The article proposes a methodology that improves the usability of ML models by reconciling the model predictions. The proposed methodology takes into account the prediction error of the ML models, by which the DR technique corrects the prediction values while satisfying certain constraints. Since in many cases the variables to be estimated are not independent of each other, for example, they correspond to balance equations. However, these constraints should be fulfilled by ML models. We present a methodology on how to integrate machine learning and data-reconciliation, and we tested the approach to estimate the elemental composition of rock samples.

With the inclusion of the constraints, the results showed more accurate outputs for four of the six target variables. The results will help geologists by enabling them to obtain mineral composition data of rocks. Furthermore, the presented methodology allows faster and cheaper access to compositional data, either with a mobile device or with devices installed in a soft sensor.

Our future research is to take constraints into account using DR during the training of the ML models, rather than performing the training and data reconciliation serially.

## Abstract

The unsustainably managed flow of nutrients combined with the rise in the generation of waste calls for urgent actions involving nutrient recovery. This work develops a mathematical programming model intended to optimise regional nutrient recovery from various waste treatment technologies. Food waste, green waste, and wastewater are evaluated in this work with an option of treating these wastes individually or as mixed streams. Five waste treatment technologies are available, each with a specific profile of nutrient recovery. The results of this work demonstrate the attractiveness of anaerobic digestion as well as the benefit of a mixed waste stream for optimum nutrient recovery.

**Keywords:** Mathematical Optimisation, Nutrient Recovery, Circular Economy, Climate Change, Sustainable Resource Management

## 1. Introduction

Nutrients such as nitrogen and phosphorus are vital for food production. Presently, there is a vast usage of inorganic fertilisers derived from ammonia and phosphate (van der Wiel et al., 2020). Phosphorus is solely sourced from phosphate rocks which are finite resources and limited in terms of their geographic availability (Álvarez et al., 2018) while nitrogen in ammonia production represents one of the major industrial energy demands and sources of greenhouse gas emissions (Liu et al., 2020). Furthermore, the existing managed flow of phosphorus and nitrogen from its source (mines) to the ocean or other aquatic environments is not sustainable (Cordell and White, 2015). The current farming and waste management practices create a significant nutrient influx to water streams, resulting in undesirable consequences e.g., eutrophication (Cordell and White, 2015). Aside from that, nutrient depletion due to current practices would induce instability in the food systems, thus driving up the costs of food production. A key solution to these problems lies in innovative waste management. In the United Kingdom, 27 million tonnes of household waste were produced in the year 2018 (DEFRA, 2022). Although close to half of this waste is recycled, much more needs to be done to align with environmental sustainability and thus create a circular economy (DEFRA, 2022). With the rise in population, the total volume of waste generated annually is projected to rise. Nutrients such as nitrogen and phosphorus should be extracted from these waste streams as they may be re-utilised as fertilisers.

In the past, several studies concerning nutrient recovery had been conducted (Mehta et al., 2014; Perera et al., 2019; Sniatala et al., 2023), which were all focused on technological advancement for nutrient recovery. There was a limited focus in terms of modelling and optimising nutrient flows from their sources (water, food, and green waste) to potential sinks e.g., land dispersion, fertilisers etc. Despite some work being done recently for optimising nutrient recovery, much of the focus was associated with transportation costs (Metson et al., 2020) and biogas generation from anaerobic digestion (Feiz et al., 2022). There has been limited emphasis on optimising nutrient recovery from these waste treatment technologies. This work, therefore, seeks to model and optimise the regional nutrient flows and maximise recovery from waste streams into valuable products such as fertilisers. Firstly, the flows of wastewater, food and green wastes are mapped to understand their resource recovery potential in creating a circular economy. Based on the available data, an optimisation model is subsequently built toward determining potential opportunities that may be present for nutrient recovery. Potential technologies such as anaerobic digestion, composting and incineration are considered in the optimisation model. This work makes use of a case study from Leicestershire County (LC) in the UK and is expected to consolidate efforts toward building a circular economy by tapping into the underexplored potentials of nutrients embedded in the waste streams, thus promoting a sustainable practice of nutrient management in a regional setting.

## 2. Problem Statement

Given a set of waste streams i.e., food waste, green waste and wastewater that may be treated by processing unit (PU)  $j$  as either an individual waste (IW) stream  $i$  or mixed waste (MW) stream  $im$ . The treatment of IW  $i$  and MW  $im$  by PU  $j$  results in the recovery of nutrient  $l$ . A superstructural mathematical programming formulation is developed to synthesise a waste treatment network for optimised nutrient recovery.

## 3. Mathematical Programming Formulation

The total flow of IW  $i$  to PU  $j \in J$  ( $x1_{i,j}$ ) and MW  $im \in IM$  ( $x2_{i,im}$ ) should equate to the total waste available ( $TW_i$ ), as shown in Eq.(1).

$$\sum_j x1_{i,j} + \sum_{im} x2_{i,im} = TW_i \quad \forall i \quad (1)$$

Next, the total flow of IW  $i \in I$  and MW  $im \in IM$  ( $x3_{im,j}$ ) to PU  $j$  should not exceed the maximum treatment capacity of PU  $j$  ( $M_j$ ), as shown in Eq.(2).

$$\sum_i x1_{i,j} + \sum_{im} x3_{im,j} \leq M_j \quad \forall j \quad (2)$$

Eq.(3) ensures that the flow of MW  $im$  to PU  $j$  equate the flow summations of IW  $i$  to MW  $im$ .

$$\sum_i x2_{i,im} = \sum_j x3_{im,j} \quad \forall im \quad (3)$$

Following this, the total recovery of nutrient  $l$  from PU  $j$  treating IW  $i$  ( $NT1_{i,j,l}$ ) and MW  $im$  ( $NT2_{im,j,l}$ ) are depicted in Eq.(4) and Eq.(5) respectively.

$$NT1_{i,j,l} = x1_{i,j} \times a1_{i,j,l} \quad \forall i \forall j \forall l \quad (4)$$

$$NT2_{im,j,l} = x3_{im,j} \times a2_{im,j,l} \quad \forall im \forall j \forall l \quad (5)$$

where  $a1_{i,j,l}$  and  $a2_{im,j,l}$  are the recovery of nutrient  $l$  from PU  $j$  treating IW  $i$  and MW  $im$  respectively.

The objective function of this optimisation problem is to maximise the total nutrient recovery, i.e., the sum of nutrients  $l \in L$  from PU  $j \in J$  treating IW  $i \in I$  and MW  $im \in IM$ , as shown in Eq.(6):

$$\max NTT = \sum_i \sum_j \sum_l NT1_{i,j,l} + \sum_{im} \sum_j \sum_l NT2_{im,j,l} \tag{6}$$

The linear programming model is implemented in GAMS using the CPLEX solver.

#### 4. Nutrient Flow Data and Operational Constraints

This work makes use of a case study from LC in the UK. Firstly, the type and mass of waste available within the LC region are presented in Table 1.

Table 1: Type and volume of waste

Waste	Waste Mass, t y <sup>-1</sup>
Food (F)	149,845
Green (G)	61,143
Wastewater sludge (W)	463,696

Based on Table 1, the three types of waste investigated in this work are food waste, green waste, and wastewater sludge. It is estimated that there are 149,845 tonnes of food waste generated annually in LC (WRAP, 2020). Meanwhile, the annual volume of green waste amounted to 61,143 tonnes (WasteDataFlow, 2021). Moving on to the wastewater, it is estimated that the total wastewater generated in LC is 0.7 m<sup>3</sup> d<sup>-1</sup> capita<sup>-1</sup>, covering both domestic households and small businesses (Severn Trent Plc, 2022). Considering that the population in LC is 712,300 (Richardson, 2022), the total annual volume of wastewater in LC is estimated to be 180.9 million m<sup>3</sup>, resulting in 463,696 tonnes of wastewater sludge annually. In this work, five PUs i.e., anaerobic digestion (AD), windrow composting (WC), bin composting (BC), incineration (IN) and the landfill (LF) are considered for treating various waste in LC. Table 2 presents the assumed maximum treatment capacity of each PU.

Table 2: Assumed maximum treatment capacity of PU

Processing Unit	Waste processing capacity, t y <sup>-1</sup>
AD	700,000
WC	300,000
BC	60,000
IN	700,000
LF	700,000

Both IN and LF are well-established technologies and are assumed to treat a maximum of 700,000 tonnes of waste, as observed in Table 2. Meanwhile, BC which is done within households is assumed to have the least waste processing capacity. In this work, AD is assumed to have a significant annual waste treatment capacity of 700,000 tonnes of organic waste due to the potential for nutrient recovery and biogas generation. Next, the recovery of nutrients  $l$  from the PU  $j$  treating IW  $i$  and MW  $im$  is presented in Table 3.

Note that the two nutrients considered in this work i.e., nitrogen (N) and phosphorus (P) may be recovered in solid (NS/PS) and liquid (NL/PL) streams.

Table 3: Nutrient recovery

Waste Stream	Processing Unit	NL, kg t <sup>-1</sup>	NS, kg t <sup>-1</sup>	PL, kg t <sup>-1</sup>	PS, kg t <sup>-1</sup>
Food <sup>a</sup>	AD	2.28	1.94	0.230	0.61
Water <sup>b</sup>	AD	0	1.80	0	1.47
Food + Green <sup>c, d</sup>	AD	2.15	1.82	0.350	0.92
Green <sup>e</sup>	WC	0	3.22	0	0.61
Food + Green <sup>e</sup>	BC	0.05	2.48	0.010	0.56
Food + Green <sup>f, g</sup>	IN	0	0	0	1.20
Food + Green <sup>f, h</sup>	LF	0.15	0	0.005	0

References: a) (Dimambro, 2015) b) (Havukainen et al., 2022) c) (Banks et al., 2018) d) (Cesaro, 2021) e) (Andersen et al., 2010) f) (Jeswani and Azapagic, 2016) g) (Šyc et al., 2020) h) (Kulikowska and Klimiuk, 2008)

Based on Table 3, AD may be used to treat food wastes, wastewater sludge as well as a mixture of food and green wastes. WC may be used for the treatment of green waste. Besides, the mixture of food and green wastes may be treated using BC, IN or LF. Although the ratio of food and green waste may change in a MW stream, this work assumes a fixed ratio of the food and green waste (9:1) in MW streams to all PUs.

## 5. Case Study

This work is solved according to Eq.(6) subject to the constraints in Eq.(1) till Eq.(5). Table 4 presents the optimised volumes of waste flows to the PUs. Note that Table 4 also includes the results of two supplementary runs that maximise the recovery of total N or P.

Table 4: Waste Flow Volume to PU <sub>j</sub>

Waste Stream	Waste flow to PU (max NTT/max total N/max total P)				
	AD	WC	BC	IN	LF
Food, t y <sup>-1</sup>	0/149,845/0	0	0	0	0
Green, t y <sup>-1</sup>	0	44,493/61,143/44,493	0	0	0
Wastewater, t y <sup>-1</sup>	463,696	0	0	0	0
Food + Green, t y <sup>-1</sup>	166,495/0/166,495	0	0	0	0

Based on Table 4, maximising the total nutrient recovery (Eq.(6)) resulted in no food waste being treated via AD as an IW stream. All food waste is combined with approximately 27% of the green waste for treatment via AD. The higher nutrient recovery of the MW stream via AD resulted in it being the primary choice of waste treatment in this optimisation problem (see Table 3). Note that all wastewater sludge is treated via AD for a similar reason. The objective function in this work is maximised at 2,559 tonnes of nutrients, comprising 1,639 tonnes of N and 920 tonnes of P. Moving on, the total recovery of N is maximised at 1,663 tonnes. All wastes are treated via AD and WC as an

IW stream. The greater N recovery from all types of waste being treated as an IW stream led to this solution. The total recovery of P is maximised at 920 tonnes, with similar results observed as to maximising the total nutrient recovery. It is good to note that if incineration is selected, the P recovery from incineration ash would require additional extraction processes before it may be applied to agricultural land or replacing phosphate for fertiliser production (Kalmykova and Karlfeldt Fedje, 2013). The results of this optimisation problem align with the aim of this work in maximising nutrient recovery and exploring the potential offered by these waste streams.

## 6. Conclusions

An optimal waste treatment plan for maximising nutrient recovery is suggested in this work based on mathematical programming models. This work is expected to aid in value-creation among waste streams that would otherwise remain unutilised. The results of this work demonstrate the importance of AD in maximising nutrient recovery. Additionally, combining the food and green waste streams presents an added value for better use of resources. Future work should include the cost analysis of potential by-products i.e., biogas, and digestate as well as emissions that may arise from the waste treatment. Also, the operational and capital costs associated with the operations of waste treatment plants must be considered for a more realistic waste management scenario.

## Abstract

The focus of the presented work is on the model-based optimization of a purification process of chemical compounds called enantiomers. As an example, the separation of asparagine monohydrate from the racemic mixture is considered, which has been proven to be effective in experiments. The experimental results indicate the need for a careful selection of operating conditions to provide the desired process performance. To describe the studied phenomena, a validated mathematical model based on population balance equations is used. Numerical optimization finds a set of operating conditions ensuring high product purity, while keeping the product contamination under a defined threshold

**Keywords:** Separation of Enantiomers, Continuous Crystallization, Population Balance Equations, Mathematical Optimization, Genetic Algorithms, Parallel Computations.

## 1. Introduction

More than ten million substances have been discovered in organic chemistry over the past two centuries (Dengale et al., 2016). Organic synthesis is becoming more and more prevalent due to the need to solve fundamental problems, such as determining the relationship between a chemical substance and its reactivity. To prevent and treat diseases, there is a need for affordable and effective drugs. To satisfy this need, chemists and pharmaceutical researchers are joining forces.

To reduce the time of drug production, great efforts are made to study already known compounds that are optical or geometric isomers.

One of the potential candidates are enantiomers, which are pairs of optically active isomers differently orientated in space (McConathy and Owens, 2003). A large interest in producing single enantiomers is confirmed by the life science industries, pharmaceuticals, and agrochemical companies. To supply pure enantiomers different approaches can be performed. The focus of this study is on the racemic approach based on separating mixtures of both enantiomers to obtain a significant amount of the desired single enantiomer characterized by high purity.

## **2. Process description**

Chemical industries have increasingly relied on crystallization as a separation and purification technology, especially for those chiral molecules that crystallize in conglomerates, where the two enantiomers are mechanically mixed in the solid phase crystallizing separately as enantiopure crystals. In this kinetically controlled process, different rates of crystallization of each enantiomer are important.

Implementing a fluidized bed crystallization approach, two tubular crystallizers are connected spatially and are capable of crystallizing both enantiomers of chiral molecules selectively out of racemic solutions. Each of the operated crystallizers consists of the cylindrical top and the conical bottom parts. Liquid solvent without crystals enters the crystallizer at the bottom, and a mixture of solvent and formed crystals quits from the crystallizer at the top. The mechanical milling element located at the bottom ensures the continuity of the process and the supply of seed crystals. The volumetric flow rate characterizes the incoming stream; the removal of crystals is carried out periodically, and the outflow rate is determined by the applied withdrawal strategy. Corresponding scheme of the process is given in Figure 1. Special attention within this work is paid to modeling the crystal's withdrawal in a pulse-wise manner how it is performed in a laboratory.

## **3. Modeling crystallization process in fluidized beds**

The fundamentals of the mathematical model applied are proposed in (Huskova, 2022). The model consists of three main components: population balances for the enantiomers in both crystallizers, distributed in one space and one property coordinate; a total mass balance for describing changes in the liquid phase; an energy balance to account for the non-isothermal nature of the process. The model distinguishes between the two types of enantiomers, as they may

crystallize at different rates The structural change in the crystal shape is not considered. Instead, the physical parameters of the model are sorted into four groups:

- crystallizer design parameters;
- thermodynamic and kinetic properties of a particular chemical compound;
- operational parameters and parameters related to the product withdrawal strategy;
- set of parameters related to the model assumptions that have been adapted within the validation procedure.

A detailed description of the mathematical model and all the related model equations can be found in (Huskova, 2022). The reference numerical solutions are obtained in Matlab by a time integration with the ODE23 integrator applying Runge–Kutta method.

Figure 1. Schematic representation of continuous crystallization in a fluidized bed described in (Gänsch et al., 2021)

#### 4. Model-based optimization

The next step after finding the reference solution and providing a model validation is to determine relevant model parameters to improve the process. The

main goal of the optimization is to improve productivity of the target compound, which in general can be expressed as follows:

$$OF = Pr^L \rightarrow \max ,$$

where  $L$  stands for a target enantiomer.

A sensitivity analysis presented in (Gänsch et al., 2021) indicates that the operational conditions and geometrical parameters of the crystallizer listed in Table 1 have the biggest leverage.

Table 1. List of optimization variables

$v_1$	$H$	Crystallizer height
$v_2$	$H_1$	Height of conical section
$v_3$	$R_1$	Radius of the bottom
$v_4$	$R_2$	Radius of the top
$v_5$	$T_{cryst}$	Crystallizer Temperature
$v_6$	$u_{emptytube}$	Empty tube velocity

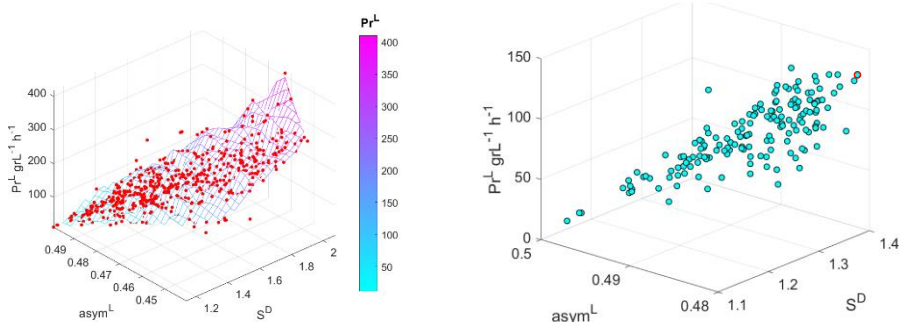

#### *Empirical threshold to nucleation assessment*

However, while analyzing productivity, it should be noted that when the sensor is in a high position, the risk of product contamination significantly increases, as was experimentally proven in (Gänsch et al., 2021). The occurrence of contamination can be explained by critical values of nucleation factors – supersaturation of the counter-enantiomer,  $S^D$ , and asymmetry of the solution,  $asym^L$  (from here on, the target enantiomer is indexed  $L$ , and the counter-enantiomer  $D$ ). From previous work, it is known that a low value of  $asym^L$  as well as a high value of  $S^D$  cause a drop in purity. Based on the experimental study, the following restrictions are proposed to ensure an acceptable product contamination:

$$\begin{cases} S^D \leq 1.4 \\ asym_L \geq 0.48 \end{cases} \quad [\text{Eq.1}]$$

#### **Optimization results**

The simulation results shown on the left-hand side of Figure 1 do not include imposed constraints. It demonstrates that the productivity of the process can reach  $400 \text{ gL}^{-1} \text{ h}^{-1}$ , however with low purity and high contamination of the product. When the nucleation factors from [Eq.1] are considered in the optimization, the achieved productivity is lower – see the right-hand side of Figure 2.

*Figure 2.* Simulation results achieved ignoring (left) following (right) the imposed nucleation factors constraints.

Also in this case, the obtained values significantly exceed the productivity noted in the available literature. Compared to the reference case study reported in (Gänsch et al., 2021), the increase in productivity reaches about 60%. The proposed approach makes it possible to ensure the minimum acceptable level of product purity and focus on increasing productivity by selecting the previously identified optimization variables.

The use of evolutionary algorithms for finding optimal solutions made it possible to avoid getting stuck in a local minimum, which would have happened with a high probability when using gradient-based approaches due to the non-convexity problem.

*Applicability of parallel computing*

Another challenge for the mathematical optimization is related to the resource intensity of the numerical solution. To ensure high accuracy of the numerical solution, the number of differential equations resulting from a discretization of the space and property coordinate exceeds 20 thousand. The elapsed time to calculate the transient to a cyclic steady state for one set of parameters exceeds several hours. The size of the developed model and time constraints lead to the inability to use a single processor to obtain optimal parameters and improve the process. In this regard, an attempt is made to directly solve the problem of reducing the computational requirements without compromising the accuracy of the developed mathematical model through parallelization methods. At each iteration, the formed sets of parameters describing the operating and design conditions were distributed among the processors, which made it possible to significantly speed up the search for the optimal solution.

## 5. Conclusions

The proposed model-based optimization approach is applied to improve the productivity and robustness of the separation of asparagine monohydrate in a fluidized bed reactor. It is demonstrated that the proposed optimal design of the crystallizer setup increases productivity, and additionally, it allows the evaluation of the nucleation factors once the suggested geometry is simulated. These recommendations can be used by experimenters to further achieve the desired purity and productivity of the process.

By shifting the focus away from asparagine monohydrate, the developed mathematical model and optimization procedure can be applied to design the purification of other substances. The study showed that substances for which the proposed fluidized bed approach is applicable should have a certain ratio of the densities of the solid and liquid phases. As an outlook, the approach may also be used to optimize particle characteristics like average particle size.

## Abstract

Naphtha cracking is the primary process for propylene (PL) and ethylene (EL) production and depends on the operating conditions, such as the coil outlet temperature and feedstock composition. The product yields, in turn, determine the profit of the naphtha cracking plant. Therefore, the operating conditions should be optimized to maximize plant profit. However, it is challenging to optimize the conditions using conventional simulation methods since a high-fidelity model is hard to develop owing to the nonlinearity and complexity of the cracking process. In this study, we used machine learning to optimize the operating conditions of a naphtha cracking furnace to maximize plant profit. First, a data-driven model was developed to predict the product yields for different operating conditions using a deep neural network (DNN). The model could predict the PL and EL yields with high accuracy ( $R^2 = 0.965$  and  $0.900$ , respectively). Next, a genetic algorithm was used for optimization based on the developed DNN model. Finally, the developed model was used with real-world plant data and product prices for 2020. The plant profit under the optimized operating conditions was 30% higher than that corresponding to the original operating conditions. Thus, the proposed method is suitable for determining the optimal operating conditions of various types of plants in order to maximize profit.

**Keywords:** naphtha cracking furnace, optimization, machine learning, genetic algorithm

## 1. Introduction

Growth in the petrochemical industry has increased the demand for ethylene (EL) and propylene (PL), which are the elementary materials for various petrochemical products. To meet this demand, EL and PL are generally produced in a naphtha cracking center (NCC), which breaks down naphtha into light and valuable hydrocarbons.

The NCC consists of four main units: a cracking furnace and quenching, compression, and distillation units, as shown in Figure 1. In the first unit, that is, the cracking furnace, naphtha is passed through the coils of the furnace as the feedstock, where it receives thermal energy for the cracking reaction from the furnace. As a result, it undergoes cracking into light hydrocarbons. In the second unit, that is, the quenching unit, the light

hydrocarbons are quenched to prevent the formation of coke and tar in the hydrocarbon mixture and recover the waste heat. In the third unit, that is, the compression unit, the light hydrocarbons receive energy for transportation. Moreover, catalyst poisons and impurities, such as  $H_2S$  and  $CO_2$ , are removed in this unit. Lastly, in the distillation unit, the light hydrocarbons are fractionated into different products, such as EL and PL.

Figure 1. Illustration of NCC for EL and PL production

Of the various units that form the NCC, the cracking furnace has the greatest impact on the product yields, which determine the profit of the naphtha cracking plant because the cracking reaction occurs in the furnace. Figure 2 describes the cracking reaction in the furnace. First, naphtha is preheated before being mixed with diluting steam. After being preheated in the convection section, this mixture is transported to the coil in the radiant section and broken into EL and PL via the cracking reaction. The products are subsequently transported to the quenching unit through the coil outlet.

Figure 2. Schematic of cracking furnace showing main operating conditions: naphtha composition and COT

The yields of EL and PL depend on the operating conditions, that is, the naphtha composition and coil outlet temperature (COT). Thus, the operating conditions of the cracking furnace must be optimized to maximize the profit of the naphtha cracking plant. However, it is challenging to optimize the conditions using conventional simulation methods since a high-fidelity model is hard to develop owing to the nonlinearity and complexity of the cracking process.

In this study, we use machine learning to optimize the operating conditions in a naphtha cracking furnace in order to maximize the plant profit. Figure 3 provides an overview of the study. First, 784 actual industrial operating data points were collected from an NCC plant. In this dataset, the naphtha composition, which included 25 components, and the

COT are used as the input variables, while the EL and PL yields are used as the output variables for the developed model. Next, a deep neural network (DNN)-based model is developed using the data. The developed model is evaluated based on the  $R^2$  values before optimization. Finally, the operating conditions are optimized for profit maximization using a genetic algorithm. For model evaluation, the optimal conditions and the corresponding profit are compared with the actual plant data for 2020.

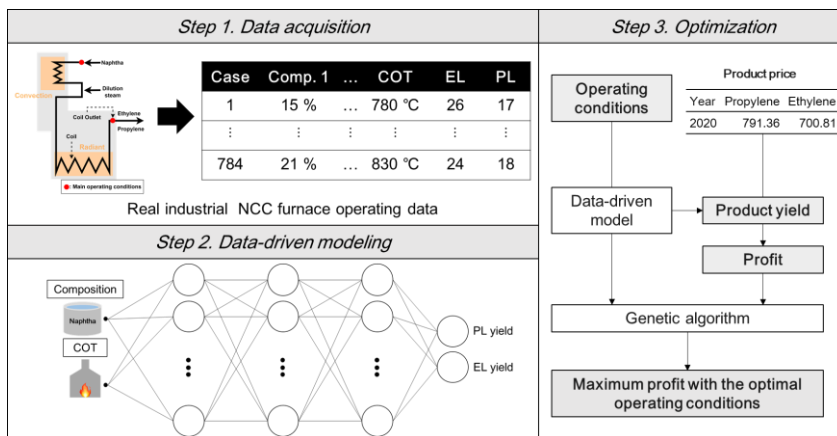

Figure 3. Overview of study

## 2. Method

### 2.1. Deep neural networks (DNNs)

DNNs have been used widely for data-driven modeling. A DNN consists of layers, including nodes and edges, that contain mathematical relationships. During data training, these relationships are updated by backpropagation. After training, the updated relationships are used as the equations for predicting the output variables based on the input variables. Therefore, a significant advantage of DNNs is that they can express the relationships that exist in a system regardless of the nonlinearity and complexity of the system.

Figure 4 shows the structure of the DNN-based model used in this study. The model consists of one input layer, three hidden layers, and one output layer, and these layers include 26 nodes, 100 nodes, and two nodes, respectively. This means that the 26 input variables, namely, the composition of the 25 naphtha components and the COT, were used to calculate the two output variables, namely, the EL and PL yields, while considering 300 functions.

Figure 4. Structure of DNN-based model used in this study

## 2.2. Genetic algorithm

A genetic algorithm (GA) is a heuristic search algorithm inspired by the biological evolution process. GAs repeat three steps for optimization, as shown in Figure 5: selection, crossover, and mutation. In the selection step, a few data points, called parents, are selected randomly and contribute to the population of the next generation. Here, “ $Obj_n$ ” is the result of the objective function of the  $n^{\text{th}}$  data point. In the crossover step, two parents are combined to form the offspring for the next generation by switching some of the input variables. Lastly, the random changes in the input variables are applied to obtain different offspring. By repeating these steps, “ $Obj_n$ ” is enhanced gradually, and the optimal data point is suggested eventually.

Figure 5. Main steps of GA: selection, crossover, and mutation

This study aimed to optimize the operating conditions of NCC furnaces for profit maximization. Thus, the objective function was defined as shown in Eq. (1), and a GA was employed to solve the optimization problem.

### Objective function

$$\text{maximize Profit} = \max \left( \text{flowrate} \times \frac{\text{yield}_{EL} \times \text{Price}_{EL} + \text{yield}_{PL} \times \text{Price}_{PL}}{\text{yield}_{total}} \right) \quad (1)$$

where  $\text{flowrate}$  is assumed to be 29 ton/h in the steady state, and  $\text{yield}_{EL}$ ,  $\text{yield}_{PL}$ , and  $\text{yield}_{total}$  indicate the yields of EL, PL, and the total product, respectively.  $\text{Price}_{EL}$  and  $\text{Price}_{PL}$  are the product prices in 2020, as shown in Table 1.

Table 1. Prices of primary naphtha cracking products in 2020

Year	Propylene	Ethylene
2020	791.36 \$/ton	700.81 \$/ton

## 3. Results and discussion

### 3.1. Model development

To develop the data-driven model, the 784 industrial data points was randomly split into 60% training, 20% validation, and 20% test datasets. In other words, 470 data points were used for model training, 157 data points are used for model validation, and the rest (157 data points) were used for model testing.

After the model had been developed using the training and validation datasets, its performance was evaluated using the test dataset based on the coefficient of determination ( $R^2$ ), which is a representative evaluation criterion for regression.  $R^2$  was calculated using Eq. (2):

$$R^2 = 1 - \frac{\sum_{i=1}^N (S_{ia} - S_{ip})^2}{\sum_{i=1}^N (S_{ia} - \bar{S}_{ip})^2} \quad (2)$$

where  $N$  indicates the number of data points,  $S_{ia}$  indicates the  $i^{\text{th}}$  actual value, and  $S_{ip}$  indicates the  $i^{\text{th}}$  value predicted by the model.

The results of the model performance evaluation are shown in Figure 6. As can be seen, even though the data point within the red box shows a relatively large error, the DNN-based model predicted the EL and PL yields with high  $R^2$  values (0.965 and 0.900, respectively). Moreover, the figure shows that the more EL the NCC furnace produces, the less the amount of PL produced. This is because it is likely that PL is decomposed into EL owing to the high COT or a lack of heavy components in naphtha. Therefore, the model showed good prediction performance and confirmed that the product yields could be changed by varying the cracking reaction conditions.

Figure 6. Parity plots and  $R^2$  values for (a) EL yield and (b) PL yield

### 3.2. Profit optimization

Using the DNN-based model and the GA, the operating conditions, that is, the naphtha composition corresponding to 25 components and the COT, were optimized to maximize the profit of the NCC plant. In addition, the base case, that is, the actual operating data for 2020, were compared with the optimization results for validation.

Table 2 shows the operating conditions and the profits for the base and optimal cases; the 25 components are encoded as “Comp.N” for reasons of confidentiality. The optimal case corresponds to a profit of 12,202 \$/h, which is 30% higher than that for the base case, which is 9,382 \$/h. Moreover, for the optimal case, COT is 42 °C higher than that for the base case, and some of the naphtha components are very different from those for the base case. This means that a high COT will increase the profit because it accelerates the cracking reaction. Furthermore, the use of the appropriate naphtha composition also increases the profit. Thus, the blending process can be considered to increase the profit.

It should be noted that the optimization process only considered the product prices. However, other factors, such as the fuel price, energy consumption, and coke formation, should also be considered in the future to obtain a more practical model.

Table 2. Operating conditions and profits for base and optimal cases

Case	COT (°C)	Comp.1	Comp.2	Comp.3	Comp.4	Comp.5	Comp.6	Comp.7	Comp.8
Base	808	3.20	8.09	2.28	0.01	0.00	2.86	0.21	0.00
Optimal	850	2.79	6.70	0.76	2.02	0.55	1.28	0.03	0.00
	Comp.9	Comp.10	Comp.11	Comp.12	Comp.13	Comp.14	Comp.15	Comp.16	Comp.17
	(wt%)								
Base	0.00	0.00	0.13	5.12	22.20	11.97	1.06	0.00	0.00
Optimal	0.00	0.00	1.93	7.84	15.87	9.14	3.87	2.55	1.10
	Comp.18	Comp.19	Comp.20	Comp.21	Comp.22	Comp.23	Comp.24	Comp.25	Profit (\$/h)
	(wt%)								
Base	0.00	0.51	22.34	16.86	3.13	0.01	0.01	0.00	9,382.01
Optimal	0.29	2.32	19.20	11.47	5.56	3.06	0.88	0.81	12,202.90

#### 4. Conclusions

The profit of NCC plants depends on the operating conditions of the cracking furnace, composition of the 25 naphtha components, and COT. Thus, these conditions must be optimized to maximize the profit. However, it is challenging to optimize the conditions because developing a high-fidelity model for optimization is difficult owing to the nonlinearity and complexity of the cracking process. In this study, we used machine learning to optimize the operating conditions in a naphtha cracking furnace to maximize the profit. First, a DNN-based model was developed using 784 industrial operating data points. The model could predict the EL and PL yields with high  $R^2$  values (0.965 and 0.900, respectively). Next, the model was integrated with a GA for optimization. The profit under the optimal operating conditions was 30% higher than that for the base case.

Despite the success in profit maximization, this study has a limitation in that it only considers the product prices for profit calculation. Thus, in the future, the model should be improved by considering the other factors that also affect the profit. The updated model should yield more practical solutions for maximizing the profit.

## Abstract

Iron production and Steelmaking are very energy-intensive processes with an estimated global energy intensity of 16.5 GJ/ton and global CO<sub>2</sub> emissions of 1.8 tons per ton of steel produced. Key solutions are required to optimize this industry but maintain its output or production. This work proposes to supplant the coal used in steelmaking with waste tires to reduce operational costs and CO<sub>2</sub> emissions through the polygeneration of products. Process synthesis techniques are used to determine the fundamental thermodynamic limitations of such a process through process performance targeting. It is found that one ton of iron and 430 kg of methanol can be potentially produced from 1.42 tons of haematite and 479 kg of waste tires. However, 63% of the carbon resource will end up as carbon dioxide, equivalent to 985 kg/ton of iron produced. This is lower than the coal route which releases about 1.05 CO<sub>2</sub> tons/ ton of iron.

**Keywords:** Waste tires, Reduction, Methanol, Iron, Thermodynamics.

## 1. Introduction

Global energy needs are constantly increasing and as a result, the natural resources that sustain these energy demands are becoming scarcer and more expensive, whilst human-generated emissions and other solid waste are increasing to critical levels. All companies are now under pressure from societies to decarbonize or reduce emissions from their processes. One such process industry is iron ore reduction and steelmaking. Iron production and Steelmaking are very energy-intensive processes with an estimated global energy intensity of 16.5 GJ/ton [1]. The whole process is dependent on natural resources for both energy needs and products. This results in global CO<sub>2</sub> emissions of 1.8 tons per ton of steel produced [2]. Key solutions are required to optimize this industry but maintain its output or production. The major contributor to carbon emissions from the industry is the use of coal. This work proposes to reduce the coal used in steelmaking with waste tires. Waste tires are derived from fossil fuels and currently at their end-of-life tires have no fundamental use and end up being dumped in landfills creating an unnecessary environmental problem. For example, South Africa produces an estimated 250 000 tonnes of waste tires per annum adding to an existing stockpile excess of 900 000 tonnes spread across 26 national storage depots without a solid plan for reprocessing or recycling [3]. Tires possess a higher volatile content, higher heating value, and low ash content than

coal [4], and can be used to replace or reduce coal in thermochemical conversion processes. This paper evaluates and determines theoretical performance targets for combined methanol synthesis and iron ore reduction using waste tires as a carbon source. The main constituents of tires are carbon and hydrogen and thus the reduction process simply involves reacting the carbon and hydrogen in waste tires with the oxygen in the iron ore to produce iron in its reduced form and carbon dioxide and water. However, in this work, we explore co-production opportunities to improve the efficiency of the process by reducing CO<sub>2</sub> and H<sub>2</sub>O production and thereby improving the material and energy efficiency of the process.

## 2. Methodology

Two thermodynamic properties, i.e., the enthalpy ( $\Delta H$ ) and the Gibbs free energy ( $\Delta G$ ) are used for process targeting. Where,  $\Delta H$  is the amount of energy requirement (input or output) across the process boundary, and  $\Delta G$  is the quality of the energy expressed in terms of the equivalent amount of mechanical work required to effect the change from feed to the product [5]. We use a systematic approach to identify feasible process targets by first defining the attainable region of the process and systematically identifying targets of interest subject to material and energy balances and thermodynamic constraints. The feasibility of the process can be analyzed in terms of their heat and work requirements. The target mass balance for all processes discussed here is met by setting two limits; the process must be adiabatic ( $\Delta H = 0$ ), and the mass balance is based on one mole of a tire. The utilization of raw materials, waste generation, and the thermodynamic efficiency of the process will be assessed using the following three metrics [6].

$$\text{Carbon Efficiency} = \frac{\text{moles of C in the desired product}}{\text{moles of C in the feed}} \quad (1)$$

$$\text{Atom Economy} = \frac{\text{mass of desired product}}{\text{Total mass of feed}} \quad (2)$$

$$E - \text{factor} = \frac{\text{Mass of waste produced}}{\text{Mass of desired product}} \quad (3)$$

Where equation 2 quantifies how much of the carbon in the feed stream ends up in the desired products. Any carbon that is not contained within a product will be lost in undesired by-products. Equation 3 provides useful information on the utilization of all the feed and waste generation. Table 1 shows the ultimate and proximate analysis of waste tires and coal used in this study.

Table 1: Ultimate and proximate analysis [7].

	Ultimate Analysis wt.%		Proximate Analysis wt.%			
	Tire	Coal		Tire	Coal	
C	85.05	67.69	Moisture	1.14	7.76	
H	6.79	4.59	Fixed Carbon	32.28	47.14	
N	0.5	1.13	Volatile Matter	62.24	34.05	
O	1.75	5.48	Ash	4.35	11.05	
S	1.53	2.3	LHV	34.9	30	MJ/kg

### 3. Results and discussion

#### 3.1. Process targeting

Let us consider the case where waste tyres, are used for the direct reduction of iron ore. The material balance is based on one mole of a tyre. For simplicity of theoretical calculation, the S and N in the tyre feed are assumed to be transferred only to  $H_2S$  and  $NH_3$ . Equation 4 shows the mass balance for iron ore reduction.

$$\Delta H = 223.393 \text{ kJ}, \quad \Delta G = 150.680 \text{ kJ}$$

Equation 4 shows that the overall process requires energy ( $\Delta H > 0$  and  $\Delta G > 0$ ) for it to be feasible. A positive  $\Delta G$  across a process indicates the amount of energy equivalent to mechanical work that must be supplied for the process to be feasible, while a positive  $\Delta H$  indicates the total amount of energy to be supplied in the form of heat or work. An additional feed of oxygen must be added to combust some of the tyre feed for heat. The addition of oxygen must meet the target of  $\Delta H = 0$  and one-mole tyre. As shown in figure 1, one mole of the tyre, can reduce 0.542 mols of iron ore and produce 1.084 mols of Fe. The process is feasible with excess work, but all the carbon available in the feed is transferred to  $CO_2$ . Thus, the carbon efficiency of the process is zero. This corresponds to about 730 kg of  $CO_2$  released to the environment per ton of iron produced during this process. When compared to coal, tyres marginally perform better in terms of iron production and carbon dioxide emissions. Figure 2 shows that for one mole of coal, the iron production decreases by 5% and the carbon dioxide emissions increase to 763 kg  $CO_2$  per ton of iron produced. The Atom efficiency as well as the E-factor for the waste tyre process is 54% and 0.87 compared to coal which is 53% and 0.89. This indicates the ability of waste tyres to replace coal. However, this is not a solution for the industry if tyres can only reduce carbon emissions by 5%. An alternative route is required where the carbon emissions per ton of iron are reduced as an incentive to transition to a waste tyre feed process. One way is to consider a co-production of methanol and iron using waste tyres. In this way, not all the carbon feed in the tyre is used for reduction, but an indirect route is utilized where the tyres are converted to syngas, and the syngas is used for the reduction and the excess syngas is used to produce methanol in a downstream process unit.

Figure 1: Reduction of iron ore with waste tyres

Figure 2: Reduction of iron ore with coal

For 100% raw material conversion efficiency and minimal impact on the environment, the law of conservation of mass implies that the elemental composition of the desired products must match that of the feed. Equation 5 shows the material balance for an integrated methanol synthesis and ironmaking process with 100% raw material conversion efficiency on tire feed. Tires contain a ratio of carbon to hydrogen close to one-to-one, therefore the eventual set of desired products (in combination), regardless of the process, must contain the same ratio of carbon to hydrogen, because any deviation would lead to the formation of unwanted products (i.e.,  $\text{CO}_2$ ), thus reducing the process material efficiency. The overall material balance for this process based on one mole of waste to produce methanol and iron ore from using waste tires for reduction is as follows:

Equation 5 shows that under ideal conditions one mole of tire feed can reduce 0.328 moles of iron ore to produce 0.657 moles of iron and 0.23 moles of methanol. However, in equation 5 we see that excess oxygen from iron ore leaves as CO and that the small ratio of hydrogen to carbon in the feed constrains the full conversion of Carbon to methanol. One can immediately see from the above equation that waste tires can never achieve the 2:1 ratio of hydrogen to carbon monoxide required for liquid fuel production. To achieve this ratio an additional amount of feed containing hydrogen often water is required, however often this additional feed comes in with extra oxygen which must leave the system as carbon dioxide. Equally, the system described in equation 5 requires energy input for it to be feasible as indicated by the positive  $\Delta H$  and  $\Delta G$ . Thus, additional oxygen can be fed to achieve a zero-energy requirement as shown in eq.6.

Therefore, supplying the required energy needed by the process in eq.5 by feeding more oxygen generates 0.669 mols of carbon dioxide thus reducing the carbon efficiency to just 33% and the chemical potential efficiency decreases from 86% to 70%. In the process

described by eq.6, further optimization can be done to convert the excess CO to methanol through the addition of water. The easiest route is to burn an additional number of tires and use water to increase the ratio of hydrogen to carbon. However, this approach also leads to increased CO<sub>2</sub> emissions. Thus, the overall material balance for a hypothetical fully integrated and adiabatic process to produce methanol and iron is shown in eq.7 and figure 3:

Carbon Efficiency = 37.3%  
 Atom Economy = 59%  
 E - factor = 0.7

Figure 3: Process diagram for methanol and iron production from waste tires.

Eq. 7 shows that having an additional amount of water increases methanol production by 62%. The carbon efficiency is 37.3%. However, the amount of iron ore reduced decreases thus which decrease elemental iron production by 23%, and by 50% when compared to the direct routes. This, therefore, means that combined iron ore reduction with methanol synthesis with waste tires as carbon feed is achievable. The atom economy is 59% an improvement of about 10% compared to the no-methanol case discussed in figure 1. The E-factor also reduced by 25% suggesting that more feed is transferred to the desired product than left as waste. By equivalence, 1 ton of iron produced consumes 478 kg of waste tires, and 1.42 tons of iron ore and 430 kg of methanol are co-produced. The production of methanol reduces the molar carbon capacity to reduce iron ore as such, the quantity of iron reduces by almost 50% this, therefore, means that per ton of iron, the process produces 980 kg of CO<sub>2</sub>. This is still lower than the coal route which is 1.05 tons per ton of iron.

### 3.2. Effect of temperature

The process described in figure 3 is an ideal process where all units in it operate at Carnot temperatures. The Carnot temperature is the single temperature at which heat can only be used to satisfy the work requirements of a process and such a process will not lose or take additional energy to the environment, in that it will be reversible. However, in real processes reaction kinetics and materials of construction limits the use of Carnot temperature which necessitates a deviation from the ideal. The blast furnace temperature is > 1200 °C,

whereas the water gas shift and methanol synthesis reactor operate at 450 °C and 220 °C respectively. Operating at a temperature other than the Carnot temperature results in the loss of some of the potential work and the energy released from other process units cannot be integrated directly into the blast furnace due to the temperature gradient. To offset the lost work, more tires are burned. However, this reduces iron production by 15% and increases CO<sub>2</sub> emissions by 6%.

### 3.3. Revenue potential

A high-level market-related revenue potential analysis is conducted using the production rates in figure 3. The revenue potential of the process is obtained by a difference in the price of selling products and the cost of feed materials. The analysis excludes the capital costs associated with each pathway. During the time of writing this manuscript, the price of pig iron was \$ 1000 per ton, methanol was \$ 370/ ton, and iron ore was \$ 101.5 per ton. The revenue analysis of the different process pathways suggests the polygeneration of methanol and iron is the most profitable. A revenue of \$1015 per ton of iron can be achieved for the polygeneration route compared to \$855 per ton for the iron-only route. But more capital investment is required for the polygeneration due to the different units required to achieve the required products.

## 4. Conclusion

The fundamental thermodynamic analysis was used to investigate the performance limits of an idealized process of co-production of methanol and iron from a feed of waste tire and iron ore. The results show that co-production with methanol reduces CO<sub>2</sub> emissions by 37.3% (from 1 mole CO<sub>2</sub> to 0.627 CO<sub>2</sub> for the methanol case) and increases revenue by 15.6% (from 855 \$ to 1015\$). The purpose of this study is to present a method that takes energy, the environment, and economics into account, that can be used to select an acceptable process pathway. It is intended to give the process engineer a macroscopic perspective of the process and its possibilities rather than to illustrate the kinetics or the reaction path.

### Abstract

The increasing concentration of carbon dioxide (CO<sub>2</sub>) in the atmosphere has compelled researchers and policymakers to seek urgent solutions to address the current global climate change challenges. In order to keep the global mean temperature at approximately 1.5°C above the preindustrial era, the world needs increased deployment of negative emission technologies. Among all the negative emissions technologies reported, direct air capture (DAC) is positioned to deliver the needed CO<sub>2</sub> removal in the atmosphere. DAC technology is independent of the emissions origin, and the capture machine can be located close to the storage or utilization sites or in a location where renewable energy is abundant or where the price of energy is low. Notwithstanding these inherent qualities, DAC technology still has few drawbacks that need to be addressed before the technology can be widely deployed. The main findings point to undeniable facts that DAC overall system energy requirement is high, and it is the main bottleneck in DAC commercialization. The proposal of this study is to unlock the potential of integrating DAC with HVAC systems. DAC with HVAC system integration can be proposed to allow for reducing indoor CO<sub>2</sub> levels to improve indoor air quality (IAQ), HVAC energy reduction using higher air recirculation ratios, a more efficient DAC system by capturing from more elevated CO<sub>2</sub> concentrated streams (indoor air), applying cooler adsorption, and adsorption at different relative humidity points. The expected reduction in the net present value of tons of CO<sub>2</sub> after 50 years is estimated to be 3000\$/tonCO<sub>2</sub> compared to the highest in the literature of 1000 \$/tonCO<sub>2</sub> [1]. This reduction in NPV is estimated based on possible energy recovery by quantifying only one benefit which is HVAC energy reduction using higher air recirculation ratios. Therefore, coupling DAC with HVAC can be economically favorable in comparison to only DAC. In the present work, a comparison between efficiencies of the stand-alone DAC unit and the one integrated with Air Handling Unit are quantitatively evaluated based on validated mathematical model. The positions of direct air capture unit within the HVAC are chosen to maximize the possible benefits. The DAC unit efficiencies throughout the hot months in Qatar are improved to be within the range of 21% to 22% compared to the range of 16% to 21% by only positioning the DAC at point 2 in the Air Handling Unit.

**Keywords:** DAC; green sorbents; HVAC; indoor air quality

## 1 Introduction

The high energy requirements of DAC lead to high capital and operating costs, which is a major challenge of the existing technologies [2]. As a possible solution, the DAC and HVAC integration was proposed as it brings benefits for both subsystems. These possible benefits are; reducing indoor CO<sub>2</sub> levels to improve indoor air quality (IAQ), HVAC energy reduction using higher air recirculation ratio and finally, more efficient DAC system by capturing from more elevated CO<sub>2</sub> concentrated streams (indoor air) and applying cooler adsorption. The integration between direct air capture unit and HVAC system is shown in Figure 2.

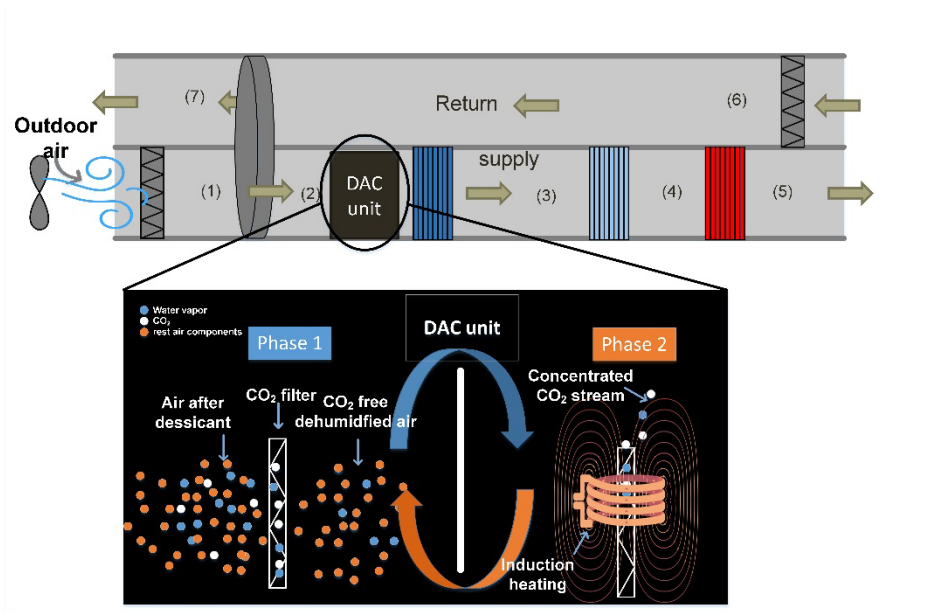

Figure 1: Air handling unit and Direct air capture Integration scheme

The current work includes two subsystems, which are a direct air capture unit and a building air handling unit. Both systems will be thermodynamically simulated for evaluating their performance and energy consumption. These two systems are expected to have better performance when combined, which will be assessed in the present work. The main AHU parameters and setpoints are presented in Table 1. A benchmark direct air capture cycle that uses temperature vacuum swing regeneration will be used in the present study. This cycle was chosen as its model accounts for the role of humidity, it uses commercial adsorbent material, and the model was experimentally validated [3].

Table 1: Air Handling Unit technical data during hot months obtained from Qatar foundation facilities

Parameter	Value
Humidity ratio	Same as point after energy recovery wheel
Relative humidity After precooler (%)	95
Dry Bulb temperature After Cooling coil (°C)	13.2
Relative humidity After Cooling coil (%)	95
Dry Bulb temperature After Reheater (°C)	21.66
Relative humidity After Reheater (%)	56
Air pressure drop through the Cooling coil (Pa)	245
Supply volume flow rate (m <sup>3</sup> /h)	39906
Exhaust volume flow rate (m <sup>3</sup> /h)	20500
Pressure drop through energy wheel (Pa)	239
Sensible energy wheel effectiveness $\varepsilon_s$	0.40
Latent energy wheel effectiveness $\varepsilon_L$	0.32

### 1.1 Methodology/Analysis

The main components of air handling unit such as energy recovery wheel, precooler, cooler, heater and fan was simulated based on the preset points in Table 1 using mass balance equation, first and second laws of thermodynamics, properties such as enthalpy, entropy, and specific exergy are determined for each component. The general energy balance equation for each component is described in [4].

$$\dot{m}_i \times h_i + \dot{Q}_i + \dot{W}_i = \dot{m}_o \times h_o + \dot{Q}_o + \dot{W}_o \quad (1)$$

The sensible and latent energy recovery wheel effectiveness  $\varepsilon_s$ ,  $\varepsilon_L$  were used to calculate temperature and humidity after the energy wheel [5].

$$\varepsilon_s = \frac{\dot{m}Cp}{(\dot{m}Cp)_{max}} \frac{T_{s,o} - T_{s,i}}{T_{s,i} - T_{e,i}} \quad (2)$$

$$\varepsilon_t = \frac{\dot{m}Cp}{(\dot{m}Cp)_{max}} \frac{\omega_{s,o} - \omega_{s,i}}{\omega_{s,i} - \omega_{e,i}} \quad (3)$$

Where  $\dot{m}$  is air mass flow rate in (kg/s),  $h$  is the enthalpy in (J/(kg K)),  $\dot{Q}$  is heat in kW,  $\dot{W}$  is the power in kW,  $Cp$  is the air specific heat in (J/(kg K)),  $T$  is the temperature in (K) and  $\omega$  is the humidity ratio in (g/kg). The subscripts s, e, i and o stand for supply, exhaust, inlet, and outlet respectively.

The adsorbent isotherm was simulated based on mechanistic co-adsorption model, which accounts for the humidity effect on CO<sub>2</sub> adsorption and was validated by experimental work [3]. The energy required for regeneration was calculated from work in reference [6]. The performance of DAC unit in different position within AHU was evaluated. The proposed positions are stand-alone DAC and at state points 2, 4, 5, and 6 which were chosen to minimize adsorption temperature and humidity while maximize achieving other benefits such as better IAQ and less HVAC cooling load. To assess the performance of DAC, the second-law efficiency of TVSA cycle-based DAC system was calculated as follow [7]:

$$\eta_{TVSA} = \frac{W_{min}}{W_{pump} + Q_H \left(1 - \frac{T_0}{T_H}\right) - Q_L \left(1 - \frac{T_0}{T_L}\right)} \quad (4)$$

$\eta_{TVSA}$  is the efficiency of DAC unit uses temperature vacuum swing adsorption,  $Q_H$  is the heat input per cycle,  $Q_L$  is the cooling load required for reaching the cycle adsorption temperature and  $W_{pump}$  is the work required for reaching the vacuum pressure,  $T_0$  is the ambient temperature,  $T_H$  is the desorption temperature and  $T_L$  is the adsorption temperature.

## 2 Results and discussion

The efficiencies of the direct air capture unit based on different relative humidity points and temperatures were shown in Figure 1. The range of temperatures and relative humidity values were chosen to cover the weather data for Qatar and the points within the air handling unit. The efficiencies in Figure 2 below were calculated for temperature vacuum swing adsorption system and a chemisorption material.

Figure 2: Direct Air Capture efficiency for different temperatures and relative humidity values

Figure 1 shows that the DAC efficiency increases as the adsorption temperature and relative humidity decrease. Based on the mentioned trend, three position of DAC in AHU were chosen and assessed to get a more efficient DAC system.

Figure 3: DAC efficiency for different positions in AHU

The efficiencies of three direct air capture units and their variation through the hot months in Qatar were presented in Figure 3. The three positions equally achieve lower indoor CO<sub>2</sub> levels and less HVAC cooling load by allowing air recirculation however, the adsorption conditions such as temperature and relative humidity is different for each position leading to different efficiencies. The calculated efficiency in Figure 3 considers the effect of these adsorption conditions only without considering other benefits. The figure shows that the best position between the three is at point 2. Although the temperature is lowest at point 4, the DAC unit efficiency was low because of the high relative humidity reaching 95%. The efficiency in position 2 was better than the stand-alone DAC unit because in position 2, the temperature and relative humidity is always lower than the ambient temperature during the hot months in Qatar. The analysis shows that the range of efficiencies can be raised from 16%-21% to 21% -22% by only positioning the DAC unit in point 2 in the Air Handling Unit.

### 3 Conclusion

In conclusion, buildings consume almost 40% of the world's energy demands, and about 50 to 82% of buildings' energy is consumed in the HVAC systems. The necessity to provide fresh indoor air, especially during and after COVID-19, and the rising energy demands, challenge researchers to reduce energy losses in the HVAC systems. The DAC and HVAC integration provides a solution for

achieving better indoor air quality, lower HVAC energy consumption and a more efficient DAC system. The present work investigated the effect of positioning the DAC unit within HVAC system and provided a higher efficiency prediction, however, the other benefits need to be quantified and a technoeconomic analysis for the integration should be conducted to compare the integration to the normal DAC system. Moreover, improving the adsorbent material CO<sub>2</sub> uptake and affinity to water could further enhance the performance of the integration.

## Abstract

Amine scrubbing and CO<sub>2</sub> liquefaction processes are generally employed in most power plants for CO<sub>2</sub> capture and storage (CCS) because they are suitable for large-scale plants. However, a significant amount of cold energy is required to cool the lean amine solution in the amine scrubbing system and liquefy compressed CO<sub>2</sub>. Hence, liquefied natural gas (LNG) cold energy, which is generally wasted in seawater during LNG regasification, should be recovered. In this study, we developed an amine scrubbing and CO<sub>2</sub> liquefaction process using waste LNG cold energy. The proposed process model comprises the following three steps: (1) LNG regasification, (2) CO<sub>2</sub> capture and regeneration, and (3) CO<sub>2</sub> liquefaction. First, in LNG regasification, the boil-off gas (BOG) is compressed, and the LNG with compressed BOG is regasified in an LNG vaporizer. To regasify the LNG, seawater is used as a heat source, and the waste cold energy in the chilled seawater is recovered in steps 2 and 3. Second, the CO<sub>2</sub> capture and regeneration process involves the use of an absorber and a regenerator, and the waste cold energy is recovered at the lean amine cooler to reduce the temperature of the lean amine solution. Finally, to liquefy CO<sub>2</sub>, cold energy derived from LNG regasification is recovered to a heat exchanger to cool the compressed CO<sub>2</sub>. Consequently, the total cold energy consumption can be decreased by 31% by recovering waste LNG cold energy. This increases the overall energy efficiency of the amine scrubbing and CO<sub>2</sub> liquefaction processes for CCS using waste LNG cold energy, thus resulting in less fuel use. We believe that the proposed approach will afford significant economic improvements and environmental protection effects.

**Keywords:** Amine scrubbing, CO<sub>2</sub> liquefaction, Liquefied natural gas, CO<sub>2</sub> capture and storage

## 1. Introduction

In many countries, natural gas (NG) emits less air pollutants than other fossil fuels and is considered the energy resource that is developing the most rapidly. NG resources are generally located in specific areas; thus, to ensure the safe long-distance transportation of

NG, it is liquefied by cooling to reduce its volume. However, a significant amount of cold energy is wasted during liquefied natural gas (LNG) regasification; thus, waste LNG cold energy recovery is crucial for improving energy efficiency. Waste LNG cold energy derived from LNG regasification can be used for CO<sub>2</sub> capture and storage (CCS). In general, amine scrubbing and CO<sub>2</sub> liquefaction processes are employed for CCS in LNG power plants. The amine scrubbing system is primarily composed of an absorber and a regenerator, and CO<sub>2</sub> capture depends on the variation in equilibrium constants based on the pKa difference between the amine and CO<sub>2</sub> via temperature control. The CO<sub>2</sub> captured during amine scrubbing is liquefied, which requires a significant amount of cold energy. To control the temperature of the absorber during amine scrubbing and liquefy CO<sub>2</sub>, waste LNG cold energy should be recovered. However, most previous studies have only focused on waste hot energy recovery, which is generated from LNG power plants, to reduce the steam energy consumed by the regenerator in the amine scrubbing system. Dual et al. conducted an optimization study to reduce steam energy consumption by a regenerator reboiler. By recovering waste hot energy from an LNG power plant, the energy consumption of the regenerator reboiler was reduced by 56%. Garlapalli et al. proposed a heat recovery unit that directly recovers waste hot energy in flue gas for CCS. Using this unit, the steam energy consumption of the regenerator reboiler can be reduced by 15% to 31%. Despite the significant amount of relevant studies performed hitherto, the following challenges are yet to be addressed. Although waste LNG cold energy can be recovered during amine scrubbing and CO<sub>2</sub> liquefaction, it was not recovered in previous studies. Cold energy constitutes approximately 50% of the total energy required. To increase the overall energy efficiency, waste LNG cold energy must be recovered. Hence, a process model for amine scrubbing and CO<sub>2</sub> liquefaction using waste LNG cold energy is developed in this study. The objective of this study is to overcome the challenge of conventional studies to increase the overall energy efficiency of LNG power plants for CCS by efficiently recovering waste LNG cold energy, which will ultimately result in less fuel use.

## 2. Methods

This section describes the process model developed for amine scrubbing and CO<sub>2</sub> liquefaction using waste LNG cold energy. Section 2.1 presents an overview of the proposed process, and Section 2.2 presents a detailed description of the process model.

### 2.1. Overview of proposed process

Figure 1 shows a simplified diagram of the developed amine scrubbing and CO<sub>2</sub> liquefaction process model based on waste LNG cold energy. The proposed process comprises three steps: (1) LNG regasification, (2) amine scrubbing, and (3) CO<sub>2</sub> liquefaction. First, in the LNG regasification process, the transported LNG is assumed to be burned with boil-off gas (BOG) in an LNG power plant. Second, the CO<sub>2</sub> in the flue gas emitted at the combustor of an LNG power plant is captured by the amine scrubbing system. In the amine scrubbing system, waste LNG cold energy is recovered at the lean amine cooler. Finally, the captured CO<sub>2</sub> is liquefied during the CO<sub>2</sub> liquefaction process, and waste LNG cold energy is used to reduce the temperature of the captured CO<sub>2</sub>.

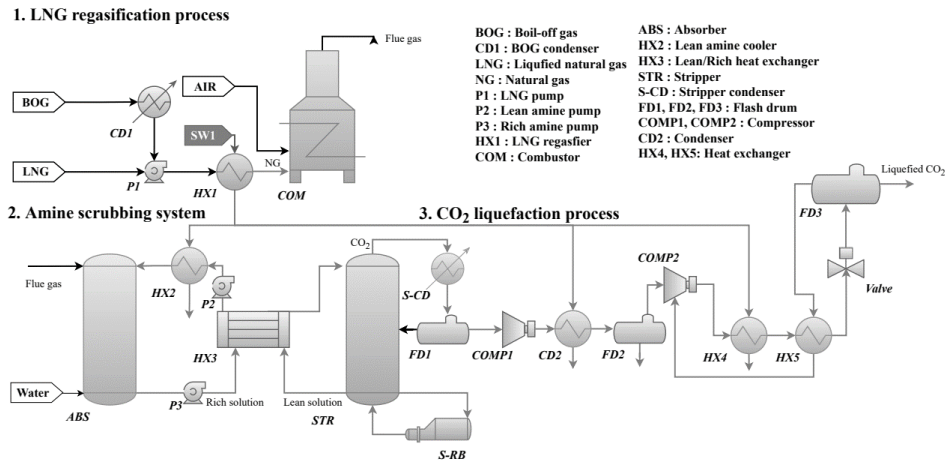

Figure 1. Simplified diagram of proposed process

## 2.2. Process model

Figure 2 shows the proposed process model for amine scrubbing and CO<sub>2</sub> liquefaction using waste LNG cold energy. To design the proposed model, Aspen Plus V10.0, and ELECNRTL thermodynamic models were employed to consider the liquid–liquid equilibria of amine solution with captured CO<sub>2</sub> and vapor–liquid equilibria of amine solution with flue gas. Subsequently, the following assumptions were considered for model development: (1) The developed process was in a steady state; (2) the temperature of the seawater for the LNG regasifier was 15 °C; (3) the LNG composition was CH<sub>4</sub> (97 wt%), C<sub>2</sub>H<sub>6</sub> (1 wt%), C<sub>3</sub>H<sub>8</sub> (1 wt%), and N<sub>2</sub> (1 wt%).

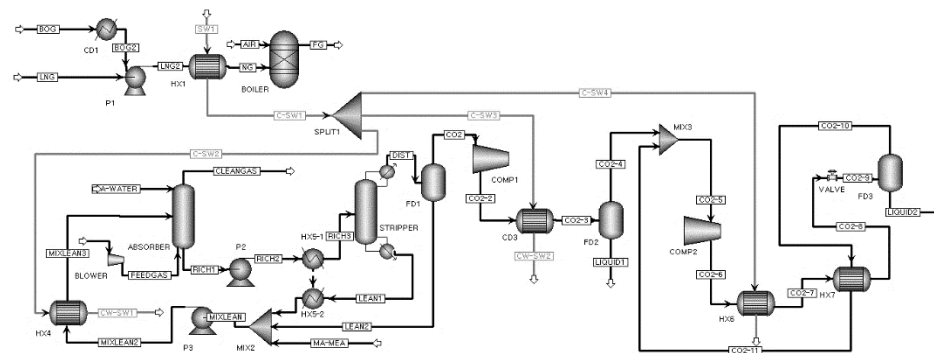

Figure 2. Developed process model of amine scrubbing and CO<sub>2</sub> liquefaction using waste LNG cold energy

### 2.2.1. LNG regasification

First, to obtain the driving force that can be supplied to an LNG power plant, the transported LNG is input to a high-pressure LNG pump with a BOG. In this pump, the pressure of the LNG is increased from 1 to 60 bar. Subsequently, the compressed LNG is input to an LNG vaporizer, and the temperature of the LNG is increased from -159 °C to

20 °C using seawater as the heat source. During LNG vaporization, a significant amount of LNG cold energy is wasted via dissipation into the sea. Thus, the waste LNG cold energy is recycled to the lean solution cooler (HX2) and each heat exchanger (CD2 and HX4) during LNG liquefaction.

### 2.2.2. Amine scrubbing system

The CO<sub>2</sub> from the LNG power plant is captured by the amine scrubbing system, which uses monoethanolamine (MEA) as a CO<sub>2</sub> absorbent. An amine scrubbing system is generally composed of an absorber and a regenerator. In the absorber, CO<sub>2</sub> is captured using a lean amine solution via an exothermic reaction (Equations 1–4).

The rich amine solution that captures CO<sub>2</sub> is discharged into the lower section of the absorber and enters the regenerator. Subsequently, it is preheated via the lean/rich heat exchanger (HX3) before entering the regenerator, which reduces the heat load on the regenerator reboiler. Finally, the rich amine solution is regenerated at the regenerator by supplying heat energy from the reboiler.

### 2.2.3. LNG liquefaction

Finally, the absorbed CO<sub>2</sub> is liquefied, and the liquefied CO<sub>2</sub> requires a significant amount of cold energy for storage. In this study, a Linde dual pressure system that utilizes a cold gas stream, which is generated by controlling a Joule–Thompson valve to cool CO<sub>2</sub>, is employed for CCS. First, the captured CO<sub>2</sub> is compressed at a low-pressure compressor (COMP1); subsequently, a high-pressure compressor (COMP2) is used to increase the pressure of the CO<sub>2</sub>, which contains CO<sub>2</sub> recycled from the flash drum (FD1). Subsequently, the temperature of the compressed CO<sub>2</sub> is decreased at each heat exchanger (HX4 and HX5) using waste LNG cold energy. Finally, the cooled compressed CO<sub>2</sub> expands through the Joule–Thomson valve (valve).

## 3. Results and discussion

This section presents the simulation results obtained using the proposed amine scrubbing and CO<sub>2</sub> liquefaction process model, which is based on waste LNG cold energy. The process for the base case involving the non-recovery of waste LNG cold energy from LNG regasification is compared with the proposed process. Table 1 shows the simulation results obtained using the proposed and base processes. Based on the results, the energy consumption of the cooler (HX2), condenser (CD2), and each heat exchanger (HX4 and HX5) was completely substituted by waste LNG cold energy. The total cold energy consumption decreased from 261 to 179 MW; thus, the cold energy saving rate was calculated to be 31% based on the recovery of the waste LNG cold energy. Finally, to conserve waste LNG cold energy, the total energy consumed by the proposed process should be 655 MW, which is 11% lower than that consumed by the base process.

Table 1. Simulation results of proposed and base processes

Classification		Base process	Proposed process	Units
LNG regasification process	CD1 (Condenser)	1.5	1.5	kW
	P1(Pump)	13.7	13.7	MW
CO <sub>2</sub> capture process	HX2 (Lean amine cooler)	13.9	0	MW
	P2 (Pump)	0.5	0.5	MW
	P3 (Pump)	3.8	3.8	kW
	Regenerator reboiler	420	420	MW
	Regenerator condenser	179	179	MW
CO <sub>2</sub> liquefaction process	COMP1 (Compressor)	30	30	MW
	COMP2 (Compressor)	12	12	MW
	CD2 (Condenser)	35	0	MW
	HX4,5(Cooler)	33	0	MW
Total energy consumption		741	659	MW

Figure 3 shows the total energy consumed by the proposed and base processes. By operating the condenser (CD1) and pump (P1), the energy consumed by the base and proposed processes was 14 MW each. In the amine scrubbing system, the energy consumed by the base process was 613 MW. Meanwhile, the energy consumed by the proposed process was calculated by 600 MW. Thus, based on the recovery of waste LNG cold energy to the lean amine cooler (HX2), the energy consumed by the proposed process is 2% lower than that consumed by the base process. The energy consumed during CO<sub>2</sub> liquefaction based on the base and proposed processes was 110 and 42 MW, respectively. Based on the recovery of the waste LNG cold energy to the condenser (CD2) and each heat exchanger (HX4 and HX5), the energy consumed during CO<sub>2</sub> liquefaction based on the proposed process was 61% lower than that consumed by the base process. Finally, the total energy consumed by the proposed process was 11% lower than that consumed by the base process, which indicates a high energy efficiency. Therefore, we believe that this study can provide valuable insights into the efficient recovery of waste LNG cold energy for CCS.

Figure 3. Total energy consumed by proposed and base processes

#### 4. Conclusion

In this study, novel amine scrubbing and CO<sub>2</sub> liquefaction processes using waste LNG cold energy was developed. The main contributions of this study are twofold. First, waste LNG cold energy wasted during LNG regasification was efficiently reused for amine scrubbing and CO<sub>2</sub> liquefaction; thus, a higher overall energy efficiency was obtained. Second, the results showed a higher energy efficiency compared with that afforded by the base process, wherein waste LNG cold energy was not recovered; thus, the proposed processes can result in significant energy and economic improvements. Additionally, the results showed that the energy consumed during CO<sub>2</sub> amine scrubbing and CO<sub>2</sub> liquefaction based on the proposed process was lower than that based on the base process by 2% and 61%, respectively; thus, the total energy consumed by the proposed process was 11% lower than that consumed by the base process. Therefore, we believe that this study can provide valuable insights into the efficient recovery of waste LNG cold energy for CCS.

# A parametric analysis of the co-gasification of biomass and plastic waste using Aspen Plus

Nomadlozi L. Khumalo<sup>a</sup>, Bilal Patel<sup>a</sup>,

*Department of Chemical Engineering, University of South Africa, Corner of Christiaan de Wet Road and Pioneer Avenue, Florida 1709, South Africa*

## Abstract

The syngas produced from biomass (BM) gasification is typically of low quality and energy content. This inhibits it from being utilized for downstream application for manufacturing of high value products. Plastic waste (PW) is a suitable co-feed since it possesses useful properties, such as high hydrogen content, low oxygen, and low moisture content.

In this study, the effects of blend ratios of (25% PE - 50% PE), and operating condition such as Equivalence Ratio (ER)) on the product gas composition, H<sub>2</sub>/CO ratio and the LHV, were evaluated using an oxygen-steam mixture as a gasifying agent. A non-stoichiometric equilibrium model for the co-gasification of BM and PW was developed in Aspen Plus. The co-gasification of BM and PW has led to high Lower Heating Value (LHV) of 9.6 MJ/Nm<sup>3</sup> and H<sub>2</sub>/CO ratio of 2 was achieved at low ER values.

**Keywords:** co- gasification, blend ratio, equivalence ratio; synergistic effect.

## 1. Introduction

Biomass is an attractive renewable resource, particularly since it is the only renewable source of carbon, that can be used to generate carbon- based fuels and chemicals. Thus, biomass can be utilized to produce a wide variety of products including biofuels, chemicals, bioproducts and energy. There are various technologies to convert biomass, however, among these technologies, gasification is a versatile technology that allows the production of a wide range of products. Gasification process is a thermochemical process that converts carbonaceous material into syngas in the presence of a gasifying agent (s) at high temperatures. The syngas needs to be of good quality and high energy content, so that it can be suitable for downstream applications. However, the syngas produced from biomass gasification has low energy density and low quality, for instance its H<sub>2</sub>/CO ratio needs to be adjusted by adding a feedstock with high hydrogen content to increase in quality.

Plastic waste has been identified as a suitable gasification feedstock It is estimated that global plastic usage will triple by 2060, with almost half ending up in landfills and less than a fifth recycled. (OECD, 2022). Therefore, valorization of waste plastic, via gasification, is seen as a viable option for large-scale implementation (Lopez et al. 2018). Plastic waste can compensate for qualities lacking in biomass such as high oxygen content, low energy density. Plastic waste has high volatile matter and is rich in hydrogen

and does not contain oxygen (Al Amoodi et al. 2013). When biomass and plastic waste are combined the syngas produced is of improved quality and has high energy density, as compared to that of pure biomass (Singh et al. 2022). The blended feedstocks of biomass and plastic waste may enhance hydrogen content in the syngas, resulting in an increased energy density of the product gas (Huber et al. 2006). During the co-gasification technology tar is reduced in the syngas as the plastic percentage increases in the feedstock mixture (Lopez et al. 2015). The quantity of syngas and the composition (e.g.  $H_2/CO$ ) ratio improves (Block et al. 2019). Co-gasification of biomass and plastic waste also assists in overcoming difficulties of seasonal biomass availability. Moreover, co-gasification eliminates operational challenges that are encountered during plastic waste gasification.

This study addresses a gap in literature in terms of determining the effect of using oxygen - steam mixture as a gasifying agent instead of single gasifying agent during the co-gasification of biomass (pine sawdust) and plastic waste (Low Density Polyethylene). Previous studies such as Pinto et al. (2002), Burra et al. (2018) and Ahmed et al. (2011), have considered the co-gasification of biomass and plastic waste, typically, using one gasifying agent such as air, steam, or oxygen, but not mixtures of gasifying agents. The effect of feedstock composition (biomass and plastic waste and their mixtures (25% PE – 50% Biomass)) in the presence of oxygen – steam mixture as gasifying agent on the product gas composition ( $H_2$ , CO), on the  $H_2/CO$  ratio of the syngas, on the Lower Heating Value (LHV) of the syngas, gas yield (GY) and on the cold gas efficiency (CGE). The synergistic interaction between the biomass and plastic waste will be evaluated. This study also aims to determine the effect of the equivalence ratio at a fixed SFR of 0.6 At value of SFR equal to 0.6 is considered optimal for the steam flowrate to enhance the steam reforming reaction and water gas shift reaction and the production of  $H_2$  and CO in the product gas (Arjoloo et al. 2022). Increasing SFR above 0.6, leads to a decrease in process temperature and that affects the syngas quality as well as it reduces the process efficiency.

## 2. Modelling framework

Aspen Plus was used to develop a non- stoichiometric equilibrium model to determine the effect of feedstock composition and operating conditions such as the equivalence ratio on the product gas composition,  $H_2/CO$  ratio of the syngas and the Lower Heating value (LHV) of the syngas. The synergistic interaction between biomass and plastic waste is also evaluated. The ultimate analysis of biomass (sawdust) was determined using an elemental analyser (C; 45.5%, H; 5%, O; 47.1%, N;0.05 % and 2.35% Ash) and the proximate analyses using a thermogravimetric method (18.45%, VM, 79.2% and Ash 2.35%). Data for plastic waste (low-density polyethylene) was sourced from the Al Amoodi et al. (2013).

Various components such as  $H_2$ ,  $H_2O$ , S, N,  $O_2$ ,  $CH_4$ , where specified as conventional, whereas, biomass, ash and plastics were specified as non- conventional species. HCOALGEN and DCOALIGT algorithm were used as enthalpy and density functions for biomass and plastic waste. The Peng-Robinson – Boston – Mathias (PR-BM) thermodynamic model was employed. This property method was selected based on its ability to correlate the low operating pressure with the higher operating temperatures  $>700^\circ C$  that are typically used in the co- gasification process (Ramzan et al. 2011). In addition, the process was assumed to operate at steady state, the gasifier is operated at

atmospheric pressure, tar and carbon formation is not considered. The model was developed based on three-unit blocks; the first unit is the RYield reactor which represents the decomposition of the non-conventional components into conventional constituents. A FORTRAN statement is utilised within Aspen Plus to accomplish this. The ultimate analyses of the feedstocks is used to determine the yield distribution. The product stream from the RYield reactor enters the second unit, modelled by the RGibbs reactor, uses the minimization of Gibbs energy to predict the product distribution from the gasifier. Gasifying agents such as steam and oxygen were introduced to the gasifier (RGibbs). The equivalence ratio (ER) and steam – to – fuel ratio (SFR) are the operating parameters that controls the amount of oxygen and steam that enter the gasifier. The gasification products from RGibbs reactor (mainly syngas) are sent to the third unit (Cyclone) which separates solids from gaseous product. The validity of the model was assessed using the relative error ( $\epsilon_r$ ) method. The output values of the product gas obtained from the experimental work (Yu et al. 2014), were compared with the values obtained from Aspen Plus for the co-gasification of biomass and plastic waste. Based on the relative error, the model and experimental values for the syngas composition are in good agreement and are considered acceptable i.e. (the relative errors for each of the variable were within +/- 15%) (De Andres et al. 2019).

### 3. Results and Discussion

#### 3.1 Effect of the equivalence ratio on H<sub>2</sub> and CO composition in the product gas for various blend ratios

Figure 3.1 (a) shows that an increase in the equivalence ratio (ER) at fixed SFR equal to 0.6 causes the H<sub>2</sub> to increase and reach maximum values and thereafter decrease as ER increases further, for feedstocks that consists of higher plastic percentage such as 50% PE and 100% PE. In Figure 3.1(b) the same pattern is observed for the CO composition for all the blended feedstocks except for biomass feedstock. It is observed that high H<sub>2</sub> and CO composition in the product gas are favoured at low ER values below 0.4. This is because at low ER values the chemical reactions such as the steam reaction, partial oxidation reaction, water – gas shift reaction, and steam reforming reaction and methanation reaction, which are responsible for the production of H<sub>2</sub> and CO are favoured.

Figure 3.1 Effect of the (a) equivalence ratio (ER) on the (a) H<sub>2</sub> and (b) CO (b) composition in the product gas.

However, at high ER values above 0.4, the combustion reactions are favoured, which are responsible for the production of  $H_2O$  and  $CO_2$ . An increase in the percentage of plastic waste in the feedstock mixture increases the  $H_2$  composition in the product gas and reduces the  $CO$  composition in the product gas. The reason for this is that plastic waste consists of high volatile matter, which enhances the  $H_2$  composition in the syngas but does not consist of oxygen content. Figure 3.1 (a) shows that a  $H_2$  composition of 49% is obtained at ER equal to 0.18 and SFR equal to 0.6, from the blend ratio of (50% PE + 50% Biomass). From the blend ratio of (25% PE + 75% Biomass) a  $H_2$  composition of 46% is attained at ER equal to 0.1 and SFR equal to 0.6. The attainment of a higher  $H_2$  composition in the product gas from the gasification of blended feedstocks indicates that there is a synergistic interaction between the biomass and plastic waste feedstocks. The highest  $CO$  composition is attained from the single feedstock (100% Biomass), which shows that in terms of the  $CO$  composition in the product gas, the co-gasification of biomass and plastic waste does not have the synergistic effect.

### 3.2 Effect of the equivalence ratio on the $H_2/CO$ ratio and the Lower Heating Value (LHV) of the syngas.

Figure 3.2 (a) and (b) exhibits that an increase in the equivalence ratio (ER) from 0.1 – 1 at fixed SFR equal to 0.6 causes the  $H_2/CO$  ratio and the Lower Heating Value (LHV) of the syngas to decrease, for all the feedstock compositions.

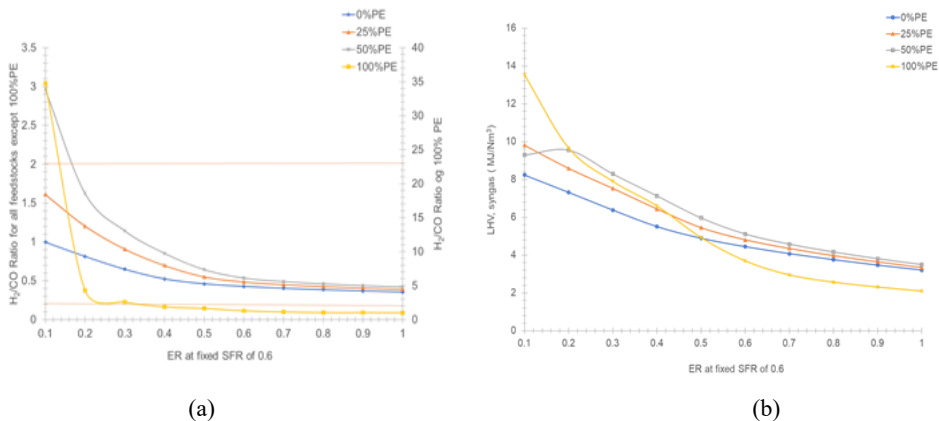

Figure 3.2 Effect of the equivalence ratio (ER) on the (a)  $H_2/CO$  ratio of the syngas and (b) Lower Heating Value (LHV) of the syngas.

This is due to the oxidation reactions that are enhanced by the increase in the amount of oxygen that enters the reactor. In Figure 3.2 (a) an increase in the  $H_2/CO$  ratio at low ER values and a fixed SFR equal to 0.6, can be attributed to the enhancement of the partial oxidation reaction, and the addition of steam which favours the endothermic reactions such as the steam-methane reforming reactions and the water gas shift reaction, which results in more  $H_2$  being produced, and this increases the  $H_2/CO$  ratio of the syngas. Moreover, the enhanced  $H_2/CO$  ratio of the syngas, is also caused by the addition of plastic waste, which contains high volatile matter and is rich in hydrogen. and the promotion of the water gas shift reaction, are the main factors that causes  $H_2$  to increase while  $CO$  decreases, thus leading to an enhanced  $H_2/CO$  ratio of the syngas. Figure 3.2 (b) shows that as ER increases the Lower Heating Value (LHV) of the syngas decreases. The high Lower Heating Value (LHV) of the syngas is favoured at low ER values below

0.4. This pattern can be attributed to the fact that at low ER values, the production of combustible gases is high, thus increasing the LHV of the syngas. In addition, an increase in plastic waste in the feedstock also contributes towards the increase in the LHV of the syngas, since increasing plastic waste results in a high hydrogen and methane composition in the syngas. Figure 3.2 (a) and (b) shows that an LHV of 9.6 MJ/Nm<sup>3</sup> was obtained from a feedstock with the blend ratio of (50% PE + 50% Biomass). The recommended value of 2 for the H<sub>2</sub>/CO ratio of the syngas and the high Lower Heating Value (LHV) of the syngas attained from the blended feedstock in the blend ratio of (50% PE + 50% Biomass) when compared to pure feedstocks indicates that there is a synergistic effect between biomass and plastic waste.

### 3.3 Effect of the Equivalence ratio on the GY and CGE

Figure 3.3 (a) shows that an increase in the equivalence ratio (ER) at fixed SFR of 0.6, causes the gas yield to increase. This is attributed to the linear relationship between the equivalence ratio and the gasifier temperature. An increase in ER, increases the gasifier temperature.

Figure 3.3 Effect of the equivalence ratio (ER) on the (a) gas yield (GY) and (b) cold gas efficiency.

The increase in the gasifier temperature increases the rate of devolatilization reactions, thus enhancing the gas production in the initial pyrolysis stage. Furthermore, the cracking and endothermic char gasification reactions are favoured at high temperatures, these reactions contribute toward the increase of the syngas yield. Figure 3.3 (b) exhibits that at low ER values, the cold gas efficiency is high, however as ER increases above 0.3, the cold gas efficiency decreases. This is because at low ER values the combustible gases such as H<sub>2</sub>, CO and CH<sub>4</sub> are high in the product gas, and that increases the LHV of the syngas, which consequently increases the cold gas efficiency. Whereas, at high ER values, there is a decrease in the combustible gases in the product gas, as these are oxidized to form CO<sub>2</sub> and H<sub>2</sub>O and thus resulting in a lower LHV of the syngas, which leads to a low cold gas efficiency. The LHV and cold gas efficiency have a linear relationship. Figure 3.3 (a) and (b) shows that increasing plastic waste fraction in the feedstock mixture increases both the gas yield and cold gas efficiency. As a result, high gas yield and high cold gas efficiency were obtained from the blend ratio of (50% PE + 50% Biomass) instead of from the blend ratio of (25% PE + 75% Biomass). This is

expected due to the nature of the plastic waste by nature which they contain high volatile matter and no oxygen content. A high cold gas efficiency of 61% is attained at ER equal to 0.24 and SFR equal to 0.6 from the blend ratio of (50% PE + 50% Biomass) (Figure 3.3 (b)).

#### 4. Conclusion

The co-gasification of biomass and plastic waste in the presence of an oxygen – steam mixture as gasifying agent has shown that the increase in polyethylene percentage in the blends, increases the H<sub>2</sub>, the H<sub>2</sub>/CO ratio of the syngas, the Lower Heating Value (LHV) (9.6 MJ/Nm<sup>3</sup>) of the syngas, the gas yield (GY) and the cold gas efficiency (GCE) (61%) of the system. This can be attributed to the low fixed carbon of polyethylene materials and that it has no oxygen. The improved outputs are determined from the blend ratio of (50% PE + 50% Biomass) instead of (25% PE + 75% Biomass) or from the biomass or plastic waste. The high yield of syngas composition, quality and energy content are favored at low ER values below 0.4, at fixed SFR equals to 0.6.

## Abstract

The ever-increasing population growth along with the diverse socio-economic pressures it creates, have led to rising demands for energy, water and food (EWF) resources. This pressure to satisfy the needs for such products has paved the way to competitive behaviors amongst the sectors' main players which might influence the efficient achievement of their objectives. Food security is one critical target that is heavily affected by the dynamics within the EWF nexus sectors. In fact, food production and supply depend primarily on the performance of water and energy systems, which involve diverse stakeholders characterised with both diverging and converging goals. Therefore, there is a need to understand and capture the competitive and collusive behaviors of each nexus sub-system as means to avoid any shortages and enhance the EWF nexus overall efficiency. The purpose of this paper is to optimise the economic and environmental performance of an EWF nexus system supplying a local food basket considering a set of renewable and non-renewable energy technologies and a range of water systems. The model is formulated as a multi-objective integer linear program that minimizes the economic costs and emissions. The model is run under two different scenarios investigating the impact of competition and cooperation on the optimal solution. Competition is modeled using Cournot game and cooperation is formulated as a Cartel, and results of the games are used as constraints restricting the optimisation framework. Results of the study assert that under competition and cooperation the water mix is mostly supplied by GW and TSE with more than 80%, while the energy production is evenly distributed amongst the three technologies. These results are highly influenced by the affordability and environmental emissions and less impacted by the behavior of the market. Findings of this study can be used to quantify the impact stakeholders' behaviors on the achievement of food security targets.

## 1. Introduction

Food security is one of the most challenging targets that many nations are striving to achieve and maintain. Food systems are governed by multiple pressures inflicted by the surrounding environment, counting climate change, political instability and market dynamics (Namany & Al-Ansari, 2021). Heavily relying on the energy and water resources to operate, the food sector's efficient functioning is also subject to the challenges faced by the water and energy sectors. Competition between water and energy industries is one of the critical issues that is often neglected when tackling food security. Competition amongst power generators and water producers can lead to fluctuations in

the quantities produced and supplied to the food system, which can disturb its operations and productivity, hence threatening the food security target. A proper modeling of competitive and cooperative behaviors is essential to reduce the impact of such volatility on the water and energy supplies to the food sector. In this regard, game theoretic techniques have been widely adopted in literature as a tool to capture competition. These models have demonstrated their efficacy in simulating competitive and collusive behaviors and in identifying the best course of action that results in mutually beneficial outcomes for the contending parties in many domains, including resources sectors (Ho et al., 2021). Considering the food sector, Saghaian and Asgari (2013) examined the non-cooperative import system of pistachios to Japan in the context of a duopolistic market made up of two significant exporting nations. The technique examined quantity competition between American and Iranian pistachio suppliers using Cournot and Stackelberg games. Addressing cooperation within the energy system, oil and gas more specifically, Gausmann (2012) proposed a model to analyze the strategic motivations for cooperation among the three major players in the European gas market, namely Qatar, Algeria, and Russia. A game-theoretic model was developed to determine each agent's interest in gas policy. Since each of these nations has distinct geopolitical goals, they will each look for a certain kind of alliance. The goal of this work is to investigate the impact of competition and cooperation in oligopolistic energy and water markets on the performance of a food system in charge of supplying a diversified food basket. Competition and cooperation between the water and energy technologies are modeled using Cournot and Cartel games and the resulting payoffs are used as constraints for an optimisation framework. The latter consists of a multi-objective integer linear program which seeks to minimize both the economic costs and environmental emissions of a configuration of renewable and non-renewable technologies. This paper is constructed such that the following section 2 presents the scenarios formulation and the mathematical representation of the optimisation model. Then, section 3 describes the main findings of the study.

## **2. Data and Methods**

The methodology developed in this work suggests a framework that assesses the influence of resource sectors' behaviors on the economic and environmental performances of an EWF nexus system delivering a food basket for the country of Qatar. Food groups considered in this study consist of perishable products, counting fruits, vegetables, poultry and meat products (Namany et al., 2019). The energy and water sectors in charge of supplying irrigation water, electricity for cultivation and fertilisers production are represented by a set of renewable and non-renewable technologies that are driven with the need of satisfying the food sector's demand for water and energy while maximising their individual profits. Two different scenarios are investigated wherein the set of energy and water technologies are either competing or cooperating to meet the food demands. Competition is modeled using Cournot game while cooperation is described by a Cartel game. Results of the games are incorporated as constraints in a multi-objective optimisation model that determines the optimal water and energy mix that would supply 40% self-sufficiency while minimising the cost and environmental impacts. The following sections describes the two different scenarios along with the optimisation model formulation.

## 2.1. Scenarios formulation

### 2.1.1. Cournot competition

Industries producing the same goods tend to compete as means to maximise their individual economic benefits, either through rising prices or increasing their outputs. In this first scenario investigated, technologies within the water and energy sectors compete between each other in order to maximise the amounts of water or power generated. The competition and the payoff of each competing technology are modeled using the Cournot game. The latter is founded on a set of assumptions entailing that players decide simultaneously and independently on the quantities to be produced and the market price of the goods is set once all players disclose their optimal quantities. In addition, Cournot is only applied when rivals are producing identical products. In this work, the water technologies counting reverse osmosis (RO), multi-stage flash (MSF), treated sewage effluent (TSE) and ground water pumping (GW) compete to produce water, and the power producers including combined-cycle gas turbine (CCGT), photovoltaics (PV) and biomass integrated gasification combined cycle (BIGCC) compete to generate power. The best response function for each water and energy technology is depicted by the following equation (1) where  $q_i$  is the individual Nash equilibrium quantity produced by each player  $i$ .  $c$  is the marginal cost of production of either water or energy, as for  $a$  and  $b$  are the parameters representing the linear inverse demand function described by equation (2), where  $P$  is the price and  $Q$  is the total quantity demanded.

$$q_i^* = \frac{a-c_i}{2b} - \frac{\sum_{i \neq j} q_j}{2} \quad (1)$$

$$P = a - b \times Q \quad (2)$$

### 2.1.2. Cartel cooperation

In the second scenario, each sector's set of technologies decide to collaborate and form cartels. Cartels occur when competitors decide to collude in order to rise prices and maintain their stability in the market. Players act in a monopoly where the optimal payoffs are distributed based on agreed-upon percentages. In this scenario, the water sector technologies and the power plants form two different cartels to maximise profits and restrict quantities. The optimal quantities produced under each scenario can be described by the following equations (3) and (4), wherein  $p_i$  is the pre-determined distribution percentage for each technology, which in this case is based on the current share of the technology in the market. As for  $j$ , it represents the index of the remaining technologies.

$$q_i = p_i \times Q \quad (3)$$

$$Q = \frac{\frac{a-c_i}{2b}}{p_i \frac{\sum p_j}{b}} \quad (4)$$

## 2.2. Optimisation model formulation

Results of the games, which are mainly payoffs of each participating technology are used as constraints for the optimisation model. The contribution of each technology to the mix is bounded by the level of the expected profit that each technology would make. If the quantity produced while participating in the mix is less than the Nash equilibrium quantity  $q_i^*$ , the technology has no incentive to be part of the mix.

The optimisation model is formulated as a multi-objective linear program aiming to minimise greenhouse gases (GHG) and the total economic costs of a configuration of water and energy technologies supplying a 40% of Qatar's food sector. The optimisation model can be described as follows:

*Objective functions:*

$$\text{Minimise: } Env = Q_w \sum_{i=1}^m x_i^w e_i^w + Q_e \sum_{i=1}^n x_i^e e_i^e \quad (5)$$

$$\text{Minimise: } Eco = Q_w \sum_{i=1}^m x_i^w c_i^w + Q_e \sum_{i=1}^n x_i^e c_i^e \quad (6)$$

*Constraints:*

$$Q_w x_i^w \geq q_i^{*w} \quad (7)$$

$$Q_e x_i^e \geq q_i^{*e} \quad (8)$$

$$\sum_{i=1}^m x_i^w = 100\% \quad (9)$$

$$\sum_{i=1}^n x_i^e = 100\% \quad (10)$$

$$x_i^w; x_i^e > 0$$

Such that:

$Env$  is the total environmental emissions in kg of CO<sub>2eq</sub>;

$Eco$  is the total economic cost in \$;

$x_i^w$  and  $x_i^{cc}$  are the decision variables representing the percentage contribution of each water and energy technology, respectively;

$Q_w$  and  $Q_e$  are the total quantities of water and energy required by the food sector in m<sup>3</sup> and kWh, respectively;

$e_i^w$  and  $e_i^e$  represent the unit carbon footprint associated the water production and energy generation in in kg of CO<sub>2eq</sub>/m<sup>3</sup> and kg of CO<sub>2eq</sub>/kWh, respectively (table 1);

$c_i^w$  and  $c_i^e$  are the unit costs associated with water production and energy generation in kg of \$/m<sup>3</sup> and kg of \$/kWh, respectively (table 1);

$m$  is the number of water technologies, counting RO, MSF, TSE and GW;

$n$  is the number of energy technologies, counting CCGT, PV and BIGCC;

**Table 1.** The optimisation model input data

Objective function	CCGT	PV	BIGCC	RO	MSF	GW	TSE
Cost(\$/kWh-\$/m <sup>3</sup> )	0.093	0.215	0.11	0.80	2.43	0.07	0.11
GWP(kg of CO <sub>2eq</sub> )	9.94E+08	9.83E+04	1.31E+08	1.71E+09	2.02E+09	1.90E+08	4.99E+08

### 3. Results and discussion

#### 3.1. Results of the games

Under Cournot competition, TSE and GW are allowed to produce larger quantities compared to the desalination technologies, due to their relatively small marginal costs. As for Cartel, the largest quantities are granted to GW, RO and MSF, thanks to their important market shares. Considering the energy technologies, the same pattern is noticed for both scenarios. This means that low marginal costs and high market shares are the factors influencing the quantities produced and hence CCGT is generating the largest quantity of energy and GW is producing the highest amount of water in both scenarios (table 2).

**Table 2.** Cournot and Cartel quantities results

		Cournot	Cartel
<b>Water Technologies (Mm<sup>3</sup>)</b>	<b>RO</b>	42.93	50.01
	<b>MSF</b>	10.68	50.01
	<b>GW</b>	160.68	125.04
	<b>TSE</b>	154.22	25.00
<b>Energy Technologies (MW)</b>	<b>CCGT</b>	2810.00	1751.29
	<b>PV</b>	1450.00	350.25
	<b>BIGCC</b>	2610.00	1401.03

### 3.2. Results of the optimisation model

Results of the multi-objective optimisation model suggest 5 optimal solutions for both Cournot and Cartel cases. Considering Cournot, the average optimal mix costs around \$210M and generates 715,6M kg of CO<sub>2eq</sub>. The optimal water configuration under this scenario is mainly consisting of GW and TSE with a slight contribution of desalination. This can be explained by the affordability of these technologies and their relatively low environmental impact. As for the energy mix, the three power generators are contributing with almost the same share, with CCGT slightly leading thanks to its low price (Figure 1). Considering the Cartel cooperation scenario, the average optimal solution has an economic cost of \$203M and emits around 792M kg of CO<sub>2eq</sub>. The slight increase in environmental impacts and decrease of the economic costs is due to the slightly higher contribution of CCGT which is affordable, yet environmentally damaging (Figure 2). Under both scenarios the participation of the water and energy technologies is almost the same, showing that the competition has almost no impact on the technology selection in this case study. This can also be explained by the fact that the equilibrium quantities generated when playing the games are profitable for all the studied technologies under both scenarios.

**Figure 1.** The water and energy configuration under Cournot competition.

**Figure 2.** The water and energy configuration under Cartel competition.

#### 4. Conclusion

Food security is a multi-faceted target involving the contribution of multiple sectors and entailing numerous risks. Competition between water technologies and energy technologies is one of the risks that can influence the productivity of the food sector due to the uncertain supplies of resources. In this paper, competitive and cooperative behaviors of these two sectors are modeled by means of Cournot non-cooperative game and Cartel cooperative game and the generated payoffs were used to restrict the contribution of some water and energy technologies in an EWF mix as part of an optimisation framework. Results of the study assert that under competition and cooperation the water mix is mostly supplied by GW and TSE with more than 80%, while the energy production is evenly distributed amongst the three technologies. These results are highly influenced by the affordability and environmental emissions and less impacted by the behavior of the market.

## Abstract

Transportation is one of the major sources of greenhouse gas (GHG) in the United Kingdom (UK), which motivates the government's policies to perform electrification of transportation and stimulate the use of electric vehicle (EV). However, many practical factors including battery costs and charging infrastructure are significantly affecting the wide utilisation of EVs. In this work, a multiple-output Gaussian processes (GPs) based Global Sensitivity Analysis (GSA) method is employed to investigate the relationship between these EV properties and the cost-performance. The variance-based GSA computations provide the detailed understandings of these key vehicle parameters for EV end-users and manufacturers. It is initially found that the total travel distances and its relevant variables available ID and fraction, and battery efficiency are the dominant factors for the cost of performance within all optimal solutions.

**Keywords:** Gaussian Process, greenhouse gas emissions, electric vehicle, global sensitivity analysis

## 1. Introduction

The impact of greenhouse gas (GHG) emissions has led to the growing commitments to net-zero emission by 2050. According to the BEIS (BEIS, 2020), Dominguez, et al, 2020), transportation is a significant source of GHG emission. The UK has therefore chosen to extensively electrify transportation and stimulate the use of electric vehicle (EV) to alleviate the GHG emissions. However, many practical factors, such as battery and ownership costs, and charging infrastructure, still inhibit the desired adoption of EVs. Thus, it is of importance to understand the relationships between the EV properties and their cost and performance. Such relationship can be obtained via Global Sensitivity Analysis (GSA). GSA calculates how much the uncertainty in outputs is attributed to the uncertainty in its individual inputs, or combinations thereof (Saltelli et al, 2008), and is a powerful tool to identify the key input variables to system outputs.

In this work, we adopt a variance-based GSA method using Gaussian Processes (GPs) (Williams & Rasmussen, 2006) to obtain the order of importance of vehicle properties to the cost and performance of EVs. The multi-output GP model is generated through the open-source ROM-COMMA software library (ROM-COMMA, 2022). GPs with automatic relevance determination (ARD) kernels allow for the semi-analytic calculation of Sobol' indices which measures the proportion of output variance attributable to each (combination of) input parameter Sobol' indices (Yearley et al., 2021). The multiple-

output GP-based GSA computations can thus provide an accurate and efficient understanding of key vehicle parameters for EV end-users and manufacturers.

## 2. Gaussian process based global sensitivity analysis

### 2.1. Gaussian process regression

In this work, we utilised GP surrogate models to build explicit relationship between the vehicle parameters  $\mathbf{x}$  and the cost-performance  $\mathbf{y} = \mathbf{f}(\mathbf{x}) + \sigma_e^2 \mathbf{I}_f$ , along with the observe data noises  $\sigma_e^2$  and the unit matrix  $\mathbf{I}_f$ . GP regression is an efficient non-parametric model technique, which also work as one statistic machine learning approach. One key assumption of GP regression is that the random output variables  $\mathbf{f}(\mathbf{x}_i)$  at any location point  $\mathbf{x}_i$  follows the normal distribution with mean value  $\mu(\mathbf{x}_i)$  and variance  $\sigma^2(\mathbf{x}_i)$ , and then prior joint Gaussian distribution  $\mathbf{f}(\mathbf{X})$  for the finite random variables  $\mathbf{X}$ :

$$\begin{aligned} \mathbf{f}(\mathbf{X}) &\sim N(\mu(\mathbf{X}), \sigma^2(\mathbf{X})) \\ \mathbf{y}|\mathbf{f} &\sim N(\mathbf{f}, \sigma_e^2) \end{aligned} \quad (1)$$

where  $\mathbf{f}(\mathbf{X}) = (\mathbf{f}(\mathbf{x}_1), \mathbf{f}(\mathbf{x}_2) \dots \mathbf{f}(\mathbf{x}_n))$ ,  $\mu(\mathbf{X}) = (\mu(\mathbf{x}_1), \mu(\mathbf{x}_2) \dots \mu(\mathbf{x}_n))$  and  $n$  is the number of samples. which are typically replaced by the zero mean function, and the covariance matrix  $\sigma^2(\mathbf{X})$  are expressed as the kernel matrix  $\mathbf{K}(\mathbf{X}, \mathbf{X})$  along with each element  $\mathbf{K}_{i,j} = \mathbf{k}(\mathbf{x}_i, \mathbf{x}_j)$ .

Here, the common radial basis function kernel was used since the automatic relevance determination kernel could provide semi-analytical computations for further variance-based GSA. The GP kernel function formulation indicates another assumption that when the inputs  $\mathbf{x}_i, \mathbf{x}_j$  are close, the corresponding output functions  $\mathbf{f}(\mathbf{x}_i)$  and  $\mathbf{f}(\mathbf{x}_j)$  are close:

$$\mathbf{k}(\mathbf{x}_i, \mathbf{x}_j) = \sigma_f^2 \exp\left(-\frac{1}{2l^2}(\mathbf{x}_i - \mathbf{x}_j)^T(\mathbf{x}_i - \mathbf{x}_j)\right) \quad (2)$$

where the kernel hyperparameter  $\sigma_f^2$  is global scale parameter while  $l = (l_1, l_2 \dots l_d)$  represents the bandwidth parameters,  $d$  is the dimension of inputs  $\mathbf{x}$ .

If the prior samples  $(\mathbf{X}, \mathbf{y})$  are collected, the predictive variable  $\mathbf{f}(\mathbf{X}')$  at the new location  $\mathbf{X}'$  and  $\mathbf{y}$  would satisfy a joint Gaussian distribution:

$$\begin{bmatrix} \mathbf{f}(\mathbf{X}') \\ \mathbf{f}(\mathbf{X}) \end{bmatrix} \sim N\left(\begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \begin{bmatrix} \mathbf{K}(\mathbf{X}', \mathbf{X}') & \mathbf{K}(\mathbf{X}', \mathbf{X}) \\ \mathbf{K}(\mathbf{X}, \mathbf{X}') & \mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma_e^2 \mathbf{I}_f \end{bmatrix}\right) \quad (3)$$

Then posterior predictive distribution  $\mathbf{f}(\mathbf{X}')|(\mathbf{X}', \mathbf{X}, \mathbf{y})$ :

$$\begin{aligned} \mathbf{f}(\mathbf{X}')|(\mathbf{X}', \mathbf{X}, \mathbf{y}) &\sim N(\mathbf{K}(\mathbf{X}', \mathbf{X})(\mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma_e^2 \mathbf{I}_f)^{-1} \mathbf{y}, \mathbf{K}(\mathbf{X}', \mathbf{X}') - \\ &\quad \mathbf{K}(\mathbf{X}', \mathbf{X}')(\mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma_e^2 \mathbf{I}_f)^{-1} \mathbf{K}(\mathbf{X}, \mathbf{X}')) \end{aligned} \quad (4)$$

The hyperparameters  $\sigma_f^2, l$  and  $\sigma_e^2$  can be obtained through maximizing the marginal likelihood on the collected data  $(\mathbf{X}, \mathbf{y})$ .

2.2. Variance-based global sensitivity analysis

With the built explicit GP surrogate model, the variance-based GSA method, also referred to as the Sobol' indices, is then performed on the mean predictive function  $\boldsymbol{\mu}(\mathbf{X}') = \mathbf{K}(\mathbf{X}', \mathbf{X})(\mathbf{K}(\mathbf{X}, \mathbf{X}) + \sigma_e^2 \mathbf{I}_f)^{-1} \mathbf{y}$ . From the probabilistic perspective, the inputs-outputs  $(\mathbf{X}', \boldsymbol{\mu}(\mathbf{X}'))$  of GP mean function are considered as the random variables. The key idea of Sobol indices method is to decompose the variance of the random outputs  $\boldsymbol{\mu}(\mathbf{X}')$ :

$$\text{Var}(\boldsymbol{\mu}) = \sum_{i=1}^d V_i + \sum_{i < j}^d V_{ij} + \dots + V_{12\dots d} \tag{5}$$

where  $V_i = \text{Var}_{\mathbf{X}'_i}(E(Y|\mathbf{X}'_i))$ ,  $V_{ij} = \text{Var}_{\mathbf{X}'_i, \mathbf{X}'_j}(E(Y|\mathbf{X}'_i, \mathbf{X}'_j)) - V_i - V_j$  and so on.

Then the important first-order index  $S_i$ , quantifying the effect of the single input  $\mathbf{X}'_i$ , can be computed as follows:

$$S_i = \frac{V_i}{\text{var}(\boldsymbol{\mu})} \tag{6}$$

Then the cumulative first-order index  $S^j$  quantifying the sum effects of the single inputs  $(\mathbf{X}'_1, \mathbf{X}'_2, \dots, \mathbf{X}'_j)$  on the total variance, can be calculated

$$S^j = \sum_{i=1}^j S_i \tag{7}$$

where  $j$  ( $j = 1, 2, \dots, d$ ) is the ranking position in the input index order  $\alpha = \{1, 2, 3, \dots, d\}$ .

Meanwhile, we computed the closed index  $S_{\ell_j}^C$  to represent the single and interaction effects of the inputs  $(\mathbf{X}'_1, \mathbf{X}'_2, \dots, \mathbf{X}'_j)$ , following the equation:

$$S_{\ell_j}^C = \sum_{\ell_i} S_{\ell_i}, \ell_i \subseteq \ell_j \text{ \& } \ell_i \not\subseteq \emptyset \tag{8}$$

where the  $\ell_j = \{1, 2, \dots, j\} \subseteq \alpha$  is the index set of inputs  $(\mathbf{X}'_1, \mathbf{X}'_2, \dots, \mathbf{X}'_j)$ .

Thus the interaction effects  $S_{\sim j}$  among the first  $j$  inputs  $(\mathbf{X}'_1, \mathbf{X}'_2, \dots, \mathbf{X}'_j)$  could be obtained as

$$S_{\sim j} = S_{\ell_j}^C - S^j \tag{8}$$

In this paper, we focus on the effects of the key parameters on the outputs. Through comparing the cumulative first-order indices  $S^j$  and the closed indices  $S_{\ell_j}^C$  within the order  $\alpha$  by decreasing the first-order index in a GSA test computation, the important input group is identified.

Here, all the Gaussian Process based Global Sensitivity Analysis computations were implemented in our open-sources ROM-COMMA software library (ROM-COMMA, 2022).

### 3. Computational results

#### 3.1. Process introduction

The objective of this work is to seek the key EV parameters for the cost and CO<sub>2</sub> emission. Here, firstly the important EV properties are considered including EV pool, 2WP (two-way power), acceleration, battery capacity, battery efficiency, battery power, range of photovoltaic (PV) output profiles, vehicle capital cost, vehicle maintenance cost, total travel distance, availability fraction, peak PV and PV cost. While the major attributions for the cost and CO<sub>2</sub> emission contain CO<sub>2</sub> emission, electricity import cost, electricity export revenue, total power imported, total power exported, total power of battery charging, total cost and total power of battery discharging. The multiple inputs-outputs relationship will be built using GP surrogate and further be analysed through the models.

#### 3.2. Data preprocessing

Through a bio-objective optimisation procedure for the cost-performance under multiple scenarios, around 2000 data pairs are generated for the multiple cost-performance under the different EV properties. By filtering the dependent inputs-outputs, the inputs of acceleration, battery capacity, battery efficiency, battery power, range of PV output profiles, vehicle capital cost, vehicle maintenance cost, total travel distance) and the outputs of CO<sub>2</sub> emission, electricity import cost, total power imported, total power of battery charging, total power of battery charging, total cost under two different optimisation strategies are chosen to construct the GP models.

#### 3.3. Computational results: GP models

For the GP model training process, a two-fold cross-validation was implemented to ensure the generalization ability of the obtained GP models. Table 1 displays the results of prediction validation. all validation criteria (the roots of mean square errors, R<sup>2</sup> value and outlier) shows that the errors of the surrogate of the selected CO<sub>2</sub> emission, total cost, the total power of battery charging and the total power imported are small enough. All the R<sup>2</sup> values are larger than 0.8, the RMSE errors are lower while the percentage of outliers are less 10%. The computational results verify the accuracy of the generated GP models. Meanwhile, Figure 1 compared the prediction of GP models and the actual observes. In generally, almost all the prediction points from the selected four parameters are close to the original observes, which indicates the efficiency of the generated GP models. Furthermore, small deviations are found for the predicted CO<sub>2</sub> emission and total imported power. That may be caused by the noises inside of the observed data.

Table 1: Prediction validation of the generated GP models for the selected output attributes

Output attributes	RMSE	R <sup>2</sup>	Outlier (%)
CO2 emission (g)	0.41	0.830	0.564
Total cost (GBP)	0.037	0.999	0.410
Total Power, Battery charging (kW)	0.061	0.996	6.410
Total Power imported (kW)	0.36	0.873	0.615

Figure 1: Tests of the GPs prediction (a) CO2 emission, (b) The total cost (c) The total power imported and (d) The total power battery charging

### 3.4. Computational results: GSA computations

With the validated GP models, GSA computations were then performed. Explicit ARD kernels contributes to the semi-analytical computations of GSA calculations, reducing the computational costs. Figure 2 summarises the results of cumulative first-order and closed indices for the four selected parameters (CO2 emission, total cost, total power imported and total power battery charging) on the eight inputs (acceleration, battery capacity, battery efficiency, battery power, range, vehicle capital cost, vehicle maintenance cost and total travel distance). It can be found, the cumulative closed indices of the first two terms all are larger than 94%, very close to 1 for all the selected four outputs. That indicates the first two input parameters total travel distance and battery efficiency are the dominant factors for the outputs. Furthermore, the small difference between the cumulative first-order and closed indices implies weak interactions effects among the input parameters. Thus, the total travel distance and its dependent variables available ID and fraction, together with another input battery efficiency are the key parameters for the cost and CO2 emission with the optimal solutions.

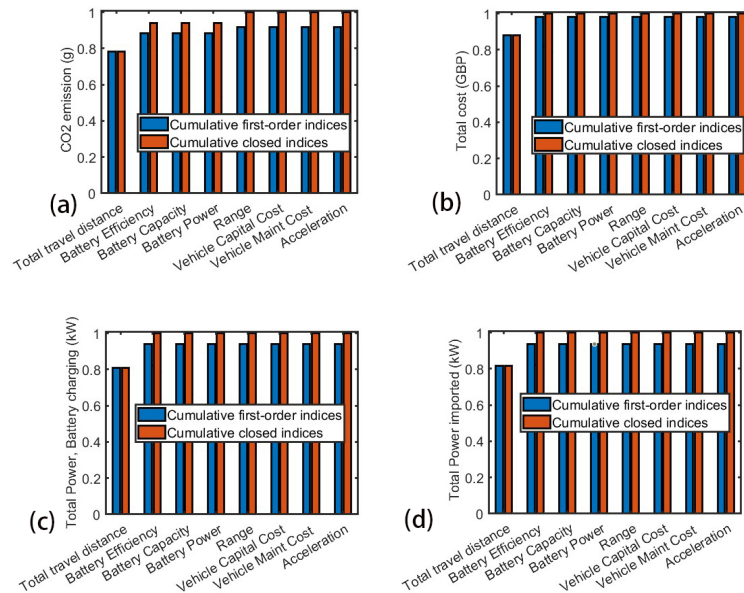

Figure 2: Computational results of the Sobol' indices (a) CO<sub>2</sub> emission, (b) The total cost (c) The total power imported and (d) The total power battery charging

#### 4. Conclusions

In this work, the multiple-output Gaussian Process based global sensitivity analysis computations are implemented between the EV properties and the cost-performance using different optimal solutions. The prediction validations indicate the high accuracy of the generated GP models while the GSA computations identify the dominant factors. It was initially found that the total travel distance and its highly relevant available ID and fraction, and battery efficiency are the key parameters for the cost and CO<sub>2</sub> emission within the optimal solutions. Further conclusions will be reached through more and general data for detailed analysis.

## Abstract

In this work, a parameter estimation framework is presented for applications where both spectral and non-spectral information are used for model parameter estimation purposes. We illustrate our methodology by studying a crystallization system, where the liquid phase is monitored by spectroscopic means, while the solid phase is characterized by particle sizing techniques. The obtained results show that our framework is capable of handling experimental data of different types, and that crystallization model parameters and associated uncertainty regions can be successfully estimated. We also found a strong influence of data uncertainty on the accuracy of the estimated parameters for secondary nucleation.

**Keywords:** Multiple-Curve Resolution, parameter estimation, crystallization kinetics, PharmaPy

## 1. Introduction

Construction of digital twins in the pharmaceutical industry is a current trend motivated by the flexibility offered by in-silico tools, allowing exploration of process conditions and configurations early in process design/planning, and by the decision support digital twins can provide for process operation in the form of process control and monitoring. In both cases, mathematical models describing the unit operations involved typically include parameters which must be estimated by comparing model predictions to experimental data collected at carefully selected process conditions.

Some of the experimental data arise in the form of spectral information (UV-Vis, IR, Raman) gathered in real time for monitoring or parameter estimation purposes. In particular, spectra from the manufacturing of active pharmaceutical ingredients (APIs) is abundant in operations such as reaction and crystallization, and also in solid processing and product formulation. The availability of such data calls for frameworks that fully utilize the rich information provided by spectroscopic data in the parameterization of first-principle models. A layer of complexity in systems characterized by spectral data lies in need for the joint treatment of spectral and non-spectral data. For instance, building first-principles crystallization models usually requires information regarding both liquid and solid phases, the former often measured by spectroscopic techniques, and the latter by particle sizing instruments. In these cases, state and sensitivity information has to be

utilized in such a way that general-purpose parameter estimation frameworks are still usable. Although selecting fixed wavelengths as traditionally practiced is also an option, fully utilizing spectroscopic information offers a more robust and direct way of calibrating the models of interest [1], and also facilitates the analysis of multicomponent systems, of special interest in crystallization for impurity analysis.

In this work, we present a framework that uses spectral and non-spectral information from a crystallization system, to estimate kinetic parameter and their uncertainty regions. For this purpose, we expand a multiple-curve resolution/alternating least-squares (MCR-ALS) methodology [1] to allow the use of both liquid-phase and solid-phase batch cooling crystallization data within a parameter estimation framework built into the PharmaPy numerical library [2]. A case study is presented demonstrating the potential of the framework for handling different data sources and types in modeling of pharmaceutical systems. Moreover, the model parametric uncertainty estimated with this framework can be further utilized in probabilistic design space determination and robust optimization.

## 2. Mathematical framework

### 2.1 Crystallization modeling

The crystallization system is modeled by using the standard method of moments:

$$\frac{d\mu_0}{dt} = B \cdot V, \quad \frac{d\mu_n}{dt} = n \cdot \mu_{n-1} G + B L_0^n, \quad n \in \{1, 2, 3\}, \quad (1)$$

with the liquid phase described by component and global material balances:

$$\begin{aligned} \frac{dC_j}{dt} &= -\frac{tr}{V_L} \left( \delta_{j,API} - \frac{C_j}{\rho_L} \right), \quad j \in \{1, \dots, n_{comp}\}, \\ \frac{dV_L}{dt} &= -\frac{tr}{\rho_L}. \end{aligned} \quad (2)$$

Liquid-to-solid mass transfer is given by  $tr = 3k_v \rho_s G \mu_2$ , and  $\delta_{j,API} = 1$  for  $j = API$  and 0 otherwise. Cooling profile  $T(t)$  was modeled as a linear trajectory at constant cooling rate. Primary and secondary nucleation ( $B = B_p + B_s$ ) and growth ( $G$ ) crystallization mechanisms are modeled by power law expressions of the form:

$$B_p = k_p S^p, \quad B_s = k_s S^s (k_v \mu_3), \quad G = k_g S^g, \quad (3)$$

where the crystallization driving force is relative supersaturation  $S = (C_{API} - C_{sol}) / C_{sol}$ , with solubility  $C_{sol}(T, x_{solvent})$ . With the included mechanisms, the model parameter set is  $\boldsymbol{\theta} = \{k_p, p, k_s, s, k_g, g\}$ . An enlarged ODE system was constructed by including the sensitivity system  $\mathbf{S} \in \mathbb{R}^{n_y \times n_\theta}$  of the crystallization model:

$$\frac{d\mathbf{S}}{dt} = \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \mathbf{S} + \frac{\partial \mathbf{f}}{\partial \boldsymbol{\theta}}, \quad \mathbf{S} \equiv \frac{\partial \mathbf{y}}{\partial \boldsymbol{\theta}}, \quad \mathbf{y} = \{\mu_1, \dots, \mu_n, C_1, \dots, C_n, V_L\}, \quad (4)$$

where the vector function  $\mathbf{f}$  in Eq. (4) represents the right hand sides of Eqs. (1) and (2).

Analytical forms for matrices  $\partial \mathbf{f} / \partial \mathbf{y} \in \mathbb{R}^{n_y \times n_y}$  and  $\partial \mathbf{f} / \partial \mathbf{y} \in \mathbb{R}^{n_y \times n_\theta}$  were adapted from [3] and incorporated into PharmaPy.

### 2.2 Parameter estimation framework

The parameter estimation problem was formulated as

$$\min_{\boldsymbol{\theta}} \frac{1}{2} \sum_{e \in E} \sum_{\ell \in L_e} (Y - Y_{data})_{\ell}^T W^{-1} (Y - Y_{data})_{\ell}, \quad (5)$$

$$\text{subject to } Y = \mathbf{h}(\mathbf{y}). \quad (6)$$

with  $\mathbf{y}$  are the states of the dynamic mode (see Eq. (4)). Summations in Eq. (5) are indexed for a set of experiments  $e \in E$ , each experiment measured at  $L_e$  sampling times.  $Y \in \mathbb{R}^{L_e \times n_y}$  collects the monitored states computed from the dynamic model,  $Y_{data} \in \mathbb{R}^{L_e \times n_y}$  collects the corresponding experimental data, and  $W \in \mathbb{R}^{n_y \times n_y}$  is a diagonal matrix of weighting factors. Since our methodology includes spectral (liquid phase) and non-spectral (solid phase) information, states are arranged as  $Y = [Y_{sp}, Y_{nsp}]$ . Following Eq. (6), simulated spectra [1] and (number-based) mean crystal size are given by:

$$Y_{sp} = \mathbf{C}(\mathbf{C}^+ A), \quad Y_{nsp} = \boldsymbol{\mu}_1 / \boldsymbol{\mu}_0, \quad (7)$$

where  $A \in \mathbb{R}^{L_e \times n_{sp}}$  is a matrix of liquid phase absorbance measured at  $n_{sp}$  wavelength values, and  $\mathbf{C}^+$  is the Moore-Penrose inverse of the concentration matrix  $\mathbf{C} = [\mathbf{C}_1, \dots, \mathbf{C}_{n_{comp}}]$ ,  $\mathbf{C} \in \mathbb{R}^{L_e \times n_{comp}}$ ,  $\boldsymbol{\mu}_0, \boldsymbol{\mu}_1 \in \mathbb{R}^{L_e}$ .

Derivative information required to solve Eq. (5) was also decomposed into spectral and non-spectral contributions (Eq. (9)), with related dynamic sensitivities  $\partial \mathbf{C} / \partial \theta_i(t)$  and  $\mathbf{S}_{\mu_0}(t) = \partial \boldsymbol{\mu}_0 / \partial \boldsymbol{\theta}$ ,  $\mathbf{S}_{\mu_1}(t) = \partial \boldsymbol{\mu}_1 / \partial \boldsymbol{\theta}$  retrieved after solving Eq. (4).

$$J = \begin{bmatrix} J_{sp} \\ J_{nsp} \end{bmatrix}, \quad J_{sp} = [J_{sp, \theta_1}, J_{sp, \theta_2}, \dots, J_{sp, \theta_{n_\theta}}]. \quad (8)$$

Each column vector  $J_{sp, \theta_i} \in \mathbb{R}^{L_e \cdot n_{sp}}$  in  $J_{sp}$  is obtained by vertically stacking the columns of the corresponding matrix given by the variable projection shown in Eq. (10) [4]:

$$J_{sp, \theta_i} = \left[ \left( P_C^\perp \frac{\partial \mathbf{C}}{\partial \theta_i} \mathbf{C}^+ \right) + \left( P_C^\perp \frac{\partial \mathbf{C}}{\partial \theta_i} \mathbf{C}^+ \right)^T \right] \cdot A, \quad \forall \theta_i \in \boldsymbol{\theta}. \quad (9)$$

where  $P_C^\perp = (\mathbf{I} - \mathbf{C} \cdot \mathbf{C}^+)$  is an orthogonal projector of the column space of  $\mathbf{C}$  [4]. On the other hand, the non-spectral contribution  $J_{nsp} \in \mathbb{R}^{L_e \times n_\theta}$  is given by:

$$J_{nsp} = \frac{\mathbf{S}_{\mu_1} \circ \boldsymbol{\mu}_0 - \mathbf{S}_{\mu_0} \circ \boldsymbol{\mu}_1}{\boldsymbol{\mu}_0^2} \quad (10)$$

where the  $\circ$  operator represents element-wise column multiplication.

### 2.3 Materials and methods

Table 1. Experimental design

Exp	%seed	Cooling rate (K/s)
1	0	-0.1
2	0	-0.3
3	5	-0.1
4	5	-0.3

Four in-silico API concentration and mean size ( $\mu_1/\mu_0$ ) datasets were generated by simulating the system described by Eqs. (1) and (2) at the experimental conditions shown in Table 1, and using the nominal parameter values shown in Table 2. Time was sampled every 5 seconds until a final temperature  $T_f = 278$  K was reached for all the simulations. Normal noise  $\mathcal{N}(0, 3)$  was added to the resulting concentration and mean size time profiles. Using the simulated concentration  $\mathbf{C}$ , in-silico spectra was calculated by the Beer-Lambert law as  $Y_{sp}^{data} = \mathbf{C} \cdot \mathbf{a}$ , where  $\mathbf{a}$  is a vector of pure component

molar absorptivity, modeled as the summation of gaussian peaks centered at the wavenumber where maximum absorbance for the three-component system (API + THF + heptane) occurs. Only initial and final mean size data were passed to the parameter estimation framework, as in practice these are the typical measurement gathered in crystallization experiments.

Initial temperature was set as the saturation temperature at a given solvent composition. Values of initial API concentration, and molar fraction of the THF + heptane solvent mixture were fixed at  $C_{API,init} = 167$  kg m<sup>-3</sup> (0.7 mol L<sup>-1</sup>) and  $x_{THF} = 0.4$  (30 %v/v), respectively according to previous works [5]. Furthermore, initial seed mass was calculated from the theoretical crystal yield using %seed in Table 1 as  $m_{seed} = (C_{API} - C_{solub}(T_f))V$  (%seed / 100).

For experiments 3 and 4 (seeded experiments), initial crystal size distribution was assumed lognormal,  $f_{init} \sim \ln \mathcal{N}(\mu = 35, \sigma^2 = 150)$ , resulting in  $\mu_1 / \mu_0 = 25 \mu\text{m}$  ( $t = 0$ ), values in the reported ranges for continuous lomustine crystallization [5].

The parameter estimation problem, Eq. (5) was solved using an in-house implementation of the Levenberg-Marquardt algorithm in PharmaPy. A weighing matrix  $W = \text{diag}([W_{sp}^T, 1])$  where  $W_{sp} \in \mathbb{R}^{n_{sp}=113}$  is a vector of 0.1's was used to account for the difference in the scales of the spectra versus crystal size, and was tuned by testing the optimizer performance at different candidate values.

## 2. Results

In order to decrease the chance of terminating at local minima, Eq. (5) was evaluated at 2<sup>6</sup> parameter realizations according to a Sobol sampling scheme, within the parameter bounds shown in Table 2. Then, the parameter realization that lead to the lowest objective function value was used as an initial estimate to perform optimization. After solving the optimization problem, the converged parameter estimates and their corresponding 95% asymptotic confidence intervals were obtained, as shown in Table 2.

The simulated dynamic profiles using the converged parameters are shown in Figure 1, where a close agreement between data and model prediction is observed. It must be emphasized that our optimization framework uses spectra as the simulated state ( $Y_{sp}$  in Eq. (7)), thus API concentration is used in Figure 1 only for illustration purposes. It is also noteworthy that primary nucleation and growth parameter estimates are very close to their corresponding nominal values, with some of their nominals being included in their corresponding confidence intervals. This shows how the methodology is effective in recovering the original parameters used to generate the in-silico data.

Table 2. Parameter information and optimization results

		Lower bound	Upper bound	Nominal	Initial	Converged
Primary nucleation	$\ln(k_p)$	11.513	34.539	19.519	21.543	$19.39 \pm 0.18$
	$p$	0.500	5.000	3.000	1.270	$2.78 \pm 0.16$
Secondary nucleation	$\ln(k_s)$	11.513	34.539	17.613	13.726	$22.02 \pm 0.32$
	$s_l$	0.500	5.000	2.000	2.707	$1.39 \pm 0.25$
Growth	$\ln(k_g)$	-36.148	2.303	-0.693	-0.665	$-0.65 \pm 0.024$
	$g$	0.000	2.000	1.000	1.054	$1.05 \pm 0.026$
<i>WSSE</i>		--	--	--	12041.82	367.46

On the other hand, it can be seen that secondary nucleation parameters significantly deviate from their nominal values, even though the model closely follows the provided data using the converged parameter estimates. As seen in Figure 1 (bottom), the level of noise used for the mean size profile significantly distorts the general trend of the in-silico data, which can have a pronounced effect on the final estimates, especially when only initial and final mean size information is being used. As a way to check the effect of noise, new in-silico datasets were generated, this time setting noise to zero for mean size. After parameter estimation (started at the initial parameter values shown in Table 2) the converged secondary nucleation parameters were closer to their corresponding nominal values ( $\ln(k_s) = 19.84 \pm 1.69$ ,  $s = 1.62 \pm 1.35$ ).

These results indicate how challenging it can be to determine true secondary nucleation parameters, and also call attention to the feasibility of decoupling this mechanism from primary nucleation. In this regard, the order of magnitude of primary and secondary nucleation can lead to one of them being underrepresented for a particular application. For illustration, the smallest ratio between the nucleation mechanisms at the highest supersaturation for the in-silico data occurs in experiment 3 ( $B_p / B_s = 95$ ). This suggests that the effect of secondary nucleation on the system dynamics will be overshadowed by primary nucleation and growth, making sensitivity with respect to secondary nucleation parameters particularly small. This has been proven to be detrimental in the context of optimization, making the numerical system ill-conditioned, which in turn makes optimization problems harder to solve. This clearly indicates the need for more experimental data that allows one to better characterize secondary nucleation, for which different model-based designs of experiment frameworks exist in the literature [6].

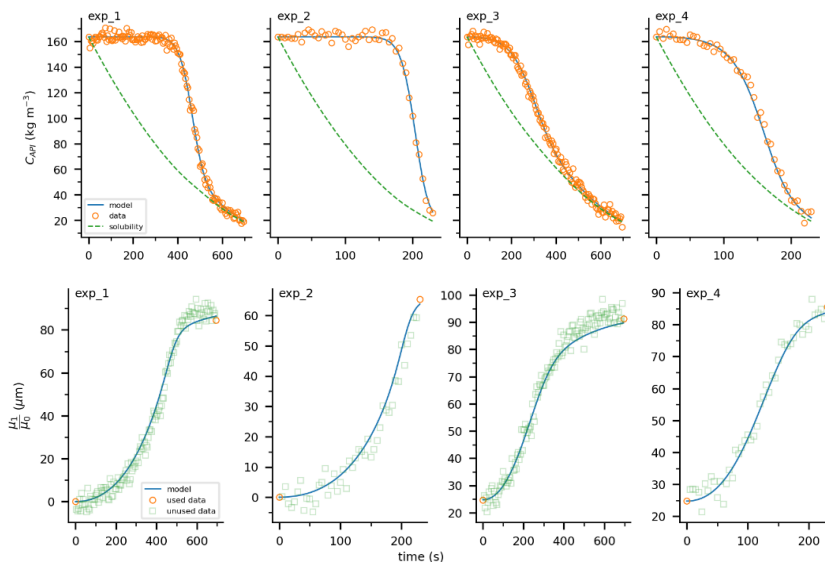

Figure 1. Predicted dynamic concentration and mean size profiles vs. corresponding in-silico data

### 3. Conclusions

In this work, we described a framework that allows the use of spectral and non-spectral information in the context of parameter estimation, and use it for the first time (to the best of our knowledge) in the context of crystallization systems. Two key elements contributed to the successful application of the framework, namely i) scaling the spectral and non-spectral contributions to the objective function and ii) properly arranging the sensitivity sources of the numerical system. This methodology can be applied to other studies in which both spectral and non-spectral information are gathered.

## Abstract

The aim of this work is to compare the performances of CO<sub>2</sub> cryogenic separation from a flue gas stream by means of flash and of distillation. Simulations have been carried out with the process simulator Aspen HYSYS<sup>®</sup> V11 (AspenTech, 2019), selecting the Peng-Robinson Equation of State and a sensitivity analysis has been performed on the CO<sub>2</sub> concentration in the feed gas and on the operating pressure (in the range 1.5-4 MPa) of the unit. Given the better performances of cryogenic distillation, which allows obtaining a CO<sub>2</sub> product at high purity at lower energy expenses, distillation has been considered for CO<sub>2</sub> capture from a flue gas from an oxy-fuel combustion power plant. A process scheme has been developed, properly selecting the operating conditions so to avoid the formation of solid CO<sub>2</sub>, demonstrating the better energy performances (ca. 10 % lower “Net Equivalent Methane” consumption) compared with those of a flash-based process.

**Keywords:** CCUS, cryogenic CO<sub>2</sub> capture, distillation, oxy-fuel combustion

## 1. Introduction

Carbon Capture Utilization and Storage (CCUS) is a key strategy to reach the goal of the Paris Agreement for the path to net-zero or even negative emissions in some scenarios. CCUS involves capturing CO<sub>2</sub> from a gas source and utilizing or storing it, with transportation being an essential step (Mazzocchi et al., 2013). Among the known carbon capture technologies, low-temperature/cryogenic separation processes - recently also considered for a profitable exploitation of low-quality natural gas reserves (Pellegrini et al., 2019) - are particularly suitable for gases with high CO<sub>2</sub> concentrations. Thus, it is one of the best options for treating flue gases from oxy-combustion processes or as a finishing treatment in hybrid systems (De Guido et al., 2021). Two aspects, namely high CO<sub>2</sub> recovery rates and high purity have contributed to the considerable attention cryogenic CO<sub>2</sub> capture technologies are gaining (Font-Palma et al., 2021). This is the motivation for this work, which focuses on distillation-based CO<sub>2</sub> capture not involving dry ice formation by a careful selection of the proper operating conditions. To the author’s knowledge, only few literature works on this topic deal with distillation techniques. After explaining the methods for the analysis (section 2), the advantage of distillation over flash has been demonstrated for further purification of a flue gas downstream of a bulk removal step. Then, a distillation-based process has been considered for CO<sub>2</sub> capture from a flue gas from an oxy-fuel combustion power plant for different CO<sub>2</sub> contents (66.8-85.5 mol%) in it and different recovery rates.

## 2. Methods

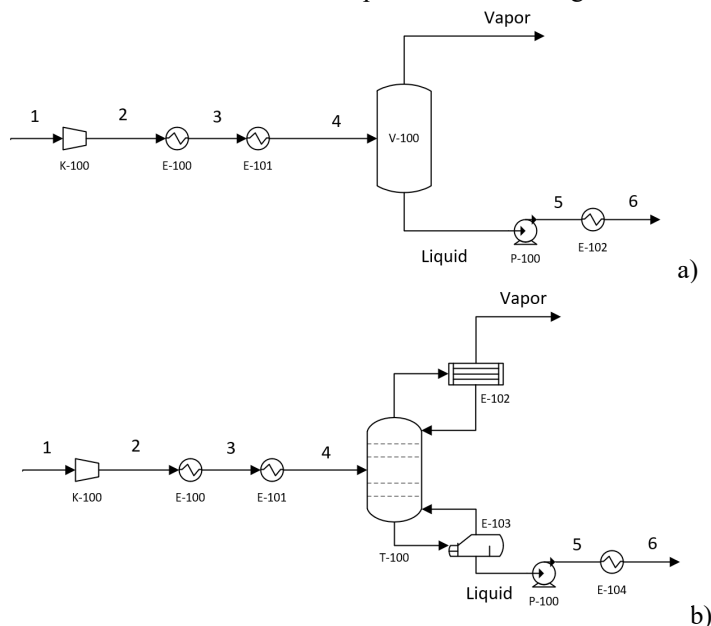

Process simulations have been carried out with Aspen HYSYS® V11 (AspenTech, 2019), selecting the Peng-Robinson Equation of State to properly represent the thermodynamic behavior of the CO<sub>2</sub>-N<sub>2</sub> system, which is representative of a flue gas mixture. In order to identify and avoid the operating conditions causing solid CO<sub>2</sub> formation, the “CO<sub>2</sub> Freeze Out” utility (De Guido et al., 2019; Spatolisano and Pellegrini, 2021a, b) was used.

The comparison among the different process schemes analyzed in this work has been carried out on the basis of an energy analysis. Since two types of energy consumption are involved in a typical cryogenic CO<sub>2</sub> capture process, both thermal and electrical, to determine the overall energy consumption the different contributions have been expressed on the same basis adopting the “Net Equivalent Methane” (NEM) method (De Guido et al., 2018). In selecting the most suitable flue gas for cryogenic CO<sub>2</sub> separation, previous findings have been taken into account. For example, van Benthum et al. (van Benthum et al., 2012) reported that a minimum concentration of 40% of CO<sub>2</sub> in the feed gas is necessary to achieve recovery higher than 70%. Therefore, according to typical flue gas compositions (Berstad et al., 2013), suitable flue gases for CO<sub>2</sub> capture at low temperature are those from oxy-fuel combustion.

## 3. Process Description and Analysis

### 3.1. Cryogenic CO<sub>2</sub> capture by flash or distillation

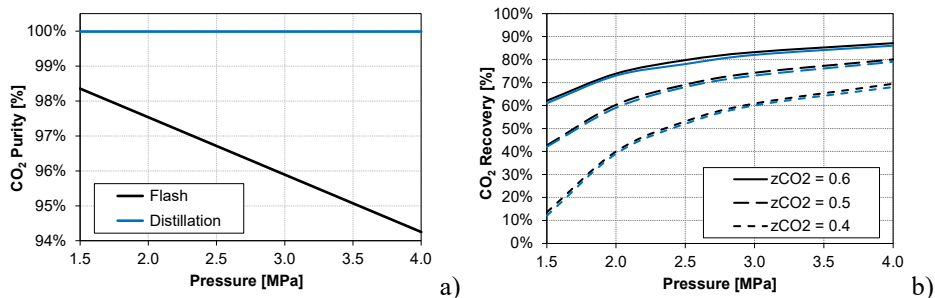

Cryogenic separation of CO<sub>2</sub> from a flue gas mixture by means of flash or distillation downstream of a bulk removal step is illustrated in Figure 1.

**Figure 1.** CO<sub>2</sub> separation from a CO<sub>2</sub>-N<sub>2</sub> mixture by: a) flash expansion; b) distillation.

To this purpose, a flue gas mixture consisting of CO<sub>2</sub> and nitrogen with a CO<sub>2</sub> content in the range 40-60 mol%, available at 0.15 MPa, has been compressed to different pressures ranging from 1.5 to 4.0 MPa. In the case of separation carried out by flash expansion, such stream has been cooled down to a suitable operating temperature selected as the lowest allowing the liquid-vapor separation without formation of solid CO<sub>2</sub>, which

maximizes CO<sub>2</sub> recovery. Such temperature was determined using the “CO<sub>2</sub> Freeze Out” utility considering a 2 K margin from the freezing temperature. Two heat exchangers are shown in Figure 1 for cooling with cooling water (CW) first (in E-100) – not accounted for in the energy analysis – and, then, in E-101 with a suitable refrigeration cycle (De Guido et al., 2015). In the case of separation by distillation, the flue gas stream has been compressed to the operating pressure of the tower (in the range 1.5-4.0 MPa), and cooled down to the corresponding dew-point temperature. The saturated vapor stream enters the distillation column, equipped with a full reflux condenser, for which the number of trays, the liquid CO<sub>2</sub> purity (99.99 mol%) and the liquid CO<sub>2</sub> recovery (determined as the highest not forming solid CO<sub>2</sub> in any tray) have been specified. The number of trays has been determined using the short-cut method implemented in the process simulator Aspen HYSYS<sup>®</sup> V11 (AspenTech, 2019), knowing CO<sub>2</sub> product purity and recovery and assigning an actual reflux ratio 30 % higher than the minimum one. In both cases, the liquid CO<sub>2</sub>-rich product is pumped to 6 MPa and heated to 293.15 K (Hasse et al., 2013). As shown in Figure 2a, increasing the operating pressure of the flash drum, the CO<sub>2</sub> product purity is lower and it is not significantly affected by feed gas composition, since the flash operating temperature is about the same (215.86 K at 1.5 MPa and 214.26 K at 4.0 MPa) for all considered pressures. On the contrary, when separation is performed by distillation, the CO<sub>2</sub> product purity remains constant and equal to the specified value. Figure 2b shows that the CO<sub>2</sub> product recovery is higher as the operating pressure increases at constant feed gas composition, and it is lower for lower CO<sub>2</sub> content in the feed gas at constant pressure, with a little difference (within 1.7 %) between separation by flash and by distillation.

**Figure 2.** Liquid CO<sub>2</sub> purity (a) and recovery (b) as a function of the operating pressure of the flash unit / distillation column (1.5-4.0 MPa) and for different feed gas compositions. Comparison between flash (black) and distillation (blue).

Separation by distillation allows obtaining a high-purity CO<sub>2</sub> product with no penalty on energy consumptions, as shown in Figure 3. Indeed, the energy requirement in terms of NEM of the distillation column (related to flue gas compression, refrigeration both at the inlet and at the condenser of the column, and pumping of the CO<sub>2</sub> product) is lower in all the simulations, and the difference with the energy requirement of the flash (related to flue gas compression, refrigeration at the inlet of the drum, and pumping of the CO<sub>2</sub> product) is higher for higher operating pressures, which correspond to higher CO<sub>2</sub> recoveries (Figure 2b). The lower energy requirement of the distillation process could be explained by taking into account the distribution of the cooling duty in the two cases. In flash separation, the whole cooling duty is due to cooling down the feed to the flash operating temperature (ca. 215 K), while in the distillation process the cooling duty is partly due to cooling down the feed to its dew-point temperature, that is higher than flash

temperature, and only a portion of the cooling duty is due to refrigeration in the column condenser, resulting in lower equivalent methane consumption.

