

---

In the Workflow 1,  $y_{LF}, y_{LF}^*$  represent output from SVR and NN.  $N_{LF}, N_{HF}$  is the number of training data points and total HF data points.  $\beta_1, \beta_2$  represent the regularization weights and  $\phi_{SVR}, \phi_{NN}$  represent the associated parameters with SVR and NN respectively. A schematic for the Workflow 1 is shown in Figure 3.

Figure 3: A schematic of the workflow for fitting the MFSMs. Part of the total HF data set (shown in blue) is used to train LF SVR model and generate LF data  $y_{LF}$

### 3. Results and discussion

To understand and visualize the effect of MF and MFSM approach on underestimator construction, we first take a 1-dimensional case study. Let us consider that the function  $f(x) = \sin(x) + \sin(10x/3)$  is available as a black-box function, with  $x \in [0, 9]$  and known global solution at  $x_{opt} = 5.14574$ . Figure 4 shows underestimators constructed using HF, MF and MFSM approaches. We can see among all three approaches, the

optimum solution identified is more accurate in MFSM approach and LF data in case of MFSM approach is more accurate in comparison to MF approach, without increasing the number of HF data collected.

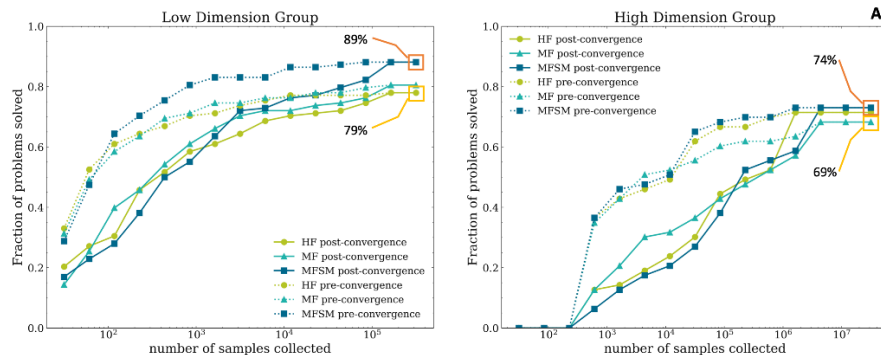

Figure 4: Comparison of constructed underestimators and LF data using HF, MF and MFSM approaches. Black-box function is shown in red dotted line, HF samples in red circles and LF samples in green circles. Underestimator is shown in solid black line.

Next, we test the performance of all three approaches on a large set of continuous box-constrained benchmark problems with known global solutions (BARON 2022). The benchmark problems were divided into two groups based on their dimensionality: lower dimensional group containing 118 problems with 2-3 variables and higher dimensional group containing 63 problems with 4-10 variables. All three approaches were initialized with  $10 \times \text{dimension} + 1$  initial samples and converge when the  $|UB - LB| \leq 0.05$  or  $|UB - LB|/|LB| \leq 0.001$ . For the performance analysis, we use the criterion  $f_{best} \leq \max(f^* + 0.01, (1.01)f^*)$  to allow a tolerance limit towards the optimal solution found.  $f^*$  and  $f_{best}$  represent the known global solution and the solution reported by DDSBB as optimum. We study the fractions of problems solved with sampling and CPU requirements based on pre and post convergence solutions. *Pre-convergence* and *post-convergence* solutions represent the optimum solution found by the algorithm *before* and *after* closing the UB-LB gap respectively. The performance curves for all three approaches are shown in Figure 5. In Figure 5A, we can see that the MFSM approach solves higher fraction of benchmark problems, and the pre-convergence solution quality is better in both low and high dimensions groups. In Figure 5B, we show the CPU requirements for the three approaches. The HF approach does not involve any surrogate fitting, so the CPU time largely corresponds to HF sampling. On the other hand, CPU time in MF and MFSM approaches also include surrogate modeling costs. As expected MFSM approach takes higher CPU time for fitting the complex MFSM structure. Thus, the advantage of this method is expected to be even greater when sampling cost increases.

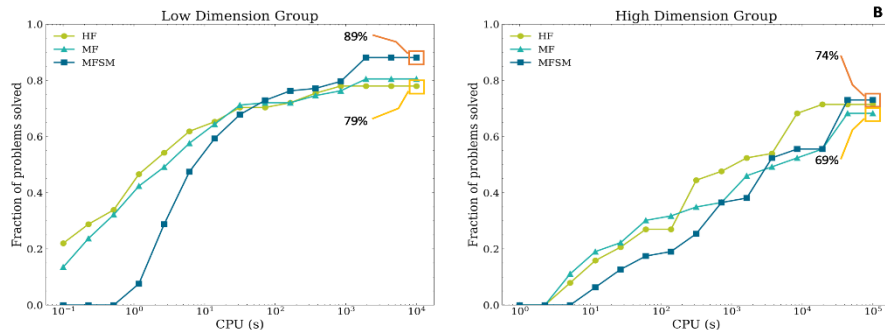

Figure 5: Performance curves of HF, MF, MFSM approaches. A) Fraction of problems solved vs sampling requirement, compared with pre and post convergence solutions reported by the algorithm. B) Fraction of problems solved vs CPU requirement.

#### 4. Conclusions

In this work, we utilized multifidelity surrogate models as composite structures to model the error between HF and LF data to improve the validity of constructed data-driven underestimators embedded within a branch-and-bound framework. Results show that using composite/hybrid multifidelity models for surrogate-based optimization is promising, because it leads to more accurate surrogates with the same sampling cost but requires additional CPU time for training.

## Abstract

The use of fossil fuels has direct environmental impacts, including the use of jet fuel. An alternative to jet fuel is biojet fuel, which can be produced from biomass. Recently the ATJ (alcohol to jet) process has been promoted as an alternative that may offer better biojet production performance compared to some other process routes. Although there are several proposals for jet fuel production using the ATJ route, no intensified alternative has been reported to increase the performance, and decrease the economic and environmental impact. In this proposal, an intensified ATJ production process is presented, considering the intensification of the pretreatment stage using a saccharification-fermentation reactor, ethanol purification considering a divided wall column, and a distillation column with two reaction zones for biojet fuel production. Once the intensified proposal was evaluated in a multi-objective optimization framework, a saving of 18% in the environmental impact was obtained, and a saving of 12% in the environmental impact.

**Keywords:** biojet production, ATJ process, process intensification.

## 1. Introduction

Despite the COVID-19 pandemic's reduced jet fuel demand, growth in the services provided by the industry is anticipated once more. This poses a difficulty, as does the fuel's intrinsic environmental impact throughout its life cycle, in an economic climate that is still dependent on finite oil. Given this, using biojet fuel as a renewable aviation fuel is a possible alternative. The production of biojet can be done by several routes, for example, from the conversion of oils. There are some other routes such as hydroprocessing of fatty acids and esters (HEFA), catalytic hydro thermolysis (CH) and hydroprocessing to depolymerized cellulosic biojet (HDCJ). These processes are not very feasible despite their low-cost processing. There are other routes to obtain it, for example, starting from alcohol (Alcohol-to-jet, ATJ) that was recently certified in April 2016 by ASTM. The ATJ process consists of 4 stages starting from ethanol, i) dehydration, ii) oligomerization, iii) hydrogenation, and iv) purification. The ATJ route has bioethanol as a raw material, which has lignocellulosic agroindustrial waste as a precursor raw material that does not require additional water or a long time to obtain it. However, one of the disadvantages is that it is a relatively expensive process and is still not sufficiently competitive in the market, compared to the conventional jet fuel production process. The process of obtaining biojet fuel has been previously studied by several authors; however, it is a process with a wide field for improvement.

Process intensification, on the other hand, is an improvement strategy that can involve the reduction of equipment size, the development of several operations in a single piece of equipment, the reduction of process times, etc. An example of an intensified process is the reactive distillation column, where a chemical reaction and a separation process based on liquid-vapor equilibrium can be carried out. Taking into consideration that the process of obtaining biojet fuel has already been previously studied and applied through the ATJ route; however, it is a process with a wide field of improvements where process intensification strategies can be implemented. Thus, the goal of this work was to design an intensified process to produce biojet fuel from Mexican lignocellulosic biomass (corn stover, and cane bagasse) having alcohols as intermediates. The process was designed and modeled considering an intensified process for pretreatment/hydrolysis/fermentation/purification for the biomass-ethanol process.

## 2. Description of the intensified process

The creation of intermediate alcohols is necessary for the whole process of producing biojet fuel from lignocellulosic biomass. The general process for producing alcohols from lignocellulosic agricultural waste includes the following steps: (1) biomass pretreatment (2) enzymatic hydrolysis (3) fermentation of sugars (4) and purification of the alcohols produced. In this manner, Figure 1 shows how the conventional turns into an intensified process in some sections of the ATJ process.

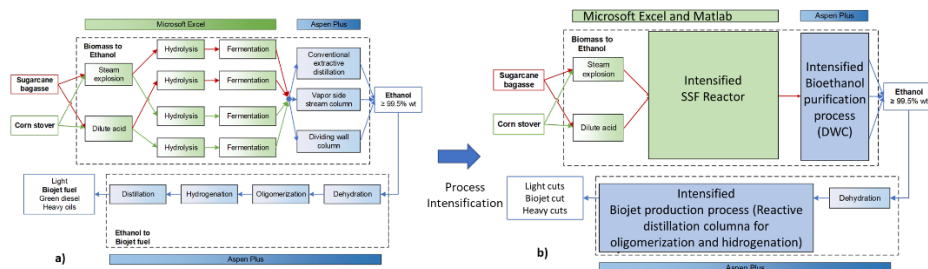

Figure 1. Description of conventional (a) and intensified (b) biojet fuel production.

The main difference between the conventional process and the intensified process is the use of the intensified fermentation-saccharification (SSF) reactor instead of separate process steps. Additionally, an intensified process is used for bioethanol separation. Finally, in the final part of the process, the oligomerization, hydrogenation, and purification stages are carried out simultaneously using a double-reactive distillation column.

## 3. Case study

According to SENER (2017), Mexico needs to replace at least 5.5% of its current demand for conventional jet fuel with biojet fuel, or 258 million liters, to develop a viable biojet fuel market. Two pretreatment alternatives, dilute acid, and steam explosion, are considered in this proposal. For the hydrolysis and fermentation section, an intensified saccharification-fermentation (SSF) reactor will be considered. Once an effluent of ethanol, water, etc. has been produced from the reactor, it will be purified in an intensified separation scheme (divided wall column). The alcohol is dehydrated in a dehydration reactor to obtain ethylene. Finally, starting from ethylene, the biojet fuel stream is obtained.

#### 4. Methodology and Process Modeling

The two feedstocks and pretreatments were combined to create the biomass-to-ethanol process, which was created using the superstructure scheme. Kinetic data were gathered from the literature to describe the pretreatment. The modeling of the intensified saccharification-fermentation reactor was carried out in the Matlab computational package considering the kinetics reported by Kadam et al. 2004. The *S. cerevisiae* strain was considered for fermentation. Aspen Plus was used to simulate the ethanol purification zone and the module ethanol-to-biojet fuel using the NRTL and ENRTL thermodynamic models, respectively. A column sequence with a vapor side stream and a column sequence of dividing wall (DWC) was proposed as enhanced methods because the expense of separation represents a well-known area of opportunity. For the dehydration reaction, a performance reactor as reported by Rivas-Interian (2022) was considered. For the replacement of the oligomerization and hydrogenation process by a reactive double distillation column, the approach previously proposed by Heydenrych et al. was considered (Heydenrych et al., 2001). The complexity of the system (alkenes starting from C2) is reflected in the following chemical equations.

The estimated Kinect parameters of power law are shown in Table 1.

Table 1. Estimated kinetic parameters of the power-law model in equations 1-16

## 5. Process Optimization

An optimization effort is implied by the quest for the design and operation parameters that maximize savings and minimize the environmental effect. The following describes these goals as well as the optimization method.

### 5.1. Objective functions

The total annual cost (TAC) and eco-indicator-99 (EI99) were chosen as the objective functions to evaluate the process' sustainability. Equations 17 and 18 were used to calculate them, respectively:

$$TAC = \frac{\text{Capital cost}}{\text{Recovery time}} + \text{Operation cost} \quad (17) \quad EI99 = \sum_b \sum_d \sum_{k \in K} \delta_d \omega_d \beta_b \alpha_{b,k} \quad (18)$$

Where  $\beta_b$  is the total amount of chemical  $b$  released per unit of reference flow due to direct emissions,  $\alpha_{b,k}$  is the damage caused in category  $k$  per unit of chemical  $b$  released to the environment,  $\omega_d$  is a weighting factor for damage in categories  $d$ , and  $\delta_d$  is the normalization factor for damage of category  $d$ . Guthrie's approach was used to compute the capital cost. The annual production of alcohol was also factored into the ethanol production process to meet Mexico's demand for biojet fuel, which accounts for 5.5% of the country's demand for conventional jet fuel (SENER, 2017). Following is a description of the objective function:

$$\begin{aligned} \text{Min}(TAC, EI99, IR) &= f(X) \\ \text{Subject to } x_m^{\vec{}} &> y_m^{\vec{}} \end{aligned} \quad (19)$$

Being the variables involved in the whole modeling process can serve as degrees of freedom of the process. The Differential Evolution with Tabu List (DETL) stochastic approach was used to optimize the case of research. The best design parameters and the best design were chosen using this methodology. It was carried out on a hybrid platform that combined Matlab, Aspen Plus, and Microsoft Excel. The following criteria were employed: 120 individuals, 1000 generations, 50% of the entire population on the tabu list, 0.0001 tabu radius, and probability of crossover and mutation of 0.9 and 0.3, respectively.

## 6. Results

In the following section, the results obtained will be shown. The results will be shown in three sections: general pretreatment section, ethanol purification, and biojet production.

### 6.1.1. Pretreatment section

As mentioned in the methodology section, two scenarios were analyzed considering two types of feedstock. As shown in Figure 2, the use of an intensified strategy (SSF reactor) considerably reduces costs compared to a conventional process in both pretreatments and with the two feedstocks considered. Figure 2 shows the optimization results of all costs associated with the entire reaction section for both processes (conventional and intensified) when considering various pretreatments. Regarding the ethanol purification process, a direct comparison with the conventional process was not performed, since in the previous work of Rivas-Interian et al. (2022) a substantial saving of the intensified process versus the conventional one was observed. Thus, Figure 3a) shows the Pareto front of the optimization results schemes of all alternatives that accomplish recovery and purity restrictions considering economic and environmental objectives for ethanol purification. On the other hand, Figure 3b) shows similar information for the biojet fuel

section after being fed with ethane to be converted by oligomerization and hydrogenation.

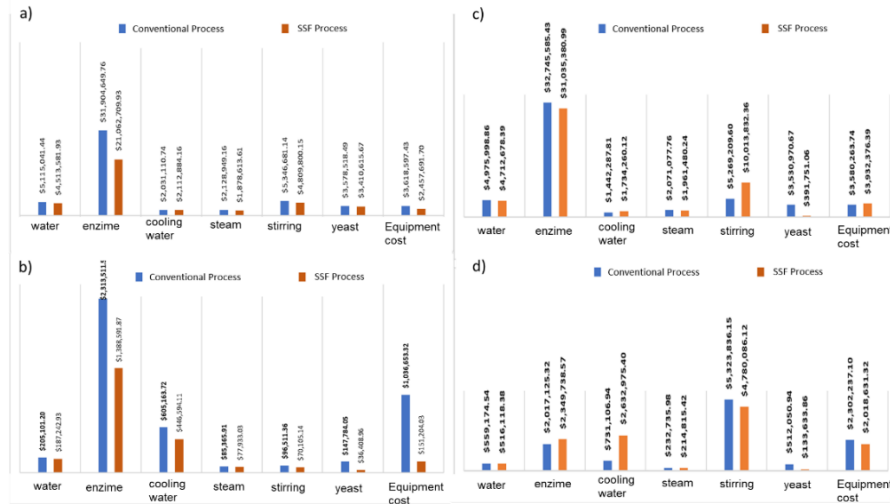

Figure 2. Comparison of pretreatment processes cost considering steam explosion a) sugarcane bagasse, b) corn stover; and dilute acid c) sugarcane bagasse, d) corn stover; and dilute acid.

Figure 3. Pareto front for the ethanol purification zone considering a split-wall column (DWC) (a), and for the biojet production zone (b).

Figure 3a) shows that a TAC and EI99, weighted by the number of kilograms produced 1.18USD/kg ethanol and 0.3015 ecopoints/kg ethanol, respectively, were obtained. These values represent a reduction of 10% for the TAC, and close to 40% in the EI99 concerning the conventional design that reports TAC values of 1.29USD/kg ethanol and EI99 is 0.4716 ecopoints/kg ethanol. Finally, Figure 3b) shows the Pareto obtained from the transformation of ethanol to biojet fuel considering the dehydration, oligomerization, and hydrogenation stages. An important aspect to consider for savings in all stages is the reduced use of smaller equipment. In the case of the pretreatment and fermentation section, the use of equipment was reduced, the purification section was carried out in a piece of single process equipment, and in the biojet production zone, the double reactive distillation column performed the work of two reactors and a separation column. These capital cost savings are immediately reflected in the overall cost of the entire process. Table 2 shows the design parameters for the SSF reactor section as well as the double reactive column for biojet production. Data for the ethanol separation section can be found in the work of Rivas-Interian et al. (2022).

Table 2. Design parameter for SSF reactor, and reactive distillation column.

Scheme	Residence time (h)	Volume (m <sup>3</sup> )	Enzyme (FPU/g cellulose)	Yeast (FPU/g cellulose)	Stirring (RPM)	Oligomerization-Hydrogenation Reactive Column	
						Number of stages	Reflux ratio
Sugar Cane/Steam	29.63	20492	9.013	0.9986	150.8353	Feed stage	24 and 30
						Side stream stage	33
Corn/Steam	29.6492	6633	18.75	0.9952	200.81	Reactive stages	12-20, 21-29
						Hold Up (l)	3.5, 48
Sugar cane/acid	32.82	62528	10.008	1.0031	150.03	Distillate flowrate (kg h <sup>-1</sup> )	5422.44
						Condenser duty (kcal h <sup>-1</sup> )	9.56216 x 10 <sup>6</sup>
Corn/acid	25.034	16455	10.7791	1.0059	18086	Reboiler duty (kcal h <sup>-1</sup> )	854153
						Jet Fuel Production (kg/h)	19935.821

The synergistic effect generated by joining the oligomerization and hydrogenation processes in a column with two reactive zones is quite good. During the parametric optimization process, it was possible to obtain design conditions that allowed obtaining a significant amount of product with better operating conditions.