**Figure 3.** Net Equivalent Methane (NEM) comparison between flash (black) and distillation (blue).

### 3.2. Distillation-based CO<sub>2</sub> capture process

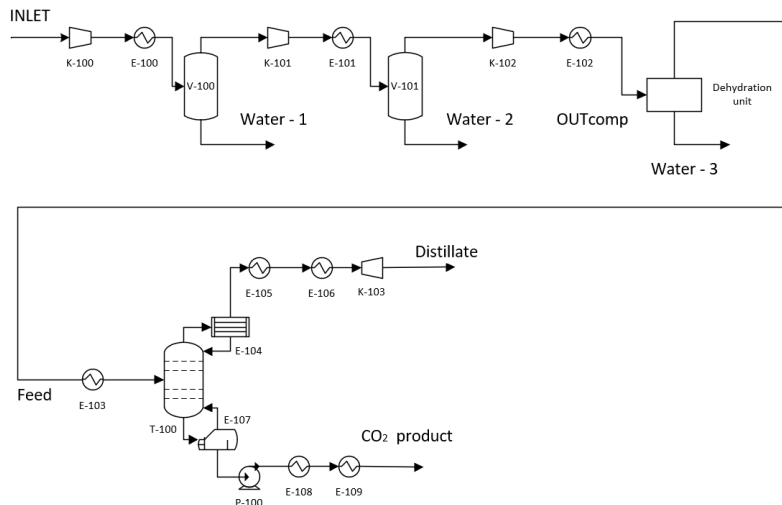

Following the results reported in the previous section, a distillation-based CO<sub>2</sub> capture process is proposed (both in a base and in an improved configuration) selecting an oxy-fuel combustion flue gas. The specific composition considered has been taken from Amann et al. (Amann et al., 2009) and is reported in Table 1.

**Table 1.** Composition (mol%) of the flue gas (Amann et al., 2009) entering the distillation-based CO<sub>2</sub> capture process.

CO <sub>2</sub>	H <sub>2</sub> O	N <sub>2</sub>	O <sub>2</sub>	Ar
66.8	3.1	18.9	5.5	5.5
74.1	3.0	11.0	5.7	6.0
85.5	3.0	0.4	5.7	5.4

The process scheme is illustrated in Figure 4 and differs from the one proposed by Amann et al. (Amann et al., 2009) for the replacement of the flash units by a distillation column for the reasons reported in the previous section. The feed gas is compressed in a three-stage process to 3.5 MPa, with intermediate cooling to 303.15 K using CW. The pressure of each stage has been determined as explained in a previous work (Pellegrini et al., 2015). After cooling in the first two stages, water is separated as liquid in two drums (V-100 and V-101), whereas the vapor stream is fed to the next compression stage. The stream exiting the compression train enters a dehydration unit (not accounted for in the energy analysis that follows, for comparison purposes with the flash-based process (Amann et al., 2009)), where the reduction of the water content to 20 ppm is accomplished. The dehydrated stream is, then, cooled to its dew-point temperature and is fed to the distillation column, equipped with a full reflux condenser, where an external refrigerant is used. The reboiler employs CW as heating medium because the heating is below ambient temperature. For all the investigated case studies (i.e., different CO<sub>2</sub> contents in the flue gas and different recoveries), the number of theoretical trays turned out to be 4 from a short-cut calculation and has been specified together with the CO<sub>2</sub> purity (99 mol%) and recovery set to the same values considered in the flash-based process (Amann et al., 2009) for comparison purposes. The distillate stream, exiting the top of the distillation column, is heated (E-105) to 293.15 K using CW, then it is heated

(E-106) to 423.15 K with steam and is expanded to atmospheric pressure in a turbine. The stream exiting the bottom of the column is pumped (P-100) to 15 MPa, heated (E-108) to 293.15 K with CW and finally heated (E-109) to 293.15 K.

**Figure 4.** Scheme of the distillation-based CO<sub>2</sub> capture process without heat integration.

The process scheme in Figure 4 (in the following, referred to as “distillation-based (A)”) can be improved from an energy point of view by using the distillate product for pre-cooling of the feed stream to the distillation column, so reducing the cooling duty supplied by an external refrigerant for bringing the feed to its dew-point temperature. Such an improved configuration is referred to as “distillation-based (B)” in the following. The results of the energy analysis are summarized in Table 2, where the relative difference has been computed with respect to the flash-based process presented in the literature (Amann et al., 2009).

**Table 2.** Results of the energy analysis (“Net Equivalent Methane” method).

CO <sub>2</sub> content [mol%]	CO <sub>2</sub> recovery [%]	NEM [kgCH <sub>4</sub> /s]			Relative difference [%]	
		flash-based (Amann et al., 2009)	distillation-based (A)	distillation-based (B)	distillation-based (A)	distillation-based (B)
66.8	75	0.6945	0.7257	0.6366	+ 4	- 8
74.1	85	0.6873	0.7138	0.6603	+ 4	- 4
85.5	75	0.5527	0.5416	0.4930	- 2	- 11
85.5	90	0.6364	0.6274	0.6025	- 1	- 5

The “distillation-based (A)” process is more energy demanding than the flash-based separation for low CO<sub>2</sub> contents in the flue gas, whereas the configuration with heat integration (“distillation-based (B)”) is less energy demanding in all cases, with the highest difference at low carbon dioxide recovery due to a decrease of column condenser and cooling (E-103) duties. An important advantage of the proposed process, compared with the flash-based one, is that a liquid CO<sub>2</sub> product ready for pumping is obtained, which is suitable for further utilization (e.g., for Enhanced Oil Recovery). Moreover, it allows specifying even a stricter specification (by carefully selecting the proper operating

conditions) on the CO<sub>2</sub> product to meet the quality requirements, in particular with respect to the residual O<sub>2</sub> content, for food-grade CO<sub>2</sub>, which will be the subject of a future work together with a techno-economic analysis.

#### 4. Conclusions

The comparison between cryogenic CO<sub>2</sub> capture by flash and distillation, not addressed in previous literature works, has shown that a CO<sub>2</sub> product at higher purity can be obtained in the latter case with lower energy consumptions, especially at higher operating pressures, although with a slightly lower (within 1.7 %) recovery. Therefore, a distillation-based process has been proposed for separating CO<sub>2</sub> out of flue gas streams typical of oxy-fuel combustion power plants. An energy comparison with the flash-based analogous process has demonstrated the better performances of the distillation-based process for several CO<sub>2</sub> concentrations (66.8-85.5 mol%) in the flue gas to be treated and different recovery rates. An important advantage of the proposed process, compared with the flash-based one, is that a high purity CO<sub>2</sub> product is obtained, which is suitable for further utilization, including in the food and beverage industry if a stricter specification, in particular with respect to the residual O<sub>2</sub> content, is assigned.

## Abstract

Machine learning is increasingly being used as a modeling technique for the analysis of complex systems even when limited knowledge is available. Here, we demonstrate the application of machine learning models to predict macroscopic properties of electrochemical polymers from molecular attributes. The computational framework proposes a novel approach to estimate molecular dynamic simulations (MD) attributes and experimental activity coefficients. Results showed that the data augmentation and embedding strategy effectively produce unique representations of each polymer. The findings from this study allow for the estimation of activity coefficients of novel polymers without the need for new time-consuming MD simulation runs. This data processing technique could then be used map to material properties that influence for electrochemical ionic separation units.

**Keywords:** Feature embedding, machine learning modeling, molecular dynamics simulations, electrochemical separations.

## 1. Introduction

It is estimated that the world's population will clock 9 billion by 2050; these fast-growing populations lead to an increase in demand for energy and water supply. For example, over 4 billion people lives in areas with severe scarcity of water (Mekonnen and Hoekstra, 2016). Also, in the energy industry, there is strong demand for greater energy supply and to reduce the carbon footprints of these processes. Both energy and water industries require the selective separation of millions of liquid components. These industries have a high demand for effective separation procedures to obtain clean water, gases, or solvents, which today make up a sizable share (10–15%) of global energy consumption (Sholl and Lively, 2016). Thus, there is a strong interest on the design and optimization of high efficiency separation processes. In ionic separation using electrodialysis and membrane

capactive deionization, the selection of the ion-exchange membrane (IEM) is very important as it can affect the energy efficiency during deionization (Palakkal et al., 2018).

Computational models that can bridge molecular descriptors to material properties and performance in electrochemical separation platforms are vital to advancing the field (Briceno-Mena et al., 2021). To understand the ionic transport between the solution and polymer, there exists a need to model the relationship defining this transport mechanism. Our primary macroscopic property of interest are the ion activity coefficients in polyelectrolytes. Activity coefficients influence the partitioning coefficient of an ion between the polymeric ion-exchange membrane and the liquid solution, and it can also affect ionic conductivity. However, accurate ion activity coefficient models based upon the physics and chemistry of the ion-exchange membranes is lacking. In fact, most activity coefficient models for ions in liquids rely upon empirical and semi-empirical approaches (e.g., Debye-Hückel or Pitzer models). These empirical and semi-empirical models often need large data sets for estimating the empirical constants in these models. Because there is a lack of data for ion activity in various ion-exchange membrane chemistries and structures, attaining effective and accurate activity coefficient models for these soft materials are elusive. Machine learning represents a unique tool to streamline model development for attaining accurate activity coefficients of polymeric ion-exchange membranes.

The Proposed ML network will bridge molecular scale attributes from molecular dynamics (MD) simulations to the ionic activity coefficients in polymeric ion-exchange membrane materials. Machine learning methods such as Support Vector Regression (SVR) and Random Forest (RFR) were used to connect the polymer fingerprint (based on chemical structure) and molecular level attributes (based on MD descriptors) to the macroscopic attribute of polymer electrolytes (i.e., activity coefficient). This work developed a ML framework that involves predicting the MD descriptors of ionomers. Ionomer molecular fingerprints, salt concentration and one-hot encoded categorical features of the salt ions were used. The main goal of this work is to predict ion activity coefficient in polymer electrolytes from the predicted MD descriptors, thereby serving as a tool for future users when there exists no MD data and experimental activity coefficient for a chosen polymer and salt ions.

## 2. Methods

More than ten original experimental reports containing ion activity coefficient values in ion-exchange membranes and thin films were collected from literature. We restricted our search to publications with detailed information about the structure of the copolymer, ion exchange capacity, water uptake and experimental ion activity coefficient. Polymer structures and salt ions represented by their SMILES representations and categorical variables, respectively were converted into numeric arrays using *RDKit* and the OneHotEncoder method in *Scikit-Learn*, respectively as shown in Figure 1.

With explicit counterions and salt ions, we simulated polyelectrolyte systems using molecular dynamics simulations. To represent polyelectrolytes, a system with 17 polymer chains, water and salt ions was prepared with PACKMOL package in conformance with experimental conditions. We adopted the OPLSAA or GAFF2 forcefield parameters and

TIP3P model for polymer and water respectively. The MD simulations were implemented in LAMMPS package. The simulations were then analyzed to compute the solvation properties of these polymer electrolyte systems including radial distribution function, coordination numbers and diffusion coefficients using final production run of 40ns long in the isothermal (fixed temperature at 300K using a Nose Hoover thermostat, constant number of particles and volume) ensemble.

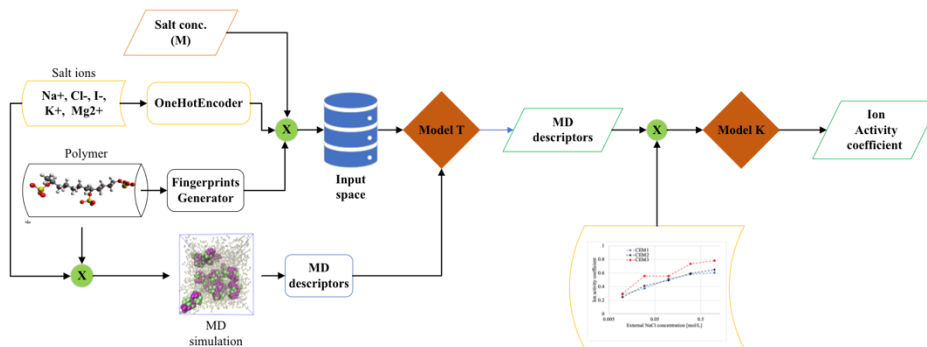

Figure 1: Workflow for modeling the prediction of MD descriptors and ion activity coefficient.

In this contribution, two regression models (Random Forest regression, RFR and Support Vector Regression, SVR) are compared to estimate the MD descriptors and ion activity coefficient. Figure 1 shows the framework for the model development. First, an ML model (*Model T*) was created to predict MD descriptors based on an input vector consisting of arrays of polymer fingerprints, one-hot encoded salt ions, salt concentration and number of water molecules per tethered ions. Secondly, another regression model (*Model K*) was created as shown in Figure 1 to predict the experimental ion activity coefficient. The input vectors consist of the MD descriptors (predictable from *Model T*) and the input matrix of model T. To train these models, the available dataset was split into training and test data. The model hyperparameters are tuned using the NSGA-II algorithm as implemented by *Pymoo*. The final model performance was quantified using coefficient of determination ( $R^2$ ), mean square error (MSE) and mean absolute error (MAE).

### 3. Results and Discussions

#### 3.1. Polymer space

Our studied dataset consists of 8 block copolymers and 3 random copolymers linked to experimental ion activity coefficients. To assess the similarity between the available copolymer, we computed the Tanimoto similarity ( $T_c$ ) which is the most popular and widely accepted similarity metrics for polymer chemistry. The results of the analysis are depicted in Figure 2. Two polymers are considered identical when the  $T_c$  equals 1 and completely different when the  $T_c$  equals 0. The similarity matrix showed that our selected polymers are very different from one another. Only the RCE and BCE forms of a polymer have high similarity values ( $>0.7$ ). This is expected because these polymer forms have

the same chemistry except with different arrangement of repeat units. Thus, a model generated from these polymers and will have a good generalization to other polymers with similar constituents because the sampled polymers exhibit great variation.

Figure 2: (a) Visualization of the similarity among the studied polymers and (b) sample space of the training and test input data used in machine learning.

During ML model development, greater attention must be given to the sample data. Specifically, by using similar train and test data, the impact of data discrepancies can be ameliorated and thus, gain a better understanding of the model's properties. To assess the conformational space of the training and test data, we computed the t-SNE plot, and the result is shown in Figure 2b. The analysis showed that the proportion of the sample space of the test data aligns strongly with that of the training set. Also, the t-SNE profile showed that the input matrix is well scattered and thus, an accurate ML model based on this input matrix will exhibit the better generalization to unseen data.

### 3.2. Prediction of MD descriptors

Figure 3. Boxplot showing the performance of the SVR model. Table 1 shows the description of the legends (A-N).

The SVR model was developed for a multi-output system. Here, the input features were transformed using principal component analysis to correct the effect of dimensionality reduction. Also, the target parameters (i.e., MD descriptors) were converted into a range (-1, 1). Afterwards, the transformed input and target data were imported to a SVR model and then trained based on the training set only. Figure 3 shows the statistical measure of the best model. From the perspective of the ML algorithm, the predicted MD descriptors exhibit close agreement with the target MD descriptors. Furthermore, the ML model based on the MF fingerprints shows a better predictive performance than the RDKit descriptor (not shown here); thus, a better representation of the studied polymer systems.

Table 1. The descriptions of the MD descriptions shown by the boxplot in Figure 3. (RDF refers to radial distribution function).

A	first minima of RDF between counterion and oxygen of water.	H	coordination number (at first minima) from RDF between charge bearing group (in polymer) and oxygen (in water).
B	peak position of RDF between counterion and oxygen of water	I	first minima of RDF between charge bearing group (in polymer) and counterion (in salt).
C	peak height of RDF between counterion and oxygen of water	J	peak position of RDF between charge bearing group (in polymer) and counterion (in salt).
D	coordination number (at first minima) of RDF between counterion and oxygen of water.	K	peak height of RDF between charge bearing group (in polymer) and counterion (in salt)
E	first minima of RDF between charge bearing group (in polymer) and oxygen of water.	L	coordination number (at first minima) from RDF between charge bearing group (in polymer) and counterion (in salt).
F	peak position of RDF between charge bearing group (in polymer) and oxygen of water	M	diffusion coefficient of water in polymer electrolyte per diffusion coefficient of pure water.
G	peak height of RDF between charge bearing group (in polymer) and oxygen of water	N	diffusion coefficient of counterion in polymer electrolyte per diffusion coefficient of pure water

### 3.3. Activity Coefficients Prediction

The model K was validated against existing datasets from the literature, giving confidence for generating additional ML models with both RFR and SVR. The test set is used to assess the model's performance on previously unexplored data. Prediction accuracy of Both RFR and SVR regression models were compared for predicting activity coefficients in figure 4a. Figure 4b illustrates the correlation between the model K predictions of the activity coefficients using RFR. An RFR architecture with max depth ( $D = 82.95$ ) with minimum sample split ( $W = 2$ ) was found to have the best hyperparameters for the model K implementation. With the optimized neural network, MSE values were 0.002 for fivefold cross-validation model training with RFR. This model might further be improved by expanding the scope of data set.

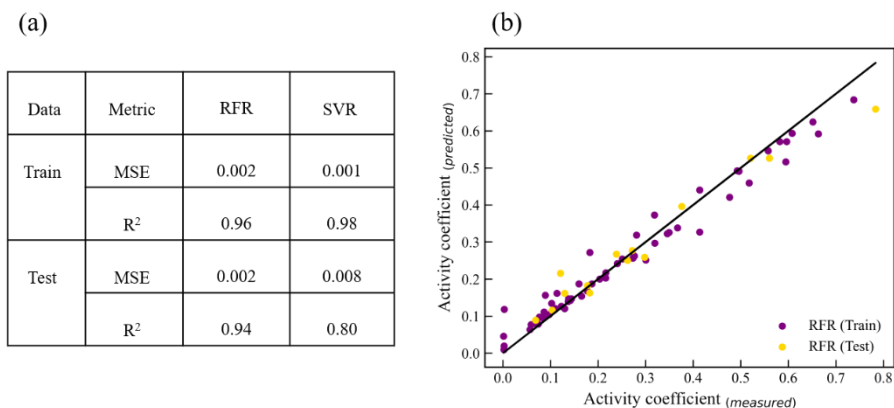

Figure 4. (a) Comparison of different model  $K$  for predictions of activity coefficients using RFR and SVR (b) Parity plot of predicted and experimental activity coefficients using the RFR.

#### 4. Conclusions

Machine learning identified physically meaningful patterns between molecular structure, molecular dynamics data and experimentally determined ionic activity coefficients in polymeric ion-exchange membranes and thin films. The outcomes of this framework can inform the rationale design of the materials that enable energy efficient and potentially selective ionic separations.

## Abstract

Hydrogen production as a renewable fuel source is an active area for the industry and researchers. NLP has been growing for the last few years as the need for extracting non-structural text data is accelerating with time. Here, in this work, we focused on the peer review articles on “Hydrogen production from alcohol” as a keyword for search in an Elsevier database. The abstracts are retrieved with the help of the “Elsevier API” key. We mainly focus on the article's abstract because it contains crucial points. The collated text data set combines two broad classes, i.e., relevant abstracts and non-relevant abstracts. The relevant abstract class stands for hydrogen production from alcohol-based abstracts. Other left-over abstracts will belong to the non-relevant class. The relevant abstracts are followed by the task of “Question and Answering” (Q&A), where we have selected a question, e.g. (a) What is the catalyst material used? Transfer learning implemented on the emerging model “BERT” will be utilized for these tasks. The finetuned BERT model is renamed H<sub>2</sub>-BERT. The H<sub>2</sub>-BERT performs well, with an accuracy of 0.980 for the train set and 0.974 for the test dataset for the classification task. For the task of Q&A, the data is prepared, fed to the “BERT” model and retrained the last layer weights. This downstream task gave outstanding results with 1.000 accuracy for the train set and an accuracy of 0.823 for the test dataset for accurately predicting the answer to their question based on the given context. This model will help readers extract the utilized catalyst name from the given text and make the process less time-consuming.

**Keywords:** Hydrogen production, NLP, H<sub>2</sub>-BERT, Classification, Q&A

## 1. Introduction

Nowadays, the requirement for energy is increasing with time, and the depletion of non-renewable energy resources is also happening [1]. Hydrogen is an excellent energy carrier and an environmental-friendly energy source for the future. Recently, many researchers have focused on the production methodology search of H<sub>2</sub> to fulfil the energy demand [2]. A quick search on google scholar will give us millions of patents and research articles. Accessing all of those sources of knowledge and digging deep will be challenging and tedious. It requires expertise in this field and a considerable time to get essential information, such as the catalyst used. All articles hide some crucial parameters that may help the industries to grow. A quick recommendation system can be built for the above reference to extract all the crucial information from available articles to ease access for academicians and industry practitioners. Machine learning and Natural language process (NLP) fields are gaining high popularity to help extract non-structural text data into structural information.

The BERT is a standard model in the NLP field, which stands for "Bi-directional encoder representation of transformers developed by google in 2018. The BERT model is well-trained on Wikipedia, Books, Journals corpus, etc. The downstream tasks performed by the BERT model are Classification, Name entity recognition (NER), and Q&A. It has two classes based on the size of layers of the encoder (i) BERT<sub>large</sub> (total parameters= 340 M, encoder layers =24) and (ii) BERT<sub>base</sub> (total parameters = 110 M, encoder layers =12). The performance of BERT encourages many researchers, so many versions of BERT have been launched. The most famous version of BERT is "Sci-BERT". It adopts the architecture of BERT and is trained from scratch with the vocab of computer science (85%) and biomedical (15%) literature. Other finetuned "BERT" are BioBERT, clinical-BERT, m-BERT, and FinBERT [3].

Implementing transfer learning on the BERT model has helped learn the hidden information from a new corpus of data. In this context, Kumar et al. have reported Classification followed by the with an accuracy of 0.997(test dataset) for Classification, and NER also has a good 0.890 (test dataset) accuracy for a finetuned BERT model called "Ex-SciBERT" [4]. Huang et al. created six battery-related BERT models with downstream tasks, Classification and Q&A [5]. Qu et al. have built a ConQA model based on the BERT model; it helps to get insights into historical data [6]. Some recent projects introduced an attention-based deep learning approach for NER tasks for material science literature and disclosed a synthesis procedure for all-solid-state batteries using a 243-article literature corpus.

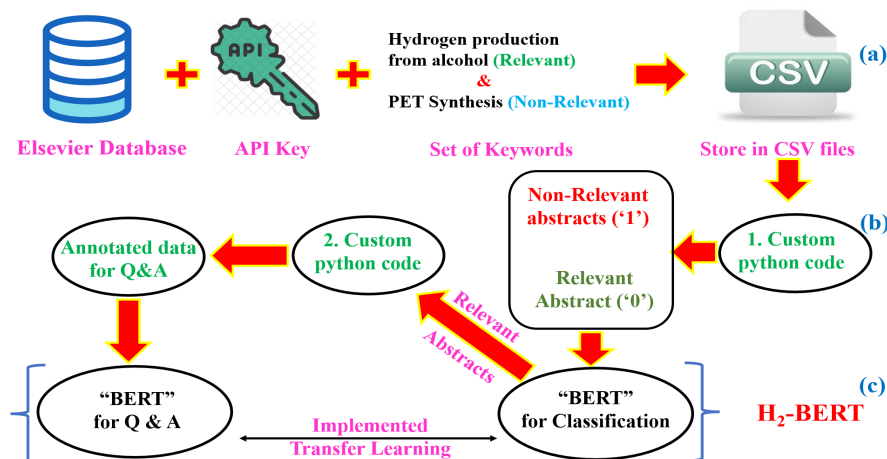

Figure: - (1) A Schematic diagram of the steps followed in this study. Where (a) signifies the steps for text extract, (b) stands for data annotation, and (c) shows transfer learning implementation on the BERT model.

In this study, we propose to develop a finetuned BERT mode for Q&A tasks related to the text that contains information on "Hydrogen production from alcohol" ". First, we will classify relevant class abstracts (means related to hydrogen production information) from the group of abstracts. The relevant abstracts will be processed, and a specific question will be asked. For clear visualization, see Figure 1, where each step of the proposed framework is showcased. The structure of the proposed study is as follows: Section 2 for data extraction and annotation, discussed the proposed model in Section 3, Section 4 for Result & Discussion and at last, a conclusive remark on the proposed study.

## 2. Data collection and annotation

We have utilized the application programming interface (API) API key to access the complete database of Elsevier. The keywords for the search are “Hydrogen production from alcohol” and a random keyword like "PET synthesis". The total number of accessible abstracts is 11397 using mentioned keywords.

The preliminary steps for cleaning all available abstracts are as follows; delete duplicate entries, some unwanted symbols, etc. These steps are implemented with the help of the "NLTK" library. For the task of Classification, relevant abstracts are marked as '0', and the rest of the other abstracts are labelled as '1'. Afterwards, only relevant abstracts are further processed for configuring the data for the task of Q&A. For both annotations of the dataset, two highly dedicated python scripts are written. The Q&A dataset has a specific question: (i) What is the catalyst material used?

The 'Chemdataextractor' library extracts the chemical entities from given relevant class abstracts, followed by a catalyst filter. It means a set of most probable catalyst elements. It helped to dig out only feasible chemical entities as catalyst material. In Figure 2, all reliable catalyst entities are shown with the help of a word cloud plot. After completion of data annotations, the datasets are fed to the BERT model for respective tasks.

Figure: - (2) All extracted catalyst entities are shown in the word cloud.

## 3. The proposed model: H<sub>2</sub>-BERT

The Classification and Q&A tasks are performed using the BERT architecture and only updating the last layer weight. The BERT architecture that we have chosen has 12 encoder layers, with each encoder's input layer could have a maximum of 512 tokens. The attention layer is the significant difference that makes the "BERT" model more robust for text mining than other sequence-to-sequence models. The BERT model can quickly produce sentiment and contextual outputs.

### 3.1. Transfer Learning Framework

Transfer learning is a method to reuse the pre-trained weights of the model by skipping the high computational power and time. In our work, we utilize transfer learning to finetune the pre-trained BERT model's last layer weights on our annotated datasets. The training is carried out on a compute cluster with a 32GB GPU in the Python environment using the “PyTorch” framework. The hyperparameters during finetuning are learning rate, number of epochs, and sequence length. We optimized the following hyperparameters for the best performance: epoch= 3, maximum sequence length = 256, learning rate = 0.000003, hidden activation =” gelu”, hidden dropout = 0.1, hidden size = 768, maximum

position embedding 512, number attention heads = 12, vocabulary size = 28996, and loss function = "Cross-entropy loss". Similarly, for the Q&A task, we have optimized hyperparameters: epochs= 10, learning rate= 0.00004, maximum sequence length = 512, optimizer= AdamW, number of best sizes =3, and loss function is cross entropy. We have implemented the early stopping in both cases to avoid overfitting the model.

## 4. Results and Discussion

### 4.1. Statistical analysis of available relevant abstracts

We have obtained a total number of relevant abstracts equal to 5864 related to "Hydrogen production from alcohol" from an Elsevier database search. We have done some statistical analysis of the abstracts represented in the box plot. The box plot presents the dataset maximum, third quartile, median, first quartile, and minimum. The upper and lower bound of the median have covered the 50%-50% of the dataset, as indicated in Figure 3. The number of sentences in abstracts and the average length of each word in the abstract is shown in Figure 3(a); approximate mean values are 7 and 5, respectively. Similarly, the number of words and a number of stop words are represented in Figure 3(b), with mean values around 200 and 143, respectively.

Figure: - (3) The box plots with statistical analysis of some key parameters are shown, (a) Number of sentences and Average length of words present, (b) Number of words and Count of stop words present in each relevant abstract.

### 4.2. Classification and Q&A using $H_2$ -BERT

An annotated dataset for Classification has two classes: relevant and non-relevant. The dataset is well balanced, approximating 50%-50% of both classes. The data set is divided into the training dataset of 70% test dataset of 30%. While training, cross-validation is 30% of the training dataset to make the model robust. The learning curve with train loss and validation loss with values 0.0694 and 0.0785, respectively. The loss function is cross-entropy.

Moreover, the confusion matrix for the test dataset is shown in Figure 4. The final accuracy, precision and recall, and F1-score value of the model for the Train and test dataset are tabulated in Table 1. The accuracy of the Train set is 0.980, and the test has an accuracy value of 0.974.

Figure: - (4) The performance evaluation of the classification task by the H<sub>2</sub>-BERT model (a) The variation of loss per epoch (b) Confusion matrix for the test dataset.

Table: - (1) The performance metric values for the task of Classification of the H<sub>2</sub>-BERT.

Type of data	Name of label	Precision	Recall	F1-score	Counts
Train	Relevant (0)	0.98	0.99	0.98	4112
	Non-relevant (1)	0.99	0.97	0.98	3865
Accuracy	0.980				
Test	Relevant (0)	0.97	0.98	0.97	1752
	Non-relevant (1)	0.98	0.96	0.97	1668
Accuracy	0.974				

Similarly, the Q&A task is performed on the architecture of "BERT" and finetuned weights of the last layer only. We have tabulated the performance of this model in Table 2, where Correct, Similar, and Incorrect predictions and total data points are mentioned. The correct answer means that the prediction and true answer are an exact match, and a similar answer means some portion of the prediction and true answer matched; the rest predictions are entirely wrong. If we consider [correct + similar] answers as right out of total data points, the calculated accuracy for Train and test are 1.000 and 0.823, respectively. At last, we took some random abstracts and checked the class of abstract, whether relevant or non-relevant abstract. Subsequently, we took only relevant classes for further processing. A question (What is the catalyst material used?) was asked, the given abstract as context. The predictions are tabulated in Table 3. These two tasks are performed sequentially.

Table: - (2) Performance of the H<sub>2</sub>-BERT for the task of Q&A.

Type of data	Correct	Similar	Incorrect	Total
Train	1734	5	0	1739
Accuracy	1.000			
Test	243	64	66	373
Accuracy	0.823			

Table: - (3) The Q&A prediction on some random abstracts, **bold**, *italic*, and underlined, used for highlighting catalyst entities are present in the abstract, which are predicted correctly, similarly and incorrectly, respectively.

Abstract	Predicted-Catalyst
.... over a series of <b>y-Al<sub>2</sub>O<sub>3</sub></b> supported metal NPs catalyst....	y-Al <sub>2</sub> O <sub>3</sub>

## 5. Conclusion

In this proposed work, we have implemented NLP tools for information extraction in the form of catalyst entities from scientific literature data. The text data are accessed with the help of the "Elsevier API key" from the complete database of Elsevier. The extracted abstracts are a mixture of relevant and non-relevant classes. The abstracts are annotated with python scripts for the classification task and Q&A task. These annotated datasets are utilized to retrain the weights of the last layer for task classification and Q&A of "BERT" architecture. The model's performance for Classification and the Train and test accuracy are 0.980 and 0.974, respectively.

Similarly, the accuracy of the finetuned model for Q&A for the Train is 1.000, and the test has 0.823, precisely answering the question. As a result, human effort is expected to be reduced in extracting the names of the catalyst entities for identifying catalysts from scientific text and making the process less time-consuming.

# Simulation of low-temperature district heat networks from mine water energy

Thomas Cowley,<sup>a</sup> Timothy Hutty,<sup>a</sup> Solomon Brown<sup>a</sup>

<sup>a</sup> *Department of Chemical and Biological Engineering, University of Sheffield, Sheffield, S1 3JD, United Kingdom, s.f.brown@sheffield.ac.uk*

## Abstract

Mine water sourced district heat networks (DHN) are a pathway for reducing emissions of the heating sector. Here, an agent-based model for network dynamics is developed and showcased through a case study in the South Yorkshire Mayoral Combined Authority (SYMCA), consisting of 3437 domestic buildings and 8 non-domestic buildings used as anchor loads. The results show that the mine water DHN achieved a levelised heat (LCOH) cost of 12.6p/kWh compared to the boiler-only scenario of 6.8p/kWh. Emissions in the region could be reduced by 83.6% and can compete with boilers with a natural gas price of 10.8 p/kWh, highlighting the potential of mine water energy for decarbonising the heating sector.

**Keywords:** energy, heat decarbonisation, district heat networks, agent-based modelling

## 1. Introduction

To meet Net-Zero by 2050, the heating sector in the UK needs innovation and development. Currently, 85% of residential buildings utilise a natural-gas grid connection composed of standalone boilers (BEIS, 2022). The UK's Sixth Carbon Budget restricts new gas grid connections by 2025 and prescribes the phase-out of boilers by 2035 (Committee on Climate Change, 2020). This allows district heat networks (DHN) to penetrate the heating sector. Approximately 25% of UK homes are built above abandoned mine workings which are flooded with water between 10-20°C (The Coal Authority, 2021). With this source of low-grade heat, large-scale heat pumps can achieve a higher coefficient of performance (COP) due to the warmer energy source and better thermal efficiency due to the proximity of the source to heat demand.

Mine water networks are susceptible to location-specific parameters, and models should include features such as GIS to improve accuracy and spatial interactions between agents. A review (J. Keirstead et al, 2012) of 219 publications found that only 44% of models incorporated spatial features, and 58% used a yearly temporal scale or greater. Additionally, only a few studies incorporate fully dynamic models, most focusing on techno-economic studies, singular node simulation, and steady-state models (J. Wang et al, 2016). The work of E. Guelpa et al (E. Guelpa, 2020) analyses the relevance of implementing network dynamics such as thermal losses, time delay propagation and thermal transience. The results found that these phenomena had a significant impact when changes to the operating mode (i.e., during the night, start-up, shut-down), demand peaks and large variations in volumetric flow rate. Similarly, work by J. Allegrini (J. Allegrini, 2015) confirms that network dynamics contributed to a 20% discrepancy between the simulated thermal peak request and the measured data. Capturing these dynamics will

vastly improve the accuracy of an extensive network simulation with variable flow at a short time resolution.

It will be of interest to project planners to gauge if a heat network project utilising mine water can reduce emissions and provide competitive heat prices to consumers (BEIS, 2018). Therefore, this work aims to model the network dynamics using an agent-based approach to decrease computational intensity, allow flexibility of location-based parameters, and incorporate network dynamics in an extensive network. Undertaking techno-economic analysis while capturing these features will help understand the trade-off between the cost and emissions of a region with mainly standalone gas boilers. Hence, the objectives are to:

- Develop an agent-based model to capture the network dynamics of DHNs
- Showcase the model through a techno-economic case study and determine at what price of natural gas the proposed heat network becomes a viable investment.

## 2. Methodology

This work aims to simulate the extraction of mine water energy from unused coal mine workings to supply domestic and non-domestic heating demand. The mine water heat is upgraded via large-scale heat pumps at a geothermal plant located above the mine workings, intersected by a borehole, and distributed around a network of pipes. A visual representation of the model is shown in Figure 1. Simulation of a DHN is an inherently complex system; therefore, to reduce the computational intensity of the model, only the phenomena that have a significant impact on the accuracy of the network dynamics are included. Thus, the following assumptions have been made:

- Water properties are constant parameters.
- Water is considered an incompressible fluid.
- Flow within pipeline agents is one-dimensional.
- Heat loss to the surroundings is one-dimensional.
- There is no degradation of piping material or insulation over the simulation time
- Axial conduction in each pipe is considered insignificant.
- The pressure drops in the pipeline agents have negligible viscous heating effects.
- Perfect mixing and adiabatic operation when flow combines at junctions.
- Non-constant terms in the momentum equation are neglected
- Pressure loss and efficiency losses within the HIU are considered insignificant

The model uses node agents, which consist of geothermal plant centres (GCs), demand centres (DCs), junctions (J) and pipes with start and end points at nodes and are classed as pipeline agents (P). An arbitrary number of pipeline agents can connect to a single node. Each node agent has several parameters, which are pre-determined and describe its location and whether there is a physical connection to the network. Each pipeline agent is tied to the corresponding start and end node agents. The length of each pipeline agent is calculated by geolocating the distance between the start and end node agents. All primary agents (GC, DC, J, P) interact with each other within a GIS space. Water packet agents are classed as secondary agents and are instantaneously generated in the case of volumetric flow or temperature changes in the network. The water packet agents allow heat propagation from a source at a finite speed, so that time delays over large distances are captured. The pipeline agents form the distribution network that follows the network's topology, while junction agents allow the splitting of flow and integration of loops. Generation centres and junctions have pumping stations that maintain the network's

pressure, and the pressure block calculates its pumping requirements. The demand model block uses a linear regression model at multiple time intervals and assigns buildings to five archetypes: non-domestic (housing), leisure, education, commercial and residential. The thermal sub-model calculates the radial heat loss from the pipe to the soil and accounts for transient heat loss when the water in the pipes is stationary, and there is no flow. The mass flow model uses linear programming to maximise the flow through the distribution network.

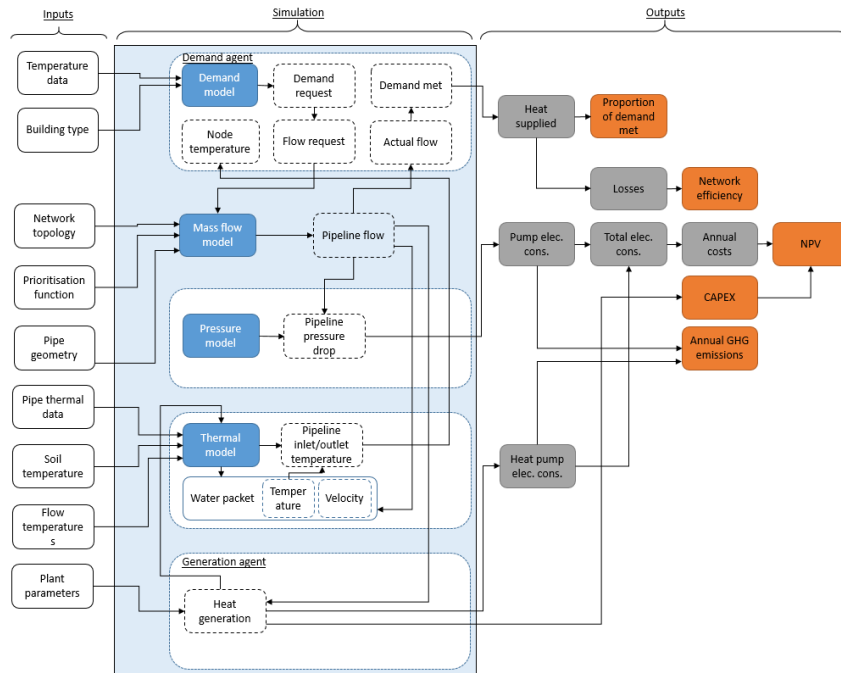

Figure 1 - Flowchart of heat network dynamic model

### 2.1. Case study

The case study location has many flooded mine workings; this provides an ambient and stable body of renewable low-grade heat. A borehole was chosen from the Coal Authority BGS database (British Geological Survey, 2022) nearest the heat demand and intersected the flooded mine workings at a temperature of 18 °C and a depth of 332 m. 3445 buildings were allocated to the five building archetypes (Commercial: 2, Education: 4, Leisure: 1, Residential: 1), with 3437 domestic buildings aggregated into 13 different demand agents. Eight non-domestic buildings are used as anchor loads to ensure consistent demand on the network. Analysis of the costs incurred by negating emissions from standalone boilers will inform the region of the use of mine water energy to decarbonise its heating sector; therefore, the case study is run with the same demand profiles generated from the demand model block for both the mine water heat network and boilers-only scenarios, while assuming an 80% efficiency for each individual boiler. Table 1 shows the parameters for the case study. A COP of 4.9 (A. David et al, 2017) has been selected as it is aligned with values from the literature that aggregate the supply and return temperatures of 58 different European heat networks. Table 2 shows the cost parameters used for the techno-economic analysis. Temperature data from 2021 (Met Office, 2021) is used as input into the demand

sub-model. The network length is generated by the model and is ca. 12 km. Pipe dimensions were calculated pre-simulation using insulation class 1 pipes (Fintherm, 2019). The maximum pipe velocity was 5 m/s to prevent rapid degradation of piping material and to adhere to noise, safety and vibration regulation.

Table 1 – Network parameters

	Value
Pump efficiency (%)	80
Motor efficiency (%)	80
Network pressure (kPa)	1,500
Supply temperature (°C)	68
Return temperature (°C)	18

Discount rate (%)	3.5

### 3. Results & Discussion

The simulation was run for one year (8760 hours) for the mine water scenario and the boiler-only scenario using temperature data from 2021. Tables 3 and 4 show the KPIs (Key performance indicators) and costs for both scenarios. The mine water scenario showed a high efficiency of 96.3% by the heat network and met 99.98% of the region's demand. This highlights the model's success in distributing the heat effectively to consumers while minimising the heat lost to the surrounding soil compared to the generated heat. 0.02% of the demand was not supplied to the consumers due to the water velocity constraints. These consumers tended to be at the end of the network.

Figure 2 shows the total demand on the network across the year and the variations over each day. As the network consists of mainly non-domestic buildings, this has a more significant effect on the demand profile of the network. The demand on the network during winter is greater than during summer, so the buildings are maintained at a comfortable temperature. Demand peaks between 6:30 and 10 am as more hot water is needed for showers before people go to work, and building heating is turned on. There are also peaks between 16:00 and 23:00, as the heating is turned back on as people get back from work. This is less prominent in the summer months, but there is still, on average, some smaller peaks in the morning. During the night, the network cools, and this is due to heat being lost when the water in the network is stagnant; this is the effect of transience in the network. Positive demand is seen on the network throughout the year due to the anchor loads provided by the non-domestic building types.

BEIS reported that the average household energy consumption of a typical domestic dwelling was 12.3 MWh/year (A. O'Mahoney, 2020); this corroborated the demand model results with an average of 12.2 MWh/year over the 3437 domestic buildings. The mine water network scenario emitted 1807 tCO<sub>2</sub>e, whereas the boiler-only scenario 11013 tCO<sub>2</sub>e, thus achieving achieved 83.59% reduction in emissions compared

to boiler-only scenario. Over a 30-year lifetime, 276 million tCO<sub>2e</sub> could be saved by 2050. Mine water LCOH (Levelised cost of heat) obtained was 12.4 p/kWh, which is slightly more economical than work by O. Gudmundsson et al (O. Gudmundsson et al, 2013), which found that geothermal DHN achieved 14.0 p/kWh for outer city projects. The boiler-only scenario obtained an LCOH of 6.8 p/kWh, significantly lower than the literature value of 11p/kWh. The disparity may have been due to lower efficiencies in actual gas boiler installation or underestimated cost parameters. The NPV (Net present value) of the boiler-only scenario is -£90.5 million, whereas the heat network NPV requires 46.3% more investment totalling -£132.4 million. The disparity in NPV is primarily due to the already extensive gas infrastructure in the UK and the price of natural gas. The mine water network scenario can abate emissions at an average cost of 151.7£/tCO<sub>2e</sub> over its lifetime.

Table 3 – KPIs from the case study

	Mine water	Boiler-only
Efficiency (%)	96.3	80
Heat demand (MWh/year)	41,964	-
Heat supplied (MWh/year)	41,955	-
Heat generation (MWh/year)	43,594	52444
Demand supplied (%)	99.98	100
Pumping power (MWh)	529.55	-
Heat pump output (MW)	18.75	-
Emissions (tCO <sub>2</sub> )	1,807	11,013
Emission savings (%)	83.59	0

Table 4 – Costs over a 30-year lifetime

	Mine water	Boiler-only
Total capital cost (£)	60,880,000	24,421,000*
Total operating cost (£)	43,077,000	-
Total energy cost (£)	28,418,000	66,054,000
Total cost over lifetime (£)	132,379,000	90,475,000
LCOH (p/kWh)	12.38	6.77

\*Both capital and operational cost

Figure 2 – Average heat demand of nodes in the heat network over the year (and over the day)

The wholesale gas price has seen a significant increase in the final quarter of 2021 due to the high demand for natural gas, and even more so in 2022 with the start of the war in Ukraine. 2020 saw the wholesale gas price at a minimum of 4.39 p/kWh, and a maximum of 27.30 p/kWh (Trading Economics, 2021); therefore, DHN would provide a more stable price of heat and improved energy security for customers by providing protection from global fluctuating gas prices. If the gas price trends upward, the mine water scenario becomes more economically attractive. The sensitivity analysis in Figure 3 shows that mine water can provide competitive prices at a natural gas price of 10.8p/kWh.

Figure 4 shows the percentage change in the LCOH when the total heat demand, capital cost and operational costs are modified by plus or minus 50%. The network is more sensitive to demand changes than operational costs, as it increases by roughly 18%

when the demand on the network is reduced by half. In contrast, it decreases by roughly 5% when demand is increased by half. Moreover, decreasing the capital and operational costs by 50% leads to a decrease in the LCOH of 16% and 24%, respectively. The energy costs of the Levelized cost method are assumed to be constant over the technologies' lifetimes. They are not the prices to sell energy. Hence, it does not reflect energy prices' short-term or long-term volatilities.

Figure 3 – LCOH as a function of gas price

Figure 4 – LCOH as a function of changes to costs and demand

#### 4. Conclusion

Utilising renewable energy sources with DHN is a possible way of decarbonising the UK's heating sector. Mine water energy paired with large-scale heat pumps is proven throughout European projects. Current research lacks accurate modelling of network dynamics. The model successfully captured the network dynamics and expected network demand profiles and obtained an efficiency of 96.3%. The case study was found to reduce the region's carbon emissions by 83.59% and provide an average LCOH of 12.38 p/kWh over the project's lifetime. Sensitivity analysis shows that the project became economically feasible at a natural gas price of 10.8p/kWh, highlighting a promising pathway to reduce emissions.

## **Abstract**

The biomass productivity of photo-autotrophic microalgae is known to be influenced by a plethora of environmental factors, with light being the most notable one. Given the critical role of light in the complex metabolic network of microalgae, conditionally directing the carbon flow either towards biomass growth or lipid accumulation, the empirical operational design of a photobioreactor system can only be suboptimal. This task becomes even more mazy in larger scales, where the culture growth results in more intensive light attenuation. The present work analyses the importance of a structured, distributed mathematical model for the design of optimal lighting policies of a photobioreactor, and investigates the successful shift of microalgae cultures from a lab to a pilot scale unit. The key contribution of this study is to help realize the performance bounds of a photobioreactor depending on its geometry and size and to showcase how to deal with the lighting policy when scaling-up of a microalgae bioreactor is desired.

**Keywords:** Lab/pilot scale photobioreactor; Structured macroscopic/kinetic model; Dynamic optimization; Light path; Photobioreactor design.

## **1. Introduction**

Despite the ever increasing academic and industrial attention and research on microalgae based biorefineries over the last decades, the commercialization of microalgae products is hindered by the low productivity of photobioreactors and open culture systems. Particularly in autotrophic cultures, light is the most notable limiting growth factor. Its availability inside the culture volume is significantly limited by the high optical density of microalgae suspensions. Since the measurement of light intensity inside the culture often requires expensive equipment, the empirical deduction of lighting policies that maximize biomass production is unfeasible. Model-based optimization has the potential to facilitate the above task, supporting the sustainable use of microalgae in nutritional and biofuel applications, and fill in the gaps in our understanding of the impact of the lighting on microalgae growth.

In this study, a multi-physics mathematical model is developed and validated, with the view to systematically obtain the optimal lighting policies that maximize biomass growth inside stirred photobioreactors. Three scenarios are devised that reflect the impact of scale up on process performance, which is assessed by proper process KPIs.

## **2. Model development**

In a photoautotrophic culture, microalgae fix CO<sub>2</sub> into organic carbon photosynthetically, and subsequently mobilize it, in the presence of nitrogen and phosphorus, to synthesize

the cellular machinery needed for cell division and maintenance. Furthermore, microalgae store their organic carbon in the form of carbohydrates and/or lipids, especially when their environment becomes limiting, i.e., nutrient exhaustion. A distributed/structured dynamical model is developed to describe the dynamic operation of typical stirred photobioreactors (PBRs) employed for microalgae cultures. The model has been built up upon the well-established Droop model (Droop, 1983), incorporating biological phenomena like photoinhibition and photo acclimation, via chlorophyll-a dynamics. Carbon allocation and product synthesis (i.e., carbohydrates, proteins, and lipids) are dependent on the internal state of the cell as well as the nutrient availability in the culture medium. The one-dimensional Cornet model (Cornet et al., 1992a, 1992b) is adopted and modified in order to describe the light gradients that develop inside the photobioreactor along with the evolution of microalgal biomass and pigment content. Tables 1 and 2 summarize the dynamic mass balances and the specific rates of the model.

**Table 1:** Dynamic mass balances of the model.

$$\begin{aligned} \frac{d(V_l[O_{2,l}])}{dt} &= Q_{l,fd}[O_{2,l,fd}] - Q_{l,out}[O_{2,l}] + V_lOTR + V_lY_{CO_2}\langle\mu\rangle X - V_lY_{CO_2}RX \\ \frac{d(V_l[CO_{2,l}])}{dt} &= Q_{l,fd}[CO_{2,l,fd}] - Q_{l,out}[CO_{2,l}] + V_lCTR + V_lY_{CO_2}RX - V_lY_{CO_2}\langle\mu\rangle X \\ \frac{d(V_l[O_{2,g}])}{dt} &= Q_{g,fd}[O_{2,g,fd}] - Q_g[O_{2,g}] - V_lOTR \\ \frac{d(V_g[CO_{2,g}])}{dt} &= Q_{g,fd}[CO_{2,g,fd}] - Q_g[CO_{2,g}] - V_lCTR \\ \frac{d(V_l)}{dt} &= -\frac{d(V_g)}{dt} = Q_{l,fd} - Q_{l,out} \\ \frac{d(V_l[N_l])}{dt} &= Q_{l,fd}[N_{l,fd}] - Q_{l,out}[N_l] - V_l\langle\rho_N\rangle X \\ \frac{d(V_l[P_l])}{dt} &= Q_{l,fd}[P_{l,fd}] - Q_{l,out}[P_l] - V_l\rho_P X \\ \frac{d(V_lXq_N)}{dt} &= \langle\rho_N\rangle \\ \frac{d(V_lXq_P)}{dt} &= \rho_P \\ \frac{d(V_lX)}{dt} &= Q_{l,fd}X_{in} - Q_{l,out}X + V_l(\langle\mu\rangle - R)X \\ \frac{d(V_l\theta X)}{dt} &= V_l\frac{K_{acc1}\theta}{\theta_{ad}}(\theta_{ad} - \theta), \frac{\theta_{ad}(I)}{q_N} = \varphi_{max}\frac{k_I^*}{k_I^* + (I)} \\ \frac{d(V_lC)}{dt} &= Q_{l,fd}C_{fd} - Q_{l,out}C + V_l\langle\mu\rangle X - V_lr_{C,Pr}X - V_lr_{C,L}C - V_lRX \\ \frac{d(V_lL)}{dt} &= Q_{l,fd}L_{fd} - Q_{l,out}L + V_lr_{C,L}C + V_lD_pPr \\ \frac{d(V_lPr)}{dt} &= Q_{l,fd}Pr_{fd} - Q_{l,out}Pr + V_lr_{C,Pr}X - V_lD_pPr \end{aligned}$$

where:  $[O_{2,i}]$   $[CO_{2,i}]$  oxygen and carbon dioxide concentrations (gas & liquid phase);  $[N_l]$ ,  $[P_l]$  nitrogen and phosphorus concentrations;  $q_N$ ,  $q_P$ ,  $\theta$  nitrogen and phosphorus and chlorophyll-a cellular quotas;  $X$ : biomass;  $C$ : carbohydrates;  $L$ : lipids;  $Pr$ : proteins;  $R$ : respiration rate;  $OTR$ ,  $CTR$ :  $O_2$  and  $CO_2$  transfer rates;  $Y_{CO_2}$ :  $CO_2$  to biomass yield coefficient;

### 3. Model validation and biomass optimization.

Experimental data from the work of Psachoulia and Chatzidoukas, (2021) were utilised in the scope of parameter tuning. The datasets contain dynamic information about the main macroscopic process variables (nutrients, biomass, intracellular products) in *Stichococcus sp.* photoautotrophic cultures in a lab stirred photobioreactor. The modified Cornet sub-model was validated offline using the experimental data from Ma et al., (2022).

**Table 2:** Specific growth/uptake/production/consumption rates of the model.

$$\rho_P = \rho_{P,max} \left( \frac{[P_l]}{K_{S,P} + [P_l]} \right) \left( \frac{q_{P,max} - q_P}{q_{P,max} - q_{P,min}} \right)$$

$$\rho_N(r) = \rho_{N,max} \left( \frac{[N_l]}{K_{S,N} + [N_l]} \right) \left( \frac{q_{N,max} - q_N}{q_{N,max} - q_{N,min}} \right) \left( \frac{q_P - q_{P,min}}{q_{P,max} - q_{P,min}} \right) \left( \eta + (1 - \eta) \frac{l}{l + \epsilon_l} \right)$$

$$\mu(r) = \mu_{max} \frac{l}{l + K_{S,l} + \frac{l^2}{K_{il}}} \frac{S_{CO_2,l}}{K_{S,C} + S_{CO_2,l}} \left( 1 - \frac{[O_2,l]}{[O_2,l,max]} \right) \left( 1 - \frac{q_{N,min}}{q_N} \right) \left( 1 - \frac{q_{P,min}}{q_P} \right)$$

$$r_{C,Pr} = \alpha \langle \rho_N \rangle$$

$$r_{C,L} = \mu_{c,s} + \mu_{c,m} = \mu_{c,m,max} \frac{q_N}{q_{N,max}} + \mu_{c,s,max} \left( 1 - \frac{q_N}{q_{N,max}} \right)$$

$$D_p = \gamma \mu_{c,s}$$

$$I(r) = I_0 \frac{4\alpha_1}{(1 + \alpha_1)^2 e^{a_2 r} - (1 - \alpha_1)^2 e^{-a_2 r}}; \alpha_1 = \sqrt{\left( \frac{E_a' k_a \theta}{E_a' k_a \theta + E_s} \right)}; \alpha_2 = (E_a' k_a \theta + E_s) \alpha_1 X$$

$$\langle z_i \rangle = \frac{1}{V_l} \int_{V_l} z_i(x) dx, \text{ where } z_i: \rho_N(r), \text{ or } \mu(r), \text{ or } I(r)$$

where:  $\rho_P$ : specific phosphorus uptake rate;  $\rho_N(r), \mu(r)$ : specific nitrogen uptake rate & specific growth rate at depth r;  $r_{C,Pr}, r_{C,L}$  specific carbon allocation rate to proteins & lipids;  $D_p$  specific protein degradation rate to lipids;  $I_0, I(r)$  Incident light intensity & light intensity at depth r.

Subsequently, the validated model was used to guide the optimization of a batch photobioreactor, in the context of biomass production, on three different spatial scales. The incident light intensity on the photobioreactor lateral surface,  $I_0$ , is the sole control variable of the problem, and is modelled as a piecewise-constant function using ten 1-day time intervals. The three different scenarios are presented below, whereas the characteristic dimensions of the three photobioreactors are detailed in Table 3:

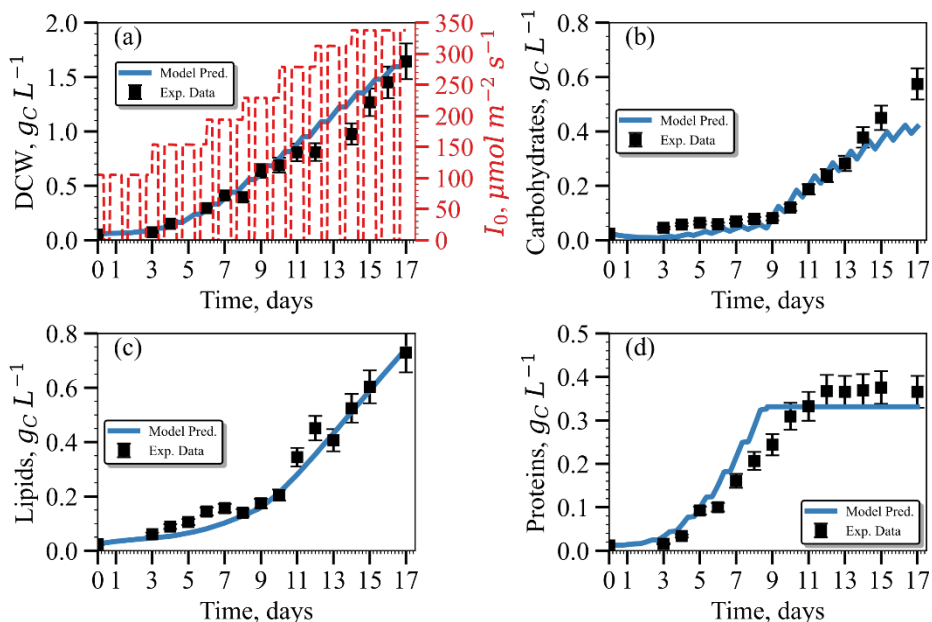

**Table 3:** Characteristic dimensions and optimization strategies of the three PBRs.

PBR ID	Diameter, T (m)	Height, H (m)	Working volume, $V_l$ (L)
1	0.16	0.16	3.2
2	0.32	0.32	25
3	0.16	9.9	200
<b>Scenario 1:</b> Maximization of the final biomass concentration in the lab PBR.			
Task: $\max_{I_0} \mathbf{Obj}_1$	$Obj_1 = X_{PBR1}$		Operational constraint $50 \leq I_0 \leq 2,000$ $\mu mol m^{-2} s^{-1}$
w.r.t model equations of <b>Tables 1 and 2</b>			
<b>Scenario 2:</b> Optimal tracking of the biomass profile achieved in the lab scale by the semi-pilot PBR.			
Task: $\min_{I_0} \mathbf{Obj}_2$	$Obj_2 = \int_0^{t_f} \left( \frac{X_{PBR1} - X_{PBR2}}{X_{PBR1}} \right)^2 dt$		Operational constraint $50 \leq I_0 \leq 3,000$ $\mu mol m^{-2} s^{-1}$
w.r.t model equations of <b>Tables 1 and 2</b>			
<b>Scenario 3:</b> Optimal tracking of the biomass profile achieved in the lab scale by the pilot PBR.			
Task: $\min_{I_0} \mathbf{Obj}_3$	$Obj_3 = \int_0^{t_f} \left( \frac{X_{PBR1} - X_{PBR3}}{X_{PBR1}} \right)^2 dt$		Operational constraint $50 \leq I_0 \leq 3,000$ $\mu mol m^{-2} s^{-1}$
w.r.t model equations of <b>Tables 1 and 2</b>			

An energy efficiency factor, adopted to compare the performance of the three PBRs, is defined as the produced biomass per unit of lighting power input:  $e = \frac{x}{\alpha \cdot I_0 \cdot A_{lat}} \cdot \left(\frac{gL^{-1}}{W}\right)$ , where  $A_{lat}$  is the illuminated surface area of the PBR and  $\alpha = 0.219$  is a conversion factor between  $\mu\text{mol m}^{-2} \text{s}^{-1}$  and  $W \text{ m}^{-2}$ .

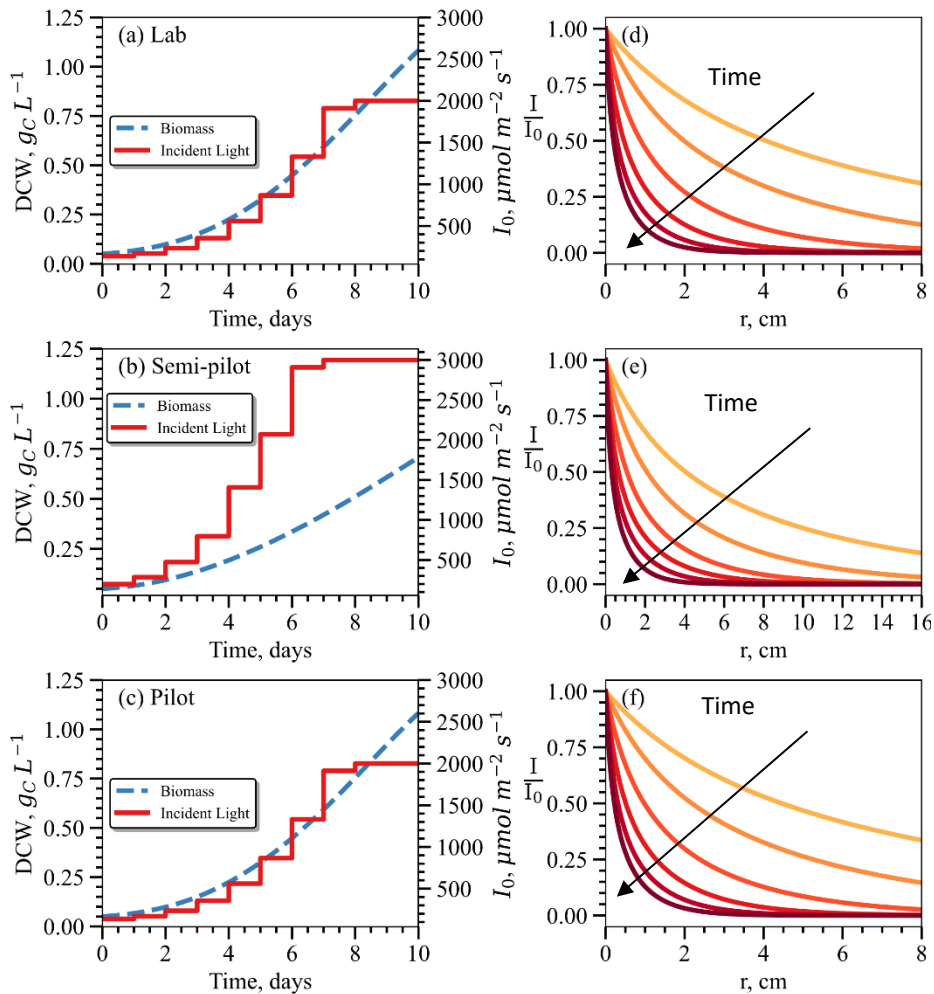

#### 4. Results and discussion.

The model predictions are plotted against the experimental data in Figure 1. The dynamic trajectory evolution of the main state variables is represented by the model, thereby establishing a sound basis for further exploration of the optimal lighting policies that maximize production on different scales.

**Figure 1:** Comparison of the model predicted time trajectories to the experimental data: a) biomass dry cell weight concentration; b) carbohydrates; c) lipids and d) proteins.

Figure 2 depicts the optimal lighting policy for a batch mode cultivation along with the corresponding biomass evolution trajectory, on the three spatial scales. The increasing culture density promotes progressively steeper light gradients inside the culture volume. This results in constantly escalating lighting demand until the point of saturation. In Scenario 1, the overall increased energy input to the system, compared to the validation experiment, results in approximately a 35% increase in volumetric productivity, demonstrating the value of model-based optimization. In Scenario 2, the lighting profile that will steer the semi-pilot PBR on the respective biomass growth trajectory attained in the lab PBR is sought. Despite the increase in light provision in this setup serious loss in biomass productivity is observed. This is entirely attributed to the large proportion of “dark volume” in the semi-pilot PBR as one can deduce inspecting the spatial profile of light distribution reducing sharply over time (Figure 2 d-f). On the contrary, in Scenario 3,

**Figure 2:** Light optimization in three spatial scales. (a-c): biomass trajectory and incident light profile; (d-f): Light gradients inside the PBRs during a batch cultivation.

the biomass evolution in the PBR with the largest height/diameter ratio is identical to its lab scale counterpart. Though it may seem that tall and skinny geometries can pave the way to a successful scale-up of microalgae cultures, one should address this matter from a techno-economic viewpoint as well. Indeed, Figure 3 demonstrates that the photobioreactor size is practically correlated with a reduced lighting efficiency, and this is consistent across the culture time horizon. This point is in agreement with the findings of Nikolaou et al., (2016). The value of ‘ $e$ ’ decreases by about one order of magnitude during scale up from the lab scale to the semi-pilot scale (increase in reactor radius from 8 cm to 16 cm), and furthermore decreases by about two orders of magnitude on the pilot scale, compared to the lab scale. This comparison indicates that PBRs with the same specific illuminated area per unit volume can attain the same productivity with identical light flux, regardless of their volume. However, in our viewpoint, the absolute light power (W) and not the luminous flux ( $W m^{-2}$ ) spent is a more appropriate criterion to gauge PBR efficiency on a techno-economic basis.

Figure 3: Dynamic evolution of the energy efficiency factor on the three different scales.

## 5. Conclusions.

In this work the notion of light limitation on photobioreactor is confirmed and quantified, and an attempt to explore strategies that maximize biomass production in photobioreactors on three different scales has been made. Results suggest that the industrial cultivation of microalgae on “traditional” fermenter like photobioreactors seems unrealistic. Furthermore, it is considered that is of utmost importance that photobioreactor design, process optimization and scale-up should be coupled activities, due to the dominant effect of the characteristic length of light distribution on the performance of these systems. We are confident that the present modeling framework can serve at the epicenter of a multi-physics platform that can provide valuable insight and guide the successful commercialization of microalgae based biorefineries.

## Abstract

Energy production from biomass has promising prospects in the domain of clean and sustainable sources. Hydrothermal Liquefaction (HTL) is an emerging process to convert biomass into energy products and is less energy intensive than other thermal conversion processes including gasification and pyrolysis, as HTL does not require pre-drying of biomass. In this study, a process simulation is developed using Aspen Plus<sup>®</sup> V10 to quantify the yield of liquefaction products including bio-crude, hydrochar and gas from various palm oil wastes; such as palm kernel shell (PKS), empty fruit bunches (EFB), palm oil fronds (POF) and their blends. The use of PKS as feedstock for HTL resulted in the highest biocrude yield of ~441 kg/tonne, whereas the EFB was linked to the lowest biocrude yield of ~293 kg/tonne. Meanwhile, the highest yield of hydrochar was achieved at ~193 kg/tonne for EFB. The gas production was also higher in the case of EFB, at about 317 kg/tonne. The blend of all three wastes yielded ~356 kg/tonne of biocrude, 102 kg/tonne of hydrochar and 387 kg/tonne of gas. In addition, the produced gas composition is dominated by CO<sub>2</sub> followed by CH<sub>4</sub>. The blended feed yielded the lowest CO<sub>2</sub> composition, which indicates the importance of feedstock blending in CO<sub>2</sub> mitigation. POF is found to be a more economical feedstock which has shown the lowest cost of 0.331USD/kg and 0.045 USD/kg. The generated biocrude replicates several petroleum properties, granting it a high potential for conventional refining into clean transportation fuels. This study provides insights and technical knowledge on HTL technology and its possible upgradation from lab and pilot into commercial scales.

**Keywords:** Liquefaction; Oil-palm waste; Aspen Plus; Biocrude; Hydrochar.

## 1. Introduction

The existence of modern life standard is in danger due to the increasing energy demand and its associated environmental impact due to the high dependency on fossil fuels. The domino effect of these issues is not only extended to energy deficiency, and the world existence inquest is due to climate change, which caught the world's attention at the research and policy level to explore new and alternative renewable and sustainable energy

sources (Ali et al., 2022). In all alternative energy resources, biomass emerges as an attractive and viable source due to its wide availability and possible conversion into all forms of energy, materials, and chemicals that are currently obtained from fossil fuels (AlNouss et al., 2022).

Biochemical and thermochemical routes can convert biomass into energy derivatives and chemicals. Biomass can be converted into gaseous, liquid, and solid fuels and value-added chemicals through thermochemical and biochemical conversion processes (Chan et al., 2019; Chan et al., 2015). The thermochemical conversion processes including gasification and incineration are used for gaseous fuel, heat, and electricity production. In contrast, pyrolysis and liquefaction are utilised for liquid fuel and char generation. All the above processes are relatively energy-extensive, with liquefaction being the least-energy consuming. Liquid fuel is vital in energy products due to its high energy density, ease of storage and transportation (Chan et al., 2015). Liquefaction of biomass is a relatively new process compared to the other process. Still, it appears to be very effective for liquid fuel production due to its low energy requirement, no drying and pre-treatment process (Chan et al., 2015). In the liquefaction process biomass is treated at a lower temperature than 400 °C and high pressure of 4 - 20 MPa using an appropriate solvent such as; water, organic solvent, and their mixture (Chan et al., 2018).

Palm oil waste (POW) is Southeast Asia's major crop, supplying 79% of the world's palm oil demand (Umar et al., 2021). POW is primarily used in the industry for electricity and heating purposes. Chan et al. (2019) reviewed the utilization of waste in Malaysia for energy production via thermochemical conversion pathway and noticed that most of POW were investigated for gasification and pyrolysis processes for gaseous fuel and bio-oil production. Umar et al. (2021) recently reviewed the POW utilisation for energy production and found that the gasification and pyrolysis processes are well investigated at pilot and commercial scales for gaseous fuel generation. On the other hand, liquefaction was mainly investigated at the lab and pilot scale levels (Chan et al., 2019). The first objective of this study is to develop a flowsheet model of liquefaction process using Aspen Plus® to investigate the process parameters on the yield of solid crude, hydro crude, and gas for each type of POW and their blend. HTL is used to produce for liquid production and gas is obtained as a by product or waste. While the second objective is to conduct a techno-economic analysis using Aspen Plus Economic Analyzer to evaluate the production cost of each product for all types of selected feedstocks. This study may provide insights for researchers, as well as policymakers to make decisions on the selection of appropriate wastes for suitable products generation.

## 2. Methodology

### 2.1 Description of process modelled

The high tech, advanced and reliable simulation modelling software are in research and commercial use for many polymer, chemicals, oil and gas, power, and biofuel sectors. (Shahbaz et al., 2021). Aspen plus is one of the most important simulation modelling software that can perform high-level simulations for solid, fluids, and gases by providing suitable fluid packages and properties. Hydrothermal liquefaction process is developed using Aspen Plus® V10 to yield the biocrude and hydrochar as illustrated in the process flow diagram presented in Figure 1. To perform a steady state smooth simulation process, some important assumptions were considered, including no temperature and pressure gradient and carbon is graphite carbon (Alherbawi et al., 2022). The feedstock including

EFB, PKS, POF, and their blend are introduced into the reactor as biomass slurry where non-conventional components are converted into conventional elements using Fortran routine based on the composition presented in Table. 1 as presented in previous study (Parthasarathy et al., 2022). Fortran routine is also employed to calculate the quantity of water to make a 20% solid concentrated slurry. The pressure of the slurry is raised up to 100 bar and heated up to 350 °C before being fed into the HTL reactor for the hydrothermal liquefaction process. The maximum biocrude and minimum hydrochar yields are restricted using a Fortran code calculation based on previous prediction models (Alherbawi et al., 2021).

Table 1. Composition of palm waste (PKS, EFB, POF and blends).

	PKS	EFB	POF	Blend
<b>Proximate analysis</b>				
Moisture	9.70	5.30	5.30	6.77
FC	14.42	20.61	17.74	17.59
VM	80.57	76.17	74.97	77.24
Ash	5.00	3.22	7.29	5.17
<b>Ultimate analysis</b>				
C	46.44	43.70	45.03	45.06
H	5.43	4.74	4.92	5.03
N	0.96	0.76	0.59	0.77
Cl	-	-	-	-
S	-	-	-	-
O	42.17	47.59	42.17	43.98

The HTL reactor is set to operate at Gibbs free energy minimization approach in which all possible products and biocrude components have been defined. Hydrochar is separated from the product stream in a hydro cyclone unit as depicted in flow diagram. The solid free product stream is directed to the three-stage flash where biocrude (liquid) and gases are separated along with aqueous phase which contain other dissolved organics.

### 2.2. Cost analysis

A techno economic analysis is performed using the Aspen Plus Economic Analyzer and based on the correlation and values presented in previous study (Parthasarathy et al., 2022). The levelized cost of biocrude and hydrochar per kg feed of PKS, EFB, POF, and their blend is calculated based on the levelized cost of energy concept.

Fig.1 Process flow diagram of hydrothermal liquefaction of (PKS, EFB.POF. and Blend).

### 3. Results and discussion

#### 3.1 Product yield distribution and gas composition

The product yield of biocrude, hydrochar and gas per tonne of all feedstocks (PKS, EFB, POF and Blend) are presented in Figure 2. It can be noticed that biocrude is the dominant product for all cases except EFB. The higher yield of biocrude is due to the higher degradation rate for the cracking of the matrix structure of lignocellulosic biomass at higher temperature of 500 °C (Chan et al., 2015). PKS has shown the highest biocrude yield of 441.56 kg/tonne. POF and the blend yielded biocrude at 359.69 and 356.02 kg/tonne, respectively. Chen et al. (2018) have also observed the increase of bio oil yield with the increase in temperature for the liquefaction of PKS. A similar trend is also reported for bio-oil production from the liquefaction of giant fennel with the increase in temperature (Aysu & Küçük, 2013). Hydrochar production is found to be the highest in the case of EFB at about 192.95 kg/tonne. The higher hydrochar production for EFB is due to higher fixed carbon content of 20% as presented in Table 1. POF was associated to hydrochar production of 159.66 kg/tonne, which is the second highest amongst all feedstocks. PKS and the blend of all palm waste have a significant lower yield of 100.73 and 101.25 kg/tonne, respectively. Although liquefaction is not known for hydrochar production, it is obtained as a by-product. In this study, the yield of hydrochar is still significant, contributing to the process's commercial viability. Gas production is an important by-product that can be obtained significantly, but its usage is limited due to the domination of CO<sub>2</sub> in gas yield. The gas production for EFB, PKS, and POF are 316.48, 236.14, and 259.85 kg/tonne, respectively. The blend of feedstocks generated highest quantity of gas at 387.48 kg/tonne, which is the highest within the products array.

Figure 2. Product yield at temperature of 500 °C for PKS, EFB, POF and Blend.

Figure 3 demonstrates the composition of the syngas attained from liquefaction of PKS, EFB, POF and their blend. It is very clear from Figure 3 that CO<sub>2</sub> is the dominant gas in the array of gasses present in syngas. The CO<sub>2</sub> content is more than 90% in syngas for all feedstocks, being the highest in PKS case at about 98.14 %. However, the palm waste blend has yielded the lowest CO<sub>2</sub> composition at 90.14%. CH<sub>4</sub> content is the second highest component which is in the range of 1 to 10% in which the blend has also shown the highest syngas composition of CH<sub>4</sub> at 9.73%. The content of H<sub>2</sub> and CO is very low (less than 0.1%) which makes it insignificant. Due to this reason, the composition of syngas and their yield for liquefaction is very rarely reported in the literature, as such gas composition is incomparable to gasification but may be compared with hydro-pyrolysis.

Figure 3. Gas composition at a temperature of 500 °C for PKS, EFB, POF and Blend.

### 3.2 Cost analysis

The cost of biocrude and hydrochar production per kg of PKS, EFB, POF and their blend is presented in Figure 4. The highest cost of biocrude and hydrochar are found for EFB which are at 0.402 USD/kg and 0.203 USD/kg, repeatedly. Whereas the second highest cost is noticed for palm oil waste blend. For POF, the cost of biocrude and hydrochar production is estimated at 0.391 USD/kg and 0.045 USD/kg, respectively. In the case of PKS, the cost of production for biocrude is achieved at 0.345 USD/kg, whereas hydrochar is obtained as a complementary product. It can be concluded that the POF can be a good source in terms of cost for biocrude and hydrochar production, which is linked to lower cost of feedstock.

Figure 4. Cost of Biocrude and Hydrochar at 500 °C using PKS, EFB, POF and Blend.

#### 4. Conclusion:

A process simulation model of Hydrothermal Liquefaction (HTL) of PKS, EFB, POF and their blend is instituted for biocrude, hydrochar, and gas production using Aspen Plus® V10. The highest production yield of biocrude is achieved at 441.56kg/tonne using PKS, with hydrochar and gas yields at 100.73 kg/tonne and 236.14 kg/tonne, respectively. Whereas the lowest yield of biocrude is attained at 293.43 kg/tonne using EFB. The blend of all three palm wastes is found to be a good option for enhanced composition and yield of gas. Where the blended feedstock yielded 387.48 kg/tonne of gas with the lowest CO<sub>2</sub> composition. While it yielded biocrude and hydrochar at 356 kg/tonne and 101.65 kg/tonne, respectively. The gas crude composition is dominated by the CO<sub>2</sub> Content which is within the range of 90 to 98% for all feedstocks. The economic analysis indicated that the lowest biocrude cost is attained using POF at 0.331 USD/kg, while PKS was associated to the highest biocrude cost at 0.345 USD/kg.

## Abstract

Many optimization problems in the process industry, such as production planning and scheduling, contain endogenous (decision-dependent) uncertainties. The endogenous uncertainties can be represented as scenarios based on the realized outcomes; hence, by nature, multistage stochastic programming (MSSP) is one approach to modeling and solving these problems. MSSP problems quickly grow and become computationally intractable as the problem size increases. We solve four MSSP problems with Type II endogenous uncertainty using absolute expected value solution (AEEV) and generalized Knapsack-problem-based decomposition algorithm (GKDA) to address the computational tractability issues. We bound the solutions using a modified Lagrangian relaxation (mLR). The results reveal that AEEV provides the smallest optimality gap.

**Keywords:** multistage stochastic program, endogenous uncertainty, heuristic approaches

## 1. Introduction

MSSP is a mathematical decision-making approach used in the process industry, such as for process synthesis (Tarhan and Grossmann, 2008), to solve optimization problems with the sequential realization of uncertainties. Uncertainty in optimization problems is classified as exogenous or endogenous, which can be further classified into Type I: decisions affect the probability distribution, and Type II: decisions affect the realization time (Goel and Grossmann, 2006). For MSSPs with type II endogenous uncertainty, implicitly enforcing non-anticipativity (NA) in the model formulation is not possible. Hence, NA constraints (NACs) are added to the model to prevent decisions from anticipating unrealized future outcomes. However, the number of NACs grows exponentially as the number of scenarios increases, resulting in computational intractability (Apap and Grossmann, 2017). Various heuristic, approximation, and decomposition methods exist for solving MSSPs with endogenous uncertainty, e.g., sample average approximation algorithm (Solak et al., 2010), improved Lagrangian decomposition framework (Gupta and Grossmann, 2014), and rolling-horizon heuristic approach (Colvin and Maravelias, 2009).

This paper applies two heuristic primal bounding approaches, AEEV (Zeng and Cremaschi, 2019) and GKDA (Zeng et al., 2018), to solve MSSP problems with Type II endogenous uncertainty and bound the solutions using mLR (Zeng and Cremaschi, 2020). It has been suggested that AEEV and GKDA yield tight primal bounds quickly, and the goal is to investigate their performance for a wider range of MSSP problems.

### 2. A general MSSP formulation under endogenous uncertainties

A general MSSP formulation under endogenous uncertainties is given in Eqs. 1-6.

$$OV = \min \sum_s p_s \sum_{i,t} G_{i,t,s}(V_{i,t}, \theta_i^s, b_{i,t}^s, \gamma_t^s) \tag{1}$$

$$g_{i,t,s}(b_{i,t}^s, \gamma_t^s, \theta_i^s) \leq 0 \quad \forall i \in I, t \in T, s \in S \tag{2}$$

$$h_{i,t,s}(b_{i,t}^s, \gamma_t^s, \theta_i^s) = 0 \quad \forall i \in I, t \in T, s \in S \tag{3}$$

$$b_{i,1}^s = b_{i,1}^{s'} \quad \forall i \in I, \forall (s, s') \in S \tag{4}$$

$$\begin{bmatrix} Z_{i,t}^{s,s'} \\ b_{i,t}^s = b_{i,t}^{s'} \end{bmatrix} \vee \begin{bmatrix} -Z_{i,t}^{s,s'} \end{bmatrix} \quad \forall (i, s, s') \in S_E, \forall t \in T, t > 1 \tag{5}$$

$$\gamma_t^s \in \mathbb{R}, b_{i,t}^s, Z_{i,t}^{s,s'} \in \{0,1\} \quad \forall (i, s, s') \in S_E, \forall t \in T, \forall i \in I \tag{6}$$

The objective function (Eq. (1)) calculates the optimum OV. The model has two decision variables,  $b_{i,t}^s$  and  $\gamma_t^s$ , with uncertain resources  $i \in I = \{1,2, \dots, I\}$ , planning horizon  $t \in T = \{1,2, \dots, T\}$ , and scenarios  $s \in S = \{1,2, \dots, S\}$ . The binary decision variable  $b_{i,t}^s$  is enforced to be identical by either initial (Eq. (4)) or conditional NACs (Eq. (5)) until scenario pair  $(s, s')$  becomes distinguishable. The decision variable  $\gamma_t^s$  is determined by scenario-specific constraints (Eqs. (2)-(3)).  $V_{i,t}$  and  $\theta_i^s$  represent deterministic and endogenous uncertain parameters. The function  $G_{i,t,s}(V_{i,t}, \theta_i^s, b_{i,t}^s, \gamma_t^s)$  calculates the contribution of a specific scenario  $s$  with probability  $p_s$  to the objective. The conditional NACs (Eq. (5)) are enforced depending on the values of the Boolean variable  $Z_{i,t}^{s,s'}$ , which is equal to one if scenario pair  $(s, s')$  is indistinguishable, and zero otherwise.

### 3. Solution approaches

#### 3.1. Absolute Expected Value Solution Approach (AEEV)

AEEV (Zeng and Cremaschi, 2019) is a primal bounding approach that converts an MSSP problem into two sub-problems, deterministic expected value sub-problems (*DEVSPs*) and recourse deterministic expected value sub-problems (*DEVSPs<sup>recourse</sup>*), by removing all NACs (Eq. (4), (5)) and indices  $s$  from the MSSP formulation. *DEVSPs* and *DEVSPs<sup>recourse</sup>* determine here-and-now decisions and corresponding recourse actions. AEEV starts by constructing a *DEVSP* at the initial time, as shown in Figure 1.

Figure 1 The schematic diagram of AEEV

The values of endogenous uncertain parameters are set to their expected values over all scenarios because there are no realizations before solving the initial *DEVSP*. AEEV stores the here-and-now decisions obtained from the *DEVSP* solutions and determines which scenarios can be differentiated based on the realized outcomes. If realizations occur and

the MSSP problem has decision variables associated with recourse actions,  $DEVSP_s^{\text{recourse}}$  is generated and solved to obtain these decision variables. If there is no realization, AEEV skips constructing  $DEVSP_s^{\text{recourse}}$ . AEEV continues to construct and solve  $DEVSP_s$  and  $DEVSP_s^{\text{recourse}}$  for the subsequent time periods with stored decisions set to solutions of prior  $DEVSP_s$  and  $DEVSP_s^{\text{recourse}}$  until the end of the time horizon. The values of endogenous uncertain parameters are expected-valued over possible scenarios at each  $DEVSP$  and  $DEVSP^{\text{recourse}}$ . At termination, AEEV provides a feasible solution and an upper bound for the MSSP model.

### 3.2. Generalized Knapsack-Problem based Decomposition Algorithm (GKDA)

GKDA (Zeng et al., 2018) is a similar primal bounding approach. It translates the MSSP problem into two types of knapsack sub-problems (KSPs) by decomposing scenario and time indices, i.e., it removes all NACs (Eq. (4), (5)) and indices  $s$  and  $t$  from the MSSP formulation. The remaining index  $i$  is translated into an item set of KSPs by enumerating all eligible decisions. Scenario-specific constraints (Eq. (2), (3)), except sequencing constraints, are transformed into KSP weight constraints. Sequencing constraints and bounds are used to determine the allowable items in a KSP from the eligible items. Item values are generally objective function coefficients, i.e.,  $V_{i,t}$  in Eq (1) translates into  $V_e$  as item values in KSPs, where  $e$  notates item  $e \in E$ . Under certain conditions, this translation does not accurately approximate the expected contribution of the associated decision to the MSSP objective function. Zeng et al. (2018) defined two conditions with approaches to better approximate item values. Condition 1 applies to problems in which gains/revenues are only realized at certain stages or are only associated with certain decision variables, and the item values are generated using the maximum potential gain approach (MPGA). Condition 2 applies to problems where an item represents a capital investment decision variable in MSSP, and the item value is generated using annual capital charges. Similar to AEEV, GKDA continues to construct and solve KSPs along the planning horizon with stored decisions of prior KSPs. At termination, GKDA provides a feasible solution and an upper bound for the MSSP problem.

### 3.3. Modified Lagrangian Relaxation (mLR)

Lagrangian relaxation (LR) is a common approach to removing complicating constraints and adding them to the objective function as penalty terms (Lin et al., 2011). For MSSP problems, NACs (Eq. (4), (5)) are complicating constraints. A standard LR dualizes these NACs to the MSSP objective function, as shown in Eq. (7).

$$\begin{aligned} OV_{LR} = \min \sum_s p_s \sum_{i,t} G_{i,t,s}(V_{i,t}, \theta_i^s, b_{i,t}^s, \gamma_t^s) + \sum_{i,s,s'} \lambda 1_{i,s,s'} (b_{i,1}^s - b_{i,1}^{s'}) \\ + \sum_{i,t,s,s'} \lambda 2_{i,t,s,s'} (1 - Z_{i,t}^{s,s'} - b_{i,t}^s + b_{i,t}^{s'}) \\ + \sum_{i,t,s,s'} \lambda 3_{i,t,s,s'} (1 - Z_{i,t}^{s,s'} + b_{i,t}^s - b_{i,t}^{s'}) \end{aligned} \quad (7)$$

In Eq. (7),  $\sum_{i,s,s'} \lambda 1_{i,s,s'} (b_{i,1}^s - b_{i,1}^{s'})$  corresponds to initial NACs (Eq. (4)), and  $\sum_{i,t,s,s'} \lambda 2_{i,t,s,s'} (1 - Z_{i,t}^{s,s'} - b_{i,t}^s + b_{i,t}^{s'})$  and  $\sum_{i,t,s,s'} \lambda 3_{i,t,s,s'} (1 - Z_{i,t}^{s,s'} + b_{i,t}^s - b_{i,t}^{s'})$  correspond to conditional NACs (Eq. (5)).  $\lambda 1_{i,s,s'}$ ,  $\lambda 2_{i,t,s,s'}$ , and  $\lambda 3_{i,t,s,s'}$ , called multipliers, are updated over the iterations to obtain tighter bounds. LR provides a lower bound. For  $\sum_{i,t,s,s'} \lambda 2_{i,t,s,s'} (1 - Z_{i,t}^{s,s'} - b_{i,t}^s + b_{i,t}^{s'})$  and  $\sum_{i,t,s,s'} \lambda 3_{i,t,s,s'} (1 -$

$Z_{i,t}^{s,s'} + b_{i,t}^s - b_{i,t}^{s'}$ ) in Eq. (7), NACs are always satisfied when scenario pairs  $(s, s')$  are distinguishable, i.e.,  $Z_{i,t}^{s,s'} = 0$ , thereby leading to looser bounds. To tighten it, Zeng and Cremaschi (2020) proposed mLR by transforming Eq. (7) into Eq. (8) where the conditional NACs are dualized only when  $Z_{i,t}^{s,s'} = 1$ .

$$OV_{LR} = \min \sum_s p_s \sum_{i,t} G_{i,t,s}(V_{i,t}, \theta_i^s, b_{i,t}^s, \gamma_i^s) + \sum_{i,s,s'} \lambda_{i,s,s'} (b_{i,1}^s - b_{i,1}^{s'}) + \sum_{i,t,s,s'} \lambda_{i,t,s,s'} Z_{i,t}^{s,s'} (b_{i,t}^s - b_{i,t}^{s'}) \quad (8)$$

Multiplier updating schemes are critical for obtaining tighter bounds. The sub-gradient optimization method (Eqs. (9) and (10)) is a commonly used technique (Fisher, 1985).

$$\lambda_n^{k+1} = \max\{0, \lambda_n^k - \gamma^k(Ax_n^k - b)\} \quad (9)$$

$$\gamma^k = scale \frac{Z(\lambda_n^k) - Z^*}{\sum_n (Ax_n^k - b)^2} \quad (10)$$

The total  $|N|$  number of multipliers at  $k + 1^{th}$  iteration,  $\lambda_n^{k+1}$  ( $n \in N$ ), is calculated with Eq. (9) (Fisher, 1981), where  $Ax_n^k - b$  is the dualized constraints transferred to the objective function, where  $x_n^k$  is solved variables, and  $A$  and  $b$  are parameters of dualized constraints. The step size at iteration  $k$ ,  $\gamma^k$ , is calculated by Eq. (10) based on the gap between the best-known primal  $Z^*$  and dual bound  $Z(\lambda_n^k)$ . *scale* in Eq. (10) is an adjustable parameter in  $0 < scale < 2$ , which is often set via trial and error. To achieve tighter bounds efficiently, Zeng and Cremaschi (2020) proposed updating *scale* at the  $k^{th}$  iteration using Eq. (11) if the ratio of dualized constraints value  $D$  to the dualized objective function value  $OV_{LR}$  is greater than or equal to 0.1. The multipliers are updated using Eq. (12), where  $N^v$  is the total number of violated dualized constraints.

$$\text{If } \frac{D}{OV_{LR}} \geq 0.1 \text{ Then } scale^k = \frac{scale^{k-1}}{1.618} \quad (11)$$

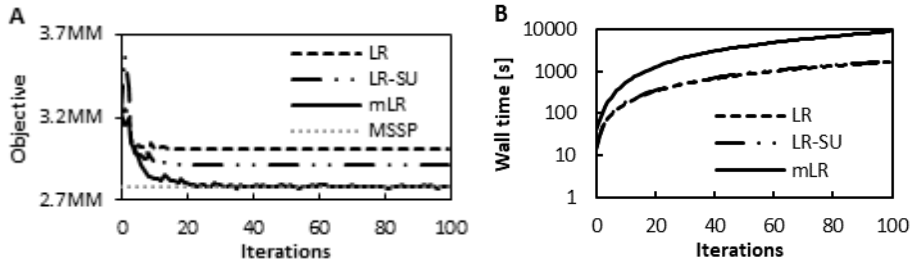

$$\gamma^k = scale^k \frac{Z(\lambda_n^k) - Z^*}{N^v} \quad (12)$$

#### 4. Case study descriptions, results, and discussion

We applied the solution approaches to four MSSP problems with Type 2 endogenous uncertainty. All problems are Mixed Integer Linear Programming (MILP) problems. Clinical Trial Planning (CTP) (Colvin and Maravelias, 2009) problem determines the timing of the clinical trials, maximizing expected profit. Artificial Lift Infrastructure Planning (ALIP) (Zeng and Cremaschi 2017) problem determines installed equipment and installation timing for exploiting shale gas, maximizing expected profit. Vehicle Routing (VR) (Hooshmand and MirHassani, 2016) problem determines customer visit order, minimizing expected cost. Open Pit Mining (OPM) (Boland et al., 2008) problem determines aggregates to be excavated and processed and their timing, maximizing expected profit. We modeled all instances in Pyomo and solved them with CPLEX 20.10 using 48 processors on a node of Auburn University Easley Cluster.

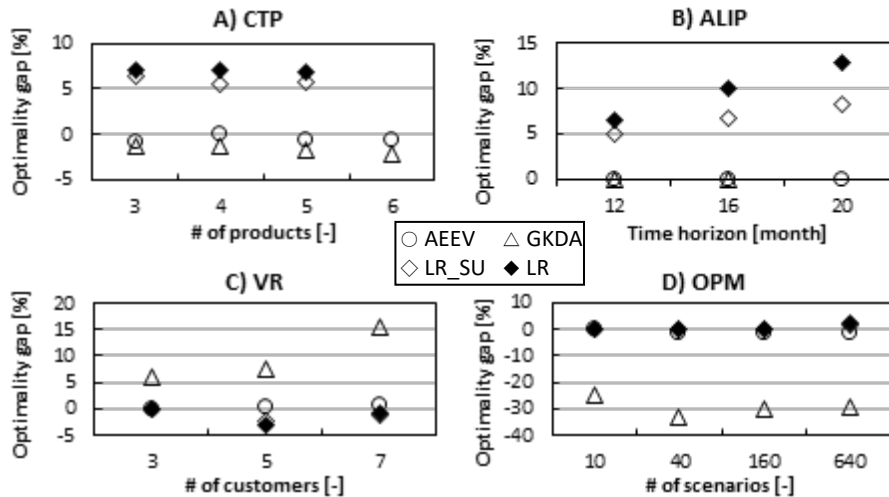

Figure 2 represents the result of mLR for an instance of ALIP with a 12-month planning horizon. mLR required significantly longer times for other instances, yielding a few to 40 iterations within 48 hours. Figure 2 A shows that mLR yields a tighter bound than LR and

LR with the new scale updating scheme only (LR-SU). However, mLR takes longer than LR and LR-SU, as can be seen in Figure 2 B. The objective function of mLR is nonlinear and cannot be decomposed if linearized due to scenario pairs  $(s, s')$  in term  $\sum_{i,t,s,s'} \lambda_{i,t,s,s'} Z_{i,t}^{s,s'} (b_{i,t}^s - b_{i,t}^{s'})$  of Eq. (8). We only applied LR-SU to other instances.

**Figure 2** A) Objective value of LR, LR-SU, mLR, and MSSP and B) Computational time of LR, LR-SU, and mLR for ALIP with a planning horizon of 12 months.

Figures 3 and 4 represent the optimality gap and computational times. LR and LR-SU results are for iteration 50. The optimality gap is defined from MSSP optimum solution. AEEV provided the best feasible solutions, and LR-SU provided tighter bounds than LR. GKDA yielded better feasible solutions for CTP and ALIP than VR and OPM because it employed Conditions 1 and 2 for item value estimation for CTP and ALIP, respectively. These results indicate the importance of item value estimation for GKDA, which is the fastest (Figure 4). LR-SU takes almost the same time as LR but yields tighter bounds. Computational time increased milder for all approaches than for MSSP.

**Figure 3** Optimality gap of solutions yielded by approaches from the MSSP solution

### 5. Conclusion and Future Directions

We applied two heuristics, AEEV, GKDA, and two bounding approaches, mLR and LR-SU, to four MSSP problems with Type II endogenous uncertainty. The results revealed AEEV provides the tightest feasible solutions. The bound yielded with mLR was tighter than LR; however, mLR required a long computational time. Computational time increased milder for all approaches than for MSSP. We plan to apply the approaches to other MSSP problems and study avenues for improving them.

## Abstract

Heterogeneously catalyzed CO<sub>2</sub> methanation is an essential process in the power-to-methane concept. To overcome the limitations of both mechanistic and data-driven models, this study presents three modeling approaches for predicting the CO<sub>2</sub> conversion using different techniques for integrating pseudo-experimental process data into process models. One approach is a data-driven model that uses multilayer perceptron regression (MLPR), a type of feedforward artificial neural network, to represent the data. Another approach is a hybrid model that integrates MLPR to estimate the reaction rate within a mechanistic model. The third approach is another hybrid model that uses MLPR to correct for a simplified mechanistic model that does not fully capture the physical behavior of the system. All models are evaluated in terms of accuracy, complexity, and reliability, and the results show that they all predict the conversion of CO<sub>2</sub> with only minor deviations. Hybrid models have the advantage of combining the strengths of mechanistic and data-driven models and, with basic process knowledge, can make accurate predictions beyond the training data. However, they also require both process knowledge and large amounts of process data.

**Keywords:** Power-to-X, Reactor Modeling, Hybrid Modeling, Machine Learning

## 1. Introduction

The intermittent nature of solar and wind power underscores the need for effective energy storage technologies. Power-to-methane (PtM) is a process that uses electrolysis to convert energy into hydrogen, which is then chemically bonded with carbon to form synthetic methane. This CO<sub>2</sub>-neutral fuel can be used in households and industries through existing distribution infrastructure (Götz, et al., 2016). However, the low efficiency, complexity, and high cost of the PtM process pose challenges to its widespread adoption (Er-rbib & Bouallou, 2013). Optimization of electrolyzer, reactor, and downstream process operation and design can address these challenges. Accurate process models are required to improve the performance of PtM systems. Traditionally, process models are established based on physical and chemical principles, but building first-principle models requires extensive data from specific laboratory experiments and is time-consuming (Zimmermann, et al., 2020). In addition, quantifying the kinetics that depend on elementary reactions and intermediates is challenging using traditional methods (Zahedi, et al., 2005). Data-driven regression models provide an alternative to mechanistic models by identifying relationships between the dependent variable and one or more independent inputs (Kahrs & Marquardt, 2007). They can be generated quickly without prior process knowledge, but

require large amounts of data and may have limited physical interpretation. Hybrid models, which combine mechanistic models with data-driven models, can describe unknown phenomena by integrating data-driven approaches into mass and energy balances or by compensating for discrepancies between the model and the plant (Von Stosch, et al., 2014). Multilevel perceptron regression (MLPR), a type of feedforward artificial neural network, represents all data-driven relationships. In MLPR, data flows from the input layer through the hidden layers to the output layer, where the hidden layers weights the inputs and pass them through a nonlinear activation function to the output. The MLPR is trained using backpropagation by describing the target with input representations. With the advancement of data-driven models, the number of parameters, runtime, and computational resources have increased significantly. Thus, it is imperative to consider metrics such as accuracy, complexity, and reliability in addition to the accuracy of the model (Menghani, 2021). In this study, the models are evaluated based on these metrics.

## 2. Methodology

The modeling approach involves generating pseudo-experimental process data using a mechanistic CSTR model for the CO<sub>2</sub> methanation and predicting this data using three models: one data-driven model and two hybrid models.

### 2.1. Data Generation via CSTR Model

The mass and energy balances for modeling a CSTR are based on the work of Bremer and Sundmacher (Bremer & Sundmacher, 2021). The balances were constructed under the assumptions that (1) the CO<sub>2</sub> methanation is a single reaction, that (2) it occurs in a single phase, and that (3) the pressure  $p$ , the gas heat capacity  $c_p$ , the heat of reaction  $\Delta_R \bar{H}$  and the effectiveness  $\eta$  for limiting catalyst mass transport are constant. Using the conversion of CO<sub>2</sub> ( $X_{CO_2}$ ), the residence time  $\tau$ , the void fraction  $\epsilon$ , the inlet concentration of CO<sub>2</sub>  $c_{CO_2}$ , and the mass flow fraction of the each component  $\omega_i$ , the steady state mass balance of the CSTR is described as

$$0 = X_{CO_2} - \frac{\tau R_{\text{meth}}(T, p, \omega_a)}{\epsilon c_{CO_2, \text{in}}} \quad (1)$$

The intrinsic reaction rate,  $R_{\text{meth}}$ , is a LHHW-type equation proposed by Koschany et al. (Koschany, et al., 2016).  $R_{\text{meth}}$  depends on the reaction temperature  $T$  and the partial pressures  $p_i$  of the components.

$$R_{\text{meth}}^{\text{LHHW}} = kp_{CO_2}^{0.5} p_{H_2}^{0.5} \left( 1 - \frac{p_{CH_4} p_{H_2O}^2}{K_{eq} p_{CO_2} p_{H_2}^4} \right) / \left( 1 + K_{OH} + \frac{p_{H_2O}}{p_{H_2}^{0.5}} + K_{H_2} p_{H_2}^{0.5} + K_{\text{mix}} p_{CO_2}^{0.5} \right) \quad (2)$$

The state variables for the energy balance of the CSTR are  $T$  and  $X_{CO_2}$ , along with the Stanton number  $St$ , the adiabatic temperature rise  $\Delta T_{\text{ad}}$ , and the operation temperature  $T_{\text{op}}$ . The energy balance is solved in steady state.

$$0 = X_{CO_2} - \frac{(1 + St)}{\Delta T_{\text{ad}}} (T - T_{\text{op}}) \quad (3)$$

The steady-state mass and energy balances are solved simultaneously for  $X_{CO_2}$  and  $T_{\text{op}}$ . To obtain the training data, 1000 different operating conditions are selecting using statistical Latin Hypercube Sampling. The sample space includes pressure ( $1 \text{ bar} < p < 10 \text{ bar}$ ), inlet temperature ( $400 \text{ K} < T_{\text{in}} < 800 \text{ K}$ ), residence time ( $0.04 \text{ s} < \tau < 0.4 \text{ s}$ ),

and the ratio of products in the feed ( $0 < x_i < 0.5$ ). The test set is created by selecting 100 evenly distributed data points across the operating temperature range.

## 2.2. Training Strategy

The pipeline used in the study combines data processing and model training. The process data are first scaled using a min-max scaler, ensuring that all representations and target variable of the MLPR were between 0 and 1. In the next step, the NAdam optimization algorithm is used to minimize the mean squared error (MSE) of the CO<sub>2</sub> predictions by training a multi-layer perceptron regression (MLPR) model using the PyTorch library. The SELU activation function is used to compute the output of the hidden layer. The MLPR hyperparameters are determined using a Bayesian optimizer that used Gaussian processes, including the number of hidden layers (1 or 2), the number of neurons per hidden layer (between 5 and 30), the batch size for the optimizer (8, 16, 32, or 64), and the learning rate (1e-2 or 1e-3). The set of hyperparameters that produced the lowest average MSE on the test set when trained with five different sets of initial weights for the MLPR parameters is selected.

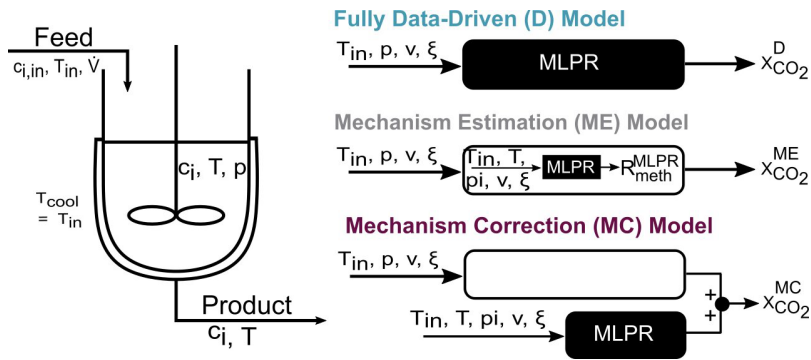

Figure 1: Illustrated schematic depicts CSTR (left) and hybrid modeling approach (right), with white boxes representing first-principle models and black boxes representing MLPR models.

In total, three different models with a data-driven component are set up. Figure 1 shows the models schematically. The fully data-driven (D) model represents mass and energy balances completely with a MLPR.  $X_{CO_2}^D$  is a function of the input representations (*repr*) namely,  $p$ ,  $T_{in}$ ,  $\tau$ ,  $\xi$  as well as the MLPR weights ( $\phi$ ) optimized during MLPR training, and can be expressed as:

$$X_{CO_2}^D = MLPR(repr, \phi). \quad (4)$$

In the Mechanism Estimation (ME) model, the mechanistic part employs the mass and energy balances, while  $R_{meth}$  is represented by an MLPR. The input representations are  $p_i$ ,  $T_{in}$ ,  $T$ ,  $\tau$ , and  $x_i$ . For the model,  $X_{CO_2}^{ME}$  is calculated from the mechanistic arguments (*args*), mechanistic parameters ( $\theta$ ), and  $R_{meth}^{MLPR} = MLPR(repr, \phi)$

$$X_{CO_2}^{ME} = f(args, \theta, MLPR(repr, \phi)). \quad (5)$$

Minimizing the MSE of the  $X_{CO_2}$  predictions determines  $R_{meth}$ . The third model, the Mechanism Correction (MC) model, utilizes a correction term to compensate for a mechanistic model that does not fully capture system behavior. The simplified mechanistic

model calculates  $X_{\text{CO}_2}^{\text{PL}}$  using a mechanistic model with a fitted power law  $R_{\text{meth}}^{\text{PL}}$  as the reaction rate. MLPR serves as the correction term  $\kappa = \text{MLPR}(\text{repr}, \phi)$ , learning the difference between  $X_{\text{CO}_2}^{\text{PL}}$  and  $X_{\text{CO}_2}$  using the representations  $p_i$ ,  $T_{\text{in}}$ ,  $T$ ,  $\tau$ , and  $x_i$ .  $X_{\text{CO}_2}^{\text{MC}}$  is calculated by summing  $X_{\text{CO}_2}^{\text{PL}}$  and  $\kappa$ :

$$X_{\text{CO}_2}^{\text{MC}} = f(\text{args}, \theta, R_{\text{meth}}^{\text{PL}}) + \text{MLPR}(\text{repr}, \phi) \quad \text{with} \quad R_{\text{meth}}^{\text{PL}} = k p_{\text{H}_2}^{n_{\text{H}_2}} p_{\text{CO}_2}^{n_{\text{CO}_2}} \left( 1 - \frac{p_{\text{CH}_4} p_{\text{H}_2\text{O}}^2}{K_{\text{eq}} p_{\text{CO}_2} p_{\text{H}_2}^4} \right). \quad (6)$$

### 2.3. Model Evaluation

The accuracy of the regression is determined by the MSE. The MSE depends on the random initialization of the MLPR parameter weights, so the model is trained 101 times with different initial weights to determine the distribution of the MSE. To ensure reproducibility, a seed is assigned to each set of initial weights, and the model with the mean MSE value among the test models is being further evaluated. Model complexity is defined by the number of parameters in the MLPR and the average CPU time required to fit the training set and predict the test set in 101 runs on a single node of a computing cluster. In addition, the performance of the model under varying amounts of test data is being examined. Fitted models are used to predict  $X_{\text{CO}_2}$  from unknown inlet temperature distributions ( $800 \text{ K} < T < 900 \text{ K}$ ) to assess extrapolation capability. Both training and test data are subjected to 5 % noise to test robustness, and the effect of noise on the predicted  $X_{\text{CO}_2}$  data is analyzed.

## 3. Results and Discussion

Three models are trained on pseudo-experimental process data as described in Section 2.2. Table 1 shows the hyperparameters, average MSEs, and average fitting times for the test and training set of all models. The left part of Figure 2 exhibits the distribution of the MSE over 101 model runs with different MLPR initial values. The results indicate that the MC model achieves the lowest average MSE on the test set, followed by the D model and the ME model. The trained models are applied to pseudo-experimental process data collected at various inlet temperatures with all other variables held constant. Figure 3 demonstrates the prediction of  $X_{\text{CO}_2}$  versus the operating temperature for each model. Despite its second-best performance in the training and test sets, the D model fails to correctly predict the pseudo-experimental temperature curves at small temperatures and residence times, due to underrepresentation of certain operating temperatures in the training set. The D model appears to overfit rather than interpolate the underrepresented data. In contrast, the ME model and MC model accurately describe the temperature curves.

The complexity of the models is determined by the MLPR architecture and the average training and prediction time (refer to Table 1). The D model trains faster. The time required to fit the data correlates with the architecture of the MLPs. Faster fitting times can be achieved by using fewer nodes per layer, larger batches, and lower learning rates. Although the ME model has the same architecture as the other models, it requires more time to train because the reaction rate is calculated using MLPR on  $X_{\text{CO}_2}$  as the target, resulting in more computational steps. The optimization of the models in this work is focused solely on accuracy. Reducing complexity by finding a Pareto front between accuracy and complexity is possible, but not the focus of this study.

Table 1: Selected hyperparameters, average MSEs, and average run times of training and test data for each model.

Model	Hyperparameters			Training		Test			
	Nodes per layer	Learn rate	Batch size	$\overline{\text{MSE}}$	Time in s	$\overline{\text{MSE}}$	Time in s	MSE ex-trap.	MSE 5% noise
D	4-25-25-1	1e-3	16	5.32e-5	61.8	4.62e-5	0.0051	4.39e-3	6.30e-4
ME	8-30-30-1	1e-3	8	6.83e-5	254.1	5.08e-5	0.0066	6.87e-3	5.43e-4
MC	8-25-25-1	1e-3	8	4.13e-5	117.7	2.86e-5	0.0071	8.39e-3	0.186

Figure 2: Left: Distribution of MSEs for models with fixed hyperparameters. Right: Model's loss function on the test data against different amounts of training data.

When extrapolating to a temperature range not covered by the training data (see Table 1), the D model performs significantly worse than when predicting unknown data within the trained temperature range. Fully data-driven models perform well only within the trained parameter range. The ME model and the MC models perform reasonably well in predicting the extrapolated data. The mechanistic framework (ME model) or the mechanistic basis (MC model) seems to improve not only the interpretability of the models but also their extrapolation ability. The MLPR part of the ME model can also be used for dynamic simulations. Since  $R$  is independent of time,  $R_{\text{meth}}^{\text{MLPR}}$  can be solved in a steady state. The predictive ability of the D model and the ME model decreases only slightly when noise is added to the training and test data. The MC model is unable to handle noisy data. In the  $\kappa$ -term of the MC model, the structural error due to the simplified model and the error due to the random noise are superimposed, resulting in an incorrect prediction of the MC model.

Figure 3: Model prediction of  $X_{\text{CO}_2}$  over the operating temperature. Model predictions are represented by dashed lines.

#### 4. Conclusion

Hybrid models are a promising approach to integrate data-driven and mechanistic models. This study proposes three modeling architectures for  $\text{CO}_2$ -methanation in a CSTR. The models are trained and tested using pseudo-experimental process data and predict  $X_{\text{CO}_2}$

with relatively small deviations. However, obtaining sufficient and high-quality process data is a challenge for all three models. The first model (D model) is straightforward to implement, but its performance is limited to the trained parameter range. The second model (ME model) uses a mechanism estimation approach and integrates a multilevel perceptron regression (MLPR) into the mass and energy balances. This approach provides a better representation of the reaction rate, including extrapolation data and noisy data, without requiring kinetic experiments. The third model (MC model) employs a mechanism correction approach, where a data-driven correction term is added to a mechanistic model. The MC model demonstrates good performance in both the trained and untrained parameter space but struggles with handling noisy data. In conclusion, the proposed hybrid models offer a way to improve the accuracy and reliability of process models for CO<sub>2</sub>-methanation

### Abstract

Current industrial (semi-)batch crystallization processes follow recipe-based temperature and antisolvent dosing trajectories obtained by extensive exploratory experimentation. This work optimizes the trajectories based on a 1-D Population Balance Equation coupled with the mass balance, (secondary) nucleation and crystal growth kinetics. The system of differential equations is solved by a High-Resolution Finite Volume Method. The method is demonstrated in a combined cooling-antisolvent crystallization that maximizes the number-average crystal size while satisfying process constraints (e.g., minimum yield). The dynamic optimization problem is solved via single shooting, where the control trajectory is discretized as piecewise linear, and the global solution is determined by multi-start single-objective optimization.

**Keywords:** crystallization, dynamic optimization, thermodynamics, population balance modelling, high-resolution finite volume method.

### 1. Introduction

The Population Balance Equation (PBE) presents a viable mathematical framework for the description of many chemical processes, such as crystallization, deposition, granulation, flocculation, milling, drying, mixing, and reactive multiphase systems such as polymerization and bioreactors (Randolph and Larson, 1971). In all these processes, it is vital to track the time evolution of a distributed property, e.g., the particle size distribution (PSD) in crystallization applications. The formulation for batch processes in the absence of breakage and agglomeration results in a hyperbolic partial differential equation for the crystal number density  $f$  [#/(kg-neat solvent.m)] in the form of eq. (1),

$$\frac{\partial f(L, t)}{\partial t} + \frac{\partial [G(L, t)f(L, t)]}{\partial L} + \frac{f(L, t)}{M} \frac{\partial M}{\partial t} = 0 \quad (1)$$

with boundary conditions  $f(L_0, t) = B(L_0, t)/G(L_0, t)$ ,  $f(\infty, t) = 0$  and initial condition  $f(L, 0) = f_{\text{seed}}(L)$ . This semi-mechanistic approach is then used to engineer processes to satisfy a set of critical quality attributes by numerically solving a system of equations.

### 2. Problem formulation and computational methods

The PBE is supplied with several auxiliary functions. First, the mole-fraction, activity dependent supersaturation (driving force) for crystal nucleation and growth is given by

eq. (2), where the denominator refers to the saturated state and  $\gamma$  and  $x$  are the activity coefficient and molar fraction of the API, respectively. The procedure to estimate the activity at supersaturated state  $\gamma_{\text{API}}$  is available elsewhere (Quilló et al., 2021).

$$\ln(\sigma_{\text{API,MFAD}}) = \ln\left(\frac{\gamma_{\text{API}}x_{\text{API}}}{\gamma_{\text{API}}^{\text{sat}}x_{\text{API}}^{\text{sat}}}\right) \quad (2)$$

The kinetic expressions for the overall linear growth rate  $\bar{G}$  and secondary nucleation are taken as empirical power law functions in this work as in eq. (3).

$$\bar{G} = k_g [\ln(\sigma_{\text{API}})]^g \quad B = k_b [\ln(\sigma_{\text{API}})]^b \quad \sigma_{\text{API}} \geq 1 \quad (3)$$

### 2.1. High-resolution Finite Volume Scheme (HR-FVM)

The HR-FVM approach allows tracking the PSD, although at additional computational effort (LeVeque, 2002). The PBE is discretized in a static, nonuniform, non-smooth, structured spatial grid which results in eq. (4), where  $N$  is the number of cells (see **Figure 1**). The growth rate  $G_n$  can be size-dependent and is evaluated at the upper boundary of cell  $n$ , where it can assume positive (growth,  $G_n^+$ ) or negative (dissolution,  $G_n^-$ ) values. The formulation allows thermal cycling if the dissolution kinetics is known by applying absorbing boundary conditions on both sides of the domain if  $\sigma_{\text{API}} < 1$ , which imply in complete dissolution of any clusters of the lowest size range.

**Figure 1.** Nonuniform grid in the characteristic size coordinate extended by ghost cells for the implementation of boundary conditions, along with indexation. The internal solution is extended by two ghost cells on each side because the flux limiter implies in a stencil of five cells.

$$\begin{aligned} \hat{F}_n^{m+1} = & F_n^m - \frac{\Delta t^m}{\kappa_{n-1/2} \Delta \xi} (G_n^+ F_n^m - G_{n-1}^+ F_{n-1}^m + G_{n+1}^- F_{n+1}^m - G_n^- F_n^m) \\ & - \left[ \frac{\Delta t^m G_n^+}{2\kappa_{n-1/2} \Delta \xi} \left( \frac{\kappa_{n-1}}{\kappa_{n-1/2}} - \frac{\Delta t^m G_n^+}{\kappa_{n-1/2} \Delta \xi} \right) (F_{n+1}^m - F_n^m) \phi_n \right. \\ & - \frac{\Delta t^m G_{n-1}^+}{2\kappa_{n-1/2} \Delta \xi} \left( \frac{\kappa_{n-2}}{\kappa_{n-3/2}} - \frac{\Delta t^m G_{n-1}^+}{\kappa_{n-1/2} \Delta \xi} \right) (F_n^m - F_{n-1}^m) \phi_{n-1} \left. \right] \\ & + \left[ \frac{\Delta t^m G_n^-}{2\kappa_{n-1/2} \Delta \xi} \left( \frac{\kappa_{n-1}}{\kappa_{n-1/2}} + \frac{\Delta t^m G_n^-}{\kappa_{n-1/2} \Delta \xi} \right) (F_{n+1}^m - F_n^m) \phi_n \right. \\ & - \frac{\Delta t^m G_{n-1}^-}{2\kappa_{n-1/2} \Delta \xi} \left( \frac{\kappa_{n-2}}{\kappa_{n-3/2}} + \frac{\Delta t^m G_{n-1}^-}{\kappa_{n-1/2} \Delta \xi} \right) (F_n^m - F_{n-1}^m) \phi_{n-1} \left. \right] \quad (4) \end{aligned}$$

The intermediate solution  $\hat{F}_n^{m+1}$  is corrected by the fractional step method in eq. (5), which allows sequential solution of the homogenous PBE and source terms (Bosetti and Mazzotti, 2020; LeVeque, 2002). The coupling with the mass balance of the solute in eq. (6) and the solvent in eq. (7) occurs by the supersaturation used to compute nucleation and growth. Moreover, the solvent mass balance leads to dilution and changes the API

solubility by altering the solution composition through the dosing stream  $Q_{in}$  [kg-neat solvent] with mass composition  $w_{in}$ . Further, the mixture volume  $V$  is obtained by eq. (8).

$$F_n^{m+1} = \hat{F}_n^{m+1}(M^m/M^{m+1}) \quad (5)$$

$$c_{API}^{m+1} = c_{API}^m - \rho_c k_v \left( 3 \sum_{n=1}^N [G_n^m F_n^m L_n^2 (\Delta L)_n] + B^m L_0^3 \right) \Delta t^m - \frac{c_{API}^m}{M^m} (M^{m+1} - M^m) \quad (6)$$

$$M_i^{m+1} = M_i^m + w_{in,i} Q_{in} \Delta t^m \quad (7)$$

$$V^m = \frac{\sum M_i^m}{\rho_{mix}} = \frac{M^m}{1/\sum(w_i/\rho_i)} \quad (8)$$

The left- and right-going propagating waves are retrieved separately by eq. (9).

$$G_n^- = \min(G_n, 0), \quad G_n^+ = \max(G_n, 0) \quad (9)$$

The nonuniformity in the spatial grid is tackled by the cell capacity  $\kappa$ , which is the ratio of the true cell size  $(\Delta L)_n$  and a computational step  $\Delta\xi$  as in eq. (10). The non-smoothness is addressed by the mean of adjacent cell capacities as in eq. (11), where  $L_{end}$  and  $L_0$  are the right and left boundaries of the discretized spatial domain, respectively.

$$\kappa_n = (\Delta L)_n / \Delta\xi, \text{ where } \Delta\xi = (L_{end} - L_0) / N \quad (10)$$

$$\kappa_{n-1/2} = (1/2)(\kappa_{n-1} + \kappa_n) \quad (11)$$

The flux limiter function  $\phi$  in eq. (12) depends on the smoothness  $\theta$  defined in eq. (13), where  $\varepsilon$  is a small number. Many possibilities of high-resolution flux limiters are available in the literature (LeVeque, 2002) (e.g. minmod, superbee, MC, Koren, van Leer), all of which are algebraic total variation diminishing (TDV) but imply in mildly different capabilities to mitigate numerical problems (e.g., diffusion, dispersion) in the obtained solution. This work uses the superbee flux limiter, as it displays minimal solution smearing while retaining near 2<sup>nd</sup>-order accuracy.

$$\phi_{n,Superbee}(\theta_n) = \max(0, \min((1 + \theta_n)/2, 2, 2\theta_n)) \quad (12)$$

$$\theta_n = \frac{F_n - F_{n-1} + \varepsilon}{F_{n+1} - F_n + \varepsilon} \quad (13)$$

The Dirichlet boundary conditions are applied by ghost cells (see **Figure 1**). The left side of the domain is limited by nuclei size  $L_0$ , and the values assigned to the ghost cells are calculated by linear extrapolation as in eq. (14) to eq. (16), i.e., by the upwind method.

$$F_{L=L_0} = [2/(\Delta L)_1](F_3 - B(t)/G(L_0, t)) \quad (14)$$

$$F_1 = -2(\Delta L)_1 F_{L=L_0} + F_3 \quad (15)$$

$$F_2 = -(\Delta L)_1 F_{L=L_0} + F_3 \quad (16)$$

The ghost cells on the right-side of the domain embody an absorbing boundary condition, where the  $L$  coordinate is artificially truncated at a sufficiently high value  $L_{end}$  to avoid particle loss to the boundary over the process time frame. The boundary condition is implemented via zero-order extrapolation, as in eq. (17).

$$F_{N+3} = F_{N+4} = F_{N+2} \quad (17)$$

The time coordinate is discretized by a forward Euler scheme, where the time step  $\Delta t^m$  is selected based on the most stringent criterion among the Courant condition for numerical stability  $\min((\Delta L)_n/G_n) \leq 1$ , the acceleration limit based on the previous time step, the minimum and maximum user-specified integration steps and the query time points. After the application of the vectorized HR-FVM scheme, the mass balance for the solute API and the dilution effect are updated using the fractional-step method. Next, the applied time step is approved or rejected based on relative tolerance checks in reference to the previous step supersaturation, solvent mass, and concentration and negative  $F$  due to small oscillations. The rejection cycle is applied up to three times before the time step is forcefully accepted, and each cycle reduces the applied time step ( $\alpha_t = 1/3$ ) prior to reapplication of HR-FVM. The summary of the algorithm is provided in **Figure 2**.

**Figure 2.** Implementation of the adaptive time scheme for the HR-FVM with error control for the custom-built partial differential equation integrator.

### 3. Dynamic optimization of cooling-antisolvent seeded (semi-)batch crystallization

The model is used to find optimal temperature and/or antisolvent trajectories that minimize (or maximize) a given goal under constraints that reflect equipment operation limits. In this case, the objective is to maximize the number average crystal size, defined by the ratio of the first to the zeroth moment of the PSD at final batch time  $t_f$  given the system parameters  $\theta$ . The nonlinear programming problem (NLP) is stated in eq. (18).

$$\begin{aligned} & \max \quad f(t_f, \theta) \\ & \text{subject to:} \quad T(k), M_{in}(k) \\ & \quad T_{\min}(k) \leq T(k) \leq T_{\max}(k) \\ & \quad R_{\min}(k) \leq dT/dt(k) \leq R_{\max}(k) \\ & \quad Q_{\min}(k) \leq dM_{in}/dt(k) \leq Q_{\max}(k) \\ & \quad 0.9 \max(\text{Yield}_{\text{theoretical}}) \leq \text{Yield}_{\text{process}}(t_f) \\ & \quad V(t_f) \leq V_{\max} \end{aligned} \quad (18)$$

The trajectories are obtained by optimizing the piecewise linear control variables at specified nodes  $T(k), M_{in}(k)$  located in regular time intervals and solving the system by HR-FVM. In this case study, the control variables were discretized in 16 nodes after preliminary numerical analysis. The optimal trajectory is determined by derivative-free, trust-region-based, multi-start optimization using the COBYLA algorithm (Powell, 1994). The method is implemented in MATLAB® 2022b, although the optimization and objective function evaluations are compiled in FORTRAN and in C++ by MEX files, respectively, which speed up calculations by at least threefold. The data for the case study with fixed batch time is given in **Table 1**.

**Table 1.** Summary of parameters for the case study.

$k_b = 7.92 \times 10^{14} \text{ \#/(kg.s)}$	$b = 6.22$	$k_g = 2.38 \times 10^{-5} \text{ m/s}$	$g = 2.37$
$\rho_c = 1300 \text{ kg/m}^3$	$k_v = 0.1$	$c_{API,t=0} = 0.33 \text{ kg/kg}$	$M_{t=0} = 0.288 \text{ kg}$
$V_{\max} = 400 \text{ mL}$	$t_{\text{batch}} = 16 \text{ h}$	$T_{\min} = 33 \text{ }^\circ\text{C}$	$T_{\max} = 60 \text{ }^\circ\text{C}$
$R_{\min} = -1 \text{ }^\circ\text{C/min}$	$R_{\max} = 0 \text{ }^\circ\text{C/min}$	$L_{\text{end}} = 1000 \text{ }\mu\text{m}$	$N = 4000$

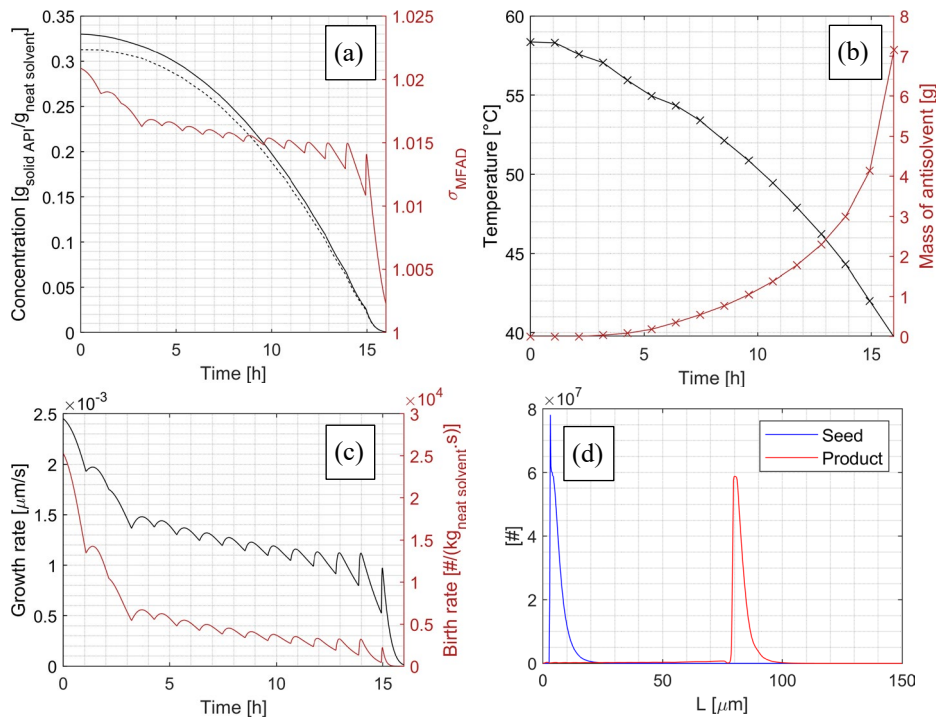

The API solubility is calculated by the Van't Hoff Jouyban-Acree model as in eq. (19).

$$\ln(x_{\text{API}}^{\text{sat}}) = \sum_{p \in \{1,2,3\}} \left( \psi_{0,p} w_p + \psi_{1,p} \frac{w_p}{T} \right) + \sum_{p,q \in \{1,2,3\}; p \neq q} \frac{w_p w_q}{T} \left[ \psi_{2,p,q} + \psi_{3,p,q} (w_p - w_q) + \psi_{4,p,q} (w_p - w_q)^2 \right] \quad (19)$$

Table 2 Van't Hoff Jouyban Acree solubility parameters. Temperature is in degrees Kelvin.

$\psi_{0,1} = -8.77$	$\psi_{1,1} = 9.43 \times 10^6$	$\psi_{2,1,2} = 7.80 \times 10^6$	$\psi_{3,1,2} = -3.40 \times 10^7$	$\psi_{4,1,2} = -3.47 \times 10^7$
$\psi_{0,2} = 17.2$	$\psi_{1,2} = -1.39 \times 10^7$	$\psi_{2,1,3} = -1.55 \times 10^7$	$\psi_{3,1,3} = -6.93 \times 10^6$	$\psi_{4,1,3} = -8.03 \times 10^5$
$\psi_{0,3} = 3.36$	$\psi_{1,3} = -3.06 \times 10^3$	$\psi_{2,2,3} = 2.07 \times 10^7$	$\psi_{3,2,3} = 7.94 \times 10^6$	$\psi_{4,2,3} = 1.15 \times 10^6$

The initial ternary solvent mass composition is  $w_1 = 0.503$ ,  $w_2 = 0.313$  and  $w_3 = 0.184$  and pure antisolvent is dosed ( $w_{\text{in},2} = 1$ ). The theoretical maximum yield is  $\approx 100\%$  due to the strong antisolvent effect. The optimization results are summarized in **Figure 3**.

**Figure 3.** (a) Solution for the mass balance for HR-FVM. Solid line and dashed black line represent the crystallizer concentration and the solubility, respectively, while the red line depicts the supersaturation. (b) Optimal piecewise linear temperature trajectory. (c) Time evolution of the growth and birth rates. (d) Seed and product number density.

The HR-FVM method using the custom-built integrator was validated by comparison with standard ODE integrators in MATLAB (i.e., ode45, ode23s) solving the equivalent NLP by the Standard Method of Moments (SMOM) with adequate solution juxtaposition.

The problem identifies that the initial supersaturation is too high and favors nucleation excessively, so the optimal trajectory starts with an isothermal hold and no antisolvent addition at the beginning. Then, cooling starts before dosing since it is a gentler form of managing the supersaturation, followed by the combined effect of both controls, which are required to satisfy the imposed yield constraint. Furthermore, the optimal profile is consisted of increasingly larger cooling and dosing rates which cause supersaturation to be nearly constant at a level that suppresses nucleation for most of the simulation while growth is consuming the supersaturation. The long but small tail in the product PSD is caused by nucleation, which constantly generates fines, whereas the seeds PSD simply propagate in the size coordinate at the speed determined by the growth rate due to the absence of dissolution and particle death events (breakage, agglomeration). The peak artifact present in the seeds PSD is smeared during the solution, but the shape of the initial PSD is mostly well-retained. The piecewise linear discretization of the controls provides significantly better results than the piecewise constant counterparts (not shown), which implies in supersaturation spikes close to the nodes due to the sudden change in solubility.

#### 4. Conclusions

Piecewise linear optimal temperature and antisolvent addition trajectories were successfully obtained from a custom-built integrator using a versatile and easily extensible implementation of the HR-FVM method to solve a PBE for a (semi-)batch crystallizer. The method at current allows grid tuning, size-dependent growth, and thermal cycles, and can be expanded to cope with more complicated source terms from breakage and agglomeration events by the fractional-step method.

The custom-built integrator for HR-FVM presented comparable accuracy to standard MATLAB integrators using SMOM while delivering more information, however, it needed 2-100 times more optimization time depending on the selected spatial grid resolution. Therefore, there are opportunities to tune the discretization (e.g., via Runge-Kutta, Crank-Nicholson for the time, adaptive spatial grid) to improve the calculations speed. The obtained control trajectory profiles led to crystals that are on average  $\approx 12.4$  times larger than the seeds and low quantity of fines, as nucleation was suppressed.

# A Systematic Framework for Iterative Model-Based Experimental Design of Batch and Continuous Crystallization Systems

Hemalatha Kilari, Yash Barhate, Yung-Shun Kang, Zoltan K. Nagy\*

*Davidson School of Chemical Engineering, Purdue University, West Lafayette, Indiana 47907, United States. \*znagy@purdue.edu*

## Abstract

A generalized and systematic framework is proposed for rapid model development of batch and continuous crystallization processes. The proposed approach uses iterative model-based experimental design (IMED or MBDoE), whereby the experiments are guided by an imprecise-model to produce information rich data that will enhance its prediction performance for further improvement of model structure, parameters, robustness and accuracy. This enables to generate a precise model that can be used for *in silico* design of experiments in broader range of process parameters as well as for efficient digital design. This paper elucidates various steps for model discrimination, selection as well as precise parameter estimation with a combination of statistical tests and optimal experimental design approaches to arrive at an accurate model. The application benefits of the proposed strategy are demonstrated through case studies for batch and continuous crystallization systems of commercial active pharmaceutical ingredients.

**Keywords:** Optimal experimental design; Model-based experimental design, Design of Experiments; Batch crystallization; Continuous crystallization.

## 1. Introduction

Crystallization is a complex solid-liquid-separation technique that is widely applied in the manufacturing of solid products. High fidelity models are necessary for process improvements to achieve customized product specifications and properties. The usual industrial practice for modelling a crystallization process involves a traditional Quality-by-design (QbD) approach where a predetermined set of crystallization experiments are designed either by prior-knowledge/intuition or traditional statistical design of experiments (DoE) that considers the effect of critical process parameters (CPPs) such as seed, supersaturation, temperature, on the critical quality attributes (CQAs) such as mean crystal size, crystal size distribution (CSD), shape and purity. When large number of CPPs are considered, this approach results in a large set of experiments that is resource intensive. This calls for a more systematic procedure for rapid model development.

Application of model-based experimental design approach for rapid model development has been demonstrated to crystallization processes in earlier studies (Chung et al., 2000; Chen et al. 2004; Pal et al., 2020). It is evident from their studies that such approach is capable of predicting information rich experiments and reduce number of experiments to obtain accurate model with precise estimates of parameters. However, the focus in those studies was on either a particular case study involving batch or a particular type of crystallization process concentrating on either model discrimination or improving

parameter precision only and are sometimes case specific. Also, with increased adoption of continuous manufacturing in the industries, it is necessary to extend this procedure to continuous crystallization systems.

The objective of this work is to propose a generalized framework that gives guidelines to follow a model building procedure for crystallization processes starting with model screening from a model structure database and conduct an iterative sequence of statistical approaches to discriminate between the models along with optimal experimental design criterion to obtain a best model with precise parameters. The experimental design in crystallization processes is posed as an optimal control problem with in a framework that enables to choose cooling recipe, seed recipe, antisolvent flow profile, experiment time, residence time, number of crystallizers, number of sampling points etc. with ease of allowing constraints on inputs and outputs. In the proposed framework, methods are presented accounting to parameter uncertainty to improve model robustness. This work presents the first generalized comprehensive study that is applied to both batch and continuous crystallization processes.

## 2. Framework Development Methodology

### 2.1. Crystallization Model

Population balance equation (PBE) governing the CSD assuming nucleation with constant nucleation size, growth and agglomeration mechanisms can be represented as follows (Szilagyi et al., 2020; Szilagyi et al., 2022).

$$\frac{\partial[(Vn(L,t))]}{\partial t} + \frac{\partial(Gn(L,t)V)}{\partial L} = V[B\delta(L-L_n) + B_{agg} - D_{agg} + B_{bre} - D_{bre}] + F_f n_f(L,t) - Fn(L,t) \quad (1)$$

$$\frac{d(Vc)}{dt} = -3Vk_v \rho_c \left[ (B_p + B_s)L_n^3 + \int_0^\infty GL^2 n(L)dL \right] + F_f c_f - Fc \quad (2)$$

$$B_p = k_p(1 + \gamma_p A)\sigma^p \exp\left(-\frac{k_p}{\ln^2(\sigma+1)}\right) \exp\left(\frac{-E_p}{RT}\right); B_s = k_s(1 + \gamma_s A)\sigma^s \exp\left(-\frac{k_s}{\ln^2(\sigma+1)}\right) \exp\left(\frac{-E_s}{RT}\right); G = k_g(1 + \gamma_g A)\sigma^g (\alpha_g + \beta_g L^{\gamma_g}) \exp\left(\frac{-E_g}{RT}\right) \quad (3)$$

From Eq (1),  $B_{agg}$  and  $B_{bre}$  are birth functions that describe production of new crystals of size  $L$  by agglomeration and breakage.  $D_{agg}$  and  $D_{bre}$  represent Death functions for the rate of consumption of crystals of size  $L$  by agglomeration and breakage. Eq (2) represents mass balance equation for crystallizing compound that accounts for solid-liquid mass transfer generated by nucleation and growth with feed and outflow streams in a crystallizer. Generalized expressions for primary & secondary nucleation and growth are shown in Eq (3). As a first step to modeling crystallization processes, experimental data is obtained for a preliminary set of crystallization experiments by monitoring the process variables throughout the experiment using in situ or inline process analytical technology (PAT) tools and offline characterization methods. An optimization problem for parameter estimation is formulated (Eq (4)) with the objective of minimizing the weighted sum of squared error ( $WMSE$ ) between experimental and model predicted values of the process parameters.

$$\min_{\theta} WMSE = \frac{1}{N_E N_S} \sum_{h=1}^{N_v} \sum_{i=1}^{N_E} \sum_{j=1}^{N_S} w_h (y_{h,i,j}^{\text{exp}} - y_{h,i,j}^{\text{mod}})^2 \quad (4)$$

Where  $N_v$ ,  $N_E$  and  $N_S$  are number of process variables, experiments and samples or data points respectively;  $w_h$  are the weights chosen to normalize the value of the objectives,  $y$  represents the process variables such as concentration, online crystal counts /sec during the operation time, final time mean size or  $D_{10}$ ,  $D_{50}$  and  $D_{90}$  values, or the entire CSD, depending on measurement and modelling techniques used.

*2.2. Optimal Experimental design for Model Identification, Discrimination and Parameter precision*

Selecting a best model from a crystallization model library consisting of combinations of various expressions for different mechanisms is a challenging task. Initial kinetic parameter estimation for some of the chosen models may give an incorrect model that still can closely represent the experimental data. It is of primary importance to statistically assess the reliability and adequacy of the model and if necessary, of the new parameter estimates. This can be done using standard checks (i.e. on residuals distributions) and statistical tests. Statistical goodness-of-fit tests such as chi-square test, F-test, student-t test, etc. can be used for assessing model identifiability and parameter estimability. The problem of over fitting and underfitting a model can be tackled well by using Akaike information criterion (*AIC*) which estimates prediction error and thereby provides the relative quality of statistical models for a given set of data. When all these statistical tests fail to screen one model as the best model, optimal experimental design criterion for model discrimination (MD) can be used, which determines experimental conditions for additional experiments to be conducted in order to maximize the divergence between models. There have been many such approaches reported so far and a modified Hunter-Reiner criterion for many rival models similar to the one reported by Buzzi-Ferraris-Forzatti (1992) has been used in our work. When a best model is selected, it is subjected to parameter refinement (PR) to reduce the parameter uncertainties and improve the predictive capability of the model. Various steps involved in the IMED procedure are illustrated in the Fig.1.

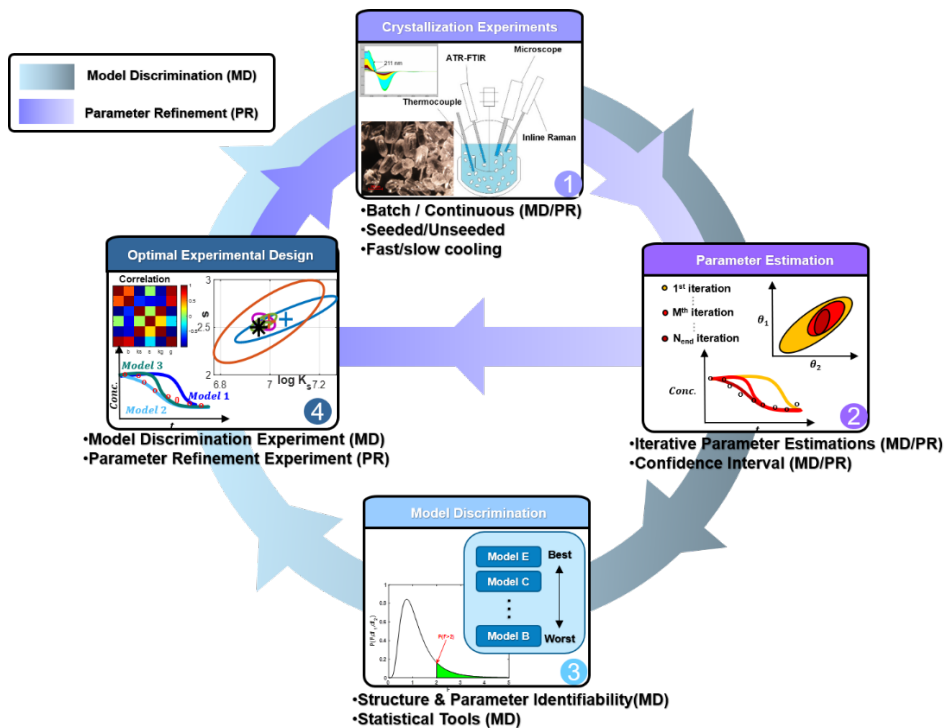

Fig.1. Iterative model-based experimental design procedure for crystallization processes

*D*-optimal design is a popular design procedure widely used for improving parameter precision that uses Fisher Information Matrix (FIM) as a metric to assess experimental information of the present experiments and prescribe a future experiment that provides with more information rich data. FIM is constructed from sensitivity matrix of process states and model parameters (Yang et al., 2022). The new experiment is obtained by maximizing the determinant of the *FIM* (which is an indirect approach of minimizing confidence region of parameter estimates). The generic mathematical representation of this *D*-optimal approach is shown below for a batch cooling crystallization and for a continuous MSMMPR crystallization system.

<i>Batch Cooling Crystallization</i>	<i>Continuous MSMMPR Crystallization</i>
$\max_{N_E, CR, Ms} [\det(FIM)]$ <p>Subject to:</p> $c_1 : Ms_{\min} \leq Ms \leq Ms_{\max}$ $c_2 : CR_{\min} \leq CR \leq CR_{\max}$ $c_3 : CR \leq 0$	$\max_{N_c, \tau_i, T_i} [\det(FIM)]$ <p>Subject to:</p> $c_1 : \tau_{\min} \leq \tau_i \leq \tau_{\max}$ $c_2 : T_{N_c} \leq T_i \leq T_f$ $c_3 : T_i < T_{i-1} \quad (i=1 \dots N_c)$

(5)

Where *CR* is the cooling rate for a linear temperature profile, *Ms* is the seed loading,  $N_E$  is the number of experiments necessary for another iteration for the batch case and  $N_c$  is number of crystallizers in a cascade of MSMMPRs for the continuous case with  $\tau_i$  being the residence time and  $T_i$ , the temperature of  $i^{th}$  Crystallizer. *FIM* is the fisher information matrix and is constructed from the sensitivity matrix with sensitivity coefficients of process variables at various sampling instants with respect to each parameter. This step yields new experimental conditions to be implemented for data collection and for parameter refinement. This procedure is iterated until a predefined model accuracy is obtained with precise parameter estimates.

### 3. Application of the Proposed Framework: Results

The benefits of the framework are tested first by application to a batch cooling crystallization case study with a known model. *In silico* experiments are generated for a combination of high/low seed loading and fast/slow linear cooling experiments. This set of four seeded experiments are used to obtain initial parameter estimates for six plausible model candidates (Table 1) that are subjected to model discrimination. It is observed that all these models closely fit the concentration and final mean size data. The AIC criteria correctly chooses model 6 as the best model. However, WMSE values are very close for other models too. Hence, it is decided to allow these models for an iteration of discriminatory experimental design (MD-OED). F-test (Sobek and Werle, 2020) is efficient in screening 3 models out of 6 for MD-OED procedure. With one iteration of the MD-OED, an unseeded experiment is obtained and this experiment is carried out *in silico* to collect experimental data for the next iteration of parameter estimation procedure. This experiment is added to the initial parameter set and a new parameter estimation is carried out for all 3 models. The unseeded experiment seems to create a better divergence between the 3 models and helps to choose the best model amongst them. Model 6 is chosen as the best model (true model) according to AIC and also F-test rejects other models choosing model 6 as the best one. Model 6 is now chosen for iterative optimal experimental design procedure for improving precision of parameters.

Table 1: Model discrimination and Selection

The IMED approach for parameter precision or parameter refinement can be carried out using either a sequential or a simultaneous approach. In the simultaneous approach a complete set of experiments with either a fixed number (e.g. in our case  $n_{exp} = 4$ ) or using the number of experiments also as a decision variable can be used to obtain the new set of experimental conditions for all experiments within a single optimization that could be implemented to collect new experimental data for parameter refinement with new parameter estimation. In the sequential approach only one new experiment is obtained at each iteration that can be implemented and the results are added to previous experimental data to carry out the new parameter estimation.

Sample results are shown for the sequential approach where one experiment is obtained with each iteration and new parameters are estimated and analyzed for parameter uncertainty. The confidence region (Fig. 2) plotted for a pair of initial parameter estimates ( $\theta_1 = \log K_p$  &  $\theta_2 = p$ ; primary nucleation parameters shown in Eq(3)) is very broad. With each iteration of the optimal experimental design, the parameters are improved as shown by shrinkage of the confidence ellipse and moving closer to the true parameter values after each iteration. Fig 2(a) shows comparison of confidence ellipse with initial parameter estimation and a model discriminatory experiment. Adding the discriminatory experiment to the parameter estimation set improved the model as it can be clearly observed that the parameter values shifted closer to the true parameter region.

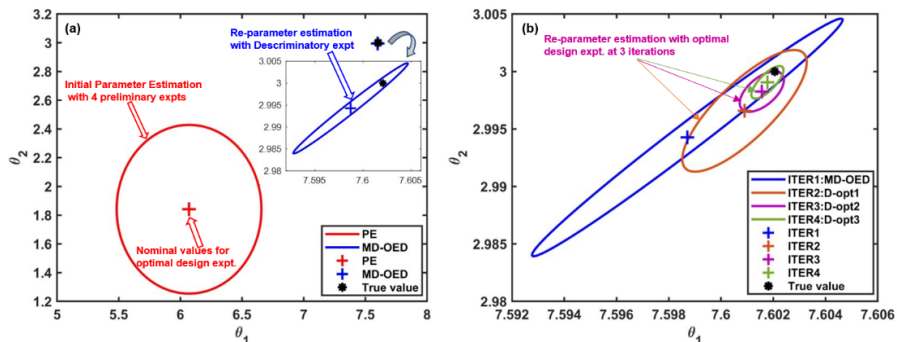

Fig.2. Confidence Ellipse plots (a) Initial Parameter Estimation (PE) & Model Discrimination expt. (MD-OED) (b) Optimally designed experiments using D-design Criterion (D-opt1, D-opt2, D-opt3) at each iteration (ITER)

Fig 2(b) shows the improvement of confidence region and corresponding parameters with each iteration of re-parameter estimation including respective D-optimal experiment. The IMED procedure is continued until no further improvement in the confidence region is obtained. In this case, 3 iterations of IMED brought the parameters closer to the true value of the parameters. Precise parameters with very narrow confidence intervals are obtained at the end of 3 iterations and found to be very close to the true parameters of the model considered. Thus, this batch case study demonstrates powerful predictive capabilities of the proposed framework. Similarly, another case study for continuous crystallization of Diphenhydramine hydrochloride is carried out and it is observed to be effective in arriving at an accurate model with precise parameters and very small confidence intervals.

#### 4. Conclusions

A generalized systematic framework is proposed for batch and continuous crystallization model development using an iterative model-based experimental design framework. The framework combines model discrimination and parameter refinement steps and is able to identify the best model structure that constitutes relevant crystallization mechanisms and drive the model with imprecise initial parameter estimates towards an accurate model with precise parameters. Future work is focused on expanding this knowledge to application scenarios that include other types of crystallization processes and multi-dimensional models to cater to a wider range of applications of crystallization modeling.

## Abstract

The successful development and timely deployment of novel technologies to compete with existing ones depend on the availability of necessary resources and associated costs. This paper introduces a multiperiod optimization model that integrates processing plants, technologies, and resources under a single network to study the impact of novel technology development on the process network design to meet the annual product demands over a planning horizon. A case study of developing post-combustion adsorption for carbon capture (CC) while meeting the annual capture targets reveals that adsorption should become commercially available within 5 years to compete with the commercially available absorption technology. The total CC cost if only absorption were available is \$13.9 billion, 6% of which could be used towards the research and development (R&D) of the adsorption technology while still making it an economically viable option.

**Keywords:** technology development; multiperiod optimization; CO<sub>2</sub> capture planning.

## 1. Introduction

Technology development requires resources for R&D, pilot plants, and demonstration projects. The availability of such resources plays a major role in the successful development and timely implementation of new technologies to compete with existing and other novel technologies (Anderson Jr and Joglekar, 2005). For example, a high cost for a necessary resource can make a novel technology economically unviable, or prolonged development time can make it uncompetitive against technologies developing at a faster pace (Davila and Wouters, 2004). Hence, it is important to study the impacts of resource availability, the associated costs, and the development time on novel technology development along with the operation of the existing technologies. This work develops a multiperiod optimization model for production planning and resource allocation for developing novel technologies and operating implemented technologies to meet the annual product demands over time.

## 2. Problem Statement

The goal is to develop an optimization-based framework to study the development of novel technologies and deployment and operation of commercial technologies by determining strategic and tactical decisions: (i) allocation of resources for technology development, (ii) selection of processes and commercial technologies to produce products, (iii) determination of production rate based on the annual product demands, and (iv) addition of expansions to the process facilities, if necessary, over time. For given yearly product demands, the objective is to minimize the total cost of technology development, implementation, and operation.

The superstructure in Figure 1 illustrates the overarching network. It consists of a set of processes ( $i \in I$ ), technologies ( $j \in J$ ), resources ( $r \in R$ ), development stages called Technology Stages ( $s \in S$ ), expansions ( $n \in N$ ), and time periods ( $t \in T$ ). The technologies  $T_j$  are in different Technology Stages ( $TS_{j1}, TS_{j2}, \dots, TS_{js}$ ). They mature to subsequent stages if the necessary resources  $R_{rt}$  are allocated during development. The technically developed and commercially available technologies at  $TS_{js}$  are used by processes  $P_i$  in the facilities  $C_{ij}$  to produce products  $X_{it}$  over the planning period  $t$ . Expansion facility  $E_{nij}$  using technology  $j$  is added for process  $i$  when demand for product  $X_{it}$  increases at time  $t$ .

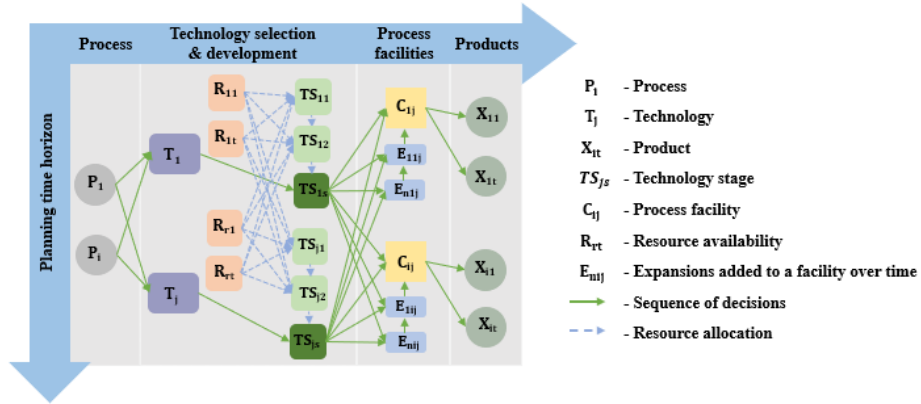

Figure 1. Superstructure of technology development and deployment to produce products.

### 3. Mathematical Model Formulation

#### 3.1. Objective

The objective is to minimize the total cost of producing a set of products over the planning horizon while meeting annual demands. The cost consists of annualized investment and annual operating costs, and R&D and demonstration project costs as given in Eq. (1).

$$\text{MinTC} = \sum_{i,j,t,n} (IC_{i,j,t,n} + OC_{i,j,t,n}) + \sum_{i,j,t} DC_{i,j,t} \quad \forall i \in I, j \in J, t \in T, n \in N \quad (1)$$

The sets  $i \in I, j \in J, t \in T$ , and  $n \in N$  represent the processes, technologies, planning periods, and capacity expansions. For process  $i$ ,  $n=1$  represents the initial facility capacity, and  $n>1$  represents the expansions. The variable  $TC$  is the total cost of investment and operation of implemented technologies and the cost of developing novel technologies. The variables  $IC_{i,j,t,n}$  and  $OC_{i,j,t,n}$  are the investment and operating costs of facility/expansion  $n$  of process  $i$  using technology  $j$  at time  $t$ . The variable  $DC_{i,j,t}$  is the technical development cost of technology  $j$  for process  $i$  at time  $t$ .

#### 3.2. Binary Variables

A binary variable  $yc_{i,j}$  is defined in Eq. (2) to represent the compatibility of technology  $j$  with process  $i$ . Technology Stages are represented by set  $s \in S$ , and a binary variable  $x_{i,j,t,s}$  is introduced in Eq. (3) to represent if technology  $j$  has been developed to at least Technology Stage  $s$  by time  $t$  for process  $i$ . If a technology is not compatible with process  $i$ , it remains in the initial stage of development ( $x_{i,j,t,1}=1 \quad \forall t \in T$  and  $x_{i,j,t,s}=0 \quad \forall t \in T, s \in \{2,3,\dots,S\}$ ). Another binary variable  $x'_{i,j,t,s}$  is introduced in Eq. (4) to denote if the resources necessary for development to stage  $s$  are available at time  $t$ . Once the technology  $j$  is commercially developed for process  $i$  ( $x_{i,j,t,s}=1$ ), a binary variable,  $y_{i,j,t,n}$ , in Eq. (5), represents the technology implementation for facility/expansion  $n$  of process  $i$  at time  $t$ .

$$yc_{i,j} = \begin{cases} 1, \text{if tech } j \text{ is compatible with process } i \\ 0, \text{otherwise} \end{cases} \quad (2)$$

$$x_{i,j,t,s} = \begin{cases} 1, \text{if tech } j \text{ is developed to at least stage } s \text{ for process } i \text{ by time } t \\ 0, \text{otherwise} \end{cases} \quad (3)$$

$$x_{i,j,t,s} = \begin{cases} 1, \text{if resources necessary for tech } j \text{ to develop to stage } s + 1 \\ \text{for process } i \text{ is available by time } t \\ 0, \text{otherwise} \end{cases} \quad (4)$$

$$y_{i,j,t,n} = \begin{cases} 1, \text{if technology } j \text{ is used in facility } n \text{ of process } i \text{ during time } t \\ 0, \text{otherwise} \end{cases} \quad (5)$$

### 3.3. Parameters

The initial Technology Stage of technology  $j$  for process  $i$  is denoted by the parameter  $ITS_{i,j}$ . The resources required for developing technologies are represented by set  $r \in R$ . The amount of resource  $r$  necessary for technology  $j$  to be developed to Technology Stage  $s$  for process  $i$  is denoted by parameter  $Q_{r,i,j,s}$ . These resources should be available for  $R_{i,j,s}$  periods for successful progression to stage  $s$ . The amount of resource  $r$  available at time  $t$  is denoted by parameter  $QT_{r,t}$ . The cost of resources at each period  $t$  is denoted  $QC_{r,t}$ .

### 3.4. Constraints and Other Variables

The Technology Stage of technology  $j$  for process  $i$  during time  $t$  is represented by the variable  $TS_{i,j,t}$ . It is computed from the binary variable  $x_{i,j,t,s}$ . Another variable called Technology Integration Level ( $TIL_{i,j,t}$ ) is introduced to incorporate a commercially developed technology  $j$  into the network for process  $i$ . It is a function of the technology's compatibility with the process ( $yc_{i,j}$ ) and its development stage for the process ( $TS_{i,j,t}$ ). If the final development stage is  $S$ , variable  $TS_{i,j,t}$  takes a value from  $1$  to  $S$ . Variable  $TIL_{i,j,t}$  is expressed in terms of  $TS_{i,j,t}$  and takes a value from  $1$  to  $S$  if the technology is compatible with the process ( $yc_{i,j}=1$ ), else  $TIL_{i,j,t}=0$  when  $yc_{i,j}=0$ . A disjunctive model is used to implement these conditions in Eq. (6). For technology  $j$  that is commercially developed for process  $i$  by time  $t$ ,  $TS_{i,j,t}=S$  and  $TIL_{i,j,t}=S$ , while for an incompatible technology for process  $i$ ,  $TS_{i,j,t}=1$  and  $TIL_{i,j,t}=0$ . Equation (7) ensures that only the technologies commercially developed for the process are implemented in process facility/expansion. The amount of each resource allocated for developing technology  $j$  for source  $i$  to stage  $s+1$  during time  $t$  is given by variable  $q_{r,i,j,t,s}$ . The cost parameter for the resources is  $QC_{r,t}$ . The development cost for technology  $j$  for process  $i$  at time  $t$  is computed by Eq. (8).

$$\left[ \begin{matrix} yc_{i,j} = 1 \\ TIL_{i,j,t} = TS_{i,j,t} = \sum_{s \in S} x_{i,j,t,s} \end{matrix} \right] \vee \left[ \begin{matrix} yc_{i,j} = 0 \\ TIL_{i,j,t} = 0 \end{matrix} \right] \quad \forall i \in I, j \in J, t \in T \quad (6)$$

$$TIL_{i,j,t} / S \geq y_{i,j,t,n} \quad \forall i \in I, j \in J, t \in T, n \in N \quad (7)$$

$$DC_{i,j,t} = \sum_{r \in R, s \in S} q_{r,i,j,t,s} QC_{r,t} \quad \forall i \in I, j \in J, t \in T, r \in R, s \in S \quad (8)$$

Equation (9) ensures that developing technology  $j$  is at least at stage  $s-1$  before it progresses to the subsequent stage  $s$ . Equation (10) computes the Technology Stage of technology  $j$  for process  $i$  at the first planning period using the initial Technology Stage parameter. The resource allocation for Technology Stage progression is represented with the disjunctive model in Eq. (11). The binary variable  $x'_{i,j,t,s}$  takes a value of  $1$  when all necessary resources for Technology Stage progression of technology  $j$  to stage  $s$  for process  $i$  are available at time  $t$ . Equation (12) enables the progression of a technology to

stage  $s$  at time  $t$  if the necessary resources are available throughout  $R_{i,j,s}$  by time  $t-1$ . A technology can progress to only one subsequent development stage for a process per period. Equation (13) ensures this condition by allowing resource allocation for only one Technology Stage progression of technology  $j$  for process  $i$  at time  $t$ . Resource allocation at every period ( $q_{r,i,j,t,s}$ ) is limited by resource availability at that period ( $QT_{r,t}$ ) in Eq. (14).

$$x_{i,j,t,s} \leq x_{i,j,t,s-1} \quad \forall i \in I, j \in J, t \in T, s \in S \quad (9)$$

$$TS_{i,j,1} = \sum_{s \in S} x_{i,j,1,s} = ITS_{i,j} \quad \forall i \in I, j \in J \quad (10)$$

$$\left[ \begin{array}{l} x'_{i,j,t,s} = 1 \\ q_{r,i,j,t,s} = Q_{r,i,j,s} \end{array} \right] V \left[ \begin{array}{l} x'_{i,j,t,s} = 0 \\ q_{r,i,j,t,s} = 0 \end{array} \right] \quad \forall r \in R, i \in I, j \in J, t \in T, s \in S \quad (11)$$

$$\sum_0^{t-1} x'_{i,j,t,s} / R_{i,j,s} \geq x_{i,j,t,s} \quad \forall i \in I, j \in J, t \in T, s \in S \quad (12)$$

$$\sum_{s \in S} x'_{i,j,t,s} \leq 1 \quad \forall i \in I, j \in J, t \in T \quad (13)$$

$$\sum_{i \in I, j \in J, s \in S} q_{r,i,j,t,s} \leq QT_{r,t} \quad \forall r \in R, t \in T \quad (14)$$

Technology  $j$  commercially developed for process  $i$  by time  $t$  ( $TIL_{i,j,t}=S$ ) can be implemented in its facility at time  $t$ . If it is implemented in facility  $n$ ,  $y_{i,j,t,n}=1$ . The facility capacity is denoted by variable  $c_{i,j,t,n}$ , and feed flow rate is denoted by variable  $f_{i,j,t,n}$ . The investment cost ( $CIC_{i,j,t,n}$ ) is a function of  $c_{i,j,t,n}$ , while the operating cost ( $COC_{i,j,t,n}$ ) is a function of  $f_{i,j,t,n}$ . If the technology is not implemented in the facility,  $y_{i,j,t,n}=0$ , and variables  $c_{i,j,t,n}$  and  $f_{i,j,t,n}$  become zero. These conditions are implemented with disjunctive model Eq. (15). Equations (16) and (17) ensure process  $i$  uses at most one technology in a processing facility, and the same technology is used in the subsequent periods.

$$\left[ \begin{array}{l} y_{i,j,t,n} = 1 \\ CIC_{i,j,t,n} = f(X_i, c_{i,j,t,n}) \\ COC_{i,j,t,n} = f(X_i, f_{i,j,t,n}) \end{array} \right] V \left[ \begin{array}{l} y_{i,j,t,n} = 0 \\ CIC_{i,j,t,n} = 0 \\ COC_{i,j,t,n} = 0 \end{array} \right] \quad \forall i \in I, j \in J, t \in T, n \in N \quad (15)$$

$$\sum_{j \in J} y_{i,j,t,n} \leq 1 \quad \forall i \in I, t \in T, n \in N \quad (16)$$

$$y_{i,j,t,n} \geq y_{i,j,t-1,n} \quad \forall i \in I, j \in J, t \in T, n \in N \quad (17)$$

#### 4. Results and Discussion

A case study of planning CC from 10 different sources over a planning period of 10 years (discretized into 10 equal time periods) to meet annual capture targets that increase biannually by 10% (from 30% to 70%) is considered. Post-combustion capture using absorption using aqueous monoethanolamine (ABS-MEA) is assumed to be commercially available, and pressure swing adsorption using methyl viologen exchanged zeolite Y (PSA-MVY) is under development. Previous studies have shown that PSA-MVY is more cost-effective than ABS-MEA for sources with CO<sub>2</sub> composition over 5% (Hasan et al. 2014, Santhamoorthy et al. 2023). The total CC cost should decrease if PSA-MVY is commercially developed during the planning period. The degree of the decrease would depend on when PSA-MVY becomes available and the emission sources using it. We demonstrate the model's capabilities by studying these factors.

Three Technology Stages, lab-scale R&D, pilot-scale testing, and commercialization, are considered. The pilot-scale plants are assumed to capture 0.1 million tons of CO<sub>2</sub> per

annum. The research funds and time for successful lab-scale R&D and pilot-scale testing are not specified as parameters in the model. Instead, it is assumed that each Technology Stage can take from one to ten years for successful testing. The total development time is the total time taken for testing these stages. The maximum research fund available is computed as the difference between total costs with and without the technology.

The emission sources data and the cost models and carbon composition limitations for the capture technologies from Hasan et al. (2014) are used to construct model parameters. The costs of pilot-scale plants are estimated by escalating the cost by a factor of 1.3 to account for the overhead costs associated with testing new technology. The nonlinear cost models for CC yielded a mixed-integer nonlinear programming model (MINLP). The solution approach developed by Santhamoorthy et al. (2023) is used to solve the problem to an optimality gap of 5%. It is a two-step approach that solves a relaxed MILP model to obtain a lower bound and an initialized MINLP model to obtain an upper bound. The steps are employed iteratively with an increasing number of segments in the relaxation step to generate tight bounds by updating the lower and upper bounds.

The optimization models are formulated in Python V3.8.6 using PYOMO V6.4.1. The MILP models are solved using CPLEX V20.10, and the initialized MINLP models are solved using DICOPT V2 through GAMS V24.8.5, all on an Intel Xeon Gold 6248R 3 GHz processor with 48 cores and utilizing a maximum of 50 GB RAM.

Different development times are assumed for PSA-MVY, and the model is solved to generate the results summarized in Figure 2. In Figure 2(a), the marker star shows the cases where there is a commercial development of PSA-MVY during the planning period. There is successful development for all cases with at most 8 years of total development time. The total CC planning cost increases as the total development time increases. Figures 2(b) and (c) show the number of sources using only PSA-MVY and both ABS-MEA and PSA-MVY for capture. More sources use only PSA-MVY for shorter total development times, leading to a lower total CC cost. As the development time increases, ABS-MEA is implemented for capture to meet the annual capture targets, while PSA-MVY is developed and implemented in an expansion facility over time. The number of sources using PSA-MVY is high when the total development time is at most 6 years. The number of cases in which different emission sources use either only PSA-MVY or PSA-MVY in the expansion capacity is shown in Figure 2(d). When the development time is longer for PSA-MVY, sources 1-4, having high emission rates, use it in the expansion capacity, while sources 5-7 still use only PSA-MVY for capture. Sources 8-10 do not use PSA-MVY since they have a very low CO<sub>2</sub> composition. The total cost of CC planning for 10 years using only ABS-MEA technology is \$13.9 billion. The total cost when PSA-MVY is developed in 2, 5, or 9 years is \$12.0, \$13.1, and \$13.7 billion, respectively. Thus, the funds that can be used towards initial R&D and lab-testing of PSA-MVY decrease as its development time prolongs.

## **5. Conclusion and Future Direction**

This paper developed a multi-period optimization model that assists the planning decisions related to technology development, implementation, and operation. A case study of CC demonstrated the capability of the model to minimize the total cost of capture planning while developing a novel technology for implementation in the network. The funds that can be allocated towards R&D of the new technology were determined based on its anticipated development time. The results revealed that some sources used only the new technology for capture despite its long development time, while others used it only

in the expansions. This work will be extended to study the effect of uncertainty in the successful progression of the technologies to subsequent development stages.

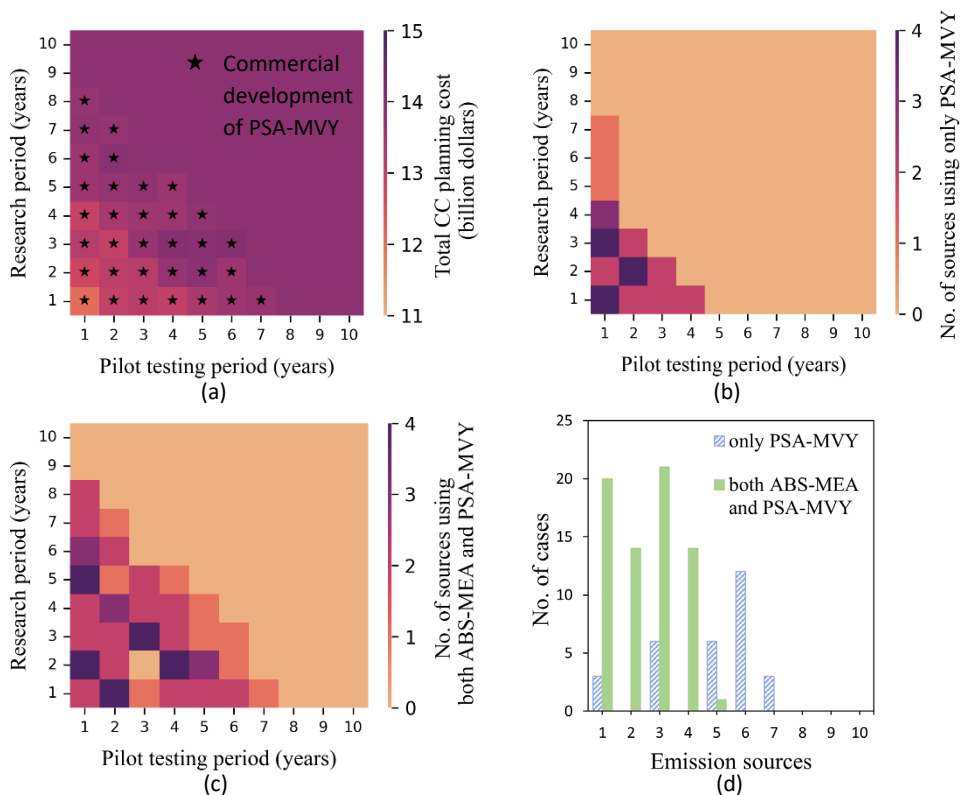

Figure 2. (a) Total cost of CC, (b) No. of sources using only PSA-MVY, and (c) No. of sources using both ABS-MEA and PSA-MVY for different cases of different development periods. (d) No. of cases in which sources use either only PSA-MVY or both ABS-MEA and PSA-MVY.

## Abstract

This work focuses on the design and development of a secure and private communication network using semi-homomorphic encryption to ensure cyber-security of model predictive control (MPC) systems. Specifically, Paillier encryption algorithm is used for encrypting-decrypting signals in the communication links. This implementation involves quantization of signals, which may result in significant errors. Thus, the MPC system is designed to ensure a certain degree of robustness with respect to quantization errors. The Encrypted Lyapunov-based MPC scheme is tuned to ensure that the calculations can be done with the available computational resources. Finally, the proposed design is implemented on a chemical process example.

**Keywords:** Model predictive control (MPC), cyber-security, encrypted control, semi-homomorphic encryption, quantization

## 1. Introduction

Cybersecurity of networked and distributed control systems has become crucial in recent years due to their increased vulnerability to targeted cyber-attacks. The integration of cloud-computing technologies with physical control systems has significantly increased process performance and decreased computational time, thus allowing real-time optimization. However, these advantages do not come without the increased threats of targeted cyber-attacks. Insecure communication channels are vulnerable to data-interception, eavesdropping on sensitive information, and data-manipulation. These cyber-attacks compromise the integrity, stability, and profitability of control systems. 77 cyber-security related incidents, on critical infrastructure, were reported from 2000 to 2019. Out of these reported incidents, a vast number of attacks were carried out on oil and energy sector industries (Parker et al., 2023). Clearly, cyber-attacks on these systems are extremely dangerous and hence it is of crucial importance to design and develop cyber-secure architectures for networked control systems.

In this work, we design and develop an Encrypted Lyapunov-based Model Predictive Control (LMPC) framework for nonlinear systems in which secure communication channels are established between sensor-controller and controller-actuator links. Specifically, Paillier cryptosystem is used to encrypt-decrypt sensitive state and input data in the network links. The designed controller is robust to the quantization errors arising as a consequence of encryption. The computational cost associated with different

quantization parameters is analyzed. Finally, the proposed framework is implemented on a multi-input, multi-output chemical process example.

## 2. Preliminaries

### 2.1. Class of Systems

In this work, we consider continuous-time nonlinear systems, described by the following nonlinear ordinary differential equation,

$$\dot{x}(t) = F(x(t), u(t)) = f(x) + g(x)u \quad (1)$$

where  $u^T = [u_1, u_2, u_3, \dots, u_m] \in \mathbb{R}^m$  is the manipulated input vector denoting  $m$  inputs and,  $x^T = [x_1, x_2, x_3, \dots, x_n] \in \mathbb{R}^n$  is the  $n$ -dimensional state vector. The manipulated inputs are constrained such that  $u \in U$ , where  $U := \{u \in U \mid u_{\min,i} \leq u_i \leq u_{\max,i}, \forall i = 1, 2, \dots, m\}$ , with  $u_{\min,i}$  and  $u_{\max,i}$  being the physical constraints on the  $i^{\text{th}}$  manipulated input.  $f(\cdot)$  and  $g(\cdot)$  are sufficiently smooth vector and matrix functions, respectively. The origin is a steady state of the nonlinear system and, without loss of generality, it is assumed that  $f(0) = 0$ .

### 2.2. Stabilizability Assumptions

We assume that there exists a feedback control law  $u = \Phi(x)$  that can render the steady-state of the nonlinear system of Eq. (1) exponentially stable in the sense that there exists a continuously differentiable control Lyapunov function  $V(x)$  such that the following inequalities hold for all  $x \in D$ , where  $D$  is an open neighborhood around the origin (Wu et al., 2019a):

$$c_1 |x|^2 \leq V(x) \leq c_2 |x|^2, \quad \frac{\partial V(x)}{\partial x} F(x, \Phi(x)) \leq -c_3 |x|^2, \quad \left| \frac{\partial V(x)}{\partial x} \right| \leq c_4 |x| \quad (2)$$

where  $c_1, c_2, c_3, c_4 > 0$ . The stabilizing controller can be constructed using the universal Sontag control law (Lin & Sontag, 1991). The closed-loop stability region for the nonlinear system of Eq. (1) is characterized as a level set of the Lyapunov function  $V(x)$ , and this closed-loop stability region is denoted as  $\Omega_\rho$ , where  $\Omega_\rho := \{x \in D \mid V(x) \leq \rho\}$ ,  $\rho > 0$ .

### 2.3. Paillier Cryptosystem and Quantization

In this paper, Paillier cryptosystem (Paillier, 1999) is used for encryption and decryption operations of state and input signals. Paillier cryptosystem is a semi-homomorphic encryption scheme in the sense that addition operations can be carried out in the encrypted space. The first step in the Paillier cryptosystem is to generate a public key  $(M, g)$  which is used for encrypting plaintext messages. The next step is to generate a private key  $(\lambda, u)$  that is used to decrypt ciphertexts. The detailed key generation steps can be found in Paillier (1999). The encryption-decryption operations in the Paillier cryptosystem are carried out on a subset of  $\mathbb{Z}_+$ . This subset is denoted as  $\mathbb{Z}_M$  and contains positive integers less than  $M$ . Thus, it is important to map the real-valued state and input data to the set  $\mathbb{Z}_M$  (Darup et al., 2017). Here, we consider signed-fixed point numbers in base 2, where  $l_1$  is the number of total bits and  $d$  is the number of fractional bits. In the first step, the function  $g_{l_1,d}(\cdot): \mathbb{R} \rightarrow \mathbb{Q}_{l_1,d}$ ,  $g_{l_1,d}(a) := \arg \min_{q \in \mathbb{Q}_{l_1,d}} |a - q|$  is used to map the real-valued data to the set  $\mathbb{Q}_{l_1,d}$ , where the elements of the set  $\mathbb{Q}_{l_1,d}$  are rational numbers from

$-2^{l_1-d-1}$  to  $2^{l_1-d-1} - 2^{-d}$  and are separated from each other by a resolution of  $2^{-d}$ . Next, we map the quantized signals to a subset of  $\mathbb{Z}_M$  using the bijective mapping  $f_{l_2,d}(\cdot) : \mathbb{Q}_{l_1,d} \rightarrow \mathbb{Z}_{2^{l_2}}$ ,  $f_{l_2,d}(q) := 2^d q \bmod 2^{l_2}$ . Once the quantized signals have been mapped to the set  $\mathbb{Z}_{2^{l_2}}$ , our data is ready for encryption. It is important to note that the encrypted data will be decrypted at the controller and at the actuator and, in that case, the resulting data will be in the set  $\mathbb{Z}_{2^{l_2}}$ . Hence, it is important to map the decrypted integer messages to the set of quantized signals,  $\mathbb{Q}_{l_1,d}$ . The inverse mapping  $f_{l_2,d}^{-1}$ , is defined as,

$$f_{l_2,d}^{-1}(\cdot) : \mathbb{Z}_{2^{l_2}} \rightarrow \mathbb{Q}_{l_1,d}, f_{l_2,d}^{-1}(m) := \frac{1}{2^d} \begin{cases} m - 2^{l_2} & \text{if } m \geq 2^{l_2-1} \\ m & \text{otherwise} \end{cases}.$$

### 3. Encrypted MPC Design

In this section, we propose an encrypted model predictive controller (MPC) scheme. In the closed-loop encrypted MPC design of Figure 1, state measurements  $x(t)$  are encrypted at the sensor, and the encrypted data is then sent to the MPC. At the controller, before performing the nonlinear optimization calculations, the encrypted state data is decrypted to obtain the quantized states  $\hat{x}(t)$ . These quantized states are provided as measurement-feedback to the MPC optimization problem. The optimal control inputs  $u(t)$  are calculated by solving an optimal control problem and are encrypted before being transmitted to the actuator. At the actuator, the encrypted control inputs data is decrypted to obtain the quantized control actions,  $\hat{u}(t)$ . These quantized control actions are applied on the nonlinear system.

Figure 1: Schematic of nonlinear system under closed-loop encrypted MPC

In the closed-loop design of Figure 1, secure communication is established in the sensor-controller and controller-actuator links. However, two types of quantization errors arise. There is a loss of information in the sensor-controller link due to quantization of states, and in the controller-actuator link due to quantization of inputs. Based on the quantization mappings and the structure of the set  $\mathbb{Q}_{l_1,d}$ , these quantization errors are bounded such that:

$$|x(t) - \hat{x}(t)| \leq \eta_1 2^{-d} \quad \text{and} \quad |u(t) - \hat{u}(t)| \leq \eta_2 2^{-d} \quad (3)$$

where  $\eta_1, \eta_2 > 0$  and  $d$  is the number of fractional bits (quantization parameter). Thus, the larger the magnitude of  $d$ , the smaller are the quantization errors in the design.

#### 4. Encrypted Lyapunov-based Model Predictive Control

In this section, we present the mathematical formulation of an encrypted LMPC for the nonlinear system of Eq. (1), with secure controller-actuator and sensor-controller communication channels. The proposed formulation is as follows:

$$J = \min_{u \in S(\Delta)} \int_{t_k}^{t_k + N} L(\tilde{x}(t), u(t)) dt \quad (4a)$$

$$\text{s.t. } \dot{\tilde{x}}(t) = F(\tilde{x}(t), u(t)) = f(\tilde{x}) + g(\tilde{x})u \quad (4b)$$

$$u(t) \in U, \forall t \in [t_k, t_{k+N}) \quad (4c)$$

$$\tilde{x}(t_k) = \hat{x}(t_k) \quad (4d)$$

$$\dot{V}(\tilde{x}(t_k), u) \leq \dot{V}(\hat{x}(t_k), \phi(\hat{x}(t_k))), \text{ if } \hat{x}(t_k) \in \Omega_{\rho} \setminus \Omega_{\rho_{\min}} \quad (4e)$$

$$V(\tilde{x}(t)) \leq \rho_{\min}, \forall t \in [t_k, t_{k+N}), \text{ if } \tilde{x}(t_k) \in \Omega_{\rho_{\min}} \quad (4f)$$

where  $\tilde{x}(t)$  is the state trajectory predicted by the process model,  $U$  is the set of physical constraints on the control inputs, and  $\Omega_{\rho_{\min}}$  is the level-set of Lyapunov function  $V$  in which the system states are ultimately bounded. The sampling period is denoted by  $\Delta$ , and  $S(\Delta)$  is the set of piecewise constant functions with a period  $\Delta$ . The optimal control input sequence,  $u^*(t | t_k)$ , is calculated by solving the MPC optimal control problem, and the first control action from the sequence is applied on the process. In the encrypted LMPC formulation, the constraint of Eq. (4b) defines the process model, Eq. (4c) defines the physical constraints on the control inputs, and Eq. (4d) is the state measurement feedback. The constraint of Eq. (4e) drives the closed-loop system state to a small neighborhood around the origin, and the constraint of Eq. (4f) ensures that the system states remain ultimately bounded in a small neighborhood,  $\Omega_{\rho_{\min}}$  around the origin. Thus, starting with an initial state  $x_0 \in \Omega_{\rho}$ , the proposed Encrypted LMPC design based on the stabilizing control law  $u = \Phi(x)$  ensures that the states of the nonlinear system of Eq. (1) remain in the stability region  $\Omega_{\rho}$  and are ultimately driven to a small neighborhood around the origin  $\Omega_{\rho_{\min}}$ .

#### 5. Chemical Process Example

In this section, we implement the proposed Encrypted LMPC design to a chemical process, specifically the system from Wu et al. (2019b). In this process, a second-order, irreversible, exothermic reaction occurs in a non-isothermal CSTR. The reaction converts a reactant,  $A$ , to the product,  $B$ , via the reaction  $A \rightarrow B$ . A heating jacket is provided to the CSTR that supplies/removes heat at a rate  $Q$ . Using mass and energy balances, the system of ODEs that describe the nonlinear process can be written as

$$\frac{dC_A}{dt} = \frac{F}{V} (C_{A0} - C_A) - k_0 e^{\frac{-E}{RT}} C_A^2, \quad \frac{dT}{dt} = \frac{F}{V} (T_0 - T) + \frac{(-\Delta H)}{\rho_L C_p} k_0 e^{\frac{-E}{RT}} C_A^2 - \frac{Q}{\rho_L C_p V} \quad (5)$$

where  $C_A$  is the reactant concentration,  $T$  is the temperature inside the reactor,  $C_{A0}$  is the inlet feed concentration, and  $Q$  is the heat added/removed from the reactor. The control objective is to maintain the CSTR at the unstable steady state  $(C_{As}, T_s) = (1.95 \text{ kmol/m}^3, 402 \text{ K})$ . This is achieved by manipulating the control inputs

$\Delta C_{A0}$  and  $\Delta Q$ . The state and input vectors of the closed-loop system are defined in terms of their deviation from steady state values:  $x^T = [C_A - C_{As}, T - T_s]$  and  $u^T = [C_{A0} - C_{A0s}, Q - Q_s]$ . Based on the smallest and largest values of the permissible inputs and possible state values (in the operating region), we get the optimal value of  $l_1 - d$  to be 18. For closed-loop simulations under encrypted LMPC, we vary  $d$  from 1 to 7 in increments of 2, and  $l_1$  changes accordingly. For  $l_2$ , it is important to have  $l_2 > l_1$ , which makes it possible to map quantized numbers from the set  $\mathbb{Q}_{l_1, d}$  to the set  $\mathbb{Z}_M$ . Hence, we select the value  $l_2 = 29$ . The prediction horizon,  $N$ , for MPC is chosen to be 2. The implementation of the encrypted MPC is done in a sample-and-hold fashion with a receding horizon. A first-principles model for the nonlinear CSTR system of Eq. (5) is used in the MPC and the nonlinear optimization package IPOPT (Wächter & Biegler, 2006) is used to solve the MPC optimization problem. The Explicit Euler method is used to simulate the nonlinear system of Eq. (1) with an integration time step of  $h_c = 10^{-4}$  hr. The sampling period is  $\Delta = 10^{-2}$  hr. The closed-loop encrypted MPC simulation results are presented in Figures 2 to 4.

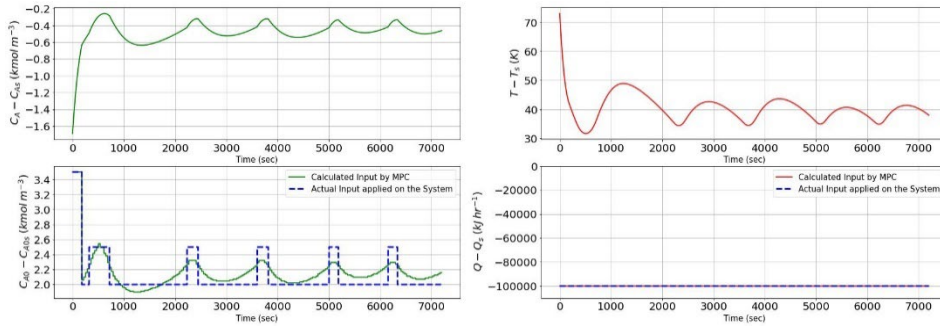

Figure 2: State and input profiles of closed-loop simulations under encrypted LMPC, with  $d = 1$ .

Figure 3: State and input profiles of closed-loop simulations under encrypted LMPC, with  $d = 3$ .

From the results of closed-loop encrypted MPC simulations, it can be observed that, for some small value of the quantization parameter  $d$ , the encrypted MPC is not able to stabilize the nonlinear system around a small neighborhood around the origin. Instead, we observe the oscillations of states around a point other than the unstable steady state.

Figure 4: State and input profiles of closed-loop simulations under encrypted LMPC, with  $d = 7$ .

Thus, for systems being operated at an unstable equilibrium, it is possible that the encrypted MPC cannot practically stabilize the system for  $d \leq d_{\text{critical}}$ , and it is important to identify this critical value of the quantization parameter. For the nonlinear system of Eq. (1), we have  $d_{\text{critical}} = 1$ . Additionally, for  $d > d_{\text{critical}}$  as the value of the quantization parameter  $d$  increases, we see improvement in MPC performance in the sense that we achieve faster convergence of states to a small neighborhood,  $\Omega_{\rho_{\text{min}}}$ , around the origin. The MPC performance improved because the quantization error significantly decreases with the increase in  $d$ . However, this improvement in performance comes at a computational cost. The computational cost increases significantly with the increase in  $d$  primarily for two reasons. Firstly, with an increase in  $d$ , the number of elements in the set  $\mathcal{Q}_{l,d}$  increase and, hence, the computational cost required to construct such a set increases significantly. Secondly, with a large number of elements in the set  $\mathcal{Q}_{l,d}$ , the number of search operations required to map real valued signals from  $\mathbb{R}$  to  $\mathcal{Q}_{l,d}$  also increase significantly. Thus, if the computational resources are limited, the MPC performance that can be achieved is also limited but one must ensure that the chosen value of quantization parameter  $d$  is larger than the critical value,  $d_{\text{critical}}$ .

## **Abstract**

Electrochemical reduction of CO<sub>2</sub> gas is a novel carbon capture technology that can potentially not only relieve the global climate crisis caused by increasing CO<sub>2</sub> gas emissions but can also restore electricity generated from clean energy sources in the form of carbon-based fuels. However, due to the complexity of the electrochemical reactions, there has been a limited effort to gain process control intuition for electrochemical reactors and the process development has been restricted to lab scale. This work aims to develop a multivariable control scheme for an experimental electrochemical reactor at UCLA by integrating artificial neural network modeling, real-time optimization, and process controller design. UCLA's experimental reactor is utilized to carry out the experiments required to construct a database to address the modeling, optimization and control tasks.

**Keywords:** Electrochemical CO<sub>2</sub> reduction; Multivariable Control; Experimental data modeling; Real-time optimization; Neural Networks.

## **1. Introduction and Reactor Description**

The percentage of renewable energy in the electricity grid has been increasing as a part of decarbonization efforts against the detrimental effects of global warming. With the current advancing awareness of sustainability, electrochemical methods have emerged as an attractive alternative to transform CO<sub>2</sub> gas into organic chemicals and synthetic fuels (De Luna et al. (2019)). However, scaling up the process to the industrial scale is limited by the lack of an effective control system and a solid understanding of the underlying physico-chemical phenomena of the process. To this end, a machine learning method is adopted to construct data-driven models mapping the critical input-output variables of the reactor and providing predictions to establish a feedback control scheme. As a continuation of the results from the previous study (Çıtmacı et al. (2022)) that focused on single-input single-output control, this work aims to develop an operational model of an electrochemical reactor with a nanoporous copper electrode using experimental data and perform multivariate control.

A gastight rotating cylinder electrode (RCE) cell reactor was used to carry out electrocatalytic experiments in this work. This electrochemical reactor consists of six major components: two electrode (working and counter electrode) chambers separated by an anion-exchange membrane, a potentiostat, a mass flow controller (MFC), a modulated speed rotator (MSR), and a temperature control block. During the operation, gas is

bubbled through 0.2 M  $KHCO_3$  electrolyte in both electrode chambers at a fixed flowrate of 20 sccm controlled by MFC. Nanoporous catalyst structure was synthesized directly on the copper cylinder electrode through the redox cycling in 4 mM KCl, and this roughened copper electrode was used as the cathode (working electrode) to electrochemically reduce  $CO_2$  into 17 different products. There are 5 gas-phase products ( $H_2$ ,  $CO$ ,  $CH_4$ ,  $C_2H_4$  and  $C_2H_6$ ) including hydrogen from the competing hydrogen evolution reaction and 12 liquid-phase products, which are produced on the electrode surface through multiple proton-electron transfer processes. Hydrodynamics and convective mass transport can be controlled systematically with the MSR, to and from the electrode for all species including reactant, intermediate, and final products. Under well-defined hydrodynamics, now the potential applied to the working electrode can be adjusted by the potentiostat, and this potential against the reference electrode and the electrical current are continuously measured and recorded. Therefore, by controlling the electrode rotation speed and the applied potential, the reaction kinetics and mass transfer effects of this process can be decoupled and studied, respectively. Lastly, the reactor is gastight such that online quantification of gas products can be performed using a gas chromatograph (GC). Liquid products, on the other hand, accumulate in the electrolyte solution and are analyzed using nuclear magnetic resonance (NMR) spectroscopy after each experiment.

## 2. Weighted-FNN Steady-State Modeling and Real-Time Optimization for Feasible Setpoints

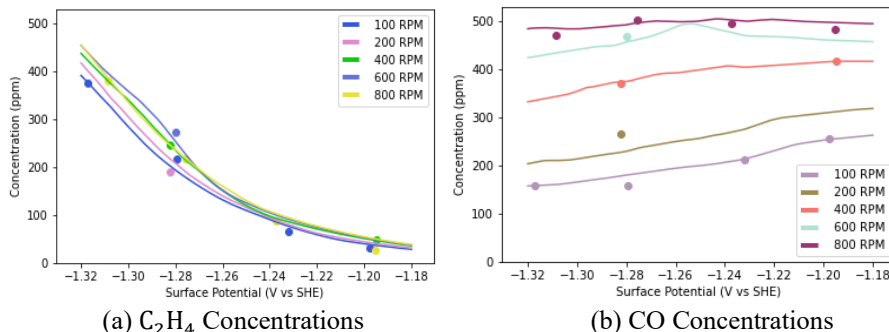

### 2.1. ML Model Trained with Statistical Weight

With the development of data and computation technologies, artificial neural networks (ANN), that have the ability to perform universal approximation for any linear/nonlinear relations (Csáji et al., (2001)), have become a popular method to address chemical and process control challenges. A feed-forward neural network (FNN) is trained with a database generated from open-loop and input step-change experiments to predict steady state concentrations of 17 products based on the applied potential and electrode rotation speed. The FNN model has one hidden layer that contains 64 neurons and a ReLu activation function. The Softplus function is selected as the activation function of the output layer to ensure non-negative prediction. Additionally, the Softplus function predicts the output with a smoother curve which aligns the physical expectation better than other activation functions with similar property such as ReLu. The mean squared error (MSE) function (Eq. 1) is utilized as the cost function to train the FNN model as:

$$L(y, \hat{y}) = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2 \quad (1), \quad L(y, \hat{y}) = \frac{1}{n} \sum_{i=1}^n \frac{1}{v_i^2} (y_i - \hat{y}_i)^2 \quad (2)$$

Although the trained FNN model can give accurate predictions (i.e., low MSE), it treats every data point in the dataset equally which increases the probability of overfitting high variance data points due to the stochastic nature of the electrochemical reaction and experimental uncertainties. To account for data variance, a weighted MSE function (Eq. 2) is adopted during the training process, where  $v_i$  is the coefficient of variance for the  $i^{th}$  data point. Specifically, data points are grouped by similar operating conditions such that averages and standard deviations under certain input conditions can be calculated and included in the weighted loss function. Therefore, the weighted-FNN is granted more tolerance of prediction error if the corresponding data point has a higher standard deviation. The weighted-FNN predictions for four gas products are represented in Fig. 1,

which displays the ability of FNN to not only provide accurate prediction based on given input conditions, but to also capture the relationship between inputs and outputs.

**Figure 1:** Weighted-FNN prediction of (a)  $C_2H_4$  and (b) CO concentrations under different electrode surface potential and rotation speed conditions.

### 2.2. Real-Time Optimization

An optimization problem can be established based on the neural network model prediction to locate the optimum operational setpoint. Specifically, by assuming that electricity consumption is the only operating cost of this process, the optimum setpoint is where the economic profit of the operation is maximized. In this work, the concentrations of  $C_2H_4$  and CO are chosen to be the controlled variables (outputs), due to their strong correlations with surface potential and electrode rotation speed (inputs), respectively. A third-party software, IPOPT is utilized to continuously solve for the optimum setpoint based on the neural network prediction and varying electricity price.

## 3. Recurrent Neural Network Dynamic Modeling of $C_2H_4$ and CO Concentrations

### 3.1. Data Fitting for Experimental Dynamics Approximation

The experimental concentration data from the GC is discrete and deficient to train a neural network model due to the limitation of separation time of chromatography. To tackle this, polynomial and sigmoid best-fits were used to enhance the training data by approximating a probable experimental trajectory between GC results. This significantly increases the number of data points and enables the training of a neural network model. The polynomial and sigmoid best-fits interpolation is demonstrated in Fig. 2, where the original dataset contains only 16 data points collected from the GC readings. After data interpolation, the available concentration estimations increase to 18000.

**Figure 2:** Example of GC data interpolation for a probable experimental trajectory from an input (rotation speed) step change experiment under constant applied potential.

### 3.2. Machine Learning Modeling of Process Dynamics

Recurrent neural network (RNN) is a popular structure to model the dynamic behaviors of chemical processes for its proven ability to fit time-series data effectively. Long-Short-Term-Memory (LSTM) models, designed to restore the exploding/vanishing gradients in basic RNN models, have a better performance in predicting time-series data and thus are used in our work as the alternative of explicit operation model in a feedback control loop (Wu et al. (2019)). Specifically, two LSTM models are trained using the enhanced dataset to predict the production rates of  $C_2H_4$  and CO respectively with three input features (i.e., surface potential, rotation speed, and current). The input data sequence contains 36 timestamps to represent a window of one-hour historical data. The time step size is chosen to be 100 seconds to reduce the computational cost. In addition, the model is trained to predict the next 800 seconds of the production rates, with 100 seconds time step. In this way, LSTM models can learn the delay response and process dead time as it is trained with a sequence of future data.

The LSTM model contains one hidden recurrent layer with 200 neurons. Simple grid search is performed to tune the hyper-parameters which demonstrates that the prediction accuracy decreases with decreasing the number of neurons and starts overfitting the data with more neurons or hidden layers. Regularization methods including recurrent dropout and  $L_2$  kernel regularization were performed to prevent overfitting further. A sigmoid function is used as the activation function of the output layer to ensure the model prediction is constrained by the maximum and minimum values in the training set. Finally, one experiment from constant input parameters and two step change experiments were used to test the model. The testing performance is shown in Fig. 3 where the predictions demonstrate a good overlap with the probable experimental trajectories.

**Figure 3:** LSTM predictions for  $C_2H_4$  production rates based on plotted input parameters, where RNN predictions are represented in continuous blue and probable experimental trajectory in dashed gray line.

## 4. Controller Tuning and Multivariable Control Architecture

### 4.1. Process Model Parameter Extraction Using Experimental Data

Two first-order plus time delay (FOPTD) models are used to describe the reaction processes, and the corresponding process parameters are extracted from experimental data. Specifically, various open-loop experiments were conducted by applying single-

variable step changes to either applied potential or rotation speed. Subsequently, the response in  $C_2H_4$  and CO concentrations, captured by the GC, are enhanced with a sigmoid function to configure a continuous trajectory of the real-time response as shown in Fig. 4. The responses are normalized for an easy comparison between various step changes. With step change responses, the dead time ( $\theta$ ) is extracted by drawing a tangent line through the inflection point, and time required to reach 63% of the final steady state is defined to be the time constant ( $\tau$ ). The mathematical expression of FOPTD model is demonstrated in Eq. 3, where  $K$  denotes the steady state gain.

$$G(s) = \frac{Ke^{-\theta}}{\tau s + 1} \quad (3)$$

However, a single FOPTD model is not enough to model the entire operation range due to the nonlinearity of the electrochemical  $CO_2$  reduction. To account for that, various FOPTD models are developed to describe different segment of the overall operational range (Fig. 5). We should check general correlations for the dead time and  $\tau$  for different step changes of rotation and potential. If there is a general correlation for the time parameters, it is possible to extract steady state gains from the weighted-FNN model. Fig. 4 is used to observe dynamic responses of  $C_2H_4$  under various rotation speed and potential changes.

The first plot clearly shows that the concentration change has similar dynamic behavior under constant rotation speed. Therefore, we can assume the same dead time and  $\tau$  for the tuning process. The second plot shows that similar dead times and  $\tau$  values can be attained for the rotation changes less than 200 RPM. These values are used in FOPTD model. A similar procedure is applied to develop the transfer function of CO concentration.

(a) Potential change under constant rotation speed (b) Rotation speed change under constant potential  
**Figure 4.** Sigmoid functions fitted to dynamic  $C_2H_4$  concentration change data, normalized between 0 and 1, to observe dead time and  $\tau$  values for FOPTD models

#### 4.2. Relative Gain Array

There are two options to implement the two-input-two-output control for this reactor, which are using 2 PI controllers or a model predictive controller (MPC). The control strategy is selected based on the individual manipulated variable-controlled variable correlations. Specifically, if there is no significant cross-coupling between the input-output pairs, it is feasible to implement the Multi-Input-Multi-Output (MIMO) control with 2 PI controllers. In the opposite case, an MPC should be considered to drive the system to the specific combination of parameters for the targeted set-points. A relative gain array (RGA) is useful to find if there are direct correlations between a specific input and output. The RGA only needs the steady state gains to be used. However, due to the

nonlinearities, we divide the operation range into 9 regions with respect to the input ranges as follows:

- Potential ranges = (-1.19, -1.26 V), (-1.26, -1.30 V), (-1.30, -1.32 V);
- Rotation ranges = (100-200 RPM), (200-400 RPM), (400-800 RPM).

These ranges are anticipated to satisfactorily linearize the process. The steady state gains are calculated from the weighted-FNN model. As a result, we found that rotation speed has a high correlation to CO concentration, whereas the surface potential is strongly correlated to  $C_2H_4$  concentration, which is shown in Fig. 5 that the diagonals of RGA are close to 1.

**Figure 5.** Relative gain array analysis for 100-200 RPM & -1.19 to -1.26 V vs SHE. (4) Multivariable control array example of FOPTD models

Therefore, two PI controllers are sufficient to control this process, in which one of the controllers will manipulate the applied potential to control  $C_2H_4$  production while the other controller will manipulate the rotation speed to control CO production rate. Furthermore, the arrays of FOPTD transfer functions will be used to determine the initial values of the PI tuning parameters using the Cohen-Coon tuning method.

## 5. Conclusion

This study carried out data-based modeling, set-point optimization and preliminary feedback control design using the open-loop experiments conducted using UCLA's experimental electrochemical reactor. Various data fitting methodologies were used to increase the size of the dataset for dynamic ML model development and extract feedback control parameters. Using the calculations presented in this paper, the closed-loop experiments will soon be conducted to drive the process between optimized set-points for  $C_2H_4$  and CO production rates.

## Abstract

Accurately predicting key performance indicators for product quality control is a research priority within the process industry. Physical models capable of predicting real-time process indicators of complex formulations are traditionally difficult to construct or retrofit, especially when the process is operated under dynamic process conditions and incorporates complex mixing phenomena. A solution to this employs the use of machine learning models to develop a soft-sensor using the information rich process data available, however this method lacks interpretability as it is difficult to extract physical information from the machine learning models, and the models are less user-friendly to implement within an existing factory advance process control system. To fill this gap, in this study we propose the use of symbolic regression, an interpretable machine learning technique, which aims to search the space over a subset of pre-defined mathematical functions to make accurate predictions of product quality. The high dimensional historical industrial data is first screened, and partial least squares is used to extract critical information regarding important operating regions and process parameters. Statistical features of critical process parameters are then employed within different symbolic regression based frameworks to obtain suitable models for batch quality prediction. Moreover, Monte Carlo sampling is adopted to estimate model uncertainty and evaluate reliability of the constructed interpretable models. To evaluate the model's performance, predictions were made for batches operated over different seasons and formulations. In addition, these models are benchmarked against a recently developed heteroscedastic noise neural network based data-driven soft-sensor. It is found that symbolic regression provided expressions with high accuracy, robustness, and responsiveness to changing process data suggesting that information about the true underlying correlation between the process data and a key performance indicator has been extracted. This research highlights the great potential of interpretable machine learning techniques for future industrial application.

**Keywords:** Machine learning, data analytics, quality control, symbolic regression, uncertainty estimation.

## 1. Introduction

Historically, mathematical models have been formulated to express relationships describing physical phenomena in order to evaluate functions at both current and future states. The predictive models were derived from first principles using conservation laws, experimental observations, and physical knowledge. However, many industrial processes contain too complex of interactions and phenomena to be described effectively via such

methods. Within Industry 4.0, access to information rich data has become more common due to the large quantity of sensor data being recorded from the industrial processes. The paradigm of machine learning can be exploited with the intention to analyse complex process data and formulate equations to characterise nonlinear and dynamic systems.

Recent works have explored the use of parametric and non-parametric data-driven models as a soft-sensor for process predictions (Kay et al., 2022; Mowbray et al., 2022). These models have proven to mitigate false confidence, have high accuracy, make uncertainty estimations representative of the data, and generalise well. However, a problem associated with such black box machine learning models is the lack of interpretability. To resolve the issue, symbolic regression can be integrated with real process data to generate statistical models representative of the industrial process. In essence, symbolic regression attempts to infer both a model and its parameters such that, for a given set of input and output data  $\{(x_i, y_i)\}_{i=1}^n$  for  $\{(x, y) \in \mathbb{R}\}$ , a function  $f$  with parameters  $\theta$  can be obtained where  $y \approx f(x|\theta)$ . A problem associated with this method is the that the search space increases exponentially with an increasing domain of operators. Knowledge of the system can be integrated to reduce this search space and reduce the dimensionality of the problem. A further complex challenge is the compromise between complexity and accuracy. Parsimonious expressions are traditionally preferred as they hold more relevance to providing understanding of the system at hand. In addition to this, more complex expressions are less robust to process changes and perform worse at extrapolation as they tend to overfit to the training data. Other works have explored the development of symbolic regression models in conjunction with neural networks to overcome the limitations of the combinatorial nature of genetic (Kim et al., 2020; Zhang et al., 2022). However, little attempts have been made to explore the use of symbolic regression in the context of soft sensing and monitoring for batch process.

## 2. Problem statement

This study focuses on the development of a statistical model based soft sensor and attempts to explore the feasibility of using symbolic regression to extract symbolic equations from a non-Newtonian fluid in a batch mixing process. Three datasets are available with the following labels: Alpha, Beta, and Gamma. Alpha and Beta were recorded from the same process line at different seasons of the year, and the Gamma data corresponds to a different formulation obtained from a similar process. We can assume process data of the form  $D = \{X, y\}$  with the predictor matrix,  $X$  being configured with  $N$  batches,  $T$  timesteps, and  $J$  sensors for  $X \in \mathbb{R}^{N \times T \times J}$ . The subsequent response matrix contains a single process measurement per batch, expressed as  $y \in \mathbb{R}^{N \times n_p}$  where  $n_p$  represents the number of process qualities measured. To ensure generalisability within the models, the data must show uniformity, thus all sensors must be shared, so  $J = 28$  for all datasets. To further ensure uniformity, an indicator depicting the beginning of a new phase of operation is used for alignment of batches. Dataset Alpha is characterised by  $N = 25$ ,  $J = 28$  process sensors, and  $T = 8000$  timesteps. Dataset Beta uses the same formulation and process equipment as Alpha in a different season with dimensionality of  $N = 14$  batches,  $J = 28$  sensors, and  $T = 3600$  timesteps. The Gamma data is comprised of  $N = 9$  batches,  $J = 28$  sensors, and  $T = 3700$  timesteps. Although, two different product formulation are tested, the target product quality of both is identical.

Typical problems associated with high dimensional datasets (Min, 2005) can be solved using dimensionality reduction, in which the data is reduced to remove redundant features and multi-collinearity, whilst still retaining sufficient information for quality prediction. We use the same approach as previous work (Hicks et al., 2021) where partial least squares (PLS) is employed, identifying 8 sensors, and 300 timesteps for accurately inferring batch quality predictions. Due to the poor capability of genetic algorithms for handling large datasets, the data is further reduced using timewise unfolding as mentioned in (Hicks et al., 2021) and taking either the mean and standard deviations or the principal components (PCA) of each individual sensor within the critical time region. This results in a 2-rank matrix of dimensions  $\mathbf{X} \in \mathbb{R}^{N \times (16 \times 28)}$ . This approach is adopted to preserve the ability of the symbolic regression models to generalise between the different datasets.

### 3. Methodology

First, we will introduce the concept of genetic algorithms and their function in symbolic regression. The principle of genetic algorithms follows Darwin’s theory of survival of the fittest and through this, populations of symbolic equations can be bred (Koza, 1994) with the objective of fitting a predictor matrix to the response matrix. Within this case study, the individuals of the population are combinations of operators, functions, and numerical constants where the operator domain is restricted to  $(+, -, *, \div, \sqrt{\quad}, \wedge, \exp, \ln)$ . An example of an individual is shown in tree diagram form in figure 1.

Figure 1: Tree diagram representation of an individual and its operator domain

Different metrics can be used to assess the generated model’s performance including its accuracy and complexity. In this study, the accuracy is defined as the average percentage error (1) and the loss function as the mean squared error (2) such that, given a functional representation,  $f$ , with input data  $\mathbf{x}$ , parameters  $\theta$ , and predictions  $\mathbf{y}$ :

$$MAPE = \frac{1}{N} \sum_{i=1}^N \frac{(y_i - f(x_i|\theta))}{y_i} \cdot 100 \text{ and } MSE = \frac{1}{N} \sum_{i=1}^N (y_i - f(x_i|\theta))^2. \quad 1$$

The complexity is defined as having a linear dependency to the sum of operators, constants and process variables used within the model structure. This dependency can be altered by assigning unique weightings to specific operators or numerical constants, however, for this study, a value of 1 was assigned to all operators and numerical constants. Let us now discuss the procedure to assess the uncertainty of the statistical models generated via symbolic regression. In essence, we will exploit the fact that, under certain conditions, the covariance matrix is equal to the inverse of the information matrix. The negative log likelihood is employed as the objective function for the optimisation of model parameters and if we consider a gaussian random vector,  $\mathbf{x}$  with mean  $\mathbf{x}^*$  and covariance matrix  $E_\theta$ , the objective function is (Hirschfeld et al., 2020):

$$obj(x) = \operatorname{argmin} \left( \frac{N}{2} (\log 2\pi\sigma^2) + \frac{1}{2} \frac{(\mathbf{x} - \mathbf{x}^*)^T (\mathbf{x} - \mathbf{x}^*)}{\sigma^2} \right) \quad 2$$

Given that the second derivative of the negative log likelihood objective function is independent of  $\mathbf{x}$ , the  $i$ th and  $j$ th components of the hessian matrix  $H$  can be obtained without knowing  $\mathbf{x}^*$ . The parameter variance can be extracted from the diagonal entries of the covariance matrix and used to estimate the model uncertainty. A gaussian distribution of parameters with mean and standard deviation  $N(\theta, \sigma_\theta^2)$  can be sampled from via Monte Carlo sampling, and the statistical models queried to produce a normal distribution of batch quality predictions,  $N(f(x_i|\theta), \sigma_f^2(x))$ . The requirements of the industrial collaborator specify that the  $MAPE < 15\%$  for soft sensor prediction and the measurement uncertainty of the equipment was quantified as being approximately 10% per standard deviation. All statistical models were optimised through using gradient based optimisation techniques in Pyomo, namely IPOPT, allowing for efficient exploration and exploitation of the parameter space such that high-quality solutions were ensured.

#### 4. Results and Discussion

The data is split into two sets, training and testing, where the training set comprises of alpha and beta, and the model's prediction performance is tested using the gamma data. To reduce the dimensionality of the feature space and thus improve the quality of the solutions, gradient boosting was applied. Using this, feature importance charts were generated for selection of process variables to use for training within the symbolic regression models as shown in Figure 2.

Figure 2: Feature importance chart generated using gradient boosting methods

The extracted symbolic equations that exhibit low complexity and high accuracy are presented in Table 1.

Table 1: MAPE and complexity values of generated symbolic expressions. Models 1-3 are constructed using the data's mean ( $X_{10}$ ) and std ( $X_{11}$ ). Model 4 is constructed using principal components ( $X_{10}$ )

Model	Symbolic expression	MAPE (Training) / %	MAPE (Testing) / %	Complexity
1	$\operatorname{Aln}( BX_{10} + C )$	9.23	13.89	6
2	$\operatorname{Aln}( \frac{BX_{10} + C}{DX_{11}^2 + E} )$	8.53	12.56	12
3	$Ae^{-BX_{11}} \operatorname{Aln}( \frac{CX_{10} + D}{EX_{11}^2 + F} )$	8.44	13.03	15

4	$Ax_{10} + B$	10.87	10.89	4
---	---------------	-------	-------	---

Models 2 and 4 were selected for further analysis due to enhanced performance within their respective groups. The predictions from models 2 and 4 on the training and validation sets are shown below in Figures 2a and 2b after being normalised.

Figure 3: Soft sensor predictions against measured data for the alpha, beta and gamma for models 2 (a) and 4 (b). The error bars represent one standard deviation.

In Figure 2, the alpha, beta and gamma data are shown as batches 1-25, 26-39, and 40-49 respectively. The soft-sensors for both models 2 and 4 are shown to be capable of predicting the training and validation batches with high accuracy with training MAPE's of 8.53% and 10.87%, and validation MAPE's of 12.56% and 10.89% respectively. Notably, the uncertainty estimations of the generated models are far lower than the measured uncertainty so does not provide an accurate representation of the data uncertainty. This is predominantly due to the simple structure used to approximate the required performance indicator. All the statistical model predictions are within three standard deviations of the measured indicator so lie within an acceptable range of values. Model 2 provides a higher training accuracy than its validation error, indicating that some overfitting to the training data has occurred, however the model seems to be more responsive to process variation within the data as the predictions cover a larger domain. Model 4 provides almost identical errors for training and validation, indicating that enough information has been captured from the training set to prevent underfitting and make informed inferences of product quality without overfitting to batch specific trends.

Overall, both models have shown good capacity for predicting on data derived from different process lines, showing that the symbolic regression technique has successfully learned correlations between the process data and batch quality.

A further conclusion to draw is that it is possible to represent the process accurately using minimal features and process sensors. Both models required the use of one shared key process variable, with model 4 only using one principal component ( $X_{10}$ ) from the sensor and model 2 using the mean ( $X_{10}$ ) and standard deviation ( $X_{11}$ ). This is indicative of the sensors individual importance to inferring batch quality and for process monitoring. This conclusion corroborates the results obtained from the generation of importance charts using gradient boosting where the same feature was identified as being highly influential.

#### 4. Conclusion

In conclusion, symbolic regression proved to be a useful tool for developing accurate, interpretable statistical models for predicting process indicators. In addition, the expressions generated were simple and could easily be integrated into an industrial process control system to assist operators with process monitoring and control presenting a substantial benefit in comparison to traditional black box machine learning techniques which are difficult to extract knowledge from. Through the use of information rich statistical features, derived from industrial data, and data driven models, it was shown possible to identify high quality solutions at low computational cost. Upon validation of the optimised statistical expressions, using the training and testing data, the soft-sensor was shown to exhibit good predictive performance and generalisation capabilities. It was also seen to be able to capture relatively large process variation within the industrial data and filter out noise. This study has presented the potential of interpretable machine learning models for use in batch quality prediction in industrial processes.

## Abstract

Biojet-fuel is a promising alternative to reduce emissions in the aviation industry. The alcohol to jet (ATJ) is considered one of the most attractive alternatives. However, the economic feasibility is an important drawback of this process. With this in mind, the process intensification offers an interesting alternative to improve the ATJ process. Nevertheless, in many cases, the intensification could lead to complex equipment that are difficult to operate. This work proposes a novel reactive catalytic distillation column to improve the oligomerization stage of ATJ process. This intensified process was designed using a sensitivity analysis. In order to determine the feasibility of operating this intensified column, a control study using PI controller and model predictive control was performed. The results showed that a reactive distillation column to intensify the oligomerization zone is feasible. This equipment only consumes 200kW. Finally, the control studies indicated that it is possible to operate the column using a traditional feedback control and model predictive control techniques with good performance.

**Keywords:** Biojet-fuel, reactive distillation, model predictive control, process intensification.

## 1. Introduction

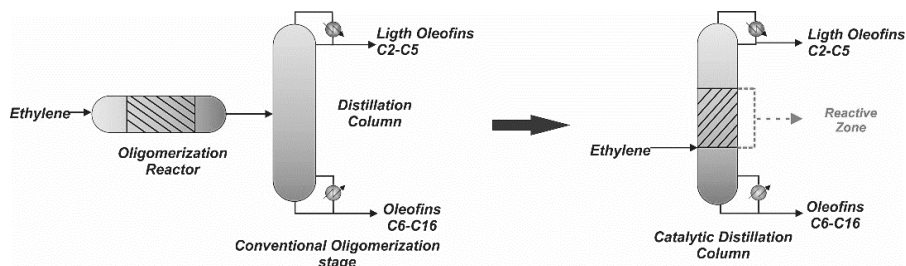

Energy has an utmost important role in our society. Energy is used to produce almost all the necessary commodities such as food, polymers, fertilizers. This energy employed to produce these commodities has several forms such as electricity, natural gas, liquid fuels, among others. In this sense, one sector that is essential for our society and which is characterized by an intensive use of energy is the transport sector. This sector consumes around 21% of the total energy demand annually, and its energy consumption is expected to increase up to 130% by 2050 which also represents an increase in CO<sub>2</sub> emissions. Among all the transport means, the aviation sector is expected to grow the fastest, doubling its energy consumptions and CO<sub>2</sub> emission in the next 20 years. For this reason, the aviation industry has proposed to reduce its CO<sub>2</sub> emissions in order to achieve a more sustainable aviation industry. The use of alternative biofuels for replacing oil-derived fuels is considered by the International Air Transport Association (IATA) as the most interesting alternative to reduce emissions (Rivas-Interian et al., 2022). These biofuels are commonly called biojet-fuels and can be produced from biomass. Nowadays, there

are several routes to produce biojet-fuel such as Fischer-Tropsch (FT-SPK), Hydroprocessed Esters and Fatty Acids (HEFA-SKP), Fisher-Tropsch with Aromatics (FT-SPK/A) and Alcohol to Jet (ATJ-SPK). In this sense, the ATJ process is considered one of the most attractive, since the alcohols are produced in abundance, offering logistical flexibility. The ATJ process consist of three reaction steps: alcohol dehydration, olefin oligomerization and hydrogenation. In this regard, oligomerization is a common stage in many jet fuel production routes, such as ATJ or aqueous phase processing. This stage is utmost importance, because it allows to achieve hydrocarbons with the exact number of carbons required by the aviation industry. This stage has two steps: a reaction stage in which ethylene is converted into larger hydrocarbons and a separation stage, in which the heavy hydrocarbons are separated from the lighter ones. This process stage is characterized by an intense use of energy, both in the reaction stage and in the separation. Therefore, one way to reduce energy consumption and increase the profitability of the ATJ process is through process intensification using reactive distillation.

Nowadays, the reactive distillation has not been explored as alternative to intensify the oligomerization zone. With this mind, this work proposes the design of a novel reactive distillation column for the oligomerization stage of ATJ process. The design parameters and operating conditions of the column were selected to increase the hydrocarbon production required for aviation industry; these hydrocarbons are in the range of C8 to C14. Since this equipment integrates the reaction and separation in a single unit and many reactions are performed inside it, a control study was carried out to determine the operation and control feasibility of this column. The control study consists of two parts: a study using PI controllers, in order to analyze the column control with common controllers in the industry. The second part is a model predictive control study in order to compare its performance with traditional feedback control using PI controllers. The integral absolute error (IAE) was selected as metric to quantify and compare the closed-loop performance for both PI and MPC controllers.

## 2. Design of reactive distillation equipment

The ATJ process considered for this study uses ethanol as raw material. This ethanol is dehydrated and converted to ethylene during the dehydration stage. In this work, it is only considered the oligomerization stage thus the ethylene is the raw material considered to this stage. Additionally, it is assumed that only linear olefins are produced during the oligomerization, this assumption is realistic because the catalysts reported in previous literature produce linear olefins, also it is a common practice to incorporate an isomerization stage after oligomerization stage to generate branched hydrocarbons. On the other hand, in this work, a catalytic distillation column is used to intensify the oligomerization stage, it consists of a distillation column with an intermediate reactive zone where the catalyst is placed and the whole set of reactions take place. The separation stages are located below and above of this reaction zone. Figure 1 shows a scheme of the reactive distillation process. The reactions that occur in the reaction zone and their respective kinetic parameters were taken from Sánchez-Ramírez et al., 2022. It is important to highlight, that the kinetic model corresponds to a set of elementary reactions of second order. A ethylene feed flowrate of 2100 kg/hr was chosen according to the information provided by Rivas-Interian et al., 2022.

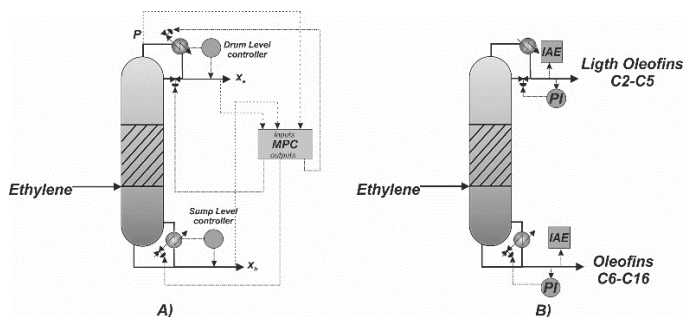

**Figure 1.** Intensification of oligomerization stage by catalytic reactive distillation.

The distillation column was designed and simulated in Aspen Plus using the RADFRAC module. The selection of thermodynamic model for the simulation was performed according to Carlson's algorithm (Carlson, 1996). Consequently, the Soave-Redlich-Kwong (SRK) was used as thermodynamic model to simulate the system, owing to the mixture contains linear hydrocarbons and the pressure required for the oligomerization is around 10–40bar. The design of the reactive distillation was performed using a sensitivity analysis in order to achieve a suitable hydrocarbon distribution and maintain low energy consumption. It is important to highlight, that according to Li et al., (2016), a suitable hydrocarbon distribution corresponds to a hydrocarbon mixture in the range of C10 to C16, being the C12 the most abundant compounds in the blend with the aim of ensuring the suitable physiochemical properties. Finally, in order to determine the improvements of intensification, the total annual costs of both the conventional and intensified oligomerization process were calculated using the Guthrie's method and data reported by Rivas-Interian et al., 2022.

### 3. Control of the reactive distillation column.

Reactive distillation columns are significantly more complex process due to integration of reaction and separation stages. The complexity of performing the separation and reaction processes in a single equipment could result in a process that is difficult to control and operate. Therefore, in order to evaluate the feasibility of operating this intensified process, a control study was performed. This control study considers the implementation of model predictive control (MPC) and compares this control strategy with traditional feedback control strategies using PI controllers. The control schemes using both MPC and PI controllers are shown in the Figure 2.

**Figure 2.** A) Control scheme using MPC B) Control scheme using PI controllers.

The integral absolute error (IAE) was chosen as metric to quantify and compare the closed-loop performance of the PI and MPC controllers. The tuning of controllers were

carried out using the minimization of IAE method, to achieve this, disturbances of -1% were performed on the manipulate variables of distillation column. Mathematically, the IAE can be defined as follows:

$$\text{Integral of Absolute Error (IAE)} = \int_0^{\infty} |y(t) - y_{sp}| dt \quad (1)$$

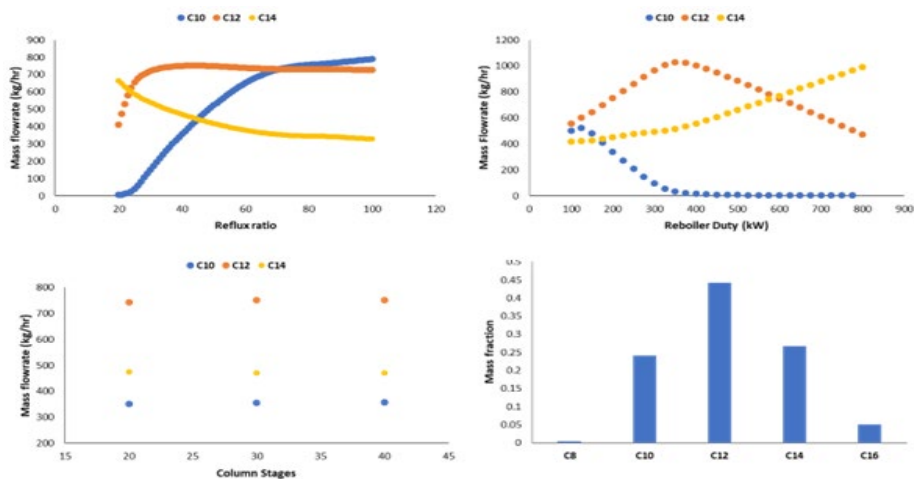

Where  $y_{sp}$  is the value of the set point for *the* control variables, whereas  $y(t)$  is the value of control variable at time  $t$ . It is important to mention, that the MPC controller uses a state space (SS) model as predictor model, this state space model was obtained by subspace identification. The subspace identification is a common method used to obtain a dynamic model when the process is very complex (Li et al., 2021). The rigorous simulation of Aspen Dynamics was used as plant model. The MPC control was implemented in a hybrid platform, which links Aspen Dynamics and the Simulink software. On the other hand, the feedback control using PI controllers was fully implemented in Aspen Dynamics. Disturbances of -1% on manipulate variables were done in order to compare the performance of control systems and to tune the controllers.

#### 4. Results

This section shows the design and control results of the catalytic column. As aforementioned, the design of reactive distillation column was performed by a sensitivity analysis in order to obtain a suitable olefin distribution. In this case, designs for 20, 30, and 40 stages were studied for the column. The results of the sensitivity analysis for the reflux ratio and reboiler duty as representative cases are shown in Figure 3. Please note, in Figure 3 as large values of reflux ratio have a positive effect on the production of C10 and C12, while more reflux ratio has a negative effect on C14. The C12 reaches a maximum concentration in reflux ratios close to 40, while for C10 and C14 the maximum concentrations are reached at higher and lower reflux ratios, respectively. Based on the results, it is concluded that a reflux ratio of 43 is the most adequate, because for this value, there is a suitable distribution of hydrocarbons, being C12 the most abundant and C10 and C14 olefins has a similar production. In addition, it was determined that a reboiler duty of 200kW is suitable since at this point the hydrocarbon distribution is very similar to that reported by Li et al., (2016). The sensitivity analysis was repeated for 30 and 40 stages finding that a greater number of stages does not benefit the production of more C10, C12 and C14. The Hydrocarbon distribution found with the best design is reported in Figure 3., also, some important design parameters are reported in Table 1. In the case of total annual costs (TAC), the results indicated that a conventional process has TAC \$582,204.90 \$/y. On the other hand, the intensified has a TAC of \$511,128.62\$/yr representing savings on costs around 13% in contrast to conventional process.

**Table 1.** Representative design parameters for the reactive distillation column.

Design Parameter	Value
Number of stages	20
Reboiler duty (kW)	200
Reflux ratio	43
Feed stage	7

**Figure 3.** Design results of reactive distillation.

With respect to control results, the composition of the most abundant compound in domes and bottoms were used as control variables. In this case, the butane (C4) and dodecane (C12) are de most abundant compounds in the top and bottom of the column, respectively. The composition of C4 was controlled with reflux ratio, while the composition of C12 is controlled using the reboiler duty of bottoms. Once identified the control variables, the tuning of controllers was performed. As aforementioned, the minimization of IAE method was used for tuning the controllers, in this case the parameters that minimize the IAE for the PI controllers at the top of column are 40 min for integral time and 20 for gain whereas the parameters for the PI controller in the bottom of column are 11.443 for gain and 70.99min integral time. In the case of MPC control, it is necessary only one controller to control the composition at the top and bottoms of the column. In this case, the parameters that minimize the IAE are a sample time of 3 min, control horizon of 10 intervals and prediction horizon of 50 intervals. Once the suitable parameters were determined, the control performance for both PI and MPC controllers are compared using their respective IAE values. The results of disturbing the reboiler duty as representative case are shown in Figure 4 whereas the IAE value is shown in Table 2

**Figure 4.** Disturbances of -1% in reboiler duty.

**Table 2.** IAE values for disturbances on reboiler duty

Control loop	C4 control loop (PI)	C4 control loop (MPC)	C12 control loop (PI)	C12 control loop (MPC)
Reboiler duty disturbance	2.86E-05	0.1091	0.0010875	0.00794

Based on the results, there is an appreciable difference between the two types of controllers. In this case, the butene composition can be controller better using a PI controller, having the PI controller up to 30% better performance than the MPC controller. However, for the dodecene control loop, the performance is very similar between both controllers. Note that the MCP control has the capability of controlling the process, however it do not fully fits to the setpoint, being the difference small due to the tolerance with which the objective function is solved in predictive control. However, it is concluded that this difference is not significant and both controllers are adequate to control the process.

## 5. Conclusions

In this work, a reactive distillation equipment was designed to intensify the oligomerization stage in the ATJ process. The intensified reactive distillation column has savings on total annuals costs of 13% in contrast to the conventional process. On the other hand, the control studies indicated that it is possible to operate this catalytic column using traditional control strategies, such as feedback control and other advanced control techniques, such as model predictive control. Finally, it is concluded that both controllers have similar performance, despite of this please note, that the PI controllers have a slight better performance due to they returned to exactly set-point value.

## Abstract

Fault detection and diagnosis (FDD) is important to ensure process safety in chemical plants. In the past decades, different FDD methods have been proposed. And data-driven methods stood out due to their high diagnosis accuracy rate. When deep learning was introduced to this field, the diagnosis accuracy became higher and higher, but the models became more and more difficult to understand. The lack of explainability and interpretability limited practical application of deep learning-based FDD methods. In this paper, we applied graph attention neural network (GAT) for FDD and achieved high diagnosis accuracy. Attention mechanism in GAT can help understand the inference process of the network. Combining the attention mechanism with the PageRank algorithm, a visualization graph can be generated to highlight the variables that are most relevant to a certain type of fault. This can be used to explain the fault diagnosis results and help us understand deep learning-based fault diagnosis better.

**Keywords:** chemical fault diagnosis, explainability, graph attention network, page rank.

## 1. Introduction

Fault detection and diagnosis (FDD) is quite critical to safe operations of chemical processes to identify abnormal events that can hardly be controlled by distributed control system. In decades, many researchers have been proposed different models of real-time FDD. These models can be categories into quantitative model-based, qualitative model-based and process history-based models (Venkatasubramanian et al., 2003). Process history-based models are further classified into qualitative and quantitative models. The latter is also commonly termed as data-driven models. Data-driven models based on deep learning have drawn much attention of researchers these years, such as DBN-based models (Zhang and Zhao, 2017), CNN-based models (Wu and Zhao, 2018), RNN-based models (Zhang et al., 2020), autoencoder-based models (Bi and Zhao, 2021) and GCN-based models (Wu and Zhao, 2021). These models achieved high diagnosis accuracy, but the lack of explainability made them hard to understand by humans thus limited their practical application.

In this paper, graph attention neural network (GAT) was applied to FDD to achieved high diagnosis accuracy. Attention mechanism built in GAT gave out local attention weights to help understand the model itself. Then a classic algorithm PageRank was applied to extend the local attention to global attention. The global attention can be used to generate

a visualization graph to highlight the variables that are most relevant to a certain type of fault. This was a great improvement of explainability of deep learning-based FDD model.

## 2. Graph Attention Network and PageRank

### 2.1. Graph Attention Network

Graph neural networks (GNNs) were proposed for processing graph-structured data, which are common in the real world. GNNs can be classified into recursive graph neural networks (RecGNNs) and convolutional graph neural networks (ConvGNNs), and the latter includes spectral-based and spatial-based ones. Because of many similarities with CNNs, spatial-based ConvGNNs have gained much attention from researchers, and the representative network structure is graph convolutional network (GCN) (Kipf and Welling, 2017). Spatial-based ConvGNNs define convolutional layers for information passing and aggregation operations. They propagate information through the connections, and aggregate the information of neighbor nodes and corresponding edges to a certain node to update its hidden embedding. Then graph readout technologies are used to obtain a node-level or graph-level representation of the information in the graph.

Graph attention network (GAT) (Veličković et al., 2018) introduced masked self-attentional layers to address the shortcomings of GCN and its variants. In convolutional operations, GAT allows for assigning different weights to different nodes within a neighborhood with efficient computation, as shown in Figure 1. The attention mechanism greatly improved the performance of the model, while bringing some model interpretability. The same advantages can be obtained by applying GAT to chemical process diagnosis.

Figure 1: Left: The attention mechanism in GAT. Right: Multi-head attention by node 1 on its neighborhood. (Veličković et al., 2018)

### 2.2. PageRank

PageRank is the founding algorithm of Google's search engine and is one of the most famous algorithms used to rank web pages in order of importance. It's named after Larry Page, one of the founders of Google Inc. Essentially, the algorithm analyzes the importance of a web page by the number and quality of its hyperlinks.

In terms of quantity, the more hyperlinks from other pages point to a web page, the more important the page is. In terms of quality, the more important hyperlinks point to a web page, the more important the page is. This is very similar to the concept of citation networks.

In addition to web ranking, PageRank has a wide range of other application scenarios. When combining with the attention mechanism in GAT, it will be possible to analyze the importance of the nodes in a graph.

### 3. Fault Diagnosis with GAT

#### 3.1. Fault Diagnosis of Chemical Processes

When applying deep learning-based models, fault diagnosis of a chemical process is generally regarded as a classification problem. Given an observation  $\mathbf{X}_t \in \mathbb{R}^{v \times w}$  at time  $t$ , the current operating state  $y \in \mathbb{N}$  of the process should be identified out of a set of operating states consisting of normal state and different types of faults. The observation  $\mathbf{X}_t$  is a matrix with the time window and process variable dimensions. The operating state or label  $y$  is an integer between 0 and  $N_c$  (the number of different fault states).  $y = 0$  means the process is under normal operating state, and  $y = c$  ( $1 \leq c \leq N_c$ ) means the fault  $c$  has occurred. With enough pairs of observations and labels, a dataset  $\{\mathbf{X}_t^{(i)}, y^{(i)}\}_{i=1}^N$  is obtained for training and testing a deep learning-based fault diagnosis model.

#### 3.2. Integrated with Process Topology

The experiments were conducted on the Tennessee Eastman (TE) process (Downs and Vogel 1993). It's a simulation process model modified based on an actual industrial process of Eastman Chemical Company in Tennessee, USA. TE process mainly consists of five unit operations and defines 20 different process disturbances. In the simulation program of TE process, 52 variables can be observed, and 20 different disturbances can be inserted at any time to make the process operate in a fault state.

GAT performs convolutional operations on a graph. Naturally, the topology between process variables can be considered as a graph in a chemical process. The graph structure used in this paper was consistent with PTCN in (Wu and Zhao, 2021). When training the model with process data, GAT performs graph convolutional operations based on the adjacency matrix corresponding to the graph.

#### 3.3. Data Preparation and GAT Model Training

To obtain enough data for training the GAT model, the simulation program of TE process ran for 3000 h in normal state. Under every different fault, the simulation program ran for 20 h after the fault inserted, and 10 sets of parallel simulations were carried out. All the data have been normalized with the mean and standard deviation calculated from data in the normal state. The normalized data were then cut to slices with the time widow of 1 h, and the data are sampled every 3 min. Data from 8 sets of parallel simulations were used for training and the rest 2 sets were used for testing.

The network structure is *GATConv(20)-GATConv(20)-GATConv(20)-FC(300, dropout=0.5)-FC(21)*. It means that the network includes 3 GAT convolutional layers with node embedding of 20 dimensions. This is followed by a fully connected layer with 300 neurons (dropout technique is used with a 0.5 ratio) and a fully connected layer with 21 neurons. It was trained for 50 epochs with Adam optimizer, the mini-batch size was set to 128 and the learning rate was set to 0.001. The trained GAT model finally got an average classification rate of 0.9399 over all the 21 classes.

The confusion matrix of the diagnosis results is shown in Figure 2. Table 1 gives FDR (fault diagnosis rate) and ACR (accurate classification rate) comparison between different types of deep learning models. It shows that the GAT model has the same excellent

diagnosis performance as PTCN. If fault 9 and 15 are not considered, the ACR is as high as 0.9731. Although the GAT model has only a very weak advantage in diagnosis performance compared to PTCN, the attention weights in the network give us an entry for an interpretability study.

#### 4. Extend from Local to Global Attention with PageRank

After the GAT model was trained well, the attention weights in it were also fixed. These weights can be used to investigate exactly which nodes or variables the network is focusing on when making inferences. Visualization of attention weights in GAT is shown in Figure 3. Every node in the attention weight graph represents a variable in TE process. The nodes are connected by edges to represent the physical connection between variables, i.e. the topology of the process. The magnitude of the attention weight is expressed with the thickness of the edges. Note that this attention mechanism only makes sense for arbitrary nodes and their neighbor nodes. For each node, the attention weights of all its incoming edges are normalized. This means that it's a local attention mechanism in GAT.

The attention weight graph also follows the same quantitative and qualitative assumptions as PageRank. When applying PageRank to the graph, it can be iterated until convergence and finally give the importance ranking of the nodes in the whole graph, as shown in Figure 3. The size of the nodes is used to indicate the importance of the variables. This importance ranking is for the whole graph and is therefore a kind of global attention. This helps us to analyze which variable is more important for fault diagnosis. In Table 2, the most important process variables for diagnosing each fault are listed and compared with the results of the manual process analysis. For some faults, affected variables can be located with the importance ranking. For those faults that are hard to identify (such as fault 9 and 15), all variables only change slightly after the disturbance is inserted. Thus, it can hardly localize some certain variables to determine the type of fault. This result indicates that the GAT model, when performing fault diagnosis, does not necessarily focus directly on the root cause of the fault, but rather identifies those sensitive variables that are strongly affected by the root cause.

Figure 3: Left: Visualization of attention weights in GAT. Right: Visualization of global attention after applying PageRank to attention weight graph.

Table 2: Comparison between variables affected by disturbances firstly and variables the GAT model focused on when diagnosing faults.  $T, P, L, Q, x, u$  mean temperature, pressure, level, flow rate, composition, control signal respectively. Subscript means unit operations or streams. Superscript means characteristics or components.

Faults	Variables affected firstly	Variables GAT focused on
Fault 1	$x_{feed}^A, x_{feed}^C, Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$	$Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$
Fault 2	$x_{feed}^A, x_{feed}^B, x_{feed}^C, Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$	$x_{feed}^A, x_{feed}^C, Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$
Fault 3	$T_{reac}, P_{reac}, L_{reac}, T_{reac}^{cwr}, u_{reac}^{cwr}$	$x_{feed}^A, x_{feed}^C, Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$
Fault 4	$T_{reac}^{cwr}, u_{reac}^{cwr}, T_{reac}, P_{reac}, L_{reac}$	$T_{reac}^{cwr}, u_{reac}^{cwr}, T_{reac}, x_{feed}^A, Q_{s1}, u_{s1}^Q$
Fault 5	$T_{cond}^{cwr}, u_{cond}^{cwr}, T_{sep}, P_{sep}, L_{sep}$	$u_{cond}^{cwr}, Q_{s4}, u_{s4}^Q$

Fault 7	$Q_{s4}, u_{s4}^Q, T_{strip}, P_{strip}, L_{strip}$	$Q_{s4}, u_{s4}^Q, T_{reac}^{cwr}$
Fault 8	$x_{feed}^A, x_{feed}^B, x_{feed}^C, Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$	$Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$
Fault 9	$T_{reac}, P_{reac}, L_{reac}, T_{reac}^{cwr}, u_{reac}^{cwr}$	$Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$
Fault 10	$T_{strip}, P_{strip}, L_{strip}, u_{strip}^{steam}, Q_{strip}^{steam}$	$T_{strip}, Q_{s1}, Q_{s4}$
Fault 11	$T_{reac}^{cwr}, u_{reac}^{cwr}, T_{reac}, P_{reac}, L_{reac}$	$Q_{s1}, u_{s1}^Q$
Fault 12	$T_{cond}^{cwr}, u_{cond}^{cwr}, T_{sep}, P_{sep}, L_{sep}$	$T_{reac}, T_{sep}$

Fault 13	$T_{\text{reac}}, P_{\text{reac}}, L_{\text{reac}}, T_{\text{reac}}^{\text{cwr}}, u_{\text{reac}}^{\text{cwr}}$	$T_{\text{reac}}^{\text{cwr}}, L_{\text{reac}}$
Fault 14	$T_{\text{reac}}^{\text{cwr}}, u_{\text{reac}}^{\text{cwr}}, T_{\text{reac}}, P_{\text{reac}}, L_{\text{reac}}$	$T_{\text{reac}}^{\text{cwr}}, Q_{s1}, u_{s1}^Q$
Fault 15	$T_{\text{cond}}^{\text{cwr}}, u_{\text{cond}}^{\text{cwr}}, T_{\text{sep}}, P_{\text{sep}}, L_{\text{sep}}$	$Q_{s1}, Q_{s4}, u_{s1}^Q, u_{s4}^Q$

## 5. Conclusion

In this paper, GAT was applied to fault diagnosis and achieved high diagnosis accuracy. After the model was trained well, PageRank was used to extend the local attention of GAT to global attention and generated the importance ranking of variables for each type of fault. This ranking helps us to understand the diagnosis process of the GAT model more deeply.

The lack of interpretability and explainability of the deep learning models limits their practical application. Future research on fault diagnosis should pay more attention to inventing more interpretable models, or better integrating first principles into data-driven models. More explainability research on deep learning models should also be conducted.

## Abstract

Combined cycle gas turbine plants (CCGTs) fulfill an important role in emission reduction of offshore power systems as the bottoming cycle (BC) produces additional power from exhaust heat of the gas turbines (GTs). With increasing integration of wind turbines, CCGTs offshore must be flexible and provide variation management to the offshore energy system across multiple time scales. This work proposes a model predictive controller (MPC) sending setpoints to the CCGT to satisfy demand in the offshore power system under fluctuating wind power. A high-speed surrogate model suitable for optimizing in an MPC is identified. A linear MPC using a quadratic cost function with process constraints is formulated. The model-based control structure is then validated in simulation for satisfying a constant power demand under disturbances introduced by fluctuating wind power.

**Keywords:** Model predictive control; steam bottoming cycle; surrogate modelling; feedforward disturbance rejection; PI-control; wind power

## 1. Introduction

Currently, natural gas fueled gas turbines (GTs) are the main source of power in offshore oil and gas installations. National and international CO<sub>2</sub> reduction targets are incentivizing offshore operators to develop emission reduction strategies such as increasing energy efficiency and low emission power generation solutions like offshore wind power. It is likely that more than one technology will be implemented (Voldsund et al., 2023), resulting in a hybrid integrated offshore power generation system (Riboldi et al., 2020). In this work, we study a system with a combined cycle (CCGT) and power from wind. In CCGTs, the bottoming cycle (BC) uses the exhaust heat from GTs to produce additional power in a steam turbine (ST) and increase thermal energy efficiency (Nord and Bolland, 2013). Due to weight and space limitations, BCs on offshore installations are designed to be low weight and compact, which affects their dynamic response (Montañés et al., 2021). As simple cycle GTs, CCGTs offshore must provide variation management to the offshore energy system across multiple time scales, stabilizing the power generation system. Decentralized control strategies for compact BCs and CCGT based on PI- and feedforward controllers were studied by Nord and Montañés (2018), and model-based nonlinear feedforward in combination with PI-controllers was developed by Zotică et al. (2022).

The requirements for disturbance rejection of CCGTs are stringent when integrating non-dispatchable wind turbines to the power generation system offshore, due to the increased variability of the net load to be covered by the CCGT. A model predictive controller (MPC) is proposed to control the setpoints to the GTs and provide setpoints to the lower PID control layer of the BC by exploiting information, e.g., of the required system power demand, wind profile forecasts, and a model of the disturbance. This enables the CCGT power output of the integrated system to minimize generation and consumption mismatches, thereby stabilizing the electrical frequency of the power system. Furthermore, the MPC framework allows for additional control objectives, such as minimizing CO<sub>2</sub> emissions and inherently handle steam temperature and pressure constraints.

## 2. System description and model

Figure 1 depicts the system considered in this work, consisting of an integrated wind-thermal electricity generation system. We assume that the thermal system should compensate for variations in wind power generation. The thermal system, a CCGT, consists of two GTs and a BC with two once-through steam generators (OTSG) connected to a common steam turbine (ST) and condenser system. A wind farm produces non-dispatchable power and the CCGT stabilizes the integrated power output. We simulate the power from the wind farm and CCGT using high-fidelity models and develop a surrogate model of the CCGT for the MPC.

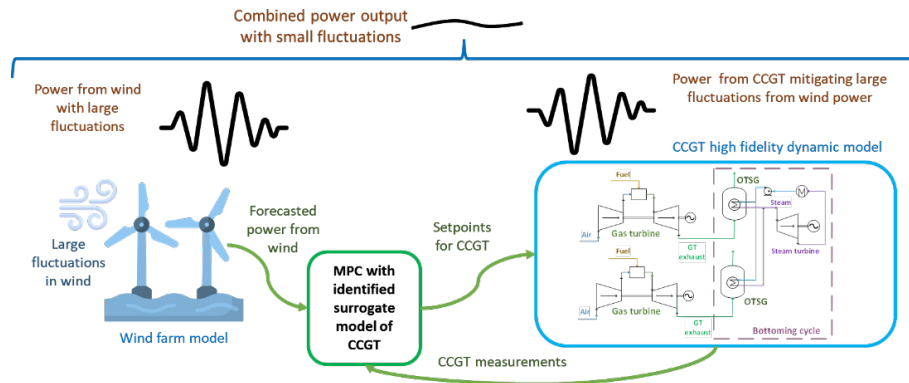

Figure 1. Conceptual description of the system.

### 2.1. Power from wind farm

The considered wind power plant consists of three wind turbines with 8 MW power rating each. The specifications are inspired by the Siemens Gamesa SG 8.0-167 DD wind turbine. The control of the wind turbines is taken as state-of-the-art grid-following maximum-power-point-tracking control, where the turbine actions are almost purely driven by the incoming wind, from which as much energy as possible is harvested. The wind turbines do not actively attempt to stabilize the electric power system. The task of stable control of the electric system is purely left to the gas turbines. This principle reflects the control of commercially available wind turbines, and the typical variation management strategy in wind-thermal systems (Burton, 2011).

The turbine layout is taken as a straight line with a spacing of ten diameters between turbines (standard, conservative spacing). A wind speed of 10 m/s with direction perpendicular to the layout (no wake) and with standard turbulence level is chosen. The

incoming wind is then obtained from a farm-scale synthetic turbulence generator providing the rotor-averaged (power-equivalent) wind speed with consistent low-frequency fluctuations and correlation between turbines (Chabaud, 2023), for a consistent representation of wind power variability.

### *2.2. High fidelity dynamic model of the combined cycle*

SINTEF Energy Research developed a high-fidelity dynamic Modelica model of the CCGT (Montañés et al., 2021; Zotică et al., 2022), using the commercial modeling and simulation environment Dymola. We utilize Modelica models from the Thermal Power Library 1.21 and adapt them to build up the combined cycle power plant models. In this work we model the thermo-hydraulics of the steam cycle of the CCGT with high-fidelity principles and apply a simplified quasi-static model for the GT based on data provided by Siemens Energy through the LowEmission Consortium. The bottoming cycle is based on the design presented in Zotică et al. (2022). For further details on the underlying models for turbine islands and steam generators, refer the work by Montañés et al. (2017) and Zotică et al. (2022). OTSG models are explained in the work by Montañés et al. (2021).

### *2.3. MPC surrogate model of the combined cycle*

In this work, the surrogate model used for the predictive controller is a linear, autoregressive model of the CCGT predicting the steam turbine power output  $P_s$ , and CO<sub>2</sub> emissions from the operation of the GTs. The parameters of the surrogate model are determined with a stability-constrained linear regression performed on data gathered from simulation of the high-fidelity dynamic model of the CCGT.

The GT power  $x_{GT}$  and GT CO<sub>2</sub> emissions  $x_{CO_2}$  are modelled dependent on the current GT load,  $u_{GT}$ ,

$$x_{GT} = f(u_{GT}) \quad (1)$$

$$x_{CO_2} = f(u_{GT}). \quad (2)$$

The dynamics of the BC are highly nonlinear. However, the lower PID control layer results in more linearized dynamics (see section 3.1) and enables the use of a linear prediction model for the MPC. In the BC, the OTSG consists of relatively large volumes and mass of metal walls that accumulate heat over time. Hence, the BC exhibits high thermal inertia at the interface of the gas turbine exhaust and steam generation in the OTSG (Montañés et al., 2021). Therefore, the surrogate model necessitates a higher order,  $n$ , for modelling the predicted ST power in the next timestep  $k + 1$ . The ST power is predicted from the temperature setpoints  $u_t$  and pressure setpoint  $u_p$  of the BC

$$x_{ST,k+1} = f(x_{BC,k-n}, u_{GT,k-n}, u_{t,k-n}, u_{p,k-n}), \quad n = 0, \dots, 5 \quad (3)$$

## **3. Control structure**

The control structure proposed in this paper consists of a lower PID control layer of the BC and GT and an upper MPC control layer to provide setpoints to the lower layer.

### *3.1. PID control layer*

The lower PID control layer keeps the superheated steam temperature at the outlet of the two OTSGs and superheated steam pressure at a setpoint given by the upper supervisory control layer (MPC). The power output of the ST is highly dependent on the enthalpy at the inlet of the steam turbine. The BC heat input is mostly given by the gas turbine operation specified as GT load. The live steam pressure is controlled by manipulating the valve upstream the ST using a pure I-controller. The temperature is controlled by

manipulating the feedwater flowrate, using a combination of model-based nonlinear feedforward for disturbance rejection and a feedback PI-controller to reject unmeasured disturbances and account for plant model mismatch. The nonlinear feedforward is derived from a simple steady-state energy balance over the OTSG. It receives measurements from the hot gas side flowrate and temperatures which are the main disturbances for the BC. The I and PI controllers are tuned from step responses using the SIMC tuning rules (Skogestad, 2003).

### 3.2. MPC control layer

The MPC provides GT setpoints  $u_{GT}$ , superheated steam temperature setpoints  $u_t$ , and the superheated steam pressure setpoint  $u_p$  to the lower PID control layer. A linear MPC using a quadratic cost function with input constraints, and the surrogate model described in 2.3 is formulated

$$\begin{aligned} \min_u \quad & \omega_d J_d + \omega_{CO_2} J_{CO_2} + \omega_a J_a \\ \text{s. t.} \quad & x_{k+1} = f(x_{k-n}, u_{k-n}), \quad n = 0, \dots, 5, \quad k = 0, \dots, N-1 \\ & g(u_k) \leq 0, \quad k = 0, \dots, N-1 \\ & x_0 = \hat{x}_0. \end{aligned} \quad (4)$$

The objective of the MPC consists of, in order priority, a power tracking cost  $J_d$  to satisfy a power demand, a CO<sub>2</sub> emission penalty  $J_{CO_2}$ , and an actuation cost  $J_a$ . The power tracking cost is calculated from the difference between the total predicted power output, consisting of the power output from the GTs  $x_{GT}$  and ST  $x_{ST}$ , forecasted wind power  $p_w$ , and the power demand  $p_d$

$$J_d = \sum_{k=0}^N (p_{d,k} - p_{w,k} - x_{GT,k} - x_{ST,k})^2. \quad (5)$$

The CO<sub>2</sub> emission penalty is a quadratic cost on the predicted CO<sub>2</sub> emissions

$$J_{CO_2} = \sum_{k=0}^N x_{CO_2,k}^2. \quad (6)$$

Lastly, the actuation cost penalizes the change in the GT setpoints  $u_{GT}$ , BC temperature setpoints  $u_t$ , and BC pressure setpoint  $u_p$  with a quadratic cost

$$J_a = \sum_{k=0}^{N-1} (u_{GT,k+1} - u_{GT,k})^2 + (u_{t,k+1} - u_{t,k})^2 + (u_{p,k+1} - u_{p,k})^2. \quad (7)$$

To simplify the tuning of the weights  $\omega$ , both the state and input variables are normalized to ensure comparability of the subobjectives  $J_{CO_2}$  and  $J_a$ . As  $J_d$  is the most important subobjective, the  $\omega_d$  is set first. Afterwards  $\omega_{CO_2}$  and  $\omega_a$  are tuned by trial and error.

## 4. Results and discussion

The proposed MPC is tested in a simulation environment introduced in 4.1. The results (see 4.2) illustrate the disturbance rejection the MPC provides given fluctuating wind power and ST power output.

### 4.1. Simulation environment

The MPC is simulated in loop with a Gaussian process model of the CCGT regressed from data gathered from the high-fidelity model. The sampling time of 5 s and prediction horizon of 5 min were chosen to account for the vastly different time dynamics of the GTs and the BC, which exhibited a closed loop settling time of  $10^0$ - $10^1$  s and  $10^2$ - $10^3$  s, respectively (Montañés et al., 2021). The simulation environment is assumed to provide full-state feedback of the ST power, GT power, and CO<sub>2</sub> emissions of the GTs. Realistic wind profiles as described in Section 2.1, assumed to be forecasted exactly, are utilized.

The simulations are formulated with CasADi (Andersson et al., 2019) and solved with IPOPT (Wächter and Biegler, 2006), where each MPC iteration is solved within 0.05 s.

#### 4.2. Results

Figure 2(a) shows the cumulative power output of the wind turbines and the CCGT. The proposed MPC can control the CCGT to provide variation management under fluctuating wind power to satisfy a constant demand of 70 MW. Figure 2(b), showing the relative power of the wind turbines, GTs, and ST scaled to the total power demand indicates that fluctuations in wind power are mainly compensated by the power output of the GTs due to their fast dynamics.

Figure 2. (a) Cumulative power output of the combined wind-thermal system. (b) Relative power output of CCGT and wind scaled to total demand.

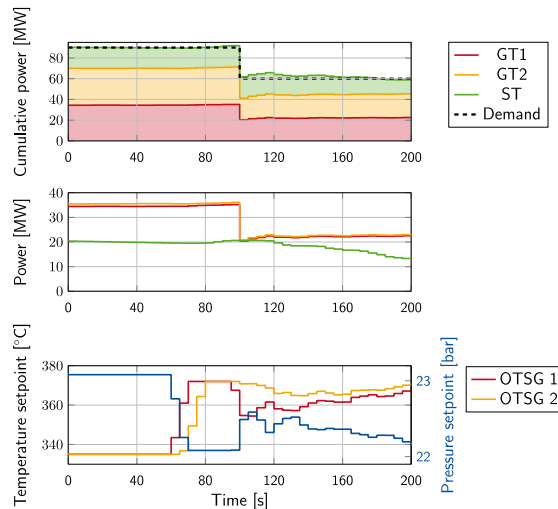

Figure 3. MPC step response showing cumulative power, GT load inputs, and steam temperature and pressure setpoints chosen by the MPC.

Figure 3 illustrates the working principle of the MPC when the power demand of the CCGT changes, e.g., due to a change in wind power or overall wind-thermal system demand. Overall, the CCGT responds sufficiently fast to the step change in power demand. The GT loads are adjusted at time of demand change, as GTs have a fast dynamic response. Furthermore, the MPC accounts for the slower dynamic response of the BC by regulating the gas turbine loads at  $t = 100$  s lower than the steady state gas turbine load at  $t \geq 200$  s. The dynamic response of the BC is improved by MPC as it regulates the setpoints to the lower PID control layer at  $t = 60$  s before the demand step change at  $t = 100$  s to account for the slower BC dynamics

## 5. Conclusion

This work proposes an MPC for CCGT control with variation management, and CO<sub>2</sub> emission reduction objectives. To formulate the MPC, a linear surrogate model is identified. As the CCGT process and the high-fidelity Modelica model are highly nonlinear, it is challenging to represent the dynamics correctly in a linear model.

Simulations show that the MPC helps to achieve variation management of the integrated wind-thermal system by controlling the CCGT under fluctuating, realistic wind profiles. Further work should address uncertain wind profile forecasts and investigate different objectives to the MPC.

## Abstract

Pharmaceutical intermediates are chemical products that play an important role in the synthesis of drugs. Different from the general chemical production process, the production process of pharmaceutical intermediates is characterized by flexible small scale, batch mode and multifunction. Therefore, optimal operation strategies are required at different stages, usually implemented by adjusting operation parameters, such as temperature and pressure along the batch for particular units and instruments. However, it is challenging to obtain the best combination of multiple parameter trajectories. In this paper, the concentration of HME, a pharmaceutical intermediate, is studied as an industrial case. A dynamic model is established to simulate the whole concentration process of HME. To promptly achieve optimal temperature and pressure in HME batch concentration, a Bayesian optimization algorithm based on Gaussian process regression model is used with the goal of minimizing the total cost. It can be seen from the results that Bayesian optimization is very competitive in dynamic simulation.

**Keywords:** batch concentration, Bayesian optimization, pharmaceutical intermediates, dynamic process simulation

## 1. Introduction

Lamivudine is an antiviral drug of nucleoside reverse transcriptase inhibitor, which can selectively inhibit the replication of hepatitis B virus. At present, the chemical synthesis method using L-menthol as the starting material is often adopted in industry (Xue et al., 2010). (2S,5R)-5-Hydroxy- [1,3] -oxathiolane-2-carboxylic acid methyl ester (HME) is an important chemical synthesis intermediate of Lamivudine, and the concentrate process of HME has a significant impact on the synthesis of Lamivudine. The synthesis route is shown in Figure 1 (where I is Lamivudine and III is HME.). Based on industrial projects, this paper focuses on the concentration of HME from its solvent mixture system and optimization of operating parameters, in order to minimize the total production cost.

The dynamic optimization of batch processes has been concerned by many researchers, and many solutions have been proposed. Yang et al. applied iterative particle swarm

optimization (PSO) algorithm to the comprehensive optimization problem of batch processes, in which objective function was set as the sum of product concentration, reciprocal of reaction time and reciprocal of energy loss, and the optimal solution was obtained by searching for optimal trajectory (Yang et al., 2017). Amini et al. proposed a new method to optimize the control of batch cooling crystallizers by genetic algorithm, and obtained the minimum and maximum values of the objective function (Amini et al., 2016). Mujtaba et al. solved the dynamic optimization of the batch reactor with a simple model through neural network, and obtained the optimal operation strategy in terms of reactor temperature (Mujtaba et al., 2006). However, the above algorithms are easy to fall into local optimum or less interpretability. Compared with the traditional optimization methods, the surrogate model of Bayesian optimization has stronger fitting ability and better interpretability, and therefore it is applied for the dynamic optimization of an HME batch concentration process in this work (Shahriari et al., 2016).

Figure 1 Synthesis route of Lamivudine

## 2. Process Modeling

HME concentration system is mainly composed of toluene, acetic acid, HME and water. The mass and mass fraction of each component are shown in Table 1.

Table 1 Mass and mass fraction of components

Component	Component quality/kg	Mass fraction
Toluene	2480	0.6727
Acetic acid	26.7	0.0072
HME	1080	0.2930
Water	100	0.0271

The dynamic concentration model is established as shown in the Figure 2. The whole concentration system consists of a jacketed distillation tank, two coolers, and two collection tanks. Instruments and controllers are equipped in necessary pipelines and equipment. Details on the control strategies are shown in Table 2.

Table 2 Details on the control strategies

Letter	Name	Control variable	Manipulate variable
A	TICT01	Temperature of T01	Heat medium flow
B	PICT01	Pressure of T01	Gas outlet flow of T01

C	TICE01	Outlet temperature of E01	Refrigerant 1 flow
D	TICE02	Outlet temperature of E02	Refrigerant 2 flow

Figure 2 Concentration model

### 3. Bayesian optimization

#### 3.1. Parameter space and Objective function

##### 3.1.1. Manipulated variable selection

In the dynamic batch simulation process, the final production cost of the concentration process is highly correlated with the temperature and pressure control. First of all, pressure has a significant impact on the bubble dew point of the system. The lower the pressure, the lower the bubble point temperature, and the easier it is for concentration. However, to ensure the lower pressure, it is inevitable to increase the load of the vacuum pump. Therefore, it is necessary to balance the pressure in the distillation tank. Secondly, due to the intermittent feature of the concentration process, different temperature control schemes are selected in industry as time changes. Therefore, difference between the set value of temperature controller and bubble point of the system in the concentration process  $\Delta T$  is selected as one of optimization variables, so that temperature control value changes dynamically with the concentration time, making temperature control scheme more suitable for industrial practice. Similarly, difference between dew point at inlet of primary cooler and the set value of temperature controller  $\Delta t_1$ , and difference between dew point at inlet of secondary cooler and the set value of temperature controller  $\Delta t_2$ , are selected as optimization variables.

##### 3.1.2. Objective function

The total production cost is defined as objective function, and it is mainly divided into two parts, one is the real operation cost  $A$ , and the other is cost  $B$  of lost solvent toluene.  $A$  mainly includes labor cost, vacuum pump cost and utility cost.  $B$  is the cost of lost solvent toluene pumped by vacuum pump, including the cost of solvent toluene and the cost of handling the extracted toluene in order to meet the requirements of environmental protection. The calculation of the cost is listed below.

$$c_1 = a \cdot t \cdot n \quad (1)$$

$$c_2 = \left( \frac{d}{10 \cdot 8000} + \frac{f \cdot (101.325 - P) / 101.325 \cdot e}{\eta} \right) \cdot t \quad (2)$$

$$c_3 = F_1 \cdot U_1 \quad (3)$$

$$c_4 = F_2 \cdot U_2 \quad (4)$$

$$c_5 = F_3 \cdot U_3 \quad (5)$$

$$A = c_1 + c_2 + c_3 + c_4 + c_5 \quad (6)$$

$$B = F_4 \cdot (U_4 + U_5) \quad (7)$$

$$\text{Objective}(P, \Delta T, \Delta t_1, \Delta t_2) = A + B \quad (8)$$

where,  $c_1, c_2, c_3, c_4, c_5$ : Cost of labor, vacuum pump, refrigerant 1, refrigerant 2, heat medium, ¥,  $a$ : Hourly salary, ¥,  $t$ : Concentration time,  $h$ ,  $n$ : Number of workers,  $d$ : Fixed cost of vacuum pump, ¥,  $f$ : Rated power of vacuum pump,  $kW$ ,  $\eta$ : Efficiency of vacuum pump,  $e$ : Electricity price, ¥/kw·h,  $F_1, F_2, F_3, F_4$ : Total flow of refrigerant 1, refrigerant 2, heat medium, solvent toluene, kg,  $U_1, U_2, U_3, U_4, U_5$ : Unit price of refrigerant 1, refrigerant 2, heat medium, solvent toluene, solvent toluene treatment, ¥/kg.

### 3.2. Algorithm introduction

In essence, the Bayesian optimization framework uses the probabilistic surrogate model to fit the real objective function, and actively selects the most ‘potential’ evaluation points for evaluation according to the fitting results to avoid unnecessary sampling. Therefore, Bayesian optimization is also called active optimization (Jones, 1998). Overall, Bayesian optimization framework can effectively use process dynamic information to improve the search efficiency. And it mainly includes two parts: probabilistic surrogate model and acquisition function.

#### 3.2.1. Gaussian process regression

Gaussian process regression model aims to quantitatively estimate the probability distribution of the predicted value and obtain the confidence interval by establishing a nonparametric probability model based on the kernel function. It is considered as an extension of multivariate Gaussian function on infinite dimensional set variables. For the existing dataset,  $D = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$ ,  $\mathbf{x}_i \in R^d$  is the input variable,  $d$  is the dimension of the input variable,  $y_i \in R$  is the target variable. When there are  $n$  experimental points in the data set, the prior knowledge of the Gaussian process regression algorithm assumes that these  $n$  points obey the multivariate Gaussian distribution  $N$  in space shown in Equation (9).

$$\begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix} \sim N \left( \begin{bmatrix} \mu(\mathbf{x}_1) \\ \vdots \\ \mu(\mathbf{x}_n) \end{bmatrix}, \begin{bmatrix} k(\mathbf{x}_1, \mathbf{x}_1) & \cdots & k(\mathbf{x}_1, \mathbf{x}_n) \\ \vdots & \ddots & \vdots \\ k(\mathbf{x}_n, \mathbf{x}_1) & \cdots & k(\mathbf{x}_n, \mathbf{x}_n) \end{bmatrix} \right) \quad (9)$$

where  $\mu$  is the mean value;  $k(\cdot, \cdot)$  is a kernel function used to measure the correlation between two input variables. The kernel function selected in this paper is Matern, which is a stationary kernel and a generalization of the radial basis function (RBF). There is an additional parameter  $\nu$ , which controls the smoothness of the resulting function. In this work,  $\nu = 5/2$ , and specific expression is as follows.

$$k(x_i, x_j) = \left( 1 + \frac{\sqrt{5}}{l} d(x_i, x_j) + \frac{5}{3l} d(x_i, x_j)^2 \right) \exp \left( -\frac{\sqrt{5}}{l} d(x_i, x_j) \right) \quad (10)$$

where  $d(\cdot, \cdot)$  is the Euclidean distance.

### 3.2.2. Confidence Boundary Strategy

Srinivas et al. proposed a confidence boundary strategy for Gaussian processes, GP-UCB (Srinivas et al., 2010). When solving the minimum value of the objective function, the acquisition function of the UCB strategy is:

$$\alpha_t(x; D_{1:t}) = \mu_t(x) + \sqrt{\beta_t} \sigma_t(x) \tag{11}$$

where, parameter  $\beta_t$  balances expectation and variance.

Then Bayesian optimization algorithm is embedded into the batch concentration dynamic model, logic diagram is shown in Figure 3. The left side of the block diagram shows the process of Bayesian optimization algorithm using simulation data to recommend the next point to be evaluated. The batch concentration dynamic model on the right side is responsible for running under the working conditions of the parameter combination recommended by Bayesian optimization algorithm to obtain new cost simulation data, and then adding the simulation data to the dynamic database to iterate until convergence. In order to achieve data interaction between Python and C++, a set of communication master control for data transmission between both parties has been developed, which can greatly improve the speed and reliability of data transmission, and remove the barriers between the algorithm and model operations.

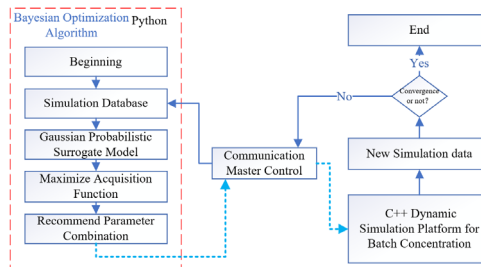

Figure 3 Logic diagram of Bayesian optimization for batch concentration

## 4. Simulation results and discussion

### 4.1. Raw simulation data set

Table 3 Raw Simulation Data

	<i>P</i>	$\Delta T$	$\Delta t_1$	$\Delta t_2$	Total cost		<i>P</i>	$\Delta T$	$\Delta t_1$	$\Delta t_2$	Total cost
1	5	0	10	20	99999	6	15	20	10	20	5736.6
2	5	10	10	20	7004.58	7	25	0	10	20	99999
3	5	20	10	20	7232.51	8	25	10	10	20	12764.32
4	15	0	10	20	99999	9	25	20	10	20	12764.57
5	15	10	10	20	4531.47						

Table 4 Iterative data

Iterations	<i>P</i>	$\Delta T$	$\Delta t_1$	$\Delta t_2$	Total cost	Iterations	<i>P</i>	$\Delta T$	$\Delta t_1$	$\Delta t_2$	Total cost
44	17.38	8.22	11.98	3.96	4443.72	285	5.04	8.39	12.68	4.25	4483.76
71	18.99	9.19	9.59	2.40	4409	320	16.55	2.02	6.65	5.97	4457.54
144	15.38	14.79	9.35	5.62	4407.43	350	24.77	6.19	8.04	7.64	4439.91

162	17.83	3.63	11.21	1.33	4442.43	428	19.05	18.22	11.34	2.16	4462.79
234	13.84	16.88	13.64	6.09	4433.9	467	15.88	14.20	10.14	5.24	4413.62

In order to obtain the initial data set of Bayesian optimization, 9 groups of different parameter combinations are selected, and target values of different combinations are calculated. As shown in Table 3, the selection of initial parameter combinations is kept in discrete state as far as possible, which is conducive to the rapid convergence of subsequent Bayesian optimization iterations.

#### 4.2. Results and discussion

Based on the initial data set, 500 iterations of Bayesian optimization calculations have been carried out for HME batch concentration process. Table 4 shows the optimal target values for every 50 iterations. It can be observed from the Table 4 that after 500 iterations, a lower target value is found, and the total cost of batch concentration is reduced to 4407.43 from 4531.47, the lowest in the initial dataset.

In terms of parameter selection, it can be seen from the iteration selection histogram of four parameters in Figure 4 that, with the support of simulation database and comprehensive consideration of the uncertainty of prediction in the Bayesian optimization iteration process, once a lower value is found, the search can be frequently continued near the point, which greatly improves the search efficiency. In terms of iteration results, after 144 iterations, it can be found that the best parameter combination is  $P=15.38\text{kpa}$ ,  $\Delta T=14.79\text{ }^\circ\text{C}$ ,  $\Delta t_1=9.35\text{ }^\circ\text{C}$ ,  $\Delta t_2=5.62\text{ }^\circ\text{C}$ , the minimum value of the objective function is 4407.43. As shown in Figure 5, the target value close to the lowest value has been obtained after 71 iterations. However, in the subsequent iteration process, there is no lower target value. The reason could be that as the times of iterations increases, the acquisition of the known value of the function increases, and the surrogate model is prone to over fitting. Therefore, the number of iterations can be appropriately reduced to avoid over fitting.

## 5. Conclusion

In this paper, Bayesian optimization algorithm based on Gaussian regression process and UCB is applied to optimize the batch concentration process of HME and obtain the optimal combination of control parameters, so as to minimize the total cost of batch concentration. After 144 iterations, the best control scheme and the lowest total cost value 4407.43 are obtained. It can be seen that Bayesian optimization algorithm has strong competitiveness in dynamic optimization, especially in the screening of control parameters. The surrogate model of Bayesian optimization also has strong fitting ability and good interpretability with the support of simulation database and comprehensive consideration of the uncertainty of prediction in iterations. In the subsequent work, the impact of different probabilistic surrogate models and acquisition functions on the optimization results can be compared.

## Abstract

Hybrid models are used increasingly for the simulation of complex physical processes, because they combine the knowledge of the physics of a process and the data obtained from process measurements. This fusion of domain expert knowledge with data leads to hybrid models that are more accurate, can extrapolate, and obey laws of physics. Surrogate modeling can be cast as a hybrid modeling approach that builds reduced-order models for complex physical phenomena with simple model structure and low computational complexity. This study presents the application of hybrid modeling developed through a simple and accurate recursive symbolic regression algorithm for the complex and ill-understood phenomenon of tool wear in precision machining.

**Keywords:** Surrogate model, Symbolic Regression, Physics-explained AI.

## 1. Introduction

With the advent of Industry 4.0, manufacturing industries have undergone the digitalization of manufacturing processes. This digitalization has enabled the collection of better and large sets of sensor data to build data-driven models. Some popular methodologies for building data-driven models are neural networks and support vector machines (Han et al. 2021, 2022) . Though these models are widely used for process health monitoring in the manufacturing industries, they tend to be limited due to data idiosyncrasies. Hybrid models overcome this shortcoming. Hybrid models infuse domain knowledge of the physics of the process in the data-driven methodologies (Yang et al. 2022). Sansana et al. (2021) classified hybrid models based on the structure of the models broadly into three categories, serial structure, parallel structure, and surrogate models. A serial structure combines a hybrid model where the mechanistic part of the model either takes care of the known process behavior, and the data-driven part is used to capture the behavior, a feature of the process that cannot be directly estimated from the mechanistic model. A surrogate model is an approximate process model, and it is a simple representation of a complex phenomenon. These attributes of the surrogate models are helpful in building models for processes/phenomena that are difficult to model directly using data from the sensors or in cases where the physics of the process/phenomenon is too complex to model. In this study, a surrogate model is built to capture the progression of a fault in a manufacturing process. As is often the case in physical processes, the progression of a process fault is dynamic and depends on its state at any given time. Therefore, incorporating the fault state to predict its future values is important in modeling the process and fault accurately. This is accomplished by building dynamic or

recursive models. This work illustrates the development of a recursive symbolic regression model.

## 2. Surrogate modeling approaches

Surrogate models are approximate models of complex physical phenomena that can be used to represent an actual physical process with low complexity. These models require less computational effort and are used in process modeling and optimization. Over the years, several mathematical software have been developed to build surrogate models. Some of the commercially available software are Eureqa (Schmidt and Lipson 2009) (now DataRobot), AI Feynman: A physics-inspired method for symbolic regression (Udrescu and Tegmark 2020), Automated Learning of Algebraic Models for optimization ALAMO (Cozad, Sahinidis, and Miller 2014, 2015; Wilson and Sahinidis 2017), and the Genetic Programming Toolbox for Identification of Physical Systems (GPTIPS) (Searson, Leahy, and Willis 2010; Searson 2015). These software toolboxes exploit symbolic regression to develop surrogate models of response variables for selected input variables. Symbolic regression gives an algebraic expression of input variables. This approach is different from traditional regression techniques because the model structure and the regression coefficients are both evolved in symbolic regression. This helps in finding unique mathematical expressions that would best represent the data. Here, we choose GPTIPS to illustrate a methodology for recursive symbolic regression.

### 2.1. GPTIPS (*Genetic programming toolbox for identification of physical systems*)

GPTIPS is a MATLAB toolbox based on genetic programming (Searson 2015). Genetic programming is a biologically inspired machine learning method that uses the principles of evolution to perform a task or operation. To perform a task/operation, GP generates a random population of tree structures and then performs mutation, selection, and crossover over the best-performing tree to build a new population. This process of GP is repeated until a tree structure is obtained that fulfills the objective or, in the case of symbolic regression, gives a model of desired complexity and accuracy. GPTIPS utilizes the aforementioned features to build empirical mathematical models using data. GPTIPS generates models using multigene genetic programming with a linear combination of nonlinear transformation of input variables. GPTIPS has a variety of tournament selection methods, such as regular tournament selection, Pareto tournament selection, and lexicographic tournament selection. To build models for symbolic regression, GPTIPS has a large set of basis functions, +, -, \*, \, mult3(product of three terms), add3(sum of three terms), tanh, cos, sin, exp, ln (natural logarithm), x2, abs, x3, Ö, exp(-x), if-then-else, >, <, exp(x2), threshold and step functions, for model building. GPTIPS provides options to select a user-defined fitness criterion for model building (the default fitness metric is the root mean squared error, RMSE). GPTIPS provides an extensive list of hyperparameters, such as the number of generations, number of populations, maximum tree depth, maximum mutation depth, tournament size, crossover, mutation, elitism, and direct reproduction, that can be tuned to improve the model fitness. These hyperparameters decide on the complexity, and the model fitness is adjusted to get a model that does not overfit the data.

## 3. Application of surrogate modeling in manufacturing

### 3.1. *Precision machining and tool wear*

Precision machining is performed using Computer Numerical Control (CNC) machines (Awasthi and Bollas 2020). CNC machines use a circular tool with high-grade metal

inserts, rotating at high speed and removing material from the workpiece as metal chips. This process results in high shear stress, friction, and high temperature at the tool interface and workpiece interface (Awasthi et al. 2022). These aggressive conditions lead to the wear of the insert surface. This gradual wear of the insert surface is called tool wear. Analysis of data and understanding of the physics of the tool wear mechanism have identified that tool wear is a function of the operating conditions and the state of the tool. Using this insight, a recursive surrogate model of the tool wear as a function of the tool wear state was developed using GPTIPS. In addition to the tool wear state, the cutting conditions impact tool wear and were considered for model building. Hence, in this study, we utilize the recursive symbolic regression methodology to build a model for tool wear.

Table 1. Machine setting for experiments performed on the HAAS machine

Machine	# of parts	Diameter (mm)	Teeth	Width of cut (mm)	Depth of cut (mm)	Feed rate mm/min	Spindle speed (RPM)
HAAS	#1-#4	20	2	10.16	2.54	710.184	2330
HAAS	#5-#7	20	2	10.16	2.54	970.483	3184

### 3.2. Machining data collection

Machining data were collected by performing experiments in a HAAS Mini Mill machining center. The HAAS mini mill is a 3-axis compact machining center. To generate data, milling was performed on an AISI 4340 cylindrical steel block of 177.8 mm diameter, and 20 HRC hardness using a tool with two Kennametal inserts of grade KC725M and a lead angle of 90°. Each of these steel blocks was called a “Part.” A spiral tool path was selected to generate tool wear data and to make a cylindrical boss height of 10.16 mm and a diameter of 76.2 mm. One complete spiral tool path was called a “Run,” and while following the path, the tool went around the workpiece five times to reduce the diameter from 177.8 mm to 76.2 mm. The width of cut for this spiral path was 10.16 mm, and the depth of cut was 2.54 mm. At the end of the spiral tool path, when a boss of 76.2 mm diameter was obtained, the machining was stopped, and the flank wear measurement was taken. This whole process was repeated four times on a part to form a boss height of 10.16 mm and a diameter of 76.2 mm. This process was performed on the HAAS machine, and tool wear data were collected. A total of seven parts were machined, parts #1-#4 were machined for the machine settings of feed rate 710.184 mm/min and spindle speed 2330 RPM, and parts #5-#7 were machined for a feed rate of 970.483 mm/min and a spindle speed of 3184 RPM. Table 1 shows the machine settings for the experiments. In the case of the HAAS machine, the flank wear measurements were estimated using the values of the tool radius change. The tool diameter was measured after each run, and for the last run of part#7, the flank wear measurements were taken using a Keyence VHX-500, with a VH-Z100 lens and OP-72402 light ring microscope. To determine the flank wear, the tool radius change was calculated from the tool diameter measurements. In milling, the tool radius change follows the same trend as that of the flank wear. Therefore, by using the tool radius change values and the flank wear value from the last run, the flank wear values were estimated because both were assumed to have the same profile. Table 1 shows the values of the machine settings of spindle speed, width of cut, depth of cut, and feed rate, which are used to build a surrogate model for tool wear using GPTIPS.

### 3.3 Methodology for recursive symbolic regression

As shown in Fig. 1, the data of inputs and response variable were collected by performing experiments. Then GPTIPS was used to develop a recursive model of the input response

variable, which contains the machine settings and an initial guess of the state of wear. This guess was updated iteratively, and a new recursive model was generated for the updated value of the state. To update the response variable in the input, the symbolic regression model obtained from GPTIPS was used to calculate the actual response variable values using the machine settings and the predictions of the response variables recursively for all the time steps. Fig. 1 shows the methodology for building a recursive symbolic regression model for the case of machining. Machine settings were the inputs, and the tool wear was the response variable. This method was applied to build a recursive model for tool wear for a milling operation. In the figure, “ $i$ ” and “ $j$ ” are the counters, where the maximum value of  $j$  is  $j_{max}$  and the maximum value of  $i$  is  $N$  (number of datapoints).  $\hat{W}$  is the predicted and  $W$  the experimental tool wear, respectively.

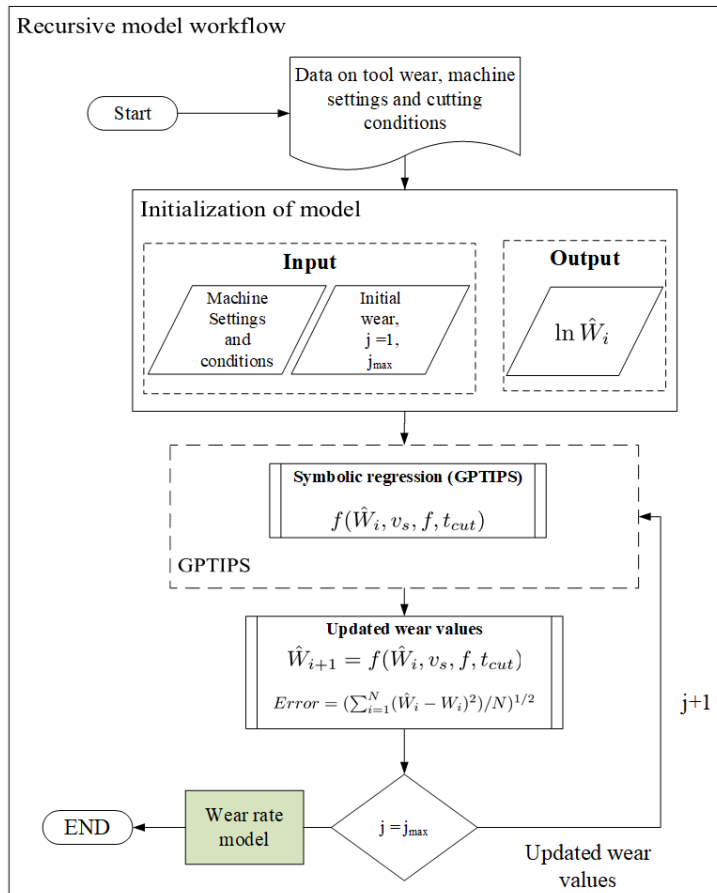

Figure 1: Workflow of the recursive model building methodology.

### 3.4 Surrogate model for tool wear

The recursive surrogate model for tool wear was developed using the methodology shown in Fig. 1. The inputs for model building were the spindle speed ( $v_s$ ), feed rate ( $f$ ), cutting time ( $t_{cut}$ ) and the natural logarithm of the tool wear ( $\ln \hat{W}_i$ ) at the current time step. The output of the model was the natural logarithm of the current wear ( $\ln \hat{W}_{i+1}$ ). The logarithm of the output was taken to reduce the variability of the data and assist in model fitting. Spindle speed and feed rate were the two input settings that changed during machining

and hence are included in model building. The complete experimental dataset was used for model building. Table 2 shows the basis function.  $\exp$ ,  $\ln$ ,  $x^3$ ,  $+$ ,  $*$ ,  $\setminus$ , used for model building. Default values were selected for crossover, elitism, mutation, and direct reproduction per-centages. The population size, number of generations, max. tree depth, and max. mutation depth were the parameters that were tuned to obtain good model fit. The number of iterations,  $j_{max}$ , were 10. After tuning the hyperparameters the best model obtained are shown in Table 2. The number of generations was 100, population size was 100, maximum tree depth was 3 and the maximum mutation depth was 2.

Table 2: GPTIPS toolbox settings for model building.

Basis functions: $\exp$ , $\ln$ , $x^3$ , $+$ , $*$ , $\setminus$
Population size : 100
Number of generations : 150
Tournament size : 10
Max. tree depth : 3
Max. mutate depth : 2
Crossover (%) : 84 (default)
Mutation (%) : 14 (default)
Elitism (%) : 15 (default)
Direct reproduction (%) : 2 (default)

$$\ln \widehat{W}_{i+1} = 108.438 \ln(t_{cut} + 3.0142) - 10.051 t_{cut} - 10.051 \ln t_{cut} - 1.768 \ln t_{cut}^2 - 4.856 t_{cut}^3 \ln \widehat{W}_i - 140.614 \dots (1)$$

Eq. (1) shows the expression of the recursive tool wear model obtained. Fig. 2 shows the plot of the actual tool wear values obtained from the experiment performed on the HAAS machine and the predictions obtained from the tool wear model. The model had an  $R^2$  value of 0.989, and as seen in the figure, the recursive tool wear model was able to capture the progression of tool wear in the machining process. The model shown in Eq. (1) is a function of the tool wear at the previous time step and cutting time. The tool wear increases with the increase in the cutting time and the term  $t_{cut}^3 \ln \widehat{W}_i$ , adds nonlinearity to the cutting profile to capture the effect of the state of the cutting tool and the cutting conditions. GPTIPS added terms  $t_{cut}$ ,  $\ln t_{cut}$ , and  $\ln t_{cut}^2$  to the term to fit the data. Overall, the model gives excellent agreement between predicted and measured tool wear for this process.

Figure 2: Tool wear predictions of the surrogate model for the wear data of the experiments performed on HAAS.

#### 4. Conclusion

This study demonstrated the use of symbolic regression to build a recursive surrogate model using an open-source genetic programming-based toolbox GPTIPS to perform symbolic regression. This approach helped to build models in the form of simple, transparent expressions, which are interpretable due to their algebraic form. This approach was applied to a manufacturing process to build a model for tool wear. A recursive tool wear model was developed, as a function of the tool wear state at any point in the manufacturing process. The model gave excellent predictions of the tool wear with a very simple and easy to interpret function.

# Demand Response in Microgrids with Attention-Based Deep Reinforcement Learning

Jiahan Xie, Akshay Ajagekar, Fengqi You

*Cornell University, Ithaca, NY 14853, USA*

## Abstract

In this work, we propose a novel multi-agent deep reinforcement learning (MA-DRL) based approach to facilitate efficient load shaping through automated demand response in a microgrid. Achieving real-time autonomous demand response with energy management systems in buildings can be challenging due to factors like uncertain system parameters, the dynamic market price, and the complex coupled operational constraints. To develop a scalable approach for automated demand response in a microgrid, it is necessary to allow for coordination between buildings in the grid to smoothen the overall demand curve. We present a MA-DRL agent that utilizes an actor-critic algorithm incorporating a shared attention mechanism to enable an effective and scalable real-time cooperation to prevent the non-coordinated peak shifting actions in the complicated building system. A computational case study conducted with nine residential buildings revealed the attention-based MA-DRL agent's ability to execute decentralized cooperative policies without knowledge of building systems models or electricity price dynamics. Viability of the proposed control approach was also demonstrated by a reduction in net electricity consumption of over 6% accompanied by reduction in carbon emissions as compared to both conventional and state-of-the-art reinforcement learning approaches for automated demand response.