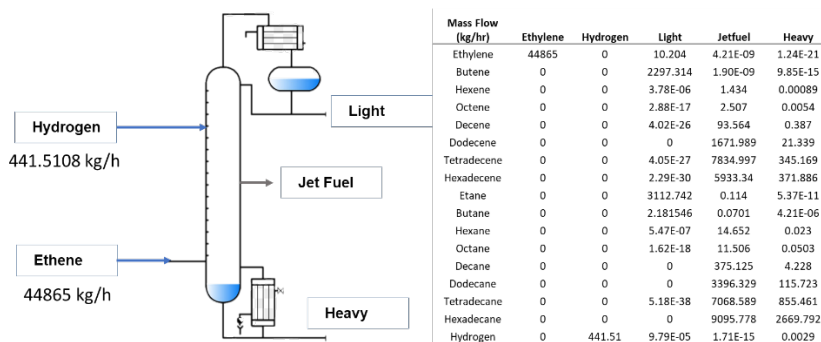

Figure 4. Mass balance for the reactive distillation column.

## Conclusions

In this work, an intensified approach to the production of biojet from biomass was presented. Process intensification strategies were applied in the pretreatment section, ethanol purification, as well as in biojet production area. Once the intensified alternatives were implemented, an improvement was observed in the economic and environmental indicators that were evaluated. In general terms, an improvement of 18% was observed in the economic indicator, and 12% in the environmental indicator when comparing the conventional and the intensified strategy.

## Abstract

Models with stochastic outputs are commonly employed to make decisions for design and operation of chemical processes. The accuracy and precision of the stochastic outputs, i.e., model predictions, should be compared to the observation based on the design and operation requirements. The area metric measures the overall mismatch between prediction and observation but does not provide precision and accuracy information separately. In this paper, we proposed a new metric called uncertainty width that decomposes area metrics into precision and bias components. This new metric enables the consideration of precision and accuracy simultaneously for model evaluation. We applied this metric to evaluate and compare the performance of three models fitted using three liquid entrainment fraction measurement datasets with different flow orientations, using Gaussian Process (GP) and Bayesian Neural Network (BNN). The results reveal that the overall prediction accuracy of GP model (GPM) is better than that of BNN model. The overestimation of the GPM prediction precision causes the high average area metric.

**Keywords:** Metrics, Machine Learning, Area Metrics, Accuracy, Precision, Uncertainty

## 1. Introduction

Design and operations decisions for chemical processes are regularly made considering various uncertainties (Sharifian et al., 2021). Models that provide predictions and their uncertainty over the target domain are essential in the risk assessment of these decisions. Before applying these decisions in chemical engineering analysis and design, the model performance evaluation must be performed. For models with stochastic outputs, the model performance is evaluated by measuring the mismatch between the model output and the true observation. Various metrics exist for this evaluation.

In classical hypothesis testing, a test is constructed under the hypothesis that the observations come from the predicted population. Decisions about rejecting or not rejecting the hypothesis can be made according to whether the test statistic falls within the critical region (Liu et al., 2011). Common hypotheses include the comparison of several moments (e.g., t-test, F-test) and comparison of full statistical distributions (e.g., Kolmogorov-Smirnov test (Haldar and Mahadevan, 2000), Anderson-Darling test (Rebba and Mahadevan, 2008)). The Bayes factor, expressed as the ratio of the relative likelihood of the null hypothesis over the alternative hypothesis, is used as the criteria (Mahadevan and Rebba, 2005). The null hypothesis is not rejected when the Bayes factor is larger than one. The Frequentist Metric evaluates the distance between the estimated mean of the observations and the mean of the predictions (Oberkampf and Trucano, 2002). The confidence bound is generated from the uncertainty of the distance.

The area metric (AM) measures the disagreement area of the cumulative distributions between the prediction and the observation (Ferson and Oberkampf, 2009). The u-pooling

method derived from the area metric is proposed to measure the global dispersion of the distributions of observation and prediction. The measures of the cumulative distribution function at each validation site, called the u-value, are aggregated over the entire input space. The evaluation of the overall disagreement between the observation and model prediction is expressed as the area difference between the u-value distribution and the uniform distribution (Ferson et al., 2008). The model acceptance is determined according to a predefined accuracy requirement for the frequentist and area metrics.

For the area metric, the mismatch between the stochastic observation and prediction can be decomposed into precision and accuracy. The precision refers to the variance of multiple predictions at one validation site. Accuracy measures the degree of closeness between the prediction and the observation (Eisenhart, 1969). Generally, models with high prediction accuracy (i.e., low average prediction bias) and precision (i.e., narrow average uncertainty) are good performers. The area metric measures the sum of accuracy and precision. For predictions with high area metric values, it is difficult to determine whether this is due to low accuracy or poor precision. The accuracy and precision should be quantified separately when the decisions depend on both accuracy and precision.

This study proposes uncertainty width to evaluate the prediction precision within the area metric. By separating the area metric into the prediction bias related to accuracy and the uncertainty width related to precision, the performance between various models can be compared, and a model can be selected according to the acceptance criterion. Large bias may be acceptable with narrow uncertainty width when the model is employed to provide a prediction range. High uncertainty may be tolerated with a low bias if a point prediction is adopted for solving the problem. The proposed metric is applied to evaluate the performance of two machine learning models built using Gaussian Process Modeling (GPM) and Bayesian Neural Network (BNN).

The uncertainty width is defined and discussed in Section 2. Section 3 presents the details of the application of the uncertainty width for model performance evaluation. The results are given and discussed in Section 4. Finally, Section 5 summarizes the conclusions and future directions.

## 2. Methodology

A graphical illustration of the area metric is given in Figure 1. For one sample, the cumulative distribution functions (CDFs) of the model prediction and true observation are plotted as  $f_1(y)$  and  $f_2(y)$ . According to the definition, the area metric is the area between the two curves. For symmetric distributions, the means of the two curves,  $\mu_1$  and  $\mu_2$ , are located at the cumulative probability value equal to 0.5. The bias of the prediction  $\mu_2 - \mu_1$ , defined as the difference between the two means, is shown as the rectangular area between  $\mu_1$  and  $\mu_2$ . Assume the two curves intersect at  $y = \mu_I$ .

The area metric is defined as the integral of the difference in area between the two CDFs and its analytical expression is given in Equation 1.

$$\int_{-\infty}^{\infty} |f_1(y) - f_2(y)| dy = \int_{-\infty}^{\mu_I} [f_2(y) - f_1(y)] dy + \int_{\mu_I}^{\infty} [f_1(y) - f_2(y)] dy \quad (1)$$

The bias between the prediction and observation mean is equal to the integral of the cumulative probability  $\int_{\mu_1}^{\mu_2} 1 dx$ . By shifting the  $f_1(y)$  to the left by  $2(\mu_2 - \mu_1)$  and shifting  $f_2(y)$  to the right by  $2(\mu_2 - \mu_1)$ , the bias can be cut into several pieces. The integrals of the resulting pieces are given in Equation 2.

Figure 1 Area Metric Decomposition

$$\begin{aligned}
 \int_{\mu_1}^{\mu_2} 1 dy &= \int_{\mu_1}^{\mu_2} [1 - f_1(y + 2(\mu_2 - \mu_1))] dy \\
 &+ \int_{\mu_1}^{2\mu_1 - \mu_1} [f_2(y + 2(\mu_2 - \mu_1)) - f_1(y + 2(\mu_2 - \mu_1))] dy \\
 &+ \int_{2\mu_1 - \mu_1}^{\mu_2} [f_1(y + 2(\mu_2 - \mu_1)) - f_1(y)] dy \\
 &+ \int_{\mu_1}^{\mu_2} [f_2(y + 2(\mu_2 - \mu_1)) - f_1(y)] dy + \int_{\mu_1}^{\mu_2} [f_1(y) - f_2(y)] dy \\
 &+ \int_{\mu_1}^{\mu_2} [f_2(y) - f_1(y - 2(\mu_2 - \mu_1))] dy \\
 &+ \int_{\mu_1}^{\mu_2} [f_1(y - 2(\mu_2 - \mu_1))] dy
 \end{aligned} \tag{2}$$

The second term in area metric shown in Equation 1 can also be decomposed into integrals given in Equation 3.

$$\begin{aligned}
 \int_{\mu_1}^{\infty} [f_1(y) - f_2(y)] dy &= \int_{\mu_1}^{\mu_1} [f_1(y) - f_2(y)] dy + \int_{\mu_1}^{\mu_2} [f_1(y) - f_2(y)] dy \\
 &+ \int_{\mu_2}^{2\mu_2 - \mu_1} [f_1(y) - f_2(y)] dy + \int_{2\mu_2 - \mu_1}^{2\mu_2 - \mu_1} [f_1(y) - f_2(y)] dy \\
 &+ \int_{2\mu_2 - \mu_1}^{3\mu_2 - 2\mu_1} [f_1(y) - f_1(y - 2(\mu_2 - \mu_1))] dy \\
 &+ \int_{3\mu_2 - 2\mu_1}^{5\mu_2 - 4\mu_1} [f_1(y) - f_1(y - 2(\mu_2 - \mu_1))] dy \\
 &+ \int_{5\mu_2 - 4\mu_1}^{\infty} [f_1(y - 2(\mu_2 - \mu_1)) - f_2(y)] dy \\
 &+ \int_{5\mu_2 - 4\mu_1}^{\infty} [f_1(y) - f_2(y)] dy
 \end{aligned} \tag{3}$$

Because  $f_2(y)$  is symmetric at  $(\mu_2, 0.5)$  and  $f_2(y + 2(\mu_2 - \mu_1))$  is shifted from  $f_2(y)$ , the functions  $f_2(y + 2(\mu_2 - \mu_1))$  and  $f_2(y)$  are symmetric at  $(\mu_1, 0.5)$ . It can also be inferred that the functions  $f_1(y)$  and  $f_1(y - 2(\mu_2 - \mu_1))$  are symmetric at  $(\mu_2, 0.5)$ . As such,  $\int_{\mu_1}^{2\mu_1 - \mu_1} [f_2(y + 2(\mu_2 - \mu_1)) - f_1(y + 2(\mu_2 - \mu_1))] dy = \int_{\mu_1}^{\mu_1} [f_1(y) - f_2(y)] dy$ . Other equal integrals of Equation 2 and Equation 3 are given in Equations 4 to 7.

$$\int_{3\mu_2-2\mu_1}^{5\mu_2-4\mu_1} [f_1(y) - f_1(y - 2(\mu_2 - \mu_1))] dy$$

$$= \int_{\mu_1}^{\mu_2} [1 - f_1(y + 2(\mu_2 - \mu_1))] dy + \int_{\mu_1}^{\mu_2} [f_1(y - 2(\mu_2 - \mu_1))] dy \quad (4)$$

$$\int_{\mu_1}^{2\mu_1-\mu_1} [f_1(y + 2(\mu_2 - \mu_1)) - f_2(y + 2(\mu_2 - \mu_1))] dy$$

$$= \int_{2\mu_2-\mu_1}^{2\mu_2-\mu_1} [f_1(y) - f_2(y)] dy$$

$$+ \int_{2\mu_2-\mu_1}^{3\mu_2-2\mu_1} [f_1(y) - f_1(y - 2(\mu_2 - \mu_1))] dy \quad (5)$$

$$\int_{\mu_1}^{2\mu_1-\mu_1} [f_2(y + 2(\mu_2 - \mu_1)) - f_1(y + 2(\mu_2 - \mu_1))] dy$$

$$= \int_{\mu_1}^{\mu_1} [f_1(y) - f_2(y)] dy \quad (6)$$

$$\int_{\mu_1}^{\mu_2} [f_2(y) - f_1(y - 2(\mu_2 - \mu_1))] dy = \int_{\mu_2}^{2\mu_2-\mu_1} [f_1(y) - f_2(y)] dy \quad (7)$$

For visualization, the equal integral pairs are shaded with the same patterns in Figure 1. The uncertainty width is defined as the difference between the area metric  $\int_{-\infty}^{\infty} |f_1(y) - f_2(y)| dy$  and the prediction bias  $\int_{\mu_1}^{\mu_2} 1 dy$ . If Equations 4 to 7 are inserted into the uncertainty width definition, Equation 8 is obtained to calculate the uncertainty width.

*Uncertainty width*

$$= \int_{-\infty}^{\infty} |f_1(y) - f_2(y)| dy - \int_{\mu_1}^{\mu_2} 1 dy$$

$$= \int_{-\infty}^{\mu_1} [f_2(y) - f_1(y)] dy + \int_{3\mu_2-2\mu_1}^{5\mu_2-4\mu_1} [f_1(y - 2(\mu_2 - \mu_1)) - f_2(y)] dy$$

$$+ \int_{5\mu_2-4\mu_1}^{\infty} [f_1(y) - f_2(y)] dy \quad (8)$$

### 3. Case Study

#### 3.1. Machine Learning Models

Two Bayesian-based machine learning techniques, GPM and BNN, are adopted to build models in this study. GPM is a supervised learning method with a theoretical basis in statistics. A GPM is characterized by its mean function and covariance function or kernel function (Williams and Rasmussen, 2006). A constant mean function and square exponential kernel function with different length scales for each input dimension are utilized. The GP prior is defined in Equation 9:

$$f \sim \mathcal{GP}(m, k)$$

$$m(x) = a, \text{ and } k(x_p, x_q) = \sigma_f^2 \exp\left(-\sum_{h=1}^d \frac{(x_p - x_q)^2}{2l_h^2}\right) + \sigma_n^2 \Delta_{pq} \quad (9)$$

In Equation 9,  $f$  represents the underlying function value at the input  $x$ ,  $m(x)$  is the mean function of the GP, and  $k(x_p, x_q)$  is the covariance function representing the spatial covariance between any two points ( $x_p$  and  $x_q$ ) at the process. In the covariance function,  $d$  is the dimension of input  $x$ ,  $l_h$  represents the characteristic length scale corresponding to the  $h^{\text{th}}$  dimension of input  $x$ ,  $\sigma_n^2$  is the output variance, and the parameter  $\sigma_f^2$  is output-scale amplitude.  $\Delta_{pq}$  is Kronecker delta, which is one if  $p = q$  and zero otherwise.

BNN applies Bayesian statistics to Neural Networks (NNs) (Goan and Fookes, 2020). Instead of treating the model weights as a fixed value, BNN assumes the weights are

random variables. After specifying the prior distribution of weights and likelihood, the Bayes theorem is applied to calculate the posterior distribution. BNN model parameters are optimized using variational learning that minimizes the Kullback-Leibler (KL) divergence to avoid intractable computations (Blundell et al., 2015). The prediction mean and variance are calculated using Monte Carlo sampling.

### 3.2. Model Performance Evaluation using Uncertainty Width

The uncertainty width is applied to evaluate and compare the performance of the selected machine learning (ML) models from both accuracy and precision perspectives. Three datasets containing liquid entrainment fraction measurements and two machine learning techniques, GPM and BNN, are used to build six ML models. The three datasets for vertical, horizontal, and inclined flow orientations are composed of 1,083, 478, and 100 samples with 9 input features representing the experimental operating conditions. For each sample, the liquid entrainment fraction prediction with its uncertainty is calculated and evaluated using the area metric. The area metric is then decomposed into accuracy (absolute bias) and precision (uncertainty width). The overall model performance is evaluated using the average area metric, average absolute bias (mean absolute error), and average uncertainty width of all the samples.

## 4. Results and Discussion

The model performance evaluation results are shown in Figure 2. The average area metric, mean absolute error (MAE), and the average uncertainty width of the models built using experimental datasets for vertical, horizontal, and inclined flow orientations are shown in Figures 2 (a), (b), and (c), respectively. The total height of each bar represents the average area metric. The MAE and the average uncertainty width values are separated and marked using different colors and shades within the area metric. While the average area metric shows the overall performance of the model, models with low MAE have better accuracy, while models with low uncertainty have better precision.

Figure 2 Model Performance of the models built using liquid entrainment fraction measurements for (a) vertical (b) horizontal (c) inclined flow orientations

Considering the overall model performance evaluated using the average area metric, the GPM and BNN fitted using datasets for vertical and horizontal flow orientations have identical performance. This observation suggests that when an entrainment fraction prediction range is used for developing a solution from the model output, the GPM and BNN performances are close. The GPM outperforms the BNN when fitted using the dataset for inclined flow orientation. For the model accuracy, the MAE of GPM, is lower than that of BNN for all three pairs of models. This observation indicates that the accuracy of the GPM is always better than the BNN. The GPM should be selected when entrainment fraction point prediction is employed to make a decision. For models built using the dataset for inclined flow orientation, both MAE and average uncertainty width

of BNN are higher than those of GPM, indicating that the GPM outperforms BNN in both accuracy and precision.

## 5. Conclusions

In this study, a metric called uncertainty width is developed to evaluate the performance of machine learning models with stochastic outputs. The prediction performance at each sample is separated into accuracy and precision by decomposing the area metric into absolute bias and uncertainty width. The average absolute error and average uncertainty bias from all samples are used to simultaneously evaluate the overall model performance, considering accuracy and precision. The new metric is applied to evaluate the performances of six models built using GPM and BNN using three datasets containing liquid entrainment fraction measurements for vertical, horizontal, and inclined flow orientations. The results suggest that GPM performs better than BNN, considering both accuracy and precision using the dataset for the inclined flow orientation. For vertical and horizontal flow orientation datasets, although the overall model performance evaluated using the average area metric are identical, the accuracy of GPM is better than that of BNN. The GPM performs better when an entrainment fraction point prediction is needed for making design and operation decisions using these models. The high area metric of GPM built using vertical and horizontal flow orientation datasets comes from the high uncertainty width, which means that GPM overestimates the prediction uncertainty. Future work will investigate the application of uncertainty width to outputs with skewed distributions.

## Abstract

Traditional process design approaches focus on exploiting economies of scale but are inefficient when designing a large number of similar processes for decentralized applications. By optimizing each process individually, these approaches do not allow for manufacturing standardization or make use of economies of numbers. In this work, we design a family of processes (i.e., multiple processes) of a carbon capture facility with various performance requirements. We identify sub-components within the process and create a small set of sub-component designs that can be shared across all the processes in the process family. We formulate this optimization problem as a nonlinear generalized disjunctive program (GDP) and, in previous work, developed two approaches for reformulating and solving this problem: one based on full-discretization of the design space (Zhang et al., 2022) and one that used Machine Learning (ML) surrogates to replace the nonlinear process models (Stinchfield et al., 2022). Using ML surrogates to predict required system costs and performance allows us to reformulate the nonlinearities in the GDP to generate an efficient MILP formulation. In this work, we apply the ML surrogate approach to design a family of carbon capture systems to cover a set of different flue gas flow rates and inlet CO<sub>2</sub> concentrations, where we consider the absorber and stripper as sub-component types.