**Keywords:** Deep reinforcement learning, multi-agent, demand response, microgrids.

## 1. Introduction

As the integration of renewable energy sources into microgrids increases, demand response presents an opportunity to reduce the strain on the electric grid by reducing electricity usage in turn lowering greenhouse gas emissions (Pistikopoulos et al., 2021). By promoting the responsiveness of the buildings, demand response can lower the peak demand and the electricity consumption and thus improve the grid's stability in the long term (Yang et al., 2022). Factors like the variability of renewable energy sources, uncertainty associated with weather and load demand, as well as fluctuation of electricity prices further complicate the demand response problem (Silva et al., 2022). Demand response can be framed as an optimization problem to optimize electricity consumption or associated costs subject to coupled spatial and temporal constraints (Sun et al., 2021). Several math programming-based approaches have been previously applied in demand response for optimal scheduling of resources in a microgrid (Jordehi, 2019; Qiu, 2021). However, as the size of these problems increases with the number of buildings and the energy storage devices (Chen, 2022), metaheuristic solution techniques have also been proposed to obtain approximate solutions at the expense of reduced computational times (Shewale et al., 2020). Optimal control techniques like model predictive control have also been successfully incorporated for demand response (Qureshi et al., 2014). Such model-based approaches rely on first-principle models that

are often simplified and may fail in a practical setting owing to the non-ideal behavior of individual energy components (Chu and You, 2015). As a result, it is necessary to develop a comprehensive solution approach that is capable of handling various sources of uncertainties present in a microgrid while overcoming the need for an accurate first-principle model.

Reinforcement learning (RL) is a promising candidate for demand response problems owing to its model-free, and adaptive learning ability (Vázquez-Canteli and Nagy, 2019). Deep reinforcement learning (DRL) utilizes deep neural networks as nonlinear function approximators to overcome computational intractability caused by the increase in problem size. Many DRL-based techniques have been proposed for demand response and energy management in smart microgrids. DRL techniques assume no knowledge of the system dynamics and have been shown to optimize peak load in residential buildings (Mocanu et al., 2018) and minimize energy costs (Yu et al., 2020) by inducing coordination between the HVAC system and energy storage devices. Multi-agent variants of DRL techniques have also been explored to reduce operating costs and peak load through distributed scheduling of energy storage systems (Yang et al., 2019). Multi-agent deep reinforcement learning (MA-DRL) techniques can be directly applied to demand response problems (Vazquez-Canteli et al., 2020), however, they may add dynamicity to the microgrid operation and yield sub-optimal policies. Another challenge lies in ensuring coordination and information exchange between the agents in a multi-agent setting to obtain joint optimal policies. To overcome these challenges, we propose a novel multi-agent approach for demand response in grid-responsive buildings that employ an actor-critic based deep reinforcement learning technique to produce efficient energy management policies resulting in reduced overall electrical demand. Utilizing the attention mechanism in DRL (Iqbal and Sha, 2019) allows for centralized training with a shared critic network while ensuring decentralized execution governed by the multi-agent setting. We also perform several computational experiments to demonstrate that buildings in a microgrid can better learn how to coordinate to decrease the net electricity consumption accompanied by a reduction in carbon emissions as compared to both conventional and state-of-the-art DRL approaches for automated demand response.

## 2. Attention-based MA-DRL for demand response

### 2.1. Problem formulation

Multi-agent Markov decision processes (MMDPs), the generalization of the Markov decision process to the multi-agent setting, is applied to formulate the demand response problem in a grid of interconnected buildings. An MMDP is a tuple  $\langle S, A_1, \dots, A_N, T, R_1, \dots, R_N \rangle$ , where  $S$  is a set of states,  $A_1, \dots, A_N$  is a collection of action sets for  $N$  agents,  $T: S \times A_1 \times \dots \times A_N \rightarrow P(S)$  is the state transition function, which defines the probability distribution over possible next states given the current state and actions for each agent, and  $R_i: S \times A_1 \times \dots \times A_N \rightarrow \mathbb{R}$  is the reward function for each agent that is a function of global state and actions of all agents. As real-world settings often feature incomplete observations, each agent  $i$  receives its private observation  $o_i \in O_i$ , which contains partial information from the global state,  $s \in S$ .

For each building  $i$ , the agent receives observation  $o_{i,t}$  at time  $t$ . The observations contain the time variable accurate to an hour, district's temperature and humidity along with their associated predictions, district's solar radiation along with its prediction, buildings' indoor temperature and humidity, buildings' non-shiftable load, buildings' storage device state of charge (SoC). Each agent has up to three continuous actions: cooling device storage, DHW device storage, and electrical device storage. Since our goal is to minimize the net electricity consumption and the carbon emissions in the district, the reward function is related to the carbon intensity in the district at time  $t$ ,  $CI_t$ , net electricity consumption of building  $i$  at time  $t$ ,  $E_{i,t}$ , and the total net electricity consumption in the whole district,  $E_t = \sum_{i=1}^N E_{i,t}$ . Empirically, we found the following reward function is helpful to reduce the electricity consumption and carbon emissions and to perform more aggressive load flattening:  $500 \min(0, E_t) \times CI_t - 0.01 \text{sign}(E_{i,t}) \times |E_{i,t}| \times E_t^3$ .

## 2.2. Multi-agent attention-based control (MAAC)

In reinforcement learning, methods that learn approximations to both policy and value functions are called actor-critic methods, where 'actor' refers to the learned policy, and 'critic' refers to the learned value function (Li, 2017). The bias introduced through bootstrapping the expected returns with temporal-difference (TD) methods is often beneficial because it reduces variance introduced by the policy gradient estimator. Specifically, the policy gradient method aims to learn a parameterized policy that can select actions without consulting a value function. The gradient estimate is expressed as follows, where  $\theta$  parameterizes the policy network  $\pi$ .

$$\nabla_{\theta} J(\pi_{\theta}) = \nabla_{\theta} \log(\pi_{\theta}(a_t | s_t)) \sum_{t'=t}^{\infty} \gamma^{t'-t} r_{t'}(s_{t'}, a_{t'}) \quad (1)$$

For the learned value function, the action-value function is typically used,  $Q_{\psi}(s_t, a_t) = \mathbb{E}[\sum_{t'=t}^{\infty} \gamma^{t'-t} r_{t'}(s_{t'}, a_{t'})]$ .  $Q_{\psi}(s_t, a_t)$  is learned through TD learning by minimizing the mean squared Bellman error based on the past system transitions sampled from the experience replay buffer  $\mathcal{D}$ :

$$\mathcal{L}_Q(\psi) = \mathbb{E}_{(s,a,r,s') \sim \mathcal{D}} [(Q_{\psi}(s,a) - y)^2] \quad (2)$$

where  $y = r(s,a) + \gamma \mathbb{E}_{a' \sim \pi(s')} [Q_{\bar{\psi}}(s', a')]$

To encourage exploration and avoid converging to non-optimal policies, the maximum entropy framework is adopted in the soft-actor-critic algorithm [11]:

$$\nabla_{\theta} J(\pi_{\theta}) = \mathbb{E}_{s \sim \mathcal{D}, a \sim \pi} [\nabla_{\theta} \log(\pi_{\theta}(a | s)) (-\alpha \log(\pi_{\theta}(a | s)) + Q_{\psi}(s,a) - b(s))] \quad (3)$$

where  $b(s)$  is a state-dependent baseline. The loss function for TD learning of the value function is also revised accordingly:

$$y = r(s,a) + \gamma \mathbb{E}_{a' \sim \pi(s')} [Q_{\bar{\psi}}(s', a') - \alpha \log(\pi_{\bar{\theta}}(a' | s'))] \quad (4)$$

The attention mechanism is used for each agent to query other agents for information about their observations and actions and incorporates that information into calculating its action-value function  $Q_i^\psi(o, a)$  for agent  $i$ . Precisely, the action-value for agent  $i$  is calculated as follows:

$$Q_i^\psi = f_i(g_i(o_i, a_i), x_i) \quad (5)$$

where  $f_i$  is a two-layer multi-layer perceptron (MLP),  $g_i$  is a one-layer MLP embedding function,  $x_i$  denotes the total contribution from other agents,  $h$  is an MLP with  $V$  as the value matrix.

$$x_i = \sum_{j \neq i} \alpha_j v_j = \sum_{j \neq i} \alpha h(V g_j(o_j, a_j)) \quad (6)$$

The attention weight  $\alpha_j$  compares the embedding  $e_j$  with  $e_i = g_i(o_i, a_i)$ , using the query-key system (Vaswani et al., 2017) and apply softmax over the similarity value between these two embeddings,

$$\alpha_j = \frac{\exp((W_k e_j)^T W_q e_i)}{\sum_{j=1}^N \exp((W_k e_j)^T W_q e_i)} \quad (7)$$

where  $W_q$  transforms  $e_i$  into a "query" and  $W_k$  transforms  $e_j$  into a "key". Because of the sharing of the set of parameters  $W_q$ ,  $W_k$ , and  $V$ , all critics are updated to minimize a joint regression loss function:

$$\mathcal{L}_Q(\psi) = \sum_{i=1}^N \mathbb{E}_{(o, a, r, o') \sim \mathcal{D}} [(Q_i^\psi(o, a) - y_i)^2] \quad (8)$$

where  $y_i = r_i + \gamma \mathbb{E}_{a' \sim \pi_\sigma(o')} [Q_i^{\bar{\psi}}(o', a') - \alpha \log(\pi_{\theta_i}(a_i | o_i))]$

Likewise, the individual policies are updated by gradient ascent on the following gradient:

$$\begin{aligned} \nabla_{\theta_i} J(\pi_{\theta_i}) = & \mathbb{E}_{o \sim \mathcal{D}, a \sim \pi} [\nabla_{\theta_i} \log(\pi_{\theta_i}(a_i | o_i)) (-\alpha \log(\pi_{\theta_i}(a_i | o_i)) \\ & + Q_i^\psi(o, a) - b(o, a_{\setminus i}))] \end{aligned}$$

where  $\setminus i$  is denoted as the set of all agents except  $i$ , and  $b(o, a_{\setminus i})$  is the multi-agent baseline. As a controller, each building will store transition tuples  $(o_t, a_t, o_{t+1}, r_{t+1})$  into its corresponding replay buffer  $\mathcal{D}$ . When the replay buffer stores enough experience and the system reaches the update time  $T_{update}$ , we sample a mini-batch  $\mathcal{B}$  and use the batch to update the critics and actors networks. The critics will take in all policy networks and perform enhanced updates through the attention mechanism. During the execution phase, each agent will download the latest updated policy networks and take actions only according to their local observations. This decentralized execution has manifested better computational efficiency.

### 3. Case study: Computational results

We compare our results with three state-of-the-art RL controllers and one Rule-based controller (RBC). The three RL controllers include Deep Deterministic Policy (DDPG) controllers, Soft-Actor-Critic (SAC) controllers, and the Multi-Agent RL with Iterative Sequential Action Selection (MARLISA) controllers [10]. The DDPG controllers and the SAC controllers do not have explicit information sharing and coordination, while the MARLISA controllers have information sharing of buildings' own future electricity consumption following a leader-follower schema. The RBCs take uniform and greedy actions, they charge 9.1% of their storage devices' maximum capacities every hour from 10pm to 8am, and release 8% of their maximum capacities every hour from 9am to 9pm. We conduct simulations with the energy demand for each building in New Orleans using a pre-recorded dataset of nine buildings. Each building consists of an air-to-water heat pump, as well as an electric heater that supplies them with DHW. The primary grid provides electricity for these devices, other electrical equipment, and appliances. Meanwhile, buildings can generate electricity using photovoltaic generation to offset some of their electricity consumption. We run simulations on the same weather data for 10 epochs to test the performance and the convergence of different RL controllers. All the RL controllers perform random action exploration for the first 250 days during the first epoch. For the SAC, MARLISA, and MAAC controllers, they perform stochastic policies for 300 more days by sampling from the policies distribution with entropy regularization. For the DDPG controllers, they have uncorrelated, mean-zero Gaussian noise for 300 more days of exploration. After 550 days into the simulation, the SAC, MARLISA, and MAAC controllers remove stochasticity and exploit their policies by taking the mean action. The DDPG controllers' actions noises scale to 0 for taking deterministic actions. The Adam optimizer is employed to update all neural networks.

Figure 1. Net electricity consumption of the buildings in the fall and spring seasons over a period of 48 hours along with the electricity pricing.

In Figure 1, we visualize the electricity demand under different RL control algorithms for a fixed period of 48 hours during the fall and spring seasons. With the proposed controller, the electricity demand starts decreasing concurrently with the increase in price, and the demand rises back when the price is lower, during which the agent can store more energy for the preparation of the next peak price period. As the simulation results have demonstrated, all the RL controllers react appropriately to price fluctuations and reduce electric demand except the DDPG method. Since DDPG relies on all kinds of tuning and tends to overestimate the Q-values, it is common to see that the controllers exploit problematic Q-functions and have learned poor policy. Furthermore, during this high-demand period, the MAAC controllers demonstrate their strong ability compared to two other RL algorithms that are also using the soft-actor-critic framework. As the demand curves have shown, the attention-based MA-DRL controllers ensure stability and less fluctuation of the demand curve. We can conclude that the attention-based MA-DRL controllers perform better in minimizing electricity consumption while performing load shaping in the meantime. Their superior abilities to reduce energy consumption and flatten the energy demand curve are essential for the reliability of the microgrids.

#### 4. Conclusion

In this paper, we introduced an attention-based MA-DRL demand response algorithm that can achieve better cooperation between the interconnected buildings to reduce electricity consumption and provide effective demand flattening in a decentralized way in the absence of any prior knowledge of the system model. Simulation results demonstrated the convergence and the efficacy of our proposed attention-based MA-DRL controllers. They achieve a significant reduction in net electricity consumption accompanied by a reduction in carbon emissions compared to both conventional and state-of-the-art RL approaches for automated demand response.

## Abstract

Kernel Canonical Variate Analysis (KCVA) is a widely used method for nonlinear system identification. Recently, it was shown that combining the Gaussian kernel with a linear kernel can improve the generalization ability of KCVA models. However, there are no known results for multi-kernel CVA as of yet, that is, when more than two kernels are combined to capture the nonlinearities from the process data. In this work, a multi-kernel designs involving two to four kernel functions are investigated in KCVA. Bayesian optimization (BayesOpt) is also proposed to tune kernel parameters by fitting a surrogate Gaussian process on the loss surface, and then searching the next best kernel mixture efficiently via the Expected Improvement policy. We demonstrate that BayesOpt is more data-efficient than other stochastic search methods in finding kernel designs. Results were verified using a series of empirical trials in an benchmark evaporator case study.

**Keywords:** system identification, multiple kernel learning, canonical variate analysis, Newll-Lee evaporator, Gaussian process regression.

## 1. Introduction

Most aspects of process control and operations inherently require a model of the physical process that accurately describe the process dynamics. In order to build these models, two main approaches exist, namely, first-principles modelling or system identification. Due to the highly complex nature of physical systems, first-principles modelling can become too tedious to perform. Hence, system identification (SysID) techniques are more preferred, since they only require an assumed general model structure to be fitted to the real process input-output data.

Many SysID methods already exist, but among these, the subspace methods are favorable since they only require matrix algebra to estimate the model from data, making them fast and non-iterative, whereas prediction error methods require an iterative minimization of a cost function to find an accurate model (Qin, 2006). For processes operating at widely varying operating conditions, nonlinear model structures must be assumed, since nonlinear dynamic behaviors are expected to appear in the data statistics. One of the recently developed nonlinear subspace methods is the feature-relevant mixed kernel canonical variate analysis (FR-MKCVA) (Pilario *et al.*, 2020), which proposed a new kernel design for kernel canonical variate analysis (KCVA) based subspace identification. The proposed kernel is a mixture of a global kernel, given by the linear kernel, and a local

kernel, given by the Gaussian radial basis function (RBF) with automatic relevance determination. Since the kernel is a convex combination of global and local types, it has been demonstrated to improve the generalization ability of the fitted model for the Newell-Lee evaporator case study (Al-Seyab & Cao, 2008). Even with a 25% increase in the input amplitude, the FR-MKCVA model provided superior fitness than linear CVA and recurrent neural nets. The KCVA framework has also been applied to fault detection (Samuel & Cao, 2015) due to its ability to handle nonlinear dynamic processes.

In this work, the FR-MKCVA model is extended by analyzing the impact of other kernel designs such as when the sigmoid and Laplacian kernels are included. We investigate kernel mixtures consisting of two to four kernel functions being combined in a convex manner. Hence, we propose a novel multi-kernel CVA algorithm. Note, however, that the search for kernel parameters become increasingly difficult with larger kernel mixtures. Hence, we also propose in this work a more robust and efficient way to tune kernel parameters via the use of Bayesian Optimization (BayesOpt). We compared the computational efficiency and accuracy of the subspace models when tuned by BayesOpt to those tuned by alternative stochastic algorithms commonly used in literature, such as particle swarm optimization (PSO), genetic algorithm (GA), simulated annealing (SA), and random search (RS). Using the Newell-Lee evaporator case study, the results show that BayesOpt is more efficient, hence, more recommended than other search methods, and that the addition of new kernel mixtures can help improve the accuracy of the subspace models as well.

This paper is organized as follows. Section 2 covers preliminary background on FR-MKCVA. Section 3 presents the BayesOpt method used in this work, as well as the kernel designs being investigated. Section 4 gives the results and discussion for each case study. Finally, Section 5 contains a summary of this work.

## 2. Feature-Relevant Mixed Kernel Canonical Variate Analysis

The FR-MKCVA method is an improved subspace identification method from the original canonical variate analysis (CVA) proposed by Larimore (1990). The idea in FR-MKCVA is to identify a nonlinear dynamic model with the state-space structure:

$$\mathbf{x}_{k+1} = \mathbf{A}\mathbf{x}_k + \mathbf{B}\mathbf{f}(\mathbf{u}_k, \mathbf{y}_{k-1}) + \mathbf{w}_k \quad (1)$$

$$\mathbf{y}_k = \mathbf{C}\mathbf{x}_k + \mathbf{D}\mathbf{f}(\mathbf{u}_k, \mathbf{y}_{k-1}) + \mathbf{v}_k \quad (2)$$

where  $\mathbf{x}_k$ ,  $\mathbf{y}_k$ ,  $\mathbf{u}_k$  are the states, outputs, and inputs, respectively,  $\mathbf{w}_k$ ,  $\mathbf{v}_k$  are the process noise and measurement noise vectors, respectively,  $\mathbf{A}$ ,  $\mathbf{B}$ ,  $\mathbf{C}$ ,  $\mathbf{D}$  are the state-space matrices, and  $\mathbf{f}(\mathbf{u}_k, \mathbf{y}_{k-1})$  is some nonlinear mapping of the input-output data where the mapping is defined by a set of kernel functions (Pilario *et al.*, 2020). To identify the model, the input-output data are first projected onto the kernel subspace using kernel principal components analysis (KPCA). KPCA employs a kernel function  $K(\mathbf{x}, \mathbf{x}')$  to act as a dot product in some nonlinear space. Through KPCA, a nonlinear set of features can be extracted from the data as follows:

$$\mathbf{f}(\mathbf{u}_k, \mathbf{y}_{k-1}) = [\mathbf{t}_k] = \left[ \sum_{j=1}^N \alpha_j^T K(\mathbf{z}_k, \mathbf{z}_j') \right]_{i=1, \dots, l} \quad (3)$$

where  $\mathbf{z}_k = [\mathbf{u}_k \mathbf{y}_k]^T$  is the input-output data set at the  $k$ th sampling instant,  $N$  is the number of training samples,  $\boldsymbol{\alpha}$  are the KPCA loadings, and  $l$  is the number of principal components. The  $l$  is chosen according to the 99% cumulative percent variance rule. The kernel design in Eq. (3) that was proposed in Pilario *et al.* (2020) is given in Table 1. After performing KPCA, the CVA algorithm is now employed. First, the features from Eq. (3) are organized into past and future Hankel matrices,  $\mathbf{Y}_p$  and  $\mathbf{Y}_f$ . Their covariances are given by  $\boldsymbol{\Sigma}_{pp} = \text{cov}(\mathbf{Y}_p, \mathbf{Y}_p)$ ,  $\boldsymbol{\Sigma}_{ff} = \text{cov}(\mathbf{Y}_f, \mathbf{Y}_f)$ , and  $\boldsymbol{\Sigma}_{fp} = \text{cov}(\mathbf{Y}_f, \mathbf{Y}_p)$ . CVA proceeds by taking the singular value decomposition (SVD) of the Hankel matrix, that is  $\boldsymbol{\Sigma}_{ff}^{-1/2} \boldsymbol{\Sigma}_{fp} \boldsymbol{\Sigma}_{pp}^{-1/2} = \mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^T$ . The CVA states are now estimated from the data as  $\mathbf{X} = [\mathbf{x}_k] = \mathbf{V}_n^T \boldsymbol{\Sigma}_{pp}^{-1/2} \mathbf{Y}_p$  where  $\mathbf{V}_n$  represents the first  $n$  singular vectors from the matrix  $\mathbf{V}$ , signifying that only the subspace of the first  $n$  states are taken as the principal subspace. Finally the state-space matrices are computed from  $\mathbf{X} = [\mathbf{x}_k]$ ,  $\mathbf{U} = [\mathbf{u}_k]$ , and  $\mathbf{Y} = [\mathbf{y}_k]$ , as follows:

$$\begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} = \text{cov} \left[ \begin{pmatrix} \mathbf{x}_{k+1} \\ \mathbf{y}_k \end{pmatrix}, \begin{pmatrix} \mathbf{x}_k \\ \mathbf{t}_k \end{pmatrix} \right] \cdot \left\{ \text{cov} \left[ \begin{pmatrix} \mathbf{x}_k \\ \mathbf{t}_k \end{pmatrix}, \begin{pmatrix} \mathbf{x}_k \\ \mathbf{t}_k \end{pmatrix} \right] \right\}^{-1} \quad (4)$$

where  $\mathbf{t}_k$  are the KPCA-extracted nonlinear features from Eq. (3).

### 3. Investigating Multi-Kernel Canonical Variate Analysis

#### 3.1. Kernel Designs

The design of the kernel function in Eq. (3) has a large impact in the performance of the identified model. In this work, various kernel designs are tested, shown in Table 1. The first kernel, namely Linear + Isotropic Gaussian RBF, only has 2 kernel parameters to tune, which are the mixture weight  $\omega$  and the kernel width  $\gamma$ . Since the hyper-parameter search space is only 2-D, this mixed kernel was used to compare the performance of BayesOpt against other search methods: Particle swarm optimization, genetic algorithm, simulated annealing, and random search.

The main metric for comparison is the  $R^2$  fitness of the model to the validation data:

$$R^2 = 100\% \times \left( 1 - \frac{\|\mathbf{y}_m - \mathbf{y}\|^2}{\|\mathbf{y}_m - \text{mean}(\mathbf{y}_m)\|^2} \right) \quad (5)$$

where  $\mathbf{y}$  are the predicted outputs from the model and  $\mathbf{y}_m$  are the reference measured outputs. The closer the  $R^2$  value to 100%, the more accurate the model. Aside from the  $R^2$ , the optimizers are also evaluated by their computational time given that all of them are provided the same budget of 100 maximum objective function evaluations.

#### 3.2. Bayesian Optimization

Bayesian optimization is a fast and efficient optimizer for black-box functions that are computationally expensive to sample. It has found many current applications such as in recommender systems, reinforcement learning, and hyper-parameter tuning in machine learning models (Shahriari *et al.*, 2016). For these reasons, BayesOpt is proposed in this work for tuning kernel parameters in multi-kernel CVA.

In BayesOpt, the adopted objective function is the fitness of the multi-kernel CVA model to the validation data. The goal is to find the kernel parameters  $\boldsymbol{\theta}$  that maximize the  $R^2$

value on a held-out validation data set. A surrogate Gaussian process (GP) model is chosen to estimate the mean  $m(\boldsymbol{\theta})$  and variance  $var(\boldsymbol{\theta})$  of the validation  $R^2$  as follows:

$$m(\boldsymbol{\theta}) = \mathbf{K}_*^T [\mathbf{K} + \sigma^2 \mathbf{I}]^{-1} \mathbf{y} \quad (6)$$

$$var(\boldsymbol{\theta}) = k(\boldsymbol{\theta}_*, \boldsymbol{\theta}_*) - \mathbf{K}_*^T [\mathbf{K} + \sigma^2 \mathbf{I}]^{-1} \mathbf{K}_* \quad (7)$$

where  $\mathbf{K}_* = k(\boldsymbol{\theta}_*, \boldsymbol{\theta})$  is the kernel matrix,  $k(\boldsymbol{\theta}, \boldsymbol{\theta}')$  denotes the kernel function in the GP,  $\sigma^2$  is the assumed noise variance and  $\mathbf{y}$  contains the validation  $R^2$  values. In this work, the chosen GP kernel is the *squared exponential* function, which is equivalent to the Gaussian RBF. Next, the Expected Improvement (EI) acquisition function is used to find the next best set of kernel parameter values  $\boldsymbol{\theta}_{next}$  to sample:

$$\boldsymbol{\theta}_{next} = \operatorname{argmax} EI(\boldsymbol{\theta}) \quad (8)$$

$$EI(\boldsymbol{\theta}) = \Delta(\boldsymbol{\theta}) \Phi \left( \frac{\Delta(\boldsymbol{\theta})}{\sqrt{var(\boldsymbol{\theta})}} \right) + \sqrt{var(\boldsymbol{\theta})} \phi \left( \frac{\Delta(\boldsymbol{\theta})}{\sqrt{var(\boldsymbol{\theta})}} \right) \quad (9)$$

where  $\Delta(\boldsymbol{\theta}) = m(\boldsymbol{\theta}) - y_i^* - \xi$ , the  $\xi$  is an exploration/exploitation parameter, the  $y_i^*$  is the maximum  $R^2$  observed so far at the  $i$ th iteration, and the  $\Phi$  and  $\phi$  are the cumulative density function and probability density function of the standard normal distribution, respectively. In this work, the max number of function evaluations is set to 100 and the  $\xi$  is made to decrease linearly from 20 to 0. The EI policy is to first explore the search space by favoring regions with high uncertainty, and then later on exploit on the regions where previous maxima were encountered. This balance between exploration and exploitation makes BayesOpt a data-efficient search algorithm (Shahriari *et al.*, 2016).

Table 1: Kernel functions investigated in this work.

Name and Function	Optimizer
Linear + Isotropic Gaussian RBF $K(\mathbf{z}, \mathbf{z}') = \omega(\mathbf{z}^T \mathbf{z}' + 1) + (1 - \omega) \exp\left(\frac{-\ \mathbf{z} - \mathbf{z}'\ ^2}{\gamma}\right)$	RS, GA, SA, PSO, BayesOpt
Anisotropic Gaussian RBF only $K(\mathbf{z}, \mathbf{z}') = \exp(-(\mathbf{z} - \mathbf{z}')^T \boldsymbol{\Gamma} (\mathbf{z} - \mathbf{z}'))$ $\boldsymbol{\Gamma} = \operatorname{diag}(1/\gamma_1, 1/\gamma_2, \dots)$	BayesOpt
Linear + Anisotropic Gaussian RBF (Pilario <i>et al.</i> , 2020) $K(\mathbf{z}, \mathbf{z}') = \omega(\mathbf{z}^T \mathbf{z}' + 1) + (1 - \omega) \exp(-(\mathbf{z} - \mathbf{z}')^T \boldsymbol{\Gamma} (\mathbf{z} - \mathbf{z}'))$ $\boldsymbol{\Gamma} = \operatorname{diag}(1/\gamma_1, 1/\gamma_2, \dots)$	BayesOpt
Linear + Isotropic Gaussian RBF + Sigmoid + Laplacian $K(\mathbf{z}, \mathbf{z}') = \omega_1(\mathbf{z}^T \mathbf{z}' + 1) + \omega_2 \exp\left(\frac{-\ \mathbf{z} - \mathbf{z}'\ ^2}{\gamma_1}\right)$ $+ \omega_3 \tanh(a\mathbf{z}^T \mathbf{z}' + b) + \omega_4 \exp\left(\frac{-\ \mathbf{z} - \mathbf{z}'\ }{\gamma_2}\right)$ $\omega_1 + \omega_2 + \omega_3 + \omega_4 = 1$	BayesOpt

### 4. Case Study

The full description of the Newell-Lee evaporator system can be found in Pilario *et al.* (2020). It consists of multiple subsystems having 3 inputs and 3 outputs overall. The system was simulated in MATLAB Simulink and it is available online through the following link: <https://www.mathworks.com/matlabcentral/fileexchange/68641-newell-lee-evaporator-system-for-system-identification>.

Since the process has six variables in total, the corresponding search space dimensions for kernel parameter tuning are 2-D, 6-D, 7-D, and 8-D for each kernel mixture proposed in Table 1, respectively. The number of states for this case study is fixed at  $n = 4$ , based on results in Pilario *et al.* (2020).

#### 4.1. Results on Bayesian Optimization

Fig. 1(a) compares various hyper-parameter optimizers in terms of computation time and maximum found, given the same budget of 100 max objective function evaluations. The box plots in this figure summarize the result of 10 trials in each optimizer. BayesOpt-2D is clearly more efficient than the other 2-D optimizers due to having one of the lowest computation times, yet highest maximum found. PSO was found to be the slowest, but it also found consistently high max values. Random Search, although fast, struggles to find the maximum. SA has a better performance than GA, but both are still less efficient than BayesOpt. To further illustrate the efficiency of BayesOpt-2D, Fig. 1(b) and (c) show, respectively, the EI surface and the surrogate GP surface laden with the sampled points. As shown, BayesOpt-2D concentrated more on the promising area near the maximum rather than needlessly exploring across the entire surface. Fig. 1(d) shows the *exact* objective function surface, which, upon comparing with Fig. 1(c), indicates that the surrogate GP can closely estimate the 2-D function given only the sampled points. The consistency of the result of BayesOpt-2D across 10 trials can also be verified in Fig. 1(e), since its converged solutions are more consistent than those from other optimizers.

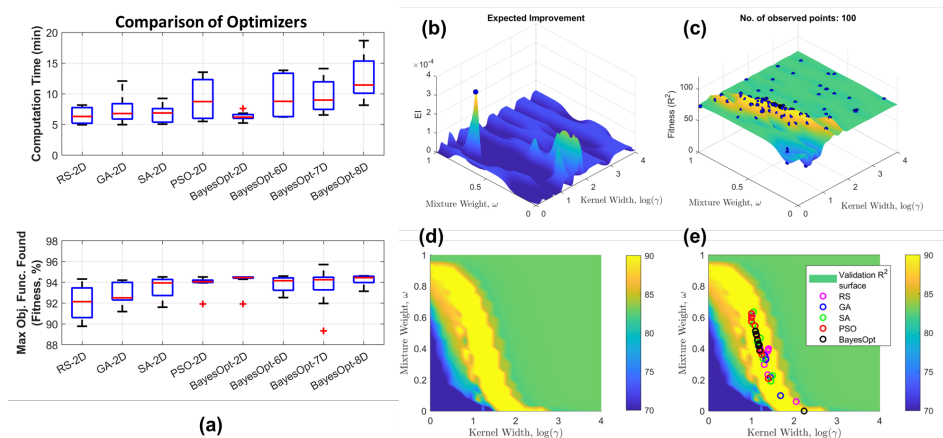

Fig. 1. Optimization results for the evaporator case study: (a) Comparison of computation time and max objective function values obtained from the 2-D, 6-D, 7-D, and 8-D hyper-parameter search repeated for 10 trials each; (b) Sample EI surface at the last iteration of a BayesOpt 2-D run; (c) A surrogate validation  $R^2$  surface showing the 100 points where the algorithm sampled the objective function; (d) The exact validation  $R^2$  surface, top view; (e) Same as (d) but showing the final converged solutions of the various optimizers.

#### 4.2. Results on the Testing of Multi-Kernel CVA models

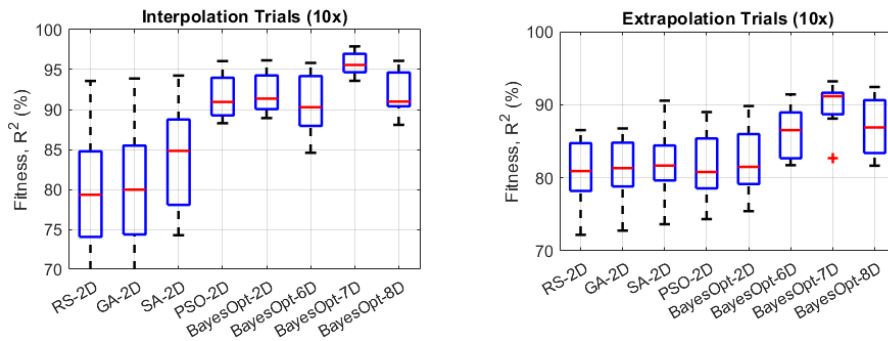

Fig. 2. Testing phase results in the evaporator case study. Each box plot summarizes 10 trials.

In Fig. 2, the validated multi-kernel CVA models are subjected to 10 interpolation data sets and 10 extrapolation data sets (with 25% increase in input amplitude) for testing. These data sets differ in the random input sequences and the random seed for noise generation. Results show that the best model is still the FR-MKCVA, but now Bayesian optimized (BayesOpt-7D) rather than subjected to random search as in Pilario *et al.* (2020). Also, the multi-kernel CVA with 4 kernels (BayesOpt-8D) was seen to be overfitting, since its performance is worse than FR-MKCVA. This indicates that 4 kernel functions may be too complex to validate with such a limited validation data set.

### 5. Conclusion

In this work, various multi-kernel designs were investigated for KCVA based nonlinear system identification. In addition, Bayesian optimization was demonstrated to be an efficient hyper-parameter search method for tuning these kernel designs. Using the benchmark Newell-Lee evaporator case study, the Bayesian optimized multi-kernel consisting of the linear and anisotropic Gaussian RBF was found to provide the best accuracy, as proven by both interpolation and extrapolation test data sets. However, our results also show that more complex multi-kernel designs are more difficult to tune as they become more prone to overfitting. In the future, this issue can be addressed by improving the search policy within BayesOpt for tuning the kernel parameters. Future work also includes the application of multi-kernel CVA to real-world case studies.

## Abstract

This paper presents a condition monitoring system development framework that incorporates process knowledge to enhance the performance of machine learning models. Essentially, the framework uses information about the process to create a representation of the process condition, which can be broken down into modules using concepts borrowed from probabilistic graphical modeling. These modules represent simpler problems for fault detection and diagnosis, which allows traditional machine learning (ML) models to perform better without the need for a larger set of training data. Using the Tennessee Eastman Process (TEP) as a case study, the framework was shown to improve detection and diagnosis of all fault types in the TEP fault library under relevant metrics for evaluating condition monitoring systems.

**Keywords:** Tennessee Eastman Process, Machine Learning, Condition Monitoring, Fault Detection and Diagnosis, Condition-based Maintenance

## 1. Introduction

Continuous manufacturing processes often require a condition-based maintenance approach in order to fully realize its benefits. This requires the effective implementation of a condition monitoring (CM) system that can holistically oversee the condition of a process. (Schenkendorf, 2016) It is often challenging to obtain a mechanistic model of the condition of a process, so most of the work in literature focused on data-driven methods such as machine learning (ML). (Yin et al., 2012) The workflow for this development can be visualized in Figure 1, where data from the equipment and sensors of a continuous tableting line are used to train a ML model that can detect and diagnose faults. Given the right dataset, this workflow can be very effective in creating high performing fault detection and diagnosis algorithms. The problem is real scenarios rarely have the right dataset available. Hence, it is often the case that traditional ML models developed in this manner underperform, and the course of action is to acquire a better dataset, which might be prohibitively expensive, and/or to use a better ML model.

Another course of action that one could take is to build on the existing knowledge about the process to develop a mechanistic model. However, level of process knowledge that is required to do this could be even more expensive than acquiring a better dataset for training a machine learning model. Hence, any available process knowledge is often neglected because it is not enough for mechanistic modeling, and modeling efforts would be directly to a purely data-driven approach. An innovative solution would be to find a way to apply this knowledge in enhancing the performance of the ML model development workflow in Figure 1. Such a framework was developed and found to be effective for a continuous pharmaceutical tableting pilot plant. (Lagare et al., 2022a)

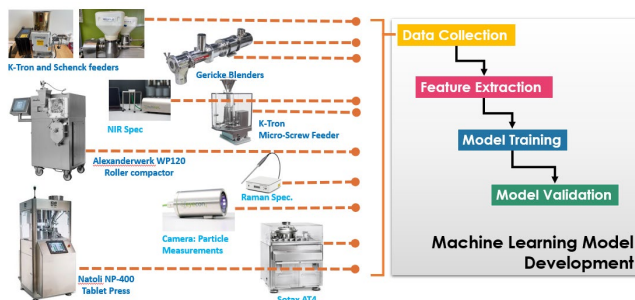

Figure 1. Machine Learning Model Development Workflow Applied to the Continuous Tableting Pilot Plant at Purdue University

It is now interesting to question the limitations of the framework, especially in its applicability towards larger processes with a larger fault library. For this purpose, the Tennessee Eastman Process (TEP) will be considered, (Downs and Vogel, 1993) which is a very different process than a continuous tableting line. First, the material streams are no longer solids, but either liquids or gases. The TEP also has more chemical components and chemical transformations are involved. There are more unit operations in the TEP and to add to its complexity, includes a recycle stream, which the pharmaceutical solids processing system does not have. Finally, the fault library of the TEP is much larger, with 22 conditions that need to be determined from 53 input variables taken from sensors and equipment across the process. (Chiang et al., 2000)

As expected, the condition monitoring system for the TEP, developed using workflow in Figure 1, showed poor performance using metrics relevant to condition monitoring. This study shows that the condition monitoring system development framework, which will be discussed in Section 2.1, was effective in improving the performance of the machine learning models in monitoring the condition of the process.

## 2. Methods

### 2.1. Condition Monitoring System Development Framework

The proposed framework adds several steps to the ML model development workflow in Figure 1, which is now depicted as a node (white) in Figure 2. The two additional steps, i.e., representation and modularization, is mainly responsible for improving the ensuing ML model development step and will be the main subject of this paper.

Figure 2. Proposed Condition Monitoring System Development Workflow

The final step of the proposed framework—integration—is critical in holistically interpreting the predictions of the modules. The result is a more robust condition monitoring system that can still function amid sensor maintenance repairs, reducing the need for product diversions and/or process shutdowns. (Lagare et al., 2022b)

#### 2.1.1. Process Representation

Process representation is the first step in the CM system development framework. This step is responsible for incorporating available process knowledge into the workflow, and its key components are shown in Figure 3.

Based on these components, the minimum process knowledge requirement to be able to perform process representation is a process flow diagram (PFD). The PFD shows the material transformations that taking place, the unit operations responsible for the material transformations, the locations of the measured and manipulated variables, and the locations of the faults in the fault library. Based on the PFD of the TEP (Chiang et al., 2000), the process condition may be represented as in Figure 4.

Figure 3. Process Representation Workflow

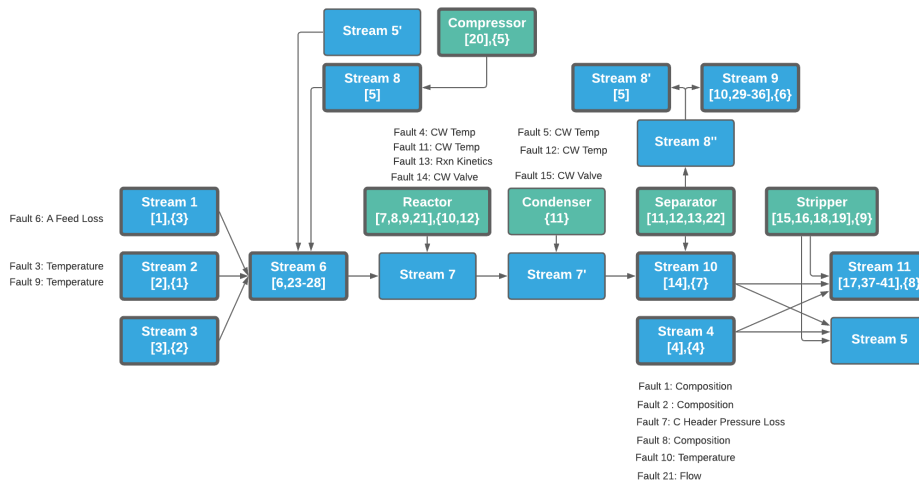

Figure 4. Process Condition Representation of the TEP depicting material and unit operation condition as blue and green nodes respectively. (The numbers in straight brackets are the designated numbers of the measured variables, and the numbers in curly brackets are the designated numbers of the manipulated variables)

### 2.1.2. Process Modularization

Once the process representation is available, it is now possible to modularize the process—i.e., break it down into smaller sections. Although there would be countless ways to do this, there are logical limitations to this combinatorics problem. First, a module must contain at least one fault. Without a fault, there is no condition monitoring job. It is thus interesting to see in Figure 4 that the faults are not dispersed throughout the process but are concentrated on certain nodes. With this first constraint, one can see that the condition representation of the TEP can be broken down into five modules, where the nodes that contain the fault can be considered the central node of the module.

Nodes directly adjacent to the central node may be included in the module, especially if the central node does not have input variables for ML model development. If these secondary nodes, do not have any measured variables, then other nodes that are directly adjacent to the secondary nodes may be added to the module. This process may be repeated until the added node has a measured variable or if there are no more nodes to add. This methodology is represented in Figure 5, and is consistent with the concept of d-separation in probabilistic graphical modeling, where observations in one probabilistic variable/node removes the probabilistic relationship between the parent and the child of

the observed node.(Bishop and Nasrabadi, 2006) Hence, if a measured variable is involved in an added node, adding a node that is conditionally dependent on that measured variable becomes unnecessary since it gives you no further information about the central node that involves the faults for the module.

Figure 5. Methodology for modularization of process condition representation

Figure 6. Reactor Condition Module

Figure 7. Stream 2 Condition Module

Another noteworthy implication of the workflow in Figure 5 is that only the central nodes are mutually exclusive among the modules, and the measured/manipulated variables in the secondary nodes may be shared. An example of a module based on the reactor condition as the central node is shown in Figure 6 and a module based on the feed stream condition is shown in Figure 7. Notice that both modules have “Stream 6” condition node as a secondary node. The dashed lines indicate the conditional independence of the central node to the rest of the condition nodes in the process condition representation.

### 2.1.3. Machine Learning Model Development Workflow

After the modularization step, ML classifiers are developed using the Model Builder feature by the ML.NET application. Model Builder can take the labelled input variables from each condition module to explore different traditional machine algorithms (i.e., not neural networks) and recommend the best one based appropriate classification metrics.(Microsoft, 2022)

### 2.2. Performance Metrics for Condition Monitoring

In this study, condition monitoring performance will be determined using five metrics: fault detection rate, false alarm rate, accuracy, normal condition certainty index (NCCI), and the overall prediction certainty index (OPCI). Fault detection rate, false alarm rate, and accuracy are standard metrics used for evaluating classifiers(Fawcett, 2006) and fault detection algorithms for the TEP.(Yin et al., 2012)

However, the two certainty indices are new metrics that is a unique contribution of this paper. These indices assume a threshold and work with classifiers (machine learning classification algorithms) that produces a probability for each possible condition in a module. For such classifiers, the condition with the highest assigned probability is considered the prediction condition and its assigned probability can be considered its prediction certainty. If the OPCI for a classifier is 0.95 for a threshold of 0.90, this means

95 out of 100 predictions made had a prediction probability/certainty higher than 0.90. The NCCI works similarly, but only considers the normal condition predictions. These certainty indices reflect the confidence of the predictions by the machine learning algorithm, which the operator can use to evaluate classifier performance. Interestingly, the NCCI has implications for novel fault detection capabilities. If the NCCI is close to 1.0, then future classification predictions that are lower than the threshold could be labelled as novel faults that would require further action by a human operator. Formulas for the OPCI and NCCI are shown below.

$$OPCI = \frac{\sum \text{Predictions} | \text{Prediction Probability} > \text{Threshold}}{\sum \text{Predictions}} \quad \text{Equation 1}$$

$$NCCI = \frac{\sum \text{Normal Condition Predictions} | \text{Prediction Probability} > \text{Threshold}}{\sum \text{Normal Condition Predictions}} \quad \text{Equation 2}$$

### 3. Results and Discussion

To evaluate the effectiveness of the framework, a base case is considered where a machine learning model is developed to use all 53 of the input variables in the TEP for predicting all 22 possible conditions (i.e., normal condition plus 21 fault types). With the framework applied, the ML development task is much simpler after modularization; for the case of the reactor module in Figure 6, the classifier only needs to classify 5 conditions (i.e., normal condition plus 4 fault types) from 16 input variables.

To determine the impact of the d-separation concept in the modularization workflow, a modified case of the framework was considered so that for each module, all the TEP variables would be used as input to determine the faults that are local to the central node of the module. For the reactor module in Figure 6, this would be using all 53 input variables to classify the 5 conditions considered in the module. This results in three cases that can be considered when evaluating the CM performance of each module. The details of these three cases when evaluating the reactor module is summarized in Table 1.

Table 1. Reactor Module Comparison Cases

	Base Case	Modular Case	Modified Modular Case
<b>No. of Faults</b>	21	4	4
<b>No. of Input Variables</b>	53	4	53

Table 2. Performance Summary for Reactor Module Faults

	Base Case	Modular Case	Modified Modular Case
<b>Fault Detection Rate (%)</b>	99-100	88-99	80-100
<b>False Alarm Rate (%)</b>	19-67	0-1	0-2
<b>Accuracy (%)</b>	33-99	89-100	94-99
<b>NCCI</b>	0.57-0.70	0.97-1.00	0.98-1.00
<b>OPCI</b>	0.33-0.89	0.95-1.00	0.92-1.00

For the faults local to the reactor module, the base case performance can be summarized in Table 2. While the fault detection rate is perfect, the other metrics, particularly the high rates of false alarms, make it unusable for condition monitoring. On the contrary, the modular cases show better performance across all metrics, with negligible false alarm rates and high certainty indices which indicate novel fault detection capabilities. For brevity, the performance summaries of the other modules would not be explicitly shown in this paper, albeit the aforementioned trends still hold for other modules. Overall, there seem to be no significant difference between the two modular cases, except for some

faults like fault 5 which saw a lower false alarm rate by 14% compared to the modified modular case.

#### 4. Conclusions

The condition monitoring system development framework that was originally developed for a continuous pharmaceutical tableting line proved to be effective for the Tennessee Eastman Process. The process representation workflow allowed the incorporation of process knowledge into machine learning model development. The ensuing modularization of the process representation simplified the machine learning model development task, which resulted in high performance classifiers that have novel fault detection potential.

For the impact of applying d-separation in the modularization workflow, it was not significant across all faults, although it yielded major improvements for some. Ultimately, this case study validates the applicability of the development framework across two different kinds of continuous manufacturing processes and suggests that it could be effective for other kinds of continuous processes.

#### 5. Acknowledgements

The authors acknowledge Dr. Ziyang Sheriff for sharing valuable insights and knowledge about the Tennessee Eastman Process, which proved valuable in shaping the direction of this research.

## Abstract

Machine learning models have emerged as a viable method to predict plant water requirements with the ability to form non-linear correlations between plant response variations and microclimate conditions. An artificial neural network is used in this work to predict irrigation water requirements in a greenhouse located in a hyper-arid region with high solar radiation and encompassing an HVAC cooling system and CO<sub>2</sub> enrichment. The prediction model is developed from direct gas exchange measurements of transpiration and takes as input parameters microclimate data including greenhouse solar radiation, temperature, humidity and CO<sub>2</sub> concentration along with hyperspectral imaging-based vegetation indices. Results demonstrate the high performance of the data-driven artificial neural network (ANN) model with microclimate and vegetation index (VI) features. The ANN model resulted in a comparatively higher performance than the FAO56 Penman Monteith empirical model and linear regression with an R<sup>2</sup> of 91.2%, RMSE and MAE of 0.0648 mm/h 0.0528 mm/h respectively. The proposed data-driven predictive model will enable the determination of irrigation water supply in greenhouses under CO<sub>2</sub> enrichment and with varying microclimatic conditions, and support the implementation of precision irrigation.

**Keywords:** Artificial neural network, Data driven model, Vegetation index, Precision irrigation, CO<sub>2</sub> enrichment.

## 1. Introduction

Agriculture in hot and arid regions faces many challenges, primarily due to unfavorable weather conditions, inarable lands, and water scarcity. The continuous development of the agricultural system and the expansion of food production plays an important role in achieving food security (Al-Ansari et al., 2018; Karanisa et al., 2021). Hence, agricultural greenhouse systems have emerged as a viable solution to help secure food by controlling the growing medium microclimate, reducing uncertainties related to the external environment and optimising resource utilisation (Ghiat et al., 2021). Optimum irrigation scheduling is particularly necessary in regions where freshwater resources are limited and require large amounts of energy for desalination and treatment. Agricultural greenhouses in hot and arid climates still face low water use efficiencies due to the inapplicable irrigation schedules applied to these systems, and the various and complex physiological and environmental interactions, which have not been rigorously studied. The current state

of irrigation scheduling in hot and arid regions is based on historical climatic data and expert observations which still poses limitations (Ali, 2010). Intelligent irrigation management such as precision irrigation has emerged as a promising method to improve the operations of agricultural greenhouses and achieve optimum water use efficiencies by ensuring the accurate amount of water inputs at the right time and space (Abioye et al., 2022). Current trends in agriculture are focused on the shift towards data driven models rather than heuristic physical models for system control and management, as they offer better predictions (Mahmood et al., 2021).

The most common methods of irrigation management are based on empirical or mechanistic evapotranspiration models that calculate crop water requirements, with the mostly used one as the Penman Monteith combination model which includes different climatic inputs in the prediction of evapotranspiration mainly solar radiation, relative humidity, temperature, and wind speed (Allen et al., 1998). Crop transpiration is a physiological measure that depends on different microclimatic factors in the greenhouse which interact nonlinearly and dynamically with each other (Stanghellini, 1987).

Machine learning methods have been adopted to estimate evapotranspiration of different vegetation crops and in different growing conditions. Models such as single layer artificial neural networks (ANN) and support vector machines (SVM) have been used because they can provide non-linear correlations between variables and eliminate the parametrisation complexities of internal factors in physical models (Fan et al., 2021). Many studies compared between different machine learning algorithms to predict plant responses. For example, Liu et al. (2009) compared artificial neural networks (ANN) and multiple linear regression (MLR) for the prediction of sap flow of pear trees based on meteorological data and soil water content. Findings from this study indicate that the ANN model had a better performance in predicting sap flow than MLR due to its superiority in predicting non-linear relationships.

This work entails the adoption of artificial neural networks (ANN) for the prediction of transpiration rates in greenhouses under CO<sub>2</sub> enrichment using three different datasets: microclimate data, gas exchange data, and hyperspectral imaging data. The ANN model is compared with the FAO 56 Penman Monteith model and linear regression using statistical performance indicators.

## **2. Greenhouse data**

The study was conducted in a semi-closed, Venlo shaped, and glass-based greenhouse located in the State of Qatar. The microclimate of the greenhouse encompasses CO<sub>2</sub> enrichment (600-800 ppm) and temperature and humidity are controlled by a heating, ventilation, and air conditioning (HVAC) system. The greenhouse is characterised by a hydroponic culture with cucumber as crops. To describe the fast-changing dynamics of plant responses, three different types of data were collected; 1) microclimate data, 2) transpiration rates; 3) hyperspectral-based vegetation indices. Microclimate data including greenhouse temperature, relative humidity and CO<sub>2</sub> concentration were collected using an aspirator box which consists of different sensors, and solar radiation using a pyranometer sensor outside the greenhouse. A gas exchange measurement system (CIRAS-3, PP systems) is used to collect transpiration measurements at the leaf level in

the greenhouse. The gas exchange system is based on infrared gas analysers (IRGA) that trace gases through their absorption in the infrared region. Hyperspectral images were collected using a HSC-2 SENOP camera that takes snapshots in the visible and near-infrared region (400-1000 nm).

### 3. Methodology

A data-based model for transpiration is developed based on microclimate parameters including solar radiation, temperature, relative humidity, and CO<sub>2</sub> concentration along with vegetation indices inside the greenhouse. Several vegetation indices (VIs) belonging to different vegetation categories including broadband greenness, narrowband greenness, light use efficiency, dry or senescent carbon, and canopy water content, were calculated for greenhouse HIS images.

The predictive model is constructed using an artificial neural network (ANN) model which accounts for nonlinearity between parameters. The ANN model is a multi-layer connected network. The input layer in the ANN model receives the input signals and passes them through the hidden layer neurons which in turn transfer them to the output layer to generate the predicted output (Figure 1). Weights are initially assigned between the input layer and the first hidden layer for each input and are passed through the activation function along with the added bias in each neuron. Weights are then updated after acquiring the first predicted output to match the actual value by minimising the loss function through an optimizer.

Figure 1: ANN model architecture.

The ANN model is implemented for the prediction of transpiration in the greenhouse. Two activation functions are adopted; the Rectified Linear Unit (Relu) for the input layer (Equation 1) and the hyperbolic tangent (tanh) for the hidden layers (Equation 2). Using different activation functions in the different layers can bring different non-linearities to the problem which can help better solve it. A loss function is used to measure how close the predicted transpiration value is to the actual value. The loss function used is the mean squared error. The ANN model updates the weights through the use of the Adam optimiser.

$$f(x) = \frac{2}{1+e^{-2x}} - 1 \quad [1]$$

$$f(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \quad [2]$$

The optimal number of hidden layers and nodes were experimentally investigated through trial and error. The testing and training sets were chosen as 30% and 70% of the total dataset respectively. Moreover, a hyperparameter optimisation was conducted to select the optimal combination of number of batch size (5, 10, 15, and 20) and Epochs number (5, 10, 50, and 100). Python 3.7 was used in the implementation of the ANN model.

The ANN model is compared against the FAO56 Penman Monteith (Equation 3) empirical model and a linear regression model (Allen et al., 1998).

$$ET_c = k_c \frac{(0.408(R_n - G) + \gamma \frac{900}{T_{mean} + 273} u VPD)}{A + \gamma(1 + 0.34u)} \quad [3]$$

The comparison between the models is assessed using four statistical indicators: the coefficient of determination ( $R^2$ ), the root mean square error (RMSE), and the mean absolute error (MAE) (Equations 4-6). The higher the values of  $R^2$  (closer to 1) and the lower the values of RMSE and MAE indicate good prediction results.

$$MSE = \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{n} \quad [4]$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{n}} \quad [5]$$

$$MAE = \frac{\sum_{i=1}^n |y_i - \hat{y}_i|}{n} \quad [6]$$

#### 4. Results and Discussion

In this work, an artificial neural network (ANN) model was implemented for the prediction of transpiration. The number of hidden layers and neurons were decided based on an experimental trial and error method. Two hidden layers with 3 neurons each were decided having only microclimate as input features. However, with the inclusion of vegetation indices as inputs, the dimensionality of the input layer increased, and the optimal number of hidden layers was found as 2 with 6 neurons. The next step entailed the optimisation of the hyperparameters batch size and Epoch number. The hyperparameter optimisation on the first dataset led to a batch size of 5 and an Epochs of 100 as the optimal parameters having the lowest RMSE value.

The ANN model reported good forecasting accuracy as compared to both the FAO56 Penman Monteith (PM) empirical model and the linear regression as shown in Figure 2. The linear regression model reported an  $R^2$  of 0.680, and an RMSE and MAE values of 0.114 mm/h and 0.0893 mm/h respectively (Table 1). The data-driven model, although it is a simple linear regression demonstrated a better performance than the empirical PM model. With the inclusion of vegetation indices, the performance of the linear regression model improved to an  $R^2$  of 0.723, an RMSE of 0.106 mm/h and MAE of 0.082 mm/h.

The ANN model with microclimate data reported values of R<sup>2</sup> of 0.747, RMSE of 0.109 mm/h and MAE of 0.0868 mm/h. In the case where vegetation indices were included as input features, the ANN model was able to fit 91.2% of the data with low tabulated errors of 0.0648 mm/h for RMSE and 0.0528 for MAE (Table 1). The inclusion of vegetation indices increased the ability of the ANN model to predict transpiration variability by 22% (Figure 3). Moreover, the comparative performance of the ANN model including VIs with the FAO56 Penman-Monteith model reveals a higher R<sup>2</sup> by 44%, and lower RMSE and MAE by 68% and 66% respectively.

Figure 2: Actual Vs predicted transpiration with ANN model

Figure 3: Actual Vs predicted transpiration with ANN model with VIs

Table 1: Model performance on testing set.

Model	RMSE (mm/h)	MAE (mm/h)	R <sup>2</sup>
Linear regression model	0.114	0.0893	0.680
Linear regression with VIs	0.106	0.0820	0.723
ANN model	0.109	0.0868	0.747
ANN model with VIs	0.0648	0.0528	0.912

## Conclusion

Food insecurity is one of the most pressing global challenges. Hot and arid regions are faced to additional environmental limitations for local food production. These regions suffer from climate dependent food production systems that entail large utilisation of natural resources. Irrigation water requirements is one of the most critical inputs in agricultural food systems and needs to be closely assessed, especially for water scarce countries. This work entails the prediction of irrigation water requirements in terms of plant transpiration for a greenhouse with CO<sub>2</sub> enrichment located in a hot and arid climate. A data-driven model is developed from microclimate, physiological, and hyperspectral data using artificial neural networks to predict transpiration in the greenhouse. Results demonstrate the low performance of the FAO56 Penman Monteith empirical model in predicting transpiration for agricultural greenhouses with CO<sub>2</sub> enrichment under high solar radiations. The data-driven artificial neural network (ANN) model with microclimate and vegetation index (VI) features presented a comparatively higher performance than the empirical ET model by increasing the model's ability to explain data variability by 44%, and reducing errors corresponding to RMSE and MAE by 68% and 66% respectively.

## Abstract

Closed environment agriculture is gaining popularity due to the exponentially increasing demand for food, a growing shortage of water, urbanization, reduction in arable land, and degrading soil quality. Greenhouses are closed environment agriculture that provides a viable solution to these problems by maintaining favorable growing conditions. However, maintaining optimum conditions inside a greenhouse is a resource-intensive process, especially in hot and arid climates. Microclimate management, especially the temperature, requires a model-based systematic approach for consistent performance. Therefore, model predictive control is an effective method of managing greenhouse temperature; however, it requires a detailed system model. Moreover, the model predictive control strategy considers the perfect knowledge of the system while not accounting for uncertainties and disturbances. This leads to sub-optimal temperatures inside the greenhouse in the presence of uncertainties. Therefore, this study proposes a robust model predictive control framework to regulate the greenhouse temperature in the presence of external disturbances/uncertainties. An artificial neural network represents the nonlinear and dynamic greenhouse system. The model inputs are solar irradiance, ambient temperature, fan speed, and HVAC control, while the greenhouse temperature is the output. Results illustrate that the robust model predictive control algorithm has superior temperature control compared to a basic model predictive control and the existing greenhouse climate management system with a root mean squared error of 0.25 °C.

**Keywords:** Robust model predictive control, Energy Assessment, Greenhouse control, Robust optimization, Artificial neural network.

## 1 Introduction

Rapidly increasing global population and climate change are adversely affecting the energy, water, and food security of different regions worldwide. Agriculture, which consumes 70% of the total water, is one of the most significantly affected sectors due to irregular weather patterns, high temperatures, droughts, etc. Furthermore, producing crops through open-field agriculture in arid regions is difficult due to the scarcity of freshwater and the harsh external environment. Therefore, efficient and protected crop production environments are required to increase crop yield and minimize resource consumption.

In this context, greenhouses provide a favorable option by protecting the crop from the external environment. Greenhouses regulate the internal climate leading to increased production and reduction of utilized resources by 10-20% and 25-35%, respectively [1].

Greenhouses also provide the benefit of year-round crop production as the microclimate is maintained in the favorable range irrespective of the external environment. The psychrometric conditions of the greenhouse's air significantly affect the cultivated crop's development and yield. Therefore, maintaining optimum conditions, especially the temperature inside the greenhouse, is critical for crop production.

Greenhouses in arid regions require cooling for almost 9-10 months of the year due to high solar irradiance and ambient temperature. In summer, evaporative cooling becomes ineffective; therefore, some greenhouses use active mechanical heat, ventilation, and air conditioning (HVAC) technologies. HVAC technologies perform better than conventional approaches such as evaporative cooling, fogging, etc. however they have a higher capital cost and are more complex to operate.

Different automatic control approaches have been adopted to operate HVAC technologies to improve their performance. One of the most effective control approaches is model predictive control (MPC) which predicts and determines the optimum control. MPC has been successfully implemented in many fields, such as agriculture, aviation, chemical plants, etc.

Mahmood et al. [2] adopted an MPC approach based on a multi-layer perceptron model for a semi-closed greenhouse. Results demonstrated that the MPC performed better than the existing greenhouse climate management system for winter and summer. Similarly, Jung et al. [3] developed an MPC strategy based on an output feedback artificial neural network (ANN) to manage the greenhouse temperature. Results illustrated that the MPC had a root mean squared error (RMSE) value of 2.45 °C while the conventional control strategy had a value of 3.01 °C. However, the performance of MPC drops in the presence of disturbances and uncertainties in the system, leading to the sub-optimal temperature inside the greenhouse. Robust MPC (RMPC) ensures consistent and effective performance in system disturbances. Chen et al. [4] developed a particle swarm optimization-based RMPC strategy for greenhouse temperature control. A nonlinear affine model represents the greenhouse temperature. Results illustrate that the proposed strategy has a superior temperature control performance in the presence of uncertainties. Similarly, González et al. [5] proposed an MPC strategy using a state space model to control the greenhouse temperature. The proposed control strategy reduced the operational cost of the greenhouse; however, it was only applicable to a linear system. Few studies have utilized a data-driven method for greenhouse temperature control; therefore, this study proposes an RMPC framework using an artificial neural network as the system model.

## 2 Methodology

The following methodology is adopted in the present study.

### 2.1 Case study: semi-closed greenhouse

The research was conducted in a semi-closed greenhouse with an active mechanical HVAC system to control the greenhouse microclimate. The greenhouse temperature and relative humidity are measured by a sensor box installed inside the greenhouse. The external climate, such as ambient temperature, solar irradiance, and external relative humidity, is measured by different sensors installed on the outside. The measured data is stored in data loggers and, based on the external and internal climate signals, is sent to the greenhouse actuators. The speed of the ventilation fan and the temperature of the chiller are used to control the microclimate of the greenhouse. The fan speed and chiller temperature are control variables, while the solar irradiance and ambient temperature are the disturbances. The values of the measured variables are given in Table 1.

Table 1: Model parameters measured at the greenhouse site.

Parameter	Value	Unit
Solar irradiance	0 – 1051	Wm <sup>-2</sup>
Ambient temperature	8.1 – 46.5	°C
Fan speed	25 – 100	%
Chiller temperature	17 – 22	°C
Greenhouse temperature	12.1 – 26.8	°C

The greenhouse operates in a closed cycle system where moisture is extracted from the air through a humidifier and then heated to a suitable temperature using an electric heater before returning it to the plantation area. The greenhouse schematic is shown in Figure 1.

Figure 1: Greenhouse operational schematic. The hot and humid air from the greenhouse is processed through a dehumidification system to remove the moisture. The treated air is then subjected to heating to reach a suitable temperature before being circulated back into the plantation area.

## 2.2 Greenhouse model

An ANN is utilized to predict the dynamic greenhouse temperature. The ANN has solar fan speed, irradiance, ambient temperature, and chiller temperature as the inputs, while the greenhouse temperature is the output. The greenhouse temperature depends on the previous and current values of the control variables ( $u$ ) and system disturbances ( $d$ ). The output is given as follows:

$$\hat{y}(t + 1) = f(u(t), u(t - 1) \dots u(t - n_t), d(t - 1), \dots d(t - n_d)) \quad (1)$$

The structure of the ANN is illustrated in Figure 2.

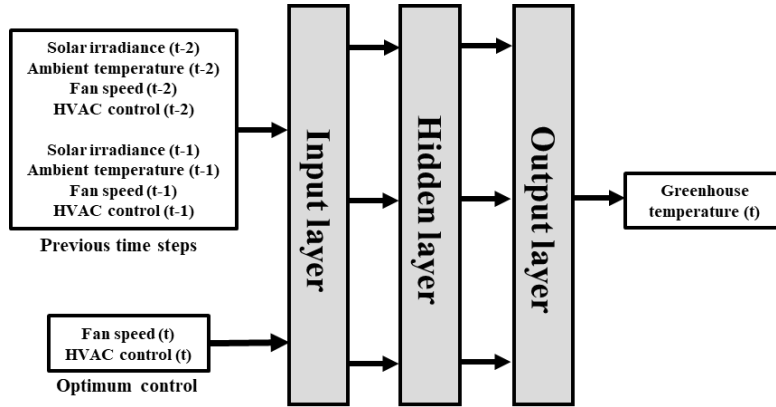

Figure 2: ANN structure

### 2.3 Robust model predictive control

MPC control strategy does not account for the possible uncertainties existing in the system, which may lead to sub-optimal temperatures inside the greenhouse. MPC strategy can be converted into an RMPC by considering the uncertainties in the system. In the present study, a minimax objective function is utilized, which minimizes the worst-case cost and is given by:

$$\underset{u}{\text{minimize}} \quad \underset{k=1,2,\dots,K}{\text{maximize}} \quad \left\{ \sum_{i=1}^P |r(t+i) - \hat{y}(t+1)|^2 \right\} \quad (2)$$

Where  $r$  is the reference trajectory,  $\hat{y}$  is the system output, and  $k=1, 2, \dots, K$  are the different realizations of the system in the presence of uncertainty to which robust optimization is applied to find the control setting.

$$u_{1min} \leq u_1(t+i) \leq u_{1max} \quad p = 0, \dots, N_u = 1, \quad (3)$$

$$u_{2min} \leq u_2(t+i) \leq u_{2max} \quad p = 0, \dots, N_u = 1, \quad (4)$$

The ventilation fan ( $u_1$ ) operates between 25-100% while the chiller temperature ( $u_2$ ) operates between 17-22 °C. The particle swarm optimization (PSO) algorithm determines the optimum control setting at each time step.

## 3 Results and discussions

The proposed control strategy was implemented in Python 3.7. The proposed RMPC strategy is compared with the greenhouse climate management system (GCMS) and a basic MPC strategy.

### 3.1 ANN prediction performance

The accuracy of the system model is critical in the performance of the control strategy. The model is evaluated for 17-18<sup>th</sup> June using 21312 data samples, having ten inputs and the greenhouse temperature as the output. The data set is split into 70% training and 30% testing data sets. The performance of ANN for two days is illustrated in Figure 3. The ANN slightly underestimates the greenhouse temperature during the peak hours while

showing very high accuracy at night. The ANN has an RMSE value of 0.39 °C and  $R^2$  value of 0.98.

Figure 3: ANN temperature prediction comparison

### 3.2 Robust model predictive control

The greenhouse is in a desert area, and due to higher temperatures, sandstorms are frequent. The solar irradiance reaching the greenhouse fluctuates during the sandstorm due to the dust particles present in the air. The varying solar irradiance affects the greenhouse temperature as the existing climate management does not account for the changing cooling load. The fluctuation leads to sub-optimal temperature during the day, and inefficient use of resources as the amount of cooling required varies. The GCMS also fails to maintain the desired temperature at night as it operates on predetermined control settings. Therefore, an RMPC strategy is proposed to improve the greenhouse's performance in the presence of uncertainty and disturbances. To analyse the performance of the proposed control strategy, additive noise is added to the SI to replicate the sandstorm fluctuations. Figure 4 illustrates the temperature control comparison between the existing greenhouse climate management system, MPC, and RMPC strategy for a two-period (30-31<sup>st</sup> March). RMPC leads to better temperature control performance as compared to GCMS and MPC. RMPC, MPC, and GCSM have RMSE values of 0.25, 0.285, and 2.32 °C.

Figure 4: Temperature control performance comparison

#### 4 Conclusion

This study proposes a data-driven robust model predictive control strategy for controlling the greenhouse temperature in the presence of uncertainties. An artificial neural network is used to predict the nonlinear greenhouse temperature. Results illustrate that the minimax-based robust model predictive control has superior performance compared to the greenhouse climate management system and basic model predictive control strategy in the presence of uncertainties due to the external environment. In future studies, the performance of the control strategies in terms of energy consumption will be analysed along with temperature control.

## Abstract

In recent years, the production of nanomaterials (NMs) has gained a considerable amount of attention and it has emerged as a flourishing field of research. The increasing interest in nanotechnology and the wide range of innovative industrial applications that NMs offer have highlighted the need to further study NM formation and develop advanced control schemes that can address multiple industrial objectives. This paper presents a new control framework for the production of functional, safe and sustainable silver NMs (Ag NMs) which combines dynamic first-principles modeling, the Model Predictive Control (MPC) architecture and the ability to integrate sensors that provide real-time toxicity data regarding the safety of the produced NMs.

**Keywords:** Nanomaterials, safety, control

## 1. Introduction

The NM case study presented in this paper focuses on the production of Ag NMs through a series of five plug flow (PFR) reactors. The inlet streams of the 1<sup>st</sup> reactor are solutions of the reducing and stabilizing agents, sodium citrate and tannic acid, and the precursor, silver nitrate. All subsequent PFRs are only fed with the precursor solution. The six flows of the above inlet streams are used as the manipulated variables of the process whereas the corresponding concentrations are regarded as measured disturbances that can occur during production. The main objective of this study is to produce Ag NMs of specific diameters that comply with the production and safety specifications. To that end, the mean diameter of the Ag NMs in the product stream of the last PFR is set to be the controlled variable.

## 2. Methods

### 2.1. First principles modeling

The development of a dynamic process model is essential for the design of the control strategy. A detailed dynamic model of the process was developed based on the discretisation of the PFRs corresponding to the nucleation and growth stages of the Ag NMs production system and the formulation of the respective mass balances. The kinetic

expressions were estimated using the available steady state experimental data. It was assumed that the formation of Ag NMs follows the Finke-Watzky two Step Mechanism (Thanh et al, 2014), which is a process of nucleation and growth where both steps occur simultaneously. The first is a slow continuous nucleation (Eq. 1), and the second is the fast autocatalytic surface growth (Eq. 2) which is not diffusion controlled (Sandoe et al, 2019). The first-principles model describing the system consists of the mass balances of the nuclei ( $A$ ) and the NMs ( $B$ ), while the ordinary differential equation describing the diameter growth depends on the NMs concentration and the autocatalytic surface growth rate.

The above system results in sigmoidal kinetic curves with the FW two-step kinetic model of slow nucleation and fast autocatalytic growth (Watzky and Finke, 2016), with respective, pseudo-elementary nucleation average rate constant,  $k_1$  and surface growth average rate constant,  $k_2$ . Experiments show that with increasing concentration of sodium citrate and/or tannic acid a decrease is observed in both the particle size and UV-vis peak position. Also, the higher concentration of metal atoms within the growing nanoparticle an increase in the particle size was seen (growth favored over nucleation). For the PFR of volume  $V$ , the mass balances for  $A$  and  $B$  and the diameter  $D$  changes are described by the Partial Differential Equations (PDEs) (3), (4) and (5), where  $v_0$  is the volumetric flow rate of the sum of the solutions flowing in the reactor:

$$\frac{\partial C_A(t)}{\partial t} = -v_0 \frac{\partial C_A(t)}{\partial V} + -k_1 C_A(t) - k_2 C_A(t) C_B(t) C_{TA}(t)^{n_{TA}} C_{SC}(t)^{n_{SC}} \quad (3)$$

$$\frac{\partial C_B(t)}{\partial t} = -v_0 \frac{\partial C_B(t)}{\partial V} + k_1 C_A(t) + k_2 C_A(t) C_B(t) C_{TA}(t)^{n_{TA}} C_{SC}(t)^{n_{SC}} \quad (4)$$

$$\frac{\partial D(t)}{\partial t} = -v_0 \frac{\partial D(t)}{\partial V} + k_3 C_A(t) C_B(t) C_{TA}(t)^{n_{TA}} C_{SC}(t)^{n_{SC}} \quad (5)$$

where  $C_A(t)$ ,  $C_B(t)$ ,  $C_{TA}(t)$ ,  $C_{SC}(t)$  are the concentrations of nuclei, Ag NM, tannic acid and sodium citrate respectively. The constants  $k_1$ ,  $k_2$  and  $k_3$  are given by the Arrhenius equation, where the parameters  $k_{o_1}$ ,  $k_{o_2}$  and  $k_{o_3}$  are the pre-exponential factors and  $E_1$ ,  $E_2$  and  $E_3$  are the activation energies. The values of the parameters are estimated using steady state experimental data from the process and the Thompson Sampling Efficient Multi-Objective (TSEMO) optimization procedure (Bradford et al, 2018). Two objectives, namely the error between the predicted NM diameter values and the experimental NM values  $f_1$  and the standard deviation of the wavelength of the peak UV-Vis absorbance  $f_2$ , are placed on the pareto front of the bi-objective optimization problem. From the pareto front, the point that is used for defining the parameter values is  $x_2 = \min_x(f_2)$ , where  $x_1 = \min_x(f_1)$ .

The system of Eqs. (3), (4) and (5) is solved using finite differences and the Method of Lines. Each PFR is discretized along the horizontal axis into  $N$  intervals; elementary Continuous Stirred Tank Reactors, where the solutions are considered homogeneous. Thus, the initial system of PDEs (3 – 5) where  $v_0$  is the volumetric flow rate of the solutions in the reactors is reformulated as a system of Ordinary Differential Equations (ODEs):

$$\frac{dC_{A,i}(t)}{dt} = -v_0 \frac{C_{A,i}(t) - C_{A,i-1}(t)}{\Delta V} - k_1 C_{A,i}(t) - k_2 C_{A,i}(t) C_{B,i}(t) C_{TA,i}(t)^{n_{TA}} C_{SC,i}(t)^{n_{SC}} \quad (6)$$

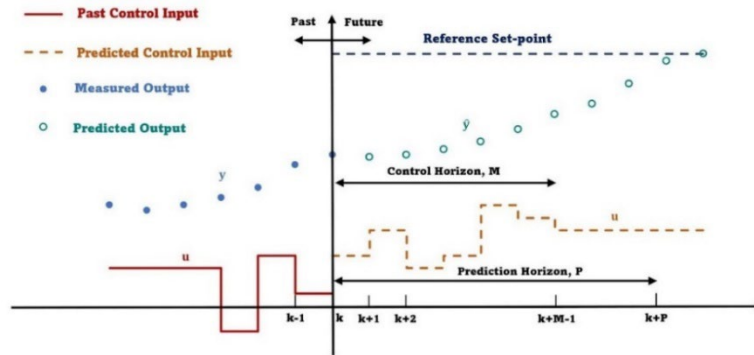

$$\frac{dC_{B,i}(t)}{dt} = -v_0 \frac{C_{B,i}(t) - C_{B,i-1}(t)}{\Delta V} + k_1 C_{A,i}(t) + k_2 C_{A,i}(t) C_{B,i}(t) C_{TA,i}(t)^{n_{TA}} C_{SC,i}(t)^{n_{SC}} \quad (7)$$

$$\frac{dD(t)}{dt} = -v_0 \frac{D_i(t) - D_{i-1}(t)}{\Delta V} + k_3 C_{A,i}(t) C_{B,i}(t) C_{TA,i}(t)^{n_{TA}} C_{SC,i}(t)^{n_{SC}} \quad (8)$$

where  $C_{A,i}$ ,  $C_{B,i}$ ,  $C_{TA,i}$ ,  $C_{SC,i}$  and  $D_i$  are the concentrations and the particle diameter at the  $i^{\text{th}}$  interval.

### 2.2. Model Predictive Control Framework

Model Predictive Control (MPC) is a control strategy that solves an online optimization algorithm at each sampling instant, to compute the optimal control action that drives the predicted output to the reference. MPC stands out among other control strategies because it can handle with ease multi-input multi-output systems and can incorporate explicitly multiple constraints on the state and input variables. The MPC configuration requires a dynamic model of the plant to make predictions about the system's future behavior over a finite time horizon (Camacho et al., 2007). The rolling-horizon concept of MPC is presented graphically in Fig. 1.

**Figure 1:** The rolling horizon concept of MPC

#### 2.2.1. Dynamic Matrix Control

This study employs Dynamic Matrix Control (DMC) as the control algorithm, which is a popular MPC variant. The values of the optimized future manipulated variables are derived by minimizing the quadratic objective function featuring the output prediction errors and the incremental changes of the manipulated inputs. The optimization problem is solved and reformulated at each time instant while the controller only implements the first control action, that has been computed.

In DMC, discrete time step-response models of the plant are integrated in the control algorithm to provide the predictions for the system's future behavior. The discrete-time step response of the system that describes the model output,  $y(t)$ , is given by Eq. (9) where  $g_i$  is the step response coefficient at each time instant  $i$  and  $\Delta u$  is the change of the

manipulated variable  $u$  between two consecutive discrete time instances (Tatjewski, 2007; Camacho et al., 2007; Mulholland, 2016):

$$y(t) = \sum_{i=1}^{\infty} g_i \Delta u(t-i) \quad (9)$$

In systems that reach a steady state within a finite horizon,  $l_{pin}$ , the prediction of the output at each time instant  $k$  can be described by Eq. (10):

$$\hat{y}(t+k|t) = \sum_{i=1}^k g_i \Delta u(t) + \sum_{i=1}^k g_i' \Delta d(t) + \sum_{i=1}^{l_{pin}} (g_{k+i} - g_i) \Delta u(t-i) + \sum_{i=1}^{l_{pin}} (g_{k+i}' - g_i') \Delta d(t-i) + y_m(t) - y_{ss} \quad (10)$$

where  $y_m(t)$  is the current state measurement,  $y_{ss}$  is the steady state,  $g_i'$  is the step response coefficient for the measured disturbance prediction model and  $\Delta d$  is the change of the measured disturbance  $d$  between two consecutive discrete time instances. The measured disturbances are incorporated into the prediction model as additional input variables that cannot be manipulated.

DMC optimizes the future manipulated variables by minimizing the quadratic optimizing function presented in Eq. (11):

$$\min_{\Delta u(k), \Delta u(k+1), \dots, \Delta u(k+N_c)} \left\{ \sum_{k=1}^{N_p} \|\hat{y}(t+k|t) - y_{sp}\|_Q^2 + \sum_{k=0}^{N_c} \|\Delta u(t+k|t)\|_R^2 \right\} \quad (11)$$

where  $\hat{y}(t)$  is the model prediction described by Eq. (10),  $y_{sp}$  is the set-point value,  $N_p$  and  $N_c$  are lengths of the prediction and control horizons and  $Q, R$  are positive definite matrices weighting the output deviations from the set-points and the incremental changes of the manipulated variables, which are defined as follows:

$$\Delta u(t+k|t) = u(t+k) - u(t+k-1) \quad (12)$$

The manipulated variables are constrained within upper and lower bounds with the following inequalities:

$$u_{min} \leq u(t+k) \leq u_{max} \quad (13)$$

The DMC algorithm was developed in MATLAB/Simulink using the external YALMIP library (Löfberg, 2004) for modelling the optimization problem. The GUROBI optimizer (Gurobi Optimization, LLC., 2022) was used to solve the problem. The step response coefficients,  $g_i$  and  $g_i'$ , were generated by introducing a step change of +10% on the initial steady state value of each input variable and by descriptising the dynamic responses of the controlled variables.

### 2.3. Configuration of control simulation platform

The first-principles model described in 2.1 plays the role of the process plant in the integrated MATLAB/Simulink platform. Fig. 2 presents the control loop including the NM production process plant and the DMC controller. The platform can be used both as an open loop simulation to observe the dynamic behavior of the system and as a closed loop simulator, after connecting the DMC controller.

### 3. Results

The tuning parameters of the DMC controller were selected by implementing random sets of disturbances and different setpoint changes on the plant and observing and evaluating the responses of the controlled outputs. Fig. 3 presents an indicative disturbance rejection case study that demonstrates the successful design of the controller, if the system starts from a steady state corresponding to the production of 50 nm Ag NMs. Fig.3 presents the disturbances on the solution concentrations (bottom right), the optimal sequences of manipulated variables (bottom left) and the dynamic response of the mean diameter (top).

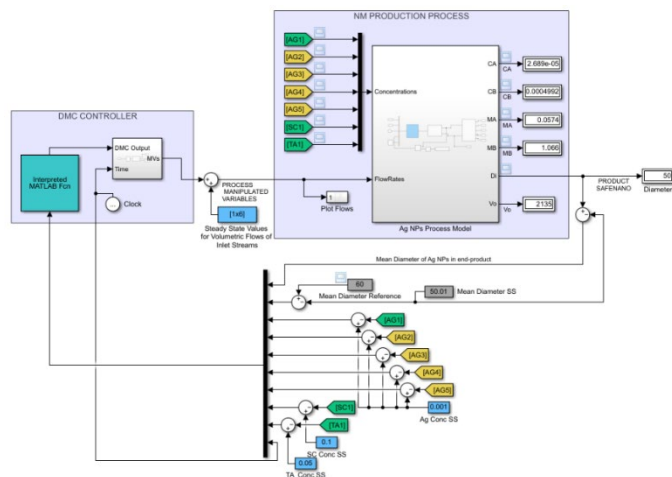

Figure 2: Integrated components of closed loop control platform

Figure 3: Dynamic response of the DMC control framework at random step changes

After five minutes of simulation time, the system is subject to a series of random step changes in all seven concentrations of the inlet streams (+10%, -4%, +5%, -9%, +8%, -10%, -10% accordingly). These disturbances tend to shift the controlled variable away from its initial state but, as Fig.3 clearly illustrates, the controller succeeds in driving it back to the desired set-point with zero offset by properly manipulating the flow rates of the inlet streams.

#### 4. Discussion

The results demonstrate the effectiveness of the DMC controller in driving the system towards desired set-points while effectively rejecting disturbances that affect closed-loop performance. The proposed approach not only offers the standard benefits of MPC formulations, such as considering constraints on the system variables, but also allows for the incorporation of additional controlled variables relevant to safety specifications for produced NMs. The method is now extended to include feedback from a UV-Vis sensor for real-time information on NM size distribution and a biomembrane sensor for efficient toxicity screening.

## Abstract

In an ever-increasing economic instability, cooperation among members of the same market can be proven an efficient way to build resilience. A growing interest has been observed among the process systems engineering community for integrating process design with game theory towards decentralised decision making. In this work, we aim to find the optimal supply chain design in oligopoly case studies by formulating a multi-period cooperative game among manufacturers and customers. Different fairness approaches are examined to maximise the firms' profits and customers' savings by determining the optimal customer allocation and sequencing of different contracts. Since the Nash fairness scheme results in a nonlinear objective, SOS2 approximation is employed resulting in an MILP class. The examined case studies are derived from a duopoly and an oligopoly in the liquid gas market. Computation results suggest that a cooperation can be beneficial for the payoffs of the firms and customers.

**Keywords:** Game theory, Fairness schemes, Supply chain optimisation, Customer allocation

## 1. Introduction

Fairness considerations within supply chain optimisation problems have increasingly attracted the researcher's attention from the PSE community. The interest in this direction stems from the fact that conventional centralised optimisation approaches fail to explicitly consider individual and potentially conflicting objectives of the different parties involved. Game theory is one approach that has been employed by researchers in the field of process design to evaluate both centralised and decentralised decision making. The case of decentralised decision making can be modelled as a cooperative game where all stakeholders' payoffs are considered in the objective function. Different fairness principles can be applied to allocate the payoff to the players of the game, the two main categories are egalitarian and utilitarian schemes. Egalitarian fairness schemes such as Rawlsian Welfare and Schmeidler's nucleolus, aim to equally split the payoff among the players of the game. In contrast, in utilitarian schemes i.e., Nash bargaining and Shapley value, the payoff of a player depends on the contribution of the player to the coalition's payoff.

An early sample of fairness consideration in PSE can be traced in the work of Gjerdrum et al. (2001), where a Nash bargaining approach was employed to solve the problem of fair profit allocation in a multi-echelon supply chain. A common implementation of game

theory can be found in supply chain applications where stakeholders have conflicting objectives (Barbosa-Povoa and Pinto (2020)). To this end, Liu and Papageorgiou (2018) employed a lexicographic min-max approach for the fair profit distribution within a multi-echelon supply chain with firms holding different bargaining powers in the market. Finding the optimum supply chain design of chemical industries under a carbon trading policy framework was examined by Salcedo-Diaz et al. (2021). Different coalition formations were evaluated among the manufacturing firms aiming to maximise their profit while at the same time comply with CO<sub>2</sub> emission caps. Salcedo-Diaz and co-workers suggested that a cooperative framework is beneficial both from an economic and environmental perspective in the examined application.

The impact of the choice of different fairness criteria for the profit allocation of a three-echelon closed loop supply chain was evaluated by Zheng et al. (2019) using the Shapley value, Schmeidler's nucleolus and equal satisfaction mechanism. Charitopoulos et al. (2020) considered a cooperative game to evaluate the fair profit allocation between manufacturing firms in oligopolies using Nash bargaining and a Naïve fairness scheme. The difference between an egalitarian and utilitarian approaches in the formation of an eco-industrial park for fair cost allocation was evaluated by Cruz-Avilés et al. (2021); the examined schemes where Nash bargaining, Social Welfare and Rawlsian Welfare.

## 2. Problem Statement

The present work aims to build on the work of Charitopoulos et al. (2020) by considering a multi-period framework in which customers can be serviced by the different firms and different contracts (Calfa and Grossmann (2015)). In addition, while in Charitopoulos et al. (2020), only the firms were considered as players of the game, here we introduce the customers as additional players aiming to maximise their savings. The proposed methodology can be implemented in different oligopolistic markets of chemical industries, for that reason the model formulation introduced in the following section will be of a generic form.

### 2.1. Model formulation outline

The key elements of the proposed model follow the outline of the model proposed by Charitopoulos et al. (2020) and entail: a) contract modeling, b) material & inventory balances, c) power consumption constraints, d) inter-firm swapping agreements, e) plant production short-cut model, f) service cost. The modeler needs to decide on the sets: i) of the planning horizon of  $P$  time periods, ii) of firms  $F$ , producing  $I$  products at known plant capacities, iii) of existing and new customers  $C$  with deterministic demand and delivery costs, iv) of distinct type of contracts  $K$ , along with the deterministic electricity costs and power consumption limits. The aim of the study is to find the optimal customer allocation and sequencing of contracts, production planning, inventory, swaps, outsourcing and energy consumption levels in order to fairly maximise the firms' profit and customers' savings.

### 2.2. Fair objective function

In the present study two fairness schemes are evaluated: the Naïve and Nash bargaining. Let the parameter  $\pi_f^{sq}$  be the profit of firm  $f$  at the status quo market, i.e., by fixing the customer allocation to a firm and assume no new customer acquisition, and  $\pi_f$  the profit variable of firm  $f$  in a cooperative framework. Both  $\pi_f^{sq}$  and  $\pi_f$  are calculated for the entire duration of the examined time horizon. For the customers' savings consideration, let the parameter  $CC_c^{max}$  be the maximum cost from purchases of a customer  $c$ , and the variable  $CC_c$  be the purchase cost of a customer, both are calculated for the duration of the examined time horizon.

### 2.2.1. Naïve scheme

The objective function for the fair customer allocation with the Naïve fairness scheme is formulated in Eq. (1). It can be observed that in this formulation no consideration of the status quo of the market are considered nor of the maximum cost to be inflicted on the customers.

$$\Omega = \sum_f \pi_f - \sum_c CC_c \quad (1)$$

### 2.2.2. Nash bargaining scheme

The Nash bargaining scheme can be perceived as maximising the geometric mean of the selected payoffs and thus results in a nonlinear objective function (Eq. (4)).

$$\Phi = \prod_f (\pi_f - \pi_f^{sq}) * \prod_c (CC_c^{max} - CC_c) \quad (2)$$

A common reformulation to the Nash fairness objective is separable programming and logarithmic transformation (Liu and Papageorgiou (2018); Charitopoulos et al. (2020); Cruz-Avilés et al. (2021)). Accordingly, it can be observed that Eq. (2) is separable in  $f$  and  $c$ , thus a logarithmic approximation can be applied to the nonlinear terms respectively.

$$\Psi_1 = \ln \Phi_1 = \sum_f \ln(\pi_f - \pi_f^{sq}) \quad (3)$$

$$\Psi_2 = \ln \Phi_2 = \sum_c \ln(CC_c^{max} - CC_c) \quad (4)$$

The reformulated objective function can be derived as the summation of Eq. (3), (4) as follows:

$$\Psi = \Psi_1 + \Psi_2 = \sum_f \ln(\pi_f - \pi_f^{sq}) + \sum_c \ln(CC_c^{max} - CC_c) \quad (5)$$

The given optimisation problem with Eq. (5) as an objective function is of MINLP class, where the nonlinear terms stem from the objective only. In order to transform the problem in a tractable MILP class, a piecewise linear approximation is performed respectively in Eq. (3), (4) using SOS2 variables (Liu and Papageorgiou (2018); Charitopoulos et al. (2020)). It is noteworthy that SOS2 approximations were initially proposed to retrieve global optimum solutions of problems with a single nonlinear function in an otherwise linear programming problem (Beale and Forrest (1976)), which makes it suitable for the examined model. Let  $\tilde{\Psi}_1$  be the linear approximation of  $\Psi_1$ , over a number of grid points  $n$ , parameter  $\tilde{\pi}_{fn}$  the profit of firm  $f$  at grid point  $n$  and  $\lambda_{fn}$  the auxiliary SOS2 variable. Hence, the approximation of Eq. (3) is derived in Eq. (6) with the complementary constraints for the SOS2 variable in Eq. (7), (8).

$$\tilde{\Psi}_1 = \sum_f \sum_n \ln(\tilde{\pi}_{fn} - \pi_f^{sq}) \lambda_{fn} \quad (6)$$

$$\sum_f \lambda_{fn} = 1 \quad \forall f \quad (7)$$

$$\pi_f = \sum_n \tilde{\pi}_{fn} \lambda_{fn} \quad \forall f \quad (8)$$

Analogously the approximation of the customer cost can be reformulated in Eq. (4) with based auxiliary SOS2 variable  $\mu_{cn}$  and the corresponding complementary constraints over the same number of grid points  $n$ . The final linearised objective for the fair customer allocation is formulated in Eq. (9).

$$\tilde{\Psi} = \tilde{\Psi}_1 + \tilde{\Psi}_2 = \sum_f \sum_n \ln(\tilde{\pi}_{fn} - \pi_f^{sq}) \lambda_{fn} + \sum_c \sum_n \ln(CC_c^{max} - \tilde{CC}_{cn}) \mu_{cn} \quad (9)$$

## 3. Case studies

For the purpose of this paper two case studies from an industrial liquid market will be examined. The first case study is a duopoly with 2 firms and 97 customers. At the status quo, Firm A serves 44 customers and Firm B 37, while there are 16 free customers that allow a market share growth. In the second case study, an oligopoly with 3 firms and 81

customers, of whom 13 are new. At the status quo, Firm A holds 21 customers, Firm B 17 and Firm C 30. The selected time horizon is one year discretised into 12 monthly time intervals. Three different contract formulations are evaluated i.e., Open, Formula and Firm, with different duration and pricing as proposed by Marousi et al. (2023). The computational experiments were carried in an Intel®Core™i9-10900K CPU @ 3.70GHZ machine using GAMS-IDE with CPLEX v.38.2 with 12 threads. The optimality gap was set to 1%. The number of grid points for both case studies was selected as  $n=1000$ . The original MINLP problem was addressed with the use of global solver BARON, however no convergence was achieved in reasonable computational time. The aspects that are of interest in this study is the impact of the different fairness schemes on the profit allocation between the firms and the savings of the customers and at the same time how does contract selection facilitate fairness allocation.

### 3.1. Duopoly

Initially it can be observed from Table 1, for the Naïve objective formulation (Eq. (1)), that Firm B has a significant profit increase while Firm A has an only a marginal improvement. This results in the reversal of the market share structure compared to the status quo. In contrast, using the Nash bargaining scheme (Eq. (9)), results in a notable profit increase for both firms, 17% for Firm A and 36% for Firm B. Since Nash scheme follows a utilitarian approach the profit allocation is distributed based on the player's contribution to the total payoff; thus, the resulting market structure closer approximates that of status quo.

Table 1 Profit increase compared to status and market share for different fairness schemes in duopoly market

	<b>%Profit change A</b>	<b>%Profit change B</b>	<b>Market share A</b>	<b>Market share B</b>
<b>SQ</b>	-	-	0.63	0.37
<b>Naïve</b>	+1.8	+80.9	0.49	0.51
<b>Nash</b>	+16.9	+36.4	0.59	0.41

To have a broader picture of the impact of the fairness schemes in the proposed model, it is necessary to evaluate the customer savings. Figure 1 displays the customer savings of the customers with the highest purchasing costs in the status quo, for different schemes. Results in Figure 1 suggest that Nash bargaining scheme leads to increased cost savings ranging from 5 to 8 % for the 5 top customers, in terms of purchasing cost, while the Naïve scheme results in lower customer savings compared to the Nash scheme.

Figure 1 Customer savings compared to status quo for customers with higher cost in duopoly for different fairness schemes

From the Gantt charts of customers #71 and #61 in Figure 2, the savings of the customers can be related to the contract choice. For both customers, status quo allocation results in the use of Formula contract, which inflicts high purchasing cost, in contrast in the Nash fairness scheme the Firm contract prevails in both customers. In the Naïve scheme a combination of all three contracts is used for customer #71 while only Formula and Firm for #61. Consequently, the lower customer savings in the Naïve scheme, compared to the Nash, can be attributed to the fact that Formula contract is selected.

Figure 2 Duopoly Gantt chart for customer allocation in firms and contracts under different fairness schemes

### 3.2. Oligopoly

In the oligopoly case study, an interesting aspect is that there is an imbalance in the market share of the status quo, as suggested by Table 3. Firm C holds more than half of the market share in terms of total profit, while Firm A has a slight advantage over Firm B. The Naïve scheme results in a more balanced market allocation, which is achieved by increasing by 100% the profit of Firm B while maintaining the profit of Firm C at the status quo levels. Although the Nash scheme allows for only a marginal increase for the oligopoly firms, the market share remains stable compared to the status quo.

Table 2 Profit increase compared to status and market share for different fairness schemes in oligopoly market

	%Profit change A	%Profit change B	%Profit change C	Market share A	Market share B	Market share C
<b>SQ</b>	-	-	-	0.25	0.20	0.55
<b>Naïve</b>	+25.0	+104.9	+0.2	0.24	0.32	0.44
<b>Nash</b>	+4.8	+2.8	+6.3	0.25	0.21	0.54

Concerning the customer savings displayed in Figure 3, Nash scheme outperforms the Naïve scheme for up to 10 times for examined customers. On average the Nash scheme results in savings of 22%, while Naïve only to 4%, suggesting that when there is a greater disproportion in the market share of the firms the Nash scheme can result in higher payoffs for the customers.

Figure 3 Customer savings compared to status quo for customers with higher cost in oligopoly for different fairness schemes

#### 4. Conclusions

Game theory has been widely used to facilitate supply chain optimisation problems under cooperation. However, the allocation of the coalition's payoff is not always straightforward and different fairness schemes can be evaluated. This paper examines the effect of different fairness schemes on the maximisation of the payoff of manufacturers and customers in cooperative oligopolies, by deciding the optimum contract and customer allocation. For the examined case studies of liquid gas market, Nash fairness resulted in higher customer savings while maintaining the market structure of the status quo.

# Artificial Neural Network-Based Real-Time PID Controller Tuning

Tate Bestwick,<sup>a</sup> Kyle V. Camarda,<sup>a</sup>

<sup>a</sup>*University of Kansas, Department of Chemical and Petroleum Engineering, 1530 West 15<sup>th</sup> Street, Lawrence, Kansas 66045, United States*

## Abstract

Proportional-integral-derivative (PID) control is well established and is still highly prevalent in chemical industries. Many methods for tuning PID controllers to keep a process running at steady-state are also well established; however, they must be retuned if the setpoint must be altered or the system dynamics change at any point in time. The purpose of this work is to use an artificial neural network (ANN) to tune a PID controller on a third order chemical system. It was found that the ANN generated parameters that resulted in smaller overshoot and less settling time than either the Ziegler-Nichols tuning method or the Tyreus-Luyben tuning method in one hundred percent of randomly generated systems.

**Keywords:** Machine Learning, Process Control, Renewable Energy, Neural Network

## 1. Introduction

The focus of this paper is the use of artificial neural networks (ANNs) to predict proportional-integral-derivative (PID) controller tuning parameters for a second-order chemical process which has a third-order closed-loop control scheme. The performance of the PID parameters determined by the ANN are compared with the performance of those obtained from the Ziegler-Nichols tuning method as well as those obtained from the Tyreus-Luyben tuning method.

PID control has been utilized and developed for at least 100 years [1]. In the last century, numerous tuning methods for PID controllers have been developed. The most famous of these methods is likely the Ziegler-Nichols method [2]. However, since 1942, numerous other methods have been introduced, including the integral of the time-weighted absolute error (ITAE) method, Fruehauf's and Chien's internal model control (IMC) method, and the Tyreus-Luyben method [3-5]. All of these methods use system dynamics to obtain heuristical controller parameters which can either be used directly or used as a baseline for finding finer-tuned parameters.

All of the aforementioned tuning methods are primarily for determining values for maintaining steady-state for a single setpoint; in order to transition to a different setpoint, the process must be repeated to obtain new values. Other control methods have been examined in more recent years which allow for more complex and wholistic process control or for automation of PID control tuning. Model predictive control (MPC), fuzzy logic PID control, and active disturbance rejection control (ADRC) are all topics of recent research. [6-8]. However, conservative industries still prefer traditional PID control, particularly if the process is of a more hazardous nature [9]. This has led to the development of using artificial intelligence (AI) to tune PID control parameters. AI-tuned

controllers have been demonstrated to be an effective means of process control for a chemical system [10].

Artificial Neural Networks are a branch of machine learning with considerable predictive power. The input nodes to the network send a signal to the first hidden layer of nodes. This signal is propagated through the first layer to a second layer, and so on until reaching the output layer. Each connection between two nodes is weighted by some function. Finally, each node has a threshold of input signals required to elicit an output greater than zero; this threshold is known as the bias. The number of hidden layers, the number of nodes in each hidden layer, and the weights and biases of each connection are tuned to best apply to the problem of interest. [11-13]

## 2. Physical System and Mathematical Model

### 2.1. Physical System Description

The system examined is two stirred tanks in series. The first tank has two inlets; an initial stream at some concentration and flowrate, and a correction stream which is

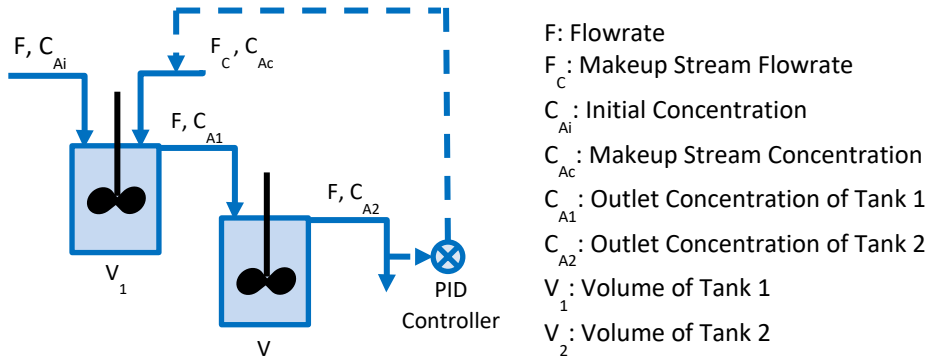

Figure 1: Two stirred-tanks in series. Solid lines represent component streams, dashed lines represent measurements or signals.

highly concentrated and at a much lower flowrate than the previously mentioned initial stream. The two are mixed together in the first tank. The outlet of this first tank is fed into the second stirred tank. The outlet of the second tank is measured, and this signal is sent to a PID controller which is used to adjust the flowrate of the correction stream. The system is depicted in Figure 1.

The following assumptions apply:

- 1) Both tanks are well-mixed at all times.
- 2) The flowrate of the correction stream is orders of magnitude smaller than the flowrate of the initial stream. Thus, the following equation applies:
 
$$F + F_c \approx F \quad 1$$
- 3) The valve on the correction stream has first order dynamics. This causes the overall control scheme to have third order dynamics.

### 2.2. Mathematical Model

The mass balance over each tank is written in equations 2 and 3 with the second assumption applied.

$$\frac{V_1}{F} \frac{d}{dt} C_{A1} + C_{A1} = \tau_1 \frac{d}{dt} C_{A1} + C_{A1} = C_{Ai} + \frac{C_{Ac}}{F} F_c \quad 2$$

$$\frac{V_2}{F} \frac{d}{dt} C_{A2} + C_{A2} = \tau_2 \frac{d}{dt} C_{A2} + C_{A2} = C_{A1} \quad 3$$

Combining these two equations yields a second order equation in which the outlet of tank 2 (measured variable) is obtained from the inlet (disturbance variable) and correction stream (manipulated variable) specifications. Solving for the concentration of the outlet of tank 2 in terms of deviation variables yields equation 4, which is written in the Laplace domain. Deviation variables are denoted as prime variables. Equation 4b relates provides a simplified notation for the inlet variable dynamics and the disturbance variable dynamics.

$$C'_{A2}(s) = \frac{1}{(\tau_1 s + 1)(\tau_2 s + 1)} C'_{Ai}(s) + \frac{C_{Ac}/F}{(\tau_1 s + 1)(\tau_2 s + 1)} F'_c(s) \quad 4a$$

$$C'_{A2}(s) = G_d(s)C'_{Ai}(s) + G_m(s)F'_c(s) \quad 4b$$

The valve on the correction stream was assumed to have dynamics which are modeled in the Laplace domain in equation 5.

$$\frac{0.01}{0.1s + 1} = G_v(s) \quad 5$$

The sensor which measures the concentration of the outlet of the second tank and converting the setpoint from engineering units to electrical signal was assumed to have negligible dynamics (equation 6). Finally, equation 7 models the PID controller.

$$\frac{1}{1} = G_s(s) = G_{sp}(s) \quad 6$$

$$\frac{K_D s^2 + K_p s + K_I}{s} = G_c(s) \quad 7$$

Equations 4-7 allow us to obtain transfer functions which describe the outlet variable response to a change in the setpoint (equation 8), the outlet variable response to the change in the disturbance variable (equation 9), the manipulated variable response to a change in the setpoint (equation 10), and the manipulated variable response to a change in the disturbance variable (equation 11).

$$\frac{G_m(s)G_v(s)G_c(s)G_{sp}(s)}{1 + G_m(s)G_v(s)G_c(s)G_s(s)} = H_{os} \quad 8$$

$$\frac{G_d}{1 + G_m(s)G_v(s)G_c(s)G_s(s)} = H_{od} \quad 9$$

$$\frac{G_v(s)G_c(s)G_{sp}(s)}{1 + G_v(s)G_c(s)G_s(s)G_m(s)} = H_{ms} \quad 10$$

$$\frac{-G_v(s)G_c(s)G_s(s)G_d(s)}{1 + G_v(s)G_c(s)G_s(s)G_m(s)} = H_{md} \quad 11$$

### 3. Methodology

The system described above was modeled in Python using the Python Controls Module [14]. Once modeled, 100,000 variations of the system above were generated. The space-time for tank 1 and the space-time for tank 2 were varied from 1.5 to 11.5 minutes at 0.2-minute increments, and the ratio of the concentration of the correction stream over the inlet flowrate ( $C_{Ac}/F$ ) varied from 20 to 1400 kg/min at an 35 kg/min increments. The Tyreus-Luyben method was used to generate baseline PID tuning parameters which could aptly respond to a setpoint step change for each system. These parameters were then further adjusted to ensure the overshoot for a setpoint step change did not exceed ten percent and the settling time for the system did not exceed the sum of the space-time for tank 1 and the space-time for tank 2. The dataset containing the further adjusted tuning

parameters was randomly split such that eighty percent of it served as the training dataset and twenty percent of it served as the testing data for the ANN which was used to predict the PID controller parameters.

The ANN was generated and trained using Keras's Python interface [15]. The neural network was structured to have three inputs, which can be easily calculated from variables which are directly measurable;  $\tau_1$ ,  $\tau_2$ , and  $\frac{C_{Ac}}{F}$ . The ANN predicts three outputs;  $K_p$ ,  $\tau_I$ , and  $\tau_D$ .

$$\frac{K_p}{\tau_I} = K_i \quad 12$$

$$K_p \tau_D = K_D \quad 13$$

The architecture and the hyperparameters related to training the ANN were varied to find a network which was both accurate and reproducible despite the randomness associated with the training method.

Once the ANN was trained, one hundred variations of the system described in section 2 were randomly generated with the constraint that  $\tau_1$ ,  $\tau_2$ , and  $\frac{C_{Ac}}{F}$  were always within the range set for the generation of the training dataset. The trained ANN was used to predict  $K_p$ ,  $\tau_I$ , and  $\tau_D$  for each system. The response to a step change in the setpoint was measured for each system using the PID controller parameters obtained by the ANN. The response from the system using PID controller parameters generated by the ANN were compared to the responses from the system using PID controller parameters obtained by the Ziegler-Nichols tuning method, and also compared with those obtained by the Tyreus-Luyben tuning method.

#### 4. Results

The ANN generated was able to be trained within a few minutes to predict the tuning parameters of the testing set with an overall  $R^2$  score of 0.919. See Table 1 (below) for ANN performance predicting each controller parameter. The PID parameters predicted by the ANN always resulted in smaller percent overshoot and a shorter settling time than parameters obtained by the Ziegler-Nichols method or those obtained by the Tyreus-Luyben method. The percent overshoot from the system using the Ziegler-Nichols

Figure 2: Measured variable response to a setpoint step-change using PID parameters predicted by the ANN, the Ziegler-Nichols method, and the Tyreus-Luyben method.

parameters was always at least 5 times larger than the percent overshoot of the system using the ANN predicted parameters; the percent overshoot from the system using the Tyreus-Luyben parameters was always at least 2.8 times larger than the percent overshoot of the system using the ANN predicted parameters; the settling time of the systems using the Ziegler-Nichols method was always at least 3.8 times larger than the settling time of the system using parameters predicted by the ANN; the settling time of the systems using the Tyreus-Luyben method was always at least 1.6 times larger than the settling time of the system using parameters predicted by the ANN. Figure 2 depicts a comparison of the response of the system using each of the three methods to obtain PID parameters. The trends which are seen in Figure 2 were consistent in all one hundred trials.

Parameter	$K_p$	$\tau_i$	$\tau_D$	Overall
R <sup>2</sup> Score	1.00	0.876	0.881	0.919

Table 1: R<sup>2</sup> score for all ANN performance on all parameters in testing set, as well as overall R<sup>2</sup> score.

## 5. Discussion

The ANN was trained using a dataset of PID controller parameters which outperformed parameters obtained from the Ziegler-Nichols method as well as those obtained from the Tyreus-Luyben method. The results verify that the ANN preserves this quality for PID controller parameters which it predicts for any system which is of the same structure as the one used to generate the training data so long as it has system parameters (space-time, inlet flowrates, and inlet concentrations) which fall within the boundaries specified by the training set. It is quite feasible that this implication extends to any system which is modelled and used to generate training data; the procedure implemented for the system detailed in this paper could be repeated for other systems, including for more complex systems. Furthermore, the procedure for generating training and testing data could be altered to meet standards for specific processes; for example, if a system requires never exceeding 1% overshoot but can tolerate a longer rise time, the ANN could be trained using parameters which meet this criteria.

It is important to note that the ANN takes inputs which capture all of the system variables which could vary across time as they appear in the transfer functions. For example, all three ANN inputs change if the disturbance variable flowrate changes. If the disturbance variable fluctuates over time, the ANN is able to predict PID controller parameters which account for the change in system dynamics. Additionally, the ANN architecture was simplified by using ratios of system variables rather than all of the system variables directly. This was possible because the system variables always appear in the transfer functions in those ratios. Specifically, the volume of tank 1 never appears in the transfer function except for when it appears in the space-time  $\tau_1$ .

Plants which run on renewable energy [16] are excellent candidates for the application of using an ANN to obtain real-time PID controller parameters. Solar and wind energy are intermittent energy sources; the amount of energy is dependent on how much sunlight or wind there is any given day. Thus, plants which run, or which will run, entirely on these energy sources do not have a consistent energy supply. While batteries may be used to store energy, the production and decommissioning of batteries is currently damaging to the environment. Having ANNs which could update tuning parameters for process setpoints would allow for adjusting process output real-time in response to energy availability. The number of batteries necessary would be considerably lowered because the process would be far more responsive to the variability of the energy sources.

The most significant implication of this work is with regard to dynamic operation or simulation. There are many scenarios in which it is preferable to account for a dynamic setpoint or time-varying inputs. Whether the inputs are inconsistent or product demand varies with time, the ability to obtain real-time PID controller parameters which meet the process performance standards could allow for a more efficient process than a static setpoint would allow. Since many processes currently use PID controllers, this implementation would not require drastic changes to the process control scheme. The computation time of ANNs is small enough that PID controller parameters could be updated every few seconds.

## 6. Conclusion

In this work, one hundred thousand variations of a third order chemical system were modelled and the parameters of the PID controller in each one were tuned to obtain previously determined acceptable output responses. These values were then used to train an ANN to predict PID controller parameters for any variation of the modelled system, and was then tested on one hundred randomly generated variations of the system. The ANN was found to predict PID controller parameters which resulted in better system performance than either the Ziegler-Nichols method or the Tyreus-Luyben method in all one hundred cases. This implies that ANNs could be used to tune PID controllers in more complex systems. Furthermore, it implies that ANNs could be used to provide real-time tuning for PID controllers in processes which could have time-varying system dynamics or setpoints.

# State of the Art Flexibility Analysis for Natural Gas Monetization Production Processes Under Uncertainties

Noor Yusuf, Ahmed AlNouss and Tareq Al-Ansari

*College of Science and Engineering, Hamad Bin Khalifa University, Qatar Foundation, Education City P.O. Box 5825, Doha, Qatar*

## Abstract

The increased demand for cleaner energy resources places a significant emphasis on monetizing natural gas into value-added products such as liquefied natural gas (LNG), ammonia and power to target different market needs. Despite the estimated growth in the demand for the different cleaner energy resources, each monetization process is subject to market uncertainties induced by global events such as pandemics, energy crises and supply chain disruptions. In this context, this study considers a promising strategic approach to investigate the economic profitability of embedding production flexibility in three natural gas monetized products (i.e., LNG, ammonia and power) subject to forecasted demand and price, and technical flexibility of each process (upper and lower production limits). The results provide decision-makers with a systematic approach to assess the economic and technical aspects of a flexible integrated LNG, ammonia, and power plant design in today's turbulent markets.

**Keywords:** Flexibility, natural gas monetization, uncertainty, LNG, ammonia.

## 1. Introduction

Natural gas (NG) is a crucial input to different processes and sectors such as household, transportation, petrochemical, agricultural fertilizers, and plastics industries. Within local markets, NG is mainly used to generate electricity using the gas-to-power (GTP) process. Furthermore, different chemical and physical monetization routes have been deployed to monetize NG into economically viable products. The monetization routes are classified based on the required final product: service-based monetization route (i.e., GTP), physical monetization route (i.e., liquefied natural gas - LNG and compressed natural gas - CNG), and the chemical monetization route (i.e., chemical conversion of natural gas into liquid products such as ammonia and methanol). The selection of a monetization route depends on factors such as international market requirements, the geographical location of gas reserves, climate in the region, gas field characteristics and gas quality.

Although renewables are expected to continue being the fastest-growing class of energy resources in the global market share, NG is expected to be the fastest-growing fossil-based energy resource due to its resilient characteristics (BP, 2014). On the other hand, energy production management has been essential to guarantee global energy sustainability, environmental sustainability, effective resources management, and economic profitability of projects. In terms of economic sustainability, producing companies must strategically decide on the final product portfolio, targeted markets, pricing, and shipping routes to optimize the project's profitability and hedge against risks. Following the various events that disrupted the global energy trade and supply chains,

such as the financial crisis of 2008, the oil markets crush of 2015, the COVID-19 pandemic in 2020, and the most recent Russian-Ukrainian crisis, the concept of production flexibility has become increasingly vital to increase the responsiveness of projects to exogenous uncertainties (Heffron *et al.*, 2021; Sarkar *et al.*, 2021; Sarkar & Seo, 2021). In a flexible production system, the decision-maker has the right, but not the obligation, to change the production capacity based on market performance to sustain profitability. In the literature, most studies focused on optimizing the production and planning of a single-product NG project subject to production flexibility based on varying demand (Bhosekar & Ierapetritou, 2020; Verleysen *et al.*, 2021; Yusuf *et al.*, 2022). There is a lack of studies that investigate the optimal production and management of integrated NG production systems. In this study, global historical and forecasted demand and price data for three NG monetization routes: LNG, power, and ammonia, are used as input to investigate the yearly optimal NG capacity allocation to the three production processes for maximum overall project profitability. Moreover, constraints in production flexibility (upper and lower limits) are considered. Fundamentally, capacity flexibility allows decision-makers to change the production level throughout the project lifetime based on market demand as a proactive response to uncontrolled exogenous uncertainties.

## 2. Methodology and Data

The methodology developed as part of this study involves performing sustainable planning within the downstream energy sector in Qatar. The designed framework serves as a decision-making tool that enables the prediction of flexible decisions for the downstream production of power, LNG, and ammonia to satisfy the local power demand and participate in the international demand for LNG and ammonia. The benefits of deploying a sustainable planning system as an allocation tool to enhance the overall economic profit are also investigated through an economic analysis of capital investment cost, operating cost, and sales revenue. This section describes the model development of the different involved processes, the tool used to execute the simulation, and the historical and forecasted data sets available to run the model.

The commercial software Aspen HYSYS is used for process modelling and simulation. The NG liquefaction process scheme evolved from condensation at constant pressure, using the Joule-Thompson method, to the energy-efficient heat exchange process using refrigeration systems. The latter is widely used in different projects worldwide. Licensors developed different technologies in the market to design cost-effective and energy-efficient processes for large-scale commercial deployment. The technologies differ based on the production capacity, refrigerants, liquefaction scheme, and equipment capacity (Al-Mutaz *et al.*, 2016; Castillo *et al.*, 2010; Danilov *et al.*, 2019). Fundamentally, the AP-X technology, an extension of the C3MR process developed by Air Products, is considered for LNG production in Qatar. While for ammonia production, NG is first reformed into syngas through steam and oxygen reforming reactions and the effluent syngas is assured of reaching the necessary 1:3 nitrogen to hydrogen ratio. After which, the syngas is cleaned from CO<sub>2</sub> and water and introduced in the ammonia synthesis loop, where ammonia is generated from the reaction of hydrogen and nitrogen at high pressures ranging from 150 to 350 bar and temperatures ranging from 430 to 480 °C. After which, the ammonia is chilled to be removed from the loop. Whereas, for power generation, the syngas generated from NG is initially conditioned before being delivered to the combustion reactor, where it burns with air. To create electricity, the effluent stream is sent into a gas turbine. The expanded gas is used to produce various forms of steam

through a series of heat exchangers, which are then utilised to create electricity utilising a steam turbine. The simulated LNG, power and ammonia models using Aspen HYSYS are assessed using a built-in economic evaluation tool. The results of the economic evaluation tool are illustrated in Table 1.

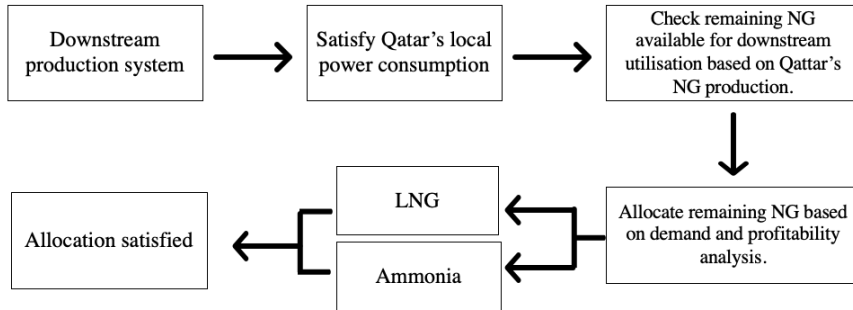

Figure 1: High-level representation of planning methodology.

Table 1. An economic evaluation of LNG, power and Ammonia using Aspen HYSYS.

Process	Power	Ammonia	LNG
<b>NG Flow (kg/h)</b>	5.40E+03	6.41E+05	1.38E+07
<b>Product Amounts</b>	Power (kWh)	Ammonia (kg/h)	LNG (kg/h)

<b>Total Annualized Cost (\$/y)</b>	2.89E+07	1.35E+09	2.56E+10
<b>Revenue (\$/y)</b>	3.16E+07	2.54E+09	1.56E+11

The simulation results and historical and forecasted market data are used as data sets for the planning and allocation formulated in Python using the MESA library (Mesa, 2016). The historical and forecasted demand and production data for NG, LNG, power and ammonia are illustrated in Figure 2. Whereas the trends of global prices of ammonia and LNG are illustrated in Figure 3.

Figure 2: Historical and forecasted demand and production data.

Figure 3: Trends of global prices of Ammonia and LNG.

The ammonia and LNG production must satisfy a minimum operating limit per train capacity and operational flexibility lower limits, as indicated in Table 2.

Table 2. Minimum operating limits (Cheema & Krewer, 2018; Yusuf et al., 2022).

Process	LNG (MTPA)	Ammonia (kg/h)
Lower limit Production capacity	5	708

### 3. Results and Discussion

With the influence of global events and supply chain disruptions on the planning and operation of different NG projects, the integration of various tools in the early design stages of a project is crucial to design a responsive integrated NG production system responsive to market changes. In this study, the results of simulated NG to ammonia, LNG, and power processes, along with historical and forecasted local power requirements in Qatar and global LNG and ammonia demand, are considered to investigate the optimal annual NG production capacity allocation to the three production processes using the python MESA library based on the optimal final product portfolio for maximum overall profitability. The optimal allocation is subject to primarily satisfying the local power demand and then distributing the remaining NG production capacity to the LNG and ammonia production processes to meet international demand. Moreover, lower production capacity limits for LNG and ammonia production processes must be met, wherein a production train cannot operate below the lower flexibility threshold due to technical infeasibility. As illustrated in Figure 4, the optimal NG distribution to LNG, ammonia and power processes from 2000 to 2033 is changing annually, subject to NG

production and demand for each product. The simulation indicates the common trend was the dominance of NG allocation to power and LNG.

In contrast, in the years 2017, 2019, and 2020, a shift to NG allocation for ammonia production is identified due to factors such as the decrease in local power requirements, the decline in global LNG demand in 2020 influenced by the COVID-19 pandemic, and the growth in NG production. Figure 5 illustrates the ammonia and LNG capacities produced in MTPA and Power generation in TWh. The associated annual profits and annualized costs for the optimal NG distribution to LNG, ammonia, and power are illustrated in Figures 6 and 7, respectively, which demonstrate that a significant share of the total profits is associated with international LNG and local power sales. Despite the minimal allocation for NG to ammonia production compared to the other monetization routes, the high selling price of ammonia in international markets reflected positively on the project's profitability. However, ammonia production is associated with high annualized costs due to the high costs of raw materials, equipment, and installation. Hence, annualized costs are an essential factor influencing the economic sustainability of a monetization route under turbulent markets.

Figure 4: Annual NG distribution (BCM) to LNG, Ammonia, and Power between 2000 and 2033.

Figure 5: Annual production capacity of LNG, Ammonia, and Power between 2000 and 2033.

Figure 6: Annual profits for LNG, Ammonia and Power sales based on optimal NG distribution.

Figure 7: Annualized costs for LNG, Ammonia and Power processes.

#### 4. Conclusion

Integrating different tools for optimal NG allocation to products is crucial in designing integrated NG production systems in turbulent markets. Despite the trend for shifting to ammonia production, this study demonstrates the importance of prioritizing power and LNG production and varied production flexibility in the studied period to achieve maximum profitability and hedge against risks. The technical limitations of production were considered for optimal NG distribution to open the door for future comprehensive studies in assessing the value of flexibility associated with each monetization route.

## Abstract

Nowadays, large amounts of data are continuously collected by sensors and monitored in chemical plants. Despite having access to large volumes of historical and online sensor data, industrial practitioners still face several challenges in effectively utilizing them to perform process monitoring and fault detection, because: 1) fault scenarios in chemical processes are naturally complex and cannot be exhaustively enumerated or predicted, 2) sensor measurements continuously produce massive arrays of high-dimensional big data streams that are often nonparametric and heterogeneous, and 3) the strict environmental, health, and safety requirements established in the facilities demand uncompromisingly high reliability and accuracy of any process monitoring and fault detection tool. To address these challenges, in this paper, we introduce a robust and reliable chemical process monitoring framework based on statistical process control (SPC) that can monitor nonparametric and heterogeneous high-dimensional data streams and detect process anomalies as early as possible while maintaining a pre-specified in-control average run length. Through an illustrative case study of the classical Tennessee Eastman Process, we demonstrate the effectiveness of this novel chemical process monitoring framework.

**Keywords:** Process monitoring, fault detection, statistical process control, CUSUM, big data streams

## 1. Introduction

Digitalization is transforming chemical and process industries. Modern chemical plants are equipped with sophisticated digital tools and infrastructures, including numerous sensors and advanced distributed control systems (DCSs), which continuously monitor the plants' equipment performance, manufacturing processes, and mass, energy, and information flows. Together, these sensors generate massive arrays of online data streams that are often *nonparametric* (i.e., data streams do not necessarily follow any specific distribution) and *heterogeneous* (i.e., data streams do not necessarily follow the same distribution). Over the past decades, a number of algorithmic approaches have been developed to effectively utilize the large volumes of historical and online sensor data for reliable online process monitoring and early fault detection. Among them, dimensionality reduction techniques, such as principal component analysis (Jackson and Mudholkar, 1979; Fezai et al., 2018) and partial least squares regression (Geladi and Kowalski, 1986), are the most popular ones in the literature (Russell et al., 2000). These dimensionality reduction-based approaches assume that the statistics characterizing the in-control profiles must also span the subspace defining the out-of-control states or faults (Woodall et al., 2004). In other words, to use the features (e.g., principal components) obtained from historical in-control process data (known as Phase I) for online monitoring (known as Phase II), one must ensure there is no profile shift during online monitoring in some otherwise undetectable direction. However, this assumption is not guaranteed as the

chemical process dynamics typically are quite complex and out-of-control states cannot be fully enumerated or anticipated a priori. Another shortcoming of dimensionality reduction-based methods is that operators and process engineers often have a hard time interpreting the results obtained because the features are in the reduced space, which does not have a one-to-one mapping to the original big data streams. Furthermore, since the number of possible distillation fault scenarios can be quite large, monitoring only the most significant subset of features can cause significant error, as the fault may not be noticeable in the selected features.

More recently, advancements in machine learning, such as support vector machine (Onel et al., 2018) and artificial neural network (Heo and Lee, 2018), offer new pathways toward chemical process monitoring and fault detection. Nevertheless, state-of-the-art machine learning-based approaches still face problems such as overfitting and poor predictive accuracy. For example, while most of the published machine learning methods perform well on training and validation sets, their fault detection accuracies rarely exceed 95% in test sets. Considering the strict EHS requirements on plant site and the severity of consequences in case of fault detection failure, such predictive accuracies are unacceptable and can be catastrophic. Furthermore, machine learning methods do not scale well for new fault scenarios that have not been encountered before. In summary, existing distillation process monitoring and fault detection frameworks are inadequate and unsuitable to address practical, sophisticated data stream characteristics and fault scenarios encountered in chemical process industries.

In this work, we introduce a generic chemical process monitoring and fault detection framework featuring nonparametric and heterogeneous big data streams. This framework can detect process mean shifts or anomalies as early as possible while maintaining a user-specified false alarm rate (or in-control average run length, IC-ARL). Specifically, we adopt and simplify the quantile-based statistical process control (SPC) framework that generalizes the proven and reliable multivariate cumulative sum (CUSUM) control charts for nonparametric, heterogeneous big data systems (Ye and Liu, 2022). To demonstrate its effectiveness in chemical process monitoring, we apply this new framework to the classic problem of Tennessee Eastman Process (Downs and Vogel, 1993) and compare the fault detection performance with PCA and SVM-based approaches for the first time.

## 2. Recent Advancements in Multivariate SPC

We use  $X(t) = (X_1(t), \dots, X_p(t))$  to denote the measurement of  $p$  data streams over the observation time  $t = 1, 2, \dots$ . We assume that the local statistic  $X_j(t)$  is i.i.d. across time  $t$  for every  $j$ . Note that the i.i.d. assumption of the data streams is often satisfied when  $X_j(t)$  measures the residual value (Zou et al., 2015). Also, we emphasize that the independency across different data streams is not required. To combine these individual local statistics into a single global monitoring statistic for fault detection, Tartakovsky et al. (2006) and Mei (2010) proposed using the maximum and the sum of local statistics to form the global monitoring statistic, respectively. Mei (2011) further proposed another global monitoring scheme known as the “top- $r$  approach” based on the sum of the largest  $r$  local statistics. Unfortunately, all these methods were developed under the assumption that all data streams follow a normal distribution, which is rarely encountered in chemical and process industries. To address this issue, various nonparametric multivariate CUSUM procedures (e.g., Liu et al., 2015) have been developed following the pioneering work of Qiu and Hawkins (2001, 2003). Although these multivariate CUSUM methods relax the normality assumption, they still assume that all data streams follow the same distribution,

thereby limiting its applicability to monitoring homogeneous data streams. Earlier this year, Ye and Liu (2022) proposed a quantile-based nonparametric SPC algorithm to construct the local statistic for each data stream. The idea is to incorporate the ordering information of in-control data measurements by categorizing them into a number of quantiles (e.g., 10 or 15) for each data stream in Phase I (Qiu and Li, 2011). Next, in Phase II, online measurements are categorized into the learnt quantiles to generate a quantile-based distribution, which is compared with the quantile-based distribution of in-control data for the detection of any mean shift. Thus, this new quantile-based SPC approach can effectively monitor heterogeneous data streams, and it does not require any prior knowledge about the fault scenarios. In the next section, we present a simplified formulation of the original quantile-based SPC framework of Ye and Liu (2022).

### 3. Formulation and Methodology

Due to space limitations, we only highlight the key results in this quantile-based SPC framework. First, in Phase I, for each data stream  $j = 1, \dots, p$ , in-control measurements are ordered and partitioned into  $d$  quantiles:  $I_{j,1} = (-\infty, q_{j,1}]$ ,  $I_{j,2} = (q_{j,1}, q_{j,2}]$ ,  $\dots$ ,  $I_{j,d} = (q_{j,d-1}, +\infty)$ , such that each quantile contains exactly  $\frac{1}{d}$  of the in-control measurements. Therefore, one can define cumulative intervals as  $CI_{j,i}^+ = [q_{j,i}, +\infty)$  and  $CI_{j,i}^- = (-\infty, q_{j,i}]$  for  $i = 1, \dots, d - 1$ . This information is then used in Phase II monitoring. Specifically, in Phase II, a vector  $\mathbf{Y}_j(t) = (Y_{j,1}(t), \dots, Y_{j,d}(t))$  is defined for each data stream  $j$ , where  $Y_{j,q}(t) = \mathbb{I}\{X_j(t) \in I_{j,q}\}$  and  $q = 1, \dots, d$ . Here,  $\mathbb{I}\{X_j(t) \in I_{j,q}\}$  is the indicator function that equals 1 when  $X_j(t) \in I_{j,q}$  and 0 otherwise. Correspondingly, one can further define two vectors,  $\mathbf{A}_j^+(t) = (A_{j,1}^+(t), \dots, A_{j,d-1}^+(t))$  and  $\mathbf{A}_j^-(t) = (A_{j,1}^-(t), \dots, A_{j,d-1}^-(t))$ , for each data stream  $j$ , such that  $A_{j,i}^+(t) = \mathbb{I}\{X_j(t) \in CI_{j,i}^+\}$  and  $A_{j,i}^-(t) = \mathbb{I}\{X_j(t) \in CI_{j,i}^-\}$ . One can show that  $A_{j,i}^+(t) = 1 - \sum_{k=1}^i Y_{j,k}(t)$  and  $A_{j,i}^-(t) = \sum_{k=1}^i Y_{j,k}(t)$ . And  $\mathbb{E}(A_{j,i}^+(t)) = 1 - i/d$  and  $\mathbb{E}(A_{j,i}^-(t)) = i/d$  for  $j = 1, \dots, p$  and  $i = 1, \dots, d$ . Therefore, detecting the mean shifts in the distribution of  $X_j(t)$  is equivalent to detecting shifts in the distribution of  $A_{j,i}^+(t)$  and  $A_{j,i}^-(t)$  with respect to their expected values. Specifically,  $A_{j,i}^+(t)$  (resp.  $A_{j,i}^-(t)$ ) is more sensitive to upward (resp. downward) mean shift (Ye and Liu, 2022). Thus, to detect upward (+) and downward (-) mean shifts, the multivariate CUMSUM procedure developed of Qiu and Hawkins (2001, 2003) was adopted by defining  $C_j^\pm(t)$  as:

$$C_j^\pm(t) = \left[ \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right) - \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}(\mathbf{A}_j^\pm) \right) \right]^T \cdot \text{diag} \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}(\mathbf{A}_j^\pm) \right)^{-1} \cdot \left[ \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right) - \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}(\mathbf{A}_j^\pm) \right) \right], \quad (1)$$

where  $\mathbf{S}_j^{\pm, \text{obs}}(t)$  and  $\mathbf{S}_j^{\pm, \text{exp}}(t)$  are two  $(d-1)$ -dimensional vectors with  $\mathbf{S}_j^{\pm, \text{obs}}(t) = \mathbf{S}_j^{\pm, \text{exp}}(t) = \mathbf{0}$  if  $C_j^\pm(t) \leq k$ , whereas  $\mathbf{S}_j^{\pm, \text{obs}}(t) = \frac{C_j^\pm(t) - k}{C_j^\pm(t)} \left( \mathbf{S}_j^{\pm, \text{obs}}(t-1) + \mathbf{A}_j^\pm(t) \right)$  and  $\mathbf{S}_j^{\pm, \text{exp}}(t) = \frac{C_j^\pm(t) - k}{C_j^\pm(t)} \left( \mathbf{S}_j^{\pm, \text{exp}}(t-1) + \mathbb{E}(\mathbf{A}_j^\pm) \right)$  if  $C_j^\pm(t) > k$ . With this, the local statistic  $W_j^+(t)$  (resp.  $W_j^-(t)$ ) for detecting upward (resp. downward) mean shift is:  $W_j^\pm(t) = \left( \mathbf{S}_j^{\pm, \text{obs}}(t) - \mathbf{S}_j^{\pm, \text{exp}}(t) \right)^T \cdot \text{diag} \left( \mathbf{S}_j^{\pm, \text{exp}}(t) \right)^{-1} \cdot \left( \mathbf{S}_j^{\pm, \text{obs}}(t) - \mathbf{S}_j^{\pm, \text{exp}}(t) \right)$ , which is shown

to be equivalent to  $W_j^\pm(t) = \max\{0, C_j^\pm(t) - k\}$  (Qiu and Hawkins, 2001). Here,  $k$  is a pre-computed allowance parameter that restarts the CUSUM procedure by resetting the local statistic back to 0 if there is no evidence of upward or downward mean shift after a while (Xian et al., 2021). To detect both upward and downward mean shifts in a data stream  $j$ , we simply define a two-sided local statistic  $W_j(t) = \max\{W_j^+(t), W_j^-(t)\}$  (Li, 2020). And the initial condition is  $W_j(0) = W_j^+(0) = W_j^-(0) = 0$  for all  $j = 1, \dots, p$ . Finally, we ranklist  $W_j(t)$  for the current time  $t$  based on its magnitude:  $W_{(1)}(t) \geq W_{(2)}(t) \geq \dots \geq W_{(p)}(t)$ , where  $W_{(j)}(t)$  denotes the  $j^{\text{th}}$  largest estimated local statistic. With this, we generalize the top- $r$  approach (Mei, 2011) to determine the stopping time  $T$  for raising an alarm and declaring the system is out of control for monitoring heterogeneous data streams:  $T = \inf\{t > 0: \sum_{(j)=1}^r W_{(j)}(t) \geq h\}$ , where  $r$  is typically much less than  $q$  (Mei, 2011), and  $h$  is a constant threshold value related to false alarm rate (Liu and Shi, 2013). A commonly used  $h$  corresponds to the false alarm (Type-I error) rate of no more than 0.0027 (classic  $3\sigma$  limit). Overall, this quantile-based SPC framework developed by Ye and Liu (2022) offers strong statistical justifications and great flexibility as process engineers can customize the choice of  $h$  based on the severity of potential failures.

#### 4. Case Study: Tennessee Eastman Process

The Tennessee Eastman Process (TEP, see Figure 1) is an extensively used benchmark case for comparative assessment of process monitoring algorithms. It consists of a reactor, a product condenser, a separator, and a stripping column. The TEP takes four feed streams (streams 1-4) and partially converts them into desired products G and H and byproduct F. As illustrated in Figure 1, the model contains 11 manipulated and 41 measured variables, as well as 28 predefined fault scenarios to choose from. To generate in-control and out-of-control process data, we utilize the MATLAB/Simulink-based GUI developed by Anderson et al. (2022). In total, 50 hours of in-control process data were generated and collected in Phase I for quantile learning and threshold value  $h$  determination.

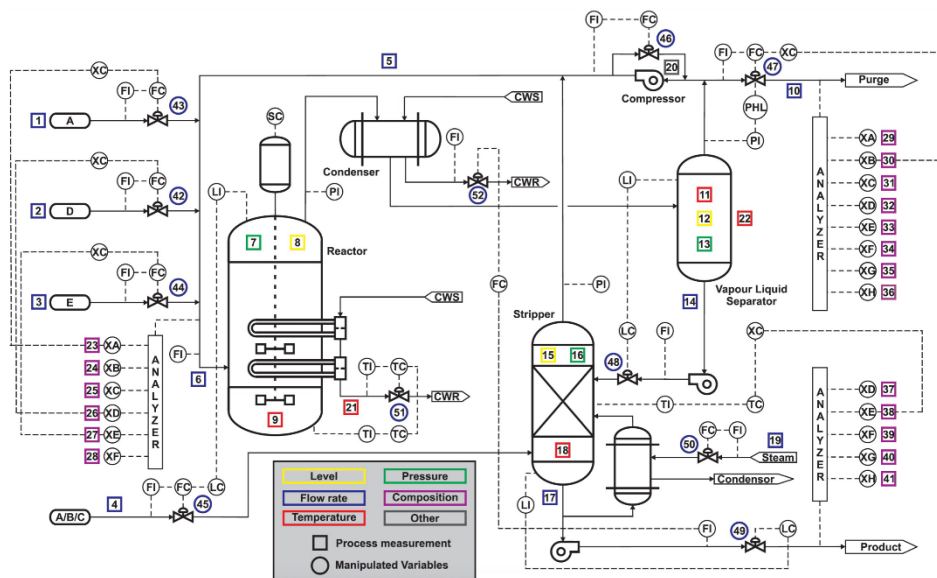

Figure 1. Schematic of Tennessee Eastman Process (source: Ma et al., 2020)

As an illustrative example, we perform process monitoring and fault detection of three representative faults, namely IDV 2, 3, and 13, as summarized in Table 1. In Phase II, we first run the process at normal operations and collect 2 hours of in-control data, followed by starting the fault and operate the process and collect 3 hours of out-of-control measurements. We compare our SPC approach with two other process monitoring algorithms commonly used in chemical industries, namely PCA and SVM. Specifically, we utilize the open source Pyphi package developed by García-Muñoz at Eli Lilly that performs multivariate PCA and Hotelling's  $T^2$  analyses (López-Negrete et al., 2010). We select and keep all principal components whose eigenvalues are greater than 1, thereby leading to a total of 15 principal components for all four fault scenarios. For SVM, we adopt the method and comparison results of Onel et al. (2018).

Table 1. Summary of fault scenarios considered in this comparison study.

Fault No.	Description	Fault Type
IDV 2	Stream 4 composition of B (with constant A/C ratio)	Step
IDV 3	Temperature in stream 2	Step
IDV 13	Reaction kinetics	Slow drift

The comparison results of fault detection speed and the corresponding false alarm rate of all three monitoring frameworks, quantified by how many additional observations (after fault is introduced) are needed for each algorithm before it realizes the process's out-of-control status and raises an alarm, are tabulated in Table 2. As we can see, among the three monitoring frameworks, quantile-based SPC framework yields the fastest fault detection speed in all three fault scenarios, while maintaining the lowest false alarm rate. Furthermore, quantile-based SPC framework only stores and uses quantile information ( $I_{j,i}$ ) for online monitoring and fault detection and is thus very computationally efficient. This result is exciting, given that a lower false alarm rate will lead to reduced fault detection speed due to more conservative monitoring behavior. While more thorough and extensive comparison studies are still ongoing, preliminary results presented in this work clearly demonstrate the effectiveness and attractiveness of this novel SPC framework in effective online monitoring of big data streams and robust, reliable fault detection.

Table 1. Summary of fault detection speed (characterized by out-of-control run length) and false alarm rate using three monitoring frameworks.

Fault No.	SPC	PCA- $T^2$	SVM
IDV 2	125 (0.27%)	216 (0.5%)	180 (0.8%)
IDV 3	95 (0.27%)	366 (0.5%)	16815 (83%)
IDV 13	128 (0.27%)	1131 (0.5%)	675 (12.7%)

## 5. Conclusion

In this work, we present a novel, powerful chemical process monitoring and fault detection framework for nonparametric, heterogeneous big data streams. In particular, the heterogeneity nature of this framework is enabled by recent advancements in SPC, such as the quantile-based multivariate CUSUM (Ye and Liu, 2022). We also compare the performance of this SPC framework with two benchmark process monitoring algorithms, PCA- $T^2$  and nonlinear SVM, in the classic example of Tennessee Eastman Process. Compared with existing dimensionality reduction or machine learning based approaches, the SPC-based framework possesses several advantages, including high reliability and accuracy with customizable, precisely controlled false alarm rate, guaranteed detection of process anomalies or mean shifts, significantly faster fault detection speed, unique

capabilities to handle nonparametric and heterogeneous big data streams, low computational costs, etc.