**Keywords:** Manufacturing, Optimization, Energy Systems, Machine Learning.

## 1. Introduction

Effectively mitigating climate change requires the broad deployment of green energy and industrial decarbonization processes. When designing *multiple* processes, a conventional design approach produces a set of unique unit designs for each process that can be expensive to manufacture. Modularity, a well-explored design approach, provides significant reductions in manufacturing costs and has proven beneficial in particular when designing multiple instances of a process (Baldea et al., 2017). However, modular designs are typically ‘numbered-up’ to achieve capacity requirements and often fail to fully exploit economies of scale. Rather than using traditional or modular design, we propose a hybrid approach that applies concepts from product family design to the design of

process systems to gain the manufacturing benefits of modularity while still obtaining process customization and economies of scale.

In product family design (PFD), a product family is broadly defined as “a set of products that share one or more common ‘element(s)’ yet target a variety of different market segments” (Simpson et al., 2014). This approach is used extensively in automotive industries, for example, where a wide variety of products are available, but designed and assembled using a smaller, commonly designed platform of sub-components. As process vendors tackle the broad deployment of large numbers of processes for industrial decarbonization, they face similar design goals. We are extending the ideas of PFD into this area of process design. In our work, the “products” are the set of processes we must design. Each individual process is referred to as a process variant; each variant is associated with a set of conditions that the process design must meet. The “common ‘element(s)’” are sub-components shared among the process variants. For our case study, we consider the design of a carbon capture system (CCS). Typically, a CCS is designed for a specific point source capture location (i.e., coal-fired power plants, natural gas combined cycle, cement, refineries, etc.) mainly based on the flue gas conditions and flowrate. PFD has the potential to accelerate the deployment of CCS for industrial processes through the simultaneous design of process families that share common sub-components. Our case study considers 12 process variants. Each process variant in the family is designed for a particular flue gas flow rate and CO<sub>2</sub> concentration. We wish to design each of these process variants using a common platform that includes shared sub-component types, in this case, the absorber and the stripper. We require one of each sub-component for each process variant (i.e., 12 absorbers and 12 strippers in total) but hope to meet all the process variant requirements with a small number of sub-component designs (e.g., here we consider a platform with only two absorber designs and two stripper designs from which to design all 12 process variants).

This approach captures the benefits of manufacturing standardization, akin to modularity, since a large number of process variants share the same common sub-component designs. At the same time, this retains economies of scale as the platform of manufactured sub-components is designed simultaneously with the set of process variants in the family. This approach has proven beneficial in other industries; companies such as Nissan, Toyota, and Boeing have reported substantial cost and time savings by using this approach (Simpson et al., 2014). However, despite documentation of significant success in other industrial manufacturing settings, PFD has largely not been applied to chemical process design. Furthermore, reported approaches have largely been heuristic, and there is a need for rigorous optimization approaches.

Our optimization problem simultaneously determines the individual *designs* of the sub-components in the platform (i.e., if we only offer two absorber designs, what should they be) and *which design* each process variant should use (i.e., for each of 12 process variants, which of the two absorber designs should each variant use). We first formulated this problem as a nonlinear GDP. We solved this problem by reformulating it as a MILP formulation based on full discretization of the design space (Zhang et al., 2022). We extended this approach, proposing another MILP reformulation that avoids discretization by utilizing ReLU activated Neural Network (NN) as piecewise linear surrogate models (Stinchfield et al., 2022, Ceccon et al., 2022). This significantly decreased pre-computation requirements for simulations and allowed us to search for an approximation of the continuous design space. In this paper, we further demonstrate this piecewise linear

surrogate approach to optimize a process family of carbon capture systems, using both an ReLU activated NN and a linear model decision tree as surrogates. We design 12 carbon capture systems with different flue gas flow rates and CO<sub>2</sub> concentrations with the absorber and stripper columns as the shared sub-components.

## 2. Optimization Formulation

The following formulation for optimization of a process family design was first proposed by Stinchfield, et al., (2022). A process variant is represented by  $v$ , and is characterized by the design requirements for that variant. The parameter set  $V$  represents all process variants. The boundary conditions of a process variant are parameterized in  $b_v$ . In our case study,  $|V| = 12$  and the boundary conditions for each variant include the flue gas flow rate and CO<sub>2</sub> concentration. The total annualized cost of a process variant is represented by variable  $c_v$ . The objection function includes a weight for each process variant,  $w_v$ , that captures the expected sales or number of installations of each variant. The variable  $p_v$  captures the performance metrics of a particular process variant. In many cases, this will be an indicator function that determines whether a particular design is feasible for the variant. This ensures that an infeasible combination of sub-component designs is not selected for a process variant  $v$ . We use trained piecewise linear surrogate models, represented by the system of equations  $f^c$  and  $f^p$ , to predict the variable cost of the variant,  $c_v$ , and the performance indicator,  $p_v$ . Piecewise linear surrogates are used because they can be represented exactly as MILPs within the optimization formulation.

The set of common sub-component types considered in the platform is given by  $K$ . In our case study,  $K = \{\text{absorber, stripper}\}$ . The set  $J_k$  includes the sub-component designs for a particular sub-component of type  $k$ . The cardinality of  $J_k$  dictates the number of sub-component designs to consider in the platform for sub-component type  $k$  (i.e., if we want two absorber designs, then  $J_k = \{1,2\}$  where  $k = \text{absorber}$ ). The variable  $\hat{d}_{k,j}$  represents the design variable values for design  $j$  of sub-component type  $k$ , while variable  $d_{v,k}$  represents the design variable values of sub-component type  $k$  for process variant  $v$ . With this, if design  $j$  is chosen for sub-component type  $k$  in variant  $v$ , then  $d_{v,k} = \hat{d}_{k,j}$ .

$$\min. \sum_{v \in V} w_v c_v \quad (1a)$$

s.t.

$$c_v = f^c(b_v, d_{v,1}, \dots, d_{v,k}) \quad \forall v \in V \quad (1b)$$

$$p_v = f^p(b_v, d_{v,1}, \dots, d_{v,k}) \quad \forall v \in V \quad (1c)$$

$$\bigvee_{j \in J_k} \begin{bmatrix} Y_{v,k,j} \\ d_{v,k} = \hat{d}_{k,j} \end{bmatrix} \quad \forall v \in V, k \in K \quad (1d)$$

$$\hat{d}_{k,j}^L \leq \hat{d}_{k,j} \leq \hat{d}_{k,j}^U \quad \forall k \in K, j \in J_k \quad (1e)$$

$$p_v^L \leq p_v \leq p_v^U \quad \forall v \in V \quad (1f)$$

$$c_v \geq 0 \quad \forall v \in V \quad (1g)$$

$$Y_{v,k,j} \in \{\text{True, False}\} \quad \forall v \in V, k \in K, j \in J_k \quad (1h)$$

The objective, Eq. (1a), is to minimize the total weighted annualized cost of all process variants,  $v \in V$ . Piecewise linear surrogates predict the cost of each variant  $c_v$ , Eq. (1b), and the performance indicator  $p_v$ , Eq. (1c). Both surrogates are functions of the boundary conditions at a particular variant,  $b_v$ , and the design of each sub-component type  $k \in K$ . The disjunctions in Eq. (1d) select which of the sub-component designs,  $j \in J_k$ , for a sub-component of type  $k$  are selected for process variant  $v$ . The number of disjunctions is equal to  $|K| \times |V|$  because we make this decision for each sub-component  $k$  and each process variant  $v$ . The number of disjuncts corresponds to  $|J_k|$  for a particular sub-component of type  $k$ , because we decide on which sub-component design,  $j \in J_k$ , to select. Eq. (1e) bounds the design variable of sub-component type  $k$ , which also corresponds to the ranges used to train the surrogate. Eq. (1f) captures the performance constraints for each process variant.

### 3. Numerical Case Study

We demonstrate this formulation by designing a process family of 12 aqueous monoethanolamine (MEA) solvent-based carbon capture variants. Each variant requires a design that captures at least 90% of CO<sub>2</sub> entering the facility. In this case study, each process variant  $v$  is described by one of three flue gas flow rates and one of four carbon dioxide concentrations. This led to  $3 \times 4 = 12$  possible combinations, representing the boundary conditions for the 12 process variants. Considering the units in the capture facility flowsheet, we chose the common sub-component types to be the absorber and stripper,  $K = \{\text{absorber, stripper}\}$ , since they contribute heavily to the overall purchase cost and have large effects on the performance of the system, thereby directly affecting operating costs.

To gather surrogate training data, we discretized the design ranges for the absorber and stripper. For the absorber, we considered 10 diameters in the range of 0.3 m – 1.2 m. For the stripper, we considered 10 diameters in the range of 10 in.–55 in. We performed a simulation of the carbon capture system for all possible combinations of the process variant boundary conditions and sub-component sizes. This led to  $12 \times 10 \times 10 = 1,200$  simulations. We used an Aspen Plus model of the aqueous MEA system for the simulations (Morgan et al., 2018). Each simulation was marked as *feasible* if the key performance requirements (e.g., CO<sub>2</sub> recovery) were met and *infeasible* otherwise. This set of data and corresponding *feasible*, *infeasible* labels were used to train a 15-node, single-layer ReLU activated NN to determine the performance indicator,  $p_v$ . The NN was imported directly in the formulation, as shown in Eq. (1c), using OMLT: Optimization and Machine Learning Toolkit (Ceccon et al., 2022). Purchase cost was estimated using the IDAES costing framework (Lee et al., 2021). Combined with estimates for annual operating cost, total annualized cost was used to train a linear decision tree (Ammari et al., 2022) and imported using OMLT, represented by Eq. (1b), to predict  $c_v$  of process variant  $v$ . Note that both surrogates are captured as piecewise linear functions, resulting in an MILP formulation.

For this case study, we considered two absorbers and two strippers for the sub-component designs (i.e.,  $J_k = \{1,2\}$  for each sub-component type). The problem was formulated using Pyomo (Bynum et al., 2021) and solved using Gurobi (Optimization, LLC Gurobi, et al., 2020). Additionally, we used OMLT and the Pyomo extension, Pyomo.GDP (Chen et al., 2022), to capture the disjunctions. The optimal designs for the two absorbers and two strippers are reported in Table (1), and Figure (1) shows which combinations of the

two possible absorber designs and two possible stripper designs were selected for each of the 12 process variants. The optimization determined the sizes for the common sub-components. The larger absorber was used for the upper right corner of the variant process space, while the larger stripper was needed only for the most demanding variant in the upper right-hand corner.

Table 1. Optimal Designs for Common Units

Sub-component $k$	Design 1 $j_1 \in J_k$	Design 2 $j_2 \in J_k$
Absorber	0.3 m. diameter	0.61 m. diameter
Stripper	0.254 m. diameter	1.075 m. diameter

Figure 1. Process Family Design

Since the optimization is performed with surrogate models, we verified this result using the original model to simulate each of the 12 process variant boundary conditions with the corresponding set of assigned absorber and stripper designs. The total annualized verified cost was  $\$1.29 \times 10^6$ , which is an overall surrogate error of approximately 2%.

Table 2. Optimization Problem Specs

Num. of Binary Variables	191
Num. of Continuous Variables	273
Num. of Constraints	720
Total Annualized Cost (Obj.)	$\$1.26 \times 10^6$

The combination of training time for both the ReLU NN surrogate and linear decision tree was approximately 300 seconds, while the optimization formulation itself took approximately 1 second along with the problem structure as described in Table (2).

#### 4. Conclusions and Future Work

We demonstrated a surrogate-based approach for optimally designing a process family of 12 carbon capture variants. We considered a platform of common sub-component designs that considered two absorbers and two strippers, whereas a conventional design approach would have generated 12 unique absorber designs and 12 unique stripper designs. This approach uses surrogates to predict required system costs and performance. This removes

the nonlinearities in the GDP and allows the transformation to an MILP. The machine learning surrogates were easily included in the optimization with OMLT, and the overall formulation solved in under a second, demonstrating tractability in this approach.

For future work, we plan on expanding the sub-component design ranges and incorporating more sub-component types. Furthermore, we plan on incorporating an estimation of savings due to economies of numbers within the optimization formulation, exploring uncertainty in weights, and quantifying the degree of flexibility our designs offer across the design space.

## Abstract

Hemicelluloses are amorphous polymers of various sugar molecules and have been widely utilized in bioenergy, mining, and textile. Through hydrolysis, hemicellulose is transformed into sugar oligomers and monomers. In this paper, we build a global optimal decision tree (GODT) model on an extensive hemicellulose hydrolysis dataset containing 1955 experimental data points from 71 published papers from 1985 to 2019. The GODT model is trained to predict xylose yield from hardwood hemicellulose hydrolysis in batch reactors. Compared with the heuristic method, our global optimal algorithm can obtain an average absolute improvement of 1.54% in test accuracy. Moreover, we demonstrate that the reasoning procedure of predictions is easy to comprehend by human decision-makers, thus contributing an explainable model for biorefining.

**Keywords:** Biorefining; Global Optimization; Machine learning; Decision Tree

## 1. Introduction

Hemicelluloses are amorphous polymers of various sugar molecules, such as xyloses, mannoses, arabinoses, glucoses, and galactoses (Scheller & Ulvskov, 2010). It is the second most component in lignocellulosic biomass, ranging from 25 to 35 wt% (Isikgor & Becer, 2015). Hemicellulose has been broadly utilized in the bioenergy, mining, textile, cosmetic and pharmaceutical industries (Spiridon & Popa, 2008). Industrial use of hemicellulose often requires that the polymer be hydrolyzed into constituent oligomers and monomers. Scale-up and commercialization of hemicellulose hydrolysis require robust models. However, the traditional kinetic models can only consider limited operating regimes and species (Fearon et al., 2020). Fortunately, extensive studies on kinetic models have contributed abundant data to enable the development of statistical models. In our previous work (Wang et al., 2022), we mined the literature on hardwood hemicellulose hydrolysis and collected a dataset containing 1955 experimental points on batch hemicellulose hydrolysis from 71 published papers dating from 1985 to 2019. Three machine learning models (i.e., ridge regression, support vector regression, and artificial neural networks (ANN)) were developed to predict the xylose yield of hemicellulose hydrolysis utilizing this dataset. This

work also showed the superior performance of ANN in predicting the xylose yield of hemicellulose hydrolysis, compared with kinetic models. However, the black-box nature of ANN makes the interpretability of predictions difficult.

This paper aims to develop an interpretable model based on decision trees to predict the xylose yield of hemicellulose hydrolysis. The decision tree is a powerful machine-learning method for classification and regression tasks. The key advantage of decision tree modeling lies in interpretability, as such models closely resemble human reasoning and are easy to comprehend by human decision-makers (Weiss & Kulikowski, 1991). For example, the operator of a biorefinery plant is more likely to understand and trust a decision tree model over black-box models (e.g., neural network) since the decision tree breaks a complex decision-making process (e.g., the efficiency of the operation) into a collection of more straightforward logical tests (e.g., temperature range).

A fundamental problem is decision tree learning, a task to find the most accurate decision tree model from a dataset. For decades, we have relied on greedy-based heuristics, such as CART (Loh, 2011), ID3 (Quinlan, 1986), and C4.5 (Quinlan, 2014), to obtain suboptimal decision trees. Recent studies based on a comprehensive benchmark have shown that global solutions obtained through mixed-integer optimization (MIO) led to an average absolute improvement in test accuracy of 1 - 5% (Bertsimas & Dunn, 2017). Despite its superior performance, existing MIO-based approaches (Bertsimas & Dunn, 2017; Aghaei et al., 2021; Verwer & Zhang, 2019) rely on all-purpose global optimization solvers and can only address a small dataset (e.g., several hundred samples). Recently, we developed a tailored reduced-space branch and bound algorithm to train optimal decision trees for classification tasks (Hua et al., 2022). The algorithm is based on the observation that decision tree learning can be formulated as a two-stage stochastic programming problem, and thus various approaches proposed in the stochastic programming community can be utilized to exploit the problem structure. This work extended the solvable optimal decision tree problem to 245,000 samples.

In this paper, we apply the global optimal algorithm proposed by Hua et al. to the biorefining dataset and show that the average training and testing accuracy can be improved by 1.70% and 1.54% compared with the heuristic method.

## **2. Problem Description**

### *2.1. Dataset Description and pre-process*

We adopt the hemicellulose hydrolysis dataset from our previous work (Wang et al., 2022). This dataset collected 1955 data points from 71 published works from 1985 to 2019. Each data point has eight numeric variables and two categorical variables. Wang et al. have demonstrated that the two categorical variables (wood and acid species) contribute little in predicting the xylose yield.

Besides, these two categorical variables need one-hot encoding to be utilized in the decision tree model, which will introduce redundant binary variables and make the decision tree modeling unstable. Therefore, we only use eight numeric variables in this paper, as shown in Table 1. Notably, there are some repeating experiments with the same reaction and biomass conditions but resulting in different xylose yields. We unified these data points with the average value of xylose yields and obtained a unique dataset with 1828 data points.

Table 1 Dataset variable list

No.	Variables	Type	Units	Range
1	Total Reaction Time	Numeric	minute	0 - 1155
2	Reactor Temperature	Numeric	Kelvin	313 - 553
3	Liquid Solid Ratio	Numeric	g liquid / g solid	1.53 - 50
4	Initial Proton Concentration	Numeric	mols/L	0-1.22
5	Particle Size	Numeric	mm	0.117 - 50
6	Isothermal Reaction Time	Numeric	minute	0 - 1140
7	Initial Hemicellulosic Xylose in Feedstock	Numeric	weight %	11.932 - 34.9
8	Xylose Yield	Numeric	%	0 - 100

To adapt to the classification decision tree algorithms, we further encoded the variable xylose yield from a numeric variable to a categorical variable with  $K$  categories. Specifically, we created two classification datasets with three and five categories. For the first dataset, the yield is either lower [0%, 30%], medium (30%, 75%), or high (75%, 100%]. For the second one, the labels of yield are very low [0, 20%], low (20%, 40%], medium (40%, 60%], high (60%, 80%], or very high (80%, 100%].

## 2.2. Problem Description

The paper aims to develop a classification decision tree to predict the encoded xylose yield of hemicellulose hydrolysis utilizing variables 1-7 in Table 1. Firstly, we randomly divide the whole dataset into training and testing datasets. Then, let  $\mathcal{S} = \{1, \dots, n_{train}\}$  be the index set of the training dataset,  $\mathcal{S}_{test} = \{1, \dots, n_{test}\}$  be the index set of the testing dataset,  $\mathcal{K} = \{1, \dots, K\}$  be the class set of the encoded xylose yield. For  $s$ th data point, we denote the encoded xylose yield as  $\mathbf{y}_s \in \{0,1\}^K$  and the feature variables as  $\mathbf{x}_s \in \mathbb{R}^P$ . Sequentially, the training dataset can be represented as  $\mathbf{X} = \{\mathbf{x}_s | \mathbf{x}_s \in \mathbb{R}^P, s \in \mathcal{S}\}$  with the label set  $\mathbf{Y} = \{\mathbf{y}_s | \mathbf{y}_s \in \{0,1\}^K, s \in \mathcal{S}\}$ . Then, the problem of this paper can be represented as finding a decision tree  $F: \mathbb{R}^P \rightarrow \{0,1\}^K$  with maximum depth  $D$  to solve the following optimization problem:

$$\min \sum_{s \in \mathcal{S}} E(F(\mathbf{x}_s), \mathbf{y}_s) + \lambda R(F) \quad (1)$$

where  $E(\cdot)$  is the misclassification error between the predicted label of tree  $F(\mathbf{x}_s)$  and the corresponding ground truth  $\mathbf{y}_s$ ,  $\lambda$  is the complexity parameter to balance the accuracy and tree complexity,  $R(\cdot)$  is the complexity function to measure the tree's complexity. After obtaining the decision tree, the labels of testing samples are predicted by  $F(\mathbf{x}_s), s \in \mathcal{S}_{test}$ .

### 3. Global Optimal Decision Tree (GODT)

Given the maximum depth of a decision tree  $D$ , the nodes of the tree are denoted as  $t \in \{1, \dots, T = 2^{D+1} - 1\}$ . We further define branch nodes as  $t \in \mathcal{T}_B = \{1, \dots, \lfloor T/2 \rfloor\}$  and leaf nodes as  $t \in \mathcal{T}_L = \{\lfloor T/2 \rfloor + 1, \dots, T\}$ . Then, the decision tree problem (1) can be reformulated in the following MIO form:

$$\begin{aligned}
 \min_{a,b,c,d,z,L} \quad & \frac{1}{L} \sum_{s \in \mathcal{S}} L_s + \lambda \sum_{t \in \mathcal{T}_B} d_t & (2) \\
 \text{s.t.} \quad & \frac{1}{2} \sum_{k \in \mathcal{K}} (y_{sk} + c_{kt} - 2y_{sk}c_{kt}) - L_s \leq 1 - z_{st}, \forall t \in \mathcal{T}_L \\
 & \sum_{k \in \mathcal{K}} c_{kt} = 1, \forall t \in \mathcal{T}_L \\
 & \sum_{t \in \mathcal{T}_L} z_{st} = 1 \\
 & a_m^T (\mathbf{x}_s + \epsilon - \epsilon_{\min}) + \epsilon_{\min} \leq b_m + (1 + \epsilon_{\max})(1 - z_{st}), \forall m \in A_L(t), t \in \mathcal{T}_L \\
 & a_m^T \mathbf{x}_s \geq b_m - (1 - z_{st}), \forall m \in A_R(t), t \in \mathcal{T}_L \\
 & \sum_{j=1}^P a_{jt} = d_t, \forall t \in \mathcal{T}_B, j \in \{1, \dots, P\} \\
 & 0 \leq b_t \leq d_t, \forall t \in \mathcal{T}_B \\
 & d_t \leq d_{p(t)}, \forall t \in \mathcal{T}_B \\
 & 0 \leq L_s \leq 1 \\
 & a_{jt}, d_t \in \{0,1\}, 0 \leq b_t \leq 1 \forall t \in \mathcal{T}_B, j \in \{1, \dots, P\} \\
 & z_{st}, c_{kt} \in \{0,1\}, \forall t \in \mathcal{T}_L
 \end{aligned}$$

where  $L_s \in [0,1]$  is the loss of sample  $s$ .  $L_s$  equals to 1 if sample  $s$  is misclassified, otherwise 0. Variables  $a, b, c, d$  are the structure variables of the decision tree. Specially,  $a_t = [a_{1t}, \dots, a_{pt}] \in \{0,1\}^P$  represents the split dimension on node  $t$ .  $b_t \in [0,1]$  is the split value on node  $t$ .  $c_{kt} \in \{0,1\}$  is the class indicator at the leaf node  $t \in \mathcal{T}_L$ .  $d_t \in \{0,1\}$  is the split indicator at the decision node  $t \in \mathcal{T}_B$ . A more detailed description of this MIO formulation can be found in Hua et al., 2022.

The fundamental idea to solve this MIO problem is to decompose the problem into a two-stage problem, in which structure variables  $a, b, c, d$  are the first-stage variables. The two-stage problem is shown as follows:

$$\text{First-stage:} \quad f(M_0) = \min_{m \in M_0} \sum_{s \in \mathcal{S}} Q_s(m) \quad (3)$$

$$\text{Second-Stage:} \quad Q_s(m) = \min_{z_s, L_s} \frac{1}{L} L_s + \frac{\lambda}{n} \sum_{t \in \mathcal{T}_B} d_t \quad (4)$$

s.t. Constraints in problem (2)

where  $m = (a, b, c, d)$  is the first-stage variables, and  $M_0 := [m^l, m^u]$  is the initial region of the first-stage variables. Then we can use the branch and bound scheme to solve the resulting two-stage problem. The key advantage here is that

we can prove that branching only on variables denoting the tree structures  $(a, b, c, d)$ , our branch and bound training algorithm can guarantee the convergence to a global optimal solution with properly designed lower and upper bounds. Moreover, the decomposable nature of our lower and upper bound methods allows us to easily parallelize the branch and bound decision tree training algorithm on thousands of CPU cores. The detailed procure of the tailored reduced-space branch and bound algorithm to solve problem (2) can be found in Hua et al., 2022.

## 4. Results and Discussions

### 4.1. Experiment setup

In our study, we randomly split the dataset into a training dataset (75% of the entire dataset) and a testing dataset (25%). We compare the performance of our global optimal decision tree (GODT) with the popular heuristic algorithm CART (Loh, 2011). Different tree depths, including 2 and 3 levels, were considered in our experiments. All experiments were executed using Julia 1.7.0 with 4 hours time limit on a high-performance computing cluster, of which each node contains 40 Intel cores at 2.4 GHz and 202 GB RAM. We executed all the experiments in parallel mode with 40 cores for two-level trees and 80 cores for three-level trees.

To compare the performance of each algorithm, we reported train and test accuracy (%) :=  $\frac{\text{correct classification}}{\text{all classification}}$ . We also reported the optimality gap for GODT as  $Gap (\%) := \frac{\text{upper bound} - \text{lower bound}}{\text{upper bound}} \times 100\%$ . This optimality gap is the worst gap of the current solution from the global optimal solution, which is a unique property of the deterministic global optimization algorithms. Heuristic algorithms such as CART cannot provide this worst gap. Besides, to fairly compare the performance, we repeated the experiments five times with five different random splits and reported means and standard deviations of each index in the form of *mean (standard deviation)*.

### 4.2. Comparison results

Table 2 shows the comparison results of CART and GODT on different datasets with 3 and 5 categories. The method with better training and test accuracy is bolded in this table. Generally, both GODT and CART perform better on the dataset with fewer categories and trees with more levels. For the optimality gap, the GODT method can obtain a small and acceptable optimality gap on two-level trees while maintaining a larger optimality gap on three-level trees. Despite the larger optimality gap on three-level trees, GODT still performs better than CART. As for accuracy, GODT can obtain average absolute improvements of 1.70% and 1.54% in train and test accuracies, respectively.

Table 2 Comparison results of CART and GODT. Each index is in the form of *mean (standard deviation)*.

Yield Category	Tree Depth	Method	Optimality Gap (%)	Train Accuracy (%)	P value	Test Accuracy (%)	P value
3	2	CART	-	64.62 (0.86)	9.80E-04	64.74 (2.62)	6.98E-04
		<b>GODT</b>	<b>0.92 (0.04)</b>	<b>65.73 (0.92)</b>		<b>66.14 (2.72)</b>	
3	3	CART	-	68.46 (1.45)	1.96E-01	67.98 (2.23)	1.96E-01
		<b>GODT</b>	<b>88.86 (0.61)</b>	<b>68.86 (0.98)</b>		<b>68.99 (1.07)</b>	
5	2	CART	-	44.24 (0.30)	2.18E-05	43.78 (1.00)	4.54E-03
		<b>GODT</b>	<b>5.27 (0.79)</b>	<b>48.61 (0.24)</b>		<b>46.51 (0.37)</b>	
5	3	CART	-	49.37 (0.59)	4.88E-02	47.12 (1.45)	1.40E-01
		<b>GODT</b>	<b>79.55 (1.70)</b>	<b>50.30 (0.83)</b>		<b>48.13 (2.91)</b>	

*Remark 1.* GODT focuses on optimizing the training accuracy in problem (2). We have proved that global optimality can be reached on the problem (2). However, there is no guarantee that the test accuracy of GODT can also be globally optimal or consistently exceed CART (considering over-fitting). Nevertheless, extensive numerical results in this paper and previous works have demonstrated that an improvement in the test accuracy can be expected on most datasets for GODT, especially when the number of samples is large (e.g.,  $\geq 1000$ ) and the tree depth is small (e.g., 2-4), since over-fitting is avoided.

*Remark 2.* The p-values of one-tailed paired t-tests show that when tree depth is 2, GODT's train and test accuracy is statistically significantly larger than CART. When tree depth is 3, the results are not statistically significant. That is possible because we have not reached a small optimality gap in these experiments. We may obtain a more significant result if we develop a more efficient global algorithm for the decision tree.

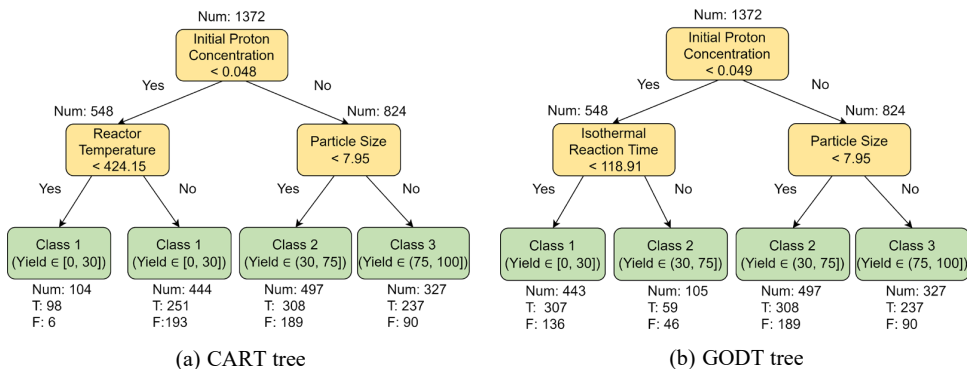

Figure 1 Decision Trees with two levels

### 4.3. Interpretability of models

The reasoning procedures of decision trees are similar to human reasoning and easy to comprehend by human decision-makers. Figure 1 shows the detailed reasoning procedures of two-level trees on the three-category training dataset in one experiment. In this experiment, the CART and GODT trees obtained a training accuracy of 65.16% and 66.40%, respectively. Notably, the optimality gap of this GODT tree is 0.92%. The CART tree selected initial proton

concentration, reactor temperature, and particle size as the reasoning variables, while the GODT tree selected initial proton concentration, isothermal reaction time, and particle size as the reasoning variables. It should be noted that the CART trees have two leaf nodes with the same parent node and the same predicted class. This kind of split is abnormal since this split does not improve accuracy. The reason for this abnormal split is that CART utilizes the Gini index as the objective function at each node to make its split decisions, which differs from the accuracy we want to optimize. This kind of split may reduce the Gini index but not influence the accuracy. As an outcome, the accuracy of the GODT tree is better than the CART tree.

## 5. Conclusion

In this paper, we developed a global optimal explainable decision tree model for hemicellulose hydrolysis. This global optimal decision tree algorithm utilizes the MIO form of the decision tree and solves the problem by decomposing the MIO problem into a two-stage stochastic programming problem. Experiments on a hemicellulose hydrolysis dataset show that the global optimal decision tree model can obtain an average absolute improvement of 1.54% in test accuracy compared to the heuristic decision tree model while providing an acceptable optimality gap. Moreover, as a nature of decision tree models, the proposed models closely resemble human reasoning and are easy to comprehend by human decision-makers. In the future, we aim to develop more efficient global optimal explainable decision tree models to achieve higher prediction accuracies and lower computational costs.

## Abstract

This work presents the numerical simulation in L -V equilibrium stage in a plate distillation column using the SPH method, considering Sieve and Bubble cap plates. To perform the simulation of the equilibrium stage, periodic conditions in temperature were established. The sizing of the column was performed in Aspen One considering an equimolar mixture of Benzene-Toluene and an operating pressure that guarantees that the cooling water temperature of the condenser is 120°F, the thermodynamic model used was Chao-Seader. The following information was obtained from the Aspen simulation: liquid and vapor velocity per stage, viscosity and density of the mixture, operating pressure, and column diameter. Data from Aspen simulation was used for the CFD simulations using DualSPHysics. The results allow it to compare the thermal distribution and the velocity fields between plate design and the time to achieve the thermal equilibrium.

**Keywords:** CFD, Simulation of Distillation, thermal equilibrium.

## 1. Introduction

Traditionally, the numerical simulation of hydrodynamics and heat transfer in distillation column has been performed with Eulerian methods. These methods use mesh for the discretization of the medium, thus generating averages in the transfer zones and interfaces between fluids. On the other hand, Lagrangian methods allow to see in detail the phenomena at the interface and to discretize the continuous medium through points meshless. In this work we propose to perform a numerical simulation of distillation columns using the SPH method (Lagrangian nature).

Distillation is a highly inefficient unitary operation and its energy consumption is high, so some authors have proposed new alternatives to improve efficiency and reduce energy consumption. Yin et al., (2002) studied the liquid retention in a packed column with Pall rings and the distribution of the fluid over the packing's. They find that the distribution of the liquid retention is not uniform due to the design of the distributor.

Fu et al., 2020 investigated the flow and retention of a liquid in a packed column with pall rings finding that the randomness of the packing generates transitions from viscous flow to turbulent regimes in a Reynolds Number range between 6.7 and 40.2. Jain et al., 2021 developed an Eulerian model to simulate multiphase gas-liquid flow in a wide variety of regimes over a manifold, finding that the discharge patterns, the uniformity and symmetry of the flow lines and the pressure drop across the manifold exhibit significant differences from each other. Pichler et al., 2021, studied heat transfer in packed columns by numerical simulations considering conduction and natural convection suggesting a correction as a function of particle diameter that can reduce up to 75% the error in surface temperature. In this work the numerical simulation of the hydrodynamics and heat transfer in one stage inside a distillation column using the Smoothed Particle Hydrodynamics (SPH) method is performed in order to compare velocity fields, retention times and heat transfer in one stage. The SPH method is a mesh-free method with which it is possible to track the interface between the fluids immersed in a flow in a clear and simple way, thus allowing a better analysis of the phenomena occurring in it.

## 2. Methodology

In this work a methodology for the simulation of the hydrodynamics and thermal equilibrium of plate distillation columns is proposed. This methodology consists of 3 stages: rigorous design of the distillation column in Aspen Plus, 3D design of the column - sieve plates and hydrodynamic analysis of the columns using the SPH method. The Aspen Plus simulation results were used as input data for SPH. The 3D design was performed in SolidWorks.

Figure 1. Methodology for the numerical simulation of the hydrodynamics and equilibrium of distillation columns.

### 2.1. Rigorous design of the distillation column in Aspen Plus

The design of the distillation column was carried out considering a binary equimolar Benzene-Toluene mixture, whose equilibrium is modeled with Chao-Seader. A Rad-Frac model was used for column equilibrium. It was proposed at 120°F to ensure cooling water in the condenser. The feed is 100lbmol/hr. According to the rigorous design, 10 stages were obtained to achieve 98% purity and recovery for each component. Table 1 shows the results obtained from the Aspen One® simulation of stages 6 and 7, which were used as input data for the SPH method.

### 2.2. Column and sieve plate sizing

The 3D design of the column and plates was carried out in SolidWorks. The design parameters used were: column diameter, effective and downspout areas, obtained in Aspen One. The distance between plates was proposed to be 0.15m. Stainless steel 316L

was chosen as construction material. Figure 1 shown in detail the 3D design of the sieve and bubble cap plates.

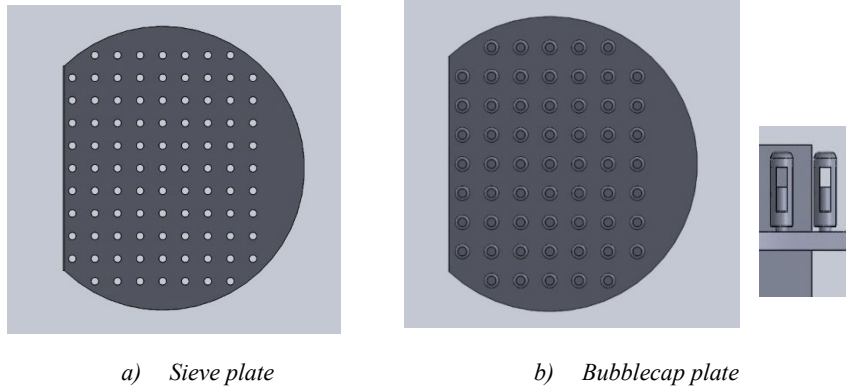

Figure 1. 3D design plates using in distillation columns. a) sieve and b) bubble cap.

Table 1. Results of the rigorous simulation of the distillation column in Aspen Plus.