## Abstract

Smart manufacturing with the help of internet of things and artificial intelligence has attracted significant attention as the modern process industry is highly integrated with information technology. Among them, statistical process monitoring (SPM) is a powerful big data analytics tool for ensuring industrial process safety. In this work, developments in multivariate SPM and corresponding monitoring indicators are briefly introduced. Researches regarding new trends of SPM, the feature-based SPM methods are reviewed and discussed, including statistics pattern analysis and statistics Mahalanobis distance. The feature-based SPM has been considered as one of possible directions in next generation SPM, which shows better process monitoring performance in both sensor faults and process faults through two case studies. Meanwhile, certain limitations and challenges also can be revealed. We discuss the reasons for these challenges from the perspective of industrial process data, and suggestions are provided accordingly to make feature-based SPM better contribute the intelligent manufacturing.

**Keywords:** multivariate statistical analysis, feature selection and extraction, sensor and process fault detection, intelligent manufacturing, internet of things.

## 1. Introduction

The widespread application of distributed control systems facilitates the rapid development of data-driven process monitoring. Statistical process monitoring (SPM), as a class of highly interpretable data-enabled modeling methods, have become a powerful tool for industrial process safety. This is achieved mainly by establishing feature extraction models from historical data to support prompt decision-making regarding the operating status of a process. Statistical process control (SPC) chart, such as cumulative sum chart (CUSUM) chart and exponentially weighted moving average (EWMA) chart could be considered as the earliest SPM, in which univariate upper and lower control limits are employed to determine whether the process is remaining in a state of statistical control (MacGregor, 1994). However, with the extensive arrangement of instruments since 1980s, the limitations of univariate SPM have been revealed. The most important one is that the correlations among process variables are not considered (MacGregor, 1994), since no model is exploited in SPC. Meanwhile, multivariate SPM (MSPM) combining latent variable models and monitoring indicators appears and rapidly develops (Kresta, et al., 1991). In last thirty years, people have witnessed various successful application of MSPM, such as principal component analysis (PCA), partial least squares (PLS) and their variants (Ji and Sun, 2022, Qin, 2012). Although MSPM has become a standard for industrial applications, there are still several challenges to be addressed. The first one is that data are assumed to be multivariate normally distributed in most MSPM methods, while the assumption is usually not satisfied because the

complex features contained in industrial data, such as nonlinearity, process dynamics, and non-Gaussianity, etc(He and Wang, 2018). Although many efforts have been made to deal with this issue through kernel tricks and dynamic latent variable models, the monitoring performance still needs to be further improved. Moreover, the monitoring indicators and corresponding boundary of control region in most methods are still determined under the assumption of normal distribution. High missing alarm rate and false alarm rate will be triggered despite several improvements in monitoring indicators have been developed. On the other hand, traditional MSPM methods focus on process faults, but the incipient sensor faults, which refers to faults with tiny magnitudes(Ji, 2021), are generally not considered. Therefore, more advanced methods need to be proposed to address the above challenges. Wang and He proposed a new concept named statistics pattern analysis (SPA), in which features of process variables rather than the process variables themselves are employed as the monitoring statistics(Wang and He, 2010). Motivated by SPA, more feature-based SPM methods have been further proposed(Ji, 2021, Shang, et al., 2017). Some researchers suggest that it can be regarded as a candidate for next generation SPM(He and Wang, 2018). However, it can be observed that current feature-based SPM methods are mostly designed for incipient sensor fault, and their superiority in monitoring process faults cannot be clearly demonstrated compared to state-of-the-art MSPM. The reason could be the lack of sufficient analysis concerning the characteristics of industrial process data. Regarding this issue, this work compares common MSPM methods and feature-based SPM methods through two cases, by which the challenges in existing feature-based SPM are analyzed. Combined with the case studies, promising suggestions for overcoming these challenges are discussed, and the potential of feature-based SPM in monitoring various types of faults in industrial processes are expected.

## 2. Related Methods

In this section, common MSPM and feature-based SPM methods used in this work for comparison are briefly introduced.

### 2.1. Multivariate Statistical Process Monitoring

MSPM methods mostly employ multivariate linear projection to obtain latent features that could explain most information of the original process variables, and then monitoring indicators are established in the feature space to perform fault detection. Considering MSPM methods have been widely reviewed in literature, only PCA is briefly introduced, and the focus will be on the summary of monitoring indicators.

#### 2.1.1. Principal Component Analysis

PCA is the most commonly used dimensionality reduction method by extracting the cross-correlation among process variables, which has been widely applied in SPM. Given a set of historical data  $X_{n \times m}$  with  $n$  samples and  $m$  variables, PCA aims to find a projection  $P_{m \times k}$  that could transform  $X_{n \times m}$  into an orthogonal space, where most information of original data can be explained,

$$X_{n \times m} = TP_{m \times k}^T + E \quad (1)$$

where  $T = X_{n \times m}P_{m \times k}$  is the score matrix,  $E$  is the residue matrix, and  $k$  represents the number of principal components. To perform fault detection, monitoring indicators could be established on the principal component space and residual space respectively.

### 2.1.2. Monitoring Indicators

$T^2$  statistic is a widely applied monitoring indicator in MSPM to measure changes in the principal component space, which is calculated as follows,

$$T^2 = \sum_{i=1}^k \frac{(p_i^T x)^2}{\lambda_i} \quad (2)$$

where  $p_i$  is the projection of the  $i_{th}$  principal component direction. Comparatively, squared prediction error (SPE) is commonly used to measure the changes in the residue space, which can be calculated as follows,

$$SPE = \sum_{i=k+1}^m (p_i^T x)^2 \quad (3)$$

Moreover, the Mahalanobis distance (MD) is also widely used to measure the changes in all projection directions.

$$MD = \sqrt{\sum_{i=1}^m \frac{(p_i^T x)^2}{\lambda_i}} \quad (4)$$

Raich and Cinar further proposed a combined indicator that could consider changes in principal component space and residue space simultaneously (Raich and Cinar, 1996),

$$\varphi_1 = c \frac{T^2}{\chi^2} + (1 - c) \frac{SPE}{\delta^2} \quad (5)$$

where  $\chi^2$  and  $\delta^2$  are the control limit of  $T^2$  and SPE statistic, and  $c$  is a weight coefficient. However, a high missing alarm rate will be triggered because  $\varphi_1$  could be less than 1 even if either  $T^2$  statistic or SPE statistic exceeds its threshold (Yue and Qin, 2001). Aiming at this issue, Yue and Qin suggested using the following combined indicator (Yue and Qin, 2001),

$$\varphi_2 = \frac{T^2}{\chi^2} + \frac{SPE}{\delta^2} \quad (6)$$

and the control limit is also derived distribution of quadratic forms. Regardless of which monitoring indicator is adopted, the challenges in MSPM mentioned before still need to be faced.

## 2.2. Feature-based Statistical Process Monitoring

The feature-based SPM is a concept proposed by Wang and He (Wang and He, 2010), where the features of process variables rather than the process variables themselves are employed as the monitoring statistics. Several related methods will be introduced in this part.

### 2.2.1. Dissimilarity of Process Data

Actually, the concept of feature-based SPM could be reflected in early methods, such as the dissimilarity of process data (DISSIM) (Kano, et al., 2002). In this work, the distribution of process variables, especially the correlation among variables, which can be regarded as a kind of feature, are monitored. Therefore, this method works better than traditional MSPM on detecting changes in correlation structure. However, certain faults cannot be effectively detected since the features of variables considered by this method are still limited.

### 2.2.2. Statistics Pattern Analysis

The concept of feature-based SPM is first proposed with SPA. In SPA, process variables are divided into moving windows, and the features of the variables including means, variance, etc. in the windows are monitored. Then the PCA is established on the selected features for fault detection. In the case study, hundreds of features are considered by SPA, and therefore it is applicable to most kinds of faults.

### 2.2.3. Statistics Mahalanobis Distance

Motivated by SPA, statistics Mahalanobis distance (SMD) is newly proposed for incipient sensor fault detection (Ji, 2021). Unlike SPA, the MD is directly established on the features of process variable as the monitoring indicator, and the results show that the SMD performs perfectly in three common incipient faults by only considering mean and variance, which greatly reduces the computational costs.

## 3. Case Studies

In this section, a common numerical example and Tennessee Eastman (TE) process are used to compare the process monitoring performance of MSPM and feature-based SPM. Datasets and the implementation of all the methods are available in literature, and the codes can be obtained by request to the corresponding author.

### 3.1. A Numerical Example of Incipient Sensor Faults

A simple multivariate process given in literature is used as the first case study (Ji, 2021). In this case, a set of 100,000 samples are generated under normal conditions as the training data, and three sets containing 4000 samples each are used as test data. The three test data sets correspond to three common incipient sensor faults, which are constant bias, gain degradation, and precision degradation. The faults are introduced in the 1500<sup>th</sup> sample, and the fault detection rate (FDR) and false alarm rate (FAR) are adopted to evaluate the fault detection performance.

**Table 1 A summary of process monitoring results for incipient sensor faults**

FDR/FAR %	PCA $T^2$	PCA SPE	MD	$\varphi_1$	$\varphi_2$	SMD	DISSIM	SPA $T^2$	SPA SPE
Fault 1	1/1	1.7/1.3	4.8/0.9	2/1	0.8/0.5	<b>98.7/0.5</b>	0.3/0	61.5/1.3	97/2.7
Fault 2	0.8/1	0.8/0.8	1.6/1.1	0.7/1.1	0.4/0.5	<b>97.8/3.6</b>	7.2/0.3	1/9.7	9/1.1
Fault 3	2.6/1.2	4.4/0.6	21.9/0.9	6.2/1.1	1.9/0.6	<b>97.5/3.7</b>	99.1/0.9	76.9/4.4	98.3/0.5

The results are summarized in Table 1. It can be found that all MSPM methods fail to detect the three incipient faults because the magnitude of the fault is low. By contrast, feature-based SPM methods perform much better. Among them, DISSIM only works on fault 3. It is reasonable because only variable correlation is considered and it has been proposed for twenty years. SPA works well in fault 1 and fault 3, but the FDR of fault 2 is low because the window in which the gain degradation is most statistically evident is when the fault has just been introduced. When the window moves forward, the dissimilarity of faulty data and normal data is not that obvious, resulting in a low FDR. Moreover, the features used in SPA are too much, which may cause redundancy and decrease the sensitivity of the model to faults. Comparatively, SMD achieves a more than 95% FDR for all faults by considering only the mean and variance, which indicating its superiority to monitoring incipient sensor faults.

### 3.2. Tennessee Eastman Process

TE process is the most commonly used benchmark process in process monitoring domain. Two faults including a random variation fault and a sensor fault are taken as examples, which both are introduced at the 160<sup>th</sup> sample.

**Table 2 A summary of process monitoring results for TE process**

FDR/FAR %	PCA $T^2$	PCA SPE	MD	$\varphi_1$	$\varphi_2$	SMD	SPA $T^2$	SPA SPE
Fault 10	29.6/0	25.8/0.6	88.4/0	45.5/0.6	28.6/0	<b>100/100</b>	79.5/-	73.9/-
Fault 21	39.3/0	47.2/3.1	54.7/1.9	49.6/3.7	40.6/0	<b>100/100</b>	99.9/-	90.8/-

The results are summarized in Table 2. The SMD cannot be applied to monitor process faults because it is developed for sensor faults, and different from sensor variables, the process variables are highly influenced by random factors. As shown in Figure 1, MD performs the best among all indicators in MSPM for fault 10 because changes in all principal components are added up to obtain the MD statistic. This fault is hard to detect for its low magnitude and the response of control systems, while the SPA still performs well as long as there are features deviated from normal operating conditions. For fault 21, a valve is fixed at a constant value. As shown in Figure 2, the fault can be detected by all MSPM methods only after it has affected process variables. It can only be timely detected by SPA because the fault is reflected in the variance of the valve, which is a monitored feature of SPA. Overall, feature-based SPM represented by SPA shows obvious advantages in monitoring both sensor faults and process variables. However, there are also several challenges should be focused on, which will be discussed in next section.

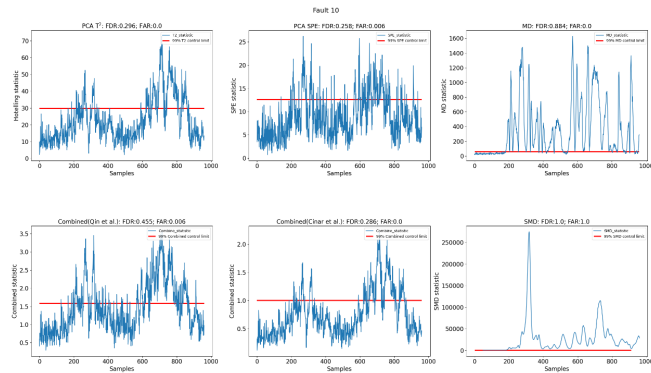

Figure 1 Process monitoring results for fault 10

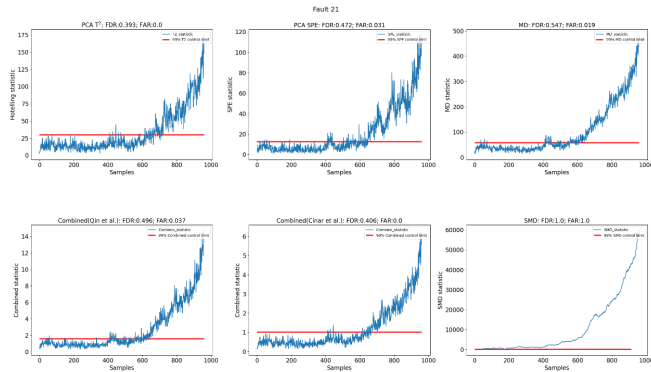

Figure 2 Process monitoring results for fault 21

## 4. Challenges and Suggestions for Feature-Based Statistical Process Monitoring

### 4.1. Redundancy of Features

The feature selection plays the most important role in feature-based SPM. The deficiency or redundancy will affect the process monitoring performance. For example, there are 265 features used for TE process in SPA. The number could be even larger for industrial processes with more variables. It can not only lead to high computational costs but also affect the sensitivity of fault detection. In particular, variable correlation, although an important monitoring statistic, will contribute at least  $m(m - 1)/2$  features. It is

suggested that features more than two orders could be excluded because they are regarding to the distribution of data, and the changes in the distribution could be reflected in other low-order statistics. Moreover, orthogonal transformation is recommended as a preprocessing to avoid the calculation of features of variable correlation.

#### 4.2. Poor Detectability

Since feature-based SPM is a class of methods using moving window technique, the detectability is an unavoidable challenge. Generally, slowly changing faults cannot be early detected by common features of the window, such as the mean and variance. To address this issue, secondary features are suggested to be employed, especially for the maximum, minimum and slope of the window.

#### 4.3. Parameter Selection

At last, the parameter selection is also a challenge that has not been effectively solved. The results of feature-based SPM are highly affected by the size of the moving window. Especially, it is not fixed, but determined according to target processes. It is suggested to be determined by a quantitative indicator obtained by information entropy or other mathematical methods in future research.

## 5. Conclusion

In this work, the performance of MSPM and feature-based SPM in monitoring both sensor faults and process faults is compared through two case studies. The results show that traditional MSPM is not applicable to monitor incipient sensor faults, while the FDR of the SMD reaches an average of 98%. Moreover, the SPA also achieves better process monitoring performance for process faults. It can be concluded that the feature-based SPM represented by SPA shows strong applicability to various types of faults in industrial processes and could be regarded as a candidate to the next generation of SPM. Existing challenges are also analyzed and corresponding solutions are discussed. Future work will focus on the development of more effective feature-based SPM method by addressing the challenges outlined in this paper.

## Abstract

In this work we develop model based control strategies for the optimization and control of the aeration of a municipal wastewater treatment plant, intermittently operated by switching the aeration on and off. The proposed strategies aim to reduce energy consumption as well as to further improve effluent quality. A two-layer hierarchical control structure is implemented: (i) the lower layer using a modified version of the GPC to control the dissolved oxygen concentration and minimize the aeration energy and (ii) the higher level (optimization layer) where standard GPC algorithm is used to obtain the optimal values for the setpoint of the dissolved oxygen in the bioreactor. The developed control strategies show good performances and significant energy savings in comparison with the conventional control systems.

**Keywords:** wastewater, MPC, hierarchical control, energy efficiency

## 1. Introduction

The optimal treatment and administration of industrial and municipal wastewater is critical in maintaining a safe and clean environment as well as supporting the health of the community. When dealing with Wastewater Treatment Plants (WWTPs) it is important that the plant operation can satisfy the requirements for the effluent water quality. Unfortunately this leads to a large amount of energy consumption. Therefore, another important goal for the WWTP, which has become a hot research topic during the last years, is energy efficiency optimization (Daverey et al. 2019, Cardoso et al. 2021).

The main part of the WWTPs is the biological treatment where the most used technology is the Activated Sludge Process (ASP). This is due to its cost-effectiveness, its flexibility and high reliability as well as the capability to produce effluent of high quality. Usually, the activated sludge processes are highly complex, nonlinear and challenging to control. Various works have focused on developing accurate models used to design and tune controllers (Harja and Nascu 2019, Naşcu et al. 2022). There has also been some focus on the development of multiple model based controllers as well as predictive (Nascu and Nascu 2016, Bernardelli et al. 2020), adaptive (Vlad et al. 2010), fuzzy (Yelagandula and Ginuga 2022) or fractional order PID control (Harja et al. 2015).

To optimize the performances of WWTP, real time control is a generally accepted method but one must also consider model uncertainties as well as the complexity of the process. In this work a control system with hierarchical structure is developed: a lower layer with process level control loops as well as a higher level dedicated for optimization.

Model based control (MPC) strategies have a variety of advantages when trying to control a process and are widely used in WWTP. They are robust against variable and unknown

time-delay and have good disturbance rejection properties. Moreover, they are able to incorporate constraints explicitly and handle uncertainty in process model parameters and model mismatch (Harja et al. 2016, Eagalapati et al. 2022). In this work MPC will be used in both layers of the control system.

## 2. Plant description an simulation platform

### 2.1. Plant Structure

The WWTP presented in this work is a medium municipal WWTP (maximum flow - 4500 m<sup>3</sup>/day). For this plant there are three main stages: mechanical or pre-treatment, biological treatment, and sludge treatment. In this work we will focus on the biological treatment, the most complex process used in WWTPs. The typical procedure for this treatment, is the activated sludge technology.

The biological treatment part is composed of two circular ring tanks. The inner ring is given by the secondary settler and the outer cylindrical tank represents the biological treatment tank. By switching the aeration on and off, they are operated alternately for nitrification and denitrification. In small and medium WWTP, as the one presented in this work, the bioreactor tank operates for nitrification and denitrification, alternatively. This results in having both processes for removal of nitrogen not spatially separated but sequentially in time by having the bioreactor operate once aerobic and once anaerobic in turn. To keep the contents of the bioreactor completely mixed, the bioreactor has to be equipped with submersible mixers. The aeration is performed by using fine bubble porous diffusers that are situated at the bottom part of the tank. The aeration required by the bioreactor is given through blowers with a maximum airflow of  $Q_{max}=1400$  m<sup>3</sup>/h as well as the capability to operate at variable airflows. After the bioreactor, in the secondary settler the cleaned water from the top of the settler will overflow to the pumping station of the effluent. The sludge that is settled is recirculated to the bioreactor. A small part of the sludge is evacuated to the sludge treatment stage. The aerated bioreactor has a volume of 6483m<sup>3</sup> and the volume of the secondary clarifier is 2048m<sup>3</sup>.

### 2.2. Mathematical model

Two models are used for the modeling and simulation of the WWTP processes: (i) The Activated Sludge Model No 1 (ASM1) (Henze et al. 2000) to simulate the biological processes from the aerated bioreactor and (ii) the double-exponential settling velocity model to simulate the transfer between the multiple layers in the settler. It is assumed that in the settler no biological processes occur.

The bioreactor tanks succeeded by a secondary settler represents the WWTP layout in the Benchmark Simulation Model no. 1 (BSM1)(Alex et al. 2008) where the first biological reactor tanks are anoxic well mixed and the next biological reactor tanks are aerated. To model the settler ten layers are used. The plant is developed such that, using nitrification and denitrification processes, it removes the nitrogen in wastewater. The nitrification takes place in the aerated tanks while denitrification takes place in the anoxic tanks.

#### 2.2.1. Modification of the Simulation Platform

The BSM1 simulation platform mentioned above has to be adjusted such that it accurately represents the real physical WWTP described. Hence, some bioreactors as well as the internal recirculation are excluded from the BSM1 model. An intermittent biological reactor tank having anoxic and aerated phases chronologically alternated, the secondary settler as well as the main recirculation remains in the model. The block diagram for the new Simulink model obtained from BSM1 is presented in Figure 1. The model initialization parameters are changed (according to the model calibration presented in (Harja and Naşcu 2020, Harja and Nascu 2019)) to match the real plant parameters.

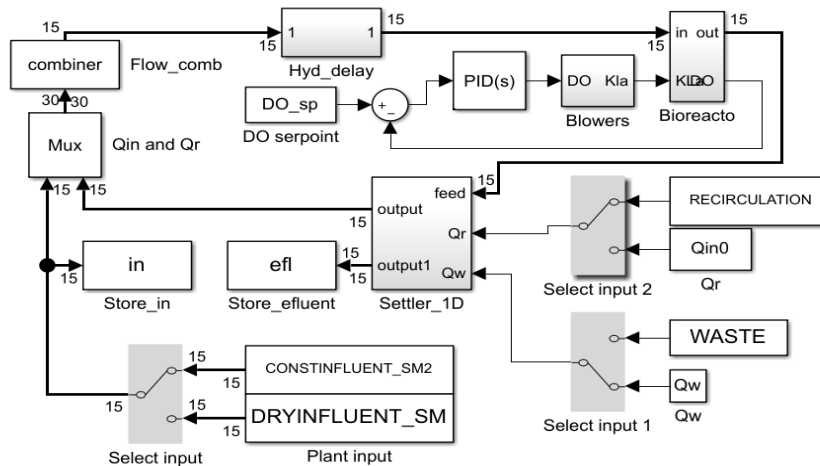

Figure 1 Modified Benchmark Simulation Model 1

To model the blowers and aeration system for the real process as accurately as possible, some modifications were performed. The variable from the BSM1 model that is used for the control of the dissolved oxygen concentration is the transfer coefficient  $KLa$ . Unfortunately, this variable cannot be used in a real plant. Therefore, to convert the aeration flow rate (further used as manipulated input for the bioreactor) into  $KLa$ , a new block is created. In technical literature, the relationship between these two variables is usually represented by an exponential model given by:

$$KLa(Q_{air}) = k_1 \cdot (1 - \exp^{-k_2 \cdot Q_{air}})$$

Using the data collected from the real process for calibration to determine the values for  $k_1$  and  $k_2$  parameters,  $k_1 = 77$  and  $k_2 = 0.0015$  were obtained.

To ensure the bioreactor with alternating nitrification and denitrification phases, the blowers are operating switching ON-OFF. To keep the DO concentration at the reference value determined by the optimization level, a control algorithm will be used.

### 3. Control Strategies

#### 3.1. Hierarchical Control Structure

A simplified diagram of the hierarchical control structure used in this paper is presented in Figure 2. For the substrate concentration control in the bioreactor, the optimization control layer comprises of a MBPC strategy. The optimal values for the DO setpoint is given by the MBPC output.

The lower layer is composed of two main control loops: (i) control of the air pressure in the air piping system and (ii) the control of the DO in the aeration tank for which the optimization level generates the setpoint. The pressure control loop design is rather straightforward and is not presented in this work, unlike the control loop for the DO concentration which poses challenging issues. The ASPs are complex processes with significant nonlinearities, large disturbances as well as uncertainty in process model parameters. These challenges will be tackled by the MBPC algorithm which is used for the control loop of the DO concentration.

In this work, two versions for the Generalized Predictive Control (GPC) method are implemented. In the optimization layer, the standard GPC algorithm is used to obtain the optimal values for the setpoint of the DO in the aeration tank. In the lower layer, a

modified version of the GPC is used to control the DO concentration and to minimize the aeration energy.

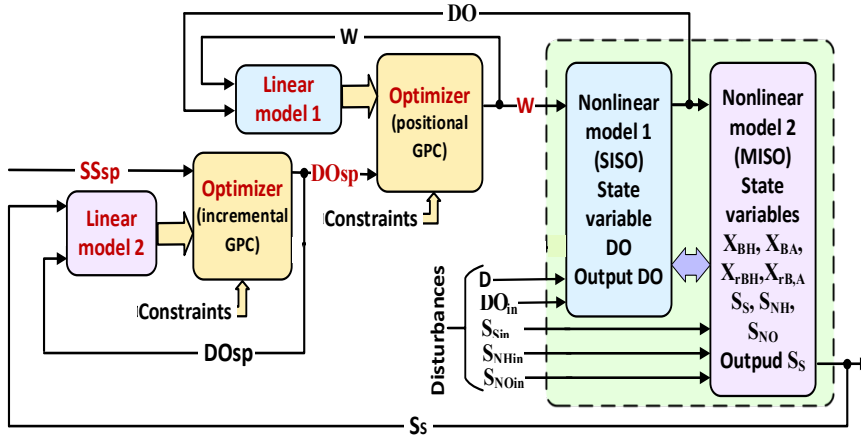

Figure 2. Hierarchical control system layers

### 3.2. GPC Algorithm

#### 3.2.1. Standard GPC Algorithm

The GPC algorithm, developed by Clarke et al is a MBPC strategy that uses the process model to compute online the process output predictions and the optimal control. The optimal control is based on the minimization of the cost function (Clarke et al. 1987):

$$J = \sum_{j=N_1}^{N_2} [y(t+j) - y_r(t+j)]^2 + \sum_{j=0}^{N_u-1} \rho \Delta u(t+j)^2 \tag{1}$$

The design parameters represent:  $N_1$  - the minimum costing horizon,  $N_2$  - the maximum costing horizon,  $N_u$  - the control horizon,  $\rho$  - the control weight parameter. The process input and output are given by  $u$  and  $y$  respectively and  $y_r$  represents the future reference sequence.

#### 3.2.2. Modified GPC Algorithm

An essential step to develop the control algorithm for DO concentration is to reparametrize the cost function (1) to include a measure of the energy that is consumed by aeration. This could lead to significant savings of energy by exploiting the fluctuation of the operating conditions. Because the aeration airflow  $W$  represents the manipulated process input given by the output, of the controller, the reparametrized cost function needs to include the controller output  $u$ , rather than the controller output increments  $\Delta u$  used in (1), to be able to minimize the airflow instead of its variations. This leads to a positional form of the cost function of the controller:

$$J = \sum_{j=N_1}^{N_2} [y(t+j) - y_r(t+j)]^2 + \sum_{j=0}^{N_u-1} \rho u(t+j)^2 \tag{2}$$

## 4. Results

The model as well as the control strategies presented in this paper are implanted in MATLAB Simulink. The model kinetic and stoichiometric parameters used in this paper are:  $Y_A = 0.24$ ,  $Y_H = 0.7$ ,  $f_P = 0.08$ ,  $i_{XB} = 0.086$ ,  $i_{XP} = 0.06$ ,  $\mu_H = 4.59$ ,  $K_S = 20.0$ ,  $K_{O,H}$

$\mu = 0.5$ ,  $K_{NO} = 0.50$ ,  $b_H = 0.4$ ,  $\eta_g = 0.6$ ,  $\eta_h = 0.8$ ,  $k_h = 2.1$ ,  $K_X = 0.025$ ,  $\mu_A = 0.5$ ,  $K_{NH} = 1.0$ ,  $b_A = 0.05$ ,  $K_{O,A} = 0.4$ ,  $k_a = 0.05$ . In one complete aeration cycle with time period  $T$ , the bioreactor is operated  $0.3T$  hours with aeration and  $0.4T$  hours without. For the design of the standard and modified GPC controllers the following tuning parameters are used: (i) for the lower layer  $N_1=1$ ,  $N_2=20$ ,  $N_u=1$ ,  $r_o=0$ , and the sampling time is  $0.01h$  (ii) for the higher layer  $N_1=1$ ,  $N_2=10$ ,  $N_u=1$ ,  $r_o=0$  and the sampling time is of  $1h$ .

Figure 3. Simulation results. a) load disturbances, b) substrate concentration in the effluent, c) DO concentration in bioreactor, d) aeration flow

It can be observed that the developed control strategies are capable of reducing the concentration of organic substances in the effluent (SSe) in the presence of the variation of the loading of the influent with organic substance (SSin) and simultaneously aiming at a reduction of energy consumption. The variation of the loading of the influent, considered as disturbances are presented in Figure 3a. Figure 3d shows how the aeration flow changes depending on the aeration requirement. As a result, the concentration of dissolved oxygen in the bioreactor changes (Figure 3c) depending on the degree of loading of the influent so as to maintain the value of the concentration of organic substances in the effluent at the reference value (Figure 3b). Figure 3b shows the simulation results for a reference value of  $120 \text{ mg/l}$  (black line) and respectively  $150 \text{ mg/l}$  (blue line).

## 5. Conclusions

In this paper we develop model based control strategies to optimize the aeration of an intermittently operated municipal wastewater treatment plant to reduce the energy consumption as well as to further improve the quality of the effluent. A two-layer hierarchical control structure is implemented: (i) the lower layer using a modified version

of the GPC to control the dissolved oxygen concentration and minimize the aeration energy and (ii) the higher level (optimization layer) where a predictive algorithm using the standard formulation of GPC is used to obtain the optimal setpoint values of the dissolved oxygen in the bioreactor. The developed strategies show good performances, the quality performances of the WWTP are maintained, disturbances from the influent are eliminated, and the content of organic substances is maintained within the prescribed limits while the energy consumption is significantly reduced.

## Abstract

Enabling reinforcement learning (RL) to explicitly consider constraints is important for safe deployment in real-world process systems. This work exploits recent developments in deep RL and optimization over trained neural networks to introduce algorithms for safe training and deployment of RL agents. We show how optimization over trained neural-network state-action value functions (i.e., a critic function) can explicitly incorporate constraints and describe two corresponding RL algorithms: the first uses constrained optimization of the critic to give optimal actions for training an actor, while the second guarantees constraint satisfaction by directly implementing actions from optimizing a trained critic model. The two algorithms are tested on a supply chain case study from OR-Gym and are compared against state-of-the-art algorithms TRPO, CPO, and RCPO.

**Keywords:** Constrained reinforcement learning, Optimization of neural network surrogates, Supply chain optimization, Optimization and machine learning toolkit

## 1. Introduction

Reinforcement learning (RL) has been central to many notable successes in machine learning, such as in self-driving cars, playing games, and operating data centers (Shin et al., 2019). Compared to traditional control strategies, e.g., model predictive control, RL does not typically consider state constraints explicitly. For many practical engineering applications, simply maximizing reward without considering the appropriateness of actions can lead to undesirable consequences. For instance, in supply chain applications, an RL algorithm may direct all goods to the cheapest warehouse without considering its maximum capacity, generating infeasible policies and/or creating massive backlogs.

Given the above, it is desirable to impose constraints on the range of behavior that can be explored in RL. This has inspired research into so-called safe RL (García and Fernández, 2015). Several methods for safe RL implicitly consider constraints using stage-wise reward or penalty functions. Alternatively, some safe RL techniques use external knowledge, e.g., imitation learning, and/or risk metrics during exploration.

This work takes advantage of two recent developments to enable explicit consideration of state constraints during deployment of RL: (i) incorporation of deep neural networks (NNs) into RL algorithms, known as deep RL, and (ii) techniques for deterministic optimization of trained NNs. We present two algorithms based on this combination. The first, called OMLT-DDPG, comprises an actor-critic method, where optimization over a critic NN gives optimal actions on which to train the actor. The second, called SAFE, is a strategy for deployment, wherein directly implementing actions from optimizing a trained critic NN guarantees constraint satisfaction.

The two proposed algorithms are applied to a multi-level supply chain case study from the `or-gym` library (Hubbs et al., 2020). Computational results demonstrate that OMLT-DDPG is significantly more sample-efficient compared to other RL methods, owing to the use of deterministic optimization. The results further show that SAFE explicitly satisfies constraints during RL deployment.

## 2. Safe Reinforcement Learning (RL) Background

Markov decision processes, or MDPs, are the foundation of RL problems. A given MDP is defined by a state space  $S$ , action space  $A$ , reward function  $R: S \times A \times S \rightarrow \mathbb{R}$ , and transition probability  $P: S \times A \times S \rightarrow [0,1]$ . The goal of RL is to learn a policy  $\pi: S \rightarrow \mathcal{P}(A)$  that maximizes a performance metric  $J(\pi)$ , usually defined as the total expected reward  $R$  over an infinite time horizon, subject to a discount factor  $\gamma$ . Safe RL methods seek to additionally enforce constraints, typically by introducing some cost function(s), analogous to reward. The inclusion of cost functions results in constrained MDP, or CMDP. Recent methods for safe RL such as constrained policy optimization (Achiam et al., 2017) and interior-point policy optimization (Liu et al., 2020) can provide safety guarantees for CMDPs, but only as simple constraints on expected total discounted cost.

**Trust-Region Policy Optimization (TRPO).** TRPO (Schulman et al., 2015) serves as the basis for several safe RL algorithms: it is a policy iteration algorithm based on computing the advantage of one policy over another, i.e., the expected improvement in the performance metric between the iterations of a policy. Schulman et al. (2015) provide a method for approximating this. As these approximate updates resemble a first-order method when the policy is differentiable, the step size between policies should be constrained. This is typically done using a trust region method, such as constraining the KL divergence to the old policy when maximizing the advantage function.

**Constrained Policy Optimization (CPO).** Achiam et al. (2017) extend TRPO to CMDPs by adding constraints on the auxiliary cost functions to the above trust-region constraint on KL divergence, resulting in the following optimization problem to find policy  $\pi_{k+1}$ :

$$\begin{aligned} \max_{\pi} J(\pi) \\ \text{s.t. } J_{C_i}(\pi) \leq d_i, \forall i = 1, \dots, m \\ D_{KL}(\pi, \pi_k) \leq \delta \end{aligned} \quad (1)$$

where  $J_{C_i}$  is the total expected cost of the  $i^{th}$  constraint over an infinite time horizon and  $\delta$  limits the step size. The objective and constraints are replaced with surrogate functions, based on the algorithm hyperparameters. Again, this problem is computationally difficult and is solved using a primal-dual method after linearizing  $J(\pi)$  and  $J_{C_i}(\pi)$ , and a second-order expansion for  $D_{KL}(\pi, \pi_k)$ . This approximation motivates a small step size  $\delta$ .

**Reward Constrained Policy Optimization (RCPO).** Tessler et al. (2018) propose RCPO, which is similar to CPO but solves an unconstrained optimization problem with Lagrange multipliers. Updating the policy then becomes a bilevel optimization problem:  $\min_{\lambda \geq 0} \max_{\pi} (J(\pi) - \lambda(J_c(\pi) - d))$ . This optimization problem can be viewed on two timescales: a faster one, where the policy is optimized, and a slower one, which involves increasing  $\lambda$  until the constraint is satisfied. This timescale decomposition is achieved by selection of different step sizes for the updates to the Lagrange multipliers and the policy.

### 3. First Algorithm: OMLT-DDPG

Our approach presented in this section incorporates the Optimization and Machine Learning Toolkit (OMLT) into Deep Deterministic Policy Gradients (DDPG).

**Deep Deterministic Policy Gradients (DDPG).** DDPG (Lillicrap et al., 2016) was conceived as a continuous-space extension to the popular deep Q-learning framework (DQN). DQN cannot be directly applied to continuous action spaces, as selecting the action with maximum Q-value at a given state becomes inefficient for high-dimensional action spaces. DDPG is an off-policy, model-free algorithm that instead uses the Q-value function to estimate the policy gradient. Specifically, DDPG keeps a parameterized policy network, known as the actor, which deterministically maps states to actions. The other component is a critic network, which behaves as the Q-value function used in DQN. The actor is trained using gradients from the critic, and the critic is trained by minimizing the difference between the expected discounted rewards (following the greedy actor) and the current Q-value assigned by the critic to the state-action pair. Most implementations maintain a replay buffer to avoid “catastrophic forgetting” of previous transitions.

**Optimization and Machine Learning Toolkit (OMIT).** The challenge of selecting the action with maximum Q-value from a given neural network (NN) can be viewed as optimization over a trained neural network (the neural network parameters are fixed during an RL step). We propose to address this using the Optimization and Machine Learning Toolkit (OMLT), an open-source package for optimization over pre-trained machine learning models (Ceccon et al., 2022). OMLT enables users to easily translate learned machine learning models to optimization formulations. OMLT 1.0 supports GBTs through an ONNX (<https://github.com/onnx/onnx>) interface and NNs through both ONNX and Keras interfaces. OMLT transforms trained machine learning models into the Python-based algebraic modeling language Pyomo (<https://github.com/pyomo/pyomo>). The literature often presents different optimization formulations as competitors, but in OMLT, competing optimization formulations become alternative choices for users.

**DDPG with Deterministic Optimization of NNs.** Algorithm 1 gives pseudocode of our proposed algorithm. OMLT-DDPG preserves properties of the DDPG algorithm, but is extended for CMDPs and benefits from deterministic optimization of trained NNs.

The algorithm is initialized with actor and critic neural networks, as well as target actor and critic NNs. For each episode the agent observes the initial state and executes the

**Algorithm 2** SAFE**Require:** Trained critic  $Q(s, a | \theta^Q)$ 1: Observe:  $s_1, c_1$ 2: Optimize:  $a_1^* = \operatorname{argmax} Q(s_t, a_i | \theta^Q)$ 3: Action:  $a_1 = a_1^*$  s.t. constraints  $c_1$ ▷ OMLT Package for  $t = 2, \dots, T$  **do**

5: Select action:  $a_t = a_t^*$ 

6:

policy defined by the actor NN, storing transitions in the replay buffer. The algorithm then samples a batch of transitions of length  $N$  and updates the critic NN against the target. Up to this point, our algorithm closely resembles DDPG; however, DDPG uses the negative value of the critic for a given state-action pair as the loss for training the actor. DDPG-OMLT instead uses the optimal actions obtained by optimizing the critic NN, subject to the problem constraints. The algorithm preserves the theoretical properties of the policy gradients used in DDPG, as the gradient of the loss used for training the actor is obtained by applying a linear operation on the gradient of the policy network.

Note that this involves solving one constrained optimization problem for each sample from the replay buffer. Therefore, we use the predicted action from the actor as the initial guess to expedite optimization. We hypothesize that in the initial stages of training the actions chosen in this manner will be suboptimal, as the critic is not accurate enough to judge state-action pairs accurately. Nevertheless, this may prove beneficial for exploration. Given the above, we introduce a warm-up period  $\sigma$ , where only the actor is fixed and only the critic is updated. Following the actor and critic updates, the target networks are also updated using “soft” updates, i.e., only a certain fraction  $\tau$  of the weights are updated. Lillicrap et al. (2016) found this to improve the stability of DDPG.

**4. Second Algorithm: SAFE**

The above DDPG-OMLT algorithm promotes safe exploration and exploitation by always incorporating environment constraints when optimizing over the critic network to select optimal actions. However, in deployment, the actor can still give an action that results in constraint violation. Here we describe a second algorithm, SAFE, that explicitly enforces constraints in deployment. In an actor-critic setting, the actor network usually gives the action to take (as implied by its name). OMLT (<https://github.com/cog-imperial/OMLT>) enables us to directly use the critic network to choose the optimal actions at each state. Specifically, we can optimize over the critic network to maximizing rewards, while enforcing environment constraints. If an actor NN is available, this can provide initial guesses for optimization. Algorithm 2 gives pseudocode for SAFE.

A key difference between OMLT-DDPG and SAFE is that OMLT-DDPG uses the constraint values in the previous timestep to evaluate the actor (after the action has been taken), while SAFE uses the constraint values in the current timestep to only take an action that is feasible. We note that SAFE is model-agnostic, meaning it can use any state-action value NN (supported by OMLT). While we only test SAFE with critic models from OMLT-DDPG, any Q-value NN that takes a state-action pair as input can be used.

**5. Results and Discussion**

We employ the multilevel supply chain case study from `or-gym` (Hubbs et al., 2020) to test OMLT-DDPG and SAFE, comparing against TRPO, CPO, and RCPO. The agent

must place replenishment orders at nodes throughout levels of a supply chain, subject to lead times and uncertain customer demand at retail nodes. Inventories are subject to capacity constraints, with excess incurring a penalty cost. Likewise, penalties are incurred for unmet demand. Full details can be found in Hubbs et al. (2020). A three-level supply chain is selected, and algorithms are run for 150 episodes, except for RCPO, which required more episodes to converge. Each experiment is repeated with five random starts.

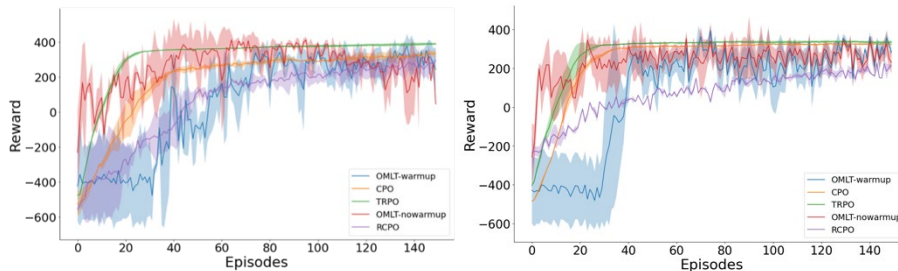

Figure 1: Rewards during training for nominal (left) and relaxed (right) supply chain.

DDPG is typically run with a lower learning rate for the actor than for the critic, allowing the two to converge on different “timescales.” However, we found OMLT-DDPG to benefit from a faster learning rate for the actor, and we set the actor and critic learning rates to, respectively, 0.005 and 0.001. We used a batch size of 8, sampled from a replay buffer size of maximum 35000. We found a strong tradeoff between performance gain and computational time related to the batch size. We use a batch size of 40000 for CPO and TRPO. To investigate the effect of the feasible region size, we consider two settings for the supply chain case study: one with the nominal constraint, and a relaxed setting, where capacity constraints are increased by 40%.

**Safe Reinforcement Learning.** Figure 1 compares the performance of the various algorithms through 150 episodes. TRPO, CPO, and RCPO exhibit more stable behavior, while OMLT-DDPG seems to fluctuate. However, for the nominal case (left), OMLT-DDPG with warm-up achieves rewards only 6% and 28% lower than CPO and TRPO, respectively, which is noteworthy as OMLT-DDPG uses  $>1000x$  fewer samples. For the relaxed case (right), OMLT-DDPG performs intermediate to CPO and RCPO, while again using significantly fewer samples. This sample efficiency may be attributed to the information gain from the use of deterministic optimization. Indeed, OMLT-DDPG achieves a reward of 200 after only four episodes, and this steep learning curve is consistent in our experiments, suggesting behavior as a “few-shot” learner.

The incorporation of the warm-up period does not seem to help OMLT-DDPG in the nominal case (left), but greatly improves performance in the relaxed case (right). In general, the lack of warm-up period results in more aggressive behavior by the agent.

**Safe Deployment.** To simulate safe deployment in production, we deploy the models trained after the 150 episodes. Specifically, we deploy the trained models in a 30-episode simulation, varying the initial state randomly. The rewards and penalties incurred by using these trained models to operate the supply chain are shown in Figure 2. We find that OMLT-DDPG outperforms the other algorithms in deployment in terms of both maximizing rewards and avoiding penalties. Compared to CPO, OMLT-DDPG achieves 21% higher rewards and 20% less penalties in deployment in the nominal case. The SAFE algorithm results in more unstable rewards, but is the only algorithm to guarantee constraint satisfaction, avoiding all penalties during deployment. This demonstrates SAFE as the most appropriate option for guaranteed safe exploitation.

Figure 2: Deployment rewards/penalties for nominal (left) and relaxed (right) cases.

## 6. Conclusions

This paper introduces two algorithms, OMLT-DDPG and SAFE, for safe reinforcement learning and deployment, based on constrained optimization over trained critic networks. The first algorithm uses an actor-critic framework; constrained optimization over the critic network is used to provide targets on which the actor is trained. We show that this algorithm is very sample efficient, resembling behavior of a “few-shot” learner. The second algorithm uses constrained optimization over a pre-trained critic network to explicitly enforce process constraints during deployment.

## Abstract

This work studies reinforcement learning (RL) in the context of multi-period supply chains subject to constraints, e.g., on inventory. We introduce Distributional Constrained Policy Optimization (DCPO), a novel approach for reliable constraint satisfaction in RL. Our approach is based on Constrained Policy Optimization (CPO), which is subject to approximation errors that in practice lead it to converge to infeasible policies. We address this issue by incorporating aspects of distributional RL. Using a supply chain case study, we show that DCPO improves the rate at which the RL policy converges and ensures reliable constraint satisfaction by the end of training. The proposed method also greatly reduces the variance of returns between runs; this result is significant in the context of policy gradient methods, which intrinsically introduce high variance during training.

**Keywords:** Safe reinforcement learning, Process operations, Inventory management

## 1. Introduction

Recent years have highlighted the importance of efficient supply chains in modern society. The field of inventory management deals with optimization of the ordering, storing, and selling of product inventory. There are many aspects of this problem that make it challenging, and a lot of benefits in doing so that make it worth investigating. Challenges include the presence of outdated “legacy” processes or the inefficient use of available physical capital. A variety of operations research methods have been used in tackling this family of problems, including dynamic programming, linear programming, and game theory. Given complex environments, however, modern inventory management also lends itself towards optimization through reinforcement learning (RL).

In the past few decades, machine learning has gained increasing popularity for its capacity to imitate the way humans learn. RL provides a framework for artificial agents to learn by interacting with an external environment and iteratively updating the way in which they act (i.e., their policy). Specifically, each interaction moves the agent to a new state and produces some quantifiable reward; the agent seeks to maximize cumulative reward (i.e., return) from its interactions. RL has proven very effective in areas such as gaming, demonstrating superhuman performance in incredibly complex games, or robotics and control, where problems can be too complex for analytical solution (Shin et al., 2019).

Real-world environments such as supply chains, may impose physical or safety limitations on the actions an agent can take. This work introduces a framework for RL in these circumstances, combining advantages of constrained and distributional RL.

*Constrained* RL algorithms extend the objective of an RL agent to include minimizing the expected costs below some threshold defined by the constraints in an environment, in addition to maximizing expected returns. In a related vein, *distributional* RL attempts to imitate the way in which organisms consider risk in decision-making, by estimating the distribution of values for all the states in the environment. The intrinsic stochasticity of many environments motivates using probability distributions to evaluate the possible future rewards associated with an action (Petsagkourakis et al., 2022). By estimating these distributions, distributional RL simplifies the parameterization of risk-adversity in RL, giving benefits in problems where constraints should be satisfied under uncertainty.

## 2. Reinforcement Learning (RL) Background

RL often employs a Markov Decision Process (MDP). An MDP is defined by the tuple  $(\mathcal{S}, \mathcal{A}, \mathcal{R}, \mathcal{P}, \gamma)$ , where  $\mathcal{S}$  is the set of states in the environment,  $\mathcal{A}$  is the set of possible actions,  $\mathcal{R}: \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$  is a reward function,  $\mathcal{P}: \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0,1]$  is the transition probability function ( $\mathcal{P}(s'|s, a)$  is the probability of transitioning to state  $s'$  by taking action  $a$  from state  $s$ ), and  $\gamma$  is a discount rate for future rewards. A policy  $\pi: \mathcal{S} \rightarrow \mathcal{P}(\mathcal{A})$  maps states to probability distributions over the possible actions ( $\pi(a|s)$  is the probability of taking action  $a$  from state  $s$ ). We denote the set of all possible stationary policies as  $\Pi$ . RL seeks a policy  $\pi$  that maximizes a performance measure, often taken as  $J_R(\pi) = \mathbb{E}_{\tau \sim \pi} [\sum_t \gamma^t R(s_t, a_t, s_{t+1})]$ , where  $\tau$  is a trajectory sampled using  $\pi$ . Denoting  $\hat{R}(\tau)$  as the discounted return of a trajectory, the on-policy state value function is denoted  $V^\pi(s) = \mathbb{E}_{\tau \sim \pi} [\hat{R}(\tau) | s_0 = s]$ , with optimal policy  $\pi^* = \operatorname{argmax}_\pi V^\pi(s)$ . Analogously, the state-action value function is  $Q^\pi(s, a) = \mathbb{E}_{\tau \sim \pi} [\hat{R}(\tau) | s_0 = s, a_0 = a]$  and the advantage function of an action is  $A^\pi(s, a) = Q^\pi(s, a) - V^\pi(s)$ .

**Trust Region Policy Optimization.** Deep RL may parameterize the learned policy as a neural network (NN) with trainable parameters  $\theta$ . Policy-gradient methods train the NN using the gradient  $\nabla_\theta J(\theta) = \mathbb{E}_\pi [Q^\pi(s, a) \nabla_\theta \ln \pi_\theta(a|s)]$ . This produces an unbiased update rule, but with large variance in the gradient estimates. Trust Region Policy optimization (TRPO) (Schulman et al., 2015a) deals with this noise by limiting the Kullback-Leibler (KL) divergence between consecutive policies to a threshold  $\delta$ :

$$\max_{\theta} \mathbb{E}_{s \sim \rho^{\pi_k}, a \sim \pi_k} \left[ \frac{\pi(a|s)}{\pi_k(a|s)} A^{\pi_k}(s, a) \right] \text{ s.t. } \mathbb{E}_{s \sim \rho^{\pi_k}} [\bar{D}_{\text{KL}}(\pi_k(\cdot | s) || \pi(\cdot | s))] \leq \delta \quad (1)$$

where  $\rho^{\pi_k}$  is the state visitation probability density under  $\pi_k$ , and  $\bar{D}_{\text{KL}}$  the average KL divergence. Problem (1) is typically solved using Monte-Carlo estimates of  $Q^{\pi_k}(s, a)$ , linearization of the objective, and second-order approximation of the constraint.

**Constrained Reinforcement Learning.** Constrained RL algorithms often consider a constrained MDP (CMDP), which includes costs  $\mathcal{C}: \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \mathbb{R}$  analogously to rewards, as well as a safety threshold  $d$ . The objective of the agent then becomes to maximize  $J_R(\pi)$  such that  $J_C(\pi) = \mathbb{E}_{\tau \sim \pi} [\sum_t \gamma^t \mathcal{C}(s_t, a_t, s_{t+1})] \leq d$ .

*Constrained Policy Optimization (CPO)* (Achiam et al., 2017) restricts policy updates similarly to TRPO, but to satisfy both the trust-region constraint from (1) and environment constraints. The proposed optimization problem can be solved efficiently using duality, where Lagrange multipliers for both the objective and environment constraints are estimated at each step. However, CPO is inherently subject to approximation errors in the estimate of the objective and constraints, which in practice lead it to converge to infeasible policies. Another way of enforcing constraints is to

augment the state-space and reshape the objective of the problem. *Safety Augmented (SAUTE) MDPs* (Sootla et al., 2022) allow for a reformulation of the problem in terms of minimization of the reshaped objective, whereby constraints are incorporated through a safety budget. This approach only modifies the environment and is compatible with most off-the-shelf RL algorithms, but the state space increases with the number of constraints, leading to scalability issues and a loss in sampling efficiency as constraints are added.

### 3. Approach: Distributional Constrained Policy Optimization

In this work we apply distributional RL to the CPO setting to balance reliable constraint satisfaction and consistent sampling efficiency, independent of the number of constraints. Distributional RL (Bellemare et al., 2017) considers the probability distribution of returns over state-action pairs, which we extend to approximate distributions of costs to manage risk aversion. Algorithm 1 shows our distributional version of CPO, which we call DCPO.

**Problem Formulation.** Consider the CPO policy update with a single constraint:

$$\begin{aligned} \pi_{k+1} &= \operatorname{argmax}_{\pi \in \Pi_\theta} \mathbb{E}_{s \sim \rho^{\pi_k}, a \sim \pi_k} [A^{\pi_k}(s, a)] \\ \text{s.t.} \quad & J_C(\pi_k) + \frac{1}{1-\gamma} \mathbb{E}_{s \sim \rho^{\pi_k}, a \sim \pi_k} [A_C^{\pi_k}(s, a)] \leq d \\ & \bar{D}_{\text{KL}}(\pi_k || \pi) \leq \delta \end{aligned} \quad (2)$$

where  $A_C^{\pi_k}$  denotes the estimated cost advantage under  $\pi_k$  for the cost function  $C$ . For small  $\delta$ , we can linearize the objective and safety constraints around  $\pi_k$ . Denoting the gradients of the objective and constraint as  $g$  and  $b$ , respectively, the Hessian of the KL-divergence as  $H$ , and defining  $c = J_C(\pi_k - d)$ , (2) can be written in terms of the step direction  $x = \theta - \theta_k$ , giving:  $x^* = \min_x g^T x$  s.t.  $\{c + b^T x \leq 0, x^T H x \leq \delta\}$ .

We note that  $g$  and  $b$  can be computed by back-propagation, and that  $H$  is always positive semi-definite, making (3) a convex optimization problem. Given a single cost function, the optimal point  $x^*$  (assuming one exists) is  $x^* = \frac{-1}{\lambda^*} H^{-1}(g - v^* b)$ , with dual variables:

$$v^* = \left( \frac{\lambda^* c - r}{s} \right); \lambda^* = \operatorname{argmax}_{\lambda \geq 0} \begin{cases} f_a(\lambda) := \frac{1}{2\lambda} \left( \frac{r^2}{s} - 1 \right) + \frac{\lambda}{2} \left( \frac{c^2}{s} - \delta \right) - \frac{rc}{s}, & \text{if } \lambda c - r > 0 \\ f_b(\lambda) := \frac{-1}{2\lambda} \left( \frac{q}{\lambda} + \lambda \delta \right), & \text{otherwise} \end{cases}$$

where  $q = g^T H^{-1} g$ ,  $r = g^T H^{-1} b$ ,  $s = b^T H^{-1} b$ . In practice  $H^{-1}$  is expensive to compute so we approximately solve for  $H^{-1} g$ ,  $H^{-1} b$  using conjugate gradients. Since  $\lambda \geq 0$ , we must restrict the optimal  $\lambda$  from the two cases above through a projection to the sets  $\Lambda_a := \{\lambda | \lambda c - r > 0, \lambda \geq 0\}$ , and  $\Lambda_b := \{\lambda | \lambda c - r \leq 0, \lambda \geq 0\}$  respectively, such that:

$$\lambda^* \in \left\{ \operatorname{Proj} \left( \sqrt{\frac{q - r^2 s^{-1}}{\delta - c^2 s}}, \Lambda_a \right), \operatorname{Proj} \left( \sqrt{\frac{q}{\delta}}, \Lambda_b \right) \right\} = \begin{cases} \lambda_a^*, & \text{if } f_a(\lambda_a^*) \geq f_b(\lambda_b^*) \\ \lambda_b^*, & \text{otherwise} \end{cases} \quad (3)$$

Note that  $H$  is computed using the quadratic constraint such that any step taken satisfies the KL-divergence constraint. In the infeasible case when  $c^2 s - \delta > 0$  and  $c > 0$ , we apply a recovery method towards constraint satisfaction,  $x^* = \sqrt{2\delta / (b^T H^{-1} b)} H^{-1} b$ .

**Distributional Value Function and Safety Baseline.** Accurate estimates of the return and safety advantages  $A^{\pi_k}$  and  $A_C^{\pi_k}$  in (2) are essential to reduce the variance associated with the policy-gradient update step. These advantage functions can be estimated, e.g.,

**Algorithm 1:** Distributional Constrained Policy Optimization (DCPO)

- Sample a set of trajectories  $\mathcal{D} = \tau \sim \pi_k = \pi(\theta_k)$
- Form sample estimates  $\hat{g}, \hat{b}, \hat{H}, \hat{c}$  using  $\mathcal{D}$ , and reshaped  $\tilde{J}_C(\pi_k), \tilde{d}$
- if** approximate CPO (3) is feasible **then**
  - Solve dual problem with reshaped constraint  $\tilde{c} = \tilde{J}_C(\pi_k) - \tilde{d}$
  - Compute new policy  $\theta^*$  using  $x^* = -\frac{1}{\lambda^*} H^{-1}(g - v^* b)$
- else**
  - Compute recovery policy  $\theta^*$  using  $x^* = -\sqrt{2\delta/(b^T H^{-1} b)} H^{-1} b$
- end**
- Obtain  $\theta_{k+1}$  through backtracking linesearch to enforce constraints in (2) over  $\mathcal{D}$

**end**

---

see Schulman et al. (2015b), and approximated with NNs. To model uncertainty, we choose to represent the return and cost value functions (used in estimating  $A^{\pi_k}$  and  $A_C^{\pi_k}$ ) using NNs whose outputs are distributions parameterized by  $N$  equally spaced quantiles in a range  $[V_{\min}, V_{\max}]$  (Bellemare et al., 2017). We employ a surrogate loss for these NNs comprising the average negative log-likelihood of obtaining the costs or returns sampled under policy  $\pi_k$ . To simplify computation of the log-likelihood, we approximate the quantile distribution as Gaussian. For a value function with parameters  $\phi$  the loss is thus  $\mathcal{L}(\phi) = -\log(p(J_R(\pi_k)|\phi))$ , which is trainable using stochastic gradient descent.

**Cost Reshaping.** To reliably satisfy constraints, we reshape the cost  $J_C(\pi_k)$  and safety threshold  $d$  based on the agent’s confidence that constraints are satisfied given a cost distribution with parameters  $\phi_c$ . Specifically, we introduce a reshaping parameter  $\rho$ , whose value is set to  $\beta \mathcal{P}(J_C^{\pi_k} > d; \phi_c)$  when  $J_C^{\pi_k} > d$  (the constraints are violated), and to  $-\beta \mathcal{P}(J_C^{\pi_k} < d; \phi_c)$  when the constraints are satisfied, with  $\beta \geq 0$ . In other words,  $\rho$  takes the value of  $\beta$  when the agent is fully confident that constraints are violated under the previous policy  $\pi_k$ , and  $-\beta$  when it is fully confident the constraints are satisfied. We then reshape  $J_C^{\pi_k}$  and  $d$  by multiplying each with  $(1 + \text{clip}(\rho, -\varepsilon, \infty))$ . The new parameter  $\varepsilon$  controls risk aversion. This reshaping only affects policy updates when constraints are satisfied, effectively avoiding large steps in directions that may increase costs. Intuitively, maximizing rewards in a constrained environment usually leads to the agent to the edges of the feasible region. We thus mitigate risk by adjusting the feasibility of the trust region depending on the confidence of constraint satisfaction.

#### 4. Results and Discussion

We consider inventory management for a multi-echelon, multi-period supply chain: the goal is to maximize profits while satisfying constraints. We use *InvManagement-v0* in the `or-gym` library (Hubbs et al., 2020). At each period  $t$ , the environment is:

$$I_{t+1}^m = I_t^m + R_{t-L_m}^m - S_t^m, \quad \forall m \in \mathcal{M}, t \in \mathcal{T} \quad (6a)$$

$$T_{t+1}^m = T_t^m - R_{t-L_m}^m + R_t^m, \quad \forall m \in \mathcal{M}, t \in \mathcal{T} \quad (6b)$$

$$S_t^m = \begin{cases} R_t^{m-1}, & \text{if } m > 0 \\ \min(I_t^0 + R_{t-L_m}^0, D_t + B_{t-1}^0), & \text{otherwise} \end{cases} \quad \forall m \in \mathcal{M}, t \in \mathcal{T} \quad (6c)$$

$$U_t^m = R_t^{m-1} - S_t^m, \quad \forall m \in \mathcal{M}, t \in \mathcal{T} \quad (6d)$$

$$P_t^m = \alpha^m (p^m S_t^m - r^m R_t^m - k^m U_t^m - h^m I_{t+1}^m), \quad \forall m \in \mathcal{M}, t \in \mathcal{T} \quad (6e)$$

Eqs. 6a–6b are mass balances for the on-hand ( $I$ ) and pipeline ( $T$ ) inventories for each stage  $m$ , where  $R$  and  $L$  denote replenishment orders and lead times, respectively.

Eq. 6c gives the sales ( $S$ ) for the retailer ( $m = 0$ ) and the rest of the pipeline ( $m > 0$ ), given demand  $D$  and backlog  $B$ . Eq. 6d describes the unfulfilled re-order quantities ( $U$ ), and Eq. 6e calculates the profit  $P$  as the sales revenue minus procurement costs, unfulfilled demand penalties, and excess inventory penalties, all subject to a discount factor  $\alpha = 0.97$ . The unit sales price  $p$ , and penalties  $k$ ,  $h$  are all known.

There are production capacity and inventory constraints on the re-order quantities  $R_t^m$ . To enforce these, we define a cost function that sums the number of constraint violations  $C(s, a) = \sum_{m \in \mathcal{M}, t \in \mathcal{T}} C(I_t^{m+1}, R_t^m)$ , where  $C(I_t^{m+1}, R_t^m)$  is the number of constraints violated at node  $m$  at time  $t$ . We use this indicator cost function rather than a continuous one in order to limit the number of constraint violations, regardless of their degree.

**Training DCPO.** All of the algorithms use separate feed-forward NNs for the policy, return value distribution, and cost value distribution of size (64, 64) with tanh activations. Running DCPO ([github.com/jaimessabalimperial/jaisalab](https://github.com/jaimessabalimperial/jaisalab)) with  $N = 102$  quantiles allowed for convergence of the learned distributions, as shown in Figure 1. Intuitively, at earlier periods the agent is more uncertain about the cost/value of a state (epistemic uncertainty). As samples are observed, the distribution converges, and remaining uncertainty likely stems from stochasticity of the MDP (aleatoric uncertainty).

Figure 1: Learned quantiles ( $N=102$ ) for the return distribution of the initial state  $s_0$ .

**Importance of Cost Reshaping.** Figure 2 shows the costs and returns incurred during training for CPO, DCPO, and ‘ablation,’ or DCPO without cost reshaping. We observe that using parametric return and cost value distributions improves the initial stages of training, with the ‘ablation’ agent learning more quickly (see episodes 0–100) to both minimize costs and maximize returns compared to CPO. Moreover, the standard deviation of the returns across replications by is reduced by 40.0% and 76.6% for ‘ablation’ and DCPO, respectively, compared to CPO at the end of training.

Figure 2: Returns (left) and costs (right) incurred by during training.

**Comparison to TRPO and Saute.** Figure 3 shows the costs and returns incurred during training for TRPO, Saute TRPO, CPO, and DCPO. TRPO is unconstrained and produces infeasible policies, more than doubling the permitted number of violations, but it attains

the largest returns. On the other hand, Saute TRPO incurs costs well below the limit by the end of training, with a clear trade-off in the low returns. DCPO seems to balance the intrinsic trade-off between returns and costs, with mean costs converging to the defined limit. Moreover, DCPO showed a reduction of 70.8% in the standard deviation of the returns relative to TRPO by the end of training. Finally, CPO converged to intermediate values for both costs and returns, potentially owing to approximation errors.

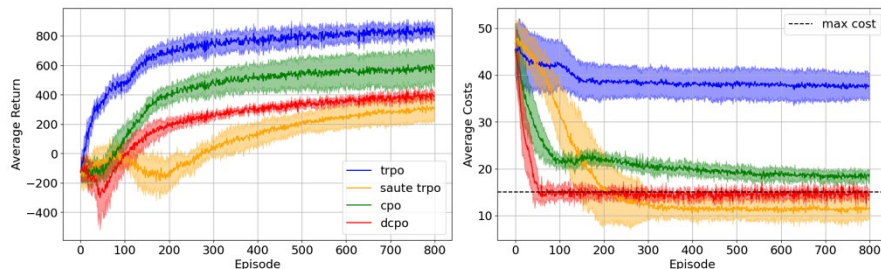

Figure 3: Returns (left) and costs (right) for algorithms over ten runs.

## 5. Conclusions

This paper introduces an approach for trust region optimization in CPO, by reshaping episodic discounted costs and the maximum allowed value using the agent’s confidence in constraint satisfaction, in turn given by an approximated cost distribution. The developed algorithm, which we call DCPO, balances the trade-off between maximizing returns and minimizing costs in a supply chain case study, such that constraints are satisfied (within one standard deviation), while reducing run-to-run variance.

## Abstract

Personalised medicine products represent a novel category of therapeutics often characterised by bespoke manufacturing lines and dedicated distribution nodes. An example of such products is Chimeric Antigen Receptor (CAR) T-cells, whose manufacturing poses challenges to volumetric scale-up, leading to increased production and supply chain costs. From a modelling perspective, such networks lead to complex large-scale supply chain models that grow exponentially as the demand increases and more therapies are tracked simultaneously throughout the supply chain. In this work, we present a hybrid model that utilizes the potential of machine learning for strategic planning by forecasting optimal supply chain structures and Mixed Integer Linear Programming (MILP) for detailed scheduling. The proposed model is robust to uncertain demand patterns and can reduce the number of linear constraints and binary variables in the original MILP by more than 64.7%.

**Keywords:** supply chain optimisation, MILP, artificial neural networks, hybrid models, personalised medicine

## 1. Introduction

Personalised medicine products are often characterised by 1:1 business models that consider parallel manufacturing lines and dedicated distribution routes. Such models are also adopted by personalised cancer therapies that use the patient's own cells as the starting material (Papathanasiou *et al.*, 2020). Chimeric Antigen Receptor (CAR) T-cells are an indicative example of patient-specific therapies that owing to their promising clinical results have pioneered the approval of cell and gene therapy products by the regulatory authorities (Young *et al.*, 2022). The commercially available CAR T-cell products are offered at high list prices ranging between \$300,000 and \$475,000. These prices can be attributed to the high manufacturing, distribution and therapy administration costs (Spink *et al.*, 2018). In addition, there is a pressing need to coordinate the manufacturing and distribution lifecycle with the patient schedule. Depending on the clinical condition and location of each patient, in-time delivery is of utmost importance for the patient's prognosis. Future scenarios indicate that cell and gene therapy products could be treating up to 60,000 patients per year by 2030 (Quinn *et al.*, 2019). Planning and scheduling the manufacturing and distribution of such therapeutics is therefore a challenging task, currently relying on white-glove logistics, which might not always

ensure a responsive and resilient supply chain network. Process Systems Engineering tools can offer a systematic approach to assist decision-making.

Previous works on the optimization of CAR T-cell therapies via Mixed Integer Linear Programming (MILP) (Triantafyllou *et al.*, 2022a), heuristics-based decomposition algorithms (Triantafyllou *et al.*, 2022b) and metaheuristics-based algorithms (Karakostas *et al.*, 2020) highlight the patient-specific nature of these therapeutics, where the full-scale model may comprise complex sets of constraints and binary variables, translating into computationally expensive optimisation problems. In this space, methodologies that rely on Machine Learning (ML) can enhance supply chain planning in the area of Operations Research (Goettsch *et al.*, 2020; Abbasi *et al.*, 2020).

In this work, we present a hybrid model that describes the end-to-end supply chain of personalised therapeutics based on Mixed Integer Linear Programming (MILP) and Artificial Neural Networks (ANNs) (Figure 1). To reduce the computational complexity of the full-space MILP model, we harness the potential of ML for strategic planning in the supply chain by forecasting the optimal supply chain network structure.

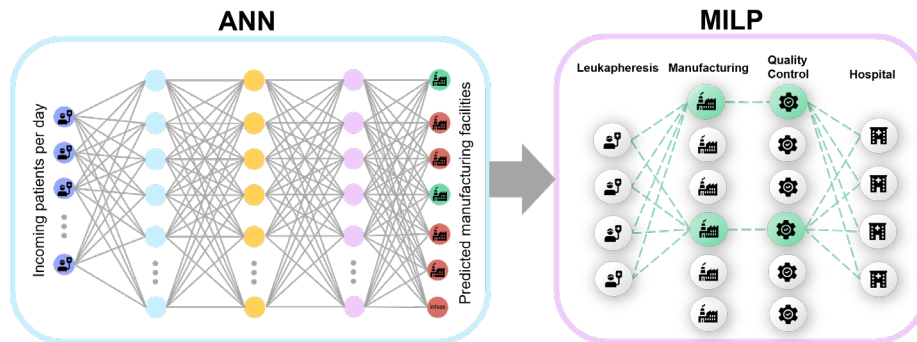

Figure 1. Proposed hybrid model for the CAR T-cell supply chain network with 4 nodes: leukapheresis centres, (b) manufacturing sites, (c) quality control sites, and (d) hospitals.

## 2. Materials & Methods

### 2.1. Mixed Integer Linear Programming (MILP) model

This study uses an in-house MILP model that describes the CAR T-cell therapy supply chain, and it is used for the identification of optimal supply chain network structures (Triantafyllou *et al.* 2022a). The supply chain superstructure consists of 4 nodes—leukapheresis centre, manufacturing site, Quality Control (QC), and hospital. CAR T-cell manufacturing starts at the leukapheresis centre, where T-cells are isolated from the patient’s bloodstream and are cryopreserved before further processing. The leukapheresis sample is then shipped to the manufacturing facility, where it is genetically engineered to express the tumour-associated antigen receptor. Lastly, the therapy undergoes in-house Quality Control (QC) and once product quality and safety are ensured, it is shipped back to the hospital for administration to the patient. We consider 4 leukapheresis sites and 4 hospitals in the UK and 6 manufacturing sites located in the UK, US and Europe. The manufacturing facilities  $m$  have a capacity of 4 ( $m_1$  and  $m_4$ ), 10 ( $m_3$  and  $m_6$ ), or 31 ( $m_2$  and  $m_5$ ) parallel lines, and a forward-looking scenario of 8 days of manufacturing is considered. The model considers demand uncertainty, manufacturing capacity limitations, patient-specificity, time and location constraints, whilst the objective is to

minimize the total supply chain cost. Finally, the total turnaround time is expressed as a non-monetary supply chain metric modelled as a constraint.

## 2.2. Hybrid model

The data-driven part of the model is responsible for strategic planning by forecasting the optimal supply chain network configuration based on the annualized demand. Specifically, the ANN model predicts the number and the location of the manufacturing facilities to optimally satisfy the demand. The mechanistic MILP model is then solved considering only the subset of manufacturing facilities chosen by the ANN, becoming a subproblem of the original planning and scheduling model. Therefore, the MILP accounts only for detailed scheduling in the supply chain, which entails optimal transport modes for the node-to-node connections, optimal allocation of patient samples in the manufacturing facilities and hospitals, and the optimal utilisation of the available parallel lines in the manufacturing sites with the scope of minimising the therapy cost and return time. The hybrid model can significantly reduce computational complexity by eliminating branches of the search space. The model's performance is assessed for different randomized annual demand scenarios (100, 200, 500, 1000, 1500 and 2000 patients).

### 2.2.1 ANN training

The ANN is trained based on sets of feasible and optimal solutions obtained from the MILP for 760 randomized demand profiles. The input features considered for the ANN are the total daily demands for a quarter of a year (90 days), assuming a recurrent demand profile per trimester. Based on three different probability distributions, namely uniform distribution, left triangular distribution, and right triangular distribution, 660 randomized demand profiles were generated for demands between 50 and 2000 patients per year (Figure 2). For each leukapheresis site  $c$ , we assume a daily capacity of 8 patients. Different probability distributions are used to account for the uncertainty in demand and lead to robust solutions as the demand distribution highly affects supply chain structures. To generate the training labels, the MILP model was solved for each demand scenario using CPLEX. All inputs were normalized.

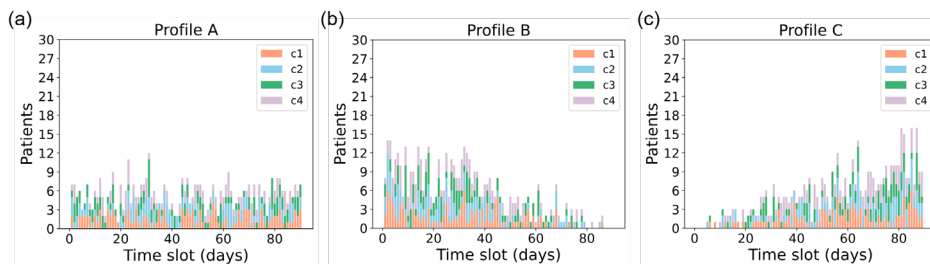

Figure 2. Randomized demand profiles for the 2000 patients' case for 3 different probability distributions: (a) uniform distribution (b) left triangular distribution (c) right triangular distribution.

A feed-forward ANN model is built in PyTorch for multi-label classification, where the labels are the 6 manufacturing facilities and the possibility of infeasible solutions due to limited facility capacity as seen in Figure 1. Multi-label classification is used so that more than one facility can be selected for each instance. However, because the original dataset was imbalanced, with classes  $m_6$  and infeasible being underrepresented, extra 100 randomized demand scenarios were generated and equally distributed for the 350, 500 and 2000 patients per year cases to balance the data and capture more instances where the

underrepresented classes are the solution. It should be noted that oversampling techniques for imbalanced classification datasets such as SMOTE do not apply to multi-label datasets. The data set is split into 80% for training and 20% for testing. The topology of the ANN was tuned using Grid Search and parameter tuning. To configure the feed-forward ANN, 90 input features, 3 hidden layers, 256 neurons at each hidden layer, and 7 output layers are used. Because multi-label classification is based on binary classification, the sigmoid activation function is used at each output layer node to predict a probability for each class in the output. The threshold that separates positive and negative classes is set at 0.5. Finally, the ReLU function is used in the hidden layers and the model is trained using the binary cross-entropy loss function and the Adam solver.

### 3. Results and discussion

The overall performance of the multi-label classification ANN model is measured by *accuracy* and additional extracted metrics from the *confusion matrix*, i.e. *precision*, *recall*, and *F-score* for each class and *micro*, *macro*, and *weighted* average of all classes (Table 2). Accuracy provides the number of correct predictions to the total number of labels (predicted and true). Precision and recall quantify the proportion of correctly predicted labels to the total number of true labels and the total number of predicted labels, respectively. On the other hand, the F1-score leads to a harmonic balance between precision and recall as it considers both. The ordinary 2-dimensional confusion matrix used in multi-class classification is undefined when it comes to multi-label classification, where each instance can be labelled with more than one class. To overcome this, the multi-label confusion matrix with one extra row (No True Label-NTL) and one extra column (No Predicted Label-NPL) is used (Heydarian *et al.*, 2022).

Table 1. Overall performance metrics for the ANN.

Class	Precision	Recall	F1-score	weight
m <sub>1</sub>	0.84	0.76	0.80	50
m <sub>2</sub>	0.92	0.88	0.90	67
m <sub>3</sub>	0.81	0.81	0.81	47
m <sub>4</sub>	0.85	0.73	0.79	15
m <sub>5</sub>	0.88	0.88	0.88	25
m <sub>6</sub>	0.78	0.90	0.84	20
infeasible	1	0.93	0.96	29
micro avg	0.84	0.84	0.84	253
macro avg	0.87	0.84	0.85	253
weighted avg	0.87	0.84	0.86	253

The resulting ANN has a train set overall accuracy of 98.5% and a test set overall accuracy of 95%. The rest of the performance metrics for each class are presented in Table 1. The ANN performs relatively well, as the average precision, recall and F1-score are above 84%. It should be noted that the ANN model is trained with three different demand distributions to better cope with demand uncertainty. This can lead to different supply chain structures for the same yearly demands. Hence, there is a possible trade-off between model accuracy and robustness to demand uncertainty.

It is observed that class m<sub>4</sub> has the lowest F1-score (0.79). The precision and recall for this class are 0.85 and 0.73, respectively, indicating more false negatives (*FN*) for this class than false positives (*FP*). By looking at the confusion matrix in Figure 3, it can be seen that the model confuses facility m<sub>4</sub> (4 parallel lines) with facility m<sub>3</sub> (10 parallel

lines) and with the no-label prediction. Specifically, while the model predicts correctly in 73% of the instances that  $m_4$  belongs to the optimal supply chain configuration, in 13% of the instances it confuses facilities  $m_4$  and  $m_3$  and in 13% of the instances, it fails to predict  $m_4$  as an extra required facility. These mispredictions are sensible as in some cases the model overpredicts by choosing a slightly bigger facility to facilitate the demand and in other cases, it underpredicts by failing to add an extra facility. In the former case, the hybrid model leads to local optimum solutions, whereas in the latter case the model leads to infeasible solutions.

Figure 3. Normalised multi-label confusion matrix with one extra row for No True Labels (NTL) and one extra column for No Predicted Labels (NPL).

Similar behaviour is observed with facility  $m_1$ , where the recall is 0.76. Figure 3 shows that in 12% of the instances the model fails to predict that  $m_1$  is a required extra facility to satisfy the demand, thus leading to infeasible solutions. It is important to note, that the classifier is very accurate in terms of infeasibilities. The precision for infeasible solutions is 100%, which means that the classifier never predicts feasible solutions as infeasible. In rare occasions (3% of the cases) the hybrid model assumes infeasible solutions as feasible.

In those cases, the MILP part of the model will determine the infeasibility of the solutions.

In Figure 4, the performance of the hybrid model is showcased in terms of model complexity by

Figure 4. Comparison of the original MILP model with the hybrid model for an increasing number of annual demands in (a) the number of constraints, and (b) the number of binary variables.

evaluating the number of constraints and binary variables for both the original mechanistic model and the proposed hybrid model. The hybrid model can reliably reduce the computational burden by decreasing the total number of linear constraints by 65%–81% and the total number of binary variables by 67%–83% as shown in Figure 4. In cases of 500 and 1000 patients per year, the hybrid model is described by almost the same number of constraints and binary variables. This is attributed to the fact that in the 1000 patients per year case, the classifier predicted that only one large facility with 31 parallel lines ( $m_2$ ) can satisfy the demand, and hence the feasible search space for the MILP model was significantly reduced.

#### 4. Conclusions

In this study, a framework that integrates a multi-label classification feed-forward neural network with a MILP model in order to decompose large-scale supply chain problems is presented. The unique CAR T-cell therapy supply chain model is used as the case study. The data-driven part of the hybrid model accounts for strategic planning and the mechanistic part is responsible for detailed scheduling. The framework proposes a novel method to account for demand uncertainty using machine learning techniques, resulting in robust supply chain structures. The overall accuracy of the classifier is 95%, with just a few cases leading to suboptimal or infeasible solutions. The computational analysis exhibited significant improvements over the original MILP model. A key novelty of this work is the ability of the hybrid model to solve larger problem instances, for which the MILP problem did not manage to converge to a feasible solution. The efficiency of the hybrid model creates new possibilities to explore, such as the use of convolutional neural networks for improved classification accuracy.

# Optimal energy management in greenhouses using distributed hybrid DRL-MPC framework

Benjamin Decardi-Nelson,<sup>a</sup> Fengqi You<sup>a</sup>

<sup>a</sup>*Cornell University, Ithaca, New York, 14853, USA*

## Abstract

In this work, we propose a framework for optimal energy management of greenhouses, which considers the presence of both discrete-valued and continuous-valued actuators in the controller design. To reduce the computational burden because of having to solve mixed-integer nonlinear optimal control problems online, we propose to decompose the system model based on the type of actuators. The underlying subproblems are solved using a hybrid deep reinforcement learning (DRL)-model predictive control (MPC) framework in a distributed manner. We use a greenhouse case study to demonstrate the effectiveness of the proposed control framework.

**Keywords:** MPC, greenhouse, energy management, deep reinforcement learning.

## 1. Introduction

Greenhouses are intensified crop production systems that have a potential to improve the resilience of the food system in a sustainable way (Chen et al., 2022). One of the main drawbacks of greenhouses is the enormous energy consumption of their microclimate control activities such as lighting, heating, ventilation, and air conditioning activities (Vadiee & Martin, 2012). Because the rule-based control methods traditionally used in greenhouses are unable to optimally manage the energy usage and ensure constraint satisfaction, optimization-based model predictive control (MPC) has been proposed as a better alternative (Hu & You, 2022). Unfortunately, the effective operation of greenhouses relies on equipment with discrete-valued actuation, like ventilation window opening and lights, which complicate the design and implementation of MPC (Chen et al., 2021). This is because the underlying centralized MPC optimization problem becomes a parametric mixed-integer nonlinear (possibly non-convex) optimization problem (MINLP), which may be challenging to solve repetitively online. To facilitate the adoption of MPC in greenhouse operation, efficient control methods are needed. The use of data-driven techniques to address robustness and computational issues in MPC is on the rise (Chen and You, 2022). In particular, the use of machine learning to assist in solving mixed-integer MPC (MIMPC) problems has received considerable attention (Löhr et al., 2020; Cauligi et al., 2021). However, the approaches focus on only linear problems. Moreover, the authors assume that solutions of the original MIMPC problem can be readily obtained. Often, these solutions for large scale MIMPC optimization problems are difficult to obtain. In this work, we propose a novel distributed hybrid deep reinforcement learning (DRL)-MPC framework to address the greenhouse optimal control problem. The proposed control framework exploits the attractive features of both DRL and MPC, that is, fast discrete-valued sequential decision making, and optimal control with constraint satisfaction (Ning et al., 2021), respectively. This is achieved by first decomposing the greenhouse optimal control problem into two sub-problems based on the type of actuation, namely discrete-valued or continuous-valued. Thereafter, we train the DRL to make the discrete-valued decisions while the MPC handles the

continuous-valued decisions. Similar to the approaches used in distributed MPC (DMPC), the two controllers cooperatively determine the optimal input sequence to be sent to the greenhouse system at each time-step in a receding horizon manner. We demonstrate the effectiveness of the proposed framework using a greenhouse case study.

## 2. Greenhouse optimal control problem

In this section, we present the details of the greenhouse model and formulate the associated mixed-integer model predictive control problem.

The greenhouse model used in this work is a discrete-time version of the model used in the study by Van Henten (2003). The model is a nonlinear system of ordinary differential equations (ODEs) described by the equation

$$x_{k+1} = f(x_k, u_k, v_k) \quad (1)$$

where  $x_k$  denotes the states of the system at time-step  $k$ ,  $u_k$  denotes the continuous-valued control actions,  $v_k$  represents the discrete-valued control actions and  $f$  represents the nonlinear ODEs. The states of the system are the crop dry weight, carbon dioxide concentration, air temperature and humidity in the greenhouse. The continuous-valued control actions are the carbon dioxide enrichment, heating and cooling systems, and the (de)humidification system. The discrete-valued control actions on the other hand are the supplemental lighting and vent opening, which can either be turned on/open or off/closed. Throughout this article, the states and the inputs are constrained to be in the sets

$$x_k \in X, u_k \in U, v_k \in V = \{0,1\} \quad (2)$$

The objective of the control system is to minimize the energy consumption while ensuring a higher crop growth rate. This control problem can be formulated as a mixed-integer MPC (MIMPC) described in Equation (3).

$$\min_{u_k, v_k} \sum_{k=0}^{N-1} L(x_k, u_k, v_k) \quad (3a)$$

$$s. t. \quad x_{k+1} = f(x_k, u_k, v_k) \quad (3b)$$

$$x_0 = x(t) \quad (3c)$$

$$x_k \in X, u_k \in U, v_k \in V \quad (3d)$$

In (3), Equation (3a) is the objective function to be minimized, Equation (3b) is the nonlinear system model described in (1), Equation (3c) denotes the initial state constraint and Equation (3d) represents the state and input constraints. At each sampling time  $k$ , the MIMPC optimization problem in (3) is solved to obtain a sequence of optimal values of the continuous-valued and discrete-valued control actions. As consistent with an MPC implementation, only the first control actions ( $u_0^*, v_0^*$ ) of the optimal sequence are applied to the system in a receding horizon manner (Mayne et al., 2000). The feasibility issue is guaranteed via soft constraints (Lu et al., 2020). As mentioned earlier, the presence of both continuous and discrete decisions in the MIMPC optimization problem (3) results in having to solve an MINLP online several times. This can be computationally difficult to solve (Shang et al., 2019). In this article, we proposed a computationally efficient hybrid distributed framework that takes advantages of the improvements in deep reinforcement learning (DRL) and standard model predictive control.

## 3. Optimal control using distributed hybrid algorithm

The presence of both discrete-valued and continuous-valued actions in the MPC formulation makes it computationally demanding to implement as an online control algorithm. In this section, we present a novel distributed hybrid algorithm that considers the strength of both model predictive control and deep reinforcement learning. The central idea we employ in this framework is to use a deep Q network (DQN) policy obtained

from DRL to make the discrete-valued decisions. By fixing the discrete decisions in the original MIMPC optimization problem in (3), a simpler nonlinear problem (NLP) can easily be solved online. To achieve this, we reformulate the MIMPC optimization problem. We begin this section by first describing the reformulation. Thereafter, we present the details of the DRL. Finally, we describe and discuss the implementation details of the proposed framework. In general, it is difficult to solve mixed-integer optimization problems. This is because the complexity of the optimization problem increases exponentially in the discrete-valued decision variables. While there have been improvements in algorithms for solving such problems, using these algorithms in an online setting may be limiting. To address this, we propose to reformulate the optimization problem such that a deep reinforcement learning algorithm learns to make the discrete-valued decisions. These decisions are then fixed in the MPC optimization problem, thus resulting in having to solve online an NLP.

Let  $\tilde{v}_k$  approximate the discrete-valued decision variables in the optimal control problem described in (3) at each time-step  $k$ . If the discrete-valued variables in (3) are fixed, then the resulting optimization problem becomes an NLP which can be solved efficiently using standard NLP solvers such as IPOPT. Notice that  $N - 1$  discrete decision variables need to be determined in the optimal control problem. In contrast to the approach proposed by Löhner et al. (2020) where only the first discrete variables are fixed with the approximated value, we take a distributed approach. The reformulated optimization problem is described in (4).

$$\min_{u_k, v_k} \sum_{k=0}^{N-1} L(x_k, u_k, v_k) \quad (4a)$$

$$s. t. \quad x_{k+1} = f(x_k, u_k, v_k) \quad (4b)$$

$$x_0 = x(t) \quad (4c)$$

$$u_k \in U, v_k \in V \quad (4d)$$

$$v_k = \tilde{v}_k \quad (4e)$$

The details of the equations in (4) remain the same as that of (3). Equation (4e) ensures that the discrete valued decisions remain fixed with the approximate values from the DQN policy. To ensure feasibility of the optimization problem, the state constraint is relaxed. The objective of the DRL neural network policy is to make one-step discrete-valued decisions  $\tilde{v}_k$  given the state information  $x_k$  (Ajagekar et al., 2023). Let us denote the neural network policy as  $P$ , then the policy is described by the mapping  $P: x_k \in R^{n_x} \rightarrow \tilde{v}_k \in R^{n_v}$  where  $n_x$  and  $n_v$  denote the dimension of the state and discrete-valued action spaces respectively. Because the state variables are continuous-valued and the actions are discrete-valued, we use DQN reinforcement learning algorithm (Minh et al., 2015).

The implementation detail of the control algorithm is summarized in Figure 1. At each time-step, an estimate of the discrete actions is used in the reformulated MPC optimization problem described in (4) to obtain the state predictions and the optimal continuous-valued actions. The state predictions are sent to the DQN policy to determine an improved estimate of the discrete-valued decisions. This procedure is repeated until the stopping criteria is achieved. Notice that the proposed framework is no different from the DMPC framework, where information is repeatedly exchanged between two or more MPC-NLPs (Christofides et al., 2013). The difference here is that the communication is between an MPC-NLP and a DQN policy. Again, like DMPC algorithms, an initial guess of the subsystem solutions is required at the start of the algorithm, and a termination criterion needs to be specified. The stopping criteria employed in this work are either the

sum of the absolute difference between any two successive discrete actions from the DQN policy is less than 1 or the maximum number of iterations is reached.

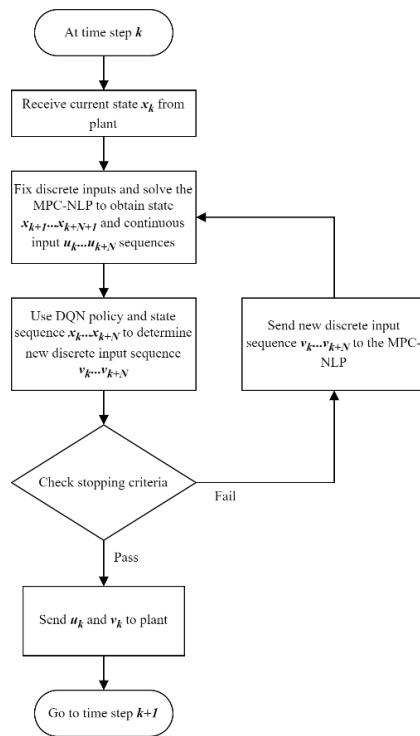

Figure 1. Implementation details of the distributed hybrid algorithm.

Figure 2. Crop growth profile after 5 days.

#### 4. Simulation results

In this section, we demonstrate the efficacy of the proposed hybrid algorithm using a case study. We begin this section by first presenting the simulation settings. Thereafter, we present the results of the proposed algorithm. In this work, we assume that the external weather conditions are known and constant. The values for the external climate conditions include external temperature of 20 °C, external humidity of 400 ppm, the solar radiation at 100 W/m<sup>2</sup> and off at night (Yang et al., 2022). The control objective is to track the setpoints for the CO<sub>2</sub> concentration, relative humidity, and greenhouse air temperature

which are determined as 1000 ppm, 70 % and 24 °C respectively. The photoperiod is set at 16 hours on period and 8 hours off period. The sampling time is fixed at 10 minutes and the MPC horizon is fixed at 12 which represents a two-hour prediction horizon. All computations were conducted on laptop with an Intel 2.2 GHz quadcore processor, 16 GB random access memory (RAM) and 2 GB of video RAM. The profiles of the greenhouse system under the action of the proposed control framework are presented in Figures 2 – 4. As can be observed in the profiles, the proposed control framework is able to ensure a steady crop growth rate. From Figure 2, the controller turns on the supplemental lighting in a similar fashion as the photoperiod to supplement the external light intensity entering the greenhouse. The controller optimally turns the supplemental lights off when it is not required, thus reducing energy consumption. Similarly, the controller uses the vent opening as an economizer to reduce the cooling requirements in the greenhouse. It is worth mentioning that the entire 5-day simulation took less than 5 minutes to complete.

Figure 3. Control profiles for the continuous-valued actions.  $u_1$ ,  $u_2$  and  $u_3$  denote the supplemental CO<sub>2</sub> supply rate, (de)humidification rate and the cooling/heating rates respectively.

Figure 4. Control profiles for the discrete-valued actions.  $v_1$  and  $v_2$  denote the on/off state of the supplemental lighting and the open/close state of the vent opening respectively.

## 5. Concluding remarks

In this article, we have presented a novel MPC algorithm to optimally manage the energy resource in a greenhouse. A DRL neural network policy is trained to determine

approximations of the discrete decisions, which is then fixed in the original MPC optimization problem. This reduces the online computational burden in the control system implementation. A simulation case study demonstrates the efficacy of the proposed approach to ensure steady crop growth in the greenhouse.

## Abstract

In this work, two model-based reinforcement learning (RL) control strategies are investigated namely a multi-agent RL and RL-based adaptive PID control. An off-policy deep deterministic policy gradient (DDPG) was adopted in both cases to achieve optimal trajectory tracking control of crystallization processes. Two case studies were considered to validate the new control strategies. The first is the cooling and antisolvent crystallization of aspirin in a mixture of ethanol and water, and the second is a 2-dimensional (2D) cooling crystallization of potassium dihydrogen phosphate in water. The optimal reference trajectories were identified using model-based dynamic optimization approaches which aim at maximizing the mean crystal size/minimizing the aspect ratio. Transfer Learning (TL) techniques and various reward-shaping strategies were also investigated to enhance the learning capabilities of the RL control. The results indicate that multi-agent RL saves massive training costs, compared to single agent, and RL-based adaptive PID exhibits excellent performance against state-of-the-art MPC.

**Keywords:** Multi-agent Reinforcement Learning; Transfer Learning; Adaptive PID; Semi-Batch Antisolvent and Cooling Crystallization; 2-Dimensional Crystallization Model.

## 1. Introduction and background

As one of the oldest purification technologies, crystallization has widespread applications in the pharmaceutical industry to separate and purify active pharmaceutical ingredients (API). One of the most critical features in pharmaceutical manufacturing is the stringent regulation associated with the product quality control where small deviations from the target quality profiles may significantly impact drug safety and efficacy and may lead to failures during clinical trials or even product recalls (Mascia et al., 2013). In recent years, thanks to the development of process analytical technologies (PAT), real-time measurement, monitoring and control of the crystal size and shape become achievable during the crystallization which opened new opportunities to implement advanced control strategies such as model predictive control and Artificial Intelligence based techniques such as Reinforcement Learning (Benyahia et al., 2021).

The most common control objective in crystallization processes is to maximize the mean crystal size due to its dramatic impact on the drug product's critical quality attributes, such as dissolution rate and efficacy, and on the downstream operations, such as filtration and drying (Fysikopoulos et al., 2019). Supersaturation is the fundamental driving force

in crystallization, which is typically generated by either cooling, evaporation or antisolvent addition (Liu and Benyahia, 2022). Over the last two decades, model-free and model-based techniques have been extensively investigated to control and optimize crystallization processes (Lakerveld and Benyahia, 2020). However, there is still an increasing demand for more robust techniques for real time monitoring, optimization, and control to achieve precision and simultaneous control of several critical quality attributes such as purity, crystal size and shape distribution.

Over the last few years, machine learning (ML) applications have witnessed rapid growth in many research and industrial areas. Reinforcement learning (RL) has been successfully implemented in dynamic systems particularly in robotics and automotive industries because of its ability to solve a wide range of sequential decision-making problems (Canese et al., 2021). Most of the MARL applications were developed for unmanned aerial vehicles (UAV), optimal path planning (Qie et al., 2019); resource allocation and energy efficiency (Cui et al., 2020). These recent successful applications have motivated further exploration of RL capabilities as a new control strategy for crystallization (Benyahia et al., 2021).

In this study, two crystallization case studies are presented where different types of RL model-based control methods are implemented. The first case study presents an antisolvent and cooling crystallization of aspirin (acetylsalicylic acid, ASA) in a mixture of ethanol (solvent) and water (antisolvent) with a mathematical model based on population balance equations (PBE) is used. The second case study presents a 2-Dimensional (2D) cooling crystallization process of potassium dihydrogen-phosphate (KDP) in water modelled using a 2-dimensional (2D) PBE to enable crystal shape prediction and control. Firstly, a model-based optimization approach is formulated to determine the reference trajectories that maximize the critical quality attributes. A MARL and RL-PID are developed as control approaches for both case studies respectively. Both RL agents are designed based on an off-policy deep deterministic policy gradient (DDPG) then trained to track several reference trajectories, which include process temperature, supersaturation, and particle size or/and shape. The performance of the proposed RL-based control strategies is compared against a single agent RL and model predictive control (MPC).

## 2. Problem Formulation

### 2.1 Process Modelling

The ultimate objective of this work is to exploit multi-agent RL and RL-based techniques to build responsive and efficient control strategies for batch and semi-batch crystallization processes. The mathematical model associated with the first case study was obtained from the literature (Nagy et al., 2008). The growth and nucleation kinetic parameters obtained from Barik et al., 2020. The 2-dimensional mathematical model associated with the second case study was obtained from Fysikopoulos et al., 2019. Both mathematical models were experimentally validated in the original studies. A few assumptions were considered to build the models which includes: (i) the vessel is assumed to be well-mixed; (ii) crystal breakage and agglomeration of fine crystals are negligible; (iii) crystals growth is size-independent. (iv) crystal growth and dissolution do not affect the total volume. For

the sake of brevity, the mathematical formulation and PBE for both models are not presented here.

### 2.2 Process optimization

The optimization strategy is required to ensure the best design options and optimal operational performance of the two crystallization simulation processes. It will also provide the reference trajectory profiles for control and operation purposes when applying the RL strategies. In this study, the model-based open-loop dynamic optimization method is implemented to maximize the mean crystal size/minimize the aspect ratio. The decision variables used in the first case study are the jacket temperature ( $T_j$ ) and the antisolvent flowrates ( $F_A$ ) whereas the process temperature is used in the second case study.

### 2.3 Reinforcement Learning

The development of effective two-agent RL and RL-PID are the primary objectives of this study. These objectives translate into tracking the reference trajectories that maximize crystal mean size, in case study one, and minimize the crystal aspect ratio in case study two. The reference profiles of the process temperature, supersaturation, particle size, and aspect ratio were computed using a model-based open-loop optimal control strategy. The RL agents in both case studies were developed using MATLAB Simulink and trained to reach the best control performance corresponding to the maximum rewards. Here, an off-policy actor-critic agent based on deep deterministic policy gradient (DDPG) was used to improve effective tracking control through computing the optimal control policies that maximize the total rewards (Benyahia et al., 2021).

#### 2.3.1 Two-agent reinforcement learning

Figure 1 shows the structure of the two-agent RL. Jacket temperature and antisolvent flowrate were used separately as the manipulated variables for each RL agent to control the crystallization process.

The RL objective is to maximize the rewards/minimize penalties. RL agent 1 receives one observation (process temperature) and takes one action (cooling rate) whereas RL agent 2 observes two controlled outputs, which are supersaturation and particle size, and takes one action (antisolvent flowrate). The two actions work together to maximize the instantaneous and cumulative rewards of the agents to achieve effective training.

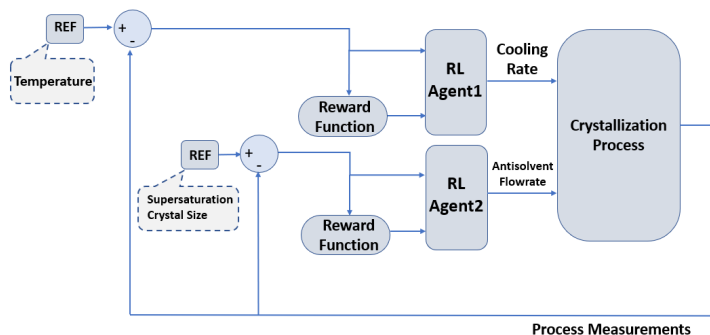

Figure 1. Block diagram of closed-loop two-agent RL.

### 2.3.2 RL-PID

The RL-PID is designed to combine an RL agent and a conventional PID control as a cascade structure to achieve effective control performance. Here, the cooling rate is used as the controlled variable and the tuning parameters of the PID,  $k_p$ ,  $k_i$  and  $k_d$ , are the agent 'actions'. The reference tracking trajectories for the RL agent are the temperature, supersaturation, crystal size and aspect ratio.

### 2.4 Reward Shaping

The reward function used in both case studies is described in figure 2 below. It is defined based on penalties only. Therefore, zero is the maximum attainable theoretical value.

$$R_t = \left\{ \begin{array}{l} \text{Penalty for temperature tracking} \\ \text{Penalty for Supersaturation tracking} \\ \text{Penalty for particle size tracking} \\ \text{Penalty for Aspect Ratio tracking} \end{array} \right\}$$

$$R_t = \left\{ \begin{array}{l} \left( 0(|T_e| \leq 0.1) \vee -10(|T_e|) \right) + \left( 0(|S_e| \leq 0.1 \times 10^{-3}) \vee -2 \times 10^4(|S_e|) \right) + \left( 0(|L_e| \leq 1) \vee -30(|L_e|) \right) + \left( 0(|AR_e| \leq 0.01) \vee -20(|AR_e|) \right) \end{array} \right\}$$

Figure 2. Simplified overview of the reward function.

### 2.5 Transfer Learning

Transfer learning (TL) is a technique which is commonly used in RL to allow the agent to learn from previous agent experiences. The main advantage of TL is to improve training performances by implementing a sequence of relatively simple and attainable training objectives to help achieve the final training target gradually (Benyahia et al., 2021). In this study, TL is utilized by training the agents with an increased number of reference trajectories sequentially. Furthermore, error tolerances were also tightened gradually to improve tracking accuracy.

## 3. Result and Discussion

The corresponding training results indicated that two-agent RL requires less training episodes compared to a single-agent RL. This key advantage may save massive time-cost in the design and implementation of advanced control systems. Figure 3 shows the validation results where the performance of the two-RL agent is compared against a single agent RL in case study one. The sum of the squared errors (SSE) is computed and shown in Figures 3d, e and f to provide more quantitative insights to compare the accuracy of both control strategies. Both control methods can achieve trajectory tracking objectives to maintain the error within the acceptable range (Figures 3a, b, and c). However, the SSE indicates that a single agent exhibits a more effective performance compared to the two-agent RL in terms of accuracy.

Figure 4 presents a comparison between RL-PID and MPC in the 2D PMB model in case study 2. Here, the MPC is also developed in MATLAB/SIMULINK using basic tuning

parameters. Overall, the RL-PID shows better performance in accuracy compared to the MPC for the 2D crystallization process of KDP.

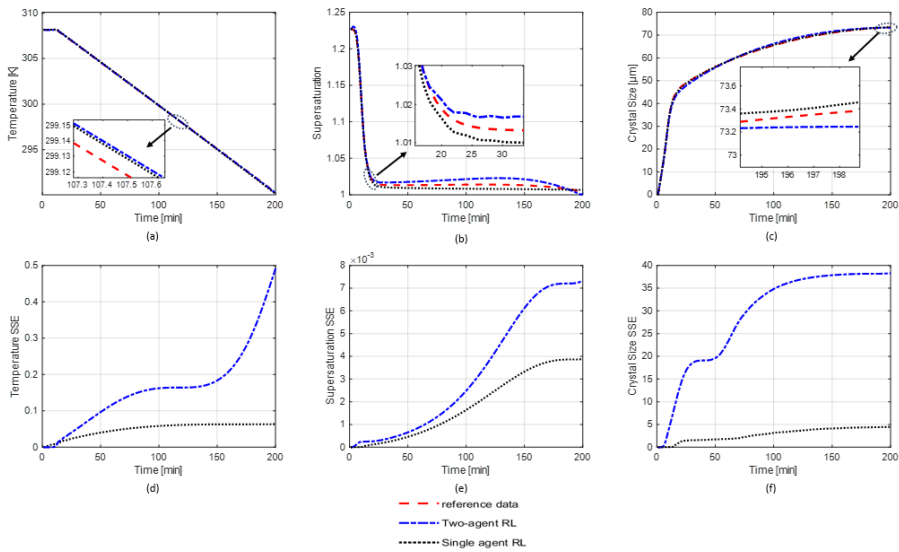

Figure 3. Validation results of the two RL agents vs single RL agent

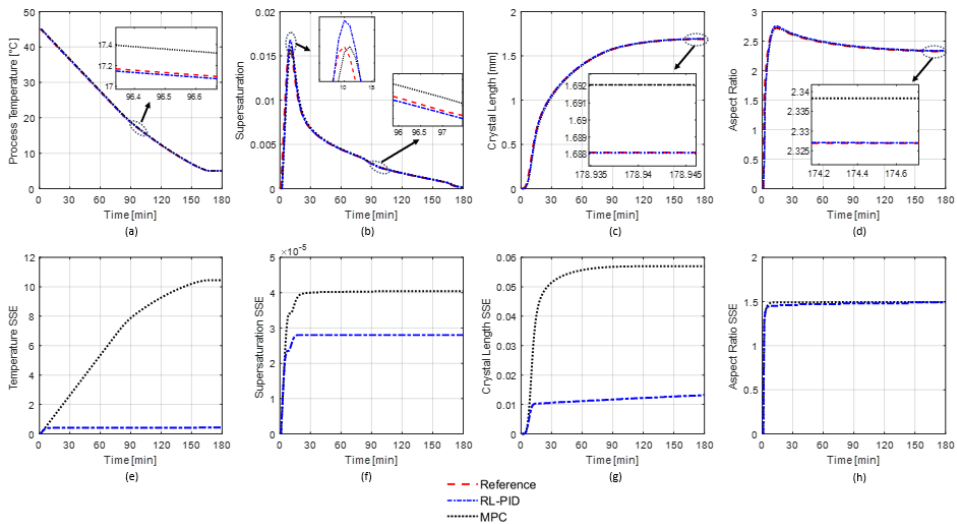

Figure 4. Overview of the comparisons between RL-PID and MPC

The simulation results depicted in Figures 4c and d show the tracking control performance of RL-PID with respect to one of the critical quality attributes, the crystal size and shape. Here, the RL-PID exhibits effectively and precise tracking performance. Figures 4e, f, g and h, provide more insights to further qualitatively investigate the performance of the RL-PID against MPC using the SSE. Overall, the RL-PID controller exhibits lower SSE compared to the MPC.

#### 4. Conclusions

A model-based RL with multiple agents and an RL-PID strategy was designed to achieve trajectory tracking control of an antisolvent cooling semi-batch and a cooling-only batch crystallization process. The proposed RL agents were based on the DDPG algorithm and were effectively trained using penalties only rewarding and transfer learning. Overall, both RL approaches exhibited excellent tracking performance. The results associated with case study one demonstrated that the two RL agents require less training time compared to the TL support single agent which reduces the training costs as a potential benefit. The results associated with case study two revealed that RL-PID can achieve more effective and accurate crystal size and shape control by tracking the optimal trajectories compared to the model predictive control.

# Globally Convergent Composite-Step Trust-Region Framework for Model-Based Real-Time Optimization

Duo Zhang<sup>a</sup>, Xiang Li<sup>b</sup>, Kexin Wang<sup>a</sup>, Zhijiang Shao<sup>a</sup>

<sup>a</sup> *College of Control Science and Engineering, Zhejiang University, Hangzhou, 310027, China*

<sup>b</sup> *Department of Chemical Engineering, Queen's University, Kingston, ON K7L 3N6, Canada*

## Abstract

In model-based static real-time optimization (RTO), trust-region framework is globally convergent for unconstrained problems. However, it remains to be seen if the trust-region strategy can handle constraints directly with theoretical optimality guarantees. This paper addresses this issue and proposes a novel composite-step trust-region framework that guarantees global convergence for constrained RTO problems. In each iteration, the trial step is decomposed into a normal step that improves feasibility and a tangential step that reduces the cost function. Simulation results show that the proposed algorithm converges to the plant optimum in the presence of structural plant-model mismatches and wrong model curvatures. The proposed composite-step approach is more advantageous than the penalty approach because it needs a smaller penalty coefficient and does not suffer from ill-conditioned problems due to a large penalty coefficient.

**Keywords:** trust region, composite step, inequality constraints, global convergence, real-time optimization.

## 1. Introduction

Model-based optimization and control are important for achieving operational excellence. However, plant-model mismatches may influence practical performance and even cause convergence problems. Thus, handling mismatches by reliable optimization algorithms aroused great interest. In static model-based real-time optimization (RTO), algorithms based on gradient matching ideas can guarantee upon-convergence optimality in the presence of structural plant-model mismatch [1,2]. However, they are not globally convergent and may cause oscillation due to an inadequate model [3].

There are two ways to achieve global convergence in RTO. First, global convergence is a byproduct of feasible-side convergence. In this case, algorithms [4,5] rely on additional plant information such as Lipschitz constants or global upper bounds, which could be hard to get. Second, globalization strategies in nonlinear optimization are adopted. Among them, trust-region method [6] is the most natural for model-based RTO problems. Bunin [7] showed that the trust-region framework can be applied to unconstrained RTO problems. In each iteration, the next input is restricted to the trust region, where plant-model mismatches are small. However, constrained RTO problems have to be converted

to unconstrained ones by the penalty function to be incorporated into this framework [8]. It remains unclear if the trust-region strategy can handle constrained RTO problems directly with theoretical optimality guarantees. There are several benefits to preserving inequality constraints. On the one hand, it is more intuitive and more compatible with existing RTO algorithms. On the other hand, it is also more reliable since the physical model restricts the trial step. This paper addresses this issue and proposes a novel composite-step trust-region framework for constrained RTO problems.

## 2. Preliminaries

### 2.1. Model-Based Static Real-Time Optimization

We consider the optimization of a continuous process operating at steady states. The plant optimization problem can be stated as problem (1).  $u$  is the input variable,  $\phi$  is the cost function, and  $g$  is the constraints. The subscript  $p$  denotes the plant.

$$\begin{aligned} \min_u \phi_p(u) \\ \text{s. t. } g_p(u) \leq 0 \end{aligned} \quad (1)$$

The mathematical representation of the plant is unknown, so the model optimization problem (2) with subscript  $m$  is solved in each RTO iteration to calculate optimal  $u$ .

$$\begin{aligned} \min_u \phi_m(u) \\ \text{s. t. } g_m(u) \leq 0 \end{aligned} \quad (2)$$

However, plant-model mismatches exist, i.e.,  $\phi_p \neq \phi_m$  and  $g_p \neq g_m$ , and may lead to suboptimal or even infeasible input. Therefore, the model needs to be adapted based on the local information around  $u_k$  at each iteration, and the model optimization problem (3) then uses this adapted model, where subscript  $k$  indicates the  $k$ th RTO iteration.

$$\begin{aligned} \min_u \phi_{m,k}(u) \\ \text{s. t. } g_{m,k}(u) \leq 0 \end{aligned} \quad (3)$$

To deal with structural plant-model mismatch, the functions  $\phi_{m,k}$  and  $g_{m,k}$  in problem (3) are supposed to satisfy condition (4) given the information of plant output ( $\phi_p(u_k)$ ,  $g_p(u_k)$ ) and plant derivatives ( $\nabla\phi_p(u_k)$ ,  $\nabla g_p(u_k)$ ). Condition (4) means gradient matching between the model and the plant and leads to KKT matching upon convergence. There are various ways to do this, e.g., [1,2].

$$\phi_{m,k}(u_k) = \phi_p(u_k) \quad (4a)$$

$$g_{m,k}(u_k) = g_p(u_k) \quad (4b)$$

$$\nabla\phi_{m,k}(u_k) = \nabla\phi_p(u_k) \quad (4c)$$

$$\nabla g_{m,k}(u_k) = \nabla g_p(u_k) \quad (4d)$$

### 2.2. Trust-Region Framework for Unconstrained Problems

Algorithms that solve problem (3) repeatedly based on local models only guarantee upon-convergence optimality. Inadequate models [3] and improper algorithm parameters [2] could lead to oscillation. To address this, Algorithm 1 based on the trust-region framework was proposed [7,8].

#### **Algorithm 1, Trust-Region Algorithm for Unconstrained Problems**

**Step 0: Initialization.** Choose an initial point  $u_0$ , an initial trust-region radius  $\Delta_0 > 0$ . Choose constants  $0 < \eta_1 \leq \eta_2 < 1$ ,  $0 < \gamma_1 < 1$ .  $k \leftarrow 0$ .

**Step 1: Model adaptation.** Build a model satisfying Eqs. (4).

**Step 2: Step calculation.** Minimize the cost function of the model to obtain the step  $s_k$ .

$$\begin{aligned} s_k = \arg \min_s \phi_{m,k}(u_k + s) \\ \text{s. t. } \|s\| \leq \Delta_k \end{aligned} \quad (5)$$

Step 3: Acceptance of the trial point. Compute the ratio

$$\rho_k = \frac{\phi_p(u_k) - \phi_p(u_k + s_k)}{\phi_{m,k}(u_k) - \phi_{m,k}(u_k + s_k)} \quad (6)$$

If  $\rho_k > \eta_1$ , then define  $u_{k+1} = u_k + s_k$ ; otherwise, define  $u_{k+1} = u_k$ .

Step 4: Trust-region radius update. Set

$$\Delta_{k+1} \in \begin{cases} \min(\Delta_k, \Delta_{\max}) & , \text{ if } \rho_k > \eta_2, \\ \Delta_k & , \text{ if } \rho_k \in [\eta_1, \eta_2), \\ \gamma_1 \Delta_k & , \text{ if } \rho_k < \eta_1. \end{cases} \quad (7)$$

$k \leftarrow k + 1$ . Go back to Step 1.

In Step 2, the trial step is determined by minimizing the adapted model cost within the trust-region constraint. After applying the trial step to the plant and getting new measurements, we compare the actual improvement to the value predicted by the model in Step 3. The trial point is accepted as the next iterate if sufficient improvement is made. Otherwise, the trust region shrinks, and hopefully, the model provides a better prediction in a smaller region.

### 2.3. Penalty Method for Constrained Problems

Constrained RTO problems are more complicated because there are two aims: minimizing the cost function and reducing infeasibility. The penalty trust-region algorithm [8] converts the constrained problem to an unconstrained one by the merit functions (8), where  $c(u)$  is the infeasibility at the current point and  $\sigma > 0$  is the penalty coefficient.  $c(u)$  is calculated by Eqs. (9).

$$f_p(u, \sigma) = \phi_p(u) + \sigma c_p(u) \quad (8a)$$

$$f_{m,k}(u, \sigma) = \phi_{m,k}(u) + \sigma c_{m,k}(u) \quad (8b)$$

$$c_p(u) = \|\max(g_p(u), 0)\| \quad (9a)$$

$$c_{m,k}(u) = \|\max(g_{m,k}(u), 0)\| \quad (9b)$$

If the penalty coefficient  $\sigma$  is large enough, then Algorithm 1 with  $\phi(u)$  replaced by  $f(u, \sigma)$  is globally convergent [8]. However, determining  $\sigma$  is not easy because it depends on the specific problem, and a too large  $\sigma$  causes numerical difficulties.

## 3. Composite-Step Trust-Region Framework

In this section, we propose a novel trust-region algorithm for constrained RTO problems that deals with inequality constraints directly.

### 3.1. Algorithm Description

#### **Algorithm 2, Composite-Step Trust-Region Algorithm**

Step 0: Initialization. Choose an initial point  $u_0$ , maximum trust-region radius  $\Delta_{\max} > 0$ , an initial trust-region radius  $\Delta_0 \in (0, \Delta_{\max})$ , and a sufficiently large penalty parameter  $\sigma > 0$ . Choose constants  $0 < \eta_1 \leq \eta_2 < 1$ ,  $0 < \gamma_1 < 1$ ,  $0 < \xi < 1$ .  $k \leftarrow 0$ .

Step 1: Model adaptation. Build a model satisfying Eqs. (4).

Step 2: Normal step calculation. Move towards feasibility.

$$n_k = \arg \min_n c_{m,k}(u_k + n) \quad (10)$$

$$\text{s. t. } \|n\| \leq \xi \Delta_k$$

Step 3: Tangential step calculation. Compute a step  $t_k$  by

$$t_k = \arg \min_t \phi_{m,k}(u_k + n_k + t)$$

$$\text{s. t. } c_{m,k}(u_k + n_k + t) \leq c_{m,k}(u_k + n_k) \quad (11)$$

$$\|n_k + t\| \leq \Delta_k$$

Step 4: Acceptance of the trial point. The composite step is  $s_k = n_k + t_k$ . Compute the ratio

$$\rho_k = \frac{f_p(u_k, \sigma) - f_p(u_k + s_k, \sigma)}{f_{m,k}(u_k, \sigma) - f_{m,k}(u_k + s_k, \sigma)} \quad (12)$$

If  $\rho_k > \eta_1$ , then define  $u_{k+1} = u_k + s_k$ ; otherwise, define  $u_{k+1} = u_k$ .

Step 5: Trust-region radius update. Set  $\Delta_{k+1}$  according to Eq. (7). Go back to Step 1.

The composite step idea comes from [6]. The overall step is decomposed into a normal step that improves feasibility and a tangential step that reduces the cost function. By adjusting  $\xi$ , we change the step size for cost reduction and infeasibility reduction, and the overall step size is bounded by  $\Delta_k$ . Since the feasible set of problem (3) may not intersect with the trust region, small infeasibility has to be allowed during the iteration as long as there is a trend toward feasibility.

In Step 1, any model adaptation approach satisfying Eqs. (4) can be used, e.g., modifier adaption [1] and generalized parameter estimation [2]. In Step 2 and 3, the inequality-constrained subproblem is solved with the updated model. In Step 4, the progress towards a critical point is measured by the decrease of the merit function  $f(u, \sigma)$ .

### 3.2. Global Convergence

Global convergence is ensured because the trust-region framework enforces a monotonic decrease of the merit function. However, there are some prerequisites. First, all the subproblems are solved globally. Second,  $\sigma$  should be large enough, so the algorithm can avoid getting stuck at an infeasible point. Third, the model update approach should be consistent, i.e., it builds similar local models given similar measurements.

## 4. Case Studies

### 4.1. Simulation Settings

We illustrate the idea by a simple quadratic optimization problem (13) adapted from [9]. Input variables are bounded by  $u_1 \in [-2, 4]$  and  $u_2 \in [-4, 2]$ . It is assumed that the measurements are noise-free and that the plant gradients are available.

$$\begin{aligned} \min_u & u_1^2 + u_2^2 + u_1 u_2 \\ \text{s. t.} & 1 - u_1 + u_2^2 + 2u_2 \leq 0 \end{aligned} \quad (13)$$

Three models with different structural mismatches are considered. The first model optimization problem (14) has the right model curvature, while the other two problems (15) and (16) have the wrong curvature in the cost function and the constraint, respectively. Models with wrong curvatures are likely to be inadequate and cause oscillation.

$$\begin{aligned} \min_u & u_1^2 + u_2^2 \\ \text{s. t.} & 1 - u_1 + u_2^2 \leq 0 \end{aligned} \quad (14)$$

$$\begin{aligned} \min_u & -u_1^2 + u_2^2 \\ \text{s. t.} & 1 - u_1 + u_2^2 \leq 0 \end{aligned} \quad (15)$$

$$\begin{aligned} \min_u & u_1^2 + u_2^2 \\ \text{s. t.} & 1 - u_1 - 4u_2^2 \leq 0 \end{aligned} \quad (16)$$

The proposed algorithm is compared with modifier adaptation [1] (no trust-region constraints, with filter gain  $K = 0.1$ ) and penalty trust-region method. The simulation begins at point  $[2, -2]$ . The maximum step size for each iteration is 2. Parameters for Algorithm 1 are selected according to [6]. For the composite-step and the penalty methods,

the penalty coefficient and the initial trust radius are 1. In Step 1 of each algorithm, the model is updated in the same way as in the modifier adaptation method. For the composite-step method,  $\xi = 0.5$ . The nonsmooth maximum operator is approximated by a smooth one [8]. Global convergence of the proposed algorithm and the influence of  $\sigma$  are studied.

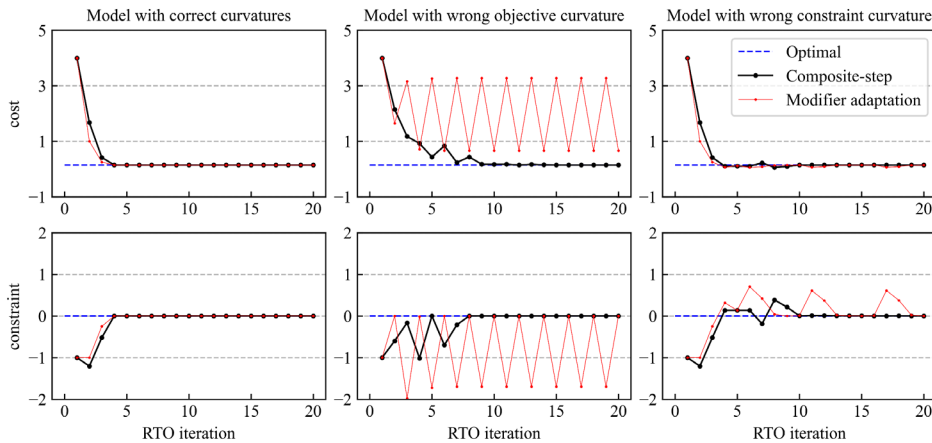

Figure 1 Evolution of plant cost and constraint using mismatched models during 20 RTO iterations. Left: simulation using model (14); middle: simulation using model (15); right: simulation using model (16). Upper: profiles of plant cost; lower: profiles of plant constraint. Black: Algorithm 2; red: modifier adaptation method [1].

Figure 2 Evolution of plant cost and constraint with different penalty coefficients during 20 RTO iterations. Left:  $\sigma = 1$ ; middle:  $\sigma = 0.1$ ; right:  $\sigma = 0.01$ . Upper: profiles of plant cost; lower: profiles of plant constraint. Black: Algorithm 2; red: penalty trust-region method [8].

#### 4.2. Global Convergence

In this subsection, we show that the proposed algorithm converges even when objective and constraints curvatures of the model are wrong. The three model optimization problems (14)-(16) are investigated. Model adaptation method (without trust-region constraints) serves as a comparison.

As Figure 1 shows, the proposed composite-step algorithm converges to the plant optimum in all three scenarios, while the modifier adaptation method fails to find the

optimum with the wrong curvature model. For both methods, the model's KKT condition matches that of the plant. However, the second-order sufficient optimality condition may be violated for the modifier adaptation method due to the wrong curvature of the model. In other words, the trust-region framework lowers the requirement for model adequacy.

#### 4.3. Penalty Coefficient

In this subsection, we investigate the effect of a small penalty coefficient on the two trust-region algorithms. RTO based on problem (14) using the composite-step and the penalty trust-region methods with different  $\sigma$  are illustrated in Figure 2.

Theoretically, both methods could be biased if  $\sigma$  is not large enough. However, our experience shows that the proposed method is less sensitive to small  $\sigma$  than the penalty method. This is because the model constraint is explicitly imposed in Step 3.

Moreover, if a very large  $\sigma$  is adopted to avoid the bias, the optimization subproblems in the penalty method may be ill-conditioned and hard to solve. The proposed composite-step approach does not suffer from this problem. The reason is that  $\sigma$  only appears when evaluating the trial point in Eq. (12), not in solving optimization subproblems (11) or (12).

### 5. Conclusions

This paper proposes a novel composite-step trust-region algorithm that directly handles inequality RTO constraints. The composite-step approach does not suffer from numerical problems caused by a large penalty coefficient in the merit function. Numerical simulations show that the proposed method is globally convergent and reduces model adequacy requirements. Future work will be focused on the rigorous proof and methods to find a proper penalty coefficient  $\sigma$  automatically.

## Abstract

This study proposed a novel fault detection and diagnosis method using continuous wavelet transform (CWT) and a three-dimensional convolutional neural network (3D-CNN). In particular, multivariate time series data from chemical plants were divided by a time-shifting window and transformed into scalograms using CWT. These scalograms were fed to 3D-CNN to generate outputs indicating the faults that occurred in the process. We applied the proposed method to a Tennessee Eastman process dataset. The proposed method adequately captures the characteristics in the time-frequency domain and exhibited good fault detection and diagnosis performances on the simulation dataset.

**Keywords:** Fault Detection, Fault Diagnosis, Deep Learning, Wavelet Transformation

## 1. Introduction

Fault detection and diagnosis (FDD) are crucial steps in process monitoring to maintain high productivity, efficiency, and safety in a chemical plant operation. Data-based FDD methods have attracted attention in recent years due to the dramatic growth of computer and information technology. Among various data-driven methods, machine learning (ML), such as deep learning, is a promising method for capturing process dynamics and nonlinearity. ML have shown great potential in various research fields (Xiong, 2022), where numerous studies have been conducted in the process engineering field (Ge, 2021).

Data preprocessing is a critical phase in developing accurate models using ML. The appropriate selection of preprocessing methods can contribute to achieving ML exhibiting high performance. Signal processing, such as Fourier transform and wavelet transform, are typical examples of preprocessing. They are used for denoising or feature extraction in various fields. Fourier transform has been applied to numerous fields, exhibiting outstanding performance for feature extraction. However, this method misses the time information of the original signal and cannot work well when the original data includes nonlinearity and non-stationarity. In contrast, wavelet transform is a powerful tool to extract the information in the time-frequency domain of the original signal. This method can be applied to nonlinear and nonstationary signals. In particular, wavelet transform has shown great potential in fault detection, including bearing and electrocardiogram. Although ML and wavelet transform have been successfully applied in other research

fields, their implementation to obtain the time-frequency information using continuous wavelet transform (CWT) is uncommon for the field of FDD for chemical processes.

Here, we proposed a combined FDD method using CWT and a three-dimensional convolutional neural network (3D-CNN). We obtained 3D inputs called scalograms for 3D-CNN from preprocessing using CWT and classified the result outputs regarding the type of fault that occurred in the chemical process.

## 2. Method

### 2.1. Continuous wavelet transform

CWT is a widely mathematically implemented wavelet transform, which can exhibit a complete view of the signal by continuously changing the scale and translation parameters (Ramin, 2022). In particular, CWT has been used for filtering out noise and fault detection and diagnosis in various fields, such as electrocardiogram analysis (Alharbey, 2022), and the development of non-steady process simulation (Hong, 2022). CWT analyses an original signal using a mother wavelet. The equation of the mother wavelet is shown below as Equation 1, where parameters  $a$  and  $b$  denoted scaling and time-shifting.

$$W_x(a, b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{\infty} x(t) \psi^* \left( \frac{t - b}{a} \right) dt \quad (1)$$

In addition, CWT produces scalograms showing the feature from the original signal in the time-frequency domain. This visualization method is also used in various fields, for instance, fault detection and feature extraction of seismic data (Ali, 2020) and filtering tool for velocity signals of a thunderstorm (Brusco, 2022).

### 2.2. 3D-CNN

We applied a 3D-CNN in the proposed method for feature extraction and classification to handle multivariable datasets. Various neural network methods have been proposed in recent years, such as Long-Short Term Memory, Recurrent Neural Network, Gaussian Neural Network, and Convolutional Neural Network (CNN). Nevertheless, CNN is an already known method for feature extraction and classification methods by our group. In particular, 2-dimensional CNN is a popular method for image recognition and classification and FDD methods for chemical processes. Moreover, CNN has been widely applied to overcome various problems owing to its great performance. (Kim, 2022)

Furthermore, 3D-CNN is a logical extension of 2D-CNN. The feature extraction scheme is the same as other dimensional CNN. However, 3D-CNN uses 3D filters to convolute 3D data and passes convoluted data to pooling layers before the fully connected layers for classification. This method has been proposed for image recognition with medical 3D scans (Pintelas, 2022), or agricultural hyperspectral images (Diao, 2022). In this study, we selected 3D-CNN to deal with multivariable from a particular chemical process.

### 2.3. Proposed method

Chemical processes have non-steady and nonlinear multivariable data. These processes can be divided by a time-shifting window. Each divided data can be transformed into a scalogram to show a particular feature of data in the time-frequency domain using CWT.

We decided that the size of a scalogram was 20 x window size. This processing was applied to each process variable to obtain 3D input data (20 x window size x the number of process variables). The generated input data was fed to the 3D-CNN model to obtain outputs representing the chemical process condition.

### 3. Case study

Tennessee Eastman process (TEP) is one of the most popular benchmarks in chemical process FDD. This process contains five main units: a reactor, a condenser, a stripper, a vapor-liquid separator, and a compressor. The process flow is shown in Figure 1. Several types of TEP simulators and datasets with different types of control loops or various fault scenarios have been developed (Bathelt, 2015, Chiang, 2000D). In this study, we used an extended TEP dataset introduced in 2017 (Rieth, 2017), which includes 20 fault operation modes of all 21 modes and 52 process variables with 41 measured and 11 manipulated variables.

In this study, we set the size of the time shift window for each preprocessing method. In particular, we set 20 for CWT and 128 for Fast Fourier Transform (FFT) and Short-Time Fourier Transform (SFT). The number of selected process values was 33, including 22 measured and 11 manipulated variables.

## 4. Result

### 4.1. Metrics for evaluation

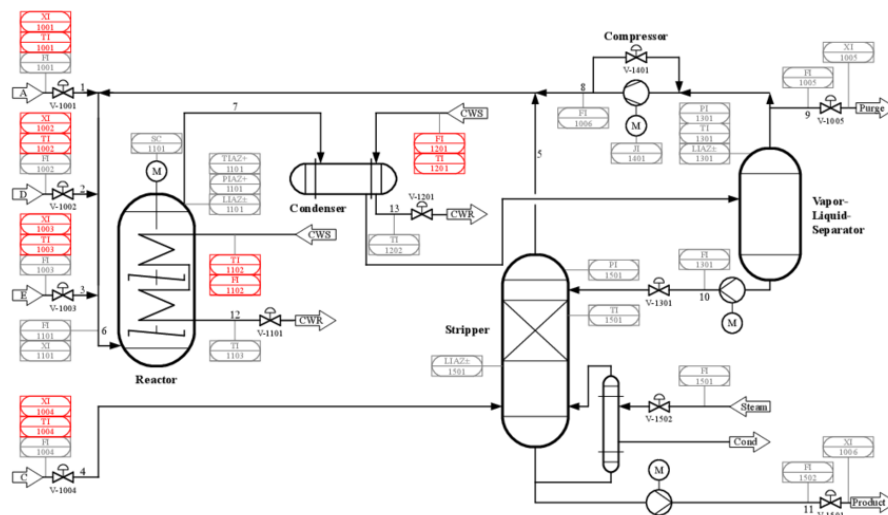

Figure 1 Process flow of TEP

We evaluated the proposed method and compared its performance using the fault detection rate (FDR) and false positive rate (FPR). TP represents true positive, and FN represents false negative.

$$\text{Fault Detection Rate (FDR)} = \frac{TP}{TP + FP} \quad (2)$$

$$\text{False Positive Rate (FPR)} = \frac{FP}{FP + TP} \quad (3)$$

#### 4.2. Application to TEP

We compared the proposed method with a combination of 3D-CNN methods with FFT and STFT. The results of the comparison are listed in Table 1. The proposed method outperformed the other preprocessing methods.

### 5. Discussion

The result of the proposed method shows excellent performance on more than half the number of faults compared to FFT and STFT. Figure 2 shows some of the input samples for 3D-CNN. We selected measured variable 1 samples of fault 6 at normal operation and when the fault occurred. We can see the change in the time-frequency domain of this variable, indicating that the proposed model learned the feature from input samples and classifies process conditions based on it.

However, fault-free (fault 00) exhibited the worst FDR result. We verified the prediction output from 3D-CNN, representing a ratio of each fault. The ratio ranged from 0 to 1. The model estimated several fault-free data as fault data of faults 3, 9, and 15. Thus, we have to solve how to divide fault-free and faulty data in future works.

Some FDR of CWT were lower than FFT and STFT. The difference in window size between these methods might be one of the reasons for this result. We compared the effect of window size on the model's ability by setting the window size from 20 to 40. The result showed that expanded window size was valid for fault 21 even though other faults were worse detected. Our next step is establishing a method to decide on the appropriate window size for the original process data.

### 6. Conclusion

This study proposed a fault detection and diagnosis model for chemical processes using CWT and 3D-CNN. CWT was used as preprocessing method for chemical process data. This method has exhibited great potential for feature extraction for non-steady and nonlinear signals in various research fields. In the proposed method, the chemical process data was first divided into samples with a set length. After that, samples were transformed into scalograms using CWT. The 3D-CNN was applied to extract the feature embedded in the time-frequency domain and perform multivariate analysis with the chemical process variables. The structure of the 3D-CNN comprised convolutional layers, pooling layers, dropout layers, and fully connected layers. The scalograms were fed to 3D-CNN to generate the outputs, representing the faults in the chemical process. The proposed method was applied to the TEP dataset introduced by Rieth et al. in 2017. Our method could capture the characteristics in the time-frequency domain well and showed better performance on more than half the number of faults than FFT and STFT. However, in the case of fault-free, the proposed model should be improved. We will train the proposed model without fault-free data and evaluate its ability to classify faults. Additionally, we will examine the method to decide the window size.

## Abstract

When operators and users face an unexpected problem regarding the process, it would be easier and less time-consuming for them to narrow down the possible causes that result in the final issue. In this study, a pilot modular plant with two Process Equipment Assemblies was considered as the use case. At first, a knowledge graph representing this process was developed in Protégé software, which semantically described not only the equipment type and connectivity but also the behavior of the process. Then, the knowledge graph was imported to Python, where the sensor data were placed in their particular position in the knowledge graph. Afterward, an algorithm was developed to query the knowledge graph and verify if the relevant equipment was functioning correctly or not. Our results indicate that this approach can reduce the cause-effect diagrams in almost all scenarios. Nonetheless, there are situations where further sensor data (e.g., the temperature in a tank) is required for the algorithm to decide.

**Keywords:** Semantic knowledge graphs; Process behavior, Cause-effect graphs; Decision making.

## 1. Introduction

The advent of the computer has significantly impacted the control of chemical processes. Indeed, the regulatory control of chemical processes (e.g., opening and closing valves) is entirely automated, resulting in higher product quality and consistency, process safety, and process efficiency (Venkatasubramanian et al., 2003). Despite these advancements, the time-consuming detection of an abnormal situation, identifying its cause, and making the best decision to resolve the problem is still a manual task. Based on the statistics, minor accidents in chemical plants occur daily, leading to workers' injuries and posing huge financial pressure on the industry. Also, it has been reported that 70% of industrial accidents are due to operators' mistakes (Venkatasubramanian et al., 2003). These suggest that developing assistant systems for fault diagnosis is a pressing need.

Notable among different methodologies used for fault diagnosis are qualitative, graph-based approaches, which were comprehensively reviewed by Venkatasubramanian et al. (Venkatasubramanian, Rengaswamy and Kavuri, 2003) and Maurya et al. (Maurya, Rengaswamy and Venkatasubramanian, 2003).

A clear superiority of graph-based methodologies is that they provide a causal structure by which one can track the propagation of an error in a chemical process. However, as the processes get more sophisticated, the graphs become more complex and challenging to navigate (especially because there exist multiple causes for one problem) (Reinartz *et al.*, 2019).

This motivates us to propose an approach for reducing the cause-effect graphs, making them more traceable. In this method, the process has been represented in the form of a knowledge graph in Protégé, in which the equipment type, connectivity, and process behavior are considered. Afterward, by importing this knowledge graph to Python and developing a program that mimics the sensor data, we were able to omit some of the unnecessary branches of the cause-effect graph. It is noteworthy to mention that to examine the applicability of our approach; it has been implemented for a use-case; namely, the Safety Demonstrator (Pelzer *et al.*, 2021).

## 2. Method

### 2.1. Cause-effect graph

As mentioned before, the Safety Demonstrator was considered as a use-case in this paper. It is a modular plant with two Process Equipment Assemblies (PEAs). As its name suggests, the Safety Demonstrator aims to investigate a secure operation; and hence, many safety controllers have been taken into account in its design. Therefore, it would be helpful for the operator if he-she received information about why one of the safety control loops is active. In this study, a cause-effect graph is proposed (see figure 1), which is defined as a directed graph in which the nodes are the events (e.g., activation of one controller), and the edges illustrate that the reason for each event is actually the event on the subsequent node. Even though it is a very beneficial tool for identifying a problem in a chemical plant, it can become very complex. Thus, the idea of this research is to automatically reduce the graph based on the specific situation.

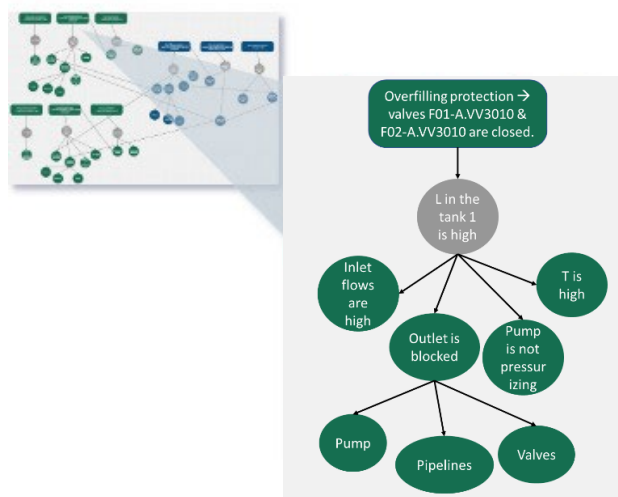

Figure 1- The cause-effect graph of the Safety Demonstrator (Gray nodes are the logics behind the controllers, rectangles show the active control system, green parts are related to PEA 1 and blue parts are related to PEA 2)

### 2.2. Semantic definition of the process

In this study, Protégé software was used to develop a knowledge graph of the investigated process. As can be seen in figure 2, it consists of 4 major classes: Equipment, Parameter, Chemicals, and Process Function. It is noteworthy to mention that the Process Function class aims to explain each equipment's phenomena semantically. To complete the definition of process function, the knowledge graph was imported from Protégé to Python with the help of owlready (a library in python for ontology descriptions) (Lamy, 2017). Then, as can be seen in figure 3 (A & D), two classes of Mass Transfer and Pressurizing and the related attributes and methods were defined. Indeed, a mass transfer takes place in an equipment when mass enters that equipment and the outlet mass is almost the same as the inlet. Also, an equipment does pressurize when the pressure of its inlet is lower than that of its outlet. These human-understandable facts are defined for the computer, as depicted in figure 3 (B).

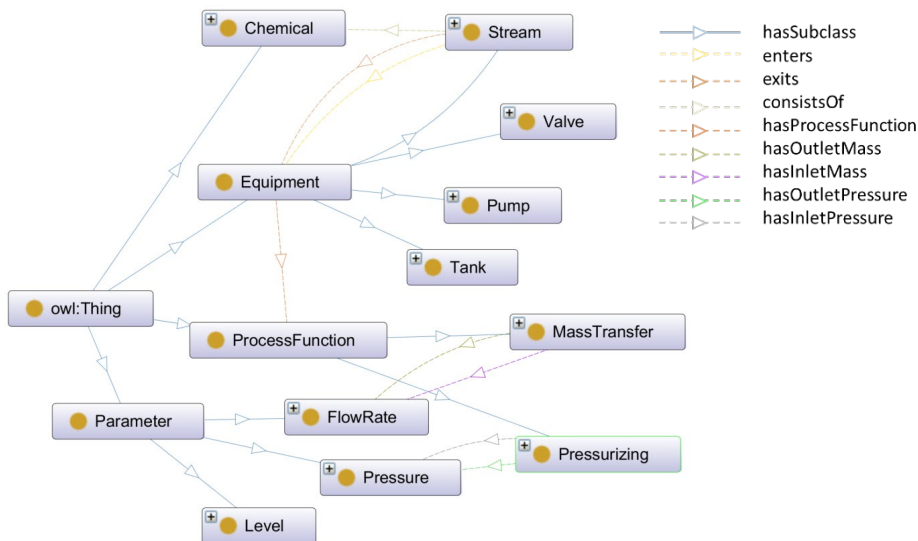

Figure 2 – Knowledge graph of the PEA1 of Safety Demonstrator developed by Protégé.

### 2.3. Algorithm

After the complete definition of the process in Python (figure 3 (A & B)), the safety control loops were also defined (figure 3 (C)). These controllers are activated when a process parameter (which has already been semantically defined) crosses the considered threshold. For instance, Overfilling-controller needs the value of the level in the tank, which has been already defined in the knowledge graph. Thus, the algorithm is aware that this value is the level of the tank, and the tank is actually connected to pump1 by stream3. The flowchart for drawing the cause-effect graph is shown in figure 3 (D). It should mention that this flowchart only considers the graph for the overfilling-controller, but a similar algorithm can be imagined for other controllers. In short, the algorithm checks whether a safety controller is active or not. If yes, then it searches for the possible reasons (based on the cause-effect graph), and if the cause is valid (based on the semantic definition of the process), it is added to the cause-effect graph.