Parameter	Liquid	Vapor
Density (kg/m <sup>3</sup> )	783.8023	4.0206
Viscosity (Ns/m <sup>2</sup> )	2.5x10 <sup>-4</sup>	9.5x10 <sup>-6</sup>
Temperature (°C)	110.39	105.99
Mass fraction	0.5886	0.5405
Velocity (m/s)	0.0261	0.0214
Coefficient of thermal diffusivity (m <sup>2</sup> /s)	7.9247E-8	
Surface tension	0.018 N/m	0.018 N/m

### 2.3. Hydrodynamics and heat transfer in SPH

SPH is a Lagrangian meshless method with applications in the field of Computational Fluid Dynamics. Originally invented for astrophysics in the 1970s (Monagan J, 1992) it has been applied in many different fields, including fluid dynamics (Alvarado-Rodríguez C.E. et al., 2019) and wastewater treatment (Mokos et al., 2015). The method uses points named particles to represent the continuum and these particles move according to the governing equations in the fluid dynamic. When simulating free-surface flows, no special surface treatment is necessary due to the Lagrangian nature of SPH, making this technique ideal for studying violent free-surface motion. Moreover, the movement of the boundaries can be set easily without the necessity of update the mesh as in the Eulerian methods. The SPH formalism used in the simulations is reported by Dominguez et al. (2021) which is set in the DualSPHysics code, in this work only the continuity equation (Eq. 1), the momentum equation (Eq. 2), the equation of state (Eq. 3) and the energy transport equation (Eq. 4) in the SPH formalism are reported. Mass transport can be added for future work (Chiron et al., 2019)

$$\frac{d\mathbf{v}_a}{dt} = -\sum_b m_b \left( \frac{p_a + p_b}{\rho_a \rho_b} + \sum_b m_b \left( \frac{4v_0 r_{ab} \cdot \nabla_a W_{ab}}{(\rho_a + \rho_b)(r_{ab}^2 + \eta^2)} \right) \mathbf{v}_{ab} + \sum_b m_b \left( \frac{\tau_{ab}^j}{\rho_b^2} + \frac{\tau_{ab}^i}{\rho_a^2} \right) \nabla_a W_{ab} \right) \nabla_a W_{ab} + g, \quad (1)$$

$$\frac{d\rho_a}{dt} = -\rho_a \sum_b \frac{m_b}{\rho_b} (\mathbf{v}_b - \mathbf{v}_a) \cdot \nabla_a W_{ab}, \quad (2)$$

$$P = B \left[ \left( \frac{\rho}{\rho_0} \right)^\gamma - 1 \right], \quad (3)$$

$$\frac{dT_a}{dt} = -\frac{1}{C_p} \sum_b \frac{m_b (k_a - k_b) (r_a - r_b) \cdot \nabla_a W_{ab}}{\rho_a \rho_b (r_{ab}^2 - \eta)} (T_a - T_b), \quad (4)$$

where the subscripts  $a$  and  $b$  are denoted for the mean particle “ $a$ ” and the neighbors particles “ $b$ ”,  $\mathbf{v}$  is the velocity,  $t$  is time,  $m$  is mass,  $P$  is pressure,  $\rho$  is density,  $v_0$  is the kinematic viscosity,  $\tau$  is the stress tensor,  $B = c_0^2 \rho_0 / \gamma$ ,  $c_0$  is an artificial sound speed, and  $\gamma = 7$ ,  $C_p$  is the specific heat of the fluid,  $k$  is the conductivity constant,  $T$  is the temperature and  $W$  is the kernel function defined in the SPH method. This method was implemented for the numerical analysis of the distillation columns under the following considerations: periodic conditions were used to perform the hydrodynamic and equilibrium analysis. The initial properties of the fluids are shown in Table 1. In all cases, no-slip conditions were considered in the interaction between fluid and boundary particles using the dynamic particle method reported by (Crespo et al., 2007a). A different resolution was used in each case due to the specific characteristics for the geometries in order to save computational time, obtained through a convergence analysis for each phase. SPH results have so far only been compared with those obtained from the Aspen One simulation.

### 3. Discussion of results

With the results obtained from the SPH numerical simulations, it is possible to analyze the velocity profile and the temperature profile inside the stage, for each plate design. In addition, it is possible to approximate the required time that each stage needs to reach equilibrium under the initial conditions established.

#### 3.1. Bubble cap plate

The simulation was performed with a total of 1,686,948 fluid particles of which 1,042,345 are liquid and 684,936 are vapor. The particles modeling the plate and column are 535,069. We simulated 30 seconds of real-time. The simulation took a total of 10.5h on the ITESI computer with an Nvidia GPU Geforce RTX 3060. Figure 2 shows the velocity field obtained in the simulation from the top and side perspectives. According to the results obtained, it can be deduced that the vapor velocity below the cap does not register fluid movement, however above it, the profile is almost homogeneous. This can be contrasted with the results of the temperature profile shown in Figure 3, for the same stages analyzed. The stagnation of the fluid shown in Figure 2 generates a retard in the homogeneity of the temperature in that zone. This is due to the fact that the temperature variation is dominated by the effect of diffusion, which means that even after 30 seconds, the final temperature corresponds to the initial value.

### 3.2. Sieve plate

The simulation was performed with a total of 1,433,006 fluid particles of which 962,243 are liquid and 470,763 are vapor. The particles modeling the plate and column are 387,365. 10 seconds of real-time were simulated. The simulation was completed in a total of 2.5h on the same ITESI computer. Figure 4 shows the velocity field obtained in the simulation from the top and side perspectives. As in the bubble cap plate, a higher velocity is obtained in the area where the fluid enters from the downspout, however, the velocity distribution is more homogeneous compared to the bubble cap plate due to the velocity generated by the vapor in the orifices. This homogeneity in the flow also generates homogeneity in the temperature as shown in Figure 5.

Figure 2. Side and top perspectives of the velocity fields in the stage for the bubble cap plate.

Figure 3. Side and top perspectives of the temperature fields in the stage for the bubble cap plate.

Figure 4. Side and top perspectives of the velocity fields in the stage for the sieve plate.

Figure 5. Side and top perspectives of the temperature fields in the stage for the sieve plate.

#### 4. Conclusions

In this work, the simulation of a stage inside a distillation column is presented. Two case studies were developed: bubble cap and sieve plates. The geometry of the column and the plates were made in SolidWorks. Then, the geometries were exported to DualSPHysics to perform the corresponding simulations, based on the parameters obtained with the rigorous simulation in Aspen One. The numerical results indicate that the height of the bubble caps is not adequate since there is no homogeneous temperature distribution in the area near the downspout towards the next stage. A proper configuration in the distribution of the caps or in the height of the caps could benefit a homogeneous distribution of velocity and temperature. In contrast to the bubble cap plate, in the sieve plate system, the velocity distribution is more homogeneous and reaches a constant temperature after about 10 seconds. Based on the methodology proposed in this paper, it is possible to evaluate the hydrodynamic and heat transfer performance of different geometries for packed or plate columns. These analyses will allow obtaining mathematical correlations with which it will be possible to quantify the impact of a design modification on the hydrodynamic performance of the column. This methodology can be extended to packed columns to determine how liquid retention increases or decreases with packing design and distribution.

## Abstract

Currently, in the oil well drilling industry, the process is monitored by pressure and temperature sensors in the well and of the drilling fluid. Instabilities can be noticed with the gravel that returns in the mud, demanding the implementation of monitoring systems. This work proposes applying computer vision techniques to monitor vibrating screens and detect particulate material flow. Experiments were conducted on a pilot screen using a suspension of sand and 0.1% xanthan gum, simulating drilling mud. Each experiment varied operating conditions, obtaining 26 videos. The methodology evaluated the response of U-Net neural networks in semantic segmentation with Python. A database of 11,140 images and corresponding templates was built. The evaluation metrics were accuracy, F1-Score, and MeanIoU. The results show high segmentation ability, with accuracy 97%, F1-Score 92%, and MeanIoU 91%. The results show that the U-Net has good segmentation capabilities and provide a promising alternative for non-invasive process monitoring.

**Keywords:** computational vision, convolutional neural networks, oil wells drilling.

## 1. Introduction

Artificial Intelligence is a science that studies the ability of machines to act similarly to humans. For this, a machine learning step is necessary<sup>[1]</sup>. Currently, several algorithms can be found in the literature capable of solving problems in various industry segments. In this context, the choice of the appropriate algorithm will depend on the final objective and nature of the data<sup>[2]</sup>.

Image acquisition of industrial processes is a common practice in facility surveillance. The rise of machine learning models and the increased processing power of computers have allowed the development of models capable of processing increasingly complex data, such as images, which has motivated various industries to explore the information that the so-called computer vision can offer. Such a perspective can bring advantages to the automation of quality control systems, sensing, and safety monitoring, with a high potential of identifying signs of operational accidents before their occurrence<sup>[3]</sup>.

Shallow learning algorithms, in general, need a feature extraction phase before they can make predictions and classifications. The manual process of feature extraction from images is costly and can generate attributes irrelevant to the proposed objective, leading

to highly complex models that do not solve the problem. When these methods are not able to provide feasible results, deep learning techniques are applied<sup>[3][4]</sup>.

One example is Convolutional Neural Networks (CNN's), traditionally consisting of two modules: general learning and specific learning. The general learning module is responsible for receiving the original image and identifying, from it, information common to a diversity of objects from convolution and pooling operations. The response is the so-called attribute vector, which stores the learned characteristics<sup>[4]</sup>. The specific learning module consists of a fully connected layer responsible for solving the problem. It takes as input the attribute vector and provides the class to which the image belongs.

Besides the classification of images as a whole, the classification of each image pixel can be performed, a particular feature of Fully Convolutional Neural Networks (FCN). In such a type of FCN, the specific learning module is replaced by another convolutional layer capable of classifying individual pixels. This type of neural network can be trained without the need for feature extraction steps and exhibits a more accurate response regarding the shape of the objects of interest<sup>[5]</sup>.

The U-net (Figure 1), a particular type of FCN, was developed for biomedical image segmentation. Given the difficulty of creating a sizeable medical image bank, U-Net was initially designed to provide high-accuracy responses regarding segmentation with a low number of images available for training<sup>[6]</sup>.

Figure 1. Representation of the U-Net architecture. Source: Silburt et al. 2018.

The U-Net architecture is formed by a sequence of contraction and expansion layers. In the shrinking step occurs dimensionality reduction, generating feature maps that preserve essential information, such as object contours. At the end of the contraction step, the expansion step occurs, which performs the opposite path, increasing the dimensionality of the image from the generated feature maps. One of the main advantages of this network is in the expansion path, which uses the output of the previous unpooling concatenated with the corresponding pooling layer to increase the number of feature maps. This feature improves the high-level feature extraction capability and makes the network learn the content and location of each pixel in the image<sup>[7]</sup>.

Some relevant uses of the U-Net, far from those cases applied to medical imaging, have been published in recent works with adaptations of this type of FCN, as follows: the detection of manufacturing defects in clothing fabrics<sup>[8]</sup>; mapping impervious surfaces from satellite images<sup>[9]</sup>; the identification of falsification in image splices using dual encoder U-Nets<sup>[10]</sup>; quantification of gas leakage in the subsea environment using CFD and fully convolutional U-net networks<sup>[11]</sup>.

The process of drilling oil wells is complex, and with advances in-depth, instabilities are more likely to occur<sup>[12]</sup>. Therefore, it is convenient to monitor all stages of the process, which is already done using sensors installed on the rig. Most of the variables currently monitored are related to the pressure and temperature conditions along the well and the drilling fluid. An interesting approach would be to evaluate the mud that reaches the surface, which can also indicate the beginning of some instabilities, such as the well collapsing and insights from the column trapped.

Thus, this work proposes using computer vision methods to detect the gravel that reaches the surface. The method evaluated the response of U-Net type fully convolutional neural networks in the semantic segmentation of images that simulate the flow in vibrating screens, the first equipment to receive the drilling mud. Another justification for using this type of network is the difficulty in obtaining images of gravel flow on actual screens, in rigs, and the adaptability of U-Net for the scenario of small image banks.

## 2. Methodology

Due to the sake of industrial secrecy related to obtaining images from the operation of the actual sieves, the behavior of this process equipment was investigated from experiments performed in a pilot-scale sieve using a suspension of sand and xanthan gum. A total of 26 videos with varied operating conditions was employed in the present study. The experiments are detailed in [P].

The tests with the proposed U-Net architecture used 11,140 flow images with their respective templates; 20% of these were used to test the FCN and 80% for the training stage. From the training data bank, 10% was used for the validation stage, which used a cross-entropy loss function. Examples of images from the database can be seen in Figure 2. The templates were obtained in a semi-automated way from the construction of image processing algorithms specific to the color, brightness, and contrast conditions present in each video. Conversion to color spaces other than RGB, histogram equalization, and digital filtering for image quality improvement were explored.

Figure 2. Examples of images from the database.

The U-Net algorithm was developed in Python, using Keras and TensorFlow. The preprocessing step performed the image acquisition in its original form, resizing to size [128, 128] and storing the data in tensors. The procedure was the same for the network input images and the template, with the difference that the input images are in color channels and the templates in binary masks.

Next, the network architecture was built using convolution, pooling, and ReLu activation layers in both the contraction and expansion stages. After input, the data goes through a normalization step that forces the pixels in each channel to assume values between zero

and one. Next, the image passes through each layer of the network, which has a depth equal to 4 levels, until it reaches the final layer, which uses a sigmoidal function to perform the pixel-by-pixel classification.

At the end of the model construction, training parameters were defined, such as early stopping criteria, which helps minimize the occurrence of overfitting and the maximum number of epochs. The model was trained, and the network was saved for later use.

### 3. Results and Discussions

During training, accuracy and loss data were collected for training and validation and used in constructing the graphs in Figure 3. It was noticed that the curves converged quickly to a model with high accuracy and low loss rate, with no indication of overfitting. The final accuracy found for this data set was 98.85% for training and 98.88% for testing.

Figure 3. (A) accuracy and (B) loss data for training and validation data.

Other metrics were implemented to evaluate the network response: accuracy, recall, F1-Score, and MeanIoU. Accuracy evaluates the hits in each class considering all positive predictions; recall is the proportion of positives correctly classified as positives. The F1-score is a balancing metric between the response of precision and recall.

The MeanIoU metric was considered the most important for this work since it is the primary metric for semantic segmentation evaluation. It checked the overlap between the prediction and the template, considering the classification value of each pixel and its location. To calculate this metric, the number of pixels that were classified as true positives, which represented the intersection between the template and the prediction, was divided by the sum of all positive pixels in both the template and the prediction, which represented the union between them. The results of the metrics and the confusion matrix can be seen in Figure 4 and Tables 1 and 2.

	TARGET		PREDICT

Figure.4 Results for the (A) training and (B) test image set.

Table 1. Metrics by class for the training and test image set.

CLASS	TRAINING			TEST		
	Recall	Precison	F1-score	Recall	Precision	F1-score
<b>SAND</b>	0.983	0.973	0.978	0.983	0.973	0.978
<b>BACKGROUND</b>	0.994	0.990	0.992	0.994	0.990	0.992

Table 2. Global metrics for the training and test image set.

	TRAINING	TEST
Mean Accuracy	0.998	0.998
Mean IoU	0.973	0.942

The results showed high segmentation ability for both training and test data, so it can be concluded that the chosen parameters for the proposed U-Net were adequate for solving this problem. The adequate segmentation performance measured how many pixels of sand suspension and background were in the image and evaluated the location of each. The prediction of the network by image response was qualitatively verified, and the result is shown in Figure 5.

Figure 5. Segmentation examples provided by the trained U-Net for images from the (A) training and (B) test set.

Inputs from the training and test data sets were tested, and the prediction results showed that the U-Net appropriately described the expected template, showing its potential for feature learning in future predictions.

#### 4. Conclusion

It can be concluded that convolutional networks are powerful tools for image processing, presenting great results with minimal pre-processing procedures for pattern corrections. Parameter tuning is an essential step for the best neural network design. In the case of supervised learning, the quality of the templates is essential to ensure the reliability of the predictions. As a proposed sequence of the present work, the authors expect to evaluate the proposed U-Net in analyzing video images from actual industrial sieves operations for estimating useful process variables for monitoring the drilling process.

This study allows the extraction of operational information from the objects of interest. In the case of this application, the calculation of estimates of percentage filling of the cutout analysis and average flow velocity of the agglomerates is under development. These parameters are not currently measured for rig screens but are useful in the online identification of instabilities and well-collapse. Extension to other areas, such as mineral

and food processing, is possible with the estimation of other variables, such as flow rate and morphological properties of particles, at macro or micro scales, provided images are available.

## Abstract

Decision-focused learning is an emerging paradigm specifically aimed at improving the data-driven learning of input parameters to optimization models. The main idea is to learn predictive models that result in the best decisions rather than focusing on minimizing the parameter estimation error. Virtually all existing works on decision-focused learning only consider the case where the unknown model parameters merely affect the objective function. In this work, extend the framework to also consider unknown parameters in the constraints, where feasibility becomes a major concern. We address the problem by leveraging recently developed methods in data-driven inverse optimization, specifically applying a penalty-based block coordinate descent algorithm to solve the resulting large-scale bilevel optimization problem. The results from our computational case study demonstrate the effectiveness of the proposed approach and highlight its benefits compared with the conventional predict-then-optimize approach, which treats the prediction and optimization steps separately.

**Keywords:** Decision-focused learning, inverse optimization, constraint learning.

## 1. Introduction

In traditional data-driven optimization, we often follow a two-step predict-then-optimize approach, i.e. we first predict the unknown model parameters from data with external features and then solve the optimization problem with those predicted inputs. Here, the learning step focuses on minimizing the parameter estimation error; however, this does not necessarily lead to the best decisions (evaluated with the true parameter values) in the optimization step. In contrast, decision-focused learning (Wilder et al., 2019), also known as smart predict-then-optimize (Elmachtoub and Grigas, 2022), integrates the two steps to explicitly account for the quality of the optimization solution in the learning of the model parameters (i.e. minimize the decision error).

Existing works on decision-focused learning, many of which are based on deep learning with differentiable optimization layers (Amos and Kolter, 2017), have shown that significantly improved solutions can be achieved compared to the traditional predict-then-optimize approach. However, virtually all of them consider the case where the unknown model parameters only affect the objective function, which simplifies the problem considerably since feasibility is not a concern. Yet in many applications, we also need to use data to predict parameters in the constraints; the treatment of this case is in theory possible but difficult using existing methods. In this work, we address this problem by leveraging methods that we recently developed for data-driven inverse optimization (Gupta and Zhang, 2022a), which provide a natural way of incorporating constraints with unknown parameters.

The goal of inverse optimization is to infer an unknown optimization model from decisions that are assumed to be optimal solutions to that optimization problem (Chan et al., 2021). While early works primarily addressed the deterministic setting in which observations are assumed to be exactly optimal solutions of the optimization model, more recent contributions focus on the case with multiple noisy observations (Aswani et al., 2018; Chan et al., 2019; Gupta and Zhang, 2022b). Decision-focused learning can be viewed as a data-driven inverse optimization problem by treating the predictive model for the input parameters as the unknown part of the overall optimization model.

In the remainder of this paper, we first present the mathematical formulation of the decision-focused learning problem where we explicitly incorporate constraints that ensure feasibility of the optimal solutions obtained from the model with the estimated input parameters. To solve the resulting large-scale bilevel optimization problem, we apply our recently proposed penalty-based block coordinate descent algorithm. In a computational case study, we demonstrate the effectiveness of the proposed approach and highlight its benefits compared with the conventional predict-then-optimize approach.