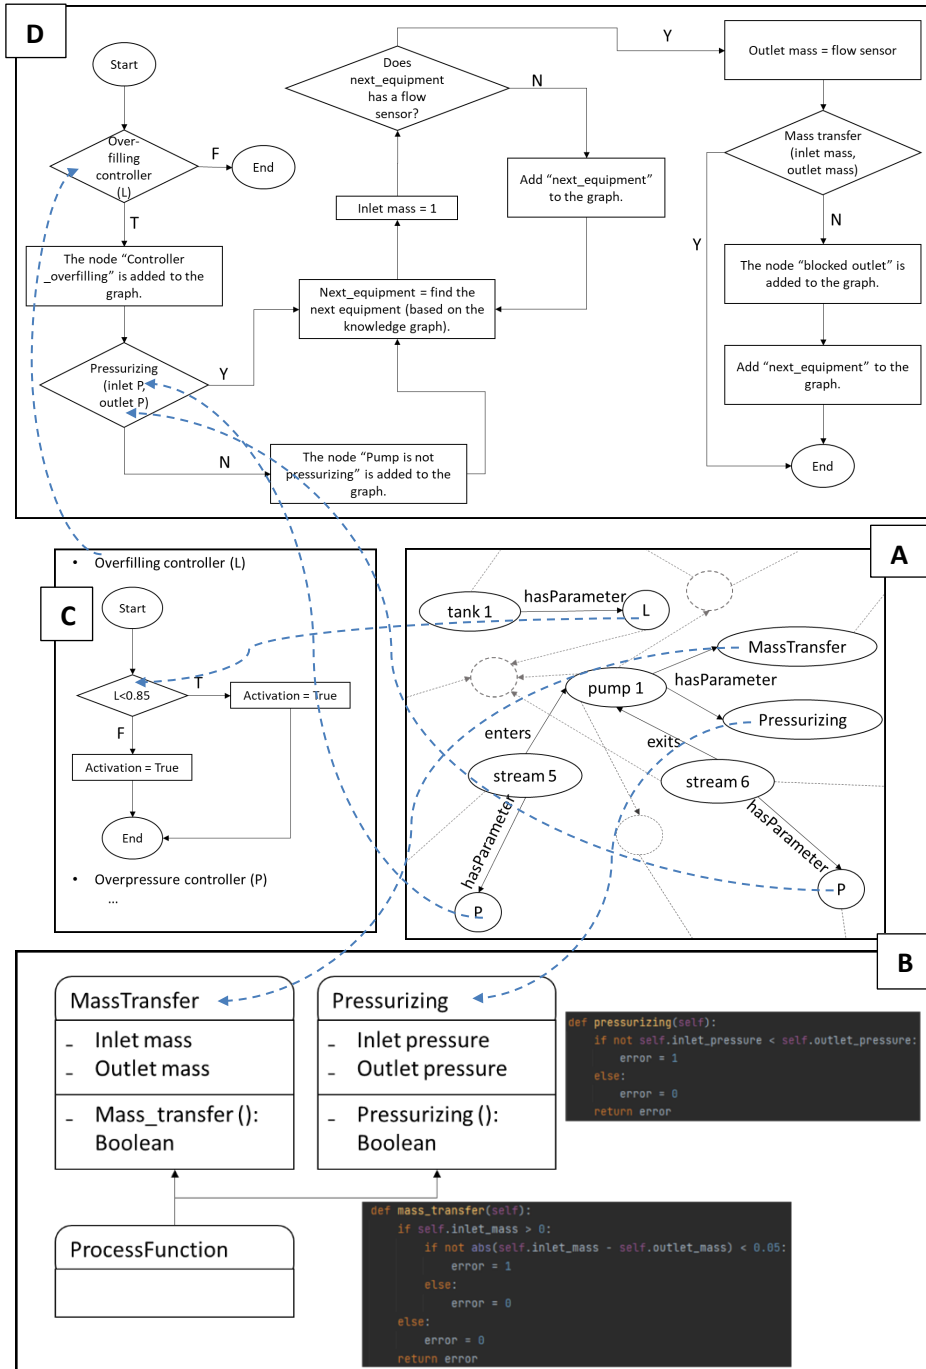

Figure 3 – A) Part of the knowledge graph from protégé (gray nodes and edges indicate that the shown nodes and edges are not the whole graph), B) Definition of process function in Python, C) Definition of the safety controllers, D) Graph development flowchart.

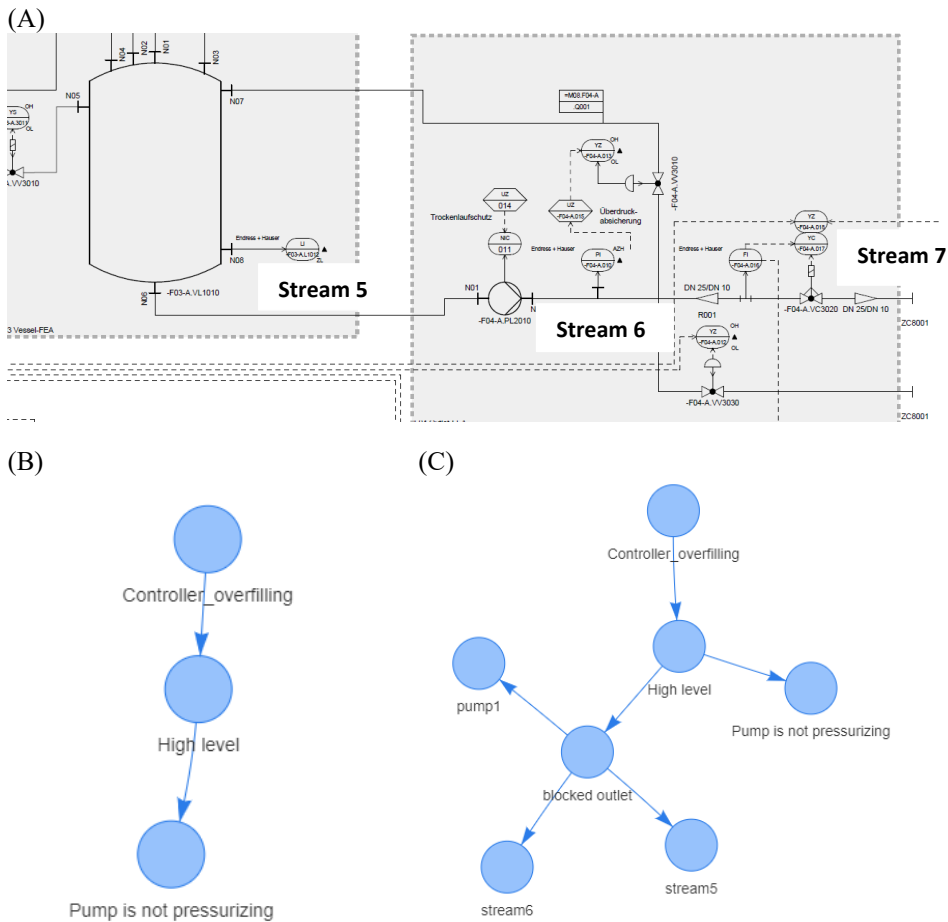

Figure 4 – A) Part of P&ID diagrams of the first PEA of Safety Demonstrator, (B) Reduced graph of a scenario in which pump is not working, (C) Reduced graph of a scenario in which pump is not working and the flow meter shows a blockage in the line.

### 3. Results and discussion

The above-mentioned method has been examined in different scenarios related to Safety Demonstrator. Because of space limitations, the scenarios investigated here are all related to PEA1 of the Safety Demonstrator (see figure 4 (A)).

- The first scenario is that pump 1 is not pressurizing the flow; i.e., the pressure after the pump (shown by the sensor) is not more than that of stream 5 (calculated from the length of the liquid in the tank), resulting in the activation of the overfilling-controller. The result of this is illustrated in figure 4 (B).
- Second scenario is that the pump is not pressurizing, and at the same time, the flow meter on stream 6 is showing a blockage. The produced graph for this scenario is depicted in figure 4 (C). Since there is no flow sensor in stream 5, our algorithm cannot precisely decide the exact point of blockage; nonetheless, it can identify it in the outlet of the tank and before the flow sensor in stream 6.

#### 4. Conclusion

The purpose of this work is to find a method to reduce cause-effect graphs, facilitating operators' problem-solving ability. To this end, a use case, namely Safety-Demonstrator, was selected, which was first semantically defined in protégé, then imported to Python, where the process behavior was defined entirely. Afterward, an algorithm was developed to communicate with the knowledge graph and, based on the process sensor data, draw the corresponding cause-effect graph. The derived results indicate that this approach is successful in considered scenarios; however, the accuracy of the results would be improved depending on the actual sensor setup on the plant side.

# Performance analysis of three-phase fluidized bed absorber for CO<sub>2</sub> capture industrial application

Flavia-Maria Ilea, Ana-Maria Cormos, Simion Dragan, Calin-Cristian Cormos  
*Babes-Bolyai University, Faculty of Chemistry and Chemical Engineering, Chemical Engineering Department, 11 Arany Janos, RO-400028, Cluj-Napoca, Romania*

## Abstract

This work aims to analyze the performance achieved using a novel CO<sub>2</sub> capture technology, more specifically three-phase fluidized bed columns, at industrial level. For this purpose, a previously developed detailed mathematical model, validated against experimental data, was adapted to scale-up. It considers the hydrodynamics, mass transfer and chemical reaction that takes place within the process and as such is able to accurately describe the chemical absorption of CO<sub>2</sub> in three phase gas-solid-liquid systems. This system relies on the process intensification which is achieved due to the much higher value of the effective mass transfer area. This is obtained through the continuous renewal of the liquid film that forms on top of the solid particles that are in movement.

A higher scale column was considered with one to three stages, in order to see in which case, the fluidization is more favored. Five different scenarios were chosen that refer to the column configuration. The results show that due to the turbulence within the system, the division of the packing in two stages, with descending static bed height, leads to an 20% increase in carbon capture rate and a 25% decrease in pressure drop.

**Keywords:** CO<sub>2</sub> capture; Process intensification; Turbulent contact absorbers.

## 1. Introduction

### 1.1. Global context and literature overview

Due to the increasing demand of electricity that cannot be fulfilled by sustainable sources, fossil fuels remain the main source of energy in the foreseeable future. As a result, the quantity of carbon dioxide emissions continues to increase over the years, having peaked at an all-time high in 2022, despite the drop that took place in 2021 due to the global pandemic situation (IPCC reports, 2022). Taking into consideration the global warming phenomenon that takes place due to the accumulation of fossil CO<sub>2</sub> in the atmosphere, there are several ongoing European initiatives meant to work against drastic climate changes. Amongst them are some of the UN 2030 sustainability objectives and the goal for EU to be climate neutral by 2050 (UN reports, 2022). The aforementioned reasons, as well as recent events, have led to the price for pollution to increase substantially, having tripled in less than a year. The mid 2022 is represented by a price of over 90 euros per ton of carbon dioxide, which gives more reason to investing in the implementation and research regarding carbon capture technologies (Arcos-Vargas et al, 2022).

Existing capture technologies, involving the post-combustion absorption of CO<sub>2</sub> in amine solutions, still face some important disadvantages that refer not only to the energy penalty, but also to the costs implied by the regeneration and recycling of the solvents (Khosroabadi et al, 2021). As such, the search for new and improved technologies remains a top priority. Turbulent contact absorbers have been used mostly in the biochemical and petroleum fields but have yet to be analyzed regarding their process

intensification potential (Ul-Haq, 2012). This equipment unit is based on the use of low-density solid particles that are chemically inert, their purpose being the intensification of the mass transfer between the counter-current flows of gas and liquid.

### 1.2. Previous work

Previous experimental work (Ilea et al, 2022) shows that the use of three phase fluidization for carbon capture leads to an important increase of 3 – 6 times in the effective mass transfer area, which leads to a proportional increase in the CO<sub>2</sub> transferred flow. This helps to increase the gas treating capacity of the absorber, as well as it minimizes the quantity of solvent needed for the CO<sub>2</sub> capture process. Based on the experimental results, a thorough mathematical model for a pilot scale CO<sub>2</sub> capture column has been developed and validated to describe the process of turbulent contact absorption through its complex hydrodynamics and mass transfer between the liquid and the gas phases. As relevant innovative aspect, this work presents the adaptation of the previously developed model to industrial scale and analyzes several possible cases in order to find the best possible configuration and parametrization of the system. The solvent used is an aqueous solution of sodium hydroxide (as it was the solvent used in experimental work).

## 2. Scaled-up three-phase absorption column

### Experimental parametrization

The parametrization of the scaled-up column considered was done in accordance with the pilot scale column used for the experimental analysis. The ratio between the column diameter and the particle diameter needs to be above the value of 6 (in the considered cases of this study, the value varies between 10 and 20). The inlet flue gas flows considered are between 1000 and 4000 m<sup>3</sup>/h, while for the liquid spray density the values were kept as for the pilot scale column, maintain at the same the packing completely wetted. This was verified by the determination of the minimum liquid flow required to avoid flow at the periphery of the reactor. The density of the particles and the void fraction were determined experimentally using 0.075 m spherical particles. The model parameters are presented in *Table 1*.

**Table 1.** Process parameters

Parameter	Pilot scale column	Scaled-up column
Column diameter [m]	0.14	1
Total static bed height [m]	0.12	1.5
Solid particles diameter [m]	0.01	0.075
Solid particles density [kg/m <sup>3</sup> ]	170, 210, 330	10 – 100
Liquid flow [m <sup>3</sup> /h]	0.1, 0.2	10 – 50
Gas flow [m <sup>3</sup> /h]	60 – 120	1000 – 4000

## 3. Mathematical model

### 3.1. Mass and energy balance

In order to most accurately describe the process, apart from the aforementioned equations, the model includes mass and energy balance equations, as presented below:

$$F_j^e = F_j^0 \pm w_j \cdot \frac{N_{CO_2} \cdot M_{CO_2}}{\rho_j} \quad (1)$$

$$\frac{dC_{CO_2}^j}{dt} = \frac{F_j^0}{w_j} \cdot C_{CO_2}^0 - \frac{F_j^e}{w_j} \cdot C_{CO_2}^j \pm N_{CO_2} - v_r \quad (2)$$

$$\frac{dC_{NaOH}^l}{dt} = \frac{F_l^0}{w_l} \cdot C_{NaOH}^0 - \frac{F_l^e}{w_l} \cdot C_{NaOH}^l - v_r \quad (3)$$

$$\frac{dT_j}{dt} = \frac{F_j^0}{w_j} \cdot T_j^0 - \frac{F_j^e}{w_j} \cdot T_j - \frac{\Delta H_r \cdot v_r}{\rho_j \cdot c_{p_j}} \mp \frac{h \cdot a_e \cdot (T_l - T_g)}{(\rho_j \cdot c_{p_j} \cdot w_j)} \quad (4)$$

\*Note: *j* subscript refers to the gas and liquid phases respectively; *v<sub>r</sub>* refers to the reaction velocity

### 3.2. Hydrodynamics and mass transfer model

The performance investigation of the carbon capture process using turbulent contact absorbers was done using a previously developed model (Ilea et al, 2022) scaled up to industrial level. The model was updated in terms of the hydrodynamics of the process, including the comprehensive correlations that calculate the liquid holdup, column pressure drops and fluidized bed expansion. The mass transfer model is based on the two-film theory and Billet & Schultes (1993) correlations. In order to describe the performance of turbulent contact absorbers in terms of effective mass transfer area coefficient, an adjustment was performed. These correlations are presented below:

$$\frac{H_s}{H_0} = \left(\frac{D_c}{d_p}\right)^{0.8861} \cdot \left(\frac{\rho_s}{\rho_g}\right)^{-0.3346} \cdot \left(\frac{w_g}{w_{lmf}}\right)^{-0.1172} \cdot \left(\frac{w_l}{w_{lmf}}\right)^{0.2318} \quad (5)$$

$$\Delta P = \rho_l \cdot g \cdot H_0 \cdot \left(\frac{H_s}{H_0}\right)^{-1.7372} \cdot Re_g^{1.2535} \cdot Ga_l^{-0.4632} \cdot Re_l^{0.3897} \cdot We_l^{0.8760} \quad (6)$$

$$h_l = 0.001884 \cdot e^{0.237 \cdot w_g} \cdot (\rho_l \cdot w_l)^{0.616} \cdot H_s^{-0.357} \cdot d_p^{-0.411} \quad (7)$$

$$a_e = a \cdot e^{11.8967} \cdot \left(\frac{w_l^2}{d_e \cdot g}\right)^{-0.0152} \cdot Fr_g^{-0.2466} \cdot Ga_l^{-0.7174} \quad (8)$$

\*Note: *g* and *l* subscripts refer to the gas and liquid phases respectively

## 4. Results and discussion

The developed mathematical model was used to analyze the performance of different system configurations. The absorber was divided in either 2 or 3 sections or left undivided. In order to ensure the possibility of the fluidization of the solid phase, decreasing the static bed height with each section was also considered, as a response to the lowering of the gas velocity. The analysis was performed using Matlab/Simulink simulation software.

### 4.1. Considered cases

Taking into consideration the aforementioned information, 5 different cases were considered in this study. The benchmark case (Case 1) refers to a single stage column, with a static bed height of the packing of 1.5 m. The second case (Case 2) refers to a two-stage column and it is represented in two different configurations: Case 2a – in which the packing static bed heights are the same for both stages (0.75 m) and Case 2b – in which the packing static bed heights descend from the bottom to the top stage (0.9 m and 0.6 m). The third case (Case 3) refers to a three-stage column and it is represented as well in two different configurations: Case 3a – in which the packing static bed heights are the same for all stages (0.5 m) and Case 3b – in which the packing static bed heights decrease from the bottom to the top stage (0.7 m, 0.5 m and 0.3 m).

**Figure 1.** *CO<sub>2</sub> capture column configurations*

#### 4.2. Influence of bed expansion on carbon capture rate and pressure drop

The columns were designed as to have a total static bed height of 1.5 m regardless of the number of stages. In order to find the most suitable configuration of the column, the carbon capture rate was assessed for all the considered cases, dependent on the total fluidized bed expansion rate. This is calculated as the ratio between the sum of the expansions per each stage and the total static bed height. This is presented in *Figure 2*. The pressure drops for each considered case are presented in *Figure 3*.

**Figure 2.** *Carbon capture rate and bed expansion*

**Figure 3.** *Pressure drops*

As shown in *Figure 2*, the carbon capture rate varies between values of 65 and 80 %. For Case 2b, the highest value of capture rate is obtained (value close to the one obtained in Case 3b). Moreover, for Case 2b, a lower value of bed expansion can be observed. This proves that in order to achieve the intensification of the mass transfer between the liquid and the gas phases, a high gas velocity is not necessary. In fact, a value slightly above the value of the minimum fluidization velocity is enough to reach the turbulence level needed to get the movement of the solid particles and, as such, the renewal of the liquid film. Due to the decreasing in static bed height with the stages and compared to the single stage column, in Case 2b a lower value of the pressure drop is also achieved, it staying at values around 1850 Pa. This is significantly lower than any other packed bed absorption columns, which is an important advantage of using turbulent contact absorbers.

#### 4.3. Influence of inlet CO<sub>2</sub> concentration on carbon capture rate

The inlet carbon dioxide concentration proved to have an important impact on the carbon capture rate. An analysis was made, ranging the concentration values between 10 % and 15 %. The results are presented in *Figure 4*.

**Figure 4.** Influence of inlet CO<sub>2</sub> concentration on carbon capture rate

It can be observed that the best performance is obtained for Case 2b (two-stage column with descending static bed height). This is due to the fact that in this case, the expansion of the fluidized bed allows for the higher values of turbulence and as such, a higher value of the effective mass transfer area is obtained, leading to the intensification of the process.

#### 4.4. Influence of gas flow on carbon capture rate

The value of the flue gas flow was varied between values of 1000 and 4000 m<sup>3</sup>/h. The results in terms of carbon capture are presented in *Figure 5*, for three of the cases.

**Figure 5.** Influence of flue gas flow on carbon capture rate

The chosen cases are the one with descending static bed height per stage, as these cases shown better results in the previous analysis. The results show once again that the higher value of the carbon capture rate is obtained in Case 2b (two stage column with descending static bed height (increased by 10 %). They also show a decrease with the increase of gas flow. This is due to the increase in the void fraction of the fluidized bed, which implicitly leads to a decrease of turbulence. As such the liquid film is not as much renewed as in the case of lower gas velocities, velocities closer to the minim fluidization velocity.

## 5. Conclusions

The presented work analyses the performance of a turbulent contact absorber using a scaled up mathematical model. The absorber is configured as having one to three stages. Five cases are considered that refer to the column having one, two or three stages. The multiple staged ones are configured in two different ways, with the static bed height per stage being equal or descending from the bottom to the top section. The results show that the highest performance is achieved in Case 2b (two stage column with descending static bed height), obtaining a capture rate 20 % higher than in the benchmark case (Case 1 – one stage column). In this case, the pressure drop also decreases with about 25 % compared to the benchmark case. It is concluded that the positive results in this case are due to the high turbulence that is found within the column, which prompts the intensification of the mass transfer between the liquid and the gas phases.

# Decentralized control for optimal operation under changing active constraints

Lucas F. Bernardino,<sup>a</sup> Sigurd Skogestad<sup>a</sup>

<sup>a</sup> *Department of Chemical Engineering, Norwegian University of Science and Technology (NTNU), 7491 Trondheim, Norway*  
*skoge@ntnu.no*

## Abstract

Optimal economic operation of chemical plants requires control of active constraints, which may change because of disturbances. In addition, one should ensure optimality with respect to the unconstrained degrees of freedom by driving the reduced cost gradient to zero. One solution is to use on-line optimizing control, but the preferred approach in industry is to use decentralized control and selectors whenever possible. In this paper, we consider a new framework based on identifying the cost gradient projections that can be left uncontrolled when each specific constraint becomes active, leading to a decentralized logic. The proposed framework is applied to the optimal operation of the Williams-Otto reactor, which has two degrees of freedom and two constraints. The projection matrix, which depends on the gradient of the constraints, is assumed constant, resulting in a simple control structure. The approach works well in simulations and it switches between the four active constraint regions.

**Keywords:** optimal operation, feedback optimizing control, decentralized control, selectors.

## 1. Introduction

In spite of the potential economic benefits, real-time optimization (RTO) is less used in industry than one may expect. There are several reasons for this, and one is that standard RTO applications operate on a slow time scale, such that for cases with frequent disturbances, optimal operation is not satisfactorily achieved. An appealing solution is to move some of the optimization problem into the control layer design, which operates on a much faster time scale. This means that one should find controlled variables (CVs) that, when controlled to constant setpoints, result in minimal economic loss. This is the idea of self-optimizing control (Skogestad, 2000), which consists of obtaining these CVs as a combination of the available measurements. Another class of feedback optimizing strategies aim to estimate the plant cost gradients in order to control them to zero (Krishnamoorthy et al., 2019).

One of the main challenges that such approaches face is the presence of changing active constraints (Jäschke et al., 2017), which may drastically change the operation mode of the system. For example, if a constraint becomes active due to a disturbance, not taking its control into account leads to infeasible operation. Similarly, if a constraint becomes optimally inactive, the control of such constraint should be given up. For a given set of active constraints, if the cost gradient is measured, it is known that the control of the active constraints together with the control of a projection of the cost gradient over the

nullspace of the active constraints' gradient leads to optimal operation (Jäschke and Skogestad, 2012). However, the existence of several active constraint regions may deem necessary the use of several independent control structures, each of them being able to provide near-optimal operation for their respective region of design. The switching between such control structures would also become an issue since the lack of a feedback-based switching strategy could lead to improper operation.

In practical applications of process systems, logic elements have been extensively used for reconfiguring control loops, which is often needed for attaining optimal operation (Reyes-Lúa et al., 2018). In particular, selectors have been successfully applied as a tool for automatic detection of active constraint switching for single input systems (Krishnamoorthy and Skogestad, 2020). In this work, we extend this analysis for multivariable systems, proposing a simple framework for decentralized optimal operation under changing active constraints, with the use of PID controllers and selectors.

## 2. Methodology

The main idea of this framework consists in identifying the optimal CVs for each region, and consequently proposing control loops for dealing with such CVs, in a way that reconfiguring is minimized. Consider the following convex optimization problem:

$$\begin{aligned} & \min J(u, d) \\ \text{s. t.} \quad & g_i = g_{u,i}^T u + g_{d,i}(d) \leq 0, \quad i = 1, \dots, n_g \end{aligned} \quad (1)$$

For the purposes of this work, we consider the steady-state cost gradient  $J_u$  to be known. Based on that, and assuming that  $n_u \geq n_g$  and all vectors  $g_{u,i}$  are linearly independent (LI), we can devise a simple control strategy for optimal operation. Firstly, the unconstrained degrees of freedom related to the nullspace of  $G_u = [g_{u,1} \ \dots \ g_{u,n_g}]^T$  will always be optimally controlled regardless of how many constraints are active, and therefore  $N_0^T J_u$ , with  $N_0$  being a basis for the nullspace of  $G_u$ , should always be controlled to zero. In addition to that, if all but one constraint is active, an extra unconstrained degree of freedom needs to be considered. The degree of freedom freed by the constraint  $g_i$  becoming inactive can be determined by the nullspace of the matrix  $G_{u,-i}$  comprised of all the remaining rows  $g_{u,j}^T$ ,  $j \neq i$ . By definition, this nullspace will include the space generated by  $N_0$ , and it is sufficient to pick any projection  $N_{g,i}$  that is LI from  $N_0$ . A unique solution can be obtained by picking  $N_{g,i}$  orthogonal to  $N_0$ .

With these definitions, we propose the following control strategy for a given active constraint set  $\mathcal{A}$ :

- if  $n_u > n_g$ , find  $N_0$  such that  $G_u N_0 = 0$  and control  $N_0^T J_u = 0$ ;
- for  $i = 1, \dots, n_g$ :

- find  $N_{g,i}$  such that  $\begin{bmatrix} G_{u,-i} \\ N_0^T \end{bmatrix} N_{g,i} = 0$ ;
- control  $g_i = 0$  if  $i \in \mathcal{A}$ ; else, control  $N_{g,i}^T J_u = 0$ .

It can be verified that the operating point defined by the forementioned CVs leads to the solution of (1). Furthermore, if decentralized PID control is used for every CV, the decision of controlling  $g_i = 0$  or  $N_{g,i}^T J_u = 0$  can be performed locally by comparing the corresponding control loops. This problem may be solved with selectors, such that constraint control becomes active when necessary, and the unconstrained degree of freedom is controlled whenever the constraint is not violated. If the system is such that

decentralized PID control can be used for every set of CVs, the framework will lead to optimal operation.

The proposed framework considers linear constraints with respect to the plant inputs, which is a strong assumption that is not accurate for most real systems. We will now demonstrate the effectiveness of the framework in a case study with nonlinear constraints, evaluating the loss that is obtained by the application of the proposed method.

### 3. Results

#### 3.1. Case study description

We now consider the optimal operation of the Williams-Otto reactor (Williams and Otto, 1960). The optimal operation of the reactor is described by:

$$\begin{aligned} \min_u J^{ec} &= p_A F_A + p_B F_B - (F_A + F_B)(p_E x_E + p_P(1 + \Delta p_P)x_P) \\ \text{s. t.} \quad g_1 &= x_A - 0.12 \leq 0 \\ g_2 &= x_E - 0.3 \leq 0 \end{aligned} \quad (2)$$

The degrees of freedom for operation are  $u = [F_B, T_R]$ , with  $T_R$  being the reactor temperature, and the considered disturbances are  $d = [F_A, \Delta p_P]$ . The solution of the above optimization problem as a function of the disturbances leads to the pattern shown in Figure 1, where each region correspond to the set of active constraints at the solution.

Figure 1: Optimally active constraints as function of the disturbances

#### 3.2. Control structure design

In order to apply the proposed framework, we linearize the constraints at a nominal point. With this, we assume a constant constraint gradient with respect to the inputs, and this ultimately results in constant cost gradient projections to be controlled inside each region. The nominal point was chosen to be the optimal point for  $d^* = [1.0 \ 0.0]$ , and the linearization of the constraints at this point results in:

$$\Delta g = \begin{bmatrix} g_{u,1}^T \\ g_{u,2}^T \end{bmatrix} \Delta u + g_d \Delta d = \begin{bmatrix} -0.0492 & 0.0032 \\ -0.0328 & -0.0026 \end{bmatrix} \Delta u + g_d \Delta d \quad (3)$$

Since  $n_g = n_u = 2$ , there are no unconstrained degrees of freedom that remain active at the fully constrained case, when  $\mathcal{A} = \{g_1, g_2\}$ . Therefore, no cost gradient projection  $N_0^T J_u$  is needed, and all operational degrees of freedom are filled by active constraint control. For  $\mathcal{A} = \{g_1\}$ , in addition to controlling  $g_1 = 0$ , we must control one cost

gradient projection  $N_{g,2}^T J_u = 0$  in order to fill the remaining degree of freedom, where  $N_{g,2}$  is chosen such that  $G_{u-2} N_{g,2} = g_{u,1}^T N_{g,2} = 0$ . Similarly, in the region where  $\mathcal{A} = \{g_2\}$ , the optimal CVs will be  $g_2 = 0$  and  $N_{g,1}^T J_u = 0$ , where  $N_{g,1}$  is chosen such that  $G_{u-1} N_{g,1} = g_{u,2}^T N_{g,1} = 0$ . In the unconstrained region  $\mathcal{A} = \{\}$ , the optimal CVs are all the components of the cost gradient  $J_u = 0$ . However, controlling  $N_{g,1}^T J_u = 0$  and  $N_{g,2}^T J_u = 0$  simultaneously implies in  $J_u = 0$ , as the constraints are independent and therefore  $[N_{g,1} \ N_{g,2}]$  is full rank. This means that the same gradient projections used for the partly constrained regions can be used for the fully unconstrained region.

The control structure that results from the application of the proposed methodology is presented in Figure 2, where  $K_{g_i}$  and  $K_{c_i}$  denote PID controllers related to control of constraints and gradient projections, respectively. It can be seen that control of  $N_{g,1}^T J_u$  can be optimally given up when the control of  $g_1$  becomes active, and the same happens with the pair  $N_{g,2}^T J_u$  and  $g_2$ . This pairing results in optimal operation for all possible active constraint regions, with the switching being performed by max selectors on the controller outputs.

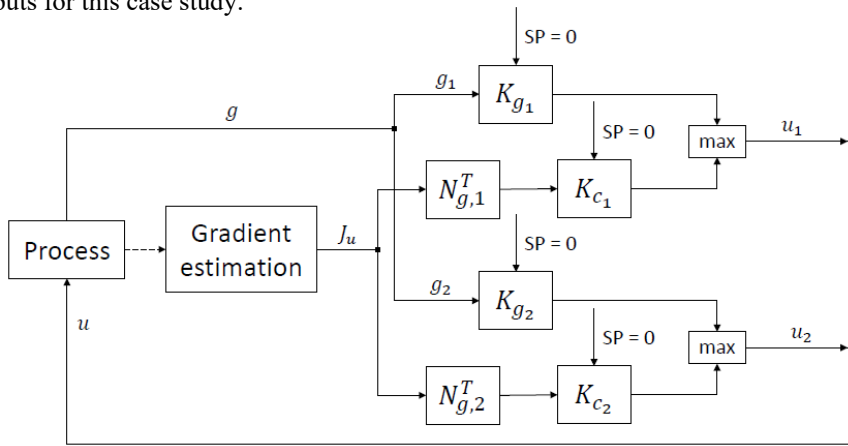

Figure 2: Control structure for optimal operation of case study

### 3.3. Simulation results

The behavior of the proposed control structure is illustrated by the simulations presented in Figure 3. The disturbance realizations were chosen such that the system operates at all active constraint regions. In the simulations,  $J_u$  was obtained using the automatic differentiation tools from CasADi (Andersson et al., 2019) with known disturbances. In practice, an estimator would be needed if the disturbances are not measured.

The system starts at the fully unconstrained region, where perfect optimal operation is possible because the cost gradient,  $J_u$ , is known. Once the system moves to the region  $\mathcal{A} = \{g_1\}$  at  $t = 4$  h, constraint violation is avoided as  $g_1 = 0$  becomes the CV chosen by the selector. Even though the inputs are not driven to their optimal value, the choice of CVs is such that low economic loss is achieved. At  $t = 6$  h, the disturbance value is equal to the nominal point, where the linearization of the constraints was performed. For this reason, the controlled cost gradient projection  $N_{g,2}^T J_u$  corresponds exactly to the optimality conditions, and perfect optimal operation is attained. At  $t = 8$  h, the system starts operating at the region  $\mathcal{A} = \{g_1, g_2\}$ . As all degrees of freedom are associated to active constraint control, perfect optimal operation is achieved. From  $t = 12$  h, the system operates at  $\mathcal{A} = \{g_2\}$ , and near-optimal operation is achieved with low economic loss.

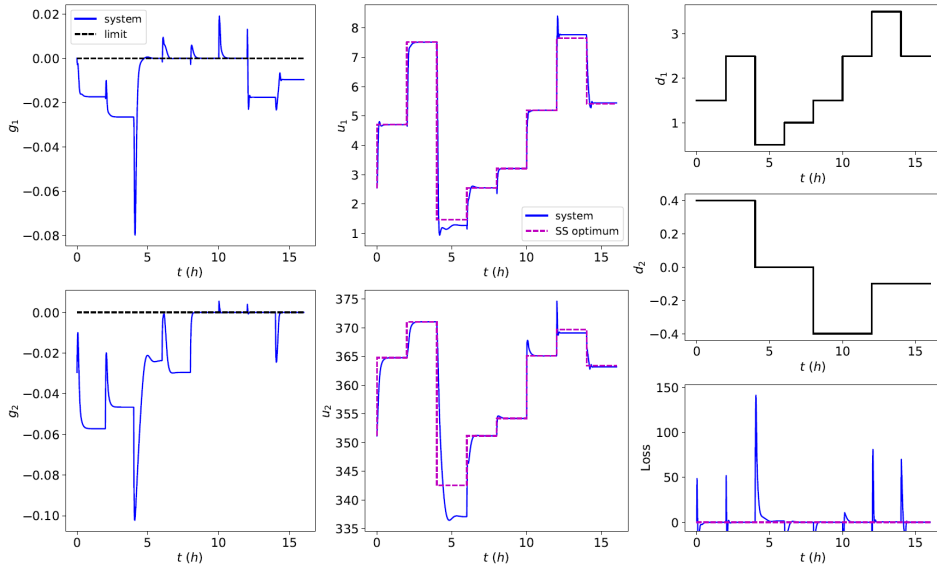

Figure 3: Dynamic simulation of proposed control structure

The steady-state economic loss for the proposed control structure is presented in Figure 4 as a function of the disturbances. Similar to what was observed in the dynamic simulations (Figure 3), the regions with nonzero loss are concentrated at the partly constrained regions. This is because the optimal CVs corresponding to the cost gradient projections change due to the nonlinearity of constraints. In contrast, the fully constrained and fully unconstrained regions mostly present zero operational loss, because the optimal CVs remain constant inside these regions, and the information about  $J_u$  is accurate. The linearization of the constraints was performed inside the region  $\mathcal{A} = \{g_1\}$ , where the operational loss is effectively zero at this reference point, and it increases as the system moves away from it. It can also be seen that optimal switching between regions is subject to errors related to the linearization of the constraints. The largest operational loss is obtained in the switching between regions  $\mathcal{A} = \{g_1, g_2\}$  and  $\mathcal{A} = \{g_2\}$ , where an inaccurate cost gradient projection is tracked, that is, controlling  $N_{g,1}^T J_u = 0$  does not lead to exact optimal operation. Therefore, the switching is not performed at the exact optimal boundary, as can be seen in the results, but it nonetheless leads to a reasonable switching policy between regions, and good resulting economic performance.

Figure 4: Steady-state economic loss of the proposed control structure as a function of disturbances (black lines represent optimal region switching)

#### 4. Discussion

The control structure resulting from the framework proposed in this work (Figure 2) makes use of selectors as simple elements for switching between operating regions. These elements are frequently used in practice for coordinating conflicting control objectives. In this work, we show how these elements can be used for the optimal operation of systems under changing active constraints in a systematic manner. The min/max nature of the selectors is ultimately related to the nature of the constraint with respect to the input (Krishnamoorthy and Skogestad, 2020).

The approach proposed in this work is based on the analysis of the partly constrained regions, where we find gradient projections that can be optimally controlled. These projected gradients are also the optimal CVs of other regions, which minimizes the number of control loops that are necessary to account for all regions. Moreover, the proposed switching operates independently for each plant input, which means that the detection of each constraint is done independently, and feasible operation is safely achieved. However, the reconfiguring of CVs done by the selectors may significantly change the interactions between loops, and therefore careful tuning of the controllers is necessary, such that a good performance is achieved regardless of which loops are active.

#### 5. Conclusion

In this work, we propose a framework for decentralized optimal operation under changing active constraints, applicable to a class of multivariable problems. Even though the approach is based on the linearization of the constraints, and therefore the quality of the linearization plays a relevant role in the economic performance, the strategy proved to be successful in a nonlinear case study, which encourages its use in other relevant problems of process systems engineering, especially when the gains from the inputs to the constraints do not change greatly in the operating range. The use of adaptive cost gradient projections would also be beneficial for improving economic performance. More theoretical aspects regarding the proposed framework will be expanded in future work.

## Abstract

Most of the existing approaches for integrating the scheduling and control layers in the process industry suffer from the solution complexity of the resulting Mixed Integer Nonlinear Programming (MINLP) program. This complexity stems from two main obstacles: i) the consideration of nonlinear closed-loop dynamics involved in the control layer and ii) the way of exchanging the information between the control and the scheduling layers. To tackle these two obstacles, this work proposes the use of a schedule-aware controller (SAC) based on deep learning (DL) models, which receives, as input, the scheduling information (i.e., production sequence, targets, and set points) along with the process conditions (values of the state, output, and control variables) to predict the optimal control actions to be applied at the next sampling periods. The method is applied to a benchmark, showing very good performance in terms of the ability to adapt the control actions in accordance with the scheduling decisions, high prediction accuracy, and reduction in the computation cost.

**Keywords:** Explicit Control- Scheduling- Integration - Machine Learning

## 1. Introduction

In process industry, the integration of decision making across different layers of the process management hierarchy is of paramount importance. In particular, integrating the scheduling and control layers can lead to significant increase in production profitability, operational reliability, and adaptability to varying environments. Most of the works that have been developed to integrate control and scheduling can be categorized into simultaneous and decoupling approaches. Flores and Grossmann (2006, 2010) proposed a simultaneous approach incorporating the nonlinear process dynamics (involved in the control layer) into the scheduling problem in the form of differential/algebraic constraints, which results in a Mixed Integer Dynamic Optimization (MIDO) problem that handles the control and scheduling simultaneously. They used a discretization method based on orthogonal collocation to transform the MIDO into a MINLP problem. Zhuge and Ierapetritou (2012) proposed a similar method able to handle online disturbances in the system dynamics. They solve the MIDO problem offline to obtain reference production sequence and control variables, which are initially implemented online. Then, once disturbances occur, the MIDO problem is updated and solved over the remaining time horizon. Conversely, the decoupling approach considers two problems: i) the scheduling

one (master), which is formulated as a MINLP and solved based on an economic objective to obtain the mid-term decisions, and ii) the control problem (primal), which is first informed by the scheduling decisions and then solved as dynamic optimization to obtain the short-term decisions. The master-primal problems are solved iteratively until convergence is achieved. Burnak et al. (2018) proposed a decoupling approach based on multi-parametric (MP) programming that consists of i) a MP scheduler, ii) a MP controller based on Model Predictive Control (MPC), and iii) a multiparametric “bridge” that connects these two layers. Martinez and Sandoval (2022) developed a nested approach that solves the scheduling problem to obtain the product switching sequence and the associated set points, which are passed to the MPC to implement them. The method is applied in a closed-loop online mode to minimize perturbations. Although both approaches demonstrated the importance of such integration for economic gain, they still have some drawbacks. In the simultaneous approach, the resulting MIDO problem is usually of large scale and can be intractable, especially in cases where the process model is of high-fidelity and/or highly nonlinear. The decoupling approach leads to more manageable optimization problems, but a significant computational effort is required to iteratively solve the control problem (Burnak et al., 2018; Martinez and Sandoval, 2022). The drawbacks of both approaches result from two main issues: i) handling the nonlinear closed-loop dynamics, and ii) the need to exchange the information between the control and the scheduling layers. To tackle the two obstacles, we propose a novel DL -based SAC that receives, as input, the med-term scheduling information (production targets, sequence, and set points) along with the instantaneous process information (state, output, and control variables) and provides the optimal control actions to be applied to the process in the future sampling period. This novel DL-based SAC represents: a) an accurate and computationally cost-effective controller (tackling the first obstacle) and, b) a controller that accommodates the scheduling decisions, adapts the control actions to pursuit these scheduling targets, and, finally, quantifies the deviation from these targets (e.g., material loss). These deviations can be sent back to the scheduler (tackling the second obstacle). Hence, this DL-based SAC could be integrated seamlessly with a higher-level scheduler.

## 2. Problem statement

Figure 1. Representation of the framework for integrating scheduling and control.

We consider a framework for integrating the control and scheduling (Figure 1), in which both layers share information. Given  $N_p$  products to be manufactured, a demand scenario for each product over of a total time period  $T_{tot}$ , and a cost function, the scheduling problem is solved to obtain the best the production sequence  $Z_{j,t_s} \in \{0,1\}$  with the associated set points  $y_{j,t_s}^{SP} \in R^{n_y}$ ,  $u_{j,t_s}^{SP} \in R^{n_u}$  and target production rates  $Q_{j,t_s}$ , where  $j =$

$1, \dots, N_p$  and  $t_s = 1, \dots, N_s = t_{tot}/\Delta t_s$ , and  $\Delta t_s$  is the scheduling time slot. Please note that the solution of the scheduling problem itself is out of the scope of this work, so only the elements highlighted in red in Figure 1 are considered.

The scheduling decisions (bold font in the formulation below) are fed to the control layer based on MPC (Eqs. (1):(4)). We denote  $t_c = 1, \dots, N_c$  the control sampling times with  $N_c = t_{tot}/\Delta t_c$  and  $\Delta t_c \ll \Delta t_s$ . At the control level, the scheduling information take constant values within the same scheduling time slot. A nonlinear high-fidelity model,  $\mathcal{F}$  and  $\mathcal{G}$  (Eq. (2)), is used to calculate the process states  $x_{t_c} \in R^{n_x}$  and outputs  $y_{t_c} \in R^{n_y}$ , and a case-dependent constraint (Eq. (3)) is considered to correlate the control actions  $u_{t_c} \in R^{n_u}$  with the production rates advised by the scheduler,  $Q_{j,t_c}$ . Denoting  $P$ ,  $R$  and  $R_1$  positive definite matrices, and  $N_{ph}$ ,  $M_{ch}$  the prediction and control horizons, respectively, the control problem can be described as follows:

$$\min_{u_{t_c+1}, \dots, u_{t_c+N_{ph}}} J = \sum_{k=1}^{N_{ph}} (y_{t_c+k} - y_{t_c+k}^{SP})^T P (y_{t_c} - y_{t_c}^{SP}) + \sum_{k=1}^{M_{ch}} (u_{t_c+k} - u_{t_c+k}^{SP})^T R (u_{t_c+k} - u_{t_c+k}^{SP}) + \sum_{k=1}^{M_{ch}} \Delta u_{t_c+k}^T R_1 \Delta u_{t_c+k} \quad (1)$$

s. t.

$$x_{t_c+k+1} = \mathcal{F}(x_{t_c+k}, u_{t_c+k}, d_{t_c+k}^T), \quad y_{t_c+k} = \mathcal{G}(x_{t_c+k}, u_{t_c+k}, d_{t_c+k}^T) \quad (2)$$

$$u_{t_c+k} \leq \mathcal{H}(Q_{j,t_c+k}, x_{t_c+k}, u_{t_c+k}, d_{t_c+k}^T) \quad (3)$$

$$x_{min} \leq x_{t_c+k} \leq x_{max}, \quad y_{min} \leq y_{t_c+k} \leq y_{max}, \quad u_{min} \leq u_{t_c+k} \leq u_{max} \quad (4)$$

$$\Delta u_{t_c+k} = u_{t_c+k} - u_{t_c+k-1}$$

At each time  $t_c$ , the measured values of the state and output variables ( $x_{t_c}$  and  $y_{t_c}$ ) are used as initial conditions for the dynamic optimization problem (Eqs. (1):(4)), which is solved to find the optimal trajectory of the control variables  $[u_{t_c+1}^*, \dots, u_{t_c+N_{ph}}^*]$ . Only the optimal control values corresponding to the first instance,  $u_{t_c+1}^*$ , are implemented in the process. The final solution of the MPC problem are the closed-loop control profiles along the entire production horizon  $[u_{t_c=1}^*, \dots, u_{t_c=N_c}^*]$  and the resulting state and output variables  $[x_{t_c=0}, \dots, x_{t_c=N_c-1}]$  and  $[y_{t_c=0}, \dots, y_{t_c=N_c-1}]$ . Since the solution complexity of this schedule-aware MPC problem could hinder the integration of the scheduling and control layers, we propose a DL-based SAC to cheaply and accurately predict the closed-loop control actions as functions of the scheduling decisions and the process conditions, as in Eq. (5), where  $l$  is a time delay and  $\mathcal{f}$  is deep learning model.

$$\hat{u}_{t_c+1}^* = \mathcal{f}(Q_{j,t_c}, \dots, Q_{j,t_c-l}, y_{j,t_c}^{SP}, \dots, y_{j,t_c-l}^{SP}, u_{j,t_c}^{SP}, \dots, u_{j,t_c-l}^{SP}, x_{t_c}, \dots, x_{t_c-l}, y_{t_c}, \dots, y_{t_c-l}, u_{t_c}, \dots, u_{t_c-l}) \quad (5)$$

### 3. Methodology steps and techniques

#### 3.1. Sampling of the scheduler outcomes

In the first step,  $N_{sc.tr}$  different scheduling scenarios are randomly synthesized over the scheduling slots  $t_s = 1, \dots, N_s$ . For each scenario  $i$ ,  $i = 1, \dots, N_{sc.tr}$  a different production sequence  $Z_{j,t_s,i} \in \{0,1\}$  (with the associated set points  $y_{j,t_s,i}^{SP}$ ,  $u_{j,t_s,i}^{SP}$ ) and/or production rates  $Q_{j,t_s,i}$  (Figure 2) is defined. The generated scenarios should contain most of the expected transitions between the  $N_p$  products and cover the full range of variability in production targets.

Figure 2. Example of two different scheduling scenarios where  $N_p = 3$  and  $N_s = 4$ .

### 3.2. Data generation: solving the MPC problem

The scheduling scenarios  $[Q_{j,t_s,i}]$ ,  $[y_{j,t_s,i}^{SP}, u_{j,t_s,i}^{SP}]$  are resampled to the control time scale to obtain the required values at the finer time grid  $t_c = 1, \dots, N_c$ , i.e.,  $[Q_{j,t_c=1,i}, \dots, Q_{j,t_c=N_c,i}]$ ,  $[y_{j,t_c=1,i}, \dots, y_{j,t_c=N_c,i}^{SP}]$ ,  $[u_{j,t_c=1,i}, \dots, u_{j,t_c=N_c,i}^{SP}]$ . Then, for each of the  $N_{sc.tr}$  scenario, the control problem (Section 2 and Eqs. (1):(4)) is solved to obtain the closed-loop control profiles along the entire production horizon  $[u_{t_c=1,i}^*, \dots, u_{t_c=N_c,i}^*]$  and the resulting state variables  $[x_{t_c=0,i}, \dots, x_{t_c=N_c-1,i}]$  and output variables  $[y_{t_c=0,i}, \dots, y_{t_c=N_c-1,i}]$ . The obtained trajectories of the state, output and control variables are unfolded together with the production targets and set points to an input-output data set for training the DL model, depending on the required input lag  $l$ . For example, in case of  $l = 0$ , the input-output dataset will be in the form  $[x_{t_c,j}, y_{t_c,j}, u_{t_c,j}^*, y_{j,t_c,j}^{SP}, u_{j,t_c,j}^{SP}, Q_{j,t_c,j}] - [u_{t_c+1,j}^*]$ ,  $j = 1, \dots, N_{sc.tr} \times N_c$ . Following the same steps, a testing dataset with  $N_{sc.tst}$  additional scheduling scenarios is also generated.

### 3.3. Development of DL-based SAC

The unfolded training data is used to fit the DL-SAC in Eq. (5), where  $\mathcal{f}$  is selected as a feedforward deep neural network (DNN), whose architecture (number of hidden layers, hidden neurons, activation functions), learning parameters, and training algorithm are chosen by a cut and try procedure that balance the DNN complexity and accuracy.

### 3.4. Testing of the DL-SAC via closed-loop deployment

In the final step, the developed DL-based SAC is used to predict the closed-loop control trajectories corresponding to the scheduling scenarios in the testing set. In each scenario, the DL-based SAC is used in a recursive way as follows:

- i. if  $t_c = 1$  consider the given initial values of the state, output, and control variables, else-if  $t_c > 1$  measure the current values of the state, output, and control variables from the process (high-fidelity model, in our case). Combine them with the target production rates and set points values (scheduling decisions), and use them as input for the SAC to predict the optimal values of the control variables at the next sampling period,
- ii. implement the predicted control variables values in the process (i.e., in the model),
- iii. if  $t_c = N_c$  stop, otherwise back to step i.

The accuracy of DL-based SAC is quantified by comparing the predicted control trajectories and the resulting state and output variables with their exact values. Normalized Root Mean Square Error (NRMSE) is used as accuracy metric.

#### 4. Application: Multi-product CSTR

As a benchmark, we consider an isothermal CSTR (Figure 3-(a)) which is fed by three reactants ( $R_i, i = 1,2,3$ ) and is operated to manufacture three products ( $P_j, j = A, B, C$ ) on a single production line (Flores and Grossmann, 2006; Burnak et al., 2018). In the CSTR, three irreversible reactions take place in parallel, see Figure 3-(b).

Figure 3: Representation of the multi-product CSTR (a) and its irreversible reactions (b).

The dynamics of the CSTR can be described by six differential equations, as follows:

$$\frac{dC_{R_i}}{dt} = \frac{q_{R_i} C_{R_i}^f - q_{tot} C_{R_i}}{V} + \mathcal{R}_{R_i} \quad \text{and} \quad \frac{dC_{P_j}}{dt} = \frac{q_{tot} (C_{P_j}^f - C_{P_j})}{V} + \mathcal{R}_{P_j} \quad (6)$$

Where  $C_{R_i}$  (state variables) are the concentrations of the reactants inside the CSTR (mol/L),  $C_{P_j}$  (output variables) are the products concentrations (mol/L), and  $q_{R_i}$  (control variables) are the reactants feed flowrates (L/min). Notice that  $q_{tot} = \sum_{i=1}^3 q_{R_i}$  is the total feed flowrate,  $V$  is the reactor volume (L), while  $C_{P_j}^f$  and  $C_{R_i}^f$  represent the concentrations in the feed-streams. To manufacture each of the three products, the scheduler determines different set points that the controller must track by manipulating  $q_{R_i}$ . The set points are  $C_{A,t_c}^{SP} = [0.3, 0.0, 0.0]$ ,  $C_{B,t_c}^{SP} = [0.0, 0.18, 0.0]$ , and  $C_{C,t_c}^{SP} = [0.0, 0.0, 0.2]$ .

We assume a scheduling scenario which consists of  $N_s = 4$  time slots with  $\Delta t_s = 120$  min ( $T_{tot} = 480$  min). At the control level,  $\Delta t_c = 2$  min therefore  $t_c = 1, \dots, N_c = 240$  instances. The MPC problem is casted as in Eqs. (1):(4) considering the following parameters:  $P = 10^2 \times [100, 0, 0; 0, 1, 0; 0, 0, 1]$ ,  $R = 0$  since no set points on the control variables,  $R_1 = 10^{-6} \times [1, 0, 0; 0, 1, 0; 0, 0, 1]$ ,  $N_{ph} = 6$ , and  $M_{ch} = 2$ . The problem is subjected to: i) a bound constraint on the inlet flowrates  $0 \leq q_{R_i, t_c} \leq 500$  L/min, and ii) an equality constraint  $\sum_{i=1}^3 q_{R_i, t_c} = Q_{tot, t_c}$ , which correlates the control variables with the production targets suggested by the scheduler, i.e. equivalent to Eq. (3). A dataset including  $N_{sc, tr} = 45$  scenarios is generated (see Sections 3.1 and 3.2) and used for training the DNN-based SAC (Eq. (6)). The DNN consists of three hidden layers with 30, 50, and 5 neurons, and is trained using Bayesian regularization backpropagation algorithm. Another dataset of  $N_{sc, tst} = 10$  scenarios is created to test the fitted DNN-based SAC. The time for generating the training data, testing data, and fitting the DNN equals to 269, 199.3, and 15.3 min, respectively.

$$\begin{aligned} & \hat{q}_{1, t_c+1}, \hat{q}_{2, t_c+1}, \hat{q}_{3, t_c+1} = \\ & = \mathcal{f}(C_{R1, t_c}, C_{R2, t_c}, C_{R3, t_c}, C_{A, t_c}, C_{B, t_c}, C_{C, t_c}, q_{1, t_c}, q_{2, t_c}, q_{3, t_c}, Q_{tot, t_c}, C_{A, t_c}^{SP}, C_{B, t_c}^{SP}, C_{C, t_c}^{SP}) \end{aligned} \quad (7)$$

Table 1 reports the performance of the DNN-based SAC over the 10 testing scenarios, in terms of i) low NRMSE of the predicted closed-loop control variables and the resulting state and output variables, and ii) a huge savings in the online computational cost. As example, Figure 4 shows the closed-loop profiles of one inlet flowrate ( $\hat{q}_2$ ), predicted by the DL-based SAC and two of the resulting outputs ( $C_C$  and  $C_B$ ) compared with their exact values obtained by MPC during specific two time slots representing the production

transition from product C to product B in scenario 4. The figure further confirms the very good capabilities of the proposed DL-based SAC.

Table 1. Accuracy and online computational time of the DL-based SAC based on the testing set.

Accuracy (NRMSE %)									CPU time *	Saved time %
$\hat{q}_1$	$\hat{q}_2$	$\hat{q}_3$	$\hat{C}_{R1}$	$\hat{C}_{R2}$	$\hat{C}_{R3}$	$\hat{C}_A$	$\hat{C}_B$	$\hat{C}_C$	0.52	99.7=(199.3-0.52)/1.99.3
0.15	0.23	0.3	0.73	1.8	1.1	0.85	2.26	1.01		

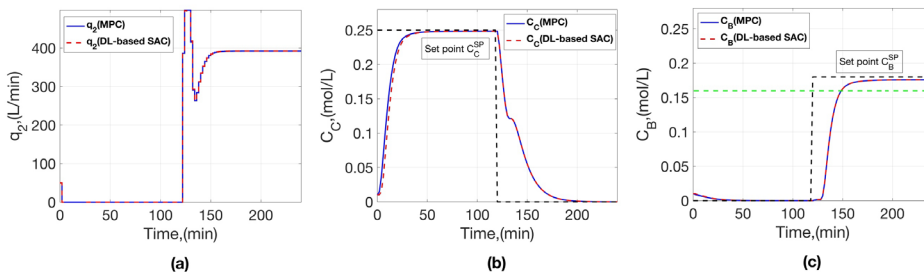

Figure 4. Predicted (red) versus exact (blue) values of the control variable  $q_2$  (a) and the resulting output variables  $C_C$  (b) and  $C_B$  (c) during transition  $C \Rightarrow B$  in the testing scenario no. 4. The green dashed line in subplot (c) represents the minimum quality threshold for product B.

The material loss and transition time during a certain transition can be calculated by comparing the output concentration with a minimum quality threshold. For example, in transition  $C \Rightarrow B$ , the output concentration  $C_B$  is compared to the quality threshold  $C_{B,\min} = 0.16$  mol/L (dashed green line in Figure 4-(c)).

## 5. Conclusions

In this paper, we present a DL-based SAC that is effectively able to receive, as input, the mid-term scheduling decisions along with the process conditions and predict the future control measures that track the scheduling targets. The results of application to a benchmark case study proves the effectiveness of the proposed DL-based SAC in terms of accuracy and very low computation time. A future research line will exploit the DL-based SAC and test its performance when integrated into scheduling problem/layer.

## Abstract

The presence of endogenous and exogenous uncertainty in process systems is one of the key reasons for deviation from set operation policies, resulting in suboptimal or even infeasible operation. In robust rolling horizon optimization (RHO) of discrete-time systems, such as MPC, the derivation of robust optimization policies is mainly characterized by the challenge associated with multiplicative unmeasurable uncertainty. Measurable uncertainty can be treated either “online” with the successive solution of optimization problems or “offline” via multi-parametric programming. We consider the development of closed-loop (explicit) robust rolling horizon solutions that correspond to MPC problems. The unmeasurable multiplicative uncertainty is reformulated into its deterministic mixed integer equivalent form. Furthermore, measurable uncertainty is treated either via online optimization or via multi-parametric programming. With this approach, we show (i) how the need for a multi-stage optimization approach can be alleviated while (ii) guaranteeing the robust nature of the final solution. We present the developments through an example of constrained LQR.

**Keywords:** robust optimization; robust control; mixed-integer programming; multi-parametric programming

## 1. Introduction

Model predictive control (MPC) is the established method for the advanced control of multivariable systems, extensively studied and applied by both the academic and industrial communities (D. Q. Mayne, 2014). An MPC problem is most commonly a convex quadratic mathematical optimization problem, whose solution is the optimal vector of inputs to regulate the operation of a system. By utilizing a rolling horizon optimization approach (RHO), the optimal vector of inputs that minimize a performance index while considering (i) the process model, (ii) the constraint set and (iii) a finite prediction horizon is calculated, however only the first control input of the sequence is applied to the system. As soon as the next measurement (or its estimate) is made available, the horizon is rolled over by a single time step, and the optimization problem is resolved. Being model-based, MPC approaches inevitably depend on the accuracy of the underlying model. In practical applications, model uncertainty is prevalent due to the mismatch between the real plant and the model used for the derivation of the control law (endogenous uncertainty) and/or unmeasured disturbances (exogenous uncertainty)

especially when multiple time scales are considered (N.A. Diangelakis et al. (2017), B. Burnak et al. (2020)). Consequently, the closed-loop behavior of the system is not as desired and constraint violations may occur. In an effort to address this challenge strategies that account for additive and multiplicative uncertainty have been developed (e.g. B. Kouvaritakis, et al, (2016) and references therein). Furthermore, robust optimization has received significant attention through the years (e.g. A. Ben-Tal, et. al, 1998, Q. Zhang et al. 2022 and references therein).

Robust explicit MPC aims to derive the explicit solution of the MPC problem by additionally guaranteeing that all sources of uncertainty are taken into account, and at least feasibility is satisfied. In this respect, multiple research efforts have been contributed that tackle the case where the uncertainty source is added to the future prediction (additive uncertainty) and the case where the future prediction is multiplicatively affected by it (multiplicative uncertainty). V. Sakizlis et al. (2004) included constraints in the design phase of the controller that guarantee that for the worst case of the additive uncertainty, the system is feasible. A. Bemporad et al. (2003) proposed a min-max approach where the solution is found for problems with a linear objective function and linear constraints for multiplicative uncertainty. K. Kouramas et al. (2013) tackled the case of explicit MPC problems with a quadratic objective function, linear constraints, and multiplicative uncertainty by employing dynamic programming and robust optimization. More recently, I. Pappas et al. (2022) demonstrated that dynamic programming can be avoided and extended it to hybrid systems by performing projections of the feasible space into the future. An open question in the robust explicit MPC field is how can the robust solution of an explicit MPC problem with a quadratic cost, linear constraints, and multiplicative uncertainty be developed, by using a single multiparametric optimization formulation. This contribution aims to provide a strategy for the later via mixed-integer and multiparametric quadratic optimization.

## 2. Problem formulation

Consider a linear discrete time dynamic model of the following form:

$$x_{T+1} = Ax_T + Bu_T \quad (1)$$

where  $x_T \in \mathcal{R}^m$  and  $u_T \in \mathcal{R}^n$  are the state and control input vectors respectively at time instant  $T$ . Instead of considering that the system and input matrices  $A \in \mathcal{R}^{m \times m}$  and  $B \in \mathcal{R}^{m \times n}$  are constant, in this study we assume that the model is uncertain and described by box uncertainty. Specifically:

$$A = A_0 + \Delta A \quad (2)$$

$$B = B_0 + \Delta B \quad (3)$$

$$\Delta A \in \mathcal{A} = \{\Delta A \in \mathcal{R}^{m \times m}: -\epsilon_A |A_0| \leq \Delta A \leq \epsilon_A |A_0|\} \quad (3)$$

$$\Delta B \in \mathcal{B} = \{\Delta B \in \mathcal{R}^{m \times n}: -\epsilon_B |B_0| \leq \Delta B \leq \epsilon_B |B_0|\} \quad (4)$$

$A_0$  and  $B_0$  are the nominal matrices of the model, while  $\Delta A$  and  $\Delta B$  are their uncertain component. This element-wise deviation from the nominal matrix value is described by  $\epsilon_A$  and  $\epsilon_B$  which are scalars. Here, in a slight abuse of terminology,  $|A_0|$  and  $|B_0|$  do not represent a norm or determinant of  $A_0$  and  $B_0$ , respectively, but their element-wise absolute values, i.e. if the element of  $A_0$  in the  $i^{\text{th}}$  row and  $j^{\text{th}}$  column is  $a_0^{ij}$  then the element of  $|A_0|$  in the same row and column is  $|a_0^{ij}|$ .

Assuming a common prediction and control horizon  $N$ , the following linear quadratic regulator problem (LQR) problem can be formulated:

$$\begin{aligned}
\min_{u_0, u_1, \dots, u_{N-1}} \quad & x_N^T P x_N + \sum_{k=0}^N x_k^T Q x_k + \sum_{k=0}^{N-1} u_k^T R u_k \\
\text{s. t.} \quad & x_{T+1} = A x_T + B u_T, \forall T \in \{0, \dots, N-1\} \\
& \underline{x} \leq x_T \leq \bar{x}, \forall T \in \{0, \dots, N-1\} \\
& \underline{u} \leq u_T \leq \bar{u}, \forall T \in \{0, \dots, N-1\} \\
& x_N \in T_s
\end{aligned} \tag{5}$$

Its objective is to find the control inputs  $u_T$ , that will drive the system to the origin in the presence of the uncertainty. The lower bounds on the inputs and states are implied to be negative and the upper bounds positive. The system and input matrices in eqn. 5 are defined as in eqns. 2-4. The weights on the states and inputs are  $Q \in \mathcal{R}^{m \times m}$  and  $R \in \mathcal{R}^{n \times n}$  respectively, while  $P \in \mathcal{R}^{m \times m}$  is the terminal cost matrix derived from the solution of the discrete-time algebraic Riccati equation for the nominal system and input matrices. The states at the end of the prediction are required to belong to the terminal set  $T_s$  (Blanchini, 1999). In the methodology section, the consideration of multiplicative uncertainty within the formulation of eqn. 5 will be shown to provide an optimization based robust counterpart for the LQR.

### 3. Methodology

The methodology presented in this section aims to ensure feasibility of the system for any value of  $\Delta A$  and  $\Delta B$  within their bounds. In other words, it aims to provide a formulation that ensures that for any realization of the multiplicative uncertainty, if the initial values of the states of the system ( $x_0$ ) lay within a feasible domain, there exists a sequence of  $u_T$  that will (a) keep the system feasible for all  $T$  and (b) will try to bring the system to the origin. It is understood that through this robustification methodology the feasible domain of  $x_0$  for which (a) can happen will be significantly reduced compared to a nominal case where no multiplicative uncertainty occurs. Conservatism of the approach is not addressed in the current work, only strict feasibility of the system under uncertainty.

The methodology can be broken down into four steps, namely: (i) Robustification, (ii) Reformulation, (iii) Reduction and (iv) Solution. Note that in the following sections the bounds on  $x_T$  and  $u_T$  are omitted for brevity but are implied and the formulations are valid for  $\forall T \in \{0, \dots, N-1\}$ .

#### 3.1. Robustification

The Robustification of the problem defined by eqns. 2-5 happens successively starting from the initial state to state  $N$  following the approach by (A. Ben Tal, et al. (1998)). Given that the states  $x_T$  and inputs  $u_T$  of the system are bounded for any time-step  $T$  we have from eqns. 2-5:

$$\begin{aligned}
\underline{x} \leq x_{T+1} = A x_T + B u_T \leq \bar{x} \\
\text{Eqns. 2-4}
\end{aligned} \tag{6}$$

The robust counterpart for a matrix  $G$  of appropriate dimensions and a constraint of the form of eqn. 7 can be expressed as in eqn. 8:

$$G x_{T+1} \leq g, \forall T \in \{0, \dots, N-1\} \tag{7}$$

$$G A_0 x_T + \epsilon_A |G| |A_0| |x_T| + G B_0 u_T + \epsilon_B |G| |B_0| |u_T| \leq g \tag{8}$$

### 3.2. Reformulation

The main challenge with eqn. (8) is the absolute values of the state and input variables in every time step. We apply a reformulation based on eqn. 8 as follows:

$$GA_0x_T + \epsilon_A|G||A_0|z_T + GB_0u_T + \epsilon_B|G||B_0|v_T \leq g \quad (9.1)$$

$$-z_T \leq x_T \leq z_T \quad (9.2)$$

$$0 \leq z_T \leq \max\{|\bar{x}|, |\underline{x}|\} \quad (9.3)$$

$$y_T \underline{u} \leq u_T \leq (1 - y_T)\bar{u}, y_T \in \{0,1\} \quad (9.4)$$

$$w_T = y_T u_T \quad (9.5)$$

$$v_T = u_T - 2w_T \quad (9.6)$$

$$0 \leq u_T - 2w_T \leq \max\{|\bar{u}|, |\underline{u}|\} \quad (9.7)$$

Eqn. (9.2-9.3) corresponds to the standard relaxation of the absolute term of  $x_T$  and its bounds, eqn. (9.4) introduces an auxiliary binary variable  $y_T$  which is equal to 0 when the input action  $u_T$  is positive and 1 when it is negative. A continuous auxiliary variable  $w_T$  is introduced in eqn. (9.5) and it represents a bilinear term between the input and auxiliary  $y_T$ . Eqn. (9.6) is used to replace  $v_T$  in eqn. (9.1) while preserving its bounds by (9.7). The bilinear term introduced can be exactly reformulated with a single McCormick relaxation since it is a product between a binary and a continuous variable, as follows:

$$w_T \geq y_T \underline{u} \quad (9.5.1)$$

$$w_T \geq u_T + y_T \bar{u} - \bar{u} \quad (9.5.2)$$

$$w_T \leq \underline{u} y_T + u_T - \underline{u} \quad (9.5.3)$$

$$w_T \leq \bar{u} y_T \quad (9.5.4)$$

By successively robustifying as in 3.1 for all time step in the output/control horizon, reformulating as in eqn. (9.x), utilizing eqn. (9.5.x) instead of (9.5) and substituting  $v_T$  with eqn. (9.6) we derive a robust counterpart of the problem in eqn. (5) that involves the original terms  $x_0$ ,  $u_T$  and the auxiliary terms  $w_T$ ,  $z_T$  and  $y_T$ .

### 3.3. Reduction

The continuous auxiliary variables  $w_T$  and  $z_T$  can be a source of primal degeneracy as described in E. N. Pistikopoulos, et. al (2020), therefore a procedure is needed to project the problem onto a space where the aforementioned variables do not exist but without affecting the feasible space of the original variables. Here, we utilize a single Fourier-Motzkin elimination step per continuous auxiliary variable. For two linear constraints of the form of eqn. (10), assuming without loss of generality  $a_1, a_2 > 0$ :

$$a_1 z_T + l_1(x_0, u_T, y_T, w_T) \leq b_1 \Leftrightarrow z_T \leq \frac{1}{a_1} (b_1 - l_1(x_0, u_T, y_T, w_T)) \quad (10.1)$$

$$a_2 z_T + l_2(x_0, u_T, y_T, w_T) \geq b_2 \Leftrightarrow z_T \geq \frac{1}{a_2} (b_2 - l_2(x_0, u_T, y_T, w_T)) \quad (10.2)$$

where  $l_1$  and  $l_2$  are linear functions of their variables we can eliminate  $z_T$  by substituting eqn. (10) with:

$$\frac{1}{a_2} (b_2 - l_2(x_0, u_T, y_T, w_T)) \leq \frac{1}{a_1} (b_1 - l_1(x_0, u_T, y_T, w_T)) \quad (11)$$

Note that in the LQR problem, given the proposed reformulation, equations of the form of eqn. (10.x) will always be present for all continuous auxiliary variables as they are bounded by definition. Also note that the procedure is repeated for all  $z_T$  and  $w_T$  thus creating a problem formulation in  $u_T$ ,  $z_0$  and  $y_T$ , i.e. a mixed-integer program. Lastly, note that the reformulation presented here is based on reformulating the auxiliary variable

$v_T$  of eqn. (9.1). There exists an equivalent reformulation for the term  $z_T$  involving binary variables which is more challenging, outside the scope of the current work but within the scope of overall research associated with this approach and currently under development.

### 3.4. Solution

The reduced problem is symbolically presented below:

$$\begin{aligned} \min_{\mathbf{u}, \mathbf{y}} \quad & [\mathbf{u}^T, \mathbf{y}^T] \mathbf{H} [\mathbf{u}^T, \mathbf{y}^T]^T + [\mathbf{u}^T, \mathbf{y}^T] \mathbf{Z} \mathbf{x}_0 \\ \text{s. t.} \quad & \mathbf{G} \mathbf{u} + \mathbf{E} \mathbf{y} \leq \mathbf{b} + \mathbf{F} \mathbf{x}_0 \\ & \mathbf{C} \mathbf{R}_A \mathbf{x}_0 \leq \mathbf{C} \mathbf{R}_b \\ & \mathbf{y} \in \mathbf{0}, \mathbf{1}^n, \mathbf{u} \in \mathcal{R}^n, \mathbf{x}_0 \in \mathcal{R}^m \end{aligned} \quad (12)$$

The matrix  $\mathbf{H}$  can be shown to be  $\mathbf{H}$  a  $\{2n \times 2n\}$  positive semi-definite matrix given that the matrices defining the LQR in eqn. (5) are positive definite. Bilinear terms between continuous and binary terms or purely binary terms that may arise due to  $\mathbf{H}$  can be exactly reformulated similar to eqn. (9.5.x). The program described by eqn. (12) can be solved online as soon as values for  $\mathbf{x}_0$  are available with the use of any local MIQP algorithm (i.e. CPLEX, Gurobi, etc.) or explicitly with the use of multi-parametric programming, treating  $\mathbf{x}_0$  as uncertain but measurable parameters, as described in E. N. Pistikopoulos, et. al (2020).

## 4. Uncertain constrained LQR example

Here we consider an LQR of a double integrator system described by eqn. (5) where  $Q = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ ,  $R = 0.01$ ,  $P = \begin{bmatrix} 2.6235 & 1.6296 \\ 1.6296 & 2.6457 \end{bmatrix}$ ,  $A_0 = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$ ,  $B_0 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ ,  $\epsilon_A = \epsilon_B = 0.1$ . The system bounds are defined as  $\bar{\mathbf{x}} = -\underline{\mathbf{x}} = [10, 10]^T$  and  $\bar{\mathbf{u}} = -\underline{\mathbf{u}} = 2$ .

Figure 1: Critical Regions of mpMIQP. The axes represent initial state values

An horizon of 2 time-steps is used. The problem is treated as discussed in section 3 and eqn. 12 is solved via multi-parametric Mixed Integer Quadratic Programming, while preserving the envelopes of solution as described in Pistikopoulos et al. (2020). The solution comprises of 108 Critical Regions (shown in Figure 1) and is able to stir the problem back to the origin from various starting points for a plethora of multiplicative uncertainty realizations. This is presented in Figure 2 where the system returns to the origin for various, random, multiplicative uncertainty realizations and two different starting points for the states, without constraint violations, an indication of successful robustification.

Figure 2: Optimal input and system response of the example for various values of multiplicative uncertainty and two starting points ( $x_0 = [-2, -4.4]$ : left,  $x_0 = [-10, 4.4]$ : right)

## 5. Concluding remarks

In this work, we presented an algorithm to solve robust explicit RHO problems via mpMIQP. Our approach is based on the (i) robustification, (ii) reformulation and (iii) reduction prior to the (iv) solution via multi-parametric programming. We demonstrated our findings on a constrained LQR case study where we exhibited that the system can be driven to the origin for any arbitrary, bounded value of the multiplicative uncertainty. Our next steps include the extension of step (ii) to other auxiliary variables and the extension to other classes of rolling horizon optimization problems.

## Abstract

With the reform of industrial production digitization and automation, process fault detection and diagnosis (FDD) has been an indispensable technical method to realize the safe and efficient production of chemical process, even if there may be some delay and inaccuracy. Fault prognosis could predict the occurrence of faults in advance, which would give operators more time and reduce the impact of faults. Frozen Pretrained Transformer (FPT) has shown language-pretrained transformers can obtain strong performance on a variety of simple non-language classification tasks. Inspired by the pre-trained models, we proposed a chemical process data prediction method based on FPT models. Specifically, we take a transformer model pretrained on natural language data and finetune some parameters on the chemical process data. And the Tennessee Eastman process (TEP) was used to demonstrate the validity of the method. Finally, we discussed the relevant issues in applying language-pretrained models to process data.

**Keywords:** Process data prognosis; Chemical process; Transformer model; Frozen pretrained model.

## 1. Introduction

In recent decades, with the reform of industrial production digitization and automation, various industrial processes have generated massive amounts of data. In order to fully process and apply these data, the computing power of machines has reached an unimaginable level (Rehman et al. 2019). In the modern chemical industry, the development of artificial intelligence technology has made outstanding contributions to industrial intelligence, but the promotion of automation and intelligence has also made modern chemical plants becoming more and more large-scale and highly complex than ever.

As the complexity of chemical engineering systems has increased, chemical process safety has been challenged to a large extent. The faults of chemical processes may cause economic losses and casualties, which pose a great threat to chemical safety (Venkatasubramanian et al. 2003). FDD has been an indispensable technical method to realize the safe and efficient production of chemical processes and has substantial theoretical and application value in the chemical industry (Bi et al. 2022). However, FDD may be not sufficient in some cases, and it is necessary to prognose the fault ahead of time. Fault prognosis mainly aims at potential and future faults, which means the research

object of fault prognosis is a future uncertain event (Smith and Randall 2015; Zhang et al. 2011). Bai et al. (Bai and Zhao 2023) explained the relationship between fault prognosis and FDD, which is shown in Fig. 1. In the process monitoring loop, the fault prognosis, located before FDD, attempts to identify that the system is in an abnormal state in advance, which would greatly reduce the probability of abnormal conditions.

Fig. 1. Relationship between fault prognosis and process monitoring (Bai and Zhao 2023).

Current fault prognosis methods can be generally classified into three types: model-based methods, knowledge-based methods, and data-based methods (Zhong, Han, and Han 2020). Data-based methods determine the status of the system within a certain period by analyzing previously observed data. With the development of automation and digitization, data-based models have been playing an increasing role in the process industry.

Fault prediction methods have evolved with the changing characteristics of industrial data. As data complexity increases, many data-driven methods are flexibly applied in nonlinear scenarios, such as Artificial Neural Networks, autoencoder, Support Vector Machine, Radial Basis Function network, Recurrent Neural Network (RNN) and long short term memory (LSTM) (Yuan et al. 2020). Transformer architecture has widespread applications, particularly in Natural Language Processing (NLP) and computer vision, which also triggered huge interests in the time series data (Wen et al. 2022). It has become common practice to train large models on unsupervised or weakly supervised objectives before finetuning or evaluating zero-shot generalization on a downstream task. Lu et al. found that pre-training in natural language can improve the performance and computational efficiency of non-verbal downstream tasks, and proposed the Frozen Pretrained Transformer (FPT) model (Lu et al. 2021), which inspired the pre-trained models for time series data.

In this paper, we propose a process data prediction method for chemical process based on FPT models. We take a transformer model pretrained on natural language data and finetune some parameters on the chemical process data. And the Tennessee Eastman process (TEP) was used to demonstrate the validity of the method. The results show that the proposed method obtain the strong performance and less consumption on the chemical process fault prognosis task. Additionally, we discussed the relevant issues in applying language-pretrained models to process data, which verified further validity of the proposed method.

The remainder of this paper is organized as follows. Section 2 reviews the basic knowledge of Transformer models and FPT model. Section 3 includes the descriptions of the proposed process data prediction method. The applications and discussions are revealed in Section 4. Section 5 gives summary.

## 2. Methodology

### 2.1. Self-attention

The attention mechanism could overcome this weakness by learning the weights of input information at different times. We show a version of a commonly used attention in Fig. 2, which was proposed as self-attention (Vaswani et al. 2017).

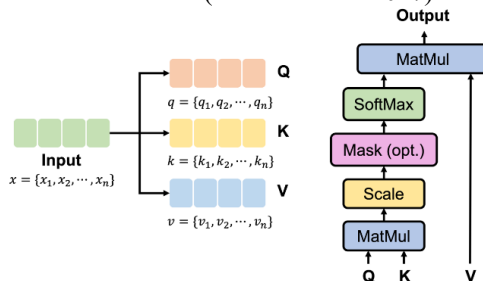

Fig. 2. A schematic diagram of self-attention.

Firstly, given an input sequence  $x = \{x_1, x_2, \dots, x_n\}$ ,  $x_i \in R^k$ , query, key and value vectors can be obtained by mapped with linear transformations and  $q_i, k_i, v_i \in R^{d_k}$  are examples to show the calculation process of each element.

$$q_i = W^q x_i, \quad k_i = W^k x_i, \quad v_i = W^v x_i, \quad i = 1, 2, \dots, n \quad (1)$$

Where  $W^q, W^k, W^v \in R^{d_k \times k}$  are learnable matrices.

Then, the similarity score of  $q_i$  and  $k_j$ , which are chosen as examples to show calculation, is calculated through a scaled dot-product function, and the SoftMax function is then used to normalize the scores and obtain the weights.

$$\alpha_{i,j} = \frac{q_i \cdot k_j}{\sqrt{d_k}} \quad (2)$$

$$\hat{\alpha}_{i,j} = \frac{\exp(\alpha_{i,j})}{\sum_{t=1}^n \exp(\alpha_{i,t})} \quad (3)$$

Finally, the output is calculated as the weighted sum of values.

$$z_i = \sum_{j=1}^n \hat{\alpha}_{i,j} v_j \quad (4)$$

### 2.2. FPT model

To investigate this hypothesis, we take a transformer model, GPT-2, pretrained on natural language data (Radford et al. 2019). GPT-2 is a transformers model pretrained on a very large corpus of English data in a self-supervised fashion. Crucially, all communication between tokens in the model are frozen. The data in each datapoint is chunked into discrete tokens, and can only reference each other via the frozen attention connections, which are not trained. Our key investigation is to analyze the performance of the model in process data prediction, which is already inherent in the language model. On the basis of the pretrained model, the model is finetuned with a minimal amount of computation on the downstream modality. The FPT model used in process data utilizes the feature extraction part of the pretrained model, and adds two fully connected layers to handle the

input process data and the output features. There are five types of parameters in the finetune process, which are input layer, output layer, layer normalization, positional embedding and input embedding.

### 3. The proposed method

The proposed process data prediction method is shown in the Fig. 3. Firstly, process data can be directly used as model input without embedding. The sequence structure of the process data can reduce the difficulty of position coding, and we can use one-hot matrix to indicate the order of input. Then the input layer expands the dimensionality of input data as needed for GPT-2. And the features of the process data are extracted by the pretrained model by NLP. Finally, the output layer gets the prediction results of the process data by the features. The dimension of the input layer is the sum of the dimension of process variables and the time dimension. The dimension of the output layer is the dimension of process variables. The number of the dimension in the GPT-2 is 762 and the number of frozen attention block is 12.

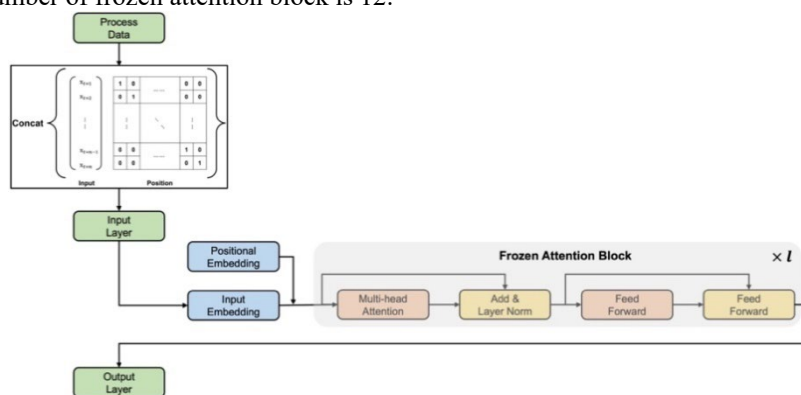

Fig. 3. The diagram of the proposed process data prediction method.

## 4. Applications and discussions

### 4.1. Applications on the TEP

TEP is a classical model benchmark for simulating chemical processes, which has been widely used as a study case for FDD and fault prognosis. It is mainly composed of 5 unit operations, including a reactor, a condenser, a recycle compressor, a vapor-liquid separator, and a stripper. The initial version of TEP simulation involves 12 manipulated variables, 41 measured variables and 20 different types of faults. In 2015, Bathelt revised the original TE model and used MATLAB's Simulink to build a new one, adding 8 measurement variables, 24 component variables, and 8 new process disturbances (Bathelt, Ricker, and Jelali 2015). In our work, the applications are based on the revised version of Bathelt, which is shown in the Fig. 4.

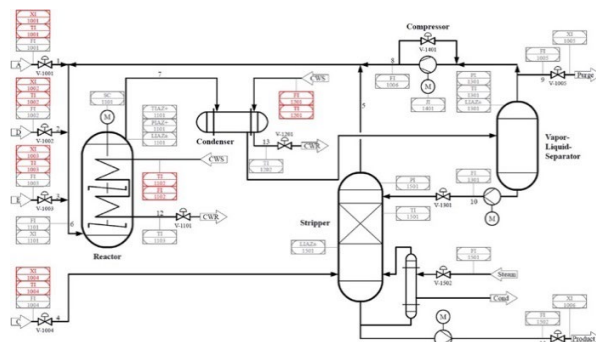

Fig. 4. P&ID of the revised TEP model (Bathelt, Ricker, and Jelali 2015).

Since the sampling frequency of component analysis measurement is much lower, we only choose the process manipulated variables and continuous process measurements except variables related to valves for dataset building. Among the common faults in the TEP, most fault types are step or random changes, which bring significant changes to the system within a short time of the fault occurrence. The process variables prediction and fault prognosis are with little necessarily in the cases, and these cases do little help for validating the effectiveness of the prediction methods in chemical process. According to the application results of the FDD methods in the abnormal state of TEP, we choose fault 13 as the target of the study, which is the fault of reaction kinetics drifting slowly.

A simulation dataset is built to assess the fault detection and identification performance of all the methods. During the simulation, 1 sample is collected every 1 min. The datasets include 10 sets of data for fault 13. Each set of data includes 480 normal samples followed by 600 fault samples, corresponding to 8h of normal data and 10h of fault data. The training dataset includes 8 sets of data and the validation dataset and the testing dataset each includes a set of data. For the selected time window, the goal of the model is to predict the changes in the 30 process variables over a future time window. And MSE of all the process variables in the time window is selected to be the loss function. We chose RNN, LSTM, BiLSTM and full GPT2 to compare the predictive performance. And the full GPT2 means that we trained all the parameters of the GPT2 model in the training stage. The prediction results of different methods with different time window are shown in the following Table. 1.

Table. 1. Prediction results of different methods.

Method	Time widow = 8	Time widow = 16	Time widow =32
RNN	0.826	1.355	<b>2.648</b>
LSTM	0.714	1.147	2.883
BiLSTM	0.737	1.157	3.842
FPT	<b>0.140</b>	<b>0.510</b>	2.774
Full GPT2	0.647	0.999	4.016

The results shown that the FPT had the best performance when the time window is 8 or 16. Theoretically, the result of full GPT2 should be a lower bound of FPT. However, due to the limited training datasets of process variables, the MSE of full GPT2 is larger than that of FPT. And it indicated that to some extent better prediction results could be achieved in the process variables using a pretrained model than a fully trained model. To the time window of 32, FPT didn't get the better performance.

When only the parameters of input layer and output layer were finetuned, the MSE was 7.808. On this basis, we only finetuned some selected parameters to find out which

parameters were most important in the GPT2 model for process variables prediction. Firstly, we only finetuned the parameters of the layer normalization, and the MSE reduced to 0.563, which indicated that finetuning the parameters of the layer normalization could improve effectively prediction results. Then we added the parameters of the position embedding to the finetuned parameters, and the MSE reduced to 0.556. Then we added the parameters of the input embedding to the finetuned parameters, and the MSE reduced to 0.551. These two increases in finetuned parameters did not effectively reduce the MSE. The results shown that the parameters of the layer normalization played the most important role in the process variables prediction.

Studies have shown that the number of layers of neural networks for process data is less than that for NLP or CV problems. In our work, the number of layers could be measured by the number of used frozen attention blocks. We finetuned the model with different numbers of frozen attention blocks to learn the most suitable model for the chemical process variables prediction. We found that the number of used frozen attention blocks was selected to be 2 to show the best results in the applications. And the MSE with the time window of 8, 16 and 32 reduced to 0.109, 0.287 and 1.667, which were better than other methods.

## 5. Summary

In the article, we proposed a process data prediction method for chemical process based on FPT models. In TEP the proposed method shown the best validity with the smallest MSE of process variables. And the FPT method could show the strong performance and less consumption on the chemical process variables prediction task. We found that the parameters of the layer normalization played the most important role in the results. And the number of used frozen attention blocks is selected to be 2, which was shown to have better results in the application of chemical process variable prediction. In the future, the application of pretrained models to process variables prediction and process fault prognosis remains widely open with many challenges left to solve.

## Abstract

Subsea pump systems are subject to many possible faults and monitoring typically relies on the measurements of key process variables. However, the measurements themselves may be subject to faults like e.g., bias. In this work, a method that combines fault detection and isolation, observability analysis and state estimation is presented and tested on a simulated pump system. The results indicate that a state estimator with correct information about which sensor has drifted gives lower estimation error than a state estimator that does not consider bias. Furthermore, we show that it is impossible to estimate the bias on all sensors simultaneously due to observability issues of the augmented system.

**Keywords:** Sensor bias, Fault detection, Subsea pump, Fault isolation, Sensor drift.

## 1. Introduction

Subsea pumping systems operate in harsh environments for long periods, making the maintenance of these pumps challenging and costly. Condition monitoring is crucial to keep these subsea pumps running for long periods and to reduce the possibility of accidents. The pumps are subject to several potential faults, and it is desirable to use measurements to detect if something is going wrong. However, the sensors that provide these measures are also susceptible to faults (e.g., gross errors). These gross errors arise from sensors malfunctioning and can significantly impact the monitoring and controlling of the subsea pump.

Given the long operation times of subsea pumps, the long-term faults (e.g., bias) are more challenging to detect than other abrupt changes. It is desirable to detect and isolate these biases as soon as possible and, if practicable, estimate their magnitude. Approaches to deal with these sensor biases can be classified as passive or active. The passive methods apply robust estimators like M-estimators, robust Kalman Filter (KF), and robust Moving Horizon Estimation (MHE) (Siddhartha et al., 2022). Passive methods efficiently handle gross errors, but no information about the bias's location and size is generated. The location of the gross errors is a valuable information for maintenance and process monitoring. On the other hand, active methods try to estimate these biases, usually representing the bias as a new time-dependent continuous parameter on the state estimation problem (Gatzke & Doyle III, 2002). However, observability problems usually arise (Gatzke & Doyle III, 2002).

In this paper, we propose to combine fault detection and isolation (FDI) methods, observability analysis and state estimators in the context of a subsea pump system. In our methodology, i) FDI is used to identify sensors with bias. ii) Then an observability analysis is performed to check if it is possible to estimate that bias, and iii) then the state estimator is extended with a bias parameter to be estimated. The FDI reduces the number of biases to be estimated, and the observability analysis assures that the bias can be estimated without worsening the state estimator's performance. This illustrates how attempting to estimate sensor bias without any *a priori* information of which sensors are failing is impractical and how combining FDI with state estimators can improve the estimation significantly. Furthermore, a Monte Carlo analysis is performed to show the advantages and limitations of that approach in multiple scenarios.

## 2. Case study: Subsea pump system

We consider a simple subsea booster pump system, as shown in Figure 1. A mixture of oil and water comes from the reservoir at pressure  $p_1$ . The pump runs with a variable speed drive (VSD) at  $\omega$  rpm, which produces a specific head,  $H$ . Given the density of the fluid,  $\rho$ , one can calculate the pressure at the outlet of the pump,  $p_2$ . The pressure  $p_3$  is determined by downstream facilities (oil platform). The choke valve has a flow rate of  $q$  and opening of  $Z$  %. The three pressures are measured, and a Venturi flowmeter measures the pressure drop over an internal orifice (not shown).

Figure 1: The subsea booster pump with its installed sensors. FT is a Venturi flowmeter.

### 2.1. Pump model

Sensor bias is a phenomenon that typically takes place in the timescale of months and years. The pressure and density changes in the reservoir are on the same timescale, and we assume the pressure on the oil platform has the same trend as the reservoir pressure. On the other hand, phenomena such as transient flow regimes happen almost instantly in the timescale of seconds. This motivates the use of a quasi-steady state model, where changes in the reservoir and  $p_3$  are modelled dynamically and the pump is modeled in steady-state (and therefore the time-subscript is  $k + 1$  on both sides of the equality sign in (4)-(6)). It is assumed that  $p_1$  and  $p_3$  decreases at the same rate, hence, they have the same parameter  $\theta_{p,1}$ . The faultless system is described by:

$$p_{1,k+1} = p_{1,k} + \theta_{p,1}\Delta t + w_{p_{1,k}} \quad (1)$$

$$\rho_{k+1} = \rho_k + \theta_{\rho}\Delta t + w_{\rho,k} \quad (2)$$

$$p_{3,k+1} = p_{3,k} + \theta_{p,1}\Delta t + w_{p_{3,k}} \quad (3)$$

$$p_{2,k+1} = p_{1,k+1} + \rho_{k+1}gH_{k+1} + w_{p_{2,k}} \quad (4)$$

$$q_{k+1} = C_v Z_{k+1} \sqrt{\frac{p_{2,k+1} - p_{3,k+1}}{\rho_{k+1}/\rho_{water}}} + w_{q,k} \quad (5)$$

where the head at time  $k$ ,  $H_k$ , is found by using the so-called pump curve.

$$H_{k+1} = \theta_{H_0} \omega_{k+1} + \theta_{H_1} q_{k+1} \omega_{k+1} + \theta_{H_2} q_{k+1}^2 \quad (6)$$

The states are  $\mathbf{x}_k = [p_{1,k}, p_{2,k}, p_{3,k}, \rho_k, q_k]^T$  and the state-propagation equations (1)-(5) can be written in the form of  $\mathbf{x}_{k+1} = \mathbf{f}(\mathbf{x}_k, \mathbf{u}_{k+1}, \Delta t) + \mathbf{w}_k$ . The stochastic process noise is defined as  $\mathbf{w}_k = [w_{p_1,k}, w_{p_2,k}, w_{p_3,k}, w_{\rho,k}, w_{q,k}]^T \sim (\mathbf{0}, \mathbf{Q}_k)$ . The process noise distribution is assumed to be constant at  $\mathbf{w}_k \sim \mathcal{N}(\mathbf{0}, \mathbf{Q})$  where  $\mathbf{Q} = 10^{-5} \mathbf{I}$ . The parameter values are  $\boldsymbol{\theta} = [\theta_{p,1}, \theta_p, \theta_{H_0}, \theta_{H_1}, \theta_{H_2}, g, C_v] = [-5.0, 5.0, 3.51 \times 10^{-5}, 3.29 \times 10^{-4}, -0.01, 9.8 \text{ m/s}^2, 47.50 \text{ m}^3/\text{h}]^T$ , where  $g$  is the gravitational constant and  $C_v$  is the valve constant. The remaining parameters describe the evolution of pressure and density in time. The initial conditions for all the simulations were  $\mathbf{x}_0 = [50.0 \text{ bar}, 64.5 \text{ bar}, 51.0 \text{ bar}, 700 \text{ kg/m}^3, 136.6 \text{ m}^3/\text{h}]^T$  and  $\mathbf{u}_0 = [65 \%, 3500 \text{ rpm}]^T$ . When there is no bias in the sensors, the sensor equations are:

$$\mathbf{y}_k = \mathbf{h}(\mathbf{x}_k) + \mathbf{v}_k = \left[ p_{1,k}, p_{2,k}, p_{3,k}, \frac{\rho_k(1 - \beta^4)}{2} \left( \frac{4q_k}{\pi d^2 C \epsilon} \right)^2 \right]^T + \mathbf{v}_k \quad (7)$$

where  $C = 1.01$  is the flow coefficient,  $\epsilon = 1$  is the expansibility factor,  $d = 0,0525 \text{ mm}$  is the Venturi throat diameter,  $D = 0,154 \text{ m}$  is the internal pipe diameter and  $\beta = d/D$ . The measurement noise is distributed as  $\mathbf{v}_k \sim \mathcal{N}(\mathbf{0}, \mathbf{R})$ , where  $\mathbf{R} = \text{diag}([0.1035, 0.1035, 0.1035, R_{venturi}])$ .

## 2.2. Pressure sensor bias

Sensor bias is a constant systematic error in measurement and sensor drift is a time-varying bias in the sensor. Hence, the measurement equation (7) must account for these biases and drift in the following manner, where  $\mathbf{y}_k^d$  is the bias/drift value at time  $k$  and  $\mathbf{y}'_k$  is the measurement equation with bias/drift:

$$\mathbf{y}'_k = \mathbf{y}_k + \mathbf{y}_k^d = \mathbf{h}(\mathbf{x}_k) + \mathbf{v}_k + \mathbf{y}_k^d \quad (8)$$

To estimate the bias/drift, we augment the state vector and model the bias/drift as a random walk. The augmented model is now given by

$$\mathbf{x}_{k+1}^a = [\mathbf{x}_{k+1}, \mathbf{y}_{k+1}^d]^T = [\mathbf{f}(\mathbf{x}_k, \mathbf{u}_{k+1}, \Delta t), \mathbf{y}_k^d]^T + [\mathbf{w}_k, \mathbf{w}_{y^d,k}]^T \quad (9)$$

where  $\mathbf{w}_{y^d,k} \sim \mathcal{N}(\mathbf{0}, \mathbf{Q}_y)$  is the distribution describing the steps of the random walk.

## 3. Combining fault detection and observability analysis to state and bias estimation.

The simultaneous estimation of states and biases in all the sensors simultaneously can make the system non-observable. To avoid these problems, this work combines FDI methods and observability analysis with state estimation. Figure 2 illustrates the methodology. The first step consists of the residual generation. The measurement ( $\mathbf{y}'_k$ ), which may have a bias or drift, is compared to the model's predicted measurement ( $\hat{\mathbf{y}}_k$ ). Then this residual is evaluated by a statistical test that is aimed in deciding if the system is fault-free or which sensor has drifted. After that, an observability analysis is performed to evaluate if the identified bias can be estimated. In the positive

case, a new term is included on the state estimator as described in section 2.2 to track the bias/ drift on the failing sensor. Otherwise, the standard state estimation is performed without adding additional bias terms.

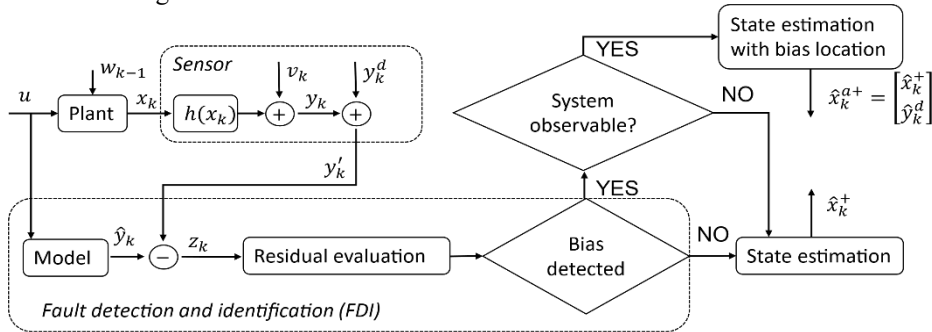

Figure 2: Conceptual flowsheet of how FDI-technique is used to update the structure of the state estimator.

### 3.1. Residual evaluation for bias detection

Three residuals are made, one for each pressure sensor, which consists of the difference between the model prediction and the measurement. Assuming a perfect model, it is possible to identify a bias in the pressure measurements since these residuals should be zero mean in a normal operating condition and different from zero when a bias occurs. To evaluate if the residuals are different from zero, the statistical method called cumulative sum control chart (CUSUM) was used (Blanke, 2016). A Gaussian distribution was assumed to represent the residual distribution ( $\mathcal{N}(\mathbf{0}, \mathbf{R})$ ), and any deviation higher than five times the standard deviation would correspond to a fault.

### 3.2. State estimation and Observability analysis

We used the Unscented Kalman filter (UKF) to obtain the optimal estimate of the true state and bias (Simon, 2006, ch. 14). The bias terms were included on the UKF as time-dependent continuous parameter as described in section 2.2. The concept of observability tells us if we can uniquely determine the state given some measurements, which is a requirement for state estimators to work. For linear systems, observability can be checked by verifying if the observability matrix has full rank. See Simon (2006, ch. 1.7.2) for a definition of the observability matrix and a discussion about observability for linear systems. In our work, we linearized the model and checked the rank of the observability matrix for the linearized model. If the (augmented) system is not observable, we did *not* include the bias term in the state estimator and used the fault-free estimator as Figure 2 shows.

## 4. Results

The results section is divided into two parts. First, in section 4.1, an illustrative simulation shows how a previous bias detection and isolation step can improve the state estimation process. Then, in section 4.2, a Monte Carlo analysis is performed to evaluate the method's performance in different scenarios.

#### 4.1. Estimator with information of bias location

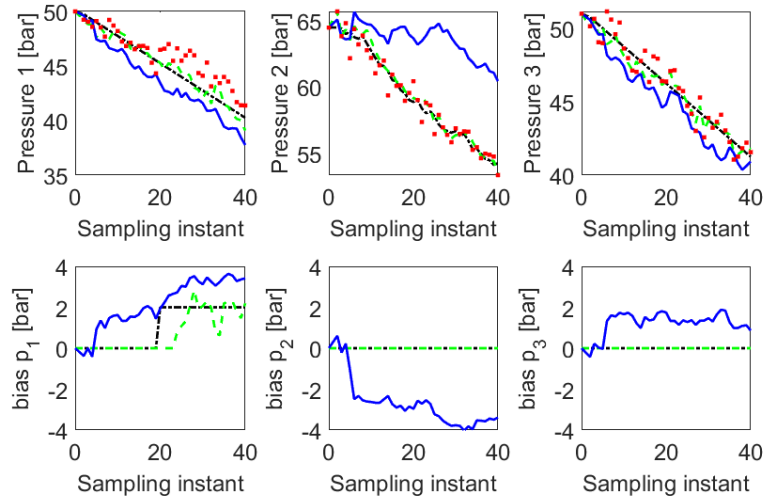

Figure 3- Comparison of true state (black), pressure measurements (red) and the estimates using  $UKF_b$  (blue) and  $UKF_{fdb}$  (green). Bias was introduced on the measurements of sensor PT1.

The model described in Section 2 was solved for a time window of 40 samplings. After 20 samples, a constant bias of 2 bar is added to the pressure sensor one (PT1). Two methodologies are compared in this scenario; first, the UKF with bias estimation ( $UKF_b$ ), where the estimators try to estimate the bias on the three sensors since the beginning of the window. Hence, the augmented state dimension is  $5 + 3 = 8$  through the entire time.

Second, our proposed method described in Section 3 is applied ( $UKF_{fdb}$ ). Here, the state dimension is 5 before sampling time 20 and after a successful FDI and observability procedure it is 6. The results of the simulation is presented in Figure 3. The results indicate that the observability problems of adding new bias parameters to be estimated arise even for a small system like the subsea pump.  $UKF_b$  fails to estimate the states and bias in all three sensors, even before the bias is added to the measurements on sensor PT1. In fact, the observability analysis showed that the states are non-observable when three bias terms are included on the estimator.

However, when just one bias term is included on the estimator, the states and the bias are observable. This explains why the  $UKF_{fdb}$  could obtain a good estimate of the states and the bias on sensor PT1.  $UKF_{fdb}$  had a slight delay in detecting the bias on sensor PT1. After that, the observability is verified, and the information on which sensors are failing is sent to the state estimator.

#### 4.2. Monte Carlo analysis

In order to perform a comprehensive analysis of the methodology, a Monte Carlo analysis was performed. This study compared three approaches:  $UKF_b$ ,  $UKF_{fdb}$  and the “standard” UKF without bias estimation. All the simulations started from the same initial condition, with 100 samplings as a time window. Three hundred random samples of different simulation features were used: time to insert the bias (between 10 and 80 samples), the magnitude of the bias (-2 bar to 2 bar), control profile (pump speed and valve opening), sensor location of the bias (sensor 1, 2 or 3) and bias or drift. The results of the simulations are summarized in Table 1.

The results show that the UKF<sub>b</sub> has poorer performance than the UKF. The system's observability must be checked before including new bias parameters to be estimated. The standard UKF is the best option in cases of non-observable states. However, when a fault detection and isolation method is applied, there is no need to include a bias term in the UKF for each sensor. Instead, only after the bias is detected a new term can be added to the UKF. The UKF<sub>fdb</sub> had a better performance in terms of state estimation, with only a slightly larger error on  $q$  and  $H$ . Besides that, it can also provide a reasonable estimate of the bias in the sensors, which is a valuable information for pump system monitoring.

Table 1: Root-mean-square error states and bias over 300 simulations. \* is “sampling instances”.

	Bias correctly Located [%]	Average delay [*]	RMSE						
			bias [bar]	$p_1$ [bar]	$p_2$ [bar]	$p_3$ [bar]	$\rho$ [kg/m <sup>3</sup> ]	$q$ [m <sup>3</sup> /h]	$H$ [m]
UKF	-	-	-	0.74	0.77	0.75	24.97	2.54	3.15
UKF <sub>b</sub>	-	-	4.89	2.32	3.57	1.92	273.61	2.40	3.08
UKF <sub>fdb</sub>	86.00	14.96	0.52	0.42	0.41	0.44	10.86	2.58	3.21

## 5. Conclusion

An approach to monitor and estimate sensor bias on subsea booster pump system was numerically evaluated. The results suggest that estimating sensor bias without any *a priori* information about which sensors are failing is impractical. Therefore, combining fault detection and observability analysis techniques with sensor estimators can improve the estimation significantly and provide helpful information for system monitoring. A more thorough structural and local observability check should be applied in future works. Also, the performance of the methods for multiple simultaneous faults should be evaluated.

## Abstract

Process industries are highly hazardous, and these hazards often lead to accidents. Over 70% of these accidents are attributed to human errors. With the advancements in technology and changing role of operators to the one involving an emphasis on cognitive aspects, most of these errors occur due to limitations in cognitive performance. One of the major constructs to understand cognitive performance is the cognitive workload. An increase in cognitive workload often leads to degradation in performance. Eye tracking has been used in several domains to assess cognitive workload. In this work, we propose a methodology to assess cognitive workload of control room operators during tasks that involve tackling process abnormalities. The methodology employs the fusion of metrics obtained from pupil and gaze data. Our results reveal that fusion of metrics provides better accuracies of classifying cognitive workload at three levels—low, medium and high workload.

**Keywords:** human errors, operator performance, cognitive workload, eye-tracking, decision trees

## 1. Introduction

Chemical and process industries are highly hazardous, and these hazards frequently result in disastrous accidents. Even though there have been tremendous increases in safety due to better process design and technical safety approaches, mishaps still happen. A significant majority of these accidents can be traced back to human errors; human errors contribute to around 60-80% of accidents (Jung et al., 2020). Nonetheless, humans form an essential layer of protection, especially in the wake of abnormalities in the process that are often outside the purview of control systems. However, with the advancements in technology in the form of digitalization, and concomitant automation (Khan et al., 2021), the role of human operators has changed more towards monitoring (during regular operation), diagnosis, and prognosis (during abnormal situations). To maintain adequate situational awareness, operators must prioritize, acquire, segregate, and integrate information from multiple sources in distributed control system (DCS). An abundance of information due to digitalization, coupled with the increased complexity of modern plants, makes these tasks cognitively challenging for an operator, especially if they are not highly skilled. Further, the increased automation which often keeps the operator out-of-loop with the system makes it even more challenging for them to develop correct mental models (understanding of the process). As a result, operators' cognitive workload can drastically increase if they are not adequately trained and assessed. An increase in

cognitive workload is known to result in the degradation of performance (Iqbal et al., 2020; Islam et al., 2017). There is a strong association between cognitive workload and human errors. While human errors are a result of mismatch between process demands and human capabilities high cognitive workload, at the most general level, is a result of mismatch between mental resources demanded by the process and those supplied by an operator (Parasuraman, 2008).

Traditional approaches of performance assessment are primarily based on process and operator action-based measures such as number of successes and failures, reaction times, deviations from standard operating procedures, and time taken to complete a task (Iqbal et al., 2021). These ignore the cognitive aspects of performance, such as cognitive workload, decision-making, information acquisition pattern, and operators' mental states while they perform a task. Hence, these also fail to unravel the underlying reasons for shortcomings in operator performance. While subjective assessment-based methods such as National Aeronautics Space Administration Task Load Index, or NASA-TLX (Hart, 2006) are employed for assessing cognitive workload, these are often criticized for being prone to subjective-bias. These can also not be used to assess changes in cognitive workload in real time, and thus have limited practical applicability. Therefore, there is a need to assess cognitive workload of control room operators objectively.

Advancements in sensory technology such as eye tracking, electroencephalography (EEG), electrocardiography (ECG) and electrodermal activity (EDA) have made it possible to tap on physiological measures as surrogates of cognitive performance (especially cognitive workload). Physiological measures are intrinsic and provide critical insights into covert factors that shape operator performance. In this paper, we discuss how fusion of gaze and pupil-based metrics obtained using eye-tracking can be employed to better characterize cognitive workload of control room operators while they control process abnormalities.

## 2. Literature

Researchers in safety critical domains such as aviation, driving and healthcare industries have attempted to understand cognitive workload using eye-tracking due to its non-invasive nature and ease of use. Eye tracking involves tracing the eyes of a person with respect to their head in order to obtain the coordinates of their gaze on an human machine interface (HMI). Eye tracking provides critical insights into visual behavior. Since about 50% of the brain's neural pathways are used for visual processing (Woo, 2019), visual behavior is important to understand cognitive aspects of performance. For instance, during stressful emergency accident situations, expert nuclear power plant operators have a different eye gaze pattern, marked by higher total fixation durations compared to novices (Liu et al., 2019); higher fixation duration reflecting the ability to extract more relevant information. Pupil diameter obtained using eye-tracking also provides crucial information about human cognitive performance. For instance, during simulated surgical tasks, it was found that higher pupil dilations corresponded to increase in complexity of the tasks (Zheng et al., 2015). Experiments conducted to assess air traffic controllers' workload revealed that increase in subjective workload translated into an increase in the amplitude of pupil diameter (Rodríguez et al., 2015). Another study revealed that changes in mental workload can be captured by frequency domain analysis of pupil diameter measurements (Peysakhovich et al., 2015).

Various physiological measures have also been fused for use in machine learning models for classifying operator mental states. For instance, eye gaze and EEG based features have been fused to develop models for differentiating between groups of learners: those who could successfully resolve a problem-solving task involving medical diagnosis via an HMI, and those who could not (Khedher et al., 2019). The study revealed that fusion of features resulted in an improved accuracy of 75% in identifying learners and non-learners. It was observed that using only set of features resulted in poor performance (18% using eye features only and 0% using EEG only) in correctly classifying failure cases (non-learners). Ding et al. (2020) found that fusion of sensors corresponding to ECG and EDA resulted in an accuracy of around 58% for classification of mental workload using neural networks. Similarly, four types of feature sets based on EDA, ECG, respiration, and blood oxygen saturation were used in a study to discriminate between high and low levels of workload corresponding to two different levels of difficulty induced during three different cognitive activities (Game, Numerical test, and Raven's test) (Hirachan et al., 2022). The authors report that respiration and SpO2 based features resulted in individual accuracies of 60% and 56% respectively. There have been a few studies focusing on multi-level classification of workload as well. For instance, McDonald et al., (2020) reported an accuracy in the range of 24% to 56% using several machine learning algorithms for classifying driver distraction based on physiological data. The focus of these studies has primarily been on simpler tasks which do not evolve dynamically.

Process industry operator's role involves dealing with tasks which evolve dynamically and the demands on the operator also vary in response to their actions. The disturbances in chemical processes primarily originate from within the plant rather than because of external environment such as nature of numeric calculations or traffic conditions. This makes the cognitive requirements of control room operators unique (Müller and Oehm, 2019) and makes it challenging to characterize the same. Our previous research on reveals that gaze analysis and pupil diameter can provide critical insights into cognitive aspects of control room operator's performance. For instance, gaze entropy can capture the differences in eye-gaze behaviour between novices and experts (Iqbal et al., 2018). The study found that with learning gaze entropy decreases reflecting increase in expertise owing to decreased cognitive workload. Pupillometry studies indicate that the diameter of the pupil correlates closely with operator's ability to successfully perform the tasks involving bringing process within safe limits (Bhavsar et al., 2015). Likewise, fixation duration and saccade duration can capture changes in operator mental states (decision making) during such tasks (Das et al., 2018). In this paper, we develop a decision tree model that can estimate cognitive workload of control room operators, *at three levels*, using fusion of gaze-based and pupil-based features.

### **3. Experimental Methodology**

We used a simulated ethanol process as an experimental testbed for conducting human subject studies. The HMI via which the operators interact with the process is shown in Fig. 1. Ten participants were involved in the study, each carrying out several repetitive trials. During a typical trial, a participant carried out six tasks (each corresponding to a disturbance scenario). The role of the operator is to bring the process variables within acceptable limits in case of a disturbance which is notified to the operator through an alarm and change in color of the tags (of disturbed variables). During these tasks, participants' eye gaze data and pupil diameter are recorded using an eye-tracker (Tobii 300). In addition, process data, alarm information, and operator actions are also recorded.

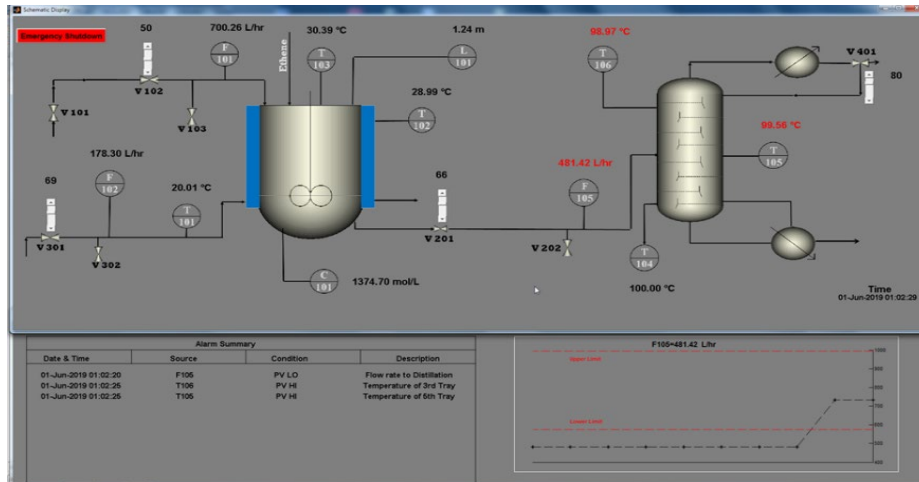

Fig. 1 Human Machine Interface (HMI) of ethanol process

From this information, we calculate integrated absolute abnormality (IAA) which measures the deviation of process variables from acceptable safe limits. We use IAA along with success/failure in a task as a surrogate to classify operators' cognitive workload into three levels- low, medium, and high. Low values of IAA correspond to low workload as these are successfully completed by the operators. On the other hand, if IAA during a task was much higher, operators failed in most of those tasks. Intermediate values of IAA correspond to low workload. Next, pupil and eye gaze-based metrics are extracted for each task (after alarm occurrence) to populate a feature matrix. These metrics for pupil include power spectral densities of pupil diameter and average pupil diameter. For gaze, these include various fixation-based metrics. A summary of these metrics is provided in Table 1. We trained decision tree models based on i) pupil-based features only ii) gaze-based features only and, iii) fusion of pupil and gaze-based features to estimate the cognitive workload of operators as well as assess the impact of fusion.

Table 1. Summary of feature categories

S. NO.	Feature	Feature Description
1	Pupil	P1: PSD of pupil diameter signal in the range 0 – 0.5Hz P2: PSD of pupil diameter signal in the range 0.5 – 1 Hz P3: PSD of pupil diameter signal in the range 1 – 1.5 Hz P4: PSD of pupil diameter signal in the range 1.5 – 2 Hz P5: Average pupil diameter
2	Gaze	G1: Longest Fixation duration/shortest Fixation duration G2: Normalized Fixation Number i.e., No. of fixations/time G3: Normalized Fixation Duration: Total fixation duration/time G4: Standard deviation of fixation duration G5: Mean of fixation duration

## 4. Results

Consider an operator O1 who performs eight trials of the experiment resulting in a total of 48 tasks. For two of the tasks, some data was missing, and therefore are not considered. Each task is labelled based on the value of integral absolute abnormality (IAA) calculated for post alarm phase of the task as discussed in Section 3.

Table 2. Cognitive workload classification accuracies of trained decision tree model

S. NO.	Feature Combination	Overall Accuracy (%)
1	Pupil only	60.87
2	Gaze only	50.00
3	Pupil + Gaze	65.22

As per the methodology discussed in Section 3, eye tracking based features are obtained for all the tasks that this operator performed. These features are then used as an input to train a decision tree and the model is tested using a 10-fold cross validation technique. It involves randomly dividing the data into 10 parts and then using 9 parts to train the model and test it on the remaining 10%. The procedure is repeated 10 times each time reserving a different one tenth of data for testing. The overall accuracies achieved using different combinations of features for operator O1 are shown in Table 2, and the results clearly highlight the benefits of the fusion of gaze and pupil-based features. Fusion of features results in an increase in classification accuracies to about 65%.

A representative decision tree for O1 trained using fusion of features is shown in Fig. 2(a). The topmost node is the root node and consists of pupil and gaze features for all the 46 tasks that the operator performed i.e., it contains a mix of features which correspond to all the levels of workload (0,1, and 2). The first split is made based on feature P4 (Power spectral density of pupil diameter in the range 1.5 to 2 Hz). This indicates that power spectral density of pupil diameter in range 1.5 to 2Hz is an important predictor of cognitive workload for this participant. For the observations for which P4 is less than 0.55 they are allocated to node 2 (on the left) otherwise to node 3. At node 2, the split is made based on G2 (Normalized Fixation Number i.e., No. of fixations/time). For the observations for which G2 is less than 0.44 they are allocated to leaf node representing workload level of 2 (medium workload). If G2 is greater than 0.22, the observations are allocated to leaf node representing workload level of 3. In a similar way, data at node 3 is split based on the learnt rules till leaf nodes are arrived. Leaf nodes represent the predictions of the target variable which in this case is cognitive workload. The confusion matrix for the decision tree trained using fusion of gaze and pupil-based features is shown in Fig. 2(b). The confusion matrix reveals that decision tree trained on fusion of pupil and gaze-based features can classify high workload levels (class 3) with an accuracy of 75%. Thus, the algorithm performs well in identifying poor performances that can pose safety challenges, and can be used to gauge adequacy of training.

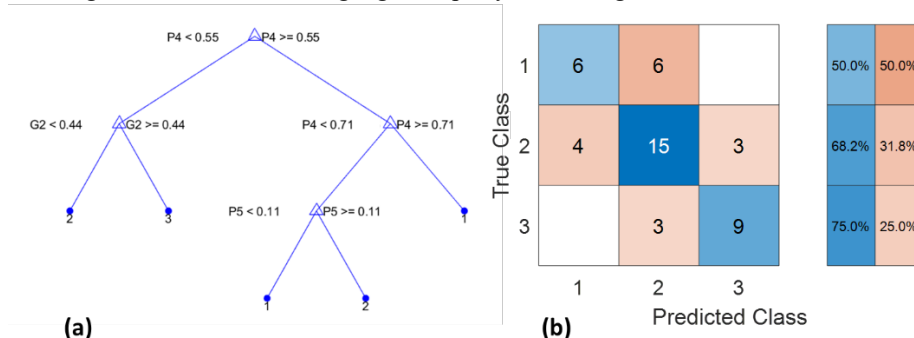

Fig. 2 a) Decision tree trained for operator O1 trained using both pupil and gaze-based features b) Confusion matrix for three levels of cognitive workload

## 5. Conclusion

In this work, we demonstrated how fusion of different categories of features (gaze and pupil) can improve classification accuracies of control room operator's performance as measured by cognitive workload—a precursor to sub-optimal performance. This is the first work of its kind, as it involves multi-level classification of process industry operator performance. The overall achieved accuracy of the model is 65.22% while it can identify poor operator performance (highest workload) with an accuracy of 75% (critical for ensuring adequacy of training). These accuracies are fairly good given the complexities and dynamic aspects of process industry tasks where operator performance is governed by the correctness of the mental models. Similar accuracies (57% for generic model) have been reported for nuclear operators (Braarud et al., 2021). This work has the potential to evaluate operator's expertise, and is thus crucial for ensuring safety in process industries. It also has the potential to guide the application of human factors by providing objective information about operator's expertise and (indirectly) impact of HMI design. In future, we plan to increase the robustness of our model by employing fusion of eye-tracking with electroencephalography (EEG) based features, and identifying other precursors of suboptimal performance. Our previous studies (Iqbal et al., 2020) reveal that EEG based-metrics have the potential to capture performance of control room operators.

## Abstract

Industrial plants are commonly subject to uncertainties during operation. Operability and flexibility are two key properties for design models with uncertain parameters. In this study, flexibility analysis is first considered, where a derivative-free optimization method based on flexibility index is designed to identify the largest rectangular flexibility space, while the optimal nominal point of uncertain parameters can be obtained. Then, a novel operability analysis method is proposed to quantify the entire system operability. Based on the critical points of uncertainties in the flexibility space, a line projection method is adopted to locate boundary points of the operational space. The volume of the operational space is calculated by the Delaunay Triangulation method, and the ratio to the physical operational ranges can be used to assess the system operability. The case study shows the proposed method is capable of dealing with the nonconvex operational spaces.

**Keywords:** Process operability; flexibility analysis; flexibility index; derivative-free optimization.

## 1. Introduction

Uncertainties are process disturbances related to variability of process parameters, which represent the degrees of freedom or manipulated variables in an industrial process, such as feed flow rates and temperatures. The uncertainties can lead to mismatch between a plant and the corresponding design model. Flexibility analysis method was proposed as a quantitative framework for measuring the capability of feasible operations (Floudas, et al., 2001; Zhao, et al., 2022), where the uncertain parameters are measured; the control variables can be manipulated to compensate any variation of uncertain parameters during operation. Flexibility index (Grossmann and Floudas, 1987) is a well-known quantitative indicator, which can define a flexibility space with a specific shape, such as a rectangle. Apart from the process flexibility, analyzing the process operability (Gazzaneo, et al., 2020) is another indispensable part of process design. Lima et al. (2010) summarized the similarities and differences between the process flexibility and process operability in great detail. The traditional process operability focuses on the examination of whether a process controller might be able to meet all the quality requirements due to limitations of the process design, in other words, whether all quality outputs are operable in the presence of disturbances; by comparison, the process flexibility is concerned with whether the process is feasible for all the desirable quality outputs due to the uncertainties. Flexibility and operability are two closely linked concepts, which have been recognized to represent two important features in the production process. In a word, with the presence

of uncertainties, the process flexibility quantifies the ability of ensuring the feasibility of quality constraints, and the process operability represents the system implementability of the corresponding flexibility. The process flexibility and operability should be assessed together. The motivation of this study is to quantify the entire system operability.

## 2. Flexibility space description through the DFO solution strategy

For a design model, the flexibility constraint is defined by the following logic expression.

$$\forall \boldsymbol{\theta} \in FS(\boldsymbol{\theta}) \{ \exists \mathbf{z} \in T_z \{ \forall j \in J [g_j(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) \leq 0], \forall i \in I [h_i(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) = 0] \} \} \quad (1)$$

where  $\boldsymbol{\theta}$  and  $\mathbf{x}$  represent uncertain parameters and state variables, respectively, and the control variables  $\mathbf{z}$  represents the degrees of freedom that can be adjusted during operation to offset different realization of  $\boldsymbol{\theta}$ . The specified set of uncertain parameters and the given physically adjustable ranges of control variables are described by lower and upper bounds. The expected deviations along the negative and positive directions,  $\Delta\boldsymbol{\theta}^-$  and  $\Delta\boldsymbol{\theta}^+$ , can be defined as  $(\boldsymbol{\theta}^U - \boldsymbol{\theta}^L)/2$ . The flexibility index  $F$  can be calculated by the maximum value of  $\delta$  in the following semi-infinite programming problem.

$$\begin{aligned} F(\boldsymbol{\theta}^N) &= \max_{\delta \in \mathbb{R}^+} \delta \\ \text{s. t. } & \max_{\boldsymbol{\theta}} \min_z \max_{j \in J} g_j(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) \leq 0 \\ & h_i(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) = 0, \quad \forall i \in I \\ & \boldsymbol{\theta}^N - \delta \Delta\boldsymbol{\theta}^- \leq \boldsymbol{\theta} \leq \boldsymbol{\theta}^N + \delta \Delta\boldsymbol{\theta}^+ \\ & \mathbf{z}^L \leq \mathbf{z} \leq \mathbf{z}^U \end{aligned} \quad (2)$$

Grossmann and Floudas (1987) proposed an active constraint strategy, where the lower-level problem is reformulated by the Karush-Kuhn-Tucker (KKT) conditions. Hence, the multilevel optimization problem can be converted into a single-level mixed-integer linear or nonlinear programming (MILP/MINLP) problem, which is given by,

$$\begin{aligned} F(\boldsymbol{\theta}^N) &= \min \delta \\ \text{s. t. } & g_j(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) + s_j = 0, \quad \forall j \in J \\ & h_i(\boldsymbol{\theta}, \mathbf{z}, \mathbf{x}) = 0, \quad \forall i \in I \\ & \sum_j \lambda_j \cdot \frac{\partial g_j}{\partial x_k} + \sum_i \mu_i \cdot \frac{\partial h_i}{\partial x_k} = 0, \quad \forall k \in K \\ & \sum_j \lambda_j \cdot \frac{\partial g_j}{\partial z_k} + \sum_i \mu_i \cdot \frac{\partial h_i}{\partial z_k} = 0, \quad \forall k \in K \\ & \sum_j \lambda_j = 1 \\ & \sum_j y_j = n_z + 1 \\ & s_j - M(1 - y_j) \leq 0, \quad \forall j \in J \\ & \lambda_j - y_j \leq 0, \quad \forall j \in J \\ & \boldsymbol{\theta}^N - \delta \Delta\boldsymbol{\theta}^- \leq \boldsymbol{\theta} \leq \boldsymbol{\theta}^N + \delta \Delta\boldsymbol{\theta}^+ \\ & \mathbf{z}^L \leq \mathbf{z} \leq \mathbf{z}^U \\ & \lambda_j \geq 0, s_j \geq 0, y_j \in \{0,1\}, \forall j \in J \end{aligned} \quad (3)$$

Moreover, if  $\boldsymbol{\theta}^N$  is unknown, the above flexibility index problem can be extended to a design centering problem shown in Equation (4), which indicates that the flexibility index model is applied for candidate nominal points,  $\boldsymbol{\theta}^N$ , which are regarded as the decision variables of the outer-level optimization problem.

$$\begin{aligned}
& \max_{\boldsymbol{\theta}^N} \delta \\
& \text{s. t. } g_j(\boldsymbol{\theta}^N, \mathbf{z}, \mathbf{x}) \leq 0, \quad \forall j \in J \\
& \quad h_i(\boldsymbol{\theta}^N, \mathbf{z}, \mathbf{x}) = 0, \quad \forall i \in I \\
& \quad \boldsymbol{\theta}^L \leq \boldsymbol{\theta}^N \leq \boldsymbol{\theta}^U \\
& \quad \text{Equation (3)}
\end{aligned} \tag{4}$$

The feasibility of  $\boldsymbol{\theta}^N$  should be guaranteed during the whole optimization process. Due to the presence of the state variables  $\mathbf{x}$  and control variables  $\mathbf{z}$ , the maximum constraint violation (MCV) of all the inequality constraints should be less than or equal to zero, i.e.,  $MCV(\boldsymbol{\theta}^N) \leq 0$ .

$$\begin{aligned}
& MCV(\boldsymbol{\theta}^N) = \min u \\
& \text{s. t. } g_j(\boldsymbol{\theta}^N, \mathbf{z}, \mathbf{x}) \leq u, \quad \forall j \in J \\
& \quad h_i(\boldsymbol{\theta}^N, \mathbf{z}, \mathbf{x}) = 0, \quad \forall i \in I \\
& \quad \mathbf{z}^L \leq \mathbf{z} \leq \mathbf{z}^U
\end{aligned} \tag{5}$$

After moving  $MCV(\boldsymbol{\theta}^N)$  to the objective function and introducing a penalty coefficient  $M$ , the DFO formulation of design centering problem can be written as

$$\begin{aligned}
& \min_{\boldsymbol{\theta}^N} -F(\boldsymbol{\theta}^N) + M \cdot \max(0, MCV(\boldsymbol{\theta}^N)) \\
& \text{s. t. } \boldsymbol{\theta}^L \leq \boldsymbol{\theta}^N \leq \boldsymbol{\theta}^U
\end{aligned} \tag{6}$$

To increase the likelihood of obtaining the largest flexibility space, the Latin hypercube sampling (LHS) strategy is applied to generate a set of points in the uncertain parameter space. Each feasible LHS point will be treated as a starting point for the DFO solution procedure. Finally, the maximum value of  $\delta$ , i.e., the flexibility index, corresponds to the final rectangular flexibility space, which can be described as

$$\theta_p^- \leq \theta_p \leq \theta_p^+, \quad \forall p \in P \tag{7}$$

where  $\theta_p^-$  and  $\theta_p^+$  represent the largest allowable range for each uncertain parameter,  $p \in P$ . Thus, the vertex set of this rectangular space contains  $2^P$  points, i.e.,

$$\text{Verts} := \{\{\theta_1^-, \theta_2^-\} \times \{\theta_1^-, \theta_2^+\} \times \cdots \times \{\theta_{p-1}^-, \theta_p^+\}\} \tag{8}$$

The optimal nominal point is  $\boldsymbol{\theta}_{op}^N := (\theta_1^N, \dots, \theta_p^N)$ , where  $\theta_p^N = (\theta_p^- + \theta_p^+)/2$ . Together with the feasible LHS points sampled in the rectangular flexibility space, denoted as FPs, we can define a critical point set  $CP$ , i.e.,

$$CP := \{\text{Verts}, \boldsymbol{\theta}_{op}^N, \text{FPs}\} \tag{9}$$

These chosen points are representative for reflecting the system flexibility, especially for the vertices, which may reflect the limitation of operations.

### 3. Quantificational description of operational space

Assuming that the control variables can be adjusted continuously within the physical ranges. For each candidate  $\boldsymbol{\theta}_k$  in the critical set  $CP$ , the corresponding operational space is the feasible region of the following system with respect to  $\mathbf{z}$ .

$$\begin{cases} g_j(\boldsymbol{\theta}_k, \mathbf{z}, \mathbf{x}) \leq 0, \quad \forall j \in J \\ h_i(\boldsymbol{\theta}_k, \mathbf{z}, \mathbf{x}) = 0, \quad \forall i \in I \\ \mathbf{z}^L \leq \mathbf{z} \leq \mathbf{z}^U \end{cases} \tag{10}$$

The solution strategy to quantifying the system operability mainly contains three steps:

(1) *Locate boundary points of operational space*

For each point of uncertain parameters in  $CP$ , given a sampling number, the LHS method is performed over the physical ranges of control variables. All the feasible LHS points that can satisfy Equation (10) form a set  $\mathbf{A}$ . In this work, we focus on exploring points on

the boundary of the operational space. A line projection method is adopted to efficiently locate boundary points. For example, through a pair of points in  $\mathbf{A}$ , e.g.,  $\mathbf{z}_1$  and  $\mathbf{z}_2$ , there are two directions,  $\mathbf{z}_1 \rightarrow \mathbf{z}_2$  and  $\mathbf{z}_2 \rightarrow \mathbf{z}_1$ . We can locate two boundary points by solving the maximization problems. The global optimization solver, e.g., GAMS/BARON, is applied to guarantee the solutions located on the boundary. After enumerating the pairs of points in the set  $\mathbf{A}$ , all the obtained boundary points define the set  $\mathbf{B}$ . The more LHS points are specified, the more boundary points we can obtain.

(2) *Delaunay triangulation for the operational space*

The boundary points illustrate the profile of the operational space, and the nonconvex parts also can be exactly captured as long as the boundary points are enough. In this work, in order to provide an effective way to quantify the operational space, a triangle meshing technique using the boundary points is proposed, which is implemented by the Delaunay triangulation method. Quickhull (Barber, 1996) is one of the most efficient methods for high-dimensional triangulations, which was developed based on the convex hull methods. As a numerical implementation of the Quickhull method in SciPy, Qhull is applied to execute the Delaunay triangulation.

(3) *Quantification of the operational space*

Since the Quickhull method creates a simplex mesh of a convex hull for a set of points, some triangles may be generated beyond the nonconvex feasible space. Thus, we should remove these infeasible triangles through checking the feasibility. In  $\mathbb{R}^d$ , the centroid of the  $k^{\text{th}}$  simplex,  $\bar{\mathbf{z}}^k$ , can be simply calculated based on its vertex coordinates.

$$\bar{\mathbf{z}}^k = \frac{1}{n+1} \sum_{i=1}^{n+1} \mathbf{x}_i^k \quad (11)$$

where  $\mathbf{x}_i^k$  is the coordinate vector for vertex  $i$  of simplex  $k$ ,  $n$  denotes the dimension. We can check the feasibility of the centroid. Thus, the nonconvex parts can be identified, and we can remove the infeasible meshes. Benefit from the Delaunay triangulation and the feasibility tests, the triangle meshing of the entire operational space is obtained. Then, we can calculate the area or volume of each simplex (triangle or polyhedron).

$$V^k = \frac{1}{n!} |\det[(\mathbf{x}_1^k - \mathbf{x}_0^k)^T (\mathbf{x}_2^k - \mathbf{x}_0^k)^T \dots (\mathbf{x}_n^k - \mathbf{x}_0^k)^T]| \quad (12)$$

where,  $k$  is the index of the simplex,  $k \in K$ . Each column of the  $n$ -by- $n$  matrix is the transpose of difference between two row vectors representing vertex  $i$  ( $i = 1, 2, \dots, n$ ) and the reference vertex  $\mathbf{x}_0^k$ , respectively. The reference vertex here defaults to the first point of each mesh. Moreover, the initial operable space is a rectangular space, and the volume can be calculated by the given adjustable ranges of the control variables, i.e.,

$$V_g = \prod (\mathbf{z}^U - \mathbf{z}^L) \quad (13)$$

Thus, we can define the system operability by the following operable space ratio.

$$FR = \frac{\sum_k^K V^k}{V_g} \quad (14)$$

#### 4. Case study

Consider the following inequalities,

$$\begin{cases} 2(z_2 - 2)(z_1 - 2) - \theta_1 \leq 0 \\ (z_2 - 2)^2(z_1 - 2)^2 - \theta_2 \leq 0 \\ 0 \leq \theta_1 \leq 2, 0 \leq \theta_2 \leq 2 \\ 0 \leq z_1 \leq 4, 0 \leq z_2 \leq 4 \end{cases}$$

where  $\theta_1$  and  $\theta_2$  can be regarded as the uncertain parameters, and  $z_1$  and  $z_2$  are the control variables. In order to evaluate the operability, the largest flexibility space of the uncertain

parameters should be first identified. According to Equation (6), the flexibility index is calculated as  $F = 1$ , which means that the flexibility space is identical to the given region, and the optimal nominal point of  $\theta_1$  and  $\theta_2$  is (1, 1).

Next, the operational space can be evaluated based on this flexibility space. Due to the nonlinearity and nonconvexity, it is generally difficult to describe the complete boundary of the operational space. According to the proposed quantification method, the profile of the operational space can be captured through the line projection approach. To fully assess the overall operability, we need describe the operational space at a critical point set of uncertain parameters. According to Equation (9), four vertices, the nominal point and two feasible LHS points are chosen as  $CP$ , i.e.,  $\{(0, 0), (0, 2), (2, 0), (2, 2), (1.0, 1.0), (1.25089, 0.70663), (0.67603, 1.61001)\}$ . Taking the point (2, 2) in  $CP$  as an example, as shown in Figure 1(a), the gray and green points are the initial and feasible LHS points in the space of control variable, respectively. Along any pair of feasible points, two boundary points can be located. Figure 1(a) also shows that the nonconvex parts can be identified. Note that the result is greatly influenced by the LHS points. The more LHS points are specified, the more likely we are to find the exact boundary. Figure 1(b) shows the feasible LHS points and all the boundary points that are identified at seven points of uncertainties in  $[z^L, z^U]$ . which indicates that seven operational spaces are overlapping, and also can verify that different uncertain parameters can correspond to different operational spaces. The outermost points depict the boundary of the entire operational space. It is worth noting that, there is only one operational point for (0, 0) and (2, 0), i.e.,  $z_1=2, z_2=2$ . Because the operational space only contains discrete points, i.e., there is no operating margin, it is very likely to lead the system uncontrollable due to unknown noise. Thus, we need avoid these uncertainties if possible.

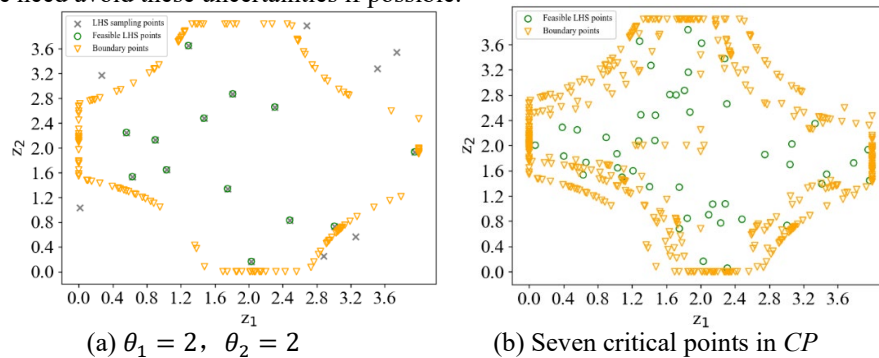

Figure 1. Boundary identification of the operational space.

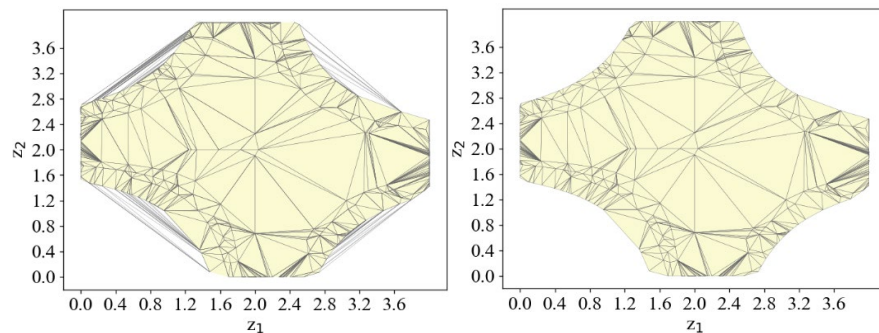

Figure 2. Delaunay triangulation of the nonconvex operational space.

Then, based on all the boundary points, the convex hull including the entire operational space can be meshed through the Delaunay triangulation method, as shown in Figure 2(a). Due to the nonconvexity, the convex hull contains many infeasible parts. Equation (11) can calculate the centroid for each triangle mesh. A feasibility check can be performed by evaluating Equation (10) at the centroid of each mesh, and the infeasible meshes can be identified and then removed, as shown in Figure 2(b). Finally, the total area of the operational space can be calculated as 10.542 by Equation (12). Based on the given ranges, the area of the given operational space  $V_g$  is 16; thus, the operable space ratio FR is 0.659.

## 5. Conclusions

Variability consistently exists in industrial process plants. Flexibility and operability are two closely linked concepts, which are recognized to represent two important features in the production process. The contribution of this work is to connect the flexibility space, the operability space and all the quality requirements closely.

In this article, a novel process operability analysis method is proposed to quantify the system operability. To assess the process flexibility and operability together, the process flexibility is designed as a prerequisite for operability analysis, which can capture the relationships between uncertain process parameters and the quality attributes, and all the specified quality constraints can be satisfied. Then, a line projection method is proposed to directly identify the boundary of the operational space, where some critical realizations of uncertainties in the rectangular flexibility space are considered. The boundary points are applied to calculate the area or volume of the operational space through the Delaunay triangulation method, and the ratio to the given physical operational ranges can assess the operability of the plant.

Challenges in analyzing the process flexibility and operability simultaneously come from the coupling relationships between the uncertain parameters and control variables. The larger flexibility and operability reflect the better performance of the design model. This work illustrates that the larger operable space ratio, the better operability will be. Thus, the proposed method has potential to guide the improvement of the process design if the operability does not meet the requirements. Once the operational space is known, we not only can provide a robust operating strategy to tackle a wide of uncertainties, but also can analyze the operating limitations. Moreover, benefit from the powerful optimization tools, the proposed method is applicable for any scales of process units or systems; however, currently only steady-state process models can be deal with, and the dynamic models are being researching.

## **Abstract**

The application of ultrasonic techniques to characterize emulsions concerning the droplet size distribution (DSD) has attracted interest in recent years, mainly due to the advantage of being a non-intrusive technique able to characterize concentrated and opaque emulsions. These characterizations occur by adjusting sound attenuation spectroscopy with the acoustic models. The most used models for this purpose are simplifying more complete models, such as ECAH, mainly due to their mathematical complexity and convergence problems. However, most of these simplified models have restrictions related to the range of applications in the wave propagation regime. Therefore, the objective of this work was to couple the acoustic models to the support vector machines (SVM), which have numerous advantages linked to their successful adaptability to nonlinear data, to acting on this limitation, thus improving the determination of the emulsion DSD. This coupling proved to be satisfactory since the SVM classified all data correctly.

**Keywords:** support vector machine; acoustic models; droplet size distribution.

## **1. Introduction**

The use of ultrasonic techniques to characterize fluids is useful in a wide range of applications, both on a laboratory and industrial scale. Compared to other techniques, ultrasound has the advantages of being a non-invasive and non-intrusive technique, in addition to being able to be applied in-line for real-time measurements.