## 2. Mathematical formulation

We assume that the optimization problem to be solved can be generally formulated in the following compact form:

$$\begin{aligned} & \text{minimize} && f(x, u) \\ & \text{subject to} && g(x, u) \leq 0, \end{aligned} \tag{1}$$

where  $x \in \mathbb{R}^n$  are the decision variables, and the model parameters are denoted by  $u$ . In this work, we assume that problem (1) is convex, with  $f$  and  $g$  being differentiable and convex in  $x$ . The model parameters  $u$  (or a subset of them) change with some external features  $r$  and are not exactly known; hence, they need to be estimated from data. The goal is to construct a predictive model  $u = m(r)$  given a set of  $N$  data points, where each data point  $i$  corresponds to a feature-output pair  $(\bar{r}_i, \bar{u}_i)$ . Given a new  $r$ , problem (1) will then be solved using the predicted values  $u = m(r)$ .

### 2.1. Conventional predict-then-optimize approach

In the conventional two-step process, the prediction of the model parameters is carried out independent from the later optimization. To obtain a predictive model  $m$ , one typically solves an empirical risk minimization problem of the following form:

$$\text{minimize} \quad \frac{1}{N} \sum_{i \in I} \ell(\bar{u}_i, m(\bar{r}_i)), \tag{2}$$

where  $I = \{1, \dots, N\}$  denotes the set of data points, and the loss function  $\ell$  is some measure of the difference between the true output  $\bar{u}_i$  and the prediction  $m(\bar{r}_i)$ . The underlying assumption is that if we minimize the difference between the true and predicted parameter values, this will also lead to optimal solutions to problem (1) that are the closest possible to the solutions we would obtain if we knew the true parameter values.

### 2.2. Decision-focused learning

In decision-focused learning, we integrate the prediction and optimization steps to construct a predictive model that directly takes the quality of the resulting optimization solution into account. We do so by solving the following problem:

$$\text{minimize } \frac{1}{N} \sum_{i \in I} f(\hat{x}_i, \bar{u}_i) \tag{3a}$$

$$\text{subject to } \hat{x}_i \in \arg \min_{\tilde{x}} \{f(\tilde{x}, u): g(\tilde{x}, u) \leq 0, u = m(\bar{r}_i)\} \quad \forall i \in I \tag{3b}$$

$$g(\hat{x}_i, \bar{u}_i) \leq 0 \quad \forall i \in I, \tag{3c}$$

where per constraints (3b),  $\hat{x}_i$  is an optimal solution to problem (1) with  $u = m(\bar{r}_i)$ . The objective is to minimize the true cost averaged over the training set  $I$ , i.e. it considers the cost of  $\hat{x}_i$  evaluated at the true parameter values  $\bar{u}_i$  for each  $i \in I$ . Importantly, constraints (3c) ensure feasibility of each  $\hat{x}_i$  given  $\bar{u}_i$ . These last set of constraints are omitted in virtually all existing works on decision-focused learning since they consider the case in which only the objective function  $f$  depends on  $u$  such that feasibility is not an issue.

### 3. Solution approach

The decision-focused learning problem (3) is a bilevel optimization problem with  $|I|$  convex optimization problems in its lower-level. We reformulate (3) into a single-level problem by replacing the lower-level problems with their KKT conditions. This results in a nonconvex nonlinear optimization problem which generally lacks regularization. To address the convergence difficulties of standard nonlinear solvers on this problem, we consider a penalty reformulation and apply an efficient block coordinate descent (BCD) algorithm. We do not provide more details about our solution algorithm here but refer the reader to Gupta and Zhang (2022a) for more details. We end this section by highlighting the fact that our approach is restricted to the case where problem (1) is a strictly convex problem and satisfies Slater’s condition.

### 4. Case study

In this section, we apply the proposed decision-focused learning approach to a (single-period) production planning problem for a small interconnected process network. This network, as depicted in Figure 1, consists of 5 materials and 3 processes. The goal is to determine the optimal quantities of raw materials to purchase and the amounts of products to manufacture to satisfy a given demands. This problem can be formulated as follows:

$$\text{minimize } z = \sum_{m \in \mathcal{M}} (\sum_{p \in \mathcal{P}} c_p y_p^2 + f_m w_m^2) \tag{4a}$$

$$\text{subject to } q_m^{\min} \leq q_m^0 + \left( \sum_{p \in \hat{\mathcal{P}}_m} \mu_{pm} y_p - \sum_{p \in \bar{\mathcal{P}}_m} \mu_{pm} y_p + w_m - d_m \right) \tag{4b}$$

$$\leq q_m^{\max} \quad \forall m \in \mathcal{M}$$

$$0 \leq w_m \leq w_m^{\max} \quad \forall m \in \mathcal{M} \tag{4c}$$

$$0 \leq y_p \leq y_p^{\max} \quad \forall p \in \mathcal{P}, \tag{4d}$$

where  $\mathcal{M}$  and  $\mathcal{P}$  are the sets of materials and processes, respectively. Further, the set  $\hat{\mathcal{P}}_m$  consists of the processes that can produce material  $m$ , and the set  $\bar{\mathcal{P}}_m$  contains the processes that consume  $m$ . The amount of a reference material produced by process  $p$  is denoted by  $y_p$  and we use  $w_m$  to specify the amount of material  $m$  purchased from the market. The conversion factor  $\mu_{pm}$  determines the amount of a material  $m$  produced or consumed by process  $p$  for one unit of the reference material. Constraints (4b) restrict the inventory levels while accounting for product demand represented by  $d_m$ , (4c) limit the

amount of a material that can be acquired from the market, and (4d) set the capacities of processes. The objective is to minimize the total production and material purchasing cost.

**Figure 1** Process network for the production planning problem (4). The minimum and maximum allowed inventory values are 0 and 200, respectively, for all materials. For all processes, the values of  $y_p^{\max}$  is set to 400.

For this case study, we consider a scenario where the conversion factors vary based on some observable external feature  $r$ . For the sake of simplicity, we assume that the change in most of the conversion factors is negligible; only  $\mu_{13}$  and  $\mu_{35}$  deviate significantly enough from their nominal values to affect optimal production decisions. Our goal is to build predictive models for these two uncertain parameters using a data set containing observed  $(r_1, \mu_{13})$  and  $(r_2, \mu_{35})$  values.

4.1. Synthetic data generation

We now describe the process used to generate the training data set for the case study. We start by assigning models (5a) and (5b) to the uncertain parameters. These are the underlying true models which are assumed to be unknown. To obtain the training data, we sample  $|I|$  values of the features  $r_1$  and  $r_2$  from the uniform distributions  $\mathbb{U}(0.1, 0.45)$  and  $\mathbb{U}(-2, 1)$ , respectively. Following that, we evaluate the models for  $\mu_{13}$  and  $\mu_{35}$  at each of the sampled feature values to complete the training data set.

$$\mu_{13}(r_1) = \frac{1}{10} (\sin(20\pi r_1) + 7r_1) + 2 \tag{5a}$$

$$\mu_{35}(r_2) = 2 + \frac{1}{10} ((r_2 - 1) r_2 (r_2 + 2)^2) \tag{5b}$$

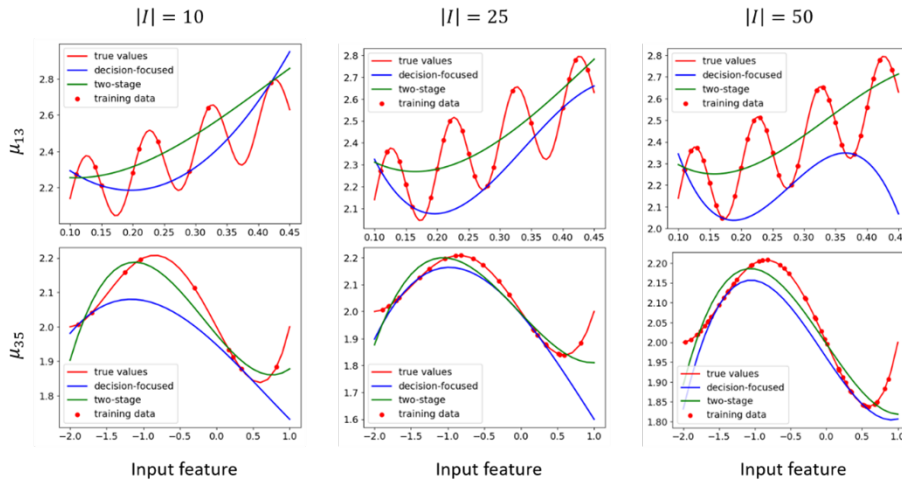

In order to estimate predictive models  $m_1$  and  $m_2$  with the proposed approach, we assume a hypothesis class consisting of cubic polynomials. We solve problem (3) using our BCD algorithm with training data sets of four different sizes: 10, 25, 50, and 100. The quality of the resulting model estimates is evaluated through a test data set of 100 unseen data points, which is generated using the same parameter generation scheme as the training data set. A model is considered good if the produced  $\hat{\mu}$  values result in production decisions that are not only close to the true optimal decisions but also feasible for the true model (i.e., problem (4) with the true  $\mu$  values).

In addition to the decision-focused approach, we also estimate cubic models for  $m_1$  and  $m_2$  using the traditional two-stage predict-then-optimize approach. Specifically, we use least squares regression to fit a cubic polynomial to the observed data. This estimated model is then used to solve problem (4) for the points in the test data set.

4.2. Results and discussion

Here we compare the performance of the models estimated using the decision-focused and two-stage approaches. Figure 2 compares the plots of the true  $\mu$  models with their

estimates obtained using the two approaches. In all cases, we find that the decision-focused approach constructs an underestimator function for the training data points. This happens because in problem (4), an optimal solution will always be such that inventories of all materials are close to or at their minimum values. If the estimated  $\hat{\mu}$  values are such that production gets overestimated, then there is a high probability that the inventory will fall below its permissible value when the process is actually run with a lower conversion value, resulting in an infeasible operation. Therefore, decision-focused learning obtains an underestimate of  $\mu$  to avoid violating the lower bound on the inventory constraint. From Figure 2, we find that as we provide more training data, the proposed approach finds better underestimators. With 50 data points, it is able to find almost perfect underestimators for both  $\mu$  parameters.

**Figure 2** True  $\mu$  models compared with their approximations estimated using the decision-focused and two-stage learning approaches

In contrast, the goal of the two-stage approach is to build the best approximation of the function itself using the provided data. The estimated model tries to closely mimic the behavior of the actual function to the extent that the assumed hypothesis class allows. This difference in approach leads to differences in performance, as seen in Table 1. The "feasible fraction" column indicates the fraction of the points in the test data set for which the estimated  $\mu$  models produced a feasible decision. The data in this column shows that the decision-focused approach significantly outperforms the two-stage approach. Moreover, one can see that for the decision-focused case, the better the estimated function underestimates the true function, the higher the fraction of the feasible points. Here since the two-stage approach does not focus on yielding underestimators, the fraction of feasible decisions is very low.

For the test data points that yield feasible decisions, Table 1 also compares the distance of those decisions from the true optimal solutions. While the decision-focused learning generates feasible solutions with a high degree of confidence, these solutions are slightly more different from the true optimal solutions compared to the two-stage approach. However, as can be seen from the last column in the table, which compares the optimality gap of the decisions generated by the two approaches, the mean optimality gap of the decision-focused approach is still less than 10% (compared to  $\sim 5\%$  in the two-stage case). This suggests that the decision-focused approach produces high quality decisions while

almost guaranteeing their feasibility.

$ I $	feasible fraction		mean $\frac{\ y(\mu) - y(\hat{\mu})\ _1}{\ y(\mu)\ _1}$		mean $\frac{\ w(\mu) - w(\hat{\mu})\ _1}{\ w(\mu)\ _1}$		mean $\frac{ z(\mu) - z(\hat{\mu}) }{z(\mu)}$

**Table 1.** A comparison of the performance of the models estimated using the decision-focused and two-stage approaches

## 5. Conclusions

In this work, we extended the decision-focused learning framework to include cases where the unknown parameters are in the constraints. We used an inverse optimization approach in which the problem is formulated as a bilevel program. Our approach allows inclusion of constraints that, with a high degree of confidence, ensure that the estimated model produces decisions that remain feasible for the true model. We illustrated our approach by applying it on a production planning problem with unknown process parameters. Our results show that the models obtained using decision-focused learning produce feasible decisions at a significantly higher rate compared to traditional two-stage learning without substantially sacrificing the optimality of these decisions.

## Abstract

Hydrogen is one of the main pillars needed for a future low-carbon economy. The biogas steam reforming process can produce hydrogen without consuming fossil-based (non-renewable) resources. In this work, a dynamic 2D heterogeneous model (at macroscale and microscale) is developed for catalytic hydrogen production, applying the biogas steam reforming process. The model was implemented in Matlab/Simulink and the simulation results were compared with literature data, obtaining good agreement. The temperature profiles and those for the gas composition were obtained, related to the height of the catalyst layer in the reactor, as well as methane profile in the catalyst particle. A special emphasis was placed on highlighting the influence of a high content of carbon dioxide on the reactor design parameters. The dynamic behavior was also studied for ramp input changes on the feed flow. Based on mass and energy balanced derived from whole process simulation, the detailed techno-economic assessment of decarbonized biogas catalytic reforming plant for flexible hydrogen & power generation was assessed to evaluate the overall advantages.

**Keywords:** Biogas catalytic reforming; Green hydrogen production; Multiscale modeling; Techno-economic assessment; Negative CO<sub>2</sub> emissions.

## 1. Introduction

Hydrogen is seen as the fuel of the future, because it has the potential to be produced and used with near-zero greenhouse gas emissions. There are several industries using hydrogen, from fertilizer production and refining processes to methanol production and synthesis of organic compounds. Biogas got significant attention as a promising renewable energy source and an energy-efficient way of converting various biowastes into energy carriers. Steam methane reforming is the most used process for hydrogen production. By using biogas to produce hydrogen, the whole process can be considered environmentally friendly (IEA 2022, Lepage et al. 2021, Nahar et al. 2017). The steam reforming process, which uses biogas as feedstock for hydrogen production, takes place in a multi-tubular reactor with side furnaces flanking tubes filled with a packed-bed of catalyst (figure 1). The tubes are made of IN-519 alloy, while the catalyst consists of nickel particles on MgAl<sub>2</sub>O<sub>4</sub> support. The reactor operates at a temperature range of 700 to 1200 K and a pressure range of 28 to 37 bar. The inlet gas contains one-part biogas and at least three parts steam (Soliman et al. 1988).

**Figure 1.** The multi-tubular reforming reactor with catalyst

between the catalyst particles, inside of reactor' tubes represent the macroscale of the system. The model of the microscale described the pores inside the catalyst particle. A special emphasis was placed on highlighting the influence of a high content of carbon dioxide on the reactor design parameters. The dynamic behavior was also studied for step and ramp input changes on the feed flow. As other relevant research contributions of present work, the detailed technical and economic assessment of decarbonized biogas catalytic reforming process for flexible hydrogen & power generation was assessed.

## 2. Mathematical model

### 2.1. Model development

The multi-scale heterogeneous dynamic model of catalytic hydrogen production by steam reforming of biogas is developed based on following assumptions: along the length of the reactor the mass transfer through the catalyst layer takes place by convective and diffusional mechanism, while for the mass transfer through the catalyst pores, just the radial direction is considered, while it is thought that the catalyst particles have a homogenous porous structure. In the case of the catalyst phase, the mass balance equations are functions of time and catalyst particle radius. Any particle at the  $z$ -position is equivalent to all other particles at the same position. The partial differential equations describing the model are presented in Table 1 (Ghouse and Adams 2013).

**Table 1.** Mass and energy balances of the reforming reactor

Observations	Equation and boundary conditions
Mass balance for the gas phase	$\frac{\partial c_i}{\partial t} = -\frac{F}{A} \frac{\partial c_i}{\partial z} - k_{Ti} (c_i - c_{ci} _{r=R_p}) - r_i \rho_{cat}$
Energy balance for the gas phase	$\frac{\partial T}{\partial t} = -\frac{F}{A} \frac{\partial T}{\partial z} - \frac{\sum_{i=1}^N \Delta H_i k_i (c_i - c_{ci})}{c p_{mix} \rho_g} + \frac{K_T A_T (T_w - T)}{c p_{mix} \rho_g A dz}$ at $z=0$ and $t>0$ $c_i _{z=0} = c_{i,inlet}$ $T_g _{z=0} = T_{inlet}$
Mass balance for the catalyst phase	$\frac{\partial c_{ci}}{\partial t} = \frac{1}{\theta_c} \left\{ 2 D_{eimix} \frac{\partial c_{ci}}{\partial r} + \frac{\partial}{\partial r} \left[ D_{eimix} \frac{\partial c_{ci}}{\partial r} \right] - r_i \rho_{cat} \right\}$ at $t>0$ and any $z$ $\left[ \frac{\partial c_{ci}}{\partial r} \right]_{r=0} = 0$ $\left[ D_{eimix} \frac{\partial c_{ci}}{\partial r} \right]_{r=R_p} = k_{Ti} (c_i - c_{ci} _{r=R_p})$

There are three reactions involved in the endothermic process described above,  $R_1$  and  $R_2$  are parallel reactions, while  $R_3$  follows them (Calistru et al. 1984, Xu and Froment 1989, Ghouse and Adams 2013):

In this work, a dynamic 2D heterogeneous model (at macroscale and microscale) is developed for catalytic hydrogen production, applying the biogas steam reforming process. The spaces

**Table 2.** Process parameters

Inlet flow, $F$ – 23.271 [kmol/h]
Inlet temperature, $T_0$ – 723 [K]
Inlet pressure, $P$ – 30 [bar]
Inlet gas composition (mole fraction):
$x_{CH_4}$ : 0.1808
$x_{H_2O}$ : 0.7981
$x_{CO}$ : 0.0049
$x_{CO_2}$ : 0.0061
$x_{H_2}$ : 0.0098
Catalyst particle diameter, $D_p$ – 0.017 [m]
Catalyst void fraction, $\theta_c$ – 0.519
Tub diameter, $D_t$ – 0.107 [m]
Tub wall thickness, $X_t$ – 0.015 [m]
Packed-bed length, $L_{cat}$ – 9.18 [m]

The developed mathematical model was implemented in Matlab/Simulink, using process parameters presented in Table 2 (Calistru et al. 1984, Soliman et al. 1988, Ghouse and Adams 2013).

Since all 247 tubes present in the reforming reactor are operated and designed identically, the simulation was performed for a single tube (Calistru et al. 1984, Ghouse and Adams 2013). The connection between the two models (macroscale and microscale) have been made with multiple functions, repetitive and nested structures.