Concerning emulsion, Challis et al. (2005) present an extensive review of what has been developed in terms of cell construction and acoustic model development. The acoustic models describe the physical phenomena of ultrasound propagation in emulsions in terms of intrinsic and viscous sound dissipation and through the acoustic scattering of waves incident on the drops. The complete model developed to characterize emulsions via ultrasound was

developed by Epstein & Carhart and Allegra & Hawley (ECAH), explained in detail by Challis et al. (2005). The authors also point out that, despite being the most complete, this model has convergence problems.

Silva et al. (2022) studied the application of several simplified models to characterize concentrated water-in-edible oil emulsions, comparing the DSD results obtained using two different techniques, ultrasound, and light scattering. The results have shown a suitable convergence with those obtained from light scattering for situations involving monomodal and bimodal droplet size distributions. However, the choice of the most suitable model for the sample depended on the wave propagation regime.

Among the challenges addressed by the alternative acoustic models to the more complex ECAH model, one main is the wavelength regime identification. It is of fundamental importance for many practical industrial applications. When finding the regime, it is possible to alternate among more suitable models to characterize a particulate system. In this case, intelligent algorithms would be a convenient alternative to mitigate the model's restriction, as suggested by (Challis et al. 2005).

The use of intelligent algorithms based on machine learning models has stood out in many applications (Simon Haykin 2008) and has a good growth perspective for the coming years (Huang et al. 2015). Machine learning models stand out for having suitable adaptability to most of the nonlinear problems in the literature for regression and classification of patterns. Some authors report such machines as universal function approximators. Among these machines, we can emphasize one good performance addressed in the literature, the support vector machine (SVM). The SVM has advantages over other techniques, such as artificial neural networks. The main one is the small number of parameters adjusted in training, implying a smaller data set.

Therefore, the objective of the present work was to develop and investigate the use of empirical models based on SVM to act in the limitations of the acoustic model. The combination of these techniques was not found in the literature. The models based on SVM can assist in wave propagation regime classification to obtain real-time measurements without the prior need to choose specific acoustic models.

## **2. Theoretical foundations**

### *2.1. Acoustic models for wave propagation in emulsion*

Sound attenuation models in the emulsion can be expressed as  $\alpha(w, r)$ , generally in  $Np/m$  unit. In which  $w$  and  $r$  are the angular frequency of sound

(Hz) and droplet radius of the emulsion, respectively (m). In this context, an important dimensionless number in this analysis is the relative wavelength:

$$ka = 2\pi r/\lambda \quad (1)$$

in which  $r$  and  $\lambda$  are the radius of the particle and the wavelength of the ultrasound, respectively. For small particles ( $ka \ll 1$ ), the acoustic scattering can be neglected. This regime is defined as a long-wave regime (LWR). On the other hand, for large particles, values of  $ka \geq 1$ , the effect of sound absorption is neglected, being defined as a short-wave regime (SWR). According to the results obtained from (Silva et al. 2022), the best model that was used in the present work for LWR was coupled phase model (Evans and Attenborough 1997), while the best model for SWR was the elastic scattering model (Feuillade and Clay 1999).

The experimental data must fit an acoustic model to obtain the DSD of the emulsion, and because of these adjustments, the distribution parameters can be calculated. This adjustment will occur by minimizing the sum of squares of errors (Equation 2).

$$\text{Minimize } J = \sum_{w_{min}}^{w_{max}} \left( \alpha_{experimental} - \int_{r_{min}}^{r_{max}} \alpha(w, r) * P(r) dr \right)^2 \quad (2)$$

$P(r)$  is the droplet radius distribution function. Some of the most used distribution functions are unimodal and bimodal. According to some authors (Silva et al. 2022), these distributions represent most particulate systems processes. Due to greater simplicity (fewer variables to be adjusted), unimodal functions are used more in ultrasonic sensor applications. Therefore,  $P(r)$  is the log-normal distribution of the droplet radius.

## *2.2. Support vector machine*

SVM is an intelligent technique used for both classification and regression. Developed by Vapnik (2000), SVM is based on the theory of statistical learning and the principle of minimizing the risk structure, reaching the global solution by transforming the regression or classification problem within quadratic programming. As highlighted in the literature, SVM has a sound theoretical basis and can achieve high performance for complex practical problems (Huang et al. 2015).

In a classification task, the objective of the SVM is to linearly separate the original data in a space with a larger dimensional characteristic. It was then solving a linear separation problem in this space. Therefore, given a data set  $T = \{\mathbf{x}_i, y_i\}_{i=1}^l$ , ( $X \in Y$ )<sup>l</sup>, where  $\mathbf{x}_i \in X = R^N$  is the input vector and  $y_i \in$

$Y = R^N$  the corresponding output, and  $l$  the total number of data pairs, the SVM classification is defined by the hyperplane given by Equation (3).

$$y = f(x) = \mathbf{w}^T \varphi(x) + b \quad (3)$$

In which  $\varphi$  is the mapping function,  $\mathbf{w}$  and  $b$  represent the weight vectors and the term bias, respectively. These parameters are estimated by minimizing the regularized risk function. More details about the algorithm can be found in (Vapnik 2000).

### 3. Experimental procedure and apparatus

The emulsion used in the analyzes carried out in this study was distilled water in sunflower oil with 5% w/w of PGPR emulsifier. Two sets of emulsions were prepared.

The first set of emulsions was prepared to produce a mono-modal distribution with a droplet radius close to 2  $\mu\text{m}$  (set 1). The second set of emulsions was produced to produce an emulsion with droplets above 10  $\mu\text{m}$  (set 2). Details of the procedure used in both production and the physical-chemical properties of the oil and water used in the study can be found in Silva et al. (2022).

The DSD's quantitative analysis was performed using the light Scattering equipment (Mastersizer 2000 - Malvern Instruments Ltd., Malvern, U.K.) that calculates the distribution using the laser diffraction principle.

The system responsible for the characterization of the emulsion through ultrasound was composed of a Parametrics square wave pulse generator (5077PR model), a pair of 6mm-diameter-Parametrics ultrasonic transducers (model V113) with a 15 MHz center frequency, and a PXI-5105 measurement platform from National Instruments. Furthermore, the cell where the emulsion sample was pumped to flow was constructed by Silva et al. (2022).

### 4. Implemented routine and SVM coupling algorithm with acoustic models

The SVM architecture developed to classify the wave propagation regime (output) presented the dispersed phase volumetric fraction  $\phi$  and the area of excess acoustic attenuation (Equation (4)) as inputs. In this case, the input is defined as  $\{\phi, Area\}$  and the output is defined as the wavelength regime classification (LWR or SWR). This architecture was chosen because it presented the best performance in relation to several different architectures studied for input variables in the SVM. Emphasizing that there is a clear relationship between the excess of attenuation and the wave propagation regime for different dispersed phase fractions.

$$Area = \int_{f_{min}}^{f_{max}} (\alpha_{emulsion}(f) - \alpha_{oil}(f))df \quad (4)$$

The SVM will act previously identifying the wave propagation regime and then choosing the model that will be applied. Thus, if the SVM classifies the data as LWR, the model that presented the best performance for this regime will be chosen similarly for SWR. The strategies for coupling the SVM to the acoustic models are summarized in the flowchart of the implemented algorithm (Figure 1).

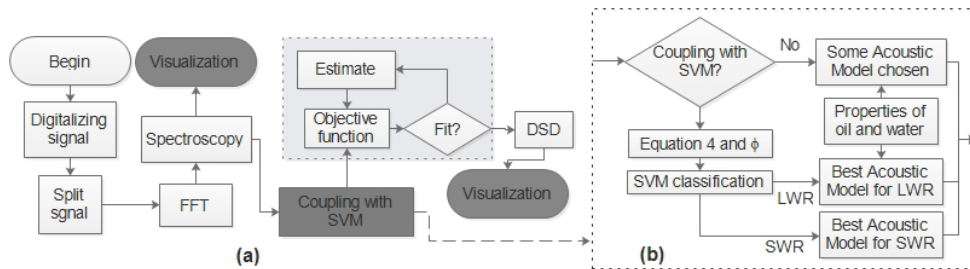

Figure 1 - Flowchart of the strategies of applying SVM.

Following the scheme shown in Figure 1, the ultrasonic signals from the transducers are digitized with the sampling rate and resolution specified previously. The signals are clipped to extract the echoes of interest. The echoes are transformed into the frequency domain, and the spectrum is extracted according to the procedure described by Silva et al. (2020). The spectrum goes to the SVM coupling flow (Figure 1b) and the optimization environment. After the adjustment, the answers are in DSD. The procedure and computational routine were developed in Python.

## 5. Results

### 5.1. Wavelength regime classification using SVM

The attenuation and experimental DSD data were subjected to calculations of the excess attenuation area (Equation 4) as a function of the dispersed phase fraction  $\phi$ . It was observed from Figure 2 that there was a linear separation between the classes of wave propagation regimes. Therefore, the kernel function in the SVM to classify the regime was linear. It can be highlighted that the classification by the SVM of the wave propagation regime proved to be an adequate strategy since the regimes for this data set were separated. The results highlight that the effects of sound energy dissipation in the LRW are more attenuating than in the SWR for a fixed dispersed phase fraction, considering the water-in-oil emulsion.

Figure 2 - Results of applying the SVM to classify the emulsions according to the wave propagation regime as a function of the excess attenuation area and the dispersed phase fraction.

### 5.2. Coupling of acoustic and SVM models

Figure 3 shows the development application. In this figure, three curves are shown. The first curvature refers to using the sum of the phase-coupled and Anderson models without coupling with the SVM. The second curve refers to the use of models with SVM coupling. And finally, the last curvature refers to the analyzes made through the Light Scattering.

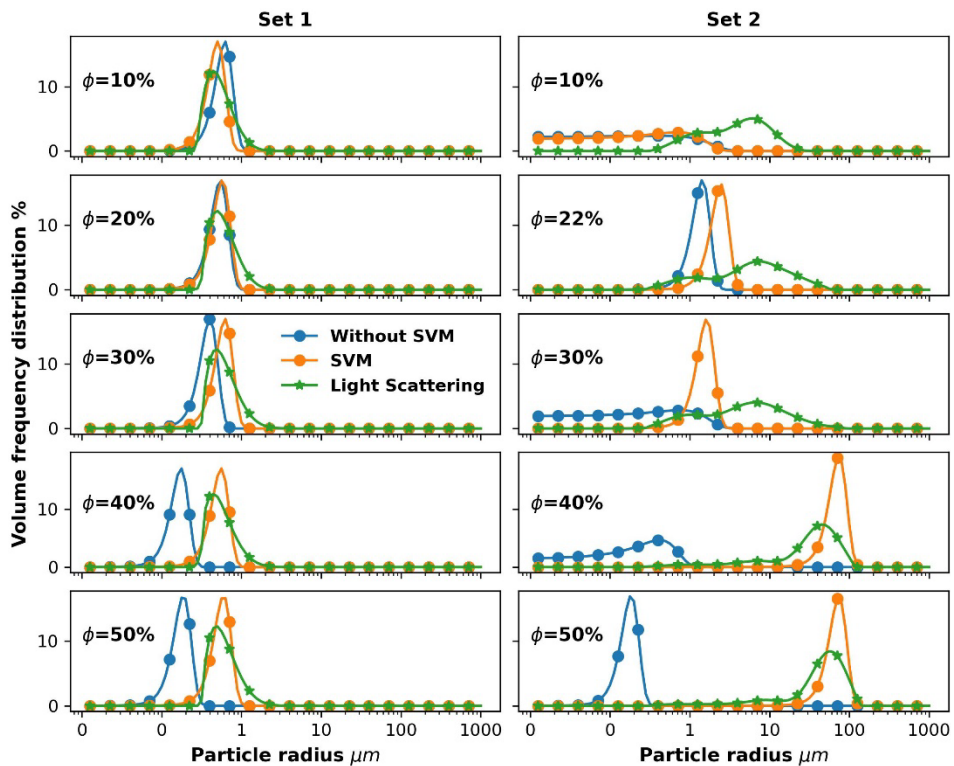

Figure 3 - DSD fitted curves from attenuation spectroscopy, and acoustic models for different phase dispersed concentrations.

## **6. Conclusion**

The present work allowed a distinct and quick procedure for analyzing the ultrasonic signal. Distinct because it does not require prior knowledge of the wave propagation regime since the SVM will act in this limitation. Fast because it requires less computational effort to converge the model in each iteration of the optimization algorithm when compared to the ECAH model. We conclude that these strategies can be implemented in an ultrasonic sensor, provided that the physical parameters, including the volumetric fraction of each emulsion phase, are previously known.

## Abstract

The use of model-based control approaches can improve the operation of many complex processes significantly but necessitates the availability of accurate dynamic process models, and the development of such models is time-consuming which is a major bottleneck for the application of advanced control. In this paper, a hybrid modeling approach is proposed, where a simple mechanistic model is augmented by a machine-learning model to compensate the plant-model mismatch based on observed data. As the data-based models cannot be trusted outside the region in which sufficiently dense training data was available, we propose to adapt the contribution of the data-based model component based on the closeness to its estimated domain of validity. We demonstrate the benefits of the novel hybrid modeling approach via the case study of an industrial distillation column for solvent recovery.

**Keywords:** hybrid modeling, dynamic modeling, validity domain, distillation column

## 1. Introduction

The stable and efficient operation of chemical processes is of high importance which is even increasing due to the trend towards more dynamic and flexible operations caused by fluctuating markets and prices and availabilities of raw materials and energy inputs. Model-based control can improve the operation significantly, especially in the case of frequent changes of the operating points. However, for the successful application of model-based control and optimization, accurate models are needed. The development of first-principles-based models requires a significant effort and can lead to large differential-algebraic equations (DAE) models that may be difficult to converge. It is therefore of interest to reduce the modeling effort and the computation times while still accurately describing the processes. An approach to reduce the modeling effort is to adapt model parameters online, e.g. by combined state and parameter estimation, to improve the model fit locally. However this is only feasible for a small number of uncertain parameters. An alternative is the use of hybrid models, i.e. combinations of mechanistic and data-based model elements. One option is to embed surrogate models in the mechanistic model to replace complex calculations e.g. of thermodynamic equilibria, see e.g. Nentwich et al. (2019). Winz and Engell (2022) proposed a systematic method to obtain embedded data-based components of hybrid models from measured data. Another frequently employed approach to hybrid modeling is to add data-based elements to mechanistic models in a parallel structure, see e.g. Bock et al. (2021) and Azadi et al. (2022). An overview of hybrid modeling techniques is given in (Von Stosch et al., 2014). A key problem in using data-based models in online applications is the trustworthiness of such models. In general, data-based models can be trusted only in regions that are dense

in training data, called the domain of validity. Several works proposed to represent the domain of validity as box constraints of the data-based model inputs. However, these approaches tend to overestimate the domain of validity. Other approaches are based on estimating the domain of validity as the convex hull of the training data. This has the shortcoming of the inability to exclude gaps in the training data and to represent nonconvex boundaries in the training data. Schweidtmann et al. (2022) suggested a novel approach to estimate the domain of validity by training a one-class support vector machine (SVM). This approach can overcome the mentioned shortcomings.

In this work, we develop a hybrid dynamic model where we combine a simple mechanistic model and a parallel data-based model that represents the deviations of the observed plant dynamics from the mechanistic model. A one-class SVM is trained on low-dimensional projections of the training data that were obtained by principal component analysis (PCA). The output of the one-class SVM is used to weight the contribution of the data-based model to the overall model, achieving a smooth transition between the full hybrid model and the simplified mechanistic model. We investigate the potential of the novel hybrid modeling approach by the application to modeling of the dynamic behavior of an industrial mother liquor distillation column.

## 2. Hybrid model with a weighted contribution of the data-based model

We propose a novel approach for obtaining reliable hybrid process models that consist of a simple mechanistic model and a parallel data-driven model for capturing the deficiencies of the mechanistic model. The developed modeling approach weights the contribution of the data-based model based on the domain of validity of the data-based model. Inside the domain of validity, the full hybrid model is used and outside this domain a smooth fading out of the contribution of the data-based element is implemented. The proposed hybrid process model is defined by:

$$x_{k+1} = f_{diff}(x_k, z_k, u_k, p_k), \quad (1)$$

$$\bar{0} = f_{alg}(x_k, z_k, u_k, p_k), \quad (2)$$

$$y_{k+1} = g(x_{k+1}, z_{k+1}), \quad (3)$$

$$e_{k+1} = f_{ML}(h_k), \quad (4)$$

$$\tilde{y}_{k+1} = y_{k+1} + \gamma_{k+1} e_{k+1}, \quad (5)$$

where  $x_k$  denotes the state vector of the simplified mechanistic model,  $z_k$  represents the vector of the algebraic states of the simplified model,  $u_k$  represents the vector of control inputs,  $p_k$  the vector of varying parameters,  $y_k$  the output vector of the mechanistic model,  $h_k$  the input vector of the data-based model,  $e_k$  the vector of the mismatches between the outputs of the full model and of the simplified model and  $\tilde{y}_k$  the output vector of the hybrid model.  $\gamma_k$  is a scalar time-dependent variable that denotes the weighting factor of the data-based model,  $f_{diff}$ ,  $f_{alg}$ ,  $g$ , and  $f_{ML}$  are nonlinear functions.

### 2.1. The domain of validity of the data-based model component

For the representation of the domain of validity, a one-class SVM is trained on low-dimensional projections of the training data of the input variables of the data-based model. These projections are obtained using principal component analysis (PCA) (Jolliffe and Cadima, 2016). The projection  $T$  of the data is defined as  $T = XW$ , where  $T \in \mathbb{R}^{N \times l}$ ,  $X \in \mathbb{R}^{N \times p}$  is the training data,  $W \in \mathbb{R}^{p \times l}$  is the loading matrix,  $N$  is the number of training samples,  $p$  is the number of input variables in training data and  $l$  is the number of the used principal components. The training data is centered and scaled before applying PCA. One-class SVM is a special case of classical SVMs that deals with the case of having only one class of data, and a maximum-margin hyperplane is sought to separate the training

data from the origin in the feature space (Schölkopf et al., 1999). Schweidtmann et al. (2022) proposed to use the decision function  $f_{DF}(h)$  of the one-class SVM to determine if a data point  $h$  belongs to the domain of validity of the data-based model by checking the inequality  $f_{DF}(h) \geq 0$ .

2.2. Weighting of the data-based model component

We propose to weight the data-based element of the hybrid model based on the function  $f_{DF}$  that indicates the closeness to the domain of validity such that the contribution of the data-based model to the overall model fades out in the regions without sufficient training data. The contribution factor  $\gamma_k$  at time step  $k$  is computed according to

$$\gamma_k = \zeta \Gamma(h_k^{s,c}) + (1 - \zeta) \gamma_{k-1}, \tag{6}$$

where  $\Gamma$  is a sigmoidal function,  $h_k^{s,c} \in \mathbb{R}^{1 \times p}$  is the vector of the scaled and centered inputs of the data-based model,  $\zeta$  is a smoothing factor, and  $0 < \zeta < 1$ . In order to ensure smooth transitions, the weighting factor  $\gamma_k$  at each time step  $k$  is exponentially smoothed. The weighting function  $\Gamma$  is designed as a sigmoidal function:

$$\Gamma(h_k^{s,c}) = \frac{1}{1 + \exp(c \times f_{DF}(h_k^{s,c} W) + \ln(\frac{\epsilon}{1 - \epsilon}))}, \quad c = \frac{2 \ln(\frac{1 - \epsilon}{\epsilon})}{z_{cut\ off}}, \tag{7}$$

where  $z_{cut\ off} \in \mathbb{R}$  and  $\epsilon \in \mathbb{R}$  are the tuning parameters of  $\Gamma$ . The weighting function  $\Gamma$  is chosen to avoid discontinuities in the process model, which can lead to numerical problems as well as abrupt control moves and chattering control behaviour.

3. Case study: Mother liquor distillation column

The considered plant is a mother liquor distillation column that is operated continuously with a varying feed due to the material fed from upstream batch processes. Figure 1 shows a schematic of the distillation column. The feed mixture consists of a low-boiling solvent, a high-boiling component, water, and other impurities. The product streams of the column are the distillate stream that consists of the low-boiling solvent with mass fraction  $w_{lb}$  and water, and the side stream that contains water of mass fraction  $w_w$  and solvent.  $w_{lb}$  and  $w_w$  must be above specified values. The sump stream is a waste stream that contains water, the high-boiling component, and impurities. The mass fraction of the high boiling component  $w_{hb}$  in the bottom stream should be below a certain limit to avoid fouling in the reboiler and the column sump. Level controllers maintain the levels of the distillate receiver and of the column sump. In addition, flow controllers are used to control the flowrates of the reflux stream, the side stream, and the steam stream. A very detailed model that was developed in Unisim Design (Honeywell, 2016) is available and is used as a virtual plant in this paper.

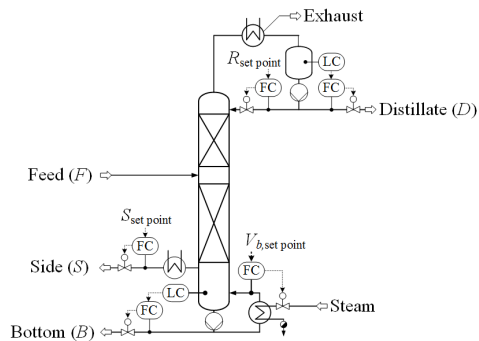

Figure 1: Distillation column schematic

4. Results

The hybrid modeling methodology explained in section 2 is applied to the mother liquor distillation column from section 3. In the simplified mechanistic model we assume that

the manipulated variables (the reflux flowrate  $R$ , the side flowrate  $S$  and the boilup flowrate  $V_b$ ) are perfectly controlled, so the behavior of the corresponding flow controllers is not included in the model. Similarly, the model does not incorporate the level controllers of the distillate receiver and the column sump. The holdup of each equilibrium stage is assumed to be constant. The model is simplified further by neglecting the energy balances of the equilibrium stages. Thus the simplified model contains only the dynamic mass and component balance equations for each equilibrium stage, the condenser and the reboiler. The vapor phase equilibrium is based on the modified Raoult's law where the liquid activity coefficient of each component is computed by the nonrandom two-liquid (NRTL) model. The saturated vapor pressure of each component at each stage is calculated by the Antoine equation. The equilibrium temperature  $T_i$  of each stage  $i$  is obtained by solving the summation equation with respect to  $T_i$ . This results in a semi-explicit index-1 DAE system, consisting of 108 differential equations and 27 algebraic equations. The DAE system is discretized in time using orthogonal collocation. Due to the simplifications performed in deriving the first-principles-based model, there is a structural mismatch between the true dynamics of the plant and the dynamics of the mechanistic model. A nonlinear autoregressive network with exogenous inputs (NARX) is used to predict and to compensate this plant model mismatch. The feedforward element of the NARX model is a feedforward neural network (FNN) consisting of 2 hidden layers, each formed of 30 neurons. The NARX model has 2 outputs which are the predicted errors of the mass fraction of the low boiling component in the top product and of the mass fraction of the high boiling component in the bottom stream  $\{e_{k+1}^{w_{lb}}, e_{k+1}^{w_{hb}}\}$ . The mass fraction of water  $w_w$  in the side stream is not corrected as the prediction of  $w_w$  by the mechanistic model is accurate enough. The NARX model can be represented as

$$e_{k+1} = f_{ML}(e_k, \dots, e_{k-d_e}, \bar{y}_k, \dots, \bar{y}_{k-d_y}, u_k, \dots, u_{k-d_u}, F_k, \dots, F_{k-d_p}), \quad (8)$$

where  $e_k$  is the vector of the mismatches  $\{e_k^{w_{lb}}, e_k^{w_{hb}}\}$ ,  $\bar{y}_k$  is the part of the output vector of the mechanistic model consisting of the mass fractions  $\{w_{lb,k}, w_{hb,k}\}$ ,  $u_k$  is the vector of the manipulated variables  $\{R_k, S_k, V_{b,k}\}$  and  $F_k$  is the feed rate. The numbers of delays  $d_e, d_y, d_u$  and  $d_p$  are chosen to be equal to 10.

The training data was generated by a reinforcement learning agent to ensure a sufficient excitation of the plant (Ortmanns et al., 2023). With a sampling time of 3 minutes, the outputs of the virtual plant were recorded over 14 (simulated) days. The training data is divided into equally sized batches, and the training objective function is the sum of the mean squared errors of the multi-step ahead predictions and of the single-step predictions over a training batch. Figure 2 shows the results of the multi-step ahead predictions of the hybrid model with the full contribution of the data-based model in the training and validation datasets. The mechanistic model has slower dynamics than the true system

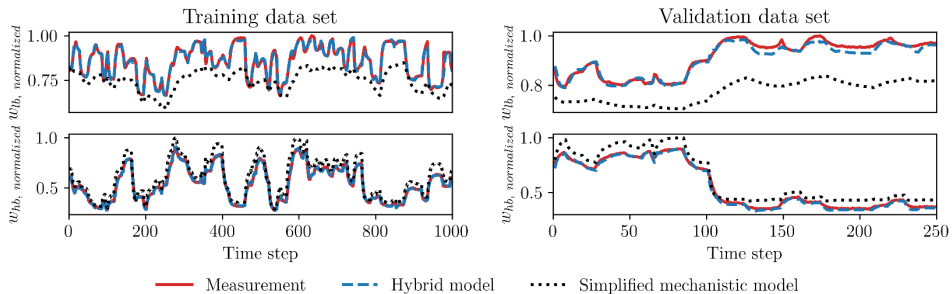

Figure 2: Results of the hybrid model with full contribution of the data-based model.

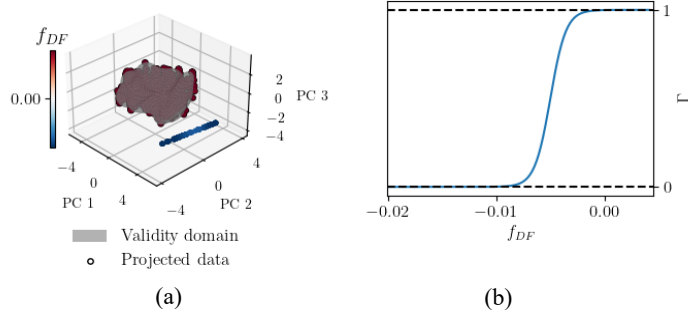

Figure 3: (a) The domain of validity of the NARX model. (b) The weighting function of the NARX model.

especially for the composition for the low boiling solvent in the distillate stream  $w_{lb}$ , while the data-based model compensates the mismatches in  $w_{lb}$  and  $w_{hb}$  very well. The manipulated variables and the feed rate were found to be the most influential inputs of the data-based model via one-at-a-time sensitivity analysis. The first three principal components explain 95% of the variation in the training data of the influential input variables. A one-class SVM was then trained on the three-dimensional projection of the training data to estimate the domain of validity of the data-based model as shown in Figure 3a. The hyperparameters of the one-class SVM were chosen such that  $f_{DF}$  is greater than zero for the projection of the training data. Figure 3a shows the projected training points in red, indicating positive values of  $f_{DF}$  according to the colour map. The projected test data points are shown in blue, yielding negative values of  $f_{DF}$  as the feed and boilup flow rates in the test data are outside the range of the training data. The relation between the weighting function  $\Gamma$  and the one-class SVM decision function  $f_{DF}$  is represented in Figure 3b. The tuning parameters of  $\Gamma$  are  $\epsilon = 10^{-3}$  and  $z_{cut\ off} = -0.01$ , so  $\Gamma$  is equal to  $10^{-3}$  when  $f_{DF} = z_{cut\ off}$ , and the value of  $\Gamma$  is 0.999 when  $f_{DF} = 0$ . The smoothing factor  $\zeta$  was chosen as 0.5.

Figure 4 shows the smooth switching from the full hybrid model to the simplified mechanistic model. As the feed rate changes to the outside of the domain of validity at the 6<sup>th</sup> time step, the weighting factor  $\gamma$  fades out leading to a better prediction quality of the mechanistic model than that of the full hybrid model without adaptation as the predictions of the data-based component get worse outside the domain of validity. Based on this modeling approach, Elsheikh et al. (2023) proposed a nonlinear model predictive controller for the considered distillation column where the domain of validity

Figure 4: Smooth decay of the contribution of the data-based model.

is in addition extended online based on the observed performance of the data-based component.

## 5. Conclusion

In this paper, the use of a hybrid model is proposed which is formed of a simple mechanistic model and a data-based model which compensates for the plant dynamics that are not represented by the mechanistic model. A one-class SVM is trained on low-dimensional projections of the training data to characterize the domain of validity of the data-based model component. The contribution of the data-based model is faded out based on the output of the SVM. For the case study of an industrial mother liquor distillation column, it is shown that the data-based component of the hybrid model can accurately compensate the deficiencies of the mechanistic model. The proposed weighting of the data-based model improves the prediction of the hybrid model, as the contribution of the data-based model diminishes smoothly in the areas with insufficient training data.

## Abstract

The unbalance between supply and demand of raw materials and products worldwide culminates in colossal challenges in global supply chains. Engineering management that relies on lean design and operation is essential for the long-term viability of the value chain to keep enterprises' operations within an acceptable profit margin at the production level in both natural resource exploration and processing transformation sites. In this work, quantity and quality dimensions of mineral raw material feedstocks are considered from a logistics perspective for an integrated mining and metallurgical supply chain. Such a complete producer-processor integration of raw materials, amounts, and properties of the concentrated mineral diet to be fed in metallurgical furnaces, follows a sequence of mined-to-fed resource management with logistics and quality constraints to be met. This includes (1) exploration and processing in the mining sites, (2) shipping of concentrated mineral pellets, and (3) logistics and mixtures of materials before the furnace feeding in metallurgical sites. In this operational decision-making set, mixed-integer solutions for resource management include the following sequence. First, it involves the assignment of equipment to be shared in different quality exploration fields (e.g., trucks and conveyor-belts). Second, conveying the crushed-ore to be mixed-stocked using shuttle-conveyor-belts in simultaneous positioning to match the qualities of the stockpiles to be ground, floated, and processed into concentrated pellets. Finally, shipping of the blended mineral pellets and metallurgical site logistics and blending mixtures before the furnace feeding. In this work, an enterprise-wide optimization of a unified mining and metallurgical of raw materials is proposed for an improved stockpiling and blending in both supply chains. Thus, their integration can be achieved to maximise the ratio of ores (in the mining field) to metals (in the metallurgical site) output while minimising operational and capital costs.

**Keywords:** Mining fields, metallurgical sites, quality-logistics.

## 1. Introduction

Most production mining operations aim for a round-the-clock operation, seven days a week, 365 days a year. In practice, semi-autogenous milling facilities run at about 95% capacity (run-time) with an efficient crushing plant running at around 85% (Jenike and Johanson, 2022). These figures should thus be extremely near to, if not greater, the actual percentage of time that the plant works after the start-up phase. However, plant availability is just one factor determining plant run-time; coarse ore's availability (in terms of quantity, but also quality) to feed the semi-autogenous grinding (SAG) milling plant or the fine crushing plant is equally crucial importance.

Stockpile management is a critical concept in the bulk materials handling supply chain at both resource exploration sites and processing plants. The port-based stockyard can

represent a mega project investment ( $\geq 1$  billion USD) with large-scale machinery and automation, e.g., autonomous haul trucks and conveyor belts, etc. Given such a significant investment in infrastructure and technology, the more efficiently raw materials can be processed through the stockyards, the less operational cost and asset installation, the faster the payback, and the higher the operating profits will be. In accordance with the industry-wide aim of optimising asset utilisation, businesses are examining how stockpile management might enhance critical key performance indicators (KPIs) such as utilisation against availability ratios. In order to preserve market dominance, manufacturers are enhancing their stockpiling strategies, taking use of technological advancements in equipment and control systems to renew stockyard infrastructure, and strengthening their capacity to do so through increased material flow and quality control (Morley and Arvidson, 2017). Automation of all or a portion of stockpile operations, replacement of older stacker-reclaimer configurations with newer frameworks, and faster, more accurate stockpile accounting are among the upgrading aims (Menezes et al., 2019). Certain mines with unique processing needs have implemented or are developing bulk ore sorting technology to pre-concentrate low-grade ore from stockpiles, bringing it to a level that is economically viable for milling (Russell, 2018).

The stockyards in both production and metallurgical sites serve as material buffers, reserves, or blendstocks between the mining and processing of the crude-ore or mineral pellets in smelting furnaces. Mining companies are faced with the challenge of balancing the benefits provided by maintaining stockpiles, e.g., guarding against supply fluctuations while also managing costs associated with stockyard management. Ore blending is an essential technique in today's large production mines. It is necessary for the mine's life cycle to be extended and dilute various harmful elements (e.g., sulfur, silica, etc.) found in different ores from the same mine. In this sense, it is also used to combine desired qualities from various ores to provide a high quality and quantity feed. Ore blending reduces input material variability and ensures a consistent flow into the processing unit. It is consequently critical that mines maintain a precise blending strategy that meets the demands of both the mine and the metallurgical processing plants.

In this work, an integrated planning for a unified mining and metallurgical of raw materials by an improved stockpiling and blending design is discussed. Thus, additional safety, stability, and predictability can be achieved to maximise the ratio of ores (in the mining field) to metals (in the metallurgical site) output while minimising the operating and capital costs. The tangible and intangible results of this integration can be applied to fuel and petrochemical industries, food processing, mining-metallurgical parks, etc., that integrates information to be included in strategic, tactical, and operational planning studies between upstream and downstream assets design and operations.

## **2. Ore blend scheduling at mining processing sites**

Kelly and Menezes (2019) have developed a smart conveying and stockpiling flow process that combines process optimisation to leverage control and automation of a cyber-physical system that allows the inventory level control of multiple stockpiles per belt. The model can optimally manage and automate the inbound recipe (by the synchronised mixtures of solid streams) and outbound delivery of mined material including, coal, iron ore, bauxite, etc. Mineral processing facilities are typically complicated systems that must contend with internal and external disturbances, a large number of cyclical loads, and a wide range of interactions. Furthermore, the reducing ore grades as well as the continual variation of raw materials are pushing the boundaries of processing facilities to their limits even further. Through mining supply chain, each process characteristics, which miners

are oriented with at each stage, offer opportunities for improvement in terms of reducing costs, energy intensity, and solve the problem of a shortage of qualified and experienced instrumentation technicians, operators, and metallurgists (Rockwell Automation, 2021).

Such control application considers advancements in manufacturing toward the Industry 4.0 (I4.0) mandate involving information and computing technology (ICT) and mechatronics (MEC) evolving together with advances in modelling and solving algorithms (MSA). For such, recent advances in network (flowsheet) optimisation as well as in solving algorithms and computer-aided resources allow fast solutions of complex discrete decision propositions. Moreover, the ICT expansion can provide the demanded velocity of the communication of the online data measurement of complete process networks for the massive volume and variety of information from the plant, which permits the viability of the addressed control strategy. Typically, the objectives of mine planning are to establish a production schedule that culminates in the selection of ore bodies that ensures the timely supply of ore of the required grade quantity and quality to the processing plant. An appropriate ore stockpiling design can significantly reduce milling time, enhance flotation processes, and raise concentrators' production efficiency and economic performance. A complete integrated smart manufacturing system among MSA, ICT, and MEC through sensing, optimising, and actuating cycles can be achieved to precisely control stockpiling process. The I4.0 deployment facilitates a wide range of control strategies for the quantities and qualities of coarse-ore in conveyor belts. This results in a total free of human-being decision, control, calculation, actuation, etc., and moving from one to multiple stockpiles per belt. Figure 1a illustrates a single shuttle-conveyor tripper car apparatus design considering quantity-logic (QL) only, optimised in Kelly and Menezes (2019) and demonstrated in a proof-of-concept demonstration in a laboratory scale in Yaqot et al. (2022). Figure 1b shows two synchronised robotic apparatus considering a blend of both quantity logic quality phenomena (QLQP).

Figure 1. a) Process network with semi-continuous feeding and segregation of solids, from Kelly and Menezes (2019). b) Process network with semi-continuous feeding and blending of solids.

### 3. Integrating mineral mining and metallurgical supply chains

In light of copper's present and potential future significance in the *electrification of everything*, as an example of one metallurgical industry, there is a need to optimise the scheduling and feed mix blending of concentrates in a copper refinery integrated to the mining operations and controls. The first stage aims to integrate metallurgical planning by means of improving operational and control strategies at the mining site, which in turn potentially yields a lean production by reducing needs of mixtures of streams in the metallurgical sites and, therefore, super dimensioned infrastructure as in today's design. Due to the non-integrated optimisation between supply and demand of raw materials and products in the mining and metallurgical supply chain, besides the super dimensioned infrastructure, remaining blending steps are necessary in metallurgical sites. The

flowsheet layout of the copper-refining plant (see Song et al., 2018) is comprised of 2 ships, 6 port piles containing initial inventories or holdups, 1 pre-blender, 3 non-concentrate materials, 6 bins, and 1 smelter, as seen in Figure 2.

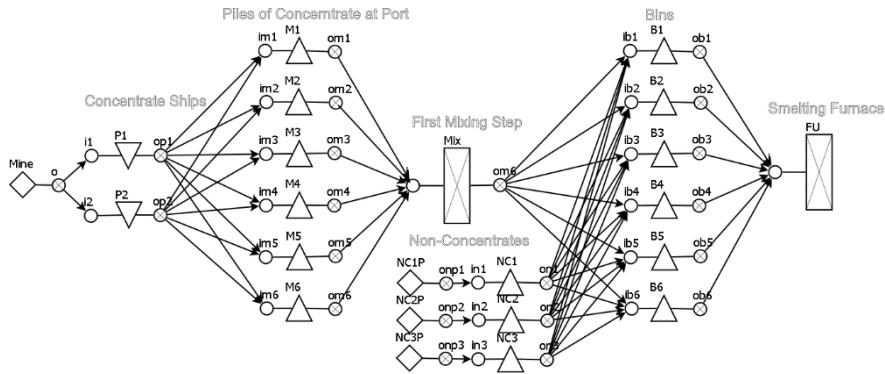

Figure 2. Network sheet for blend-scheduling of a copper-refining plant.

Therefore, quantity and quality constraints of mineral raw material feedstocks must be considered from a *qualogistics* perspective for an integrated mining and metallurgical supply chain. For this producer-processor integration of raw materials, both amounts and properties of the concentrated mineral diet to be fed in metallurgical furnaces follows a sequence of mined-to-fed resource management with logistics and quality constraints to be met. As seen in Figure 3a, this includes: (1) exploration and processing in the mining sites, (2) shipping of concentrated mineral pellets, and (3) logistics and mixtures of materials before the furnace feeding in metallurgical sites. Figure 3b shows the concatenation of solutions to be integrated as proposed, as example, in Menezes et al. (2017) for an enterprise-wide optimization connecting raw materials operations and their processing considering quality throughout the crude-oil supply chain.

In this operational decision-making set integrating mining and metallurgical supply chains, mixed-integer solutions for resource management include the following sequence. First, it involves the assignment of equipment to be shared in different quality exploration fields (e.g., trucks and conveyor-belts). Second, it demands conveying the crushed-ore raw material to be mixed-stocked using shuttle-conveyor-belts in simultaneous positioning (as illustrated in Figure 1a) to match the qualities of the stockpiles to be ground, floated, and processed into concentrated pellets. Finally, it depends in shipping and metallurgical site logistics and blending mixtures before the furnace feeding as illustrated in Figure 2.

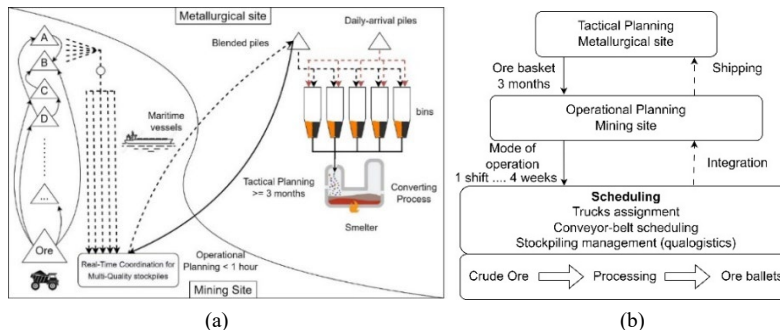

Figure 3. Integrating scheduling of stockpiles in mining-metallurgical sites.

#### 4. Tactical metallurgical and operational mining problems

As proposed in Figure 3a, the tactical planning determines the recipe of segregated crushed-ore raw materials from the mines, whereby it is considered 4 different components (Cu, S, Fe, Rest). In the furnace (FU), there are amounts of quality balances from Kelly et al. (2018) as a linear approximation to find the P1 to P5 (crushed-ore raw materials) and NC1 (non-concentrated or recycled material) that are made of minerals (A to F) or alloys (NC1) in which the results of the FU feed components made by 4 different elements are given as inputs of the operational mining example in Figure 5, whereby the profiles of the level of services of the equipment are shown in Figure 6.

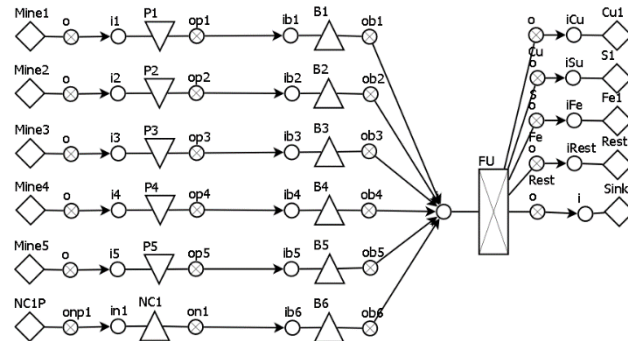

Figure 4. Tactical metallurgical planning to determine FU feed recipes in the furnace.

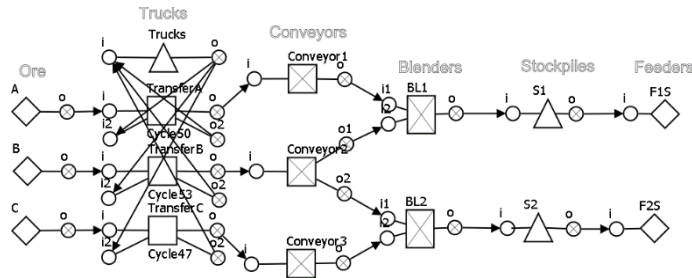

Figure 5. Operational mining scheduling for exploration and process of crushed ore.

Figure 6. Level of services of the equipment in the operational mining.

## 5. Conclusion

The disparity between the global supply and demand for raw materials and finished goods creates enormous hurdles for global supply networks. In order to maintain an appropriate profit margin at the production level in both resource exploration and processing transformation sites, it is crucial that businesses use key performance indicators that are based on lean design and operation. As a result of recent developments in the coordination of integrated operations, a comprehensive view of integrated supply and demand throughout the value chain is now attainable, from resource reserves all the way to custom-made feedstocks of blended components intended for final products. This concept, which integrates information to be included in strategic, tactical, and operational planning, scheduling, and control studies between upstream and downstream assets' design and operations, is also used in the fuel and petrochemical sectors, as well as the food processing industry, mining-metallurgical parks, and other similar areas. From a logistics point of view, this study looks at the quantity and quality of mineral raw material feedstocks for an integrated mining and metallurgical supply chain. A mined-to-fed resource management procedure with logistical and quality constraints must be satisfied for such a fully integrated producer-processor raw material, quantity, and property of the concentrated minerals diet to be fed in metallurgical furnaces. Therefore, maximising the ore-to-metal ratio in the mining field and metallurgical site while lowering operational and capital expenses necessitates a higher level of safety, stability, and predictability.

## Abstract

Automatic detection of steady state periods is a necessary step for many tasks related to real time operation of a process. Based on the insight that the time series of a controlled process variable at steady state resembles a mean reverting process, we fit a first order auto-regressive model to a window of data and use the Dickey-Fuller test to test for this mean reverting property. We compare the proposed approach on two synthetic data sets and one experimental data set and find that the method performs well in comparison to methods in the literature. As the method is computationally inexpensive, only requires two parameters, and is interpretable, we suggest that this is an effective steady state detection tool.

**Keywords:** Steady state detection, Process Monitoring.

## 1. Introduction

The identification of steady state periods in industrial process operations is an essential initial step for many typical tasks, e.g. parameter estimation, abnormal event identification, and real time optimization. Incorrect identification of steady state can severely impact operation, e.g., updating a steady state model with dynamic data can lead to reduced profits and/or unstable operation. Although steady state can be reliably identified by human operators (in low-dimensional data), the automatic identification of steady state, especially with substantial amounts of online data in high dimensions, is still challenging. In this work we use the Dickey-Fuller test to identify steady state time windows, and demonstrate its effectiveness in comparison to other methods in the literature based on their performance on experimental and synthetic data.

Most approaches in for steady state detection in the process engineering literature use 1) a statistical test, or 2) a classification based machine learning method. In this work we focus on the former due to their interpretability, and simple transfer between applications due to their relatively small amount of tuning parameters. Methods relying on statistical tests either tend to perform this test on characteristic values of the system or parameters of a model fitted to online data (Rhinehart, 2013). A key difference between such methods is in the construction of the statistical test, i.e. whether steady state is the null or alternate hypothesis. Although most methods have steady state as the null hypothesis, identification of steady state by the alternate hypothesis is a statistically stronger claim (Rhinehart, 2013).

In this work we fit an auto-regressive (AR) model and use the Dickey-Fuller test to test the null hypothesis that the process is transient. The method is simple to tune, having only

two parameters: the size of the time window and the significance level used in the statistical test. In process engineering, the Dickey-Fuller test has been used in fault detection, however to the authors knowledge it has not been applied to steady state detection.

## 2. Background literature

We briefly outline three methods from the steady state detection literature that make use of a statistical test. In all these methods some quantity based on recent measurements is determined (e.g. a slope), and a statistical test is performed on this quantity (Rhinehart, 2013). Furthermore, in the first two methods we consider a rolling time-window of  $N$  recent measurements.

### 2.1 Method 1: Slope of a line

The simplest approach to steady state detection is to fit a linear model to the data:

$$y_k = mt_k + c \quad (1)$$

where  $y$  is a measured process variable,  $t_k$  is the  $k^{\text{th}}$  time point,  $m$  is a slope, and  $c$  the intercept. After fitting this line by linear least squares, one can check the null-hypothesis of steady state by testing if the slope is zero using a t-test at some significance level. However, this approach violates some assumptions, in particular the  $y$  variables at different time points are not independent, i.e.  $y_{k+1}$  depends on  $y_k$ , and  $y_{k-1}$  and so on.

### 2.2 Method 2: Kelly and Hedengren

In this approach, we test if the process can be described as being at some value, and subjected to independent, identically distributed white noise (Kelly and Hedengren, 2013). As before, we consider the linear model in equation 1. To estimate the parameters averages of the intercept,  $c$ , and gradient,  $m$ , are used. Note that if there is gradient is zero then the intercept is the mean value. If the data is sampled uniformly in time by  $\Delta t$ , then these are given by:

$$m = \frac{1}{N\Delta t} \sum_{k=2}^N y_k - y_{k-1} \quad (2)$$

$$c = \frac{1}{N} \left( \sum_k^N y_k - m\Delta t \right) \quad (3)$$

The standard deviation of the noise,  $\sigma_n$ , can then be estimated as:

$$\sigma_n = \sqrt{\frac{\sum_k^N (y_k - mt_k - c)^2}{n - 2}} \quad (4)$$

Lastly, steady state identification is performed pointwise by checking if the deviation of the data point from the intercept is within a factor of the standard deviation of the noise. This cut-off point is given by a Student's critical value,  $t_{crit}$ , at some significance level and degree of freedom  $N$ :

$$s_k = \begin{cases} 1 & \text{if } |y_k - c| \leq t_{crit} \sigma_n \\ 0 & \text{else} \end{cases} \quad (5)$$

$$S = \frac{1}{N} \sum_{k=1}^N s_k \quad (6)$$

where  $S$  represents the fraction of time in the window “at steady state”. If  $S \geq 0.5$ , then the entire window is at steady state.

### 2.3 Method 3: Cao and Rhinehart

This method relies on the idea that the ratio of two different estimates of the time series’ variance at the same time point should be close to one when the process is at steady state (Cao & Rhinehart, 1995). The first estimate of the variance at  $t_k$ ,  $\sigma_{1,k}^2$ , is given by the filtered squared difference between the process measurement, and a filtered value of the measurement,  $y_{f,k}$ . First the filtered measurement is calculated, and used to calculate a filter of the mean square deviation,  $v_k^2$ :

$$y_{f,k} = \lambda_1 y_k + (1 - \lambda_1) y_{f,k-1} \quad (7)$$

$$v_k^2 = \lambda_2 (y_k - y_{f,k})^2 + (1 - \lambda_2) v_k^2 \quad (8)$$

Assuming the process is at steady state and the measurements are uncorrelated, then the variance,  $\sigma_{1,k}^2$ , can be directly estimated as (Cao & Rhinehart, 1995):

$$\sigma_{1,k}^2 = \frac{2 - \lambda_1}{2} v_k^2 \quad (9)$$

The second estimate of the variance,  $\sigma_{2,k}^2$ , is given by filtering the difference between two consecutive measurements:

$$2\sigma_{2,k}^2 = \lambda_3 (y_k - y_{k-1})^2 + (1 - \lambda_3) 2\sigma_{2,k-1}^2 \quad (10)$$

Lastly, the ratio of these two variances are taken to calculate an R statistic:

$$R_k = \frac{\sigma_{1,k}^2}{\sigma_{2,k}^2} \quad (11)$$

The null hypothesis is that the process is steady, corresponding to a ratio close to 1. If  $R_k$  is greater than some critical value,  $R_{crit}$  then the null hypothesis is rejected.

## 3. Proposed method

The proposed method is based on the insight that the time series of a controlled process variable at steady state, subject to stochastic disturbances, resembles that of a *mean reverting process*, i.e. it tends to some mean point despite the stochasticity of the system. In the example of a controlled process unit, this would be due to the relevant controllers rejecting disturbances, or the system settling to a new operation point.

The first step in the approach is to find the mean value in the time window,  $\mu$ , and subtract this from each data point:

$$\tilde{y}_k = y_k - \mu \quad (12)$$

Then we consider the first order auto-regressive (AR) model:

$$\tilde{y}_{k+1} = p\tilde{y}_k + n_k \quad (13)$$

where  $\tilde{y}_k$  is the transformed measurement at time  $t_k$ ,  $n_k$  is some random variable with mean zero and finite variance, and  $p$  is a variable estimated by linear least squares on the data in the time window. A value of  $|p| < 1$  means that the process is mean reverting, as as the absolute disturbance from the mean will deterministically decrease at each iteration. After estimating  $\hat{p}$ , we then perform a one-sided confidence test on the null-hypothesis that  $|p| = 1$ , i.e. the process is in a transient state, by calculating the test statistic  $\tau$ :

$$\tau = (\hat{p} - 1) \sqrt{\frac{(N - 2) \sum_{k=2}^N \tilde{y}_k^2}{\sum_{k=2}^N (\tilde{y}_k - \hat{p} \tilde{y}_{k-1})^2}} \quad (14)$$

If the test statistic is less than the critical value from the Dickey-Fuller distribution then the null hypothesis is rejected, i.e. the process is at steady state. The critical values can be found from response surfaces fit to the distribution (MacKinnon 2010). The asymptotic results of this test do not require assumptions of normality or homoscedasticity (MacKinnon 2010). Lastly, note that if the process variable is controlled off-set free to some set-point, then one could use the set-point instead of calculating the mean value.

#### 4. Results

We compare the proposed method (DF) against the line slope, Cao & Rhinehart (CR, 1995) and Kelly & Hedengren (KH, 2013) methods on two synthetic data sets and one experimental data set.. For brevity these acronyms are used throughout this section. For these data sets we label steady state and transient periods based on 1) knowledge of when the system inputs are changing and 2) inspection of the data in the time windows. For the methods with time windows and significance level as hyper-parameters we use a time window of 30 seconds, and significance level of 95%. For the method of Cao & Rhinehart (1995) we use the recommended values of  $\lambda_1 = 0.2, \lambda_2 = \lambda_3 = 0.1, R_{crit} = 2$ .

##### 4.1 Low level of normally distributed noise

We first consider a synthetic example with a low level of Gaussian noise. This is an easier task than the others and therefore serves to give a baseline of the methods performance. The results are summarized in Figure 1. From a visual inspection, the proposed DF method performs the most consistently, with the worst performance by the slope method. For all the methods the primary source of error is due to the delay that occurs when the system goes from transient to steady state (around 180s, 360s, and 540s in Figure 1). In contrast, the transition from steady to transient state is captured without a significant delay. The transition to steady state is harder to detect due to the presence of the transient in the time window, as this heavily influences the fit of the models and the filtered variance. Note that if the DF method is used with a set-point instead of the mean then this delay would be reduced, i.e. the delay for this approach comes from taking the mean of the data.

##### 4.2 Moderate level of t-distributed noise

In this comparison we consider the same process as in section 4.1, but now use t-distributed noise, with a larger variance, instead of Gaussian noise. The t-distribution has heavier tails than the normal distribution leading to a high probability of “high-magnitude” noise, leading to a more challenging classification. The experiment is summarized in Figure 2, with “spikes” due to change in distribution clearly shown in Figure 2a. The aim of using this distribution is 1) to test the methods against higher noise levels, 2) to test against non-normally distributed noise.

Apart from the general decrease in performance, the clearest difference when comparing Figure 2b vs 1b is that DF, KH, and CR have a higher rate of false identification of steady state. This does not occur with slope method, as this approach is extremely sensitive to noise. As in section 4.1 the DF method has the best performance.

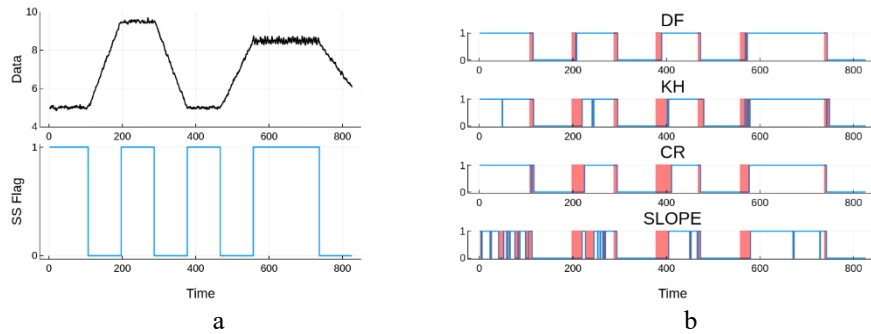

Figure 1: Synthetic data with low levels of Gaussian noise and identified steady state periods (A), and steady state predictions (B). In A and B, a steady state flag of 1 indicates steady state. The shaded red regions in B indicate a mismatch between the predicted and true system state

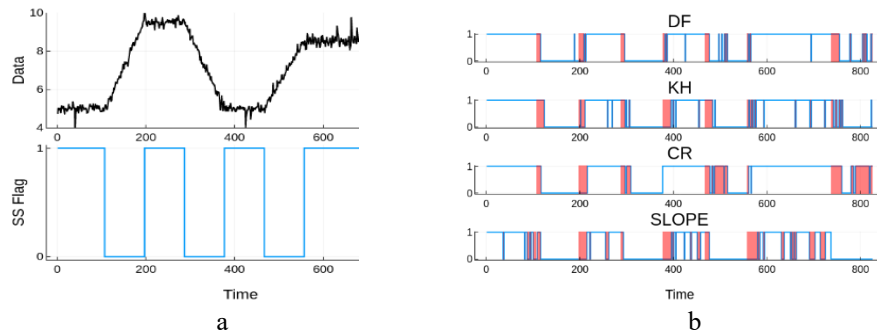

Figure 2: Synthetic data with moderate levels of t-distributed noise and steady state periods (A), and steady state predictions (B).

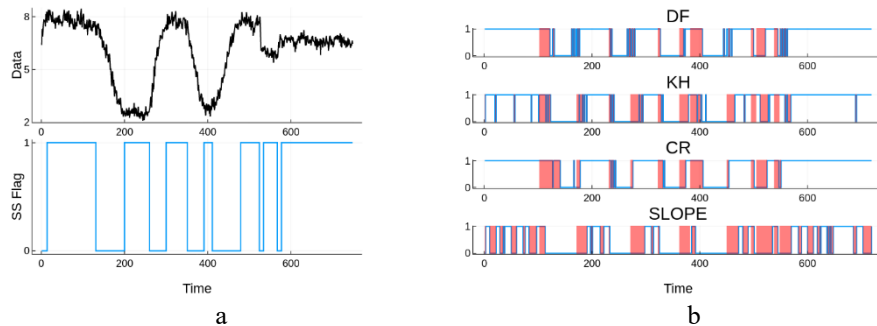

Figure 3: Experimental data with steady state periods (A), and steady state predictions (B)

### 4.3 Experimental data

Lastly, we consider the steady state algorithms applied to real experimental measurements from a lab rig with the experiment summarized in Figure 3, and Table 1.

Table 1: Summary statistics of the steady state detection algorithms applied to the experimental data, shown in Figure 3. The bolded entries indicate the best method for a statistic

STATISTIC	DF	KH	CR	SLOPE
PRECISION	0.85	0.83	0.81	<b>0.86</b>
RECALL	<b>0.90</b>	0.78	0.89	0.44
F1 SCORE	<b>0.87</b>	0.81	0.85	0.58
$\phi$ COEFFICIENT	<b>0.60</b>	0.46	0.51	0.29

This is a real system with a relatively large amount of noise, leading to worse performance compared to the synthetic results by all the methods. In addition there are two step changes between 500 and 600 seconds, which results poorer performance in this section, as shown in Figure 3. A positive aspect of the CR and DF methods are that they are more consistent as they have much less false flags within the SS and transient periods.

Summary statistics of the methods on this data set are shown in Table 1 and serves as quantitative evidence of the visually better performance of the DF method in Figure 3. Precision is the fraction of correct SS predictions over all SS predictions, while recall is the fraction of correct SS predictions over all true SS periods. The F1 score is the harmonic mean of precision and recall. Lastly the  $\phi$  coefficient is a balanced metric that requires reliable performance in both SS and TS prediction. In general, the proposed DF method performs the best, except for the precision metric where the simple line slope method performs similarly due to rarely identifying steady state, as shown in Figure 3.

## 5. Conclusions

In conclusion, we present the application of the Dickey-Fuller test for use in steady state detection and compare it with other methods in the literature on a range of examples. Based on summary statistics of these methods, the Dickey-Fuller test performs the best overall. The method is simple to implement and only requires two-hyperparameters. Further work could extend the approach to multivariate system using approaches suggested in the literature (Rhinehart, 2013, Kelly and Hedengren, 2013).

## Abstract

In this work, a new approach to characterize the residence time distribution (RTD) using supervised and unsupervised learning techniques was investigated. The NIR spectral data from the feed frame was used to capture the dynamic response of a continuous tableting line.

The data-driven approaches investigated in this study using MPCA and PLS-DA were able to successfully capture the main variation of the step change performed during the RTD experiments. Its good performance compared with the traditional RTD characterization methodology offers the potential to be used to predict the RTD parameters. This could contribute to making the RTD determination procedure more efficient and reduce the need to make offline measurements.

**Keywords:** data-driven modeling, NIR, MPCA, continuous manufacturing, tableting

## 1. Introduction

The progressing adoption of continuous manufacturing in the pharmaceutical industry still faces a series of challenges to achieving its full potential. Tracing any disturbance along the line in real-time is essential to guarantee the quality of the final tablets, as it contributes to significantly reducing the amount of product to be discarded, making continuous operation a more sustainable option compared to the current batch manufacturing. The Residence Time Distribution (RTD) is a widely used method that defines the probability distribution of the time that a particle stays inside a system. The RTD can be determined experimentally by measuring the concentration of the product over time using process analytical tools (PAT) such as Near Infrared (NIR) (Bhalode et al.).

Most continuous tableting lines have NIR probes located in the feed frame of the tablet press. The spectral data obtained from these measurements are normally used to measure the blend uniformity of the powder material right before being compressed. This probe operates in-line, and it can measure every second. This high measurement frequency offers the possibility to extract more information about the dynamic response of the process compared with the information obtained from the API concentration measurements of the limited number of samples extracted at the end of the line. The use of in-line NIR measurements has the potential to provide a real-time prediction of the concentration of the drug substance in the tablet (Hetrick et al.). In this study, a novel approach was explored to exploit all the information from the spectral data to capture a more detailed dynamic response to a step change experiment. We propose to use the NIR

spectral data to predict the dynamic response of a step change in the drug substance concentration to characterize the RTD. To achieve that, supervised and unsupervised data-driven approaches were used and compared. The unsupervised learning method, a variation of PCA called Multiway Principal Component Analysis (MPCA) and the supervised method, Partial Least Squares Discriminant Analysis (PLS-DA) were applied to the NIR spectral data. Both techniques were compared to see which one can better capture the dynamic response of the step change to be used for RTD modeling.

## 2. Theory and Methods

### 2.1. RTD model

Determining the RTD process model is a critical step in product and process development, and it is an essential part of the control strategy to detect non-conforming material at the outlet of the CM line. Developing a clear connection between the different inline measurements (i.e., process parameters and PAT data) and the product characteristics at specific locations is a key aspect. When a drop in the product quality is detected at a certain point, the affected fraction of the product needs to be discarded. This means that the travel time of the product through the line, and the amount of material needs to be known to accurately discard the affected material. This information is obtained from the RTD characteristics of the material in the specific production line. Traditional models that describe RTD are based on the exit-age distribution  $E(t)$ , described by Equation (1), where  $C(t)$  is the time-dependent concentration of a tracer at the outlet of the unit operation.

$$E(t) = \frac{C(t)}{\int_0^{\infty} C(t) dt} \quad (1)$$

The RTD was generally modelled as an ideal PFR + 2 CSTRs in series. Its expression can be written as in Equation (2). Where  $\theta$  is the time delay, and  $\tau_1$  and  $\tau_2$  represents time constants.

$$E(t) = \frac{e^{-\frac{t-\theta}{\tau_1}} - e^{-\frac{t-\theta}{\tau_2}}}{\tau_1 - \tau_2} \quad (2)$$

The calibrated RTD model is product specific and consists of two parts: determination of RTD model parameters and determination of RTD model uncertainty. Once calibrated, the RTD model parameters can be used to calculate the % potency at the tablet press outlet on the CM line. Additionally, the RTD model uncertainty is used to calculate the out-of-specification limits for tablet quality. A series of experiments are performed at different conditions to calibrate the RTD model for a given product.

### 2.2. Experimental data

The dataset used in this study was obtained from 13 RTD characterization runs for a Direct Compression setup. For each run, a step change was applied to the API mass flow and its response was measured in terms of API concentration (%). This concentration is what is usually used to fit the RTD model in Equation (2). To obtain these measurements, a number of tablets are sampled, and their concentration is measured offline. To develop and test the new approach, NIR spectral data of the same 13 runs obtained from the probe located in the feed frame of the tablet press was used. For every run, the measurement of absorbance over a certain wavelength range was measured during the duration of the step change study. This results in a three-dimensional data structure: runs (or batches), measurements over time, and variables (in this case the wavelengths), which can be written in the form of a three-way array.

Table 1. Step changes applied to the API mass flow for every run

Run name	Step change	Run name	Step change	Run name	Step change
Run 1	100%-->85%	Run 6	100%-->130%	Run 11	100%-->70%
Run 2	85%-->100%	Run 7	100%--> 85%	Run 12	100%-->115%
Run 3	100%-->70%	Run 8	100%-->85%	Run 13	115%-->100%
Run 4	100%-->115%	Run 9	100%-->85%		
Run 5	115%-->100%	Run 10	85%-->100%		

2.3. MPCA and PLS-DA

Principal component analysis (PCA) is a commonly used unsupervised data-driven method for dimensionality reduction. PCA transforms the original data into a latent variable model and a residual error. In this model, the latent variables are oriented in the direction that gives the greatest variance of the scores. In other words, it offers a way to summarize the main trends of the data in a reduced number of variables. Due to the three-dimensional nature of the spectral data, a variation of the classic PCA called Multiway PCA (MPCA) was chosen. Commonly used for batch process monitoring, MPCA, unfolds the three-way array into a large 2-dimensional matrix. Due to different durations of the RTD runs, a variable-wise unfolding was chosen (Figure 1). In this way, PCA can be used for the resulting 2D unfolded matrix regardless of the run duration.

The MPCA method was compared to the PLS-DA. PLS is a supervised learning data-driven method that also achieves dimensionality reduction through the latent variable space. The main difference with PCA is that in PLS the latent variables are extracted by obtaining the directions of the largest covariance between input and output. The discriminant analysis variation of PLS is used for classification and the output vector is defined as the class labels to be classified. In this study, the class labels corresponded to the setpoint concentrations before and after applying the step change (Pedersen et al.).

Figure 1. MPCA variable-wise unfolding of a dataset with unequal experiment duration

3. Results and discussion

3.1. MPCA and PLS-DA to NIR data

3.1.1. Pre-treatment

The first step in the data pre-treatment was to omit the measurements in which the line was stopped. To filter out the noise in the spectra data and find the most relevant information for the given product, extreme wavelength values were not considered.

A standard normal variate (SNV) was applied to the dataset. It is a common pre-processing step in spectral data analysis that neutralizes the offset of NIR signals and corrects scattering effects and makes all spectra from different runs comparable. In this

method, a normalization of the data is performed by subtracting each spectrum by its own mean and dividing it by its own standard deviation.

Prior to applying MPCA and PLS-DA, and after applying the SNV for each run, mean centering and scaling were applied to normalize the data along the different runs.

### 3.1.2. MPCA vs PLS-DA

The MPCA model was applied to the pre-treated data. Following the Wold's R criteria, the optimal rank of the model was found at 3. However, with only 2 latent variables, the model was able to explain 94% of the system variation. Similarly, PLS-DA model was trained and cross-validated using only the data corresponding to the steady state, so the model could find the correlations between the data and the label vector. The optimal rank was found to be 2. Once the rank of the PLS model was fixed at 2, the model was applied to the whole spectral data. The results of both models can be visualized by plotting the 1<sup>st</sup> latent variable against the 2<sup>nd</sup> (Figure 2).

Figure 2. Scores of 1<sup>st</sup> LV against 2<sup>nd</sup> LV for both MPCA (left) and PLS-DA (right) models. The long shape of the clusters corresponds to the time evolution of the data during the step change, meaning that the edges of every cluster group the time points during steady state (before and after the step change) and the intermediate points correspond to the moment of the dynamic step change

Figure 3. Scores over time for MPCA model of LV1 and LV2 in two cases: (left) when LV1 mostly summarizes the variation caused by the step change and (right) when it is LV2 that captures this variation

In both cases, the same phenomenon is observed: some of the run's variation is captured in a perpendicular direction from the other runs. However, MPCA makes a better job in

capturing these variations aligned with each LV. For this reason, MPCA scores were chosen as the input signal for the RTD model fit. Figure 3 shows the concentration profiles of two of the runs, which exemplify the two behaviors identified in Figure 2. For runs 1, 2, 6, 7, 8, 9 and 10 it is LV1's scores that best capture the dynamic step change, for the other runs it is LV2 that best captures this variation.

3.2. RTD model fit

The scores of the different runs were used to fit the RTD model and it was compared with the model obtained using the traditional methodology using the experimental concentration data. The data was fit to the RTD model in terms of concentration  $C(t)$  by combining Equation (1) to Equation (2) using the fmincon MATLAB function. For every run and approach a set of three RTD parameters were obtained:  $\theta$ ,  $\tau_1$  and  $\tau_2$ .

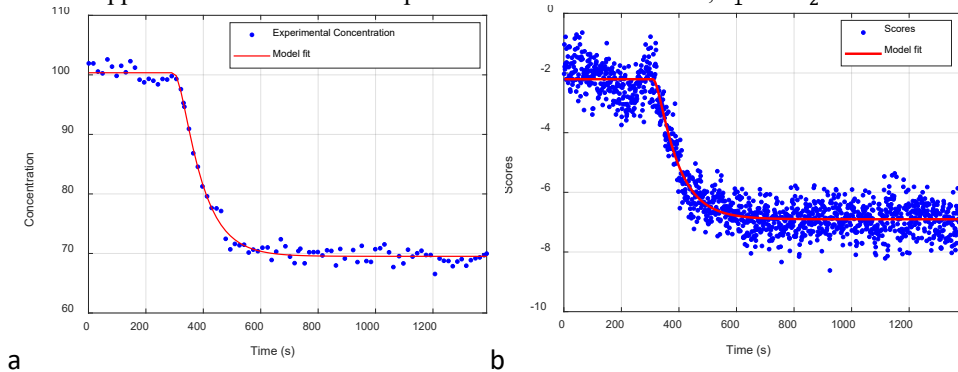

Figure 4. Example of input data and RTD model fit for experimental concentration data (a) and for scores data (b)

Figure 5. Parity plot of measured vs predicted tablet concentration using the RTD model for the traditional approach using measurements from tablet samples (left) and the new approach using the scores from the feed frame spectral data (right)

Using the set of RTD parameters of the run at target conditions (in this study, run 11) the predicted concentration was calculated with the RTD model. To assess the performance of the model prediction in this study, the root mean square error of prediction (RMSEP) was calculated for every run and for the two approaches using Equation (3), where  $C_{RTD\ model}$  represents the tablet concentration calculated with the RTD model,  $C_{measured}$  is the measured concentration, and  $N$  is the number of samples for every run (Hurley et al.). In the case of the experimental concentration data, the average RMSEP was 1.868

and for the scores data approach, the average RMSEP of all the runs was 1.873. A parity plot is shown in Figure 5 for both approaches, where the  $R^2$  for the experimental concentration data and scores data is 0.9877 and 0.9875, respectively. This indicates that the new approach using the scores of the MPCA performs at the same level as using the measured tablet concentration data, and both approaches do a good job in predicting the tablet concentration.

$$RMSEP = \sqrt{\frac{C_{RTD\ model} - C_{measured}}{N}} \quad (3)$$

#### 4. Conclusion

The goal of this study was related to exploiting the spectral information from the PAT data. The raw spectral data from the NIR probe located in the feed frame was used to extract the dynamic response during the RTD studies in the tableting process. An unsupervised and supervised data-driven method was applied to the spectral data to summarize the dynamic information. MPCA and PLS-DA methods were able to successfully capture the dynamic response of the step change in a single latent variable for every run. This latent variable was used as the input signal for the RTD model fit, and its performance in determining the RTD parameters was compared to the current method using tablet concentration measurements. This new approach was able to approximate the RTD parameters for every run. Moreover, the model prediction given by the scores data performs equally well as when using the tablet concentration data. These results indicate the new approach may provide an alternative to approximate the quality of the tablets using the NIR measurements from the feed frame. This could contribute to making the RTD determination procedure more efficient and lowering the need to make offline measurements.

### Abstract

In Power-to-Ammonia (P2A) plants the ammonia reactor is required to operate over a wide operating window between 20% to 125% of the nominal load. We formulate a rigorous model for an ammonia synthesis loop with a three-bed adiabatic quench-cooled ammonia reactor. Given a steady-state solution to the ammonia synthesis loop, we evaluate the total power input for the P2A plant composed of the electrical utility for H<sub>2</sub> and N<sub>2</sub> production, and compression work. The total power input and the electrical efficiency for storing electrical energy in NH<sub>3</sub> are evaluated over a wide range of reactor H<sub>2</sub> flow, N<sub>2</sub>/H<sub>2</sub>-ratio and recycle-ratio of the reactants. In this way, we can identify the optimal reactor flow for a given power input to the P2A plant. The optimum is revealed to be at a significantly greater N<sub>2</sub>/H<sub>2</sub>- and recycle-ratio than used in conventional ammonia plants. This reflects the very expensive production of H<sub>2</sub> via electrolysis in P2A compared to conventional production via steam-methane reforming.

**Keywords:** Power-to-Ammonia, Optimization, Flexible operation.

### 1. Introduction

Ammonia is perceived as one of the most promising mediums for chemically based storage of renewable energy sources, e.g. wind and solar power. In P2A, electrical energy from renewable sources is used to generate the reactants, hydrogen via electrolysis and nitrogen via air separation. Due to the intermittent nature of renewable energy sources, P2A plants are required to operate over an operating window from 20% to 125% of the nominal load (Armijo & Philibert, 2020). This defines entirely new operation requirements for ammonia reactors, which are conventionally operated with a stable and reliable supply of reactants from steam-methane reforming. Due to the highly energy-intensive process of hydrogen production, ammonia plants are traditionally located in areas where natural gas is cheap and readily available. But in P2A the hydrogen is produced from electrical energy, which makes the hydrogen more costly to produce. In this study, we investigate the optimal operation of an ammonia synthesis loop in P2A with varying power inputs.

### 2. System description and specifications

Figure 1 shows a schematic illustration of the P2A plant considered in this work. The ammonia is produced by the Haber-Bosch process in an adiabatic quench cooled reactor (AQCR), which is a commonly used reactor in the industry (Inamuddin et al., 2020). Due to equilibrium limitations, the single-pass conversion of the reactor is around 25 %. Therefore, a relatively large recycling of reactants is required. Rosbo et al. (2022) describe mathematical models of the units in the synthesis loop (reactor, heat exchanger, purge, and separator). We use the case study defined by Rosbo et al. (2022) based on a

100MW plant with operating pressure, temperatures, and reactor flowrates scaled from a conventional ammonia reactor.

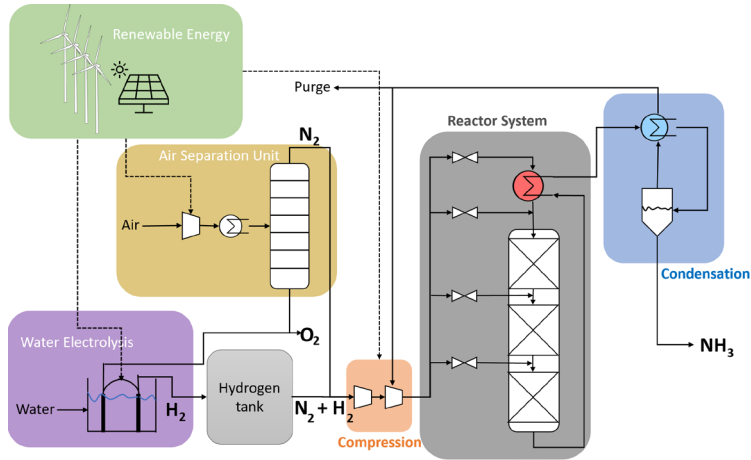

Figure 1: Schematic illustration of the main units in a P2A plant. Electricity is supplied from renewable sources and used in the electrolyser, air separation unit (ASU), and compressors.

### 2.1.1. Pressure drop

The reactor bed is assumed at constant pressure in the mathematical model as the pressure drop is not significant. However, the work of recycle compression relates to the pressure drop over the reactor. Thus, we assess the pressure drop over a bed via Ergun's equation,

$$\frac{dP}{dl} = \frac{180\mu^g (1 - \epsilon)^2}{d_p^2 \epsilon^3} v_s + \frac{1.75\rho^g (1 - \epsilon)}{d_p \epsilon^3} v_s^2$$

in which  $P$  is the pressure,  $l$  is bed length,  $\mu^g$  is the gas viscosity,  $\rho^g$  is the gas density,  $d_p$  is the catalyst particles hydraulic diameter and  $v_s$  is the superficial gas velocity.

## 3. Energy requirements for synthesis loop

### 3.1. Electrolyser

The production of hydrogen from water consumes most of the power input of the P2A plant. Hydrogen is produced in the electrolyser at a cost of 48 kWh/kg corresponding to an electrolyser efficiency of 67% compared with the low heating value of hydrogen (Armijo & Philibert, 2020).

### 3.2. Air separation unit

The nitrogen feed stream is produced in an air separation unit by cryogenic distillation. The power requirement of the air separation unit (ASU) is mainly from the air compression train. The electrical utility for air separation is set to 0.115 kWh/kg nitrogen (Morgan et al., 2014).

### 3.3. Compressors

The synthesis feed gas requires extensive compression from a few bars up to the operating pressure of the ammonia reactor at 200 bars. The work of an isentropic compression from pressure  $P_{in}$  to  $P_{out}$  is

$$W_{comp.}^{isen.} = H(P_{out}, T_{out}^{isen.}, N) - H(P_{in}, T_{in}, N) \quad (1)$$

The outlet temperature for the isentropic compression,  $T_{out}^{isen.}$ , can be found from solving

$$S(P_{out}, T_{out}^{isen.}, N) - S(P_{in}, T_{in}, N) = 0 \quad (2)$$

which is done using Newton's method. We use the thermodynamic tool ThermoLib for evaluating the state functions  $H$  and  $S$  (Ritschel et al., 2016). The actual compressor work,  $W_{comp.}$ , can be found from

$$W_{comp.} = \frac{W_s}{\eta_{isen}} \quad (3)$$

where  $\eta_{isen}$  is the isentropic efficiency ( $\eta_{isen} = 0.75$ ). The compression of the feed gas is carried out by multistage compression with a maximum compression ratio of 4.

### 3.4. Total power input and energy efficiency of the P2A plant

The total power is given as the sum of the individual contributions from  $H_2$  production,  $W_{H_2}$ ,  $N_2$  production,  $W_{N_2}$ , and compressors

$$W_{tot} = W_{H_2} + W_{N_2} + W_{comp.} \quad (4)$$

We define the energy efficiency as

$$\eta_E = \frac{LHV_{NH_3} \dot{m}_{NH_3}}{W_{tot}} \quad (5)$$

Where  $LHV_{NH_3}$  is the lower heating value of  $NH_3$ . The energy efficiency,  $\eta_E$ , describes how well the electrical energy is stored as chemical energy in ammonia.

## 4. Results

### 4.1. Nominal case with conventional reactor feed stoichiometry

For the nominal case, based on a conventional reactor configuration, the total power requirement for the P2A plant is 104.2 MW and the electricity to ammonia efficiency is 50.35%. Figure 2 shows the division of the electrical utility between  $H_2$  and  $N_2$  production, and compressor work. The electrolyser is consuming the largest fraction of the total power input (91%), while the ASU and compressor consumes relatively equal amounts of electricity (4% and 5%).

Case	$W_{tot}$ [MW]	$\eta_E$
Nominal	104.2	50.35%
Optimal	118.1	50.52%
Opt. norm	104.2	51.29%

Left: Figure 2: Fractional energy requirements in nominal P2A plant.

Right: Table 1: Total work and energy efficiency for the nominal and optimised reactor configuration.

The reactor valve settings are optimised using the optimisation algorithm presented by Rosbo et al. (2022). Table 1 shows the total power input and energy efficiency with optimised reactor quench flows. The conversion is about 10% higher for the optimised reactor and, consequently, more reactants are consumed. Therefore, the optimised configuration uses more power at 118.1 MW. Compared to the nominal case, the energy efficiency is increased to 50.52%. For comparison at an equal power input the optimised solution is scaled down to match the power utility of the nominal case. In this way, we obtain an energy efficiency of 51.29%.

### 4.2. Operating at larger $N_2/H_2$ -ratio

By optimising the reactor system, we increase the energy efficiency by almost 1%. This was achieved by keeping  $N_2/H_2$  at the stoichiometric ratio in the reactor feed, which reflects operation in a conventional ammonia plant. However, from the pie chart in Fig-

ure 2 it is evident that in P2A the hydrogen is very costly to produce. Thus, in P2A it may be more energy efficient to operate at a  $N_2/H_2$ -ratio larger than the stoichiometric ratio. By operating with  $N_2$  in excess we facilitate greater conversion of  $H_2$ . We define the stoichiometry factor,  $S_{N_2/H_2}$ , based on the  $N_2/H_2$ -ratio in the reactor feed,  $N_{Rf}$ , as

$$S_{N_2/H_2} = \frac{3N_{Rf,N_2}}{N_{Rf,H_2}}$$

Figure 3a displays the  $NH_3$  production rate as a function of the hydrogen reactor feed rate relative to the nominal case and stoichiometry factor,  $S_{H_2/N_2}$ . The total power input,  $W_{tot}$ , is overlaid by black contours.

Figure 2a:  $NH_3$  production rate overlaid with contours of total power input.

Figure 3b: Energy efficiency,  $\eta_E$  overlaid with contours of total power input.

Figure 3b shows the energy efficiency in the plane of relative  $H_2$  reactor feed flow and  $S_{N_2/H_2}$ . Observe that the optimal stoichiometry factor is as high as 2.7 to 3.8 over the power range. Naturally, the energy efficiency is increasing for lower power input as the reactor is converting the reactants more efficiently at lower throughput. The red curve identifies the maximum energy efficiency for a given power. The optimal curve is moving towards higher stoichiometry factor for lower power input. At lower reactor throughput the reactor is slightly oversized, and it is advantageous to operate with relatively more nitrogen. Operating with excessive flow of  $N_2$  yields a significantly improved energy efficiency at approximately 53.5% for a power input around 104 MW. This clearly illustrates the difference in operation of an ammonia reactor for P2A compared with conventional operation. Figure 4a and 4b show accumulative graphs of the electrical power consumption and reactor flowrate, respectively. Although the reactor is operated at close to equal flowrate of  $N_2$  and  $H_2$ , the power input for the ASU and compressors is still only a small fraction of the total power consumption.

Figure 4a Accumulated energy.

Figure 4b Accumulated flow rate.

### 4.3. Operating at a larger recycle-ratio

In the above analysis we kept the flow of argon in the reactor constant. From Figure 4a it is observed that the compressor work is relatively small compared to the amount of power used for hydrogen production. By reducing the purge fraction, we can facilitate more overall conversion of hydrogen. This is at the cost of a higher recycle stream and more compression work. In practise we vary the recycle by changing the reactor flowrate of argon. Figure 5 shows surfaces of constant power input as a function of normalised H<sub>2</sub> flowrate,  $S_{N_2/H_2}$  and Ar/N<sub>2</sub>-ratio. The red curve illustrates the optimal reactor inlet flows for a given power consumption. The argon to nitration ratio in the reactor feed is ranging from 0.6 to 1.8, which is significantly higher than a conventional ratio of 0.13. Figure 5 shows, we can obtain an energy efficiency of around 56% by operating with a large recycle-ratio even for power inputs above 100 MW.

Figure 5 Surfaces of constant power input as a function of normalised H<sub>2</sub> flowrate,  $S_{N_2/H_2}$  and Ar/N<sub>2</sub>-ratio. The surfaces color depicts the electrical efficiency.

Figure 6a displays the electrical utility of the main P2A units for achieving optimal energy efficiency. Note the compression work is increased and the ASU power input decreased compared with Figure 4a. The larger recycle-ratio causes excess N<sub>2</sub> to quickly build up, which lowers the requirement of fresh feed N<sub>2</sub> production. Figure 6b shows the reactor feed flow of H<sub>2</sub>, N<sub>2</sub> and Ar achieving maximum energy efficiency. Clearly, a large amount of inert Argon is built up in the synthesis loop.

Figure 6a Accumulated energy.

Figure 6b Accumulated flowrate.

## 5. Discussion

This study suggests that in P2A the synthesis reactor should be operated at significantly higher  $N_2/H_2$ -ratio than stoichiometric to obtain maximum energy efficiency. Additionally, we found that larger recycle of reactants compared to conventional operation increased the energy efficiency. We assume that the effectiveness factor of the catalyst particles is independent of the gas concentrations. Most literature on modelling of ammonia reactors use either the Temkin-Pyzhev rate expression or Dyson's equation (Dyson & Simon, 1968). These rate expressions from 1940 and 1968 are naturally developed at conventional reactor conditions with a stoichiometric  $N_2/H_2$ -ratio. Therefore, the validity of these rate expressions is unclear when operating at large excess of  $N_2$  and inert argon. Nielsen et al. (1964) investigated the reaction rate of ammonia synthesis on iron catalyst under various temperatures, pressures, flow rates and even five runs with changing  $N_2/H_2$ -ratio. These results suggested that the reaction rate may be negatively affected at lower flowrates, but the Temkin-Pyzhev equation yielded relatively accurate results at more industrially relevant flow velocities. Traditionally, argon is not mentioned as a poisonous species for ammonia catalysts and no literature seems to discuss the effect of argon on catalyst activity. Clearly, more experimental research needs to be conducted on how operating at large excess of  $N_2$  and inert argon affects the ammonia catalyst. But this study indicates that better utilisation of the electrical energy in P2A can be achieved by operating the ammonia reactor at non-traditional conditions.

## 6. Conclusion

This paper has investigated the optimal operation of an ammonia synthesis loop for P2A using steady state optimisation. We identified the optimal distribution of electrical energy between  $H_2$  and  $N_2$  production, and compression work for power inputs ranging from around 20% to 125% of the nominal load. We found the optimum to be at significantly larger  $N_2/H_2$ - and recycle-ratios compared with conventional ammonia plants. Operating with large excess of  $N_2$  and recycle-ratio ensures a high conversion of  $H_2$ , which is extremely costly to produce in P2A. However, the effect of operating at large excess of  $N_2$  and inert argon on the ammonia catalyst needs to be further investigated experimentally.

## Abstract

Simultaneous blending and scheduling optimisation represents a mixed-integer nonlinear programming (MINLP) problem, whereby the binary variable relaxation that forms a nonlinear programming (NLP) in the first stage of a full-space algorithm (without dropping any decision variable) may lead to convergence issues. Furthermore, there is no guarantee to reach a global optimal solution since it solves an NLP problem to then address the mixed-integer linear programming (MILP) problem in outer-approximation algorithms. On the other hand, by neglecting quality variables and constraint of the blends or mixtures in the MILP problem, in a decomposed or non-full space problem (when dropping nonlinear constraints), infeasibilities or local optimal solutions may be found in the second stage NLP programs. In this case, there will be a change that from the MILP resulted assignments of the components to be blended, quality to specify the final blended material in the NLP problem may not be suffice. Or even if so, local optimal solution may occur. To skip these issues, an MILP-NLP decomposition is tailored to solve, in the first stage, the MILP logistics problem of the blend-scheduling optimisation whereby the blending relationship for each property quality is approached as amounts of quality balances. In such constraints, the blended quality variable is replaced by the bounds of the specifications plus the slack variable or less the surplus variable to close the linear quality balance. However, this MILP-NLP decomposition with a blending approximation in the MILP still cannot avoid convergence issues or local optimal inherent to the NLP stage and is dependent on the volume- or mass-based material flow and blended property governing rules. Then, we apply an optimisation-simulation algorithm to converge the MILP solution to a global optimal by considering a substitution of the current blending error successively in the next MILP solution. Nevertheless, this algorithm can be applied only in continuous mixtures, but we introduce the novel strategy to solve batch mixtures by using component quantities found in a continuous mixture topology as inputs.

**Keywords:** blending operations, scheduling optimisation, MILP, NLP, decomposition.

## 1. Introduction

Blending and scheduling processes are considered crucial steps in crude-oil and metallurgical refineries, food processing sites, pulp and paper productions, to name a few. The main goal in these processing industries is to transform different raw materials into

useful products such as gasoline, diesel, and kerosene (from crude-oils) and copper alloys (from minerals). Stricter constraints from environmental regulations and lower profit margins from commodity falling prices have been considered for the blending of these streams to achieve better efficiency in the operations and to adhere to specifications (Lotero et al., 2016). The blending process is a significant stage that helps the processing sites to convert low-value raw materials to higher added-value products, with consideration to eliminate giveaway or excess of qualities and off-specification products.

Most (if not all) of the blend-scheduling solutions in the market are either simulation-based or simple linear programming (LP) approaches. These tools are limited in terms of capability since the simulation-based ones are entirely based on trial-and-error of the binary variables, which is time-consuming and difficult to change or readjust. Also, linear programming software is limited to a fixed or given operation, in general, addressing a single-period problem. A proposed solution that can provide multi-period solution with automated decision-making in a blend-scheduling perspective is a breakthrough in the quantity-logic-quality decisions in the aforementioned industries. This becomes explore in optimisation problems since the blending of streams presents a nonlinear (NLP) behavior, which brings difficulties on convergence and cannot avoid local optimal solutions. For an optimisation of a blendshop or blend-scheduling problem, the blending and assignment of equipment (and their modes) and of material streams represents a mixed-integer nonlinear programming (MINLP), whereby, to avoid MINLP convergence issues when scaling-up blend-scheduling problems, we proposed a successive substitution approach based on optimisation-simulation methods to iteratively reduce the error inherent by using factor-flows or amounts of quality balances from Kelly et al. (2018). In equality balances of input-output amounts of qualities, the outputted amounts of qualities are calculated by the quality specification multiplied by the total flow of material plus the slack variable or less the surplus variable to close the linear quality balance, whereby this additional variable, known as factor-flows, close the balance of each property.

## 2. Problem statement

In the continuous mixture of the blend-scheduling represented in Figure 1, it is produced diesel by blending light diesel gasoil in R1 and light cycle oil in R2. Both intermediate components have similar specific gravity (SG) and sulfur concentration (SC) to produce diesel, whereby specifications on the final diesel qualities should be maintained within bounds. Their qualities are: R1 with 0.80 of SG and 0.90 of SC (at \$ 85 cost); R2 with 0.95 of SG and 1.20 of SC (at \$ 70 cost); and D1 with 0.875 of SG and 1.05 of SC to specify (at \$ 100 as selling price per barrel). There are four cases to be addressed in this work to avoid an MINLP inherent to blend-scheduling problems. Cases 1 to 3 are applied to continuous blending (Figure 1) and case 4 to batch mixtures (Figure 1, small topology).

1) *MILP-NLP decomposition*: nonlinear quality balances are neglected in the MILP problem, then the assignments of the S1 to S4 tanks to the blender are fixed to 0 or 1 in the following NLP solution.

2) *MILP-NLP decomposition*: using factor-flow balances where the nonlinear quality constraints are approximated in the MILP problem as amounts of qualities (Kelly et al. 2018), whereby the blended quality variable is replaced by the bounds of the specifications plus the slack variable or less the surplus variable to close the linear quality

balance. Then, the assignments of the S1 to S4 tanks to the blender are fixed to 0 or 1 in the following NLP solution.

3) *SS-MILP iteration*: successive substitution of an optimisation-simulation method considering the error between the factor-flow approximated property calculated by the quantities of the components found in the MILP and the volume- or mass-based blended property governing rules (from the simulation step) for the same amounts of the components. The quality error is used in the next MILP optimisation until convergence.

4) *SS-MILP iteration and MILP-NLP batch*: the amounts or quantity flows from the tanks S1 to S4 to the blenders converged in the SS-MILP algorithm are fixed in the blend-scheduling case without the blender (as seen in Figure 1, small topology)

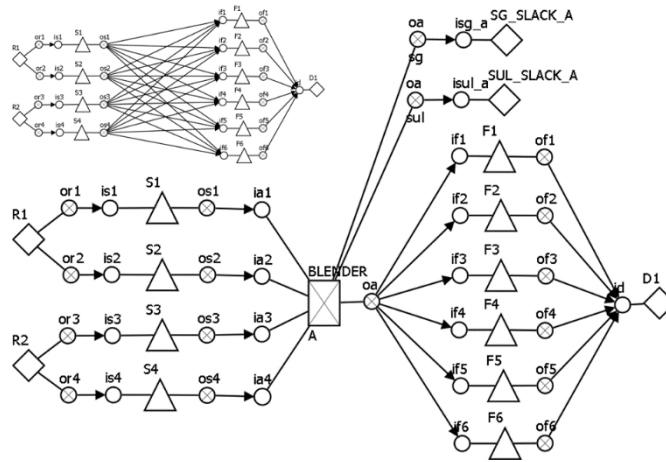

Figure 1: Blend-scheduling using a continuous and batch (small) mixture topology.

### 3. Mathematical modelling

The objective function in Eq.(1) maximises the diesel production, where  $x_{j,i,t}$  represent the selling product and consumed components in the diesel production at time  $t$ . Following the unit-operation-port-state superstructure (UOPSS) formulation from Kelly (2005), in the MILP problem, all flows and holdups are governed by semi-continuous constraints (relating binary and continuous variables) of the shapes to themselves, such as  $\bar{x}_{j,i,t}^L y_{j,i,t} \leq x_{j,i,t} \leq \bar{x}_{j,i,t}^U y_{j,i,t} \forall (j, i) \in JI, t$  considering outlet port set  $j$  to inlet set  $i$ . The sets  $I$  and  $J$  represent in- and out-ports, respectively, while the set  $JI$  defines connecting flows between out- and in-ports. The semi-continuous constraints for throughputs  $x_{m,t}$  of the unit-operations  $m$  for the blender are controlled by  $\bar{x}_{m,t}^L y_{m,t} \leq x_{m,t} \leq \bar{x}_{m,t}^U y_{m,t}$  and the holdup or inventory level  $xh_{m,t}$  by  $\bar{x}h_{m,t}^L y_{m,t} \leq xh_{m,t} \leq \bar{x}h_{m,t}^U y_{m,t}$ . In the indices in the summations from Eq.(1) to (7), the subsets of the  $I, J$ , and  $JI$  follow the flowsheet in Figure 1, considering  $i \in I_{do}$  as inlets of downstream unit-operations and  $j \in J_{up}$  as outlets of upstream unit-operations. For  $x_{j,i,t}, x_{m,t}, xh_{m,t} \geq 0; y_{j,i,t}, y_{m,t} = \{0,1\}; zsu_{m,t} = (0,1)$ :

$$Max Z = \sum_t \left( \sum_{product} x_{j,i=D1,t} - \sum_{components} x_{j=R1 \text{ or } R2,i,t} \right) \quad (1)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{j \in J_{up}} x_{j,i,t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{j \in J_{up}} x_{j,i,t} \quad \forall (i, m) \in (M_{Blender}, M_{Product}), t \quad (2)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{i \in I_{do}} x_{j,i,t} \leq y_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{i \in I_{do}} x_{j,i,t} \quad \forall (m, j) \in (M_{Blender}, M_{Component}), t \quad (3)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{j \in J_{up}} x_{j,i,t} \leq x_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{j \in J_{up}} x_{j,i,t} \quad \forall (i, m) \in M_{Blender}, t \quad (4)$$

$$\frac{1}{\bar{x}_{m,t}^U} \sum_{i \in I_{do}} x_{j,i,t} \leq x_{m,t} \leq \frac{1}{\bar{x}_{m,t}^L} \sum_{i \in I_{do}} x_{j,i,t} \quad \forall (m, j) \in M_{Blender}, t \quad (5)$$

$$xh_{m,t} = xh_{m,t-1} + \sum_{j_{up} \in J} x_{j_{up},i,t} - \sum_{i_{do} \in I} x_{j,i_{do},t} \quad \forall (i, m, j) \in M_{TK}, t \quad (6)$$

$$\sum_i \sum_{j_{up}} x_{j_{up},i,t} = \sum_{i_{do}} x_{j,i_{do},t} \quad \forall ((j_{up}, i), (j, i_{do}), t), m \in M_{Blender} \quad (7)$$

$$mu_{j,t}^L y_{m,t} \leq \sum_{i_{do}} y_{j,i_{do},t} \leq mu_{j,t}^U y_{m,t} \quad \forall (m, j) \in M_{Blender}, t \quad (8)$$

$$mu_{i,t}^L y_{m,t} \leq \sum_{j_{up}} y_{j_{up},i,t} \leq mu_{i,t}^U y_{m,t} \quad \forall (i, m) \in M_{Product}, t \quad (9)$$

$$y_{m_{up},t} + y_{m,t} \geq 2y_{j_{up},i,t} \quad \forall (m_{up}, j_{up}, i, m), t \quad (10)$$

$$y_{m,t} - y_{m,t-1} - zsu_{m,t} + zsd_{m,t} = 0 \quad \forall m \in M_{Blender}, t \quad (11)$$

$$y_{m,t} + y_{m,t-1} - zsu_{m,t} - zsd_{m,t} - 2zsw_{m,t} = 0 \quad \forall m \in M_{Blender}, t \quad (12)$$

$$zsu_{m,t} + zsd_{m,t} + zsw_{m,t} \leq 1 \quad \forall m \in M_{Blender}, t \quad (13)$$

Equations (2) and (3) represent the semi-continuous constraints relating neighboring flows of the  $JI$  connections to the throughputs of unit-operation setups they are connected to. Different from the semi-continuous constraints to itself (of the shapes to themselves), Eq.(2) and Eq.(3) allow the flows throughout the connections only if the nodes (the unit-operations) are true. On the other hand, Eq.(4) and Eq.(5) balance the in-out material flows of the connections to the throughputs of the unit-operations, whereby there is a process transformation such as in the blender. The unit-operations' inventory or holdup quantity balance of tanks are calculated in Eq.(6). Equation (7) is the material flow balance in the blender. Multi-use constraints control the use of the blender's outlet in Eq.(8) and the inlet of the product demand point  $DI$  in Eq.(9).

Equation (10) represent the constraint for the structural transitions that allow the setup  $y_{m,t}$  of connected out-port-states  $j$  and in-port-states  $i$  unit-operations. When the setup of unit-operations  $m$  and  $m'$  is equal to the unitary, by implication, the setup variable of the arrow stream  $y_{j,i,t}$  between the neighbor unit-operations must be true, and vice-and-versa. These logic valid cuts reduce the tree search in branch-and-bound methods. The temporal transition in Equations (11) and (12) control the operations for semi-continuous blenders from Kelly and Zyngier (2007). The binary variable  $y_{m,t}$  manages the start-up ( $zsu_{m,t}$ ) switch-over ( $zsw_{m,t}$ ) and shut-down variables ( $zsd_{m,t}$ ), which are relaxed in the interval  $[0,1]$ . Equation (13) guarantees the integrality of the relaxed variables.

For the NLP problem, the binary variables found in the MILP are fixed. The quality balance constraints in the blender are defined in Eq.(14) for the volume-based property  $v_{j,p,t}$  for  $p \in P_v$  (as in SG) and in Eq. (15) for the mass-based property  $w_{j,p,t}$  for  $p \in P_w$  (as in SC). Equations (16) and (17) represent the quality balances for volume- and mass-based properties in tanks. The quality variable for the out-ports of a tank unit-operation ( $m \in M_{TK}$ ) is the quality of the blend within the tank  $v_{j,p,t} = v_{m,p,t}$  and  $w_{j,p,t} = w_{m,p,t}$ .

$$v_{j,p,t} \sum_{j_{up}} x_{j_{up},i,t} = \sum_{j_{up}} v_{j_{up},p,t} x_{j_{up},i,t} \quad \forall j \in M_{Blender}, p \in P_v, t \quad (14)$$

$$w_{j,p,t} \sum_{j_{up}} v_{j_{up}=sg,p,t} x_{j_{up},i,t} = \sum_{j_{up}} w_{j_{up},p,t} v_{j_{up}=sg,p,t} x_{j_{up},i,t} \quad \forall j \in M_{Blender}, p \in P_w, t \quad (15)$$

$$v_{m,p,t} xh_{m,t} = v_{m,p,t-1} xh_{m,t-1} + \sum_{j_{up}} v_{j_{up},p,t} x_{j_{up},i,t} - v_{m,p,t} \sum_{i_{do}} x_{j,i_{do},t} \quad (16)$$

$$\forall (i, m, j) \in M_{TK}, p \in P_v, t$$

$$w_{m,p,t} v_{m,p=sg,t} xh_{m,t} = w_{m,p,t-1} v_{m,p=sg,t-1} xh_{m,t-1} + \sum_{j_{up}} w_{j_{up},p,t} v_{j_{up},p=sg,t} x_{j_{up},i,t} -$$

$$w_{m,p,t} v_{m,p=sg,t} \sum_{i_{do}} x_{j,i_{do},t} \quad \forall (i, m, j) \in M_{TK}, p \in P_w, t \quad (17)$$

#### 4. Results

The optimisation for the proposed problems (to produce 100 K barrels per day) for 10 days of time-horizon and 1 day as time-step uses an Intel Core i7 machine at 2.2 GHz (6 threads) with 32 GB of RAM. In the case 1, for the MILP, there are 552 constraints (122 equality) for 312 continuous variables and 210 binary variables with 400 degrees-of-freedom (variables minus equality constraints). For the NLP, there are 531 constraints (491 equality) for 621 continuous variables with 130 degrees-of-freedom. The results using GUROBI 10.0 and CPLEX 20.0 for the MILP blend-scheduling cases are solved within 1 second. And the NLP are solved by linking these solvers to sequential linear programming quadratic engine (SLPQPE) in the modelling platform Industrial Modeling and Programming Language (IMPL) used in this work (see Kelly and Menezes, 2019).

1) *MILP-NLP decomposition*: the MILP solution yields \$ 440 and it gets infeasible in the NLP. Since the nonlinear quality balances are neglected in the MILP problem, the assignments to produce diesel selects the S3 or S4 tanks to the blender at a reduced cost. However, then the NLP problem is solved it is not possible to meet the specification since better SG and SC qualities from S1 or S2 tanks are needed.

2) *MILP-NLP decomposition*: the MILP solution yields \$ 380 and the NLP \$ 320. By using factor-flow balances with the nonlinear quality constraints approximated in the MILP as amounts of qualities, whereby the blended quality variable is replaced by the bounds of the specifications plus the slack variable or less the surplus, S1 or S2 tanks are assigned. Then, for the binary variables fixed in NLP problem, it is possible to meet the specifications of SG and SC qualities. However, as seen in the solution in Table 1, the flows are not optimal since in several days the blend-shop uses only S1 or S2 tanks.

3) *SS-MILP iteration*: successive substitution of an optimisation-simulation method considering the error between the factor-flow approximated property calculated by the quantities of the components found in the MILP and the volume- or mass-based ad hoc blended property governing rules (from the simulation step) for the same amounts of the components. The quality error is used in the next MILP optimisation until convergence. It reaches the global optimum solution within two SS iterations

4) *SS-MILP iteration and MILP-NLP batch*: the amounts or quantity flows from the tanks S1 to S4 to the blenders, converged in the SS-MILP algorithm, are fixed in the blend-scheduling case without blender. In the MILP-NLP batch case, with the SS-MILP quantities fixed in the outlets of the S1-S4 and inlets of the F1-F6 tanks (within an adjusted time-step that permits one batch flow at a time), the solution yields a feasible and optimal results with 0% gap between the MILP and NLP problems.

Table 1. Results of the cases in the blend-scheduling problems.

day	Case 2-MILP (380 K USD)				Case 2-NLP (320 K USD)				Case 3 (371.6 K USD)			
	S1	S2	S3	S4	S1	S2	S3	S4	S1	S2	S3	S4
1	50.0		50.0		58.7		41.3		54.3		45.7	
2	50.0		50.0		100.0				54.3		45.7	
3		50.0		50.0		100.0				54.3		45.7
4		50.0		50.0		100.0				54.3		45.7
5	50.0		50.0		100.0				54.3		45.7	
6		50.0		50.0		100.0				54.3		45.7
7		50.0	50.0			100.0				54.3	45.7	
8		50.0	50.0			91.3	8.7			54.3	45.7	
9		50.0		50.0		92.4		7.6		54.3		45.7
10	50.0		50.0		57.6			42.4	54.3			45.7

## 5. Conclusion

The importance of approximating an NLP blending as an LP factor-flow approach in the MILP stage is considered in this work, whereby factor-flow variables by equalizing in-out amounts of qualities in the blender allow global optimal solutions since it avoids NLP problems in a second stage of the MILP stage. For batch mixture topology, the drawback of the factor-flow approach by considering a convergent and continuous point of mixture can be circumvented when fixing the material flows of the components found in the SS-MILP (case 3) as inputs in the MILP-NLP batch case, adjusting of needed the time-step.

## Abstract

This work introduces a framework for developing data-driven dynamic models for wastewater treatment plants (WWTPs) by using a limited amount of data. More specifically, a system identification problem is defined that estimates a number of critical parameters included in the COST/IWA benchmark simulation model No.1 (BSM1), which is adapted to a real WWTP. Identification of these parameters is performed by formulating an optimization problem, which is solved by utilizing a novel cooperative particle swarm optimization (CPSO) method. The identified model is then used to generate big volumes of dynamic data for training radial basis function networks (RBFNs), which are suitable for being integrated in process control configurations, like model predictive control schemes. The proposed optimization method is validated using statistical testing and is shown to compare favorably against alternative methods, while evaluation metrics indicate that the developed models predict the dynamic behavior of the plant with high accuracy.

**Keywords:** Cooperative particle swarm optimization; identification; modeling; radial basis function neural networks; wastewater treatment plants

## 1. Introduction

Wastewater treatment plants (WWTPs) are considered to be a major component in circular economy due to their ability of receiving large volumes of polluted water as influent and allowing the maximum percentage of it to be reused. Developing automatic control schemes for WWTPs is a challenging task, not only due to the multiple and highly complex biological and biochemical phenomena taking place in the various processes, but also because strict environmental regulations have to be met. The performance of WWTP control systems can be improved, by incorporating mathematical models capable of accurately capturing the system dynamics. On the other hand, developing such models that are also simple enough to be incorporated in control schemes, is a challenging task.

Data-driven technologies, such as artificial neural networks (ANNs) appear as a promising solution due to the ability to capture the nonlinear dynamics of WWTPs with satisfactory accuracy (Sadeghassadi et al., 2018), and the potential to be easily integrated within advanced model predictive control (MPC) methodologies (Papadimitrakakis &

Alexandridis, 2022). On the other hand, training ANNs for WWTP modelling needs big volumes of data (Matheri et al., 2021). Unfortunately, due to the limited number of sensors available in WWTPs, the volumes of experimental data collected from the process are usually not sufficient; at the same time the collected data are of low quality due to several reasons (e.g. discontinuity, missing values, sensors failures, steady-state operation for long intervals), which lead to poor predictive performance of the developed models.

In this work, a novel approach is proposed for overcoming the problem of limited data availability in order to build highly accurate ANN models, suitable to be incorporated in MPC schemes. More specifically, a system identification problem is first defined, where the objective is to identify the critical parameters of the COST/IWA benchmark simulation model No. 1 (BSM1) (Alex et al., 2008), adapted to a real WWTP. The identification task takes the form of a complex nonlinear optimization problem, which is solved efficiently by introducing a novel cooperative particle swarm optimization (CPSO) (Kapnopoulos & Alexandridis, 2022) approach, specifically customized for WWTPs. The identified BSM1 model is used next to generate large volumes of dynamic data suitable for building high accuracy models that are based on radial basis function networks (RBFNs), trained with the fuzzy means (FM) algorithm (Alexandridis et al., 2013).

The rest of this work is structured as follows; in section 2, the formulation of the system identification problem is described and the proposed CPSO solver is presented. The next section presents the proposed method for developing dynamic WWTP models, including a brief description of the RBF architecture and the FM algorithm. The method is evaluated through a case study presented in section 4. Finally, the paper ends with concluding remarks and directions for future work.

## **2. System identification using cooperative particle swarm optimization**

### *2.1. Parameter identification of the Benchmark Simulation Model No. 1 (BSM1)*

BSM1 is a detailed WWTP model as described in (Alex et al., 2008). For the purposes of this work, the original BSM1 model has been adapted to a real WWTP, located in Greece. This procedure involved modifications to both structural and functional aspects of the original BSM1. The layout had to be adopted in terms of the number of process lines and the volume of the reactors and the secondary settlers. In addition, the capacity of aeration and pumping systems was modified. As far as the functional interventions are concerned, the average influent flow rate of the actual plant was used and correspondingly, the internal and external recirculation flow rates were also modified. Fig. 1 depicts a schematic representation of the particular WWTP.

The BSM1 model includes 14 kinetic and 5 stoichiometric parameters involved in the mass-balance equations of each reactor, the default values of which are fixed. Proper adaptation of this generic model to an actual WWTP requires an accurate estimation of these parameters. In this work, an identification scheme for estimating these parameters is proposed, using limited dynamic process data that can be directly collected from specific sensors of the WWTP, such as nitrate and nitrite concentration of the anoxic tanks, dissolved oxygen of the aerobic tanks and the ammonia and nitrite and nitrate concentration of the last aerobic tanks.

The identification process is carried out by formulating a nonlinear optimization problem, where the objective is to minimize the mean squared error (MSE) between the actual

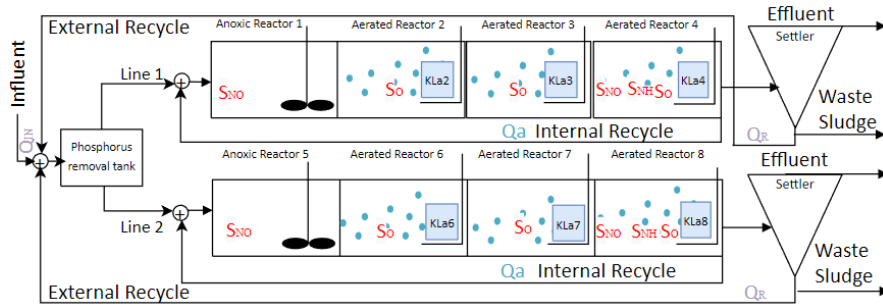

Fig. 1: Schematic Representation of the real WWTP under study

process data and the data generated at discrete time instances, in particular every 15 minutes, by imposing a limited number of steps on the manipulated variables of the identified BSM1 model. The resulting optimization problem exhibits several unwelcome properties, including high dimensionality, multimodality and noise contamination, which render the use of standard optimization methods inefficient.

### 2.2. Cooperative particle swarm optimization

Particle swarm optimization (Alexandridis et al., 2013), is a metaheuristic search method based on a population of potential solutions, called particles. Each particle explores the search space based on the personal and global best position achieved at each iteration of the algorithm. The standard PSO algorithm groups all the design variables into one swarm, optimizing them simultaneously. However, the high number of parameters involved in this particular problem makes it difficult for the solver to approach a satisfactory solution. To remedy this situation, we introduce a cooperative PSO method (CPSO), which takes into account correlations between the design variables and splits them accordingly into several groups, thus forming distinct swarms. Each swarm evolves independently in the search space while concurrently exchanging information with the rest of the swarms. In each iteration, the positions and velocities of the particles of each swarm are updated according to the following equations:

$$P_k v_{i,j}(t + 1) = w \cdot P_k v_{i,j}(t) + c_1 \cdot r_{1,i}(t) \cdot [P_k y_{i,j}(t) - P_k x_{(i,j)}(t)] + \dots + c_2 \cdot r_{2,i}(t) \cdot [P_k \hat{y}_j(t) - P_k x_{i,j}(t)]$$

$$P_k x_{i,j}(t)(t + 1) = P_k x_{i,j}(t) + P_k v_{i,j}(t + 1) \tag{1}$$

where the position of the  $i$ -th particle in  $j$ -th dimension is denoted by  $P_k x_{i,j}(t)$  for the  $k$ -th swarm. The velocity of each particle is denoted by  $P_k v_{i,j}(t)$ ,  $P_k y_{i,j}(t)$  represents the position of the best particle of each swarm and  $P_k \hat{y}_j(t)$  denotes the position of the global best particle. Coefficients  $c_1, c_2$  correspond to the local and global adjustment weights,  $w$  is the inertia weight and  $r_{1,i}, r_{2,i}$  are uniformly distributed random numbers. As each swarm now contains only a part of the design vector, the value of the objective function is calculated by creating a context vector which combines the particles of each swarm with the global best particles of the remaining swarms. A more detailed description of CPSO can be found in (Kapnopoulos & Alexandridis, 2022). This customized CPSO methodology has a number of advantages over standard PSO, including a finer-grained assignment which avoids the two steps forward - one step back problem, and the fact that each swarm evolves independently in the search space, thus, improving the diversity of the solution. These advantages ultimately lead to a highly accurate estimation of the BSM1 parameters.

### 3. Dynamic modelling using radial basis function neural network models

RBF neural networks represent a special type of ANNs used for application to various problems of diverse nature, including MPC controller design (Papadimitrakis & Alexandridis, 2022), because of their simple architecture and their high approximation capabilities. For a typical structure of an RBF neural network with  $N$  input variables,  $L$  hidden nodes and one output variable, the output of the RBF network for an observation  $t$  is calculated as:

$$\hat{y}(t) = \sum_{l=1}^L w_l \varphi_l \left( \sum_{n=1}^N (x_n(t) - \hat{x}_{l,n})^2 \right)^{1/2} \quad (2)$$

where  $\varphi$  represents the radial basis function used,  $x_n$  is the input space vector of the network,  $\hat{x}_l$  is the center of the  $l$ th hidden neuron, and  $w_l^T = [w_1, w_2, \dots, w_L]$  is the vector of synaptic weights that connect the hidden layer with the output layer. The radially symmetric function employed in this work was the thin plate spline (TPS) function:

$$\varphi(x) = x^2 \log(x) \quad (3)$$

In order to tune the structure of nodes of the hidden layer, the centers are selected employing the unsupervised FM algorithm, which has found numerous successful applications in different scientific fields (Papadimitrakis & Alexandridis, 2022). The FM algorithm uses fuzzy partitions of the input space to determine the number and locations of the hidden nodes. A detailed description of the algorithm can be found in (Alexandridis et al., 2013). After the estimation of the hidden node centers, weights are calculated by using linear least squares, implemented in matrix form:

$$w^T = Y^T \Phi (\Phi^T \Phi)^{-1} \quad (4)$$

where  $\Phi = [\varphi_1, \varphi_2, \dots, \varphi_L]$  and  $Y$  are the measured target values.

In order to produce dynamic RBF models with the aforementioned approach, past values of the process manipulated variables, the measured disturbances and the measured state variables - except from the output variable - are used as inputs to the RBF network.

## 4. Results and Discussion

### 4.1. System identification

The proposed identification scheme is employed by initially applying pseudorandom binary sequences on the BSM1 model input variables and disturbances. Data for the 12 measured state variables are collected for a 2-month period with a sampling period of  $T_s = 15 \text{ min}$ , which is a time interval suitable for controller design (Alex et al., 2008); the data are then corrupted with Gaussian noise  $\sim N(0, \sigma)$ , where  $\sigma$  is 2.5% of the mean measured value for each variable. This set of data is introduced to the CPSO identification scheme for estimating the values of the BSM1 kinetic and stoichiometric parameters.

The parameters to be estimated are separated into distinct swarms based on the different processes they affect during the operation of the plant. The first two swarms consist of the 8 and 5 parameters related to the heterotrophic and autotrophic phenomena, respectively. The 3 parameters affecting hydrolysis and the unique parameter influencing ammonification, form the 3<sup>rd</sup> and 4<sup>th</sup> swarm, respectively. The remaining parameters related to the COD in biomass and in products from the biomass, constitute the 5<sup>th</sup> swarm.

For comparison purposes, the employed CPSO solver was tested against standard PSO and a modified PSO methodology (Mezura-Montes et al., 2011). The algorithms are individually tuned using literature suggestions in conjunction with a trial-and-error procedure. Due to the inherent stochastic nature of the algorithms, 15 runs are executed for each algorithm and the superiority of CPSO is validated by running a two-sample *t*-test. Table 1 summarizes the results. As it can be seen, the performance of CPSO is superior in terms of the best or the average solution with a statistical significance higher than 90%, while it also manages to produce more consistent results, as indicated by the standard deviation values.

#### 4.2. Dynamic modeling

The proposed method can produce dynamic models for different process variables; in this work, we present the results for the ammonia mass concentration ( $S_{NH}$ , g N.m<sup>-3</sup>) in the last aerated tank (Reactor 4) in Line 1. The input features were: (A) lags for all the manipulated variables, i.e. oxygen coefficients ( $K_L a$ , d<sup>-1</sup>) in all the aerated reactors and the internal recycling flows ( $Q_a$ , m<sup>3</sup> d<sup>-1</sup>) for both lines, (B) lags for measured plant disturbances, i.e. the flow rate ( $Q_{input}$ , m<sup>3</sup> d<sup>-1</sup>) and ammonia influent ( $S_{NH_{input}}$ , g N.m<sup>-3</sup>) and (C) lags for all the measured state variables, i.e. dissolved oxygen concentration ( $S_O$ , g (-COD).m<sup>-3</sup>) in all aerated tanks, nitrite and nitrate nitrogen mass concentration ( $S_{NO}$ , g N.m<sup>-3</sup>) for all the anoxic tanks and aerated reactors 4, 8, and ammonia mass concentration ( $S_{NH}$ , g N.m<sup>-3</sup>) for reactor 8. The number of past values for each feature was decided empirically by performing step tests and observing the dynamic responses of the measured output variables. The total number of input features was equal to 46. Using the BSM1 model with parameters identified by the proposed CPSO scheme, a large dataset containing 10 years of simulated data with 15 minutes sampling was generated in order to train the RBFN with the procedure described in the previous section. To properly evaluate the RBFN model predictive abilities, a new testing dataset was produced, spanning 5 years of operation, using this time the BSM1 with the original parameters and contamination with noise; this dataset allows for an unbiased evaluation of the RBFN predictions, as it is built using the original model and thus is independent from the RBFN training data generation procedure. The mean absolute error (MAE) between RBFN predictions and the original BSM1 data and the R<sup>2</sup> coefficient were found equal to 0.88 g N.m<sup>-3</sup> and 0.99, respectively. A visual comparison between the actual and predicted values is shown in Figure 2. It can be seen that the proposed framework manages to produce RBFN models that accurately track the data produced by the original BSM1 model, despite using a very limited amount of data from it (just two months in this case).

### 5. Conclusions

This work introduces a dynamic modelling scheme to derive highly accurate data-driven predictive models for WWTPs by using only a limited amount of data. The collected data are fed to a novel CPSO-based identification scheme, to accurately estimate the values of the kinetic and stoichiometric parameters of the BSM1 model. The performance of this method is verified through comparisons against two other PSO algorithms.

*Table 1. Performance Metrics*

Algorithm	Fitness Average	Fitness standard deviation	Best Fitness	Average Function Evaluations	p-value
CPSO	0.00068	0.00014	0.00041	2348	-
Standard PSO	0.00223	0.00244	0.00045	2726	0.0311
Modified PSO	0.00106	0.00076	0.00044	2535	0.0885

Fig. 2. Results for the RBF-based ammonia concentration model (a) actual vs predicted values for the whole testing dataset and (b) actual and predicted values vs time for an arbitrary selected window of the testing dataset

The identified model is used to produce large volumes of dynamic data for training discrete time RBF predictive models. The results indicate that the derived models are capable of predicting the dynamic behavior of the WWTP with high accuracy, while at the same time being much simpler than first-principle-based models; these properties make them ideal candidates for integration in MPC schemes, a step which will be pursued as feature research.

## Abstract

This paper presents two visualization tools that use meter data to facilitate power management in the industrial sector. The first determines typical daily load profiles based on shape and magnitude with a clustering algorithm. A whole year's worth of electricity consumption can then be visualized on a calendar featuring typical daily profiles on a single screen. Different clustering algorithms and scaling techniques are compared for twelve plants from four different industrial sectors. Data scaled between 0 and 1 or with the normal distribution and the k-Means algorithm showed the best performance. The second tool specifically addresses the management of maximum power demand by suggesting power shedding levels and showing their impacts on billing.

**Keywords:** electricity consumption, power demand, cluster analysis, operational control, SME energy efficiency

## 1. Introduction

To achieve net-zero emissions by 2050, electrification is the preferred option for industrial decarbonization in Québec, Canada, since the vast majority of the power generated by its public electric utility, Hydro-Québec, comes from renewable resources and it is competitively priced (Hydro-Québec, 2022). Therefore some pathways to achieve climate targets predict an increase in electricity demand of the order of two-thirds more than current levels (Dunsky, 2021). The substantial increase in demand for both energy and capacity required for this transition could limit decarbonization potential or require major investments in infrastructure, which would in turn lead to rising energy costs and delays. It is therefore essential that every industrial sector optimize its energy use and maximize its flexibility. In this context, the current role of a utility is not only to supply energy, but also to facilitate such a transition in the most efficient way possible. With limited resources and information, demand side management in small and medium-sized industries is particularly challenging (Thiede et al., 2013). The focus of programmes should be to facilitate knowledge creation among industries (Palm et al., 2020).

Previous work (Narciso and Martins, 2020; Richard et al., 2017; Zhou et al., 2013) confirmed the benefits of using machine learning strategies and visualization tools to facilitate the understanding of electricity consumption. However, most of these works focus on a single industrial activity do not confirm the method performance when analyzing different production processes. The proposed solution is a platform to help industries better understand their energy consumption and act accordingly. It comprises three modules: the first focuses on metering and public data; the second introduces

production data and the third integrates an IoT solution. This paper focuses on the first module, more specifically the description of two visualization tools. The first one is a clustering algorithm that groups typical daily load profiles of a production plant based on shape and consumption level (“amplitude”) from a year’s worth of meter data. A whole year’s electricity consumption can be visualized on a calendar featuring typical daily profiles on a single screen. Automatically generated typical profiles help industrial customers relate the shape of the profiles to their production schedule. This may stimulate a discussion about various demand side management measures, often related to operational control. Different clustering algorithms and scaling techniques are compared in Section 2 of this paper. The second visualization tool specifically addresses the management of maximum power demand by suggesting and evaluating power shedding levels and is discussed in Section 3. Finally, Section 4 presents the conclusion.

## 2. Typical daily load profiles (clustering)

### 2.1. Methodology

#### 2.1.1. Data

Contrarily to Zhou et al. (2013) who use clustering algorithms for load classification purpose, *i.e.* segmentation of electricity consumers, this work aims to analyze electricity consumption of a single production plant by identifying typical daily load profiles, and therefore, energy consumption patterns. To verify the performances of the algorithms of the proposed solution, three plants from each of four different industrial processes were considered: pharmaceutical (plants A to C), chemical (plants D to F), food (plants G to I) and plastic and rubber (plants J to L). To avoid loss of information, no features were extracted and no outliers were removed so that both good and bad consumer practices could be identified if unusual load profiles recur. However, if missing data (or non-existent data) is greater than 10% of all data for a given day, this day is removed from analysis; otherwise, missing values are interpolated. Raw data corresponds to the plant’s electrical energy consumption (kWh) for every 15 minutes for the whole year 2021. The data is organized such that each day,  $i$ , is represented by a vector with 96 dimensions ( $L_i = [x_{i1}, x_{i2}, x_{i3}, \dots, x_{iN=96}]$ ). All the data is organized in a  $365 \times 96$  matrix. However, the inclusion of a supplementary dimension representing this vector norm (as a representation of consumption level) is included as an option to evaluate the impact of this “load amplitude”. The vector norm is calculated using Eq. (1):

$$\|L_i\| = \left( \sum_{j=1}^N |x_{ij}|^2 \right)^{1/2} \quad \text{Eq. (1)}$$

As mentioned, this module aims to identify the typical consumption profile. Then, the average consumption in each time step for each cluster is considered as the expected one. Therefore, given a consumption profile and belonging to a cluster, it is possible to evaluate the consumption of a plant considering its deviation.

#### 2.1.2. Clustering algorithm

Clustering analysis is a machine learning tool to identify patterns by forming groups of data that are similar to one another but different from other groups. This technique is an unsupervised learning method because target values are not known. Most of this work has been aimed at comparing the consumption of different plants, buildings and industries (Zhou et al., 2013). However, Richard et al. (2017) and Bourdeau et al. (2021) have shown the advantages of using clustering to find the typical profiles that represent the expected

behaviors of plant/building consumption. Before selecting the specific clustering method, the data to be analyzed had to be prepared. In addition to the treatment mentioned above, three different data scaling techniques were used: based on the vector norm (each day is scaled individually), min-max of the whole matrix (between 0 and 1) and normal (or Gaussian) distribution of the whole matrix. These scaling techniques are represented in the following equations:

$$L_i' = L_i \cdot [1/\|L_i\|] \tag{Eq. (2)}$$

$$x_{ij}' = \frac{x_{ij} - \min(X)}{\max(X) - \min(X)} \tag{Eq. (3)}$$

$$x_i' = \frac{x_i - \mu}{\sigma} \tag{Eq. (4)}$$

where  $L_i'$  is the scaling vector for day,  $i$ ,  $x_{ij}'$  is the normalized value ( $j$  is the 15-minutes interval between readings) and  $\mu$  and  $\sigma$  are respectively the mean and standard deviation of all data (whole year,  $X$  matrix). When the norm is included as the last dimension, it is scaled considering all the norms of all vectors.

This paper summarizes the performance evaluation of the most common clustering methods used for load classification:  $k$ -means (Bourdeau et al., 2021),  $k$ -shape (Yang et al., 2017), Gaussian mixture model (GMM) (Wang et al., 2022), and fuzzy  $c$ -means (FCM) (Zhou et al., 2013). Each clustering method is evaluated using the three scaling techniques mentioned above. The number of clusters is obtained by maximizing the silhouette score (Rousseeuw, 1987), which is also used to compare the performance of clustering strategies. The silhouette score for an object  $i$  belonging to cluster  $A$  is defined in Eq. (5).

$$S(i) = \frac{b(i) - a(i)}{\max(a, b)} \tag{Eq. (5)}$$

where  $a$  is the average intra-cluster distance and  $b$  is the average shortest distance to another cluster Euclidian distance is used for these calculations. The range of this score is  $[-1,1]$ , therefore the value closest to 1 represents the best clustering strategy.

## 2.2. Results

In this section, we present the results of the clustering strategies. Figure 1 shows the average silhouette scores for all clustering methods and the three corresponding scaling techniques. In general,  $k$ -means, GMM and FCM algorithms performed the best. The number of clusters for GMM and  $k$ -means are higher than or equal to FCM (Table 1).

Table 1. Number of clusters for all clustering strategies (min-max scaling technique)

Plant/Algorithm	A	B	C	D	E	F	G	H	I	J	K	L
$k$ -means	3	3	2	2	2	2	3	3	6	2	3	5
$k$ -shape	4	2	2	3	2	2	2	4	2	3	2	2
GMM	3	3	2	2	3	2	2	3	6	3	3	6
FCM	3	2	2	2	2	2	3	3	5	2	3	2

A higher number of clusters allows for more information on plant performance and production behavior to be obtained. However, GMM is more sensitive to outliers, so unusual loads are identified as a cluster with one profile, which can affect the silhouette score and induce distortions. This is the case for the plant G, which explains why the number of clusters is higher for  $k$ -means than for GMM. On the other hand, it can be seen

in Figure 1 that scaling based on the vector norm is less successful. Although adding the norm as an additional dimension increases the score, it is still worse than other techniques. The supplementary dimension for the other scaling techniques does not have a significant effect.

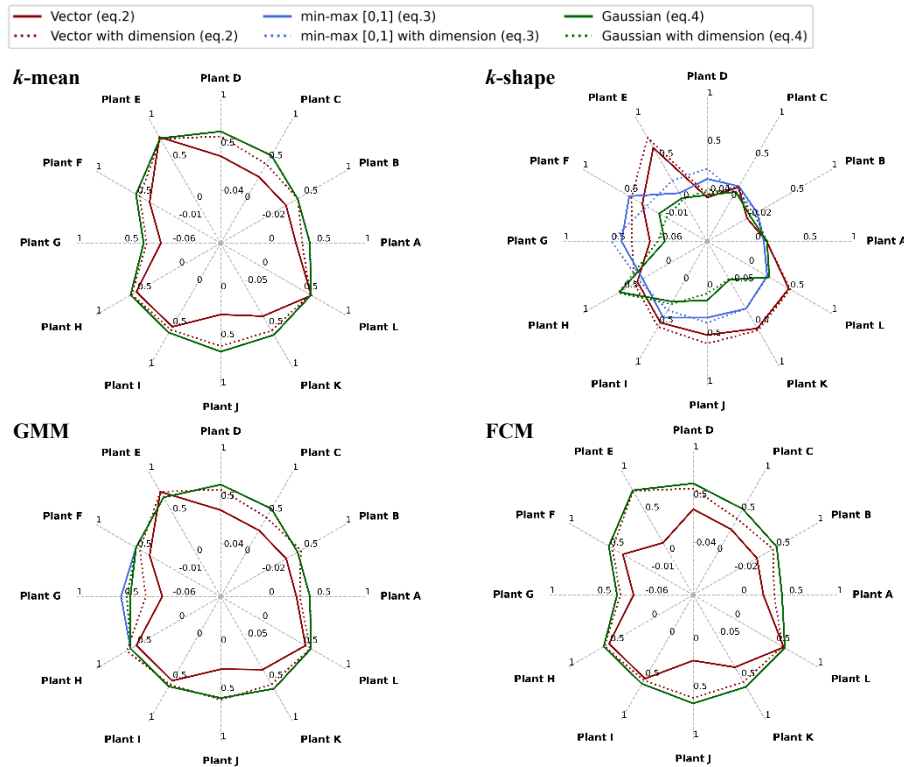

Figure 1. Average silhouette scores for all clustering strategies

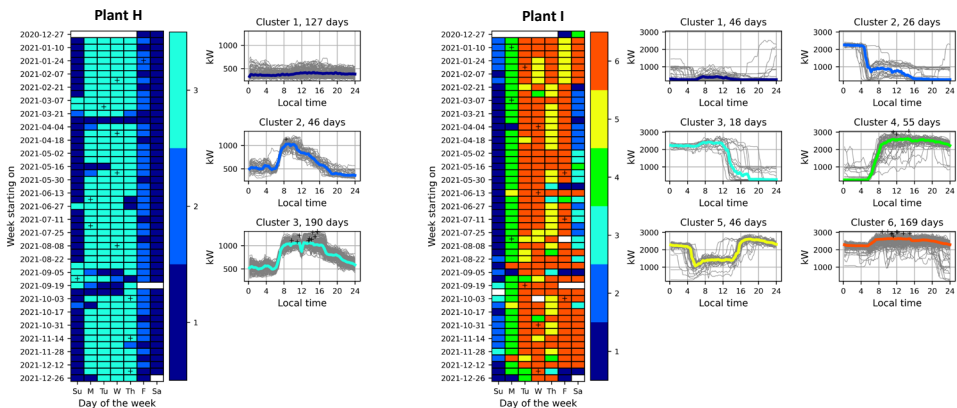

Figure 2. Cluster distribution on calendar and suggested clusters for plants H and I with *k*-means and min-max scaling technique.

Figure 2 presents the proposed display. The clustering strategy allows production days to be distinguished from non-production days and identifies the shape of some typical

production profiles. For instance, plant I cluster 5 represents days when maintenance was being performed on major equipment. The module can incite customers to stop unnecessary loads during non-production hours. For example, plant H had a nighttime load that was half of its load during the day. The day and time of the peaks that induced power demand costs are indicated with a plus sign (+).

### 3. Peak power demand management tool

#### 3.1. Methodology

The second visualization tool aims to raise interest in power demand management by comparing how three different levels of power shedding can impact electricity billing. The structure of the rate in Québec for business customers includes billing demand (CAD/kW) and energy charges (CAD/kWh) (Hydro-Québec, 2022).

The proposed indicator to demine load shedding levels is based on the marginal cost of electricity during peaks. The highest peaks typically account for a limited quantity of energy, but significantly affect billing demand. Hence, above a given level, if power demand costs are distributed over energy, the marginal energy cost increases to a few dollars per kWh. The power threshold,  $P_{Threshold}$ , (in kW), is calculated using the marginal energy,  $e_{marg}$  (in kWh) and the distributed power demand cost parameter, DPDC (in CAD/kWh), using:

$$e_{marg} = \int_{\text{Billing period}} (P(t) - P_{Threshold}) \cdot (H(P(t) - P_{Threshold})) dt \quad \text{Eq. (6)}$$

$$P_{Threshold} = P_{max} - \frac{DPDC * e_{marg}}{PDC} \quad \text{Eq. (7)}$$

where  $P_{max}$  is the maximum power demand of the billing period and PDC is the power demand cost, CAD15.154/kW (Hydro-Québec, 2022). Marginal energy is modeled by equation (6). Where  $H$  is the Heaviside step function. The proposed algorithm to resolve this problem is as follow. All power data is sorted in descending order based considering the accumulated value of time on the abscissa axis. This relationship between power and time allows us to obtain the time  $t_{Threshold}$  according to a fixed  $P_{Threshold}$ . Then, equation (8) can be used to obtain the marginal energy. These equations are solved iteratively until reaching a convergence in the value of DPDC to CAD1.00/kWh (based on experience) to determine the minimum plausible load shedding power level. The two additional levels were evenly divided based on power demand.

$$e_{marg} = \int_0^{t_{Threshold}} (P - P_{Threshold}) dt \quad \text{Eq. (8)}$$

Not only the DPDC parameter is significant to customers, but this indicator also indirectly allows for the shape of the profile and the cut-off time to be taken into account. It also facilitates price comparisons with alternative energy sources.

#### Results and discussion

Table 2 shows results of the peak power demand management tool. Figure 3 shows a month in winter for plants B and D.

Figure 3. Peak power management tool example and impact on billing for plant B and plant D

Table 2. Summary of peak power management tool

Period		Winter month				Summer month			
Plant	Shedding	$P_{\text{threshold}} - P_{\text{max}}$ (kW)	Power demand savings (CAD)	% savings on total bill	Distributed power demand costs above threshold (CAD/kWh)	$P_{\text{threshold}} - P_{\text{max}}$ (kW)	Power demand savings (\$ <sup>CAD</sup> )	% savings on total bill	Distributed power demand costs above threshold (CAD/kWh)
B	1	263-288	397	3.47%	38.60	301-324	359	3.01%	1.56
	2	244-288	685	5.99%	5.43	298-324	406	3.40%	1.40
	3	222-288	1028	8.98%	0.99	287-324	584	4.90%	0.93

	2	821-921	1562	4.77%	2.20	847-896	767	2.30%	2.08
	3	772-921	2334	7.13%	1.00	823-896	1139	3.42%	0.99

#### 4. Conclusion

The combined use of clustering algorithm  $k$ -means and scaling data, either between 0 and 1 or using the normal distribution, for cluster analysis achieved the best performance in determining typical profiles in the plants analyzed, i.e., silhouette score, number of clusters, and number of profiles per cluster. For these scaling techniques, the vector norm (as a measure of consumption level) has no effect on the results. The silhouette score can clearly identify different typical profiles. However, more detailed divisions may be required to identify different groups of typical profiles with similar consumption levels but with different consumption shapes. An optional feature integrating a user choice is considered in the proposed solution. Future work could be aimed at improving and evaluating other metrics that would suggest efficient and meaningful clustering for the customer.

In this study, we have also confirmed the great variability in electricity consumption, even within the same industrial sector. This calls for further work on robust solutions to meet this challenge. In the same vein, although twelve different plants (representing four different industrial sectors) are evaluated in this study, a results validation is included in the following stages of the project to consider other types of industries, batch and continuous processes, as well as customer experience. The power demand cost savings calculated in the peak power management tool and the distributed power costs in kWh clearly illustrate the effect of shedding power and can encourage customers to manage peak power demand. They would be able to see the number of hours and quantity of the power to shed and the resulting savings. Future work will focus on the validation of the cut-off threshold and methodology as they relate to customer experience (technical and financial feasibility).

## Abstract

In this work we present a hybrid monitoring approach for fault detection using the Tennessee Eastman (TE) process. We benchmark our proposed approach against previous methods in the available literature and analyze the benefits and shortcomings. The hybrid monitoring approach contains two steps. First, from a model-based perspective, a dynamic model of the TE plant is constructed using commercial dynamic simulation software and data is generated from the TE plant and its model. In the second step, a data-driven analysis is conducted. This involves training different fault detection models with the previously obtained datasets to detect plant faults as early as possible. The results show that combining datasets can improve the traditional pure data-driven monitoring performance with only plant data. This work highlights the usefulness of combining process modeling and machine learning in the monitoring and prognostics fields when data availability from the actual process is limited.

**Keywords:** Tennessee Eastman, monitoring, Aspen HYSYS, machine learning, fault detection.

## 1. Introduction

Process monitoring and fault detection is critical in the process industry in terms of improving process performance, reducing plant halts, and therefore improving return of investment. Generally, we can approach process monitoring from a model-based or a data-driven point of view. Model-based perspectives—for instance, observers and parity equations—are based on traditional control theory and are well-suited for small systems [1]. However, this approach has not transcended to industry-scale processes due to the difficulty in adapting the high complexity of these processes to this kind of models. Data-driven methods can overcome this issue by being trained using only output data of the system. Therefore, they can describe the complexity of a system without the need to know the intrinsic process details, which can be time-consuming and impractical to identify. However, data-driven approaches do not extrapolate well to regions of the state space not

observed in training. In these cases, given judicious assumptions, model-based approaches can extrapolate and allow better interpretability. We can see that both approaches show advantages and disadvantages, and the choice will vary depending on the specific case.

In this work, we present a hybrid fault detection approach that merges data fed directly from the plant and model data derived from first principles. The goal is to evaluate if there is any benefit in using a model to boost the information we provide the fault detector. In this way, we take advantage of rigorous simulation to enhance the results of a pure data-driven approach. Early examples of this kind of hybrid approach can be found in Schwarte and Isermann (2002) [2], however, in our opinion, this research theme can be further improved.

The paper is organized as follows. Section 2 outlines a short review of data-driven fault detection methods and formalizes the hybrid approach. Section 3 describes the case study selected for this work, the Tennessee Eastman process. Then, Section 4 shows the results of the benchmark. Finally, Section 5 summarizes the conclusions of the work.

## 2. Fault detection

Fault detection is the branch of process monitoring that studies how to identify events that cause a variable or property of the system to deviate from an allowed range. Figure 1 summarizes a possible process monitoring and fault diagnostic framework based on Aldrich and Auret (2013) [3]. In this scenario, the monitoring system is trained with normal operation conditions (NOC) data only, therefore a semi-supervised approach is followed. A semi-supervised approach provides the advantage of not needing real fault data for training, which may be expensive or impractical to obtain—e.g., operating the plant to off-control states or introducing dangerous disturbances just to acquire data. Supervised classifiers may struggle with any kind of new fault that was not previously trained for; therefore, they can be easily outperformed by semi-supervised approaches.

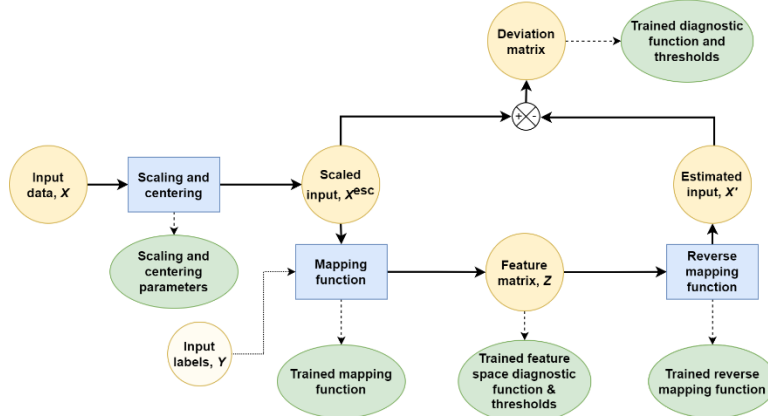

Figure 1. Semi-supervised fault detection framework, with data preprocessing, mapping, and reconstruction steps.

A monitoring system such as that in Figure 1 works as follows: it develops a series of features,  $Z \in \mathbb{R}^{n \times n_z}$ , based on a raw dataset,  $X \in \mathbb{R}^{n \times m}$ , which is usually preprocessed to improve performance, and tries to reconstruct the input into  $X' \in \mathbb{R}^{n \times m}$ .  $n$  is the number of instances of the dataset, and  $m$  and  $n_z$  are the size of the input and the latent space, respectively (typically  $m > n_z$ ). Process monitoring compares the reconstructed

input with the actual input and extracts the result of the in-control or out-of-control state of the plant.