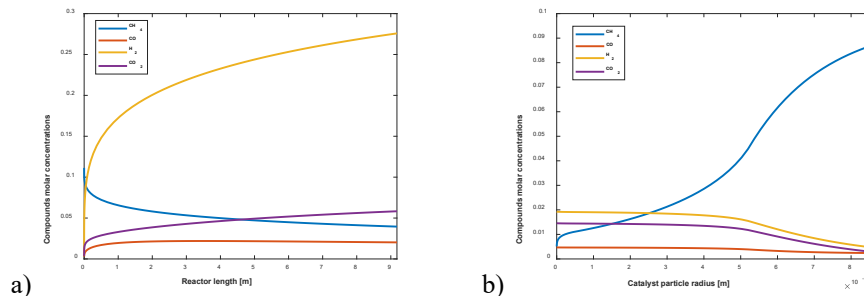

2.2. Results and discussions

**Table 3.** Model validation

Parameter	Model	Literature
CH <sub>4</sub> conversion	69.10%	71.66%
H <sub>2</sub> fraction	69.00%	70.60%

The predicted values of the developed mathematical model were compared with literature data in terms of CH<sub>4</sub> percentage conversion and H<sub>2</sub> mole fraction at exit in dry basis - Table 3 (Calistru et al. 1984, Ghouse and Adams 2013, Soliman et al. 1988).

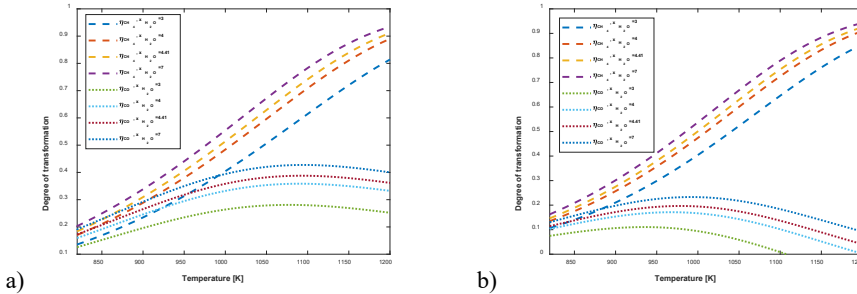

Based on simulations results, the profiles for the gas molar concentrations in the macroscale (reported to the length of the reforming reactor) and in the microscale (reported to the catalyst particle radius) were obtained (Figure 2). It can be observed that the hydrogen is produced manly in the first half of the reforming reactor length. In the case of the microscale, close to the interface, due to the mass transfer, the density of reactants is higher than into the particle center.

**Figure 2.** Variations of chemical species concentrations  
a) macroscale and b) microscale

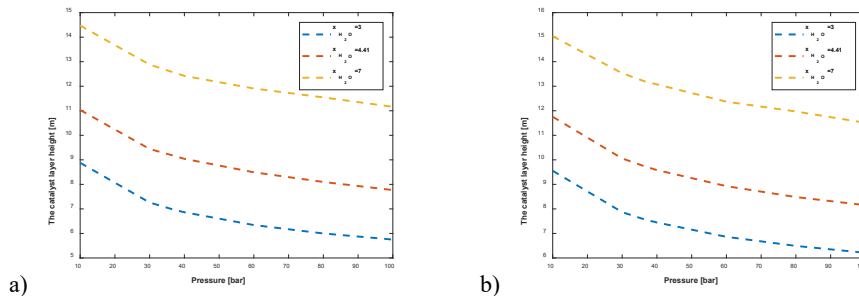

The biogas high content of carbon dioxide could influence the reactor design parameters. Simulations of the model were performed to observe how the degrees of transformation, and hence the conversions of the reactions are changed at a pressure of 30 bar, different  $\dot{x}_{H_2O} = H_2O_{(g)} : CH_4$  and  $\dot{x}_{CO_2} = CO_2 : CH_4$  molar ratios in the reactor feed gas, for a temperature between 820-1200 K. The upper temperature limit was chosen according to the limitations imposed by the material from which the reactor tubes are made. Comparing Figures 3a and 3b for the same molar ratio of  $H_2O_{(g)} : CH_4$ , reaction methane conversion ( $R_1$ ) is favoured by an excess of  $CO_2$ . If in Figure 3a the corresponding yellow line  $\dot{x}_{H_2O}=4.41$  barely reaches the value of 0.90 for  $\eta_{CH_4}$ , in

Figure 3b it exceeds it, reaching a value of 0.92. The carbon monoxide conversion ( $R_2$  reaction), it is strongly based by an excess of  $CO_2$ , (Figure 3a), for  $\dot{x}_{H_2O}=4.41$ ,  $\eta_{CO}=0.35$ , and in Figure 3b) for the same  $\dot{x}_{H_2O}$ ,  $\eta_{CO}<0.1$ .

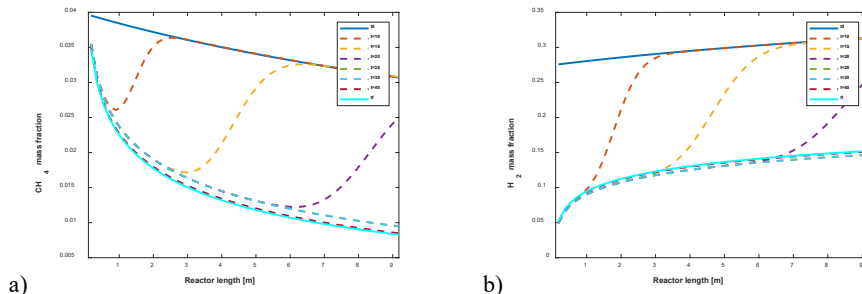

**Figure 3.** Variation of transformation degrees with temperature for a)  $P=30$  [bar]  $\dot{x}_{CO_2}=0.03$  and b)  $P=30$  [bar]  $\dot{x}_{CO_2}=0.75$

How an excess of  $CO_2$  in the reactor inlet flow requires a change in the height of the catalyst packed-bed to achieve the same results is presented in Figure 4. Although the excess  $CO_2$  is very large, the catalyst layer height increases by a maximum of one meter and the desired reaction is favored.

**Figure 4.** Variation of catalyst layer height with pressure at different  $\dot{x}_{H_2O}$  a)  $P=30$  [bar]  $\dot{x}_{CO_2}=0.03$  and b)  $P=30$  [bar]  $\dot{x}_{CO_2}=0.75$

The dynamic behaviour of the process was investigated by implementing a ramp signal disturbance of -20% on the biogas feed flow (Figure 5). The simulations showed that for the ramp signal disturbance, the system needs a long time to reach the new steady state values, as the disturbance propagated with a delay from one end of the reactor to the other. It is also observed that when the biogas feed flow rate is reduced, the amount of methane is reduced and the produced hydrogen quantity increases.

**Figure 5.** Dynamic profiles at -20% biogas feed flow a) Methane and b) Hydrogen

### 3. Techno-economic evaluation

The biogas catalytic reforming process for hydrogen & power co-generation with CO<sub>2</sub> capture feature was evaluated also in term of overall techno-economic performances. As decarbonization method, the pre-combustion CO<sub>2</sub> capture using reactive gas-liquid absorption with Methyl-D-Ethanol-Amine (MDEA) solvent was used. The overall process was modeled and simulated using ChemCAD software, the mass and energy balances being employed for calculation of main performance indicators. As illustrative concept, 100 MW thermal hydrogen output with 65% CO<sub>2</sub> capture rate were considered. For the economic evaluation methodology, the overall International Energy Agency - Greenhouse Gas R&D Programme method (reported in IEAGHG, 2017) was used. In terms of main economic assumptions, the ones defined in Cormos et al. (2022) was used. For instance, the capital costs were estimated using the cost correlation method with the most recent values of Chemical Engineering Plant Cost Index (CEPCI). The levelized costs of hydrogen and power were calculated based on Net Present Value (NPV) method with an internal rate of return of 8%. The CO<sub>2</sub> removal and avoidance costs were calculated using as benchmark a biogas reforming plant without CO<sub>2</sub> capture feature as reported in Cormos et al. 2022.

Table 4 presents the overall techno-economic and environmental performances. As can be noticed, the cumulative energy efficiency is high enough (66.50%) as well the decarbonization rate (65%). The economic parameters (e.g., hydrogen production cost, CO<sub>2</sub> capture costs) look promising in comparison to relevant studies (IEAGHG, 2017) based on natural gas as fuel input. For instance, the utilization of biogas (renewable source) into the decarbonized reforming plant gives overall negative CO<sub>2</sub> emissions.

**Table 4.** Techno-economic performance indicators

Parameter	Unit	Value
Biogas input flowrate	t/h	31.22
Lower heating value of biogas	MJ/kg	17.58
Thermal energy of biogas	MW <sub>th</sub>	152.45
Gross power production	MW <sub>e</sub>	8.00
Ancillary electricity consumption	MW <sub>e</sub>	6.50
Hydrogen thermal energy	MW <sub>th</sub>	100.00
Net power production	MW <sub>e</sub>	1.50
Hydrogen thermal efficiency	%	65.59
Net power efficiency	%	0.98
Cumulative energy efficiency	%	66.57
CO <sub>2</sub> capture rate	%	65.00
Specific CO <sub>2</sub> emissions	kg/MWh	172.50
Capital investment cost	M€	129.95
Specific capital investment cost	€/kW net	1280.00
Operational & maintenance cost	€/MWh	37.95
Levelized cost of hydrogen	€/MWh	61.42
Levelized cost of electricity	€/MWh	60.60
CO <sub>2</sub> removal cost	€/t	24.12
CO <sub>2</sub> avoidance cost	€/t	28.65

### 4. Conclusions

The 2D heterogeneous multiscale dynamic model for the biogas steam reforming process presented in this paper has been validated with data available in the literature. Particular attention was paid to how a higher CO<sub>2</sub> concentration influences the reactor design parameters while favoring the methane conversion (R<sub>1</sub>). The dynamic response of the system was highlighted by its response to a ramp disturbance of the feed flow.

When the feed flow rate decreases, the amount of methane decreases, but the amount of hydrogen increases in the reactor. In addition, a detailed techno-economic evaluation of hydrogen and power co-generation based on biogas reforming with CO<sub>2</sub> capture feature was done to illustrate its key advantages e.g., high energy efficiency, competitive hydrogen production cost, negative CO<sub>2</sub> emissions (due to CO<sub>2</sub> capture capability) etc.

# Modeling hierarchical systems via nested generalized disjunctive programming

Hector D. Perez,<sup>a</sup> Ignacio E. Grossmann<sup>a</sup>

<sup>a</sup>*Carnegie Mellon University, 5000 Forbes Ave, Pittsburgh 15207, USA*

## Abstract

Modeling systems with discrete-continuous decisions is traditionally done in algebraic form with mixed-integer programming models, which can be linear or nonlinear in the continuous variables. A more systematic approach to modeling such systems is to use Generalized Disjunctive Programming (GDP), which extends the Disjunctive Programming paradigm proposed by Egon Balas. GDP allows modeling systems from a logic-based level of abstraction that captures the fundamental rules governing such systems via algebraic constraints and logic. Although GDP provides a more general way of modeling systems, it warrants further generalization for systems presenting a hierarchical structure. This work extends the GDP literature to address alternatives for modeling and solving systems with nested (hierarchical) disjunctions. We also provide two theorems on the relaxation tightness of such alternatives, establishing that a explicitly modeling nested disjunctions is superior to the traditional approach for dealing with nested disjunctions.

**Keywords:** generalized disjunctive programming, hierarchical systems, discrete-continuous optimization.

## 1. Introduction

Discrete-continuous optimization is one of the main modeling approaches for addressing design, planning, and scheduling problems in Process Systems Engineering (PSE) (Grossmann, 2012). Raman and Grossmann (1994) present a new modeling paradigm that extends the work done by Balas (1985) on disjunctive programming. This new paradigm, called Generalized Disjunctive Programming (GDP), was further developed by others in the PSE community over the years to account for additional features, such as nonlinearities and nonconvexities, in the problems encountered (Grossmann & Trespalacios, 2013). GDP relies on the intersection of disjunctions of convex sets to model the feasible space. Boolean variables are used as the indicator variables for each convex set, meaning that if True, the constraints in the disjunct are enforced. Logical constraints are also included to describe the relationships between the Boolean indicator variables via propositional logic and constraint programming logic.

The present work extends the GDP theory to allow modeling hierarchical systems, which are commonly encountered in PSE, and more particularly in Enterprise-Wide Optimization (EWO) (Grossmann, 2012), and flowsheet superstructure optimization (Türkay & Grossmann, 1996). Multi-level decisions can be concisely modelled via nested disjunctions. However, traditional GDP does not consider such formulations. Existing GDP literature suggests reformulating nested disjunctions into equivalent single-level disjunctions (Vecchiotti & Grossmann, 2000). Such an approach requires introducing

additional Boolean variables and logical propositions. An alternate approach is used in the work by van den Heever and Grossmann (1999), in which a direct or inside-out reformulation to MI(N)LP is performed. We formalize these two approaches and provide theoretical proofs on the tightness of their continuous relaxations. The model tightness and computational performance of the different approaches are compared. A series of examples are used to show the modeling and computational advantages obtained by explicitly modeling nested disjunctions.

## 2. GDP Modeling Overview

The classical GDP formulation is given below, where  $x$  is the set of continuous variables (bounded between  $x^{LB}$  and  $x^{UB}$ ),  $f(x)$  is the objective function,  $r(x) \leq 0$  is the set of global constraints,  $g_{ij}(x) \leq 0$  is the set of constraints applied when the indicator Boolean  $Y_{ij}$  is *True* for disjunct  $j$  in disjunction  $i$ .  $\Omega(Y)$  defines the set of logic constraints, which are described via propositional logic on a subset of Boolean variables. These constraints describe the interactions between the Boolean variables via clauses that contain with one or more of the following logic operators: AND ( $\wedge$ ), OR ( $\vee$ ), implication ( $\Rightarrow$ ), equivalence ( $\Leftrightarrow$ ), and negation ( $\neg$ ). The set of logic constraints may also include cardinality clauses of the form *choose exactly* (or *at least* or *at most*)  $m$  Boolean variables from a subset of Booleans to be *True* (Yan & Hooker, 1999). Cardinality clauses are indicated with the notation  $(Y_s \ \forall s \in S)_m$ , which means that at least  $m$  of the Boolean variables  $Y_s$  are *True*. An alternative is to use predicate logic to define the following predicates:  $\Xi(m, Y_s \ \forall s \in S)$  for *exactly*  $m$  are *True*,  $\Lambda(m, Y_s \ \forall s \in S)$  for *at least*  $m$  are *True*, and  $\Gamma(m, Y_s \ \forall s \in S)$  for *at most*  $m$  are *True*. GDP models typically include a cardinality clause to enforce that exactly 1 disjunct is chosen in each disjunction, i.e.,  $\Xi(1, Y_{ij} \ \forall j \in J_i) \ \forall i \in I$ . The GDP literature often uses the exclusive OR operator,  $\underline{\vee}$ , to define this constraint. However, such an operator is only correct for proper disjunctions (non-overlapping disjuncts). Thus, to avoid any ambiguity, we use the predicate logic notation,  $\Xi(1, Y)$ , here instead.

$$\begin{array}{ll}
 \min z = f(x) & \text{(GDP)} \\
 \text{s. t.} & r(x) \leq 0 \\
 & \bigvee_{j \in J_i} \left[ \begin{array}{l} Y_{ij} \\ g_{ij}(x) \leq 0 \end{array} \right] \quad \forall i \in I \\
 & \Xi(1, Y_{ij} \ \forall j \in J_i) \quad \forall i \in I \\
 & \Omega(Y) \\
 & x^{LB} \leq x \leq x^{UB} \\
 & x \in \mathbb{R}^n \\
 & Y_{ij} \in \{\text{True}, \text{False}\} \quad \forall i \in I, j \in J_i
 \end{array}$$

One of the main advantages of modeling discrete-continuous problems using GDP is the collection of methods that are available for optimizing such systems (Grossmann & Trespalcios, 2013; Trespalcios & Grossmann, 2016). These include, 1) reformulating to mixed-integer (non)linear models (MI(N)LP) via either Big-M or Hull reformulations, 2) logic-based decomposition methods such as Logic-based Outer Approximation (LOA), 3) disjunctive branch-and-bound, 4) basic steps, and 5) hybrid cutting planes. The reader is referred to the above references for a detailed understanding of each of these solution methods.

### 3. Extended formulation for hierarchies

#### 3.1. Hierarchical GDP

We propose extending the GDP paradigm to include multi-level decisions by means of nested disjunctions. Although the notion of nesting disjunctions to represent hierarchical decisions is not new, the limitations in the traditional GDP notation have made it difficult to exploit the benefits of nesting disjunctions. One of the first references to nested disjunctions is found in the work by Vecchietti and Grossmann (2000), which describes the transformations required to conform to the current GDP notation.

Therefore, from a model development point of view, the use of disjunction nesting is shown to add value. However, its implementation has often required breaking the explicit hierarchical structure. An exception is the work by Van Den Heever and Grossmann (1999), which does not transform the nested GDP into a logically equivalent single-level GDP, but rather suggests performing the hull reformulation on the inner disjunction and then reformulating the outer disjunction.

The proposed extension to the classical GDP notation for hierarchical systems is given below for a 2 level GDP (*2L-GDP*), where the upper-level decisions,  $Y$ , enforce the constraints  $g(x) \leq 0$  and the nested decisions,  $W$ , which have constraints  $h(x) \leq 0$ . Here the cardinality clause of selecting exactly one disjunct from the upper-level decisions,  $Y$ , is expressed explicitly, along with a new set of cardinality rules that enforce selecting exactly one of the lower-level decisions,  $W$ , if and only if the upper-level decision has been selected, and selecting no lower-level decisions when the upper-level decision is not selected. This constraint is expressed as the conjunction of two cardinality rules:  $[Y_{ij} \Rightarrow \exists(1, W_{ijkl} \forall l \in L_{ijk})] \wedge [\neg Y_{ij} \Rightarrow \exists(0, W_{ijkl} \forall l \in L_{ijk})] \forall i \in I, j \in J_i, k \in K_{ij}$ . In the GDP literature, this constraint has been traditionally written as  $Y_{ij} \Leftrightarrow \bigvee_{l \in L_{ijk}} W_{ijkl} \forall i \in I, j \in J_i, k \in K_{ij}$ . However, such a logic proposition is incomplete because it would allow the following to occur:  $Y_{ij} = False$  and  $W_{ijkl} = True$  for more than 1 index  $l \in L_{ijk}$ . As a result, the cardinality rule  $\Gamma(1, W_{ijkl} \forall l \in L_{ijk}) \forall i \in I, j \in J_i, k \in K_{ij}$  should be added to ensure that no more than 1 literal  $W_{ijkl}$  can be *True*. A more compact form would be to use the predicate constraint,  $\exists(t(Y_{ij}), W_{ijkl} \forall l \in L_{ijk})$ , where  $t(\cdot)$  is a unary function that maps a Boolean variable to its binary counterpart (i.e.,  $t(True) = 1$  and  $t(False) = 0$ ). For simplicity, we make a slight abuse of notation, dropping the mapping function  $t(\cdot)$ , and using the expression  $\exists(Y_{ij}, W_{ijkl} \forall l \in L_{ijk})$  instead. Such a model can be generalized to a multi-level hierarchical GDP with  $n$  levels.

$$\begin{aligned}
 \min z &= f(x) && (2L-GDP) \\
 \text{s. t. } & r(x) \leq 0 \\
 & \bigvee_{j \in J_i} \left[ \begin{array}{c} Y_{ij} \\ g_{ij}(x) \leq 0 \\ W_{ijkl} \\ \bigvee_{l \in L_{ijk}} \left[ h_{ijkl}(x) \leq 0 \right] \forall k \in K_{ij} \end{array} \right] && \forall i \in I \\
 & \exists(1, Y_{ij} \forall j \in J_i) && \forall i \in I \\
 & \exists(Y_{ij}, W_{ijkl} \forall l \in L_{ijk}) && \forall i \in I, j \in J_i, k \in K_{ij} \\
 & \Omega(Y, W) \\
 & x^{LB} \leq x \leq x^{UB}
 \end{aligned}$$

$$\begin{array}{ll}
x \in \mathbb{R}^n & \\
Y_{ij} \in \{True, False\} & \forall i \in I, j \in J_i \\
W_{ijkl} \in \{True, False\} & \forall i \in I, j \in J_i, k \in K_{ij}, l \in L_{ijk}
\end{array}$$

### 3.2. Equivalent Single-level GDP

Previous references to GDP with nested disjunctions in literature have proposed transforming the 2L-GDP model into the equivalent single-level GDP (2E-GDP) given below (Vecchiotti & Grossmann, 2000). Here, the nested disjunction is extracted and a dummy or “slack” disjunct is added to preserve feasibility. Thus, if none of the nested disjuncts is selected, the slack disjunct is selected, which contains the entire feasible set for  $x$ . The exclusive cardinality rule on the inner Boolean variables,  $W$ , is also augmented to include the slack Boolean variable,  $W_{ijk0}$ . This slack variable is, however, not included in the linking logic constraint for the upper and lower-level decisions. This ensures that the nested decisions are only selected if their master Boolean is *True*. This method for transforming a nested disjunction can also be applied to the multi-level system *ML-GDP*.

$$\begin{array}{ll}
\min z = f(x) & (2E-GDP) \\

\end{array}$$

Although the above formulation, allows modeling hierarchical systems in the standard GDP notation, it has two major drawbacks: 1) the explicit hierarchical structure is lost, and 2) although the equivalent single-level GDP model is logically equivalent to the nested GDP model, it requires introducing additional disjuncts and Boolean variables. Introducing “slack” disjuncts and Boolean variables results in models whose continuous relaxations are less tight, as given in the below theorem.

### 3.3. Tightness of Continuous Relaxations

The following two theorems address the advantages of modeling multi-level decisions problems via Hierarchical GDP, rather than the traditional single-level GDP approach. The advantages are shown by discussing the tightness of the continuous relaxations of these two approaches. For proofs of these theorems see Perez and Grossmann (2023).

*Theorem 1.* Let *rML-GDP-HR* denote the continuous relaxation of the mixed-integer program (MIP) obtained from a multi-level hierarchical GDP via the hull reformulation, and let *rME-GDP-HR* denote the continuous relaxation of the MIP obtained from the

equivalent single-level GDP via the hull reformulation. The feasible space of the former is contained within the feasible space of the latter, meaning  $rML-GDP-HR \subseteq rME-GDP-HR$ .

*Theorem 2.* Let  $rML-GDP-BM$  denote the continuous relaxation of the mixed-integer program (MIP) obtained from a multi-level hierarchical GDP via the Big-M reformulation, and let  $rME-GDP-BM$  denote the continuous relaxation of the MIP obtained from the equivalent single-level GDP via the Big-M reformulation. The feasible space of the former is contained within the feasible space of the latter, meaning  $rML-GDP-BM \subseteq rME-GDP-BM$ .

### 3.4. Graphical Example of Model Tightness

Consider the hierarchical (nested) GDP constraint system given in (1), which can be expressed as the equivalent single-level GDP in (2). Each of these models is reformulated to a MIP using the Big-M reformulation, with both a loose  $M$  value and a tight  $M$  value, and the Hull reformulation. Their continuous relaxations are then projected onto the  $x_1, x_2$  plane in *Figure 1*. The projections show that flattening via basic steps is advantageous when the hull reformulation is performed, but not necessarily when the Big-M reformulation is performed with a tight  $M$  value. Preserving the explicit hierarchical relationship via nested GDP reduces the feasible region of the continuous relaxation more than the equivalent single-level GDP approach in both the Big-M and hull reformulation cases. Furthermore, in this example the Big-M reformulation with a tight  $M$  on the nested GDP model produces the same relaxation as the hull reformulation on the equivalent GDP model with only a fraction of the model size. It should also be noted that, in this example, the convex hull of the system is obtained when either the hull reformulation is applied to the nested GDP or to the flattened GDP after two basic steps. The continuous relaxation of either of these two formulations will yield the optimum.

$$\left[ \begin{array}{c} Y_1 \\ 1 \leq x_1 \leq 3 \\ 4 \leq x_2 \leq 6 \end{array} \right] \vee \left[ \begin{array}{c} Y_2 \\ 8 \leq x_1 \leq 9 \\ 1 \leq x_2 \leq 2 \end{array} \right] \quad (1)$$

$$\left[ \begin{array}{c} W_1 \\ 1 \leq x_1 \leq 2 \\ 5 \leq x_2 \leq 6 \end{array} \right] \vee \left[ \begin{array}{c} W_2 \\ 2 \leq x_1 \leq 3 \\ 4 \leq x_2 \leq 5 \end{array} \right]$$

$$\Xi(1, \{Y_1, Y_2\})$$

$$\Xi(Y_1, \{W_1, W_2\})$$

$$\left[ \begin{array}{c} Y_1 \\ 1 \leq x_1 \leq 3 \\ 4 \leq x_2 \leq 6 \end{array} \right] \vee \left[ \begin{array}{c} Y_2 \\ 8 \leq x_1 \leq 9 \\ 1 \leq x_2 \leq 2 \end{array} \right] \quad (2)$$

$$\left[ \begin{array}{c} W_1 \\ 1 \leq x_1 \leq 2 \\ 5 \leq x_2 \leq 6 \end{array} \right] \vee \left[ \begin{array}{c} W_2 \\ 2 \leq x_1 \leq 3 \\ 4 \leq x_2 \leq 5 \end{array} \right] \vee \left[ \begin{array}{c} W_3 \\ 1 \leq x_1 \leq 9 \\ 1 \leq x_2 \leq 6 \end{array} \right]$$

$$\Xi(1, \{Y_1, Y_2\})$$

$$\Xi(1, \{W_1, W_2, W_3\})$$

$$\Xi(Y_1, \{W_1, W_2\})$$

## 4. Conclusions

The contribution of this paper has been to extend GDP for modeling hierarchical systems via nested disjunctions. Such an approach results in more intuitive models, but has not

been formalized in the past, as classical GDP does not consider disjunction nesting. The notation and logic constraints for such structures is provided, along with theoretical proofs to the tightness of such models, versus equivalent single-level GDP models. It is shown that mixed-integer programming reformulations of nested GDP models have tighter relaxations than the reformulations of their single-level counterparts in both the hull reformulation, as well as the Big-M reformulation when tight  $M$  values are used.

**Figure 1.** Projections of the continuous relaxations of Example 4.1 for different reformulations (Big-M = Big-M Reformulation, Tight-M = Big-M Reformulation with tight  $M$  values, Hull = Hull Reformulation; equivalent = equivalent single-level GDP, nested = multi-level hierarchical GDP). Projection areas, relative to Big-M are indicated in %.

## Abstract

Soft-sensors can provide real-time estimates of unmeasured process variables to improve process control and performance. A Multi-Input-Multi-Output system is considered, where the outputs need to satisfy a linear constraint (e.g. balance equations), while the output variables are predicted using machine learning (ML) models. The key idea is that data reconciliation (DR) can be used to modify both the measurements and the model predictions to meet the prescribed constraints. In addition, the model prediction errors can be used as weighting factors for data reconciliation.

The paper summarizes the mathematical derivation and application of the approach to predict the composition of various rocks in an industrial environment. The results show that the proposed, integrated ML+DR approach greatly contributes to the models' usability. Furthermore, we obtained smaller model errors in four cases out of the six properties, and the prediction sum also considers the constraints.

## 1. Introduction

This paper proposes a methodology that can improve ML models applied in industrial processes and help optimization based on digitization tools. Moreover, during the Industry 4.0 processes, software sensors' use is becoming more widespread [1]. The motivation of the work is that the use of correlations between process parameters can make the industrial application of machine learning algorithms more efficient and robust. These options include various ML algorithms that can replace traditional quality assurance processes. During the development of ML models of Quality 4.0 techniques, we can estimate only specific parameters with sufficient accuracy in many cases. The key idea is that in many cases the variables to be estimated are not independent of each other, for example they have to satisfy some balance equation, but these constraints are not taken into account when teaching ML models. We recommend a data reconciliation technique to meet the limits, thus increasing the applicability of ML models.

The DR technique has already been used for energy monitoring chemical processes, which considers the balance equations' consistency. In addition to the DR method, principal component analysis (PCA) can also use to forecast operating costs. The advantage of this method is that if we apply the PCA technique, the reliability of the data increases significantly, which increases the accuracy of this estimated cost.[2], furthermore, DR and PCA are also excellent for error detection [3] [4]. Xie et al.

investigated the industrial application of sodium-aluminium solution vaporization. They presented that DR is a key technique in improving the accuracy of measured and predicted data in the case of a chemical process [5]. The DR-based approach results in better data quality and, thus, fewer operational errors [6]. Furthermore, DR is used in the control design of online processes, where the goal is to estimate the valid values of erroneous measurements within limits. Non-linear DR was used in material flow analysis for the systematic and efficient management of material flow and inventory [7] or even for eliminating errors caused by measurement noise in the control of reactor processes [8]. For example, the hierarchical DR provides a high-quality measurement of predicting a natural industrial system's material and heat energy consumption [9]. In addition, DR can be used in 4.0 quality, and there is a large literature on Fourier transform infrared spectroscopy (FTIR) measurement techniques and dielectric spectroscopy techniques for predicting the concentration of different metabolites. DR using FTIR belongs to Dabros et al. according to them, the predictive performance of the primary models was found to be poor, but with DR techniques the problem can be improved by real-time mass and elemental balance [10].

We present a machine learning and data reconciliation-based approach (see Section 2) to predict elemental composition of rocks, where the predictions need to satisfy a linear constraint (a balance equation). Furthermore, since the model predictions are loaded with errors, the standard deviation of the model errors can be used in data reconciliation to modify the predicted values. The accuracy of the ML models with and without using DR are compared (see Section 3).

## 2. Data reconciliation-based integration of machine learning models

This section introduces the methodology of our approach to integrate ML and DR techniques to improve the quality of ML predictions. The goal is to predict several related variables, where the predictions need to satisfy some constraints, e.g. balance equations. In order to achieve the highest accuracy of the ML predictions, and to fulfil the constraints, we recommend to integrate ML and DR techniques.

We consider a Multi-Input-Multi-Output system with  $N$  samples and  $N_m$  measurement variables. The measurement outputs of the  $k$ -th sample can be written as in Equation 1.

$$\mathbf{y}_k = f(\mathbf{x}_k, \boldsymbol{\theta}) + \boldsymbol{\varepsilon}_k \quad (1)$$

where  $\mathbf{y}_k = [\mathbf{y}_k^{(1)}, \dots, \mathbf{y}_k^{(N_m)}]^T$  is the measurement vector of the  $k$ -th sample,  $\mathbf{x}_k$  is the input features of the  $k$ -th sample, and  $\boldsymbol{\varepsilon}_k$  is the measurement error at the  $k$ -th sample. The  $k$ -th sample of the  $i$ -th output variable can be defined as Equation 2.

$$y_k^{(i)} = f_i(\mathbf{x}_k^{(i)}, \boldsymbol{\theta}^{(i)}) + \varepsilon_k^{(i)} \quad (2)$$

where  $y_k^{(i)}$  is the  $i$ -th output variable as the  $k$ th sample,  $f_i$  is the  $i$ -th model,  $\mathbf{x}_k^{(i)}$  stands for the input features for the  $i$ th model at the  $k$ th sample,  $\boldsymbol{\theta}^{(i)}$  is the model parameters of the  $i$ th model and  $\varepsilon_k^{(i)}$  represents the model error for the  $i$ th model at the  $k$ th sample.

The prediction of the model at the  $k$ th sample is represented as  $\hat{\mathbf{y}}_k = [\hat{y}_k^{(1)}, \dots, \hat{y}_k^{(N_m)}]^T$ , and the prediction of the  $i$ th model at the  $k$ th sample ( $\hat{y}_k^{(i)}$ ) can be calculated as presented in Equation 3.

$$\hat{y}_k^{(i)} = f_i(\mathbf{x}_k^{(i)}, \boldsymbol{\theta}^{(i)}) \quad (3)$$

The measurement variables are not independent of each other, because they need to satisfy a linear constraint, while the measurements are loaded with errors ( $e_k$ ), hence this constraint is not fulfilled.

$$g(\mathbf{y}_k) + e_k = 0 \quad (4)$$

where  $g()$  is an equality constraint function.

Data reconciliation calculates minimal correction of the predicted variables to make them verify a set of model constraints. It minimizes the difference between the predicted and reconciled values considering the variance of the variables and ensures that reconciled parameters satisfy some equality and inequality constraints. Similarly, the corrected model predictions for the  $k$ th sample are represented as  $\tilde{\mathbf{y}}_k = [\tilde{y}_k^{(1)}, \dots, \tilde{y}_k^{(N_m)}]^T$ .

$$\min_{\tilde{\mathbf{y}}_k} (\hat{\mathbf{y}}_k - \tilde{\mathbf{y}}_k)^T \mathbf{Q} (\hat{\mathbf{y}}_k - \tilde{\mathbf{y}}_k) \quad (5)$$

$$\text{s.t.} \quad g(\tilde{\mathbf{y}}_k) = 0 \quad (6)$$

where  $\tilde{\mathbf{y}}_k$  is the corrected value by data reconciliation, the  $\mathbf{Q}$  is the inverse covariance matrix of the measurements/predictions error, the  $g(\tilde{\mathbf{y}}_k)$  is a model equality constraint. In the inverse covariance matrix  $\mathbf{Q}$  the standard deviation of the measurement errors are presented, as in Equation 7.

$$\mathbf{Q} = \begin{bmatrix} 1/\sigma_1^2 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & 1/\sigma_{N_m}^2 \end{bmatrix} \quad (7)$$

In case of a linear constraint Equation 5 becomes the following:

$$\mathbf{A}\tilde{\mathbf{y}}_k = \mathbf{b} \quad (8)$$

where  $\mathbf{A}$  is the incidence matrix, and  $\mathbf{b}$  stands for constraint values.

The analytical solution of the system of Equations 5 and 8 is the following:

$$\tilde{\mathbf{y}}_k = (\mathbf{I} - \mathbf{Q}\mathbf{A}^T(\mathbf{A}\mathbf{Q}\mathbf{A}^T)^{-1}\mathbf{A})\hat{\mathbf{y}}_k + \mathbf{Q}\mathbf{A}^T(\mathbf{A}\mathbf{Q}\mathbf{A}^T)^{-1}\mathbf{b} \quad (9)$$

where  $\mathbf{I}$  is the identity matrix,  $\mathbf{Q}$  is the inverse covariance matrix,  $\mathbf{A}$  is the incidence matrix and  $\mathbf{b}$  is the constraint values.

In the developed methodology, industrial data collection in a data store provides input data to the ML models. The essence of the developed methodology is that various DR

restrictions are applied after the models are incorporated, which enables more accurate and robust ML models. As a result, we can build more effective multivariate data analysis on our industrial processes. Figure 1 shows in a general diagram how the developed technique can be applied in an industrial environment. The essential part of the methodology is shown with the orange arrows, and the blue dashed line shows the traditional approach in the following figure.

Figure 1: Diagram of the recommended method

### 3. Data reconciliation-based integration of machine learning models

A mineral composition prediction model was built on 618 rock samples, where the target variables were mass percentage of quartz, clay content without kaolinite, kaolinite, plagioclase with K-feldspar, calcite and dolomite. The reference measurements were performed with an X-ray diffraction (XRD) device. PLS models were trained on pretreated spectra from FTIR measurements, and individual models were trained for each of the six target variables. Optimal number of factors for PLS models were tuned based on the results of 10-fold cross-validation. The ML input spectra of samples were scanned (4 scans co-added) from 1998 to 600  $\text{cm}^{-1}$  in attenuated total reflectance (ATR) mode by using a Spectrum 400 spectrometer equipped with a Universal ATR (UATR) accessory, which contains a single reflection diamond/ZnSe composite crystal.

Table 1 summarizes the target values of a chosen sample, the predictions (ML(PLS)) and the reconciled predictions (ML(PLS)+DR).

Table 1. Prediction and reconciled results a chosen sample (weight%)

	Quartz	Clay without kaolinite	Kaolinite	Plagioclase + K-feldspar	Calcite	Dolomite	sum
Target	49	16	1	17	10	7	100
ML (PLS)	49.39	17.95	1.637	14.32	10.51	8.053	101.86
ML(PLS)+DR	49.21	17.55	1.085	14.19	10.36	7.605	100

The reconciled predictions for five of the six output variables were better compared to the non-reconciled model predictions. Table 2 summarizes the results obtained for all 618 rock samples, as well as the standard deviation of the reference measurement. The performance indicators of the models were the cross-validation error ( $RMSE_{cv}$ ).

Table 2. Reference measuring standard deviation, optimal factor number of the PLS,  $RMSE_{cv}$  (%) results of ML and ML + DR models

	Quartz	Clay without kaolinite	Kaolinite	Plagioclase + K-feldspar	Calcite	Dolomite
Factor number	8	5	9	9	5	8
ML(PLS) $RMSE_{cv}$	5.934	6.265	1.467	3.263	4.173	2.414
ML(PLS) + DR $RMSE_{cv}$	5.924	6.232	1.624	3.260	4.172	2.481

The values of the six target variables ranged from 1.47 to 6.27 with the ML solution and from 1.62 to 6.23 with the ML+DR technique. The accuracy of the ML models constructed from FTIR spectra approaches the uncertainty of the reference measurement in two cases (kaolinite, dolomite), and the ML+DR models give better results when the six properties are considered together. In the latter case, the ML+DR models perform worse for kaolinite and dolomite (Table 2). This can be explained by the fact that these models already performed very close to the accuracy of the reference models.

#### 4. Conclusion