### 2.1. Types of semi-supervised data-driven fault detection methods

One of the fundamental fault detection methods is *univariate statistical monitoring* [4], which obtains the operation limits using statistical theory and hypothesis testing. Given a level of significance,  $\alpha$ , and assuming Gaussian distribution on the input data, our null hypothesis would assume normal operation, while the alternative hypothesis would imply the existence of faults. This way, if the mean and standard deviation of the tracked variable,  $x$ , is  $\mu$  and  $\sigma$  respectively, we say that the process is in normal operation conditions (NOC) if  $x$  is inside the following range:

$$\mu - c_{\alpha/2}\sigma \leq x \leq \mu + c_{\alpha/2}\sigma, \quad (1)$$

where  $c_{\alpha/2}$  is the standard normal deviate for the  $1 - \alpha/2$  percentile. This approach considers serial relationships between a variable state in different time steps, but fails to include spatial relationships, i.e., the influence between different variables at the same instant in a complex process.

To consider this influence, we need to work with a *multivariate statistical monitoring* approach. In this case, instead, the Hotelling's  $T^2$  test should be used [4]. To this end, the statistic is  $T^2 = \mathbf{z}^T \mathbf{z}$ , where the feature vector,  $\mathbf{z} \in \mathbb{R}^{n_z}$ , is  $\mathbf{z} = \Lambda^{-1/2} V^T \mathbf{x}'$ , with  $\mathbf{x}' \in \mathbb{R}^m$ .  $\Lambda \in \mathbb{R}^{n_z \times n_z}$  is the diagonal matrix containing the  $n_z$  eigenvalues of the covariance matrix of the training dataset,  $X$ , and  $V \in \mathbb{R}^{n_z \times m}$  is the matrix of the eigenvectors of the same eigenvalue decomposition. Equation (2) shows how to compute the  $T^2$  detection threshold for an  $\alpha$  level of significance when we use the sample covariance matrix,

$$T_\alpha^2 = \frac{m(n-1)(n+1)}{n(n-m)} F_\alpha(m, n-m) \quad (2)$$

The output of this fault detection approach is a confidence ellipse for which we accept a new measurement as NOC if it satisfies  $T^2 < T_\alpha^2$ . If we cannot assume a Gaussian distribution or the input dataset is too small, we would need to consider more robust hypothesis tests [5].

The multivariate detection approach can be further improved by dimensionality reduction techniques such as Principal Component Analysis (PCA), Fisher Discriminant analysis (FDA), Partial Least Squares (PLS), or Canonical Variate Analysis (CVA) [4]. These perform the same multivariate statistical testing but now apply it to a lower dimensional dataset that is more representative of the actual trends of the system, rejecting noise and non-useful information. For instance, PCA projects the raw data into the lower dimensional space created by the  $k$  eigenvectors corresponding to the highest eigenvalues of the covariance matrix, being  $k < m$ . Then, the detection threshold can be calculated using Equation (2), with  $k$  number of features instead of the original number of features  $m$ . If several timesteps are stacked in the same time window that is fed to the PCA algorithm to also account for serial relationships, we call this method Dynamic PCA (DPCA). The added time series analysis tends to outperform standard PCA.

More advanced techniques for fault detection include the use of machine learning models. Given that, we are focusing on semi-supervised approaches in which we have only NOC data from the plant, a vanilla neural network classifier architecture does not apply to a semi-supervised approach. It is here where auto-associative networks or autoencoders appear.

Autoencoders (see Figure 2) use an encoder set of layers to transform a single input instance  $\mathbf{x}$  into a latent space representation  $\mathbf{z}$ , typically of lower dimensionality than the input data, and then use the decoder layers to return a reconstruction of the input  $\mathbf{x}'$  from the latent representation obtained by the encoder [6]. As in Figure 1, the deviations

between the actual input and the reconstruction are used to determine if the instance corresponds to normal operation or not. Unlike the previous approaches, autoencoders can capture nonlinear relationships between the different variables, therefore being useful for more complex processes. For this reason, these models are also sometimes called nonlinear PCA (NLPCA).

Figure 2. Autoencoder architecture.

A set of the different methods presented in this section will be tested with both pure data-driven and hybrid dataset approaches, the latter being explained next.

### 2.2. Hybrid fault detection approach

In this section, we present a hybrid fault detection approach that adds the advantages of model-based methods to data-driven approaches, while considering the tools already available in the process industry. This method leverages process simulation models to improve the dataset preprocessing step using software such as Aspen HYSYS.

Here, the plant and the model use the same high-level vector of control signals,  $\mathbf{u}$ , as inputs; and their outputs,  $\mathbf{y}$  and  $\mathbf{y}^*$ , respectively, are compared. This results in the so-called residual generation,  $\mathbf{r}$ . Residuals will make up the datasets for training and cross-validation, and therefore will be fed to the selected fault detection method: limit sensing, PCA, autoencoder, etc. Figure 3 summarizes the procedure.

Figure 3. Hybrid fault detection framework.

The hybrid procedure is expected to show better invariant metrics with respect to faults and anomalies in the process: the plant output  $\mathbf{y}$  can be affected by external disturbances, hence intrinsic changes and its comparison with the ideal behavior represented by the model  $\mathbf{y}^*$  can be more efficient as a process monitoring indicator. Note that data harmonization between model and plant must be studied to minimize differences and account for model mismatches. This is assumed as a preliminary condition in this paper and will not be analyzed here.

## 3. Case study – The Tennessee Eastman process

The Tennessee Eastman (TE) process is a virtual plant that Downs and Vogel designed based on an Eastman Chemical Company process [7]. In this virtual plant, a series of reactants, A, C, D, and E are processed to obtain two products, G and H, as pure as possible, with an unavoidable inert component mixed in the feed, B, and a byproduct, F.

To obtain the desired products, the system is made up of five unit operations: a reactor, a condenser, a liquid-vapor phase separator, a compressor, and a stripper column. Figure 4 shows a process flow diagram of the complete system.

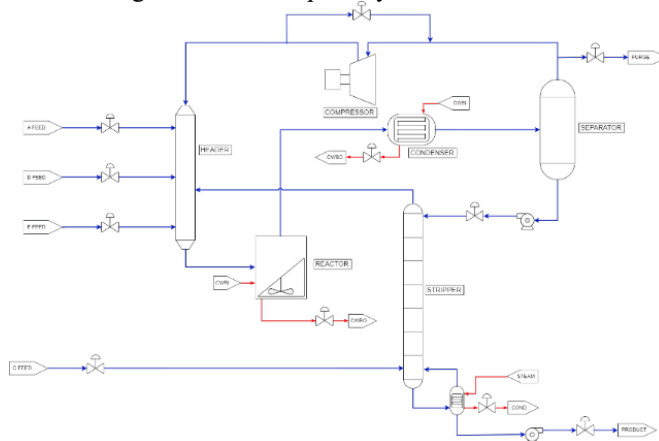

Figure 4. The Tennessee Eastman process.

In terms of the user interface, the TE process presents 41 measurable variables with noise and delay and 12 first-order dynamics actuators that allow for external interaction with the system. The process allows the activation of 20 types of disturbances at any point during the simulation. These can work as the faults to be detected by the monitoring system. The disturbances represent step changes, drifts, random noise, and component malfunctions in the supply conditions, cooling streams, and actuators of the plant.

For this work, we modeled the TE process in Aspen HYSYS, a dynamic simulator widely used in the process industry. We use the original TE script as the *plant* and the HYSYS simulation as the *model*, and collect data from the steady-state operation of both. The training dataset includes normal operation from both plant and model, and the validation dataset includes the activation of different disturbances for the plant and fault-free operation for the model. The new datasets are created according to the scheme in Figure 3, and we apply the monitoring methods summarized in Section 2 to compare them with pure data-driven approaches found in the literature.

#### 4. Results

The results of the hybrid approach over the TE process data are shown in Figure 4 using previous literature results for comparison [4]. We selected the  $F_1$  score,

$$F_1 = \frac{TP}{TP + 0.5(FN + FP)} \quad (3)$$

as the target performance metric to harmonize the different results. TP stands for the number of true positives, FN for the number of false negatives, and FP for the number of false positives predicted by the data-driven model. Therefore,  $F_1$  represents the harmonic mean of precision (the percentage of instances predicted as positive that are correctly classified) and recall (the percentage of true positive instances that are correctly classified).  $F_1$  is widely used because it works as an effective way to balance the effect of false negatives and false positives in classification models. Note that, in the framework of fault detection, positive instances correspond to faults, and negative instances correspond to normal operation.

Figure 5 shows the results. Note that all pure data-driven approaches have similar performance and the hybrid approaches tend to perform better. The DPCA pure data-driven score from the literature shows a small unexpected drop that can be explained by a high false positive ratio caused by the specific threshold calibration procedure used in [4]. The  $F_1$  score heavily penalizes unbalances between false positives and false negatives, therefore the unexpected behavior. Results strongly suggest that accounting for first principles through rigorous simulation can improve data-driven approaches.

Figure 5. Comparison between pure data-driven (literature) versus hybrid dataset performance.

## 5. Conclusions

This work describes the hybrid fault detection approach and analyses its performance using the classical Tennessee Eastman process. To conduct this benchmark, the Tennessee Eastman original script is assumed to be the actual plant, and an Aspen HYSYS model is built to try to replicate it and generate a new residuals dataset. The results show that the hybrid approach is an interesting framework that tends to improve monitoring performance, even when applied to the most basic monitoring approaches. Future work will introduce more complex datasets, including dynamic plant operation, and perform fully supervised classification, taking advantage of the models to replicate faults and feed them into the fault detection methods and comparing them to the residual-based approach.

# Data-Driven Process Monitoring for Knowledge Discovery: Local and Global Structures

Estelle E. Seghers, José A. Romagnoli

*Department of Chemical Engineering, Louisiana State University, Baton Rouge,  
Louisiana 70803, United States of America*

## Abstract

In industrial processes, the amount of raw data generated can add complexity in the analysis and understanding of the process dynamics. Being able to properly interpret this data can help improve plant operation. A platform is introduced for monitoring of industrial processes and optimization of the model-building process. FASTMAN-JMP (FAST MANUAL Data Manipulation implemented in JMP [1]) is a tool developed in Python to apply various data mining and machine learning techniques quickly and easily to better understand valuable patterns and hidden trends in process data. It is shown that local and global structures in the data set can be visualized and related to actual process operations through the identification of the variables responsible for the separation between selected given clusters. Furthermore, adequate comparisons of these algorithms can be difficult, having different loss functions with many parameters. We aim to decipher these algorithms, and how they work in the context of industrial data. Results are presented for an industrial case study of a pyrolysis reactor.

**Keywords:** process monitoring, data mining, knowledge discovery, machine learning, data-driven modeling.

## 1. Introduction

The digital data being created today has surpassed many projected values, reaching roughly 44 zettabytes ( $10^{21}$  bytes) generated every year as of 2020 [2]. This era of big data introduces an opportunity to improve industrial plant operation and control with increased productivity and safety. Data mining and machine learning algorithms present a way to achieve increased knowledge discovery in industrial processes, but it is also vital to understand how these methods function. Of particular interest is understanding the granularity of these analyses performed with industrial data, namely in how machine learning methods distinguish and illustrate the global and local structures present in data. In the context of industrial chemical engineering plant data, global structures generally suggest overall trends in the process (over a period of hours, or days, or longer) while local structures generally refer to short term fluctuations in certain process variables or controllers. Dimensionality reduction, also known as feature extraction, is a particularly important component within an unsupervised approach for analysing process data.

Most of the discussions in the computer science community deal with synthetic data and the main conclusion may or may not be relevant when dealing with industrial process data. In the author's opinion there is a need for a proper discussion on these issues in the context of industrial manufacturing process data. A Python-based data analysis graphical user interface, called FASTMAN-JMP (FAST MANUAL Data Manipulation implemented in JMP [1]), was developed using Python libraries (NumPy, pandas, sci-kit learn, etc.) and incorporated as an add-in into JMP, a statistical data analysis software, to facilitate the

use and visualization of different methods for data mining and knowledge discovery. With the availability of such a powerful environment, the concepts of global and local data structures are first analyzed using data from an industrial pyrolysis reactor. It will be shown that local and global structures in the data set can be visualized within the Self Organizing Maps (SOM) [3] and related to actual process operations through a subspace greedy search (SGS) algorithm [4] allowing for the identification of the variables responsible for the separation between any two given clusters. Furthermore, when running alternative dimensionality reduction algorithms, it is not clear how these results yield trustworthy representations of the original data distribution and, more importantly, if they lead to proper characterization of the process states. Even comparisons of these algorithms can be difficult having different loss functions with many parameters. Consequently, another goal of this work is to decipher these algorithms, and how they work in the context of industrial chemical engineering process data.

## **2. Understanding the Data: Global and Local Structures**

The goal of dimensionality reduction is to reduce the number of features in a dataset to obtain a compressed representation that is useful for analysis, by retaining as much “structure” in the data as possible. There are many algorithms for dimensionality reduction, and they can generally be discussed in the context of two principal archetypes: those that primarily aim to preserve global structure (overall trends in the process over a period of hours, or days, or longer) and those that primarily aim to preserve local structure (short-term fluctuations in certain variables or controllers). There is no strict definition of what constitutes global or local structure preservation, but global structure-preservation methods may be thought of as preserving overall placement of large clusters of observations, i.e., the data at the extremes in high-dimensional space are also at the extremes in low-dimensional space.

In contrast, local structure-preservation methods focus on preserving neighborhoods of observations, so that near neighbors in the high-dimensional space are still near neighbors in the low-dimensional space. If the data lie along manifolds or in clusters, that information will not necessarily be preserved when projecting to a very low number of dimensions. That is, a technique which preserves global structure does not necessarily preserve which points are close neighbors in the high-dimensional space.

## **3. Dimensionality Reduction: Global and Local Structure Preservation**

In Principal Components Analysis (PCA) [5], a very popular very popular dimensionality reduction technique, the extracted principal component vectors graphically illustrate most of the variance in the data, and therefore primarily captures the global structure of the dataset while ignoring the detailed local structure information among the process data. Since the development of PCA, a class of dimensionality reduction techniques, known as manifold learning, has been developed in the pattern recognition area, including t-SNE [6], UMAP [7], and more recently TriMAP [8]. These methods are popular in biological applications and have been used in chemical manufacturing applications ([6], [9], [10]). However, one critical drawback of these methods is that they were either designed to preserve local structure or struggle with balancing the preservation of both global and local structures. Furthermore, these methods can be sensitive to initialization, and more importantly, they can be difficult to understand and tune.

Pairwise Controlled Manifold Approximation and Projection (PaCMAP) is a dimensionality reduction technique developed by Wang et al. [11] that uses a stochastic gradient descent algorithm, boasts effective and reliable performance with preserving

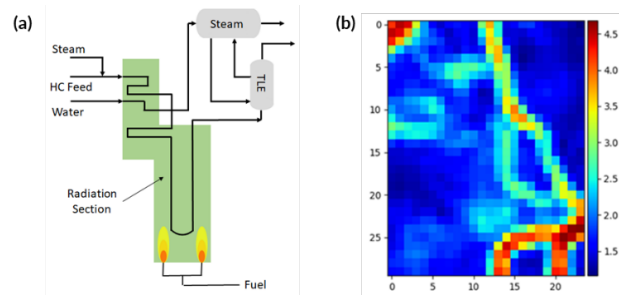

local and global structure alike, and performs significantly faster than other contemporaneous dimensionality reduction methods. Of interest to note is that none of the previously described methods are able to smoothly transition from local structure preservation to global structure preservation or vice versa through manipulation of parameters, however, PaCMAP can and does so automatically by dynamically adjusting its own parameters over a series of iterations through three distinct phases using a unique loss function. PaCMAP performs this optimization of the low-dimensional embedding by using three kinds of pairs of datapoints: neighbor pairs, mid-near pairs, and further pairs. The PaCMAP algorithm applies the initialization procedure selected to set the initial values of the low-dimensional embedding (initialization can be done randomly or using PCA). Once initialized, the values are then optimized. The algorithm uses the Adam Optimizer to reduce the loss function. The overall loss function is defined as:

$$\begin{aligned} Loss^{PaCMAP} = & w_{NB} \cdot \sum_{i,j} \frac{\tilde{d}_{ij}}{10 + \tilde{d}_{ij}} && (\text{neighbors; strong attraction}) \\ & + w_{MN} \cdot \sum_{i,k} \frac{\tilde{d}_{ik}}{10,000 + \tilde{d}_{ik}} && (\text{mid-near pairs; weak attraction}) \\ & + w_{FP} \cdot \sum_{i,l} \frac{1}{1 + \tilde{d}_{il}} && (\text{further pairs; repulsion}) \end{aligned}$$

where  $d$  is the scaled distance between a pair of observations,  $i$  and  $j$  are neighbors,  $i$  and  $k$  are mid-near pairs,  $i$  and  $l$  are further pairs, and  $w$  refers to the weights of all the pairwise interactions that change over the course of iterations. In general, the goal is to strongly attract neighbor pairs, weakly attract mid-near pairs, and repulse further pairs to properly construct the global and local structures. In the first stage of the PaCMAP algorithm's optimization, the initial embedding of points is improved to preserve primarily the global structure. In the second phase, the focus eases to improving the local structure while maintaining the developed global structure by moving to a higher weighting of neighbor pairs. Finally, by more heavily weighting the further pairs and neighbor pairs, the third phase shifts to refinement of the local structure without adjusting the global structure.

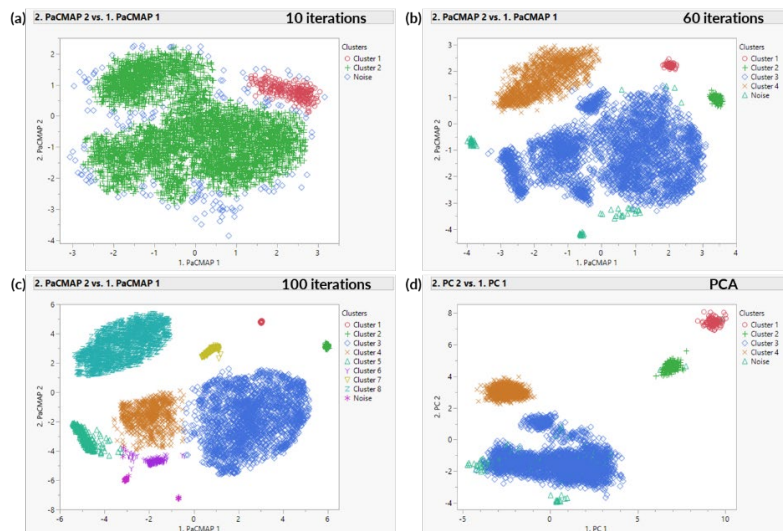

#### 4. FASTMAN-JMP Use-Case of an Industrial Pyrolysis Reactor

The implementation of this tool was tested using an industrial pyrolysis reactor case study. The use of an industrial dataset illustrates the suitability and effectiveness of using FASTMAN-JMP to apply the methodology and algorithms discussed to complex problems in the chemical engineering industry. The industrial pyrolysis reactor dataset analyzed covers a period of several months. The reactor, which is a very well-known chemical process unit, cracks heavy hydrocarbons into higher-value, lighter hydrocarbons. These datasets depict multiple modes of steady-state operation as well as process drift due to a buildup of equipment coke. The chemical reaction occurs in a fired furnace that is heated by burning fuel gas, as shown in **Figure 1**. This pyrolysis reactor takes a naphtha feed, injects it with steam, and cracks it into ethylene at extremely high temperatures. The entire process has 27 variables, including hydrocarbon flow, steam flow, cracking temperatures per coil, and coil outlet temperature. Also shown in **Figure 1** is the associated SOM plot, where the axes are the coordinates of the nodes present in the map. As illustrated by the distinct borders of contrasting colors, several main regions and subregions can be visualized in the SOM plot as an indication of the data structure i.e., global and local events. In this application the process is moving along different regions during the full cycle of operation.

**Figure 1:** (a) Pyrolysis reactor process scheme; (b) SOM plot

**Figure 2** illustrates the 2D projection results of initial stages of the PaCMAP algorithm using PCA initialization as the number of iterations increases. These results are at the very beginning of the first stage of the PaCMAP algorithm. There are very few clusters identified initially, categorizing most of the data into one large grouping. This is also revealed in the clusters projected on the SOM plots in **Figure 3** (corresponding to the clusters identified in **Figure 2**) as indicated by the dots overlaying the SOM. In **Figure 2.a**, “Cluster 1” includes datapoints that cover an area on the SOM with very distinct divisions (the bottom right corner in **Figure 3.a**) and “Cluster 2” encompasses the entire remainder of the area on the SOM (the projected cluster shown in **Figure 3.a**), with both clusters grouping together data that would otherwise be separated based on the more granular SOM coloring. Clearly, this dimensionality reduction method initially identifies the global structure of the data (i.e., the main process events) then gradually eases its global structure optimization and begins optimization of the local structure. Finally, in the later stages, the algorithm focuses on refining the local structure. In comparison to the early stages of the PaCMAP algorithm, **Figures 2.d** and **3.d** correspond to the results using PCA projection which focuses on global data structure. The PCA results are equivalent to those after just 60 iterations of the PaCMAP algorithm.

**Figure 2:** (a) PaCMAP results after 10 iterations; (b) PaCMAP results after 60 iterations; (c) PaCMAP results after 100 iterations; and (d) PCA results

**Figure 3:** PaCMAP cluster projection on the SOM: (a) after 10 iterations; (b) after 60 iterations; (c) after 100 iterations; and (d) PCA cluster projection on the SOM

This is also corroborated in **Figure 4** where the time evolution of the hydrocarbon flow rate in coils 1 and 4 is shown (solid and dashed, respectively). The highlighted section of the data corresponds to the conditions identified as “Cluster 3” in **Figures 2.b** and **3.b**. The identification of key process variables responsible for the cluster formation is performed using the subspace greedy search (SGS) algorithm [4].

**Figure 4:** Time evolution of hydrocarbon flows for coils 1 (solid; top) and 4 (dashed; bottom)

Shown in **Figure 5** is a graph of the value of the PaCMAP loss function for the pyrolysis reactor dataset as a function of number of iterations. As discussed before, the loss function changes over the course of the PaCMAP algorithm stages based on the weights of neighbor pairs, mid-near points, and further points. As shown, the loss is slightly improved as the number of iterations increases in the second and third stages. However, the largest rate of the improvement (i.e., the most noticeable change in the embedding) occurs in the first stage, with the focus on the global structure development primarily focusing on mid-near pairs.

**Figure 5:** PaCMAP loss function evolution as a function of iterations

The sharp transitions in **Figure 5** are due to the distinct changes in the loss function weightings at the onset of the three optimization phases. Of course, since this is based on the relative amount of neighbor pairs, mid-near pairs, and further pairs present in a dataset and the distances between these points, the qualitative trend may differ between datasets.

## 5. Conclusions

The concepts of global and local data structures were analyzed using data from an industrial pyrolysis reactor. It was shown with FASTMAN-JMP that local and global structures in the data set can be visualized and related to actual process operations allowing for the identification of the variables responsible for the separation between any two given clusters. Furthermore, it was shown that PaCMAP is an effective and reliable dimensionality reduction technique that preserves both local and global structures and performs significantly faster than other methods. By building up an understanding of how these dimensionality reduction algorithms work and how to tune parameters – a process made easier with FASTMAN-JMP – we can more effectively use these powerful tools to visualize and extract knowledge from large, high-dimensional datasets in the chemical manufacturing industry.

## Abstract

Low-density polyethylene is a polymer obtained via free-radical polymerization at high pressures in both tubular and autoclave reactors. At high pressures, ethylene can suffer an explosive decomposition (“decomp”), leading to runaway reactions. Several disturbances that can lead to “decomp”, such as excess initiator in feed, feed impurity, controller failures, etc. The present work focus on the development of a fault detection algorithm to detect failures in high-pressure pumps in the autoclave process. These pumps inject the initiator and are prone to failures such as leaks, cylinder failures, reversal system failure and check valve failures. The fault detection algorithm was developed to early detect failures in the pumps. The methodology consisted in developing data-driven models to monitor the process. The models were developed using data from an industrial autoclave reactor unit and were tested against failures events that happened between 2019 and 2022, with at least 70% of the events successfully detected between 5 and 50 minutes prior to the failure.

**Keywords:** fault-detection, polyethylene, statistical process control, data-driven models.

## 1. Introduction

Low-density polyethylene (LDPE) is a polymer obtained via free-radical polymerization in bulk in both tubular and continuous autoclave reactors, at high pressure. Free-radical polymerization includes mainly four elementary reactions: initiation, propagation, bimolecular termination, and chain transfer reactions. In this type of polymerization, the polymer microstructure and properties are intrinsically related to the reaction. For instance, the long and short-chain branches observed in LDPE are due to chain transfer reactions to polymer species and backbiting reactions (Hamielec and Tobita, 2000). In order to generate the free radicals to initiate the polymerization, chemical initiators can be used, at low concentrations. These initiators decomposes thermally generating radicals for monomer addition. Commercial thermal initiators include azo and peroxides compounds, and in the case of LDPE, the initiation depends both on the temperature and the pressure of the system.

Free-radical polymerization is highly exothermic ( $\Delta H_{\text{poly}}$  of 24 kcal mol<sup>-1</sup> for LDPE), therefore, the heat removal and temperature control play an important role in both productivity, product quality and process safety. In industry, there are two main processes to produce LDPE, in tubular and in autoclave reactors. In both cases, the reaction is carried out at high pressures (1500-2000 atm) and high temperatures (150-230 °C). An

important reaction that also occurs at high temperature and pressure is the explosive decomposition of ethylene (Zhang et al., 1996), forming hydrogen, carbon, methane, and other low-saturated and unsaturated hydrocarbons. This undesired reaction affects both tubular and autoclave reactors and can lead to a runaway (“decomp”).

Several disturbances that can lead to “decomp”, such as excess initiator in feed, feed impurities, feed inlet temperature, controller failures, mechanical frictions, inadequate mixing, etc (Zhang et al., 1996). Ultimately, all these disturbances can cause hot spots in the reactor, which can initiate the runaway. As Zhang et al. (1996) have pointed out, the decomposition occurs in order of milliseconds, and it is irreversible once it has started. Therefore, several works have been developed to predict failures in LDPE reactors.

Sivalingam et al. (2015) developed a predictive model to detect decomposition for high-pressure ethylene/vinyl acetate copolymerization in an autoclave reactor. The energy balance error was used as a reference to normal operation, considering the heat released by reaction and the sensible heat absorbed by the feed and products. The heat of stirring and lost to the environment were not considered. A principal component analysis (PCA) on heat balance model components was performed, using data from normal operation, under steady state, with 1s time interval for calibration. Control charts based on heat balance allowed detecting impending decomposition of the reactor. Sharmin et al. (2008) also developed a data-driven model to detect failures in LDPE reactors. The methodology coupled the global energy balance terms (reaction, products and reactants enthalpy), calculated using the industrial data, and PCA method to detect decomposition in the reactor. The heat released by the reaction was obtained using the overall conversion in the reactor. The model could detect decomposition with a lead-time about 30 seconds.

The main objective of the present work was the development of a fault detection algorithm to detect failures in high-pressure pumps used in the autoclave reactors of LDPE polymerization. Particularly, the modeling approach presented here takes into account the initiator injection, which is known to be a potential cause of decomposition. Besides that, the heat released by the reaction was accounted using the definition from the free-radical polymerization. The fault detection tool was developed using plant data from an industrial autoclave reactor unit and was tested against pump leakages events that happened between 2019 and 2022.

## 2. Methodology

The methodology consisted in developing data driven models coupled with the energy balance to monitor the process. In order to do that, the following models were developed: (i) charts of the residuals for the energy balance model; (ii) control charts of a process KPI and; (iii) a PCA model using Hotelling’s T-squared statistic using the energy balance as input.

### 2.1. Historical data for calibration and validation

The fault detection tool was developed using plant data from an industrial autoclave reactor unit and was tested against pump failure events that happened between 2019 and 2022. The reactor has three pumps that inject initiator at different reactor heights and has monomer feeds along the reactor. The process variables collected to monitor the energy balance were: monomer feed mass flow rates, monomer feed temperature, initiator mass flow rate and temperature along the reaction height, with 1 second sampling time. Another process variable collected specifically related to the pump operation is the “pump output” variable, that is an indirect measurement of the number of pulses of the pump piston, also with 1 second sampling time. The dataset was cleaned, and data recorded during start-up, shut downs, and containing corrupted values were removed, and the cleaned dataset was

divided in two sets (calibration and validation). The calibration set contains the cleaned base without the 2h before and after the failure in each pump.

### 2.2. Charts of the residuals for the energy balance error model

The energy balance for each zone of the continuous autoclave reactor at steady-state operation and neglecting the heat transfer to the surroundings and the shaft work can be written as:

$$\dot{m}_{in}c_pT_{in} + \dot{m}_{feed}c_pT_{feed} - \dot{m}_{out}c_pT_{out} + R_p(-\Delta H_p)V = 0 \quad (1)$$

where,  $\dot{m}_{in}$ ,  $\dot{m}_{feed}$  and  $\dot{m}_{out}$  are the mass flow rate entering the zone (in), of the fresh monomer entering the zone (feed) and the feed leaving the zone (out);  $c_p$  is the specific heat capacity of the mixture;  $T_{in}$ ,  $T_{feed}$  and  $T_{out}$  are the temperature of the feed entering the zone (in), of the fresh monomer (feed) and the feed leaving the zone (out);  $R_p$  is the polymerization rate;  $-\Delta H_p$  is the polymerization enthalpy;  $V$  is the zone volume.

The polymerization rate,  $R_p$  can be obtained from the free-radical polymerization kinetics, assuming pseudo steady-state for the radicals:

$$R_p = k_p[M] \sqrt{\frac{2fk_i[I]}{k_t}} \quad (2)$$

where,  $k_p$ ,  $k_i$  and  $k_t$  are the propagation, initiation and termination rate constants;  $f$  the initiator efficiency;  $[M]$  the monomer concentration; and  $[I]$  the initiator concentration. Accounting the polymerization rate as a function of initiator concentration allows the model to be sensitive to changes in the initiator feed, which is associated with failures in the injection pumps. The kinetic rate constants used in the model are from the work of Zhang et al. (1996). During normal operation, the energy balance should be equal to zero at all times within reasonable limits (Sharmin et al., 2008), and when failures occurs in the pumps, the energy balance error will exceed the normal threshold limits, indicating that the system is moving away from the normal condition operation. The error balance in reactor zone  $i$  is:

$$Error_i = \dot{m}_{in}c_pT_{in} + \dot{m}_{feed}c_pT_{feed} - \dot{m}_{out}c_pT_{out} + R_p(-\Delta H_p)V \quad (3)$$

The error in the energy balance was calculated for the normal operation (calibration set) and can be applied to each reactor zone sequentially. The upper and lower control limits (UCL and LCL, respectively) for the error in each reactor zone are calculated from the average ( $\overline{Error}_i$ ) and standard deviation ( $\sigma_i$ ) of the in control dataset.

$$UCL_i/LCL_i = \overline{Error}_i \pm L\sigma_i \quad (4)$$

where  $L$  is the control limit width, typically,  $L = 3$ .

### 2.3. Monitor a process KPI

A KPI can be used to monitor the failures, using the process variables “pump output” and the temperature of the reactor zone in which the pump is injecting the initiator.

$$KPI_i = \frac{\left( \frac{T_{zone\ i}}{T_{zone\ i}} \right)}{\left( \frac{Output\ pump\ i}{Output\ pump\ i} \right)} \quad (5)$$

This KPI is normalized and sensitive to the failures in the individual pumps, once when the pump is leaking, less peroxide is entering the reactor zone and, as consequence, the reactor zone temperature decreases and the “pump output” increases, because of the temperature reactor control policy. During normal operation, the KPI should vary within the normal limits, and when failures in the pumps occur, the KPI will exceed the normal threshold limits, indicating that the system is moving away from the normal condition. The UCL and LCL for the KPI were calculated in the same way as the energy balance error.

#### 2.4. PCA model

PCA is a multivariate statistic technique commonly used to statistic quality control and fault detection. This method is ideal for handling a large number of highly correlated data and noisy process variables. PCA decomposes the observation matrix  $\mathbf{Y}$  (process data) in a linear combination:

$$\mathbf{Y} = \mathbf{TP}^T = \sum_{i=1}^q t_i p_i^T \quad (6)$$

where,  $t_i$  are the principal component score,  $p_i$  are the loading vector (eigenvalues of the covariance matrix of  $\mathbf{Y}$ ) and  $q$  is the number of measured quality variables. Usually, most of the variability in the data is retained by the first principal components (MacGregor and Kourti, 1995). The data matrix used for the PCA model contains the scaled the elements of the energy balance (Equation 3). In order to build the quality control charts based on PCA, the model was developed using historical data from steady state, when only common cause variation was present. For new measurements, the observations can be projected using the loading vectors to obtain the scores,  $t_{i,new}$ . The Hotelling's  $T^2$  is used for the multivariate control charts. The upper control limit (UCL) for  $T^2$  is obtained according to MacGregor and Kourti (1995).

### 3. Results

#### 3.1. Charts of the residuals for the energy balance error model

The energy balance error was evaluated for the calibration dataset, according to Equation 3, allowing the determination of the UCL and LCL of the control charts for each one of the three pumps present in the process. Table 1 shows the percentage of events detected, lead-time and percentage of false alarms for the model.

The lead-time is the warning time of the model before the event occur, although the average lead-time is presented in the results of Table 1, there is a distribution of warning times for the events, as depicted in the histogram of lead-time in Figure 1. Some events can be detected between 5-35 minutes before the failure, and others can be detected between 95-125 minutes before the event. The broad range of warning times is related to the different failures modes present in these pumps, as leaks, cylinder failures, reversal system failure and check valve failures. Depending on the failure mode, the fault can happen very fast, reducing the model warning time. Then, the broad warning time is associated to the inherent nature of the failures.

#### 3.2. Monitor a process KPI

The percentage of events detected, lead-time and percentage of false alarms for the model using the process KPI (Equation 5) are presented in Table 1. Compared to the energy balance error model (Table 1), the KPI monitoring has smaller warning times, once the KPI model depends only on the actual value of the process variables and is not able to represent an energy accumulation in the process, as the energy balance is. Despite of that,

the KPI model can detect more events than the energy balance error for the middle pump. Figure 2 presents the control chart for the KPI during a failure event; it is possible to observe the KPI value moving away from the control limits around 1 hour before the failure. After the pump maintenance, the KPI value returns to the normal operation limits.

Table 1: Percentage of events detected, lead-time (min) and percentage of false alarms for the models.

Method	Pump	Events detected (%)	Average lead-time (min)	False alarm (%)
Energy balance error model (L=3)	Top	42.86%	58.33	9.10%
	Middle	40.00%	13.75	5.56%
	Bottom	88.89%	6.88	6.79%
KPI model (L=3)	Top	42.9%	29.00	5.80%
	Middle	80.0%	8.38	7.70%
	Bottom	55.6%	13.40	4.50%
PCA model (alpha = 0.01)	Top	100.0%	51.43	17.35%
	Middle	70.0%	34.29	8.84%
	Bottom	88.9%	30.00	12.01%

Figure 1: Histogram of lead-time (min) for the failures events for the energy balance error model.

Figure 2: Control chart for the normalized KPI during a failure event. KPI (.) UCL/LCL (red --) and failure event (black --).

### 3.3. PCA model

Table 1 presents PCA model performance, using the energy balance terms as input. The results show that combining the energy balance model with the multivariate statistic approach of PCA provides a fault detection algorithm that can detect more events with increased warning times for the failures in the peroxide pumps. The  $T^2$  control chart in Figure 3 shows the validation data for a failure event in one of the pumps.

Figure 3: Control chart for the  $T^2$  statistic during a failure event.  $T^2$  (.) UCL (red --) and failure event (black --).

## 4. Conclusion

This work presented the study of fault detection models for LDPE autoclave reactors peroxide pumps. The failures in initiator pumps can lead to the explosive decomposition of ethylene and are critical for process control and safety. Data-driven models combined with phenomenological knowledge of the system play an important role to improve fault detection algorithms, as showed in this paper. The model developed was tested against failures events that happened between 2019 and 2022, with at least 70% of the events successfully detected between 5 and 50 minutes prior to the failure. The development of tools that can support the operation of this process is still a challenge, due to the non-linear and fast nature of the process.

## Abstract

Electrical Submersible Pump (ESP) has deteriorated performance due to free gas in its intake, which may result in two undesirable phenomena: surging and gas lock. In this sense, this work investigates and determines features set — based on ultrasonic and process data — to identify these undesirable phenomena. The experimental data was obtained with a fixed ESP rotational speed (3500 rpm), varying the inlet water flowrate (1 to 60 kg/min) and air flowrate (0.02 to 0.1 kg/h). The ultrasonic measurements were carried out using a 2.25 MHz transducer. Using ultrasonic echo energy and time of flight signals, and the pump discharge pressure, it was possible partitioning the experimental data into two sets using *K*-means clustering tool. One of these groups is mainly composed of ESP operating points in surging or gas lock conditions, and another predominantly consists of ESP stable conditions.

**Keywords:** Electrical Submersible Pump; surging; gas lock; ultrasonic; clustering.

## 1. Introduction

Electrical Submersible Pump (ESP) is widely applied to lift oil from offshore wells to production facilities (Takacs, 2017). The ESP performance is negatively affected due to the presence of free gas in pump intake. The free gas in ESP intake can result in two undesirable phenomena: surging and gas lock (Verde, 2016). Surging occurs when the pump head decreases as the liquid flowrate decreases. In turn, gas lock occurs when the liquid pumping stops due to blockage of free gas at ESP intake. Operating the ESP in surging or gas lock conditions can lead to severe instabilities, such as abrupt shutdowns due to fluctuations in the load of the motor coupled to the ESP.

Experimental investigations have been developed to predict the operating conditions that results in surging or gas lock during ESP operation under liquid-gas flow. Such investigations resulted in empirical or semi-empirical models to identify the ESP operating points in which surging or gas lock occurs (Turpin; Lean; Bearden, 1986; Zhu, 2017). However, these models require input variables not measured in real-time or continuously in individual oil wells equipped with ESP, such as liquid flowrate, gas flowrate, and free gas in ESP inlet. In order to develop an alternative technique, Oliveira (2014) carried out an experimental investigation whose results demonstrate the potential of ultrasonic measurement technique to identify the surging during ESP operation under liquid-gas flow.

In this context, this work aims to investigate and determine features set, based on ultrasonic and process data, capable of identifying the unstable operating conditions —

surging or gas lock — and stable operating conditions during ESP operation under liquid-gas flow.

## Material and methods

### 1.1. Test plant

The test plant was built to acquire ultrasonic and process data during ESP operation. It was composed of three flowlines: single-phase liquid flow line, single-phase gas flowline and two-phase liquid-gas flow line. An illustrative diagram of the setup is shown in Figure 1. The liquid and liquid-gas flow line are composed of a 23 mm inner diameter ASTM 240 – AISI 304 stainless steel. The gas flow line is a polyurethane tube of 8 mm inner diameter.

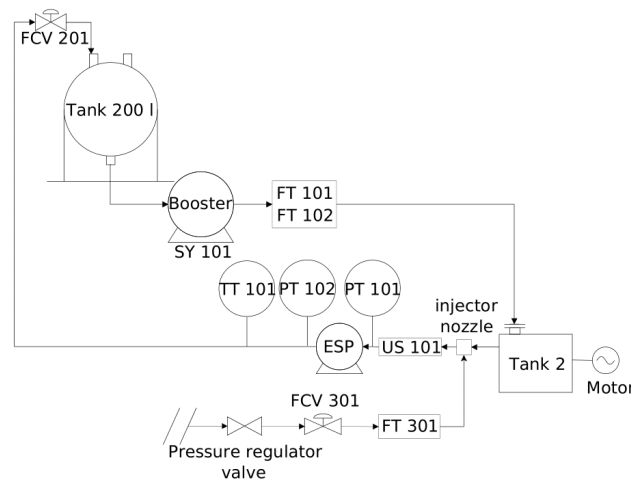

Figure 1 – Experimental setup diagram.

The liquid flow line begins at the 200 liters separator tank (Tank 200 l) which has the function of separating the gas and liquid phases from the two-phase mixture and feeds liquid to the booster pump. The booster, a centrifugal pump (KSB / Megablock 40-25-160 GG), was driven by 3 HP motor that was controlled by an inverter frequency drive (SY-101). The booster kept constant the pressure at the ESP intake (Schlumberger / D475N). After the booster, a Coriolis mass flowmeter (FT-101/FT-102) was installed to measure the liquid mass flow and liquid density. The ESP was driven by a 1 HP electric motor (WEG / W22 IR3 PREMIUM).

The gas flow line was fed by an external air supply system. The pressure regulator valve kept at the 5 bar g the air pressure upstream the control valve (FCV 301), which controlled the amount of air in ESP intake. To measure the gas mass flowrate, a Coriolis mass flowmeter (FT 301) was installed. The gas flow line ends at the injector nozzle, where the liquid-gas flow line begins.

The injector nozzle was installed at 35 cm upstream of the ESP intake. A porous medium was used as the injector nozzle to ensure uniform distribution of the gas in form of bubbles into the liquid flow. After the injector nozzle, an annular flow occurs with the outside inner diameter of 52 mm and the shaft diameter of 20 mm.

In the horizontal position, the inlet and outlet flow conditions of the ESP was monitored by one temperature transmitter (TT 101), one ultrasound structure (US 101) and two pressure sensors (PT 101 and PT 102). At the US 101, the ultrasound transducer was fixed

in a non-invasive and non-intrusive way. Besides, the FCV 201 was placed after the ESP to regulate the flowrate of liquid-gas flow. A sample rate of 4 Hz was used to acquire the process data.

### 1.2. Description of ultrasonic measurement technique

The ultrasonic measurement system consists of an ultrasound support (US 101), an ultrasonic transducer, and a device for generating and digitizing ultrasonic signals. The function of the US 101 support is to accommodate the ultrasonic transducers orthogonally to the flow in a non-invasive and non-intrusive way. This structure was made using polyacetal material, internal diameter of 52 mm, 10 mm delay line and a hole to accommodate transducers positioned perpendicular to the flow. Industrial coupling gel was used to perform the coupling of the ultrasonic transducer with the inner wall of the ultrasonic support. The ultrasonic measurements were performed using only one piezoelectric ultrasound transducer (Olympus - V106-SM) with a central frequency of 2.25 MHz.

The ultrasonic signal generation and digitization device (US Ultratek - DSPUT5000-2) was used in pulse-echo mode, that is, the system emit and capture waves through the same transducer. The device has 8-bit vertical resolution and a maximum sampling rate of 100 MHz. The parameters of the ultrasonic acquisition device were: pulse voltage of -300 V, a pulse width of 222 ns; sample rate of 25 MHz, a pulse repetition frequency of 1 kHz, a digital gain of 40 dB; damping of 620  $\Omega$ , an acquisition time of 15 s; and 720 points in depth per wave. Such values were defined according to the fundamentals of signal sampling (Holman, 2012), and the technical guidelines of the manufacturers of the ultrasonic acquisition board and ultrasonic transducers.

The Figure 2-a represents a schematic mode of the ultrasonic wave propagation through solid and liquid based medium. At the wall-flow interface, part of the wave intensity associated with the initial pulse ( $P_0$ ) is reflected in the first wall pulse reflection ( $R_{WF}$ ). The remainder is transmitted to the liquid based medium. After that, the transmitted pulse will propagate until reaches the liquid-gas ( $R_{LG}$ ) or shaft-flow ( $R_{SF}$ ) interface, in which the wave will be reflected to the ultrasound. A typical ultrasonic echo signal is illustrated in the Figure 2-b. The position of the liquid-gas ( $R_{LG}$ ), shaft-flow ( $R_{SF}$ ) interface and first wall pulse reflection ( $R_{WF}$ ) is indicated.

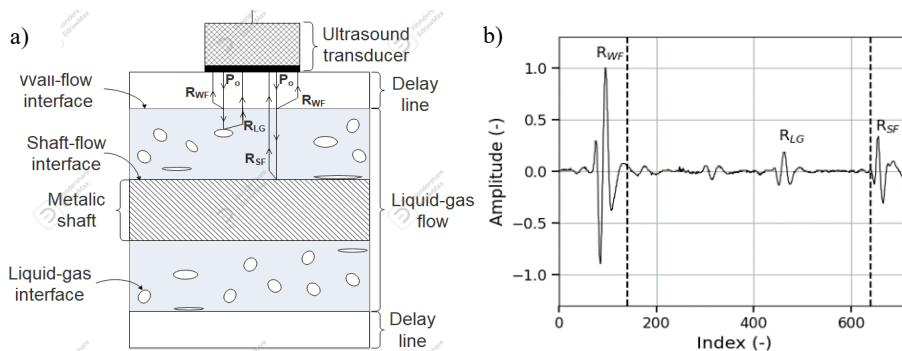

Figure 2 – Schematic ultrasonic mode of the wave propagation and reflection at the wall and two-phase flow (a). Echo signal containing two-phase flow reflection (b).

### 1.3. Experimental design and procedure

The test matrix has 9 experimental conditions for single-phase, and 26, 23 and 20 experimental conditions for two-phase with gas flowrate of 0.02 kg/h, 0.06 kg/h and 0.10

kg/h, respectively. Each experimental condition was experimentally measured in 4 replicates to evaluate the reproducibility, totalling 312 sample acquisitions. Each sample acquisition lasted 30 s for the process data under constant ESP rotation (3500 RPM) and intake pressure (100 kPa). The gas mass flowrate ( $m_G$ ) were experimentally adopted according to the ESP capacity to deal with the total amount of free gas in its intake. The experiments were carried out with water as the continuous phase and air as the dispersed phase. During the experiments, the temperature remained in the range of 24 to 26 °C.

In summary, the procedure adopted for the execution of the matrix was: a) The first acquisition was obtained from the condition in which the intake pressure was 100 kPa and the pump head was equal to zero, which corresponds to the maximum liquid flowrate in that condition; ii) afterwards, the variables of interest corresponding to the next acquisition point were adjusted, waiting 2 minutes to stabilize the flux in the new condition; iii) ultrasonic measurements and process data were acquired; iv) the new experimental condition (acquisition) was adjusted, and ultrasonic and process data were collected until the experimental points of the test matrix finished.

## 2. Results and discussion

### 2.1. ESP performance curves

Figure 3 shows the ESP performance curves under single-phase and two-phase flow conditions investigated experimentally in this work. The ESP operation under two-phase flow conditions can exhibit two phenomena: surging and gas lock. The surging phenomenon implies an abnormal behavior, the pump head decreases as the liquid flowrate decreases. The beginning of surging (surging point) corresponds to the curve peak in the ESP performance curve under two-phase flow. It is noticeable that as the gas flowrate increases, the stable region — the right side of the curve peak — became narrower due to the less capacity of the ESP to deal with free gas in its intake. The gas lock occurs when the pump head is approximately null after beginning of surging. In face of that, we can divide the two-phase performance curves in two regions: stable and unstable.

Figure 3 – ESP performance curves under single-phase and two-phase flow.

### 2.2. Echoes signals and process data - Feature extraction

The features used to cluster the ESP operating points were obtained by processing the ultrasonic echoes signals and pump discharge pressure data. Four features were extracted: arithmetic mean of echoes energy signals from ultrasonic wave reflections in liquid-gas

interface ( $\bar{E}_{LG}$ ); arithmetic mean of echoes energy signals from ultrasonic wave reflections in liquid-shaft interface ( $\bar{E}_{SF}$ ); time of flight standard deviation from ultrasonic wave reflections in liquid-gas interface ( $t_{LG}$ ); and variation coefficient of ESP pressure discharge ( $\bar{P}_D$ ). The features mathematical definitions are available in Table 1. These features were normalized between -1 and 1 before applying the  $K$ -means clustering.

Table 1 – Features definitions

$\bar{E}_{LG}$	$\bar{E}_{SF}$
$mean \left[ \left( \sum_{k=140}^{640} (A_k)^2 \right)_i \right] \quad (1)$ $i = 1, 2, \dots, 15000$	$mean \left[ \left( \sum_{k=640}^{720} (A_k)^2 \right)_i \right] \quad (2)$ $i = 1, 2, \dots, 15000$
$t_{LG}$	$\bar{P}_D$
$std[\text{argmax}(A_{120:640})_i] \quad (3)$ $i = 1, 2, \dots, 15000$	$std[(P_D)_i] / mean[(P_D)_i] \quad (4)$ $i = 1, 2, \dots, 120$

### 2.3. $K$ -means clustering

To execute  $K$ -means clustering, the method  $k$ -means++ was adopted for handling centroids initialization (Guha *et al.*, 2003). In addition, two metrics were used to assess the clustering performance: silhouette coefficient and rand index (Rousseeuw, 1987; Hubert; Arabie, 1985). Figure 4-a shows these metrics score versus the number of clusters due to  $K$ -means application to ESP experimental data. Facing these metrics scores, it is reasonable to consider clustering the data in 2 generated clusters due to the highest values of the rand index and silhouette coefficient. Figure 4-b indicates the ESP experimental data distribution into 2 clusters. The amount of 279 samples data was partitioned into two clusters. Cluster 1 has grouped 138 samples, and Cluster 2 grouped has 141 samples. There are samples of data obtained experimentally at the same operating condition (acquisition) partitioned in different clusters. These samples are associated with acquisitions 14, 15, 16, and equal to 0.02 kg/h; acquisition 10 and equal to 0.06 kg/h; acquisition 6 and equal to 0.1 kg/h. These acquisitions in performance curves are identical or closer to surging points. Despite having samples associated with identical acquisitions in different clusters, it is notable that Cluster 1 is predominantly composed of ESP experimental data in stable conditions, and Cluster 2 is majorly formed by ESP experimental data in unstable conditions. These results indicate that features used in  $k$ -means clustering can be used to identify if the ESP is operating or not in surging or gas lock conditions (unstable conditions).

### 3. Conclusions

This work suggests that is possible identifying surging or gas lock phenomena (unstable conditions) in ESP operation under two-phase flow by using the following features extracted from ultrasonic echoes signals and process data:  $\bar{E}_{LG}$ ;  $\bar{E}_{SF}$ ;  $t_{LG}$ ; and  $\bar{P}_D$ .  $K$ -means clustering was used to cluster the ESP experimental data by using the features previously mentioned. According to silhouette coefficient and rand index scores, it is reasonable to cluster the ESP experimental data in 2 clusters. The generated Cluster 1 is predominantly composed of ESP experimental data in stable conditions, and Cluster 2 is majorly formed by ESP experimental data in unstable conditions. The silhouette coefficient and rand

index scores for this clustering were 0.5 and 0.93, respectively. Thus, these results indicate that features used in  $K$ -means clustering can be used to identify the two undesirable phenomena during ESP operation.

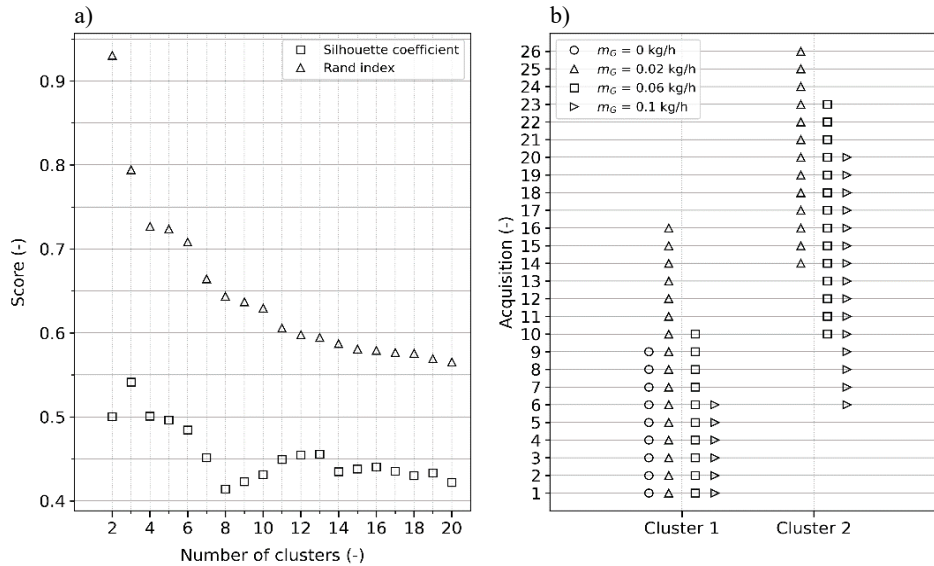

Figure 4 - Number of clusters analysis based on metrics score (a) and visual representation of the ESP experimental data grouped in only two clusters (b).

## Abstract

The bubble flow is a flow regime present in various fields. A usual equipment that operates with the bubble flow is the bubble column. Many papers deal with determining flow regime, hold up, and mass transfer coefficient in a bubble column. However, little attention has been given to the measurement of the gas flowrate. In this context, this work presents a technique to predict the gas flowrate in a bubble column from ultrasound signals using a new set of ultrasonic variables combined with process variables using a feedforward artificial neural network (ANN). Experiments were carried out in a 2-meters-long-bubble column, with inner diameter of 52.5 mm using a single 2.25 MHz ultrasound transducer. The gas flow rate varied in the range of 0 to 4 liters per minute. The best architecture obtained for ANN has one hidden layer with 36 neurons. The test mean absolute error was 0,1 LPM.

**Keywords:** flow rate, artificial neural networks, monitoring, ultrasound, soft computing.

## 1. Introduction

The bubble flow is a flow regime present in various fields, like the pharmaceutical, biochemical, and petrochemical industries (Shu et al., 2019). A usual equipment presents in these industries, that operates with the bubble flow, is the bubble column. A bubble column can be used as a reactor that operates with a stagnant liquid phase, in which the gas flows throughout. Many papers deal with determining flow regime, bubble size, liquid hold up, and mass transfer coefficient in a bubble column using machine learning (Biessey et al., 2021; Serraa et al., 2020; Supardan, 2003). However, little attention has been given to the measurement of the gas phase flowrate in a bubble column direct from the combination of ultrasonic and process signals without intermediate needed analysis, like calculation of velocity and liquid hold up. In addition, according to the findings of Mudde & Saito (2001), it is expected that the method developed here using bubble columns can be applied in two-phase liquid-gas bubble flow and get similar results. In this context, this work proposed a new set of ultrasonic variables combined with pressure drop for gas flowrate prediction in a bubble flow using a 52.5 mm inner diameter vertical bubble column based on feedforward artificial neural network. The ultrasonic signals were acquired using just one ultrasound transducer.

## 2. Material and methods

### 2.1. Experimental setup

The experimental setup consists of a pipe with an internal diameter of 52.5 mm and a length of 2 m arranged vertically (Figure 1). The two-phase line was instrumented with two pressure sensors (PT 20 and PT 21) to measure the void fraction of the dispersed phase and a temperature sensor (TT 20) to obtain the physical properties of the two-phase mixture. Ultrasonic measurements were performed with a single inclined at  $10^\circ$  with the flow, located at support (UT 10).

The air flow line contains a pressure regulator, a rotameter (FI 10), a check valve, a pressure sensor (PT 10) and a temperature sensor (TT 10). The gas injection was performed through a porous structure positioned at the base of the bubble column (gas injection).

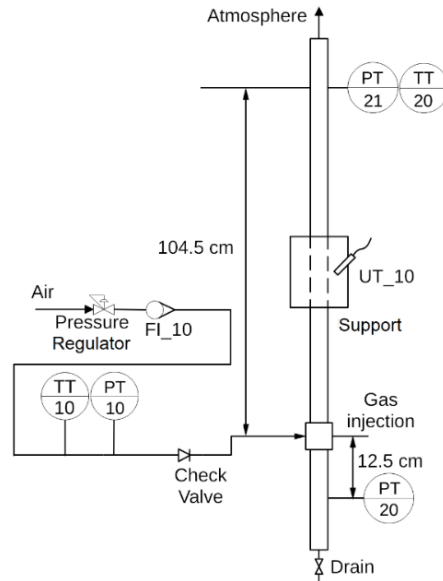

Figure 1 – P&ID diagram of the experimental setup.

### 2.2. Ultrasonic instrumentation

The ultrasonic measurement system basically comprises an ultrasonic transducer and a ultrasound device (US Ultratek/DSPUT5000-2) for generating, receiving and digitalizing ultrasonic signals (Figure 2). In all experiments, the transducer remained confined between the support and a spring, which is pressed by a cable gland. Industrial Vaseline was used to perform the acoustic coupling between the transducer and the ultrasonic spool. The support, made with Delrin polymeric material, was installed 60 cm above the air injection point. During the experiments, the transducer was installed with inclination  $\theta = 10^\circ$ . Besides, the transducer (Panametrics/ M106-SM) with a central frequency of 2.25 MHz was used.

The ultrasound device with 8 bits of vertical resolution was used for generation, reception and digitization of ultrasonic signals. The sampling frequency (50 MHz) was defined in order to respect Nyquist's theorem, which defines the minimum frequency as being at least twice the highest frequency to be observed. The damping (620  $\Omega$ ), along with the gain (60 dB), will be experimentally defined in order to return the highest amplitude values without signal saturation. The pulse frequency (2 kHz) was defined based on the ability of the system to detect the same bubble at least twice throughout the ultrasonic

measurement volume. The pulse width (222 ns) was defined based on the manual of manufacturer, based on the central frequency of the transducer. Furthermore, a transducer supply voltage of  $-300 V_{P-P}$  was used.

Figure 2 - Components of the ultrasonic measurement system.

### 2.3. Test matrix and procedure

The test matrix was defined based on the flow pattern map of Shah et al. (1982), considering only the bubble flow pattern in all experiments. In this way, the minimum and maximum flow limit was defined from 0 to 4 liters per minute (LPM). Experiments were carried out varying the flowrate from 0 to 4 LPM with increments of 0.5 LPM, that is, 9 measurements. Each measurement was repeated 4 times, that is, 36 measurements. The experiments were carried out with water as the continuous phase and air as the dispersed phase. The mixture temperature of the experiments was maintained in the range of 20 to 22 °C.

In each experimental condition, 15 s of ultrasonic measurements and 120 s of process data at 1 Hz of acquisition frequency were acquired. All ultrasonic echoes had 1,000 points in depth, the necessary to capture half cross-section area of the pipe, resulting in one ultrasonic echo signal per experimental measurement. In summary, the experimental procedure adopted was: i) Fill the vertical pipe with tap water until it reaches 1.2 m above the gas injection point and keep it constant; ii) define the pre-defined gas flowrate randomly; iii) wait 60 s for flow stabilization; iv) acquire ultrasonic and process data; v) return to the ii step until the final of the test matrix.

### 2.4. Topology of artificial neural network

The ANN developed and used to predict the gas flow rate was developed in Python programming using the scikit-learn library. The ANN was chosen because it has the ability map non-linear relationships between inputs and outputs. In the training step, the Adam optimization algorithm was used. The ANN input ultrasonic variables used were: mean energy signal ( $\bar{E}$ ); standard deviation of the energy signal ( $\sigma_E$ ); mean transit time ( $\bar{ToF}$ ); standard deviation of transit time ( $\sigma_{ToF}$ ). The ANN input process variable used was the mean pressure drop ( $\Delta P$ ). The ultrasonic echo signal (matrix of 30,000 rows by 1,000 columns) was processed to return energy ( $E$ ) and transit time ( $ToF$ ) signals in which were calculated the associated mean and standard deviation, according to definitions presented in Table 1. Indeed, the  $\bar{E}$ ,  $\sigma_E$ ,  $\bar{ToF}$ ,  $\sigma_{ToF}$  and  $\Delta P$  was used to feed the ANN.

The output variable was the gas flow rate. The mathematical definition of  $E$  and  $ToF$  signal associated with echoes signals are presented in Table 1. The dataset was randomly divided in two groups: i) 75% for training; and ii) 25 % for test step. In training step, 10 % of the training dataset was used for validation. The best architecture was defined using GridSearchCV optimization method (Pedregosa et al., 2011). It was tested the number of

neurons on hidden layer in the range of 1 to 50 and identity, relu, hyperbolic tangent and logistic as activation functions. Besides, the performance of the artificial neural network was evaluated using the mean square error (MSE), mean absolute error (MAE), and determination Coefficient ( $R^2$ ) of the straight line that fits predicted versus actual values of gas flow metrics.

Table 1 - Definition of energy and transit time signals.

$E_i = \sum_{j=1}^n [e_{(i,j)}]^2$	$ToF_i = \text{argmax}_{e_{(i,j)}flow} - \text{argmax}_{e_{(i,j)}wall}$
$E = [E_1, E_1, \dots, E_m]$	$ToF = [ToF_1, ToF_2, \dots, ToF_m]$

Where:  $e_{(i,j)}$  is the value of echo in row  $i$  and column  $j$  with  $m$  rows and  $n$  columns;  $E_i$  is the energy associated with row  $i$ ;  $ToF_i$  is the transit time associated with row  $i$ ; and  $\text{argmax}_{e_{(i,j)}flow}$  and  $\text{argmax}_{e_{(i,j)}wall}$  are the position of maximum echo amplitude value in the flow and wall region, respectively.

### 3. Results and discussion

#### 3.1. Ultrasonic echoes

The Figure 3 illustrates the ultrasonic echoes referring to the 2,000 ultrasonic pulses (1 s) emitted for the single-phase (0 LPM) and two-phase simulated bubble flows. Dividing the wall signal from the signal in the position of the dashed line, where from the begging to the dashed line is the wall region, it is possible to note the sensitivity of the transducer with the passage of bubbles in the ultrasonic measurement region. In addition, it is observed that the reflected signals from the liquid-gas interfaces of the bubbles are not limited to a specific region of half cross-section area, showing the relative uniformity distribution of the bubbles across the half cross sectional area of the pipe.

Figure 3 - Ultrasonic echoes for single-phase (0LPM) and two-phase flows in the vertical bubble flow.

The Table 2 shows the limits of values associated with ultrasonic ( $\bar{E}, \sigma_E, ToF, \sigma_{ToF}$ ) and process ( $\Delta P, Q$ ) signals. These variables were used as input, except the variable  $Q$  that was uses as output.

Table 2 - Range of the ultrasonic and process variables.

Variable	$\bar{E}$	$\sigma_E$	$\overline{ToF}$	$\sigma_{ToF}$	$\Delta P$	$Q$
Units	[V <sup>2</sup> ]	[V]	[ $\mu s$ ]	[ $\mu s$ ]	[kPa]	[LPM]
Minimum value	0.17	0.015	650.30	404.74	10.56	0
Maximum value	3.39	2.656	1018.06	495.55	12.64	4.0

3.2. ANN for prediction of gas flow rate

The ANN which presented the best prediction of gas flow rate had an architecture with 36 neurons in only one hidden layer, and rectified linear unit (relu) as activation function. The ANN predictions and absolute error for training and test set are illustrated in Figure 4 and 5, respectively. The ANN score metrics calculated for the training set are the following: MSE (0.007); MAE (0.063); and R<sup>2</sup> (1.000). In turn, the score metrics calculated for the test set are: MSE (0.013); MAE (0.078); and R<sup>2</sup> (0.998).

Figure 4 - ANN performance comparison for train step (left) and absolute error values between actual and prediction value of the gas flow rate for training (right).

Figure 5 - ANN performance comparison for test step (left) and absolute error values between actual and prediction value of the gas flow rate for testing (right).

The results of test step, illustrated in Figure 5, showed that the distribution of the absolute error was close to the obtained in training step, which represents a good agreement between the prediction and actual gas flowrate for test and train step. As a consequence, the MAE, MSE and  $R^2$  are also in good agreement in relation to the train step results. Therefore, the metrics score relative to test set suggest a satisfactory generalization capability of ANN developed to predict gas flowrate.

The results of gas flowrate prediction also indicates that the choose ultrasonic variables ( $\bar{E}$ ,  $\sigma_E, ToF, \sigma_{ToF}$ ) together with process variable ( $\Delta P$ ) have the ability to represent the physics of the flow. The energy ( $E$ ) captures the frequency and intensity of the bubble reflection in the echoes, the transit time ( $ToF$ ) captures the location of the bubbles reflection in the ultrasonic echoes and the pressure drop ( $\Delta P$ ) infer about the concentration of the bubble in the two-phase mixture. Indeed, the physical representativity of the choose variable contribute to the good agreement in the results. Further, the good results indicate that these ultrasonic and process variables could be used together to estimate the gas flow rate in bubble columns.

#### 4. Conclusions

The results showed the ability of the ANN to predict the gas flow rate. The mean absolute error from the reference was 0.1 LPM and the majority of the error in training and test was in the range of -0.1 to 0.1 LPM. From the agreement between the predicted and actual gas flow rate, we concluded that the ANN based model proposed is promising to estimate gas flow rate in bubble flows using ultrasonic combined with process data as input. Further, the selected ultrasonic variables ( $\bar{E}$ ,  $\sigma_E, ToF, \sigma_{ToF}$ ) and the process variable ( $\Delta P$ ) showed good ability to represent the bubble flow phenomena and predict the gas flowrate. To increase the robustness of the proposed ANN based technique we proposed tests with different fluid as continuous and dispersed phase and in other pipe inner diameters.

## Abstract

The crystallization process has been applied in pharmaceutical, fine chemicals and food industries and is the main process in the pharmaceutical industry for particle formation. This process is used for separation and purification, recovering as much solute as possible and producing crystals with the desired length. In this work, a nonlinear model predictive controller based on neural networks (NN-NMPC) was proposed to control the coefficient of variation and length of crystals for the potassium sulphate batch cooling crystallization. The neural networks were designed using an optimizer to choose the best hyperparameters with simulated and experimental data. They were trained to predict the first four moments and the concentration in order to calculate the coefficient of variation and the length of crystals. The potassium sulphate crystallization process was modelled using a population balance model solved by the method of moments, considering the nucleation, growth and dissolution mechanisms. This rigorous model was used to represent the real process for the controller's performance evaluation. Differently from previous studies, the neural networks were trained considering the saturated and the undersaturated thermodynamic conditions. The controller's performance was studied for servo cases, analyzing the efficiency of the NN-NMPC to reach different set-points using the process temperature as the manipulated variable. The operation in the undersaturated and saturated conditions guarantees more degrees of freedom to control both variables (coefficient of variation and length of crystals), manipulating only the temperature. The proposed approach efficiently achieved the desired set-points. The controller also presented good performance for a case considering plant-model mismatch. The NN-NMPC performance was compared to an NMPC based on the phenomenological model, showing similar behavior with reduced computational effort, evidencing that the NN-NMPC has great potential to be applied in real time for the crystallization process.

**Keywords:** Crystallization, neural networks, NMPC, servo control, dissolution.

## 1. Introduction

The crystallization process is used for product separation and purification, generating a solid crystalline product. The regulatory requirements must be respected for an efficient crystallization process, producing crystals with the desired size distribution. Therefore, the crystallization process needs effective control to achieve this goal<sup>[1]</sup>. Another challenge of crystallization processes consists of modeling this phenomenon, which is

usually done using the population balance approach. However, this can take too much effort because of the necessity of using different models to describe the mechanisms of this process. Data-driven models, in particular, neural networks, have mainly been applied to model and control chemical processes because they can capture intrinsic nonlinearities<sup>[2]</sup>. Nevertheless, there is a lack of applications in the literature using neural networks to model the crystallization process under saturated and undersaturated conditions.

This work aims to model a crystallization process to predict the moments of the particle-size distribution and the solute concentration with neural networks. Unlike other works, this study considered data under saturated and undersaturated conditions, using only one model to predict each state variable under different conditions. Also, the current work proposes control strategies for the crystallization process different from the study of Moraes et al.<sup>[3]</sup>, which focuses on modeling it. Five neural networks were trained using experimental and simulated data, and the hyperparameters were chosen considering an optimization approach. The capacity of the neural networks was tested to predict the state variables  $n$  sampling times in the future, making good predictions for large horizons. Moreover, the proposed networks were used as an internal model in a Nonlinear Model Predictive Controller (NMPC).

## 2. Neural Networks Models

Neural networks are mathematical models that try to represent the correlation between input and output patterns. The most applied neural network in the literature consists of the feedforward network, particularly the multilayer perceptron (MLP) network. An MLP network comprises an input layer, an output layer, and one or more hidden layers<sup>[4]</sup>. In the current work, five MLP networks were developed to predict the moments and the solute concentration of a potassium sulfate batch crystallization process.

The dataset consisted of ten experimental batches in the saturated condition and five in the subsaturated condition developed by Moraes et al.<sup>[3]</sup> in LABCADS/UFRJ. In these experiments, the moments and the solute concentration were determined for different temperatures, totaling 724 patterns. Also, simulated data were generated using a population balance model for the saturated condition and a population balance model for the undersaturated state, developed by Moraes et al.<sup>[3]</sup>. Therefore, 15 batches were simulated, considering different temperatures and initial and saturation conditions, producing a total of 6800 simulated patterns. The training dataset was composed of seven experimental batches in the saturated state, four experimental batches in the subsaturated condition, and eleven simulated batches, totaling 5726 patterns. The test dataset was composed of the 1798 patterns of the simulations and experiments that were not used for the training. A sampling time of 1.25 min was adopted in the experiments and simulations, considering the same value adopted in the experiments of Moraes et al.<sup>[3]</sup>. The batches chosen to compose the training and test datasets were randomly selected, using in the test dataset experimental and simulated data for the saturated and undersaturated states with conditions not used in training.

The inputs and outputs of each NN are shown in Table 1, in which  $T$  is the process temperature,  $C/C_{eq}$  is the ratio between the solute concentration and the concentration of the solute in equilibrium,  $\mu_i$  is the  $i^{th}$ -order moment, and  $k$  is the sampling time. Different

combinations of inputs were investigated. The NNs were developed using the Scikit-learn library from Python. Furthermore, the hyperparameter of each neural network was chosen using an optimization approach from a Python library called Optuna. The optimization problem consisted of finding the activation function, number of hidden layers, number of neurons in the hidden layer, batch size, and learning rate that leads to  $R^2$  values of the test samples close to one.

**Table 1:** Inputs and outputs of the developed neural networks.

Neural Network	Inputs	Outputs
1	$T(k-1), C/C_{eq}(k-1), \mu_0(k-1),$ $T(k), C/C_{eq}(k), \mu_0(k)$	$\mu_0(k+1), \dots, \mu_0(k+n)$
2	$T(k-1), C/C_{eq}(k-1),$ $\mu_0(k-1), \mu_1(k-1),$ $T(k), C/C_{eq}(k), \mu_0(k), \mu_1(k)$	$\mu_1(k+1), \dots, \mu_1(k+n)$
3	$T(k-1), C/C_{eq}(k-1),$ $\mu_1(k-1), \mu_2(k-1),$ $T(k), C/C_{eq}(k), \mu_1(k), \mu_2(k)$	$\mu_2(k+1), \dots, \mu_2(k+n)$
4	$T(k-1), C/C_{eq}(k-1),$ $\mu_2(k-1), \mu_3(k-1),$ $T(k), C/C_{eq}(k), \mu_2(k), \mu_3(k)$	$\mu_3(k+1), \dots, \mu_3(k+n)$
5	$T(k-1), C/C_{eq}(k-1), C(k-1),$ $T(k), C/C_{eq}(k), C(k)$	$C(k+1), \dots, C(k+n)$

The hyperparameters used in the networks are presented in Table 2, and all neural networks were trained using the Adam algorithm.

**Table 2:** Hyperparameters of the neural networks.

Neural Network	Hidden Layers	Number of Neurons	Activation Function	Batch Size	Learning Rate
1	4	55; 55; 55; 55	Relu	15	Constant
2	3	45; 45; 45	Relu	5	Constant
3	4	45; 45; 45; 45	Relu	5	Constant
4	4	40; 40; 40; 40	Relu	5	Adaptive
5	1	15	Logistic	135	Constant

The  $R^2$  values for predictions two, five, ten, fifteen and twenty steps forward for the test samples are presented in Table 3. It can be observed that the neural networks could efficiently predict the moments and the solute concentration of a batch crystallization process, even for large prediction horizons. Therefore, the neural networks to predict  $\mu_0, \mu_1,$  and  $\mu_2$  were used as the internal model of an NMPC.

**Table 3:**  $R^2$  values, considering the test samples and different prediction horizons.

Neural Network	2 steps	5 steps	10 steps	15 steps	20 steps
1	0.9998	0.9996	0.9986	0.9987	0.9977
2	0.9997	0.9997	0.9989	0.9956	0.9941
3	0.9997	0.9995	0.9980	0.9963	0.9932
4	0.9998	0.9997	0.9990	0.9982	0.9970
5	0.9995	0.9987	0.9955	0.9947	0.9901

### 3. Nonlinear Model Predictive Control

The controlled variables chosen for the optimization problem were the coefficient of variation and the crystal length, which are calculated by Equations 1 and 2, respectively. The manipulated variable  $u$  is the process temperature. The MPC goal is to minimize the process performance index  $J$ , the objective function of the problem shown in Equation 3. The parameters  $\delta$  and  $\varphi$  are the weights of the outputs, and  $\gamma$  is the weight of the increment input. The parameters  $\delta$ ,  $\varphi$  and  $\gamma$  were tuned as 1, 10 and 5, respectively. The superscript  $SP$  indicates the set-point value of the controlled variable. The prediction horizon  $P$  was defined as 10, and the control horizon was tuned as 1. The optimization constraint is given by Equation 4.

$$V = \sqrt{\frac{\mu_2 \mu_0}{\mu_1^2} - 1} \quad (1)$$

$$L = \mu_1 / \mu_0 \quad (2)$$

$$J = \sum_{j=1}^P \{ \delta [V(k+j) - V^{SP}(k+j)]^2 + \varphi [L(k+j) - L^{SP}(k+j)]^2 \} + \gamma [\Delta u(k)]^2 \quad (3)$$

$$-1 \leq \Delta u(k) \leq 1 \quad (4)$$

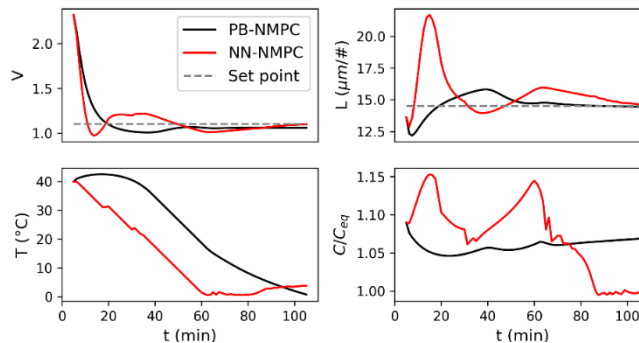

In the control loop, the process was simulated based on the model developed in the study of Moraes et al.<sup>[3]</sup>, and a sampling time of 1.25 min was adopted. This optimization problem was solved using Successive Quadratic Programming (SQP) algorithm with absolute accuracy of  $10^{-10}$  and relative accuracy of  $10^{-8}$ . The performance of the controller based on the neural networks was compared to a controller based on the phenomenological model. For the NMPC based on the population balance model, the optimization problem was solved using the IPOPT solver, defining a tolerance of  $10^{-8}$ .

The controller was tested for set-points equal to 16 and 14.5  $\mu\text{m}$  for the crystal's length and 1.0 and 1.1 for the coefficient of variation. The results of the simulations for both controllers are shown in Figures 1 and 2, in which PB-NMPC is the NMPC based on the phenomenological model developed by Moraes et al.<sup>[3]</sup>, and NN-NMPC is the NMPC based on the neural networks. In the first case, the PB-NMPC reached the set-point for the coefficient of variation but could not get the set-point for the length. However, the NN-NMPC could achieve both set-points during this simulation. In the second case, the

NN-NMPC could reach both set-points, but the PB-NMPC presented a small offset for the coefficient of variance. Even with the advantage of the NN-NMPC, the PB-NMPC presented a mean squared error (MSE) equal to 1.7437 for the crystal's length and 0.0787 for the coefficient of variation in the first scenario, while these values were 0.5731 and 0.0526 in the second case studied. In contrast, the NN-NMPC shown an MSE equal to 4.9396 for the crystal's length and 0.0970 for the coefficient of variation in the first case, while these values were 4.1703 and 0.0428 in the second scenario. In both cases, the ratio  $C/C_{eq}$  was higher than one almost all the time, indicating that the simulations happened basically in the saturated condition. This situation was expected because the process does not stay too long in the subsaturated condition and rapidly tries to reach equilibrium ( $C/C_{eq}$  equals to one).

**Figure 1:** Control loop results for set-points equal to 16  $\mu\text{m}$  and 1.0.

**Figure 2:** Control loop results for set-points equal to 14.5  $\mu\text{m}$  and 1.1.

The performance of the controllers was tested to achieve the same set-points of 16  $\mu\text{m}$  and 1.0 but considering mismatches in the growth coefficient and the dissolution coefficient, using a difference of 10% on their original values. The results for this case are presented in Figure 3, showing similar results to the previous case. The NN-NMPC could reach both set-points once again, while the PB-NMPC could not reach the set-point for the crystal's length. The MSE values were 4.9370 for the crystal's length and 0.0921 for the coefficient of variation considering the NN-NMPC, while these values were 1.5551 and 0.0792 for the PB-NMPC.

**Figure 3:** Control loop results considering mismatches.

#### 4. Conclusion and Prospects

In this study, neural network models were developed to predict the first four moments and the solute concentration of a batch crystallization process. The hyperparameters of the neural networks were defined using an optimization approach. The capacity of the neural networks was tested to predict these values from two to twenty sampling times ahead, verifying  $R^2$  greater than 99% for the test samples in all cases analyzed. Moreover, the neural networks have the advantage to use only one model to make predictions of a particular state variable under the saturated and undersaturated conditions. The neural network models were used as the internal model of an NMPC to control the crystal's length and the coefficient of variation manipulating the temperature. The proposed controller could efficiently maintain the controlled variables in the set-points, showing similar results to an NMPC based on the phenomenological model. The simulations remained mostly in the supersaturation condition, since the process remains quickly in the undersaturation region and seeks to reach equilibrium. Moreover, the controller could efficiently handle mismatches in the model. The proposed strategy reached the set-points efficiently and with low computational cost, showing a potential to be used in real crystallization processes. A similar application could be made to a continuous crystallization process for future work.

## Abstract

Recently, it has been shown that rectified linear unit (ReLU) based neural networks (NN) are mixed integer linear representable and therefore can be incorporated into mixed integer linear programming frameworks. In this work we propose a novel tightening procedure that is based on a multiparametric programming formulation of the corresponding ReLU-reformulated optimization problem. The bounding procedure features 1) the generation of valid tight bounds on the individual auxiliary variables introduced from the ReLU NN reformulation, and 2) bounds on groups of input and output variables to these ReLU NNs. The tightened bounds are valid for all parameter realizations, and thus can be reused between different problem realizations. This tightening only needs to be computed a single time and thus the overall procedure is once-and-offline. As this bounds-tightening procedure is applied offline, more computationally expensive methods for formulation tightening can then be applied to the online case. We demonstrate the effectiveness of this method in a case study of model predictive control of a nonlinear chemostat where the dynamics are approximated with a ReLU NN.

**Keywords:** Multiparametric Programming, Model Predictive Control, Neural Network

## 1. Introduction

Multiparametric programming has garnered much interest in the control literature since it was shown that Model Predictive Control (MPC) problems can be formulated as multiparametric programs (Bemporad et al., 2000; Pistikopoulos et al., 2021) where these restated MPCs are typically referred to as multiparametric MPCs (mpMPC). The feature of multiparametric programming often used in the control literature is that it allows for the generation of explicit algebraic solutions to the MPC problem ahead of time that are functions of the uncertain parameters,  $\theta$  (Pappas et al., 2021; Pistikopoulos et al., 2021). Another feature of the multiparametric program formulation is that it represents the set of all possible optimization problems given a parametric uncertainty set  $\Theta$ , and it is this aspect that will be explored in this work. A prototypical multiparametric program is shown in eqn. 1. With  $x \in \mathbb{X}$  being the set of decision variables, and  $\theta \in \Theta$  being the set of uncertain parameters. Here,  $f(x, \theta)$  is the objective function,  $g(x, \theta) = 0$  is the set of equality constraints, and  $h(x, \theta) \leq 0$  are the inequality constraints.

$$\begin{aligned}
\min_x \quad & f(x, \theta) \\
\text{s.t.} \quad & g(x, \theta) = 0 \\
& h(x, \theta) \leq 0 \\
& x \in \mathbb{X}, \theta \in \Theta
\end{aligned} \tag{1}$$

It has been shown that ReLU-based NNs are mixed integer linear representable using one of the various reformulation strategies that have been proposed in the literature, such as the partition-based reformulation approach by Tsay et al. (2021) and the Big-M reformulation as proposed by Grimstad and Andersson (2019) and Fischetti and Jo (2018). Various methods have been explored to accelerate the solution of these optimization problems, such as deriving tighter bounds and reformulations (Tjandraatmadja et al., 2020; Tsay et al., 2021; Grimstad and Andersson, 2019) and finding the explicit solution of the resulting multiparametric program (Katz et al., 2020). Here, bounds-tightening refers to finding tight ranges for the auxiliary variables introduced in the reformulation of NNs. In the case of bounds-tightening, the literature has focused on finding tighter bounds for individual optimization problems and has not thoroughly explored the case where one can tighten and reuse bounds over sets of optimization problems, such as those that can be represented by multiparametric programming formulations, e.g., eqn. 1.

In this work, we propose a multiparametric programming-based strategy for generating tight bounds for ReLU-based NN reformulations that can be reused for all realizations of optimization problems,  $\theta \in \Theta$ . These are tight bounds that are valid for all possible problem realizations and thus can be effectively reused between parameter realizations,  $\theta \in \Theta$ . This reusing of tight bounds between problems allows for the bounds-tightening to be calculated once-and-offline for any particular multiparametric program with ReLU-based NN constraints. The effectiveness of this approach is displayed on a ReLU-based NN MPC of an unstable nonlinear chemostat process.

## 2. Method

This section is separated into two subsections. The first subsection briefly describes the Big-M MILP reformulation of ReLU-based NN. The second subsection gives an overview of the proposed bounds-tightening procedure.

### 2.1. ReLU Neural Network Reformulation

A ReLU-based NN is in essence a continuous piecewise affine function and thus can be represented via mixed integer linear constraints, in the same way that any other continuous piecewise affine function can be. With ReLU-based NN, the only non-linearity that must be addressed is the ReLU activation function itself. This is a rectification function where if the input is less than 0, then it is rectified to 0; otherwise, the input is not altered by the activation function. This can be modeled with the max function,  $\max(0, x)$ . This can be effectively linearized by introducing auxiliary variables.

The Big-M reformulation for layer  $k$  of a ReLU-based NN is shown in eqn. 2. Where the input to hidden layer  $k$  is  $z^{k+1}$ , the weight and bias values of the layer are  $W^k$  and  $b^k$  respectively, and the output of the hidden layer is  $z^{k+1}$ . Auxiliary slack variables  $s^k$  and selection variables  $y^k$  are introduced to linearize the max function exactly. In the case  $y_i^k = 0$ , then  $(W^k z^k + b^k)_i > 0$  and thus does not to be rectified so  $s_i^k = 0$ ; similarly, in the case of  $y_i^k = 1$ , then  $(W^k z^k + b^k)_i < 0$  and thus  $z_i^{k+1}$  needs to be rectified to zero

via  $s_i^k$ . Initial bounds for  $M^{s_i^k}$  and  $M^{z_i^k}$  are typically found via interval arithmetic (Grimstad and Andersson (2019)). As long as the Big-M values are significantly large, i.e. provide a true upper bound to the auxiliary variables, the resulting reformulation is valid. However, if these values are made overly large, the computational performance of the resulting optimization problem will be affected. More details on this reformulation can be found in the works of Grimstad and Andersson (2019), Fischetti and Jo (2018), and Tjandraatmadja et al. (2020).

$$\begin{aligned}
 z^{k+1} = \max(0, W^k z^k + b^k) \quad & \rightarrow \quad \begin{aligned} z^{k+1} &= W^k z^k + b^k + s^k \\ z^{k+1} &\geq 0 \end{aligned} \\
 z^{k+1} \geq 0 \quad & \rightarrow \quad \begin{aligned} 0 &\leq s_i^k \leq M^{s_i^k} y_i^k \\ 0 &\leq z_i^{k+1} \leq M^{z_i^k} (1 - y_i^k) \\ y_i^k &\in \{0,1\} \end{aligned} \end{aligned} \quad (2)$$

### 2.2. Tightening Procedure

While the Big-M reformulation of the ReLU-based NN typically allows for the use of standard MIP solvers, such as Gurobi or CPLEX, the formulation does not typically lead to a tight mathematical program (Grimstad and Andersson, 2019; Tsay et al., 2021). Instead of proposing a bounds-tightening procedure for a particular problem realization, we propose tightening over all possible problem realizations,  $\theta \in \Theta$ .

By having an explicit parameterization of an optimization problem, as represented in eqn. 1, the parametric uncertainty space,  $\Theta$ , can directly be used to find tight valid bounds on all optimization variables. By promoting the parameters,  $\theta$ , into decision variables in the reformulated optimization problem, tight worst-case bounds can be found for each variable via MILP optimization, such as can be seen in eqn. 3. These bounds are valid for every possible parameter realization in the uncertainty space and allow for these bounds to be shared between optimization problems with different parameter realizations,  $\theta \in \Theta$ .

$$\begin{aligned}
 \min_{x,z,s,y,\theta} \quad & x_i \\
 \text{s.t.} \quad & g_{\text{reformulated}}(x, z^1, \dots, z^M, s^1, \dots, s^M, y^1, \dots, y^M, \theta) = 0 \\
 & h_{\text{reformulated}}(x, z^1, \dots, z^M, s^1, \dots, s^M, y^1, \dots, y^M, \theta) \leq 0 \\
 & x \in \mathbb{X}, \quad \theta \in \Theta \end{aligned} \quad (3)$$

A similar optimization problem, as shown in eqn. 3, is solved for every variable in the formulation, e.g.,  $s_i^k$ ,  $z_i^k$ ,  $y_i^k$  and  $\theta_i$ , for both the upper and lower bounds of each variable given the parameters,  $\theta \in \Theta$ .

### 3. Case Study: Unstable Nonlinear Chemostat

The proposed methodology is applied to a ReLU-based NN MPC for the unstable nonlinear chemostat process adopted by Eaton and Rawlings (1992). The model equations of the considered process are shown in eqn. 4, describing the dynamics of the biomass,  $x$ , and the substrate,  $s$ , with time along with the substrate inhibition model,  $\mu(s)$ . In this process the specific parameters are  $s_f = 4$ ,  $y = 0.4$ ,  $\mu_{\max} = 0.53$ ,  $k_m = 0.12$ ,  $k_1 = 0.4545$ . The dilution rate,  $D$  is the input variable that can be manipulated to change the trajectory of the states,  $x$  and  $s$ , of the process.

$$\begin{aligned}
\frac{dx}{dt} &= (\mu(s(t)) - D(t))x(t) \\
\frac{ds}{dt} &= (s_f - s(t))D(t) - \frac{\mu(s(t))x(t)}{y} \\
\mu(s) &= \frac{\mu_{\max}s(t)}{k_m + s(t) + k_1s(t)^2}
\end{aligned} \tag{4}$$

The dynamics of the chemostat process are then approximated by a ReLU-based NN model with 3 hidden layers with 15 nodes in each hidden layer. The NN was generated via the following procedure. A data set was constructed by simulating 1,000,000 randomly generated initial states and input actions inside of the operating window,  $(x, s, D)$ , for a single time step to build an input-output data set,  $(x(t), s(t), D(t)) \rightarrow (x(t + \Delta t), s(t + \Delta t))$ . The input action,  $D(t)$ , was held constant for the entire time interval,  $\Delta t$ , in a zero-order old fashion. This input-output data set was split into a train and test set with a 90/10 ratio. The NN model was then trained via stochastic gradient decent (sgd) to a fit performance of  $9.16 \cdot 10^{-5}$  MSE, and  $6.9 \cdot 10^{-3}$  MAE. This model was then validated on the test set with a performance of  $9.3 \cdot 10^{-5}$  MSE and  $6.3 \cdot 10^{-3}$  MAE, indicating that a predictive model was generated that has acceptable performance for this application.

The multiparametric MPC (mpMPC) for this process can be seen in eqn. 5. Here the objective is to maximize the biomass production at each time period,  $i$ . The predictive model of this MPC is based on the NN that was generated in the previous step. The states of the system are bounded above and below, as is the input action. For this case study, the control and output horizon are 7-time steps.

$$\begin{aligned}
&\max_{x,s,d} \sum_{i=0}^N x_i \\
\text{s.t. } &x_{i+1}, s_{t+1} = \text{NN}(x_t, s_t, D_i), \quad \forall i \in \{0, \dots, N-1\} \\
&0.1 \leq x_i \leq 2.0, \quad \forall i \in \{0, \dots, N\} \\
&0.1 \leq s_i \leq 2.0, \quad \forall i \in \{0, \dots, N\} \\
&0.05 \leq D_i \leq 0.6, \quad \forall i \in \{0, \dots, N-1\} \\
&x_0 = \theta_0, s_0 = \theta_1, \theta \in \theta
\end{aligned} \tag{5}$$

Firstly, the proposed bounds-tightening procedure is applied to the NN separate from the overall optimization problem. Here tight upper and lower bounds on the auxiliary variables were found that are valid for all problem realizations,  $\theta \in \theta$ . This tightening of the individual NN took only 11.5 seconds. These tightened bounds were then used when generating the Big-M reformulation of the mpMPC. It was found that 12 of the 45 auxiliary binary variables in each NN were only feasible at either 0 or 1 and thus could effectively be removed from every problem instance.

The MILP-reformulated mpMPC has 701 continuous variables, 315 binary variables, and 2,221 constraints. Tight upper and lower bounds were then found for  $x_i$ ,  $s_i$ , and  $D_i$ , as well as sums of these variables, e.g.,  $\sum x_i$ , which are valid for any problem realization,  $\theta \in \theta$ . These bounds were added as constraints to the reformulated mpMPC. This once-and-offline bounds-tightening process took 2,941 seconds.

The effectiveness of the once-and-offline bounds-tightening procedure is shown in a control case study where the computational burden of the ReLU NN-based MPC is compared with and without the proposed bounds-tightening procedure. For these computational experiments, we used Gurobi 10.0 as the MILP solver and used a computer with an Intel i7-12700k and 32GB DDR4 RAM. Here, we take the system at the initial state realization of  $\theta = (0.2, 0.5) = (x_0, s_0)$ . Without the proposed bounds-tightening procedure applied, the MPC problem hit the time-out limit of 8,000 seconds, explored 21,976,708 nodes, and performed 334,045,961 simplex iterations with a gap of 9.9%. Utilizing the proposed bounds-tightening procedure where valid tight bounds are generated for all problem realizations ahead of time, the ReLU-based NN MPC problem was solved to proven optimality in only 5.36 seconds, explored 14,046 nodes, and performed 205,700 simplex iterations. The predictive performance of the NN model and the effect of applying the optimal inputs,  $D_t$ , that were generated by the MPC to the process can be seen in Figure 1.

*Figure 1. Evolution of the chemostat process with time given the dilution rates,  $D_t$ , from the MPC compared to the prediction of the NN inside the MPC.*

*Figure 2. Histogram and box plot of time to solve each problem in the problem set.*

Another computational study was performed, where 500 random initial state realizations of the chemostat system,  $\theta = (x_0, s_0) \in \Theta$  were generated. The corresponding MPC problems for each initial state were solved utilizing the calculated tight bounds. Each problem was solved to optimality; if the resulting problem was found to be infeasible, the time to solve was reported as the time to prove infeasibility. The average time to solve the pre-tightened MPC problems was 4.37 seconds, with a maximum of 8.48 seconds.

The distribution of the solve times for these control problems is presented in Figure 2. As a comparison, 5 problems were attempted without the improved bounds; however, they all timed out at 8,000 seconds without a proven optimal solution. As shown, this proposed procedure leads to significant reductions in the time to solve, especially when compared to the case where these precomputed bounds are not provided.

#### 4. Conclusions

In this work, a once-and-offline bounds-tightening procedure for ReLU-based NN multiparametric programming problems was developed. This method finds tight bounds for every auxiliary variable introduced via the Big-M reformulation that is valid for every realization of the parametric uncertainty set,  $\theta \in \Theta$ , allowing for the reuse of these bounds between problems. In addition, bounds on the input and output variables of the NN were computed, removing the need to generate new bounds for each optimization problem. The tightened bounds on the auxiliary, input and output variables furnish a much more computationally tractable optimization problem, and this was demonstrated in the case study where a ReLU-based NN MPC was implemented for a chemostat process. The proposed method made the controller computationally feasible, taking only 5.36 seconds compared to the untightened case which timed out at 8,000 seconds.

In the future, we plan to apply the proposed tightening procedure to the partition reformulation of ReLU-based NNs as proposed by Tsay et al. (2021) to analyze if similar computational acceleration can be realized in those ReLU-based NN reformulations. We plan to apply this to other realizations of multiparametric mixed integer programming formulations. Hierarchical MPC, which consists of layers of MPC and is typically stated as a multilevel optimization problem, is of keen interest to the authors. In the case of two controllers where the lower-level controller is a convex Quadratic Program, this can be reformulated as a multiparametric mixed integer program that could have the same tightening procedure applied to it.

## Abstract

Gas pipelines form complex highly integrated networks to transport natural gas with dynamic operation due to time varying demands, composition, and ambient conditions. These can be modeled and optimized through non-linear optimal control problems with model equations, operation bounds and uncertainty descriptions. In this study, we use a multistage Economic Nonlinear Model Predictive Controller (eNMPC) to find optimal operational policies for networks with dynamic demands and uncertain parameters. This approach relies on constructing a scenario tree by generating extreme cases of the uncertain parameters with separate control sequences to address constraint violations in each case. For demonstration, we assume that the efficiency of the compressors is uncertain. Under this uncertainty we show that standard eNMPC, designed with a nominal value of compressor efficiency, violates constraints in the plant. We demonstrate that multistage eNMPC prevents constraint violations in all uncertain realizations and provides a promising robust control strategy for these networks.

## 1. Introduction

Natural gas is the cornerstone of the electric grid and significant increases in consumption are projected in the coming years. Gas is transported from suppliers to consumers using large pipeline networks, which operate under time varying conditions such as temperature, customer demands and gas composition. Pipeline networks typically consist of supply nodes, demand nodes, compressor stations and individual lines of various diameters and lengths. Compressor stations are used to supply boost pressure to the gas to compensate for friction losses, and this is a major operating cost (Liu et al. (2020)). Moreover, a major issue in pipeline operation is the presence of uncertainty. Liu et al. (2020) used a robust optimization approach to optimize gas networks with demand and composition uncertainty. Also, two-stage stochastic optimal control for pipeline networks has been performed by Zavala (2014) with a focus on uncertainty in gas demands. However, this work assumes that uncertain profiles will resolve in time after a fixed horizon, but it was not implemented in a moving horizon approach. In contrast, we consider a multistage MPC in which the value of the uncertain parameter is revealed at each sampling time. Lin et al. (2022) demonstrated the effectiveness of multistage NMPC to handle uncertainty in pumping treatment in hydraulic fracturing. The advantage of using an eNMPC over tracking NMPC for optimal pipeline operation was demonstrated in a deterministic setting by Gopalakrishnan and Biegler (2013). In this paper, we extend this approach through multistage eNMPC for optimal control of gas-pipeline networks under uncertainty.

There are multiple uncertain parameters that can be considered in the operation of gas pipelines such as uncertainty in demand, gas composition, compressor efficiency, etc.

Although the concept of multistage eNMPC can be generalized to any uncertain parameter, we choose the uncertainty in compressor efficiency to demonstrate the results of this work. The uncertainty in compressor efficiency is due to time-varying flow of gas through the compressors and ambient conditions of operation such as temperature and relative humidity. Moreover, compression unit failures are extremely challenging for gas transmission systems and a significant issue for gas operators (Tran et al. (2018)). Using multistage eNMPC to control gas-pipeline networks with uncertainty is therefore a promising direction for further research.

## 2. Model Formulation

We first define the pipeline momentum and mass balances, compressor equations, node balances and equations that describe the network interconnections (Zavala (2014)). We assume isothermal gas flow through a horizontal pipe. The momentum balance and mass balance equation for a given line  $l \in L$  with a given value of parametric uncertainty  $w \in \Omega: \{1, 2, \dots, N_\Omega\}$  is given by:

$$\frac{1}{A_l} \frac{dF_l(t, x, w)}{dt} + \frac{dP_l(t, x, w)}{dx} + \frac{8\lambda_l c^2 F_l(t, x, w) |F_l(t, x, w)|}{\pi^2 D_l^5 P_l(t, x, w)} = 0 \quad (1) \quad \frac{dP_l(t, x, w)}{dt} + \frac{c^2}{A_l} \frac{dF_l(t, x, w)}{dx} = 0 \quad (2)$$

where  $t \in T$  and  $x \in X$  are points in time and space domains respectively.  $P_l$  and  $F_l$  refer to the pressures and flows in line  $l$  and  $c$  is the speed of sound of the gas.  $A_l$  is the cross-sectional area of the pipeline and  $D_l$  is the diameter of the pipeline  $l$ . Area and friction factor ( $\lambda_l$ ) equations are:

$$A_l = \frac{\pi D_l^2}{4} \quad \forall l \in L \quad (3) \quad \lambda_l = \left[ 2 \log_{10} \left( \frac{3.7 D_l (mm)}{(\text{rugosity})} \right) \right]^{-2} \quad (4)$$

In the pipe network we consider the node set  $\mathcal{N}$  and line set  $L$ . For each node  $n \in \mathcal{N}$  we define a set of supplies  $S_n$  and demands  $D_n$ .  $L^{in}$  is the subset of lines bringing gas to node  $n$  and  $L^{out}$  is the subset of links which take out gas from node  $n$ .  $s_i(t, w)$  represents the actual supply flowrate from supply  $i$  and  $d_j(t, w)$  represents the actual demand flowrate from demand  $j$ . The flow balances at the nodes are given by:

$$\sum_{i \in S_n} s_i(t, w) + \sum_{l \in L_n^{in}} F_l^{in}(t, w) = \sum_{j \in D_n} d_j(t, w) + \sum_{l \in L_n^{out}} F_l^{out}(t, w) \quad \forall n \in \mathcal{N} \quad (5)$$

$F_l^{in}$  and  $P_l^{in}$  are dummy flows linked to the pipeline flows by the boundary equations:

$$F_l(t, \bar{L}_l, w) = F_l^{in}(t, w) \quad (6) \quad F_l(t, 0, w) = F_l^{out}(t, w) \quad \forall l \in L, w \in \Omega, t \in T \quad (7)$$

where  $\bar{L}_l$  is the length of line  $l$ . In addition to the pipelines and the nodes, we have compressor stations associated with some pipelines. We define a set of pipelines which have a compressor associated with them as  $L_a$  (active lines) and a set of pipelines which don't have a compressor as  $L_p$  (passive lines). The power consumed in the active lines  $L_a$  is given by:

$$\text{Power}_l(t, w) = T_{in}(t, w) c_p \frac{F_l(t, 0, w)}{\eta_l(t, w)} \left[ \left[ \frac{P_{in,l}(t, w) + \Delta P_l(t, w)}{P_{in,l}(t, w)} \right]^\beta - 1 \right] \quad \forall l \in L_a, w \in \Omega, t \in T \quad (8)$$

$T_{in}$  is the temperature of the inlet stream.  $\eta_l(t, w)$  is the efficiency of the compressor in line  $l$  which is an uncertain parameter.  $\beta$  is the compression coefficient which is calculated as  $\beta = \frac{c_p - c_v}{c_p}$ . The boundary conditions for the pipeline pressures are:

$$P_n^{rec}(t, w) = P_1(t, \bar{L}_1, w) \quad \forall l \in L, t \in T, w \in \Omega \quad (9)$$

$$P_1(t, 0, w) = P_{in,1}(t, w) \quad \forall l \in L_p, t \in T, w \in \Omega \quad (10)$$

$$P_1(t, 0, w) = P_{in,1}(t, w) + \Delta P_1(t, w) \quad \forall l \in L_a, t \in T, w \in \Omega \quad (11)$$

$P^{rec}$  are the pressures received at the nodes from the pipelines. The time domain  $t$  is discretized using an implicit Euler method with equally spaced points each having  $\Delta t$  length. We represent each point in the discretized time set by the index  $\tau$ . The space domain along the length of each line is discretized using a forward discretization scheme with  $N_x$  equally spaced points with each segment having a length of  $\Delta x$ . We define  $\bar{X} = \{1, 2, \dots, N_x - 1\}$ . Spatial and temporal discretizations were chosen based on simulation results obtained from the model. The differential states from the resulting differential-algebraic equations (DAEs) correspond to spatially discretized flows and pressures. The algebraic state equations include the node balances, compressor power expression and the boundary conditions. A dynamic optimization problem is formulated to minimize the boost cost of the compressor while meeting the demands without depleting the linepack inventory (gas stored in the pipelines at the end of operation). Fixing the supply pressure and demand flows leaves us with the compressor boost pressures as the control variables.

### 2.1. eNMPC Formulation

eNMPC provides a sequence of controls for a given horizon. The first control input is implemented in the plant. The new state of the plant is then sampled and acts as a new starting point for the controller. The horizon of the controller is then advanced by one sample time and the process repeats again. We consider an eNMPC horizon of 24 hours and a total time of 48 hours. The points on the discretized horizon are defined by the set

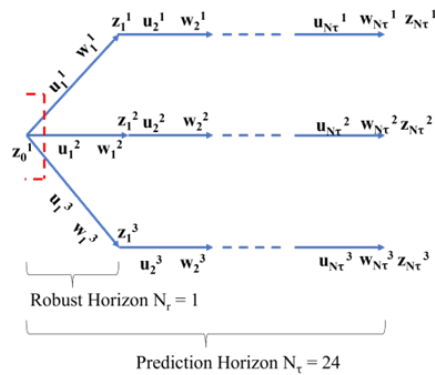

Figure 1. Scenario tree with a robust horizon  $N_r = 1$  for multistage eNMPC

the linepack inventory, we use a lower bound on linepack flow and pressure. The optimization problem for each control horizon is formulated as:

$$\begin{aligned}
 \min_{\Delta P_{l,\tau}(w)} \quad & \sum_{l \in L_a} \sum_{\tau \in \hat{T}} C_{pr} \times Power_{l,\tau}(w) \Delta t \\
 d_{j,\tau}^{target} - d_{j,\tau}(w) = 0 \quad & \forall \tau \in \hat{T}, \forall j \in D_n, \forall n \in \mathcal{N}, \forall w \in \Omega \\
 P_{l,N_r,k}(w) \geq P_{LB} \text{ bar} \quad & \forall l \in L, \forall k \in \{2, 3, \dots, N_x\}, \forall w \in \Omega \\
 F_{l,N_r,k}(w) \geq F_{LB} \text{ kmol/hr} \quad & \forall l \in L, \forall k \in \bar{X}, \forall w \in \Omega \\
 s_{LB} \leq s_{i,\tau}(w) \leq s_{UB} \quad & \forall i \in S_n, \forall n \in \mathcal{N}, \forall \tau \in \hat{T}, \forall w \in \Omega \\
 P_{LB}^{rec} \leq P_{j,\tau}^{rec}(w) \leq P_{UB}^{rec} \quad & \forall j \in D_n, \forall n \in \mathcal{N}, \forall \tau \in \hat{T}, \forall w \in \Omega \\
 0 \leq Power_{l,\tau}(w) \leq Power_{UB} \quad & \forall \tau \in \hat{T}, \forall w \in \Omega
 \end{aligned}
 \quad \left. \begin{array}{l} \text{Demand} \\ \text{constraints} \\ \text{Terminal} \\ \text{bounds} \\ \text{Variable} \\ \text{bounds} \end{array} \right\}$$

Constraints (1)-(12), discretized in  $\hat{T}$  and  $\bar{X}$

$\hat{T} = \{1, 2, \dots, N_\tau\}$ . The goal of the optimization problem is to minimize the boost cost of the compressor while meeting the demands, without completely depleting the inventory. The boost cost is calculated based on the power of the compressor and the cost of electricity. Assuming the cost of electricity is  $C_{pr}$  \$/kWh, the boost cost can be calculated as:

$$J(w) = \sum_{l \in L_a} \sum_{\tau \in \hat{T}} C_{pr} \times Power_{l,\tau}(w) \Delta t \quad (12)$$

To meet the demands we have equality constraints between the target demands and the actual demands. To avoid depletion of

The above constraints are labelled as (13). This formulation holds for the dynamic optimization of a pipeline network where the value of the uncertain parameter is known. In case of uncertain efficiency it is useful to implement Multistage eNMPC as it considers explicit realization of uncertainty by considering a scenario tree. In accordance with the standard setup of multistage eNMPC (Lucia et al. (2013)) we choose three realizations of the uncertain parameter: minimum, nominal and maximum in set  $\Omega = \{w^{min}, w^{nom}, w^{max}\}$ . Non-anticipativity constraints enforce equal values of the control variables for branches  $b$  and  $\bar{b}$  with the same parent node. Figure 1 shows a scenario tree with a robust horizon  $N_r = 1$ . The level of uncertainty stays the same after the robust horizon. This allows us to have only two non-anticipativity constraints and the problem size remains tractable. Since the efficiency at each time point is an uncertain parameter, we have  $N_\tau$  uncertain parameters. The optimization problem for a multistage NMPC is then formulated as:

$$\min_{\Delta P(w_\tau^b)_{\{\tau \in T\}}} \sum_{w_\tau^b \in \Omega} \frac{1}{|\Omega|} J(w_\tau^b)$$

$$\Delta P_\tau^b = \Delta P_\tau^{\bar{b}} \text{ if } , z_{\tau-1}^b = z_{\tau-1}^{\bar{b}} \quad \forall b, \bar{b} \in B, \forall \tau \in \{1, \dots, N_r\} \quad \text{Nonanticipativity constraints}$$

$$w_\tau^b = w_{\tau+1}^b \quad \forall \tau \in \{N_r+1, \dots, N_\tau-1\}$$

Where B denotes the set of all branches in the scenario tree.  $z_\tau^b, \Delta P_\tau^b, w_\tau^b$  are the states, controls, and uncertain parameters at stage  $\tau$  in branch  $b$ . The objective function is the average of the objectives of the nominal NMPC. The system is modeled in IDAES (Lee et al. (2021)), with Pyomo DAE (Nicholson et al. (2018), Bynum et al. (2021)) and is solved using IPOPT version 3.13.2 (Wächter and Biegler (2006)).

### 3. Model Formulation

Figure 2(a) Gas pipeline network

Figure 2(b) Dynamic demand profile at demand nodes

A pipeline network with five demands, one supply and three compressor stations is considered to demonstrate the proposed approach (Liu et al. (2020)). Figure 2(a) shows the network structure while the gas flow demand for each demand node is shown Figure 2(b). It is assumed that the profile repeats over a period of 24 hours. Node 1 is the supply node with a fixed gas supply pressure of 100 bar. Node 2 is a junction node with only inlet and outlet pipeline with no demand or supply. It is assumed that at the initial state, compressor  $c_1$  provides a boost pressure of 20 bar. This is necessary to obtain a consistent initial condition for our dynamic system. We use an upper bound of 60 MW on

compressor power. A standard NMPC is used on this network to find the optimal control

Figure 3(a) Boost pressure in compressor  $c_1$

Figure 3(b) Boost pressure in compressor  $c_2$

Figure 3(c) Pressure at node 4 & 5

Figure 3(d) Power profile of compressor  $c_1$

actions with no plant-model mismatch. The NMPC has a horizon of 24 hrs with a sampling time of 1 hr. Under deterministic conditions, the eNMPC controller finds the optimal boost pressure profiles compressors  $c_1$  and  $c_2$  in the network as shown in Figure 3(a) and Figure 3(b), respectively. The pressures at nodes 4 and 5 are also at their lower bounds as shown in Figure 3(c). For the given set of initial and

boundary conditions, there is no boost pressure required in compressor  $c_3$ . Figure 3(d) shows that the power in compressor  $c_1$  is at its bound and is likely to experience bound violations under uncertainty in compressor efficiency.

### 3.1. Introducing uncertainty in plant

Now we consider uncertainty in the efficiencies of all three compressors. Five randomly generated efficiency profiles are applied, with efficiency at each time point taking one of the three extreme values  $\{0.55, 0.7, 0.85\}$ . The standard eNMPC modeled with nominal compressor efficiency of 0.7 is unaware of this uncertainty and therefore is likely to violate the power bound in multiple efficiency realizations. It can be seen from Figure 4(a) that the power bound in compressor  $c_1$  is violated beyond 15 hours with standard

Figure 4(a) Compressor  $c_1$  power profiles using standard eNMPC with plant-model mismatch

Figure 4(b) Compressor  $c_1$  power profiles using multistage eNMPC with plant-model mismatch

eNMPC. (The different colors indicate the power profiles obtained in each uncertain scenario). Multistage eNMPC as shown in Figure 4(b) doesn't violate the power bound in any case. The average cost obtained using standard eNMPC was US\$37885 while a multistage eNMPC predicted a cost of US\$42963. The optimal solution obtained using

the multistage eNMPC is 13.4% more expensive compared to the standard eNMPC, this represents the cost of handling uncertainty. The multistage eNMPC finds alternate control

Figure 5. Boost pressure profiles obtained using standard eNMPC vs Multistage eNMPC

profiles which are robust to uncertainty and don't lead to bound violations in the plant. Figure(5) shows a comparison between the controls found by the multistage eNMPC and the standard eNMPC. We see that multistage eNMPC predicts the same control sequence as a standard eNMPC until 15 hrs. Beyond 15 hrs, multistage eNMPC suggests that a lower boost pressure should be used in compressor  $c_1$  to avoid the power bound violation. But, to supply gas above the minimum demand pressure at nodes 4 and 5, a higher boost pressure is used in compressor  $c_2$ . Also, unlike the deterministic case, Compressor  $c_3$  provides boost pressure, which is required to satisfy the lower bounds on terminal pressure.

#### 4. Conclusions and Future Work

Standard eNMPC with fixed, nominal compressor efficiency finds the optimal control sequence without violating any bounds. On the other hand, when standard eNMPC encounters parametric uncertainty, we observe bound violations due to plant-model mismatch. The multistage eNMPC approach results in a control policy which does not violate any bounds in the uncertain plant. In the future, we plan to apply these eNMPC strategies to larger, more complex problems and investigate how they scale up to real world GASLIB networks (Schmidt et al. (2017)).

### **Abstract**

We propose a new time-bucket MILP model for lot-sizing and scheduling problems arising in multistage production processes. The time-bucket model benefits from advantages of both continuous and discrete time representations while overcoming their shortcomings. In particular, we show how the time-bucket model allows to easily include a variety of typical, important real-world constraints, can be solved with moderate computer effort, and thus promotes MILP for large-scale, industrial problems. To illustrate that, we apply the time-bucket approach to the flow shop problem of a batch formulation and filling process from an industrial pesticide production. We reconcile the MILP solution with a validated discrete event simulation (DES) model of the process to obtain optimal and real-world feasible results. A comparison of the MILP-DES solution to a manually optimized solution for a one-month production data set shows that more than 17% of production capacity can be freed up and significant improvement in on-time delivery.

**Keywords:** Production planning and scheduling; mixed-integer linear programming; discrete event systems in manufacturing; modeling of manufacturing operations.

### **1. Introduction**

Production scheduling of large-scale, industrial processes is widely recognized as a challenging optimization task both by academic and industrial researchers. With an increasing availability of real-time process data, ever-growing computational capabilities, and the advance of digital twins, optimal production scheduling has gained new relevance. However, there is still a large gap between industrial reality and academic research. As pointed out in Harjunkski (2016), practitioners are confronted with many different challenges, when building their solutions in an industrial environment. While mixed-integer programming (MIP) is a well-established optimization technique in asset-heavy industries such as petrochemicals Castro et al. (2018), and discrete manufacturing industries such as semiconductors Qin et al. (2019) and automotive Gnoni et al. (2003), it is relatively new to industries such as specialty chemicals Borisovsky et al. (2019), pharma Sarin et al. (2014); Costa (2015), and consumer goods Sel et al. (2015); Clark et al. (2011). Alternatives such as discrete event simulation (DES) address natural drawbacks of MILP such as the curse of dimensionality but do not provide bounds on the solutions. Despite research efforts with MIP and DES Frazzon et al. (2016); Nikolopoulou and Ierapetritou (2012), real-world scheduling problems with dozens of

products, multiple production lines, changeover costs, and lot-sizing still can only be solved to sub-optimality or require massive computational resources. Herein we propose a new time-bucket mixed-integer linear programming (MILP) model for lot-sizing and scheduling problems arising in multistage production processes. The main idea behind time-bucket models based on Fleischmann and Meyr (1997) is to partition time into fixed-length macro-periods and flexible length micro-periods that lie within the macro periods. This model formulation allows to easily include a variety of typical, important real-world constraints and can be solved with moderate computer resources. We apply our approach to a real-world case study of a large-scale industrial make-and-fill process of an agrochemical production plant, and show that our modelling approach is able to capture the different characteristics of the problem efficiently. We analyse the evolution of the bounds to ensure that the exact search procedure of a MIP-solver can be truncated after short time with near-optimal solutions. In this way, a 1-month production data set can be solved with a moderate computational resources and within 1 hour solution time.

## 2. Time-bucket MILP formulation

### 2.1 Time-bucket approach

In the time-bucket MILP model mass balances, resource allocations, shift schedules, and due dates are modeled in the fixed time grid, while production quantities and changeover times are modeled in the flexible time grid. The fixed time grid consists of macroperiods, while the flexible time grid consists of microperiods. Macroperiods are fixed time intervals with uniform length, that are defined globally. As shown in Figure 2, there is a configurable number of microperiods  $s \in \mathcal{S}_t$  in each macroperiod  $t \in \mathcal{T}$ . Microperiods are flexible time intervals with variable length, that are defined per processing resource. Binary changeover variables  $y_{pp'ls}$  indicate changeovers from product  $p$  to  $p'$  on processing resource  $l$  in microperiod  $s$ . Each microperiod consists of a fixed sequence of 4 phases, set-up start, production, idle, and set-up end as shown in Figure 1.

Figure 1: Microperiods consist of setup start, production, idle and setup end phase.

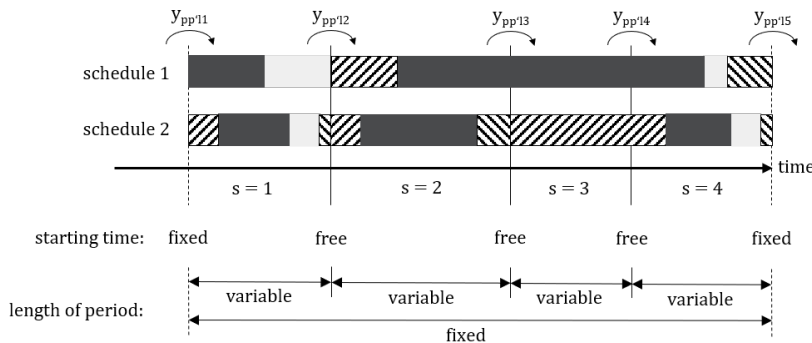

Figure 2: 2 possible schedules on a resource  $l$  in one macroperiod with 4 microperiods  $s$ .

The length of phase production is determined by the production quantity  $q_{pls}$  of a product  $p$  in microperiod  $s$  on a processing resource  $l$ . The lengths of phases set-up start and set-up end are determined by the sequence-dependent changeover times before and after the

production. The phase idle provides an optional interval for idle time. *Example.* We consider a processing resource  $l$  in a macroperiod with 4 microperiods as shown in Figure 2. In *schedule1* two production phases take place. The same time structure also allows to model 3 production phases as shown in *schedule2*. The changeover times must be taken into account using the setup start and setup end phases. If no changeover time is required the production phase can cover full microperiods. Similarly, long changeover times and idle times can be modeled. Since the microperiods are defined per processing resource  $l$  and have variable lengths the time bucket formulation provides a highly flexible time representation for MILP models.

### 2.2 MILP formulation

A crucial variable of the MILP model are production orders  $q_{p|s}$ . They express that a quantity of a product  $p \in P$  is produced on processing resource  $l \in L$  during the microperiod  $s \in S_t$  of macroperiod  $t \in T$ . Production orders seize processing resources for a minimum duration which depends on (1) the product  $p$  because of product dependent processing parameters (for example viscosity), (2) the resource  $l$  because of resource dependent processing parameters (for example milling efficiency) and (3) the quantity of the production order, which must be greater than a single batch size  $q_{min,l}$  at resource  $l$ . To describe (1) and (2) a production coefficient  $a_{p,l}$  is defined, which corresponds to the production rate of product  $p$  on the resource  $l$ . A changeover time  $ct_{pp'l}$  for subsequent products  $p$  and  $p'$  is defined for each resource  $l$ . The corresponding binary changeover variable  $y_{pp'ls}$  indicates whether a changeover from product  $p$  to  $p'$  takes place during the microperiod  $s$  on resource  $l$ . Furthermore, we distinguish intermediate products  $p \in IP \subset P$  and finished products  $\hat{p} \in FP \subset P$ . Since an intermediate product can be converted into different finished products, bill of material coefficients  $b_{p\hat{p}}$  are defined as indicator parameters. Demands  $D_{\hat{p}t}$  are defined with respect to finished product  $\hat{p}$  in macroperiod  $t$ . Similarly, the backlog quantities  $B_{\hat{p}t}$  are defined for finished product  $\hat{p}$  in macroperiod  $t$ .

### 2.3 Objective function

We suggest a 2-step, monolithical solution approach with warm start. In the first optimization step, we define the minimization of all backlog quantities  $B_{\hat{p}t}$  as the objective as shown in Equation 1.

$$\min \sum_{\hat{p} \in FP} \sum_{t \in T} B_{\hat{p}t} \tag{1}$$

In the second optimization step, the binary changeover variables  $y_{pp'ls}$  are initialized with the result of the first step. The objective of the second step is the minimization of the total changeover time  $y_{pp'ls} ct_{pp'l}$  as shown in Equation 2.

$$\min \sum_{\substack{s \in S_t \\ t \in T}} \sum_{\substack{p, p' \in P \\ l \in L}} y_{pp'ls} ct_{pp'l} \tag{2}$$

## 3. Case Study

We consider the scheduling problem of a flexible flow shop in an industrial manufacturing plant for crop protection chemicals as shown in Figure 3. The problem originates from the last two stages in the manufacturing process of pesticide chemicals, which are also known as product formulation and filling. The formulation and filling process takes place in a multi-product batch plant with 2 stages. In the first stage mixing, milling and reactions of raw materials take place, which results in bulk product. In the

second stage, bulk product is filled into final containers. The first and second stage each consist of 7 individual processing lines. We consider 50 unpackaged products and 83 finished products. We assume product-sequence and line-specific changeover costs, and minimum lot-sizes. There are 7 optional buffer tanks to decouple the two stages and maximize their utilization. Different shift schedules for the two stages determine how many lines can be operated simultaneously. The bottleneck of the process varies with production demand and the shift schedules.

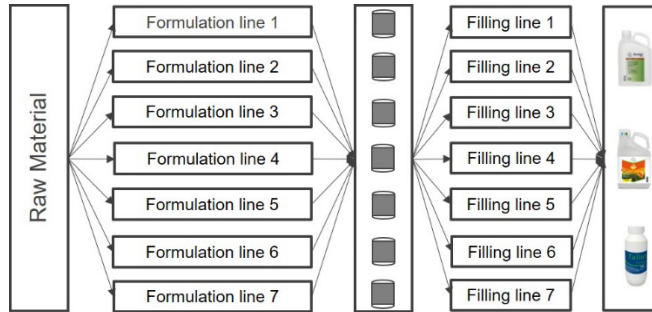

Figure 3: Schematic overview of the formulation and filling process.

## 4. Results

### 4.1 MILP Solution

We optimize the formulation and filling process for a 1-month production period. For the original demand data, we find a solution with no production backlog and 110 hours of changeover time with a remaining gap of 27.3% after a total solution time of 1.22 hours as further specified in Table 1. Optimization step 1 shows that the 1-month production demand  $D_{pt}$  can be satisfied without backlog in a makespan less than 31 days after 805 seconds solution time. Consequently a no-backlog constraint  $\Sigma B_{pt} = 0$  is enforced in the second optimization step, which minimizes the total changeover time to a value of 110 hours after 3600 seconds solution time. For the alternative demand scenarios we observe similar results.

Table 1: MILP results for different 1-month demand scenarios.

Set	Changeover (h)	Gap (%)	1st (s)	2nd (s)
Org	110	27.3	805	3600
2	130	35.1	659	3600
3	134	38.8	1033	3600
4	120	26.0	739	3600
5	120	21.8	828	3600

Since the optimality gap of the second optimization step is greater than 0 for all instances, we investigate the evolution of bounds and gap in the second optimization step over the course of 4 hours. As shown in Figure 4, the remaining gap is decreasing further for all instances after 3600 seconds. However, that is mainly due to the improvement of the lower bounds. Near-optimal solutions are found relatively quickly as indicated by the upper bounds in Figure 5. Consequently, the MIP-search can be truncated early despite relatively large remaining gaps. We conclude that the proposed MILP formulation provides near optimal solutions within 30 minutes solution time, but a proof of optimality is costly due to weak lower bounds.

Figure 4: Evolution of the remaining gaps (%) for 5 demand scenarios.

Figure 5: Evolution of the upper and lower bounds for 5 demand scenarios.

#### 4.2 DES validation

For validation the MILP result is reconciled using a validated DES model of the process. We compare the resulting MILP-DES schedule with a manually optimized DES (manual-DES) schedule. To obtain the latter, production experts generate campaign lists and refine them iteratively using the DES model. From the makespans of the MILP-DES schedule and the manual-DES in Table 2, we conclude that the MILP approach is able to generate schedules that do not violate the delivery dates at the end of the month, while the manually optimized schedule contains backlog of approximately 2%. The adherence to delivery dates and demand quantities is ensured by minimizing the total backlog in the first optimization step (see Equation 1). When comparing the occupancy times of all lines in the formulation and filling stage, we observe that MILP-DES approach reduces the number of occupancy time by a total of 1218 machine hours. Approximately 10% formulation capacity and 27% filling capacity is freed as a result of minimizing the total changeover times in the second optimization step (see Equation 2).

Table 2: DES reconciled results.

Approach	Bcklg (%)	Mkspan (d)	Form (h)	Fill (h)
MILP-DES	0	31	3309	2251
manual-DES	1.988	33.75	3674	3104

A direct comparison of the schedules shows that the MILP-DES solution in Figure 7 contains a higher number changeovers on the filling lines to synchronize with the formulation stage. As a result of this synchronization less changeover costs are incurred on the formulation lines and no backlog is produced (see Table 2). A high number of changeovers on the filling lines also is justified by the fact that they are relatively inexpensive compared to formulation changeovers because filling lines consist of a smaller number of machines and less cleaning effort is needed.

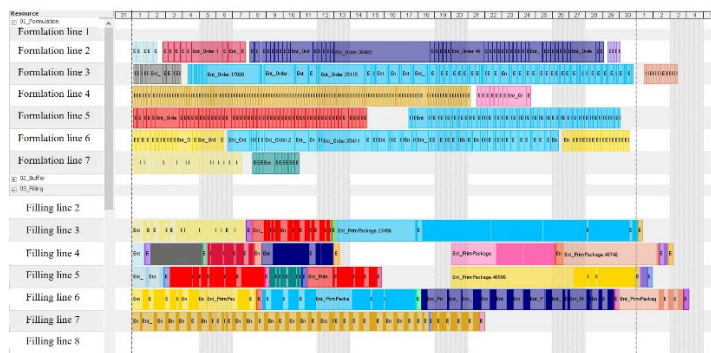

Figure 6: Manually-optimized DES schedule of 7 formulation lines (top) and 7 filling lines (bottom).

Figure 7: MILP-optimized DES schedule of 7 formulation lines (top) and 7 filling lines (bottom).

## 5. Conclusion

We showed that scheduling problems can be solved using a new time-bucket MILP formulation, which allows to include important real-world parameters such as lot-sizing, sequence dependent changeovers, buffer of intermediate bulk product, and operator schedules. We demonstrated the applicability of the time-bucket formulation with an industrial case study of a 2-stage agrochemical production process, for which we proposed a 2-step, monolithic solution procedure of the MILP model followed by a DES reconciliation step. We compared results of the MILP-DES approach with the results of

a DES-aided, manual optimization approach, and observed that counterintuitive yet better schedules are found with respect to production backlog and resource utilization. We conclude that the time-bucket formulation represents viable industrial solution, that can be adopted for similar problems.

## Abstract

Oil and gas production wastewater (i.e., produced water) may contain appreciable concentrations of rare-earth elements and critical minerals (REE/CMs), such as lithium, that can be recovered. However, each individual produced water source may have insufficient concentration or volume to meet the economic and operating requirements of the recovery facility. Therefore, there is the need to appropriately blend multiple sources to meet recovery and water reuse demands. Optimal stream mixing operation planning can be posed as a multiperiod blending problem (MPBP) to provide quantity and quality guarantees over time. We present several formulations to solve the MPBP for the recovery of REE/CMs from produced water and propose a decomposition approach that leverages strategies in general disjunctive programming to enhance its performance. We compare these proposed formulations/strategies via two illustrative case studies on recovering lithium from a network of produced water sources.

**Keywords:** Multiperiod Blending, Lithium Recovery, Mixed-Integer Nonlinear Programming, Decomposition

## 1. Introduction

Wastewater streams from oil and gas production (i.e., produced water) are expected to surpass 60 million barrels of water per day by 2030 in the U.S. alone (Wright, 2022). The treatment needed to mitigate the environmental impact of these wastewater streams is expensive due to high salinity and contaminant levels (Gaustad et al., 2021). Hence, a significant portion of produced water in the U.S. is simply disposed of via underground injection.

Notably, however, produced water sources may contain appreciable concentrations of critical minerals (CMs) such as lithium which are crucial for manufacturing electronics, pharmaceuticals, batteries, renewable energy generators, and more (Quillinan et al., 2018). Moreover, establishing a sustainable REE/CM supply chain is a critical concern of many industrial and governmental stakeholders. Thus, the recovery of REE/CMs from produced water has the potential to add sufficient economic value to incentivize the use of treatment technologies that mitigate the impact of produced water on the environment.

Operating a water network for the recovery of REE/CMs from multiple produced water sources is highly complex since REE/CM concentrations vary dynamically and geographically, there are limited storage locations, and treatment/recovery facilities have strict inlet-flow requirements (Gaustad et al., 2021). Such a system can be modeled as a classic multiperiod blending problem where source

streams with time-varying compositions are blended in pooling tanks to satisfy quality and quantity demand requirements. Classic pooling formulations such as the one proposed in Haverly (1978) use bilinear terms to track compositions along the network. However, such formulations are often difficult to solve due to their inherent nonconvexity (Gounaris and Floudas, 2008). This difficulty is compounded by multiperiod models that incorporate binary variables.

In this work, we investigate several multiperiod blending problem (MPBP) formulations and solution strategies to optimally plan the delivery of lithium-rich streams for recovery and water reuse in development activities. In particular, we adapt the direct, generalized disjunctive programming, and decomposition MPBP approaches as described in Kolodziej et al. (2013) and Lotero et al. (2016) to a representative produced water network case study. It is shown that such strategies are key to guiding the treatment of a multi-enterprise produced water blending and determine whether such a system is feasible and economically viable.

## 2. Problem Formulation and Solution Strategies

### 2.1. Basic Problem Setup and Nomenclature

The multiperiod blending problem (MPBP) is defined over a set of supply tanks  $\mathcal{S}$ , blending tanks  $\mathcal{B}$ , and demand tanks  $\mathcal{D}$  interconnected by a set of edges  $\mathcal{A}$ . The problem seeks to determine the optimal mixing schedule over a discretized time horizon  $\mathcal{T}$  that maximizes the operation profit, while meeting flow and concentration specifications for each component  $q \in \mathcal{Q}$ . The initial conditions for each tank  $n \in \mathcal{N} := \mathcal{S} \cup \mathcal{B} \cup \mathcal{D}$  are specified via the initial level of every tank  $I_n^0$  and its corresponding compositions  $C_{qn}^0$ . The incoming flow  $F_{st}^{IN}$  at each supply  $s$  is known with an incoming composition  $C_{qst}^{IN}$  that varies over  $t$ . The nodal inventories and flows are restricted by tank and pipeline capacities, which are denoted  $[I_n^L, I_n^U]$  and  $[F_{nn'}^L, F_{nn'}^U]$ , respectively. Required demand varies with time and needs to satisfy specifications on the flow  $[FD_{dt}^L, FD_{dt}^U]$  and concentration  $[C_{qd}^L, C_{qd}^U]$ . The MPBP formulations considered here assume that blending tanks do not operate at steady-state. Mixing requires that the tanks be charged at one period of time and discharged at another period (Lotero et al., 2016).

### 2.2. Direct MIQCP Formulation

We model the MPBP directly as a mixed-integer quadratically constrained program (MIQCP). The MIQCP formulation follows from extending steady-state pooling formulations to incorporate multiperiod scheduling. Here, binary variables  $x_{nn't} \in \{0,1\}$  are introduced to indicate the existence of flow at each time period. This addition enables us to enforce a minimum flow in the pipeline, when the flow exists. We obtain the MIQCP formulation by adapting the formulation presented by Kolodziej et al. (2013) to handle time-varying concentration in the supply:

$$\max \sum_{t \in \mathcal{T}} \left[ \sum_{(n,d) \in \mathcal{A}} \beta_d^T F_{ndt} - \sum_{(s,n) \in \mathcal{A}} \beta_s^T F_{snt} - \sum_{(n,n') \in \mathcal{A}} (\alpha_{nn'}^N x_{nn't} + \beta_{nn'}^N F_{nn't}) \right] \quad (1a)$$

$$\text{s.t. } F_{nn'}^L x_{nn't} \leq F_{nn't} \leq F_{nn'}^U x_{nn't}, \quad (n, n') \in \mathcal{A}, t \in \mathcal{T} \quad (1b)$$

$$C_{qd}^L - M(1 - x_{bdt}) \leq C_{qbt-1} \leq C_{qd}^U + M(1 - x_{bdt}), \quad q \in \mathcal{Q}, (b, d) \in \mathcal{A}, t \in \mathcal{T} \quad (1c)$$

$$C_{qd}^L - M(1 - x_{sdt}) \leq C_{qst}^{IN} \leq C_{qd}^U + M(1 - x_{sdt}), \quad q \in \mathcal{Q}, (s, d) \in \mathcal{A}, t \in \mathcal{T} \quad (1d)$$

$$I_{st} = I_{st-1} + F_{st}^{IN} - \sum_{(s,n) \in \mathcal{A}} F_{snt}, \quad s \in \mathcal{S}, t \in \mathcal{T} \quad (1e)$$

$$I_{bt} = I_{bt-1} + \sum_{(n,b) \in \mathcal{A}} F_{nbt} - \sum_{(b,n) \in \mathcal{A}} F_{bnt}, \quad b \in \mathcal{B}, t \in \mathcal{T} \quad (1f)$$

$$I_{dt} = I_{dt-1} + \sum_{(n,d) \in \mathcal{A}} F_{ndt} - FD_{dt}, \quad d \in \mathcal{D}, t \in \mathcal{T} \quad (1g)$$

$$x_{nbt} + x_{bn't} \leq 1, \quad (n, b), (b, n') \in \mathcal{A}, t \in \mathcal{T} \quad (1h)$$

$$I_{bt}C_{qbt} = I_{bt-1}C_{qbt-1} + \sum_{(s,b) \in \mathcal{A}} F_{sbt}C_{qst}^{IN} + \sum_{(b',b) \in \mathcal{A}} F_{b'bt}C_{qb't-1} - \sum_{(b,n) \in \mathcal{A}} F_{bnt}C_{qbt-1}, \quad q \in \mathcal{Q}, b \in \mathcal{B}, t \in \mathcal{T} \quad (1i)$$

$$I_n^L \leq I_{nt} \leq I_n^U, \quad n \in \mathcal{N}, t \in \mathcal{T} \quad (1j)$$

$$C_q^L \leq C_{qbt} \leq C_q^U, \quad q \in \mathcal{Q}, b \in \mathcal{B}, t \in \mathcal{T} \quad (1k)$$

$$FD_{dt}^L \leq FD_{dt} \leq FD_{dt}^U, \quad d \in \mathcal{D}, t \in \mathcal{T} \quad (1l)$$

$$F_{nn't} \geq 0, x_{nn't} \in \{0, 1\}, \quad (n, n') \in \mathcal{A}, t \in \mathcal{T} \quad (1m)$$

Where  $\beta_d^T$  is the unit profit of demand  $d$  satisfied,  $\beta_s^T$  is the unit cost of supply stream  $s$ ,  $\beta_{nn'}^N$  is the unit transportation cost,  $\alpha_{nn'}^N$  is the fixed transportation cost,  $F_{st}^{IN}$  is the incoming flow from supply tank  $s$  at time period  $t$ ,  $F_{nn't}$  is the flow between node  $n$  and node  $n'$  at time  $t$ ,  $FD_{dt}$  is the flow directed to demand tank  $d$  at period  $t$ , and  $M \in \mathbb{R}$  is a sufficiently large big-M constant. For simplicity in presentation, the edge set  $\mathcal{A}$  can refer to a subset of edges depending on the indices being used where  $n$  refers to general nodes and  $s$ ,  $b$ , and  $d$  refer to supply, blending, and demand nodes, respectively. The formulation allows flows to go directly from the supply to the demands without blending if and only if they meet the required specifications. Also note that Equation (1h) enforces that blending tanks cannot be charged, mixed, and discharged simultaneously. The key complicating factor of Problem (1) is that Equation (1i) involves bilinear terms.

### 2.3. Generalized Disjunctive Programming Formulation

Generalized disjunctive programming (GDP) is a framework for naturally posing mathematical programs that incorporate symbolic logic relationships between the variables (Grossmann and Trespalcios, 2013). In the MPBP, the bilinear mass balance shown in (1i) only needs to be considered when tanks are charging. Hence, this nonconvex equation can be omitted when a tank is discharging. Using GDP, we can define  $Y_{bt} \in \{\text{True}, \text{False}\}$  to specify whether or not, at a given period, tank  $b$  is charging ( $Y_{bt} = \text{True}$ ) or discharging ( $Y_{bt} = \text{False}$ ). With this, we can replace Equation (1i) in Problem (1) with the following disjunction that accounts for the operational mode of the tank:

$$\left[ \begin{array}{l} I_{bt} = I_{bt-1} + \sum_{(n,b) \in \mathcal{A}} F_{nbt} \\ I_{bt}C_{qbt} = I_{bt-1}C_{qbt-1} + \sum_{(s,b) \in \mathcal{A}} F_{sbt}C_{qst}^{IN} \\ \quad + \sum_{(b',b) \in \mathcal{A}} F_{b'bt}C_{qb't-1}, \quad q \in \mathcal{Q} \end{array} \right] \vee \left[ \begin{array}{l} -Y_{bt} \\ I_{bt} = I_{bt-1} - \sum_{(b,n) \in \mathcal{A}} F_{bnt} \\ C_{qbt} = C_{qbt-1}, \quad q \in \mathcal{Q} \end{array} \right] \quad (2)$$

for each  $b \in \mathcal{B}$  and  $t \in \mathcal{T}$ . Note that bilinear terms are only considered in the left disjunct. Also, the mass balances in both disjunctions have fewer terms since they leverage the tank operational mode to only consider active flows.

Formulation (1) has other constraints that enforce logical implications on variables, which are amenable for GDP reformulation. For instance, Equation (1b) activates the flow  $F_{nn't}$  only if  $x_{nn't} = 1$  during that period. Hence we can also redefine the flow existence as a Boolean variable  $X_{nn't} \in \{\text{True}, \text{False}\}$  and rewrite Equation (1b) with the following disjunction:

$$\left[ \begin{array}{l} X_{nbt} \\ F_{nb}^L \leq F_{nbt} \leq F_{nb}^U \end{array} \right] \vee \left[ \begin{array}{l} -X_{nbt} \\ F_{nbt} = 0 \end{array} \right], \quad (n, b) \in \mathcal{A}, t \in \mathcal{T}. \quad (3)$$

Equations (1c) and (1d) can be reformulated via similar GDP disjunctions. Moreover, Equation (1h) can be reformulated using GDP logical propositions:

$$X_{nbt} \Rightarrow Y_{bt}, \quad (n, b) \in \mathcal{A}, t \in \mathcal{T} \quad (4a)$$

$$X_{bnt} \Rightarrow \neg Y_{bt}, \quad (b, n) \in \mathcal{A}, t \in \mathcal{T} \quad (4b)$$

All these GDP equations are substituted into Formulation (1) to yield the GDP-based MPBP, which generalizes the GDP formulation proposed in (Lotero et al., 2016) to account for time-varying concentrations (prevalent in produced water constituents). Note that this formulation extends the one presented in (1) to account for the tank operating mode to yield fewer bilinearities after operating modes are determined.

#### 2.4. GDP with Redundant Constraints (RC)

Typically, mixed-integer solvers employ continuous relaxations of the problem (by relaxing variable integrality) to iteratively obtain an optimal solution. Tight relaxations often provide high-quality solutions relative to the mixed-integer formulation, which can accelerate solver convergence. One way to tighten relaxations is to include additional constraints therefore redundant that provide no additional modeling information but further restrict the feasible region.

We derive redundant constraints for our GDP formulation by tracking component flow origins:

$$F_{mn't} = \sum_{r \in \mathcal{R}} \tilde{F}_{rnm't}, \quad (n, n') \in \mathcal{A}, t \in \mathcal{T} \quad (5a)$$

$$I_{bt} = \sum_{r \in \mathcal{R}} \tilde{I}_{rbt}, \quad b \in \mathcal{B}, t \in \mathcal{T} \quad (5b)$$

where  $\mathcal{R} := \mathcal{S} \cup \widehat{\mathcal{B}}$  is the set of possible initial origins,  $\widehat{\mathcal{B}}$  is the set of blending tanks with nonzero initial inventory, and  $\tilde{F}$ ,  $\tilde{I}$ , and  $\tilde{C}^0$  are the flows, inventories, and initial composition identified by origin, respectively. Following Lotero et al. (2016), we employ other redundant constraints to strengthen the GDP formulation, and we refer the reader to that work for more details and analysis on the tightness of the relaxation.

#### 2.5. Two-Stage MILP-MIQCP Decomposition

We can pose a two-stage decomposition to the above GDP formulations for complex MPBPs that incur high computational cost. We define an upper-level problem that omits the bilinear species balances to obtain a linear formulation that provides an upper bound  $UB$  on the optimal solution and candidate operating states of  $Y_{bt}$ . Then we define a lower-level problem that fixes  $Y_{bt}$  in the full formulation to the values provided by the upper-level problem and removes the bilinear terms corresponding to idle/discharging tanks. When feasible, the lower-level problem provides a lower bound on the optimal solution. Integer cuts are added to the upper-level problem after each run of the lower-level problem as shown in (Lotero et al., 2016):

$$Z \leq -(UB - Z^i) \left( \sum_{b \in \mathcal{B}, t \in \mathcal{T} | \hat{y}_{bt}^i = 1} y_{bt} - \sum_{b \in \mathcal{B}, t \in \mathcal{T} | \hat{y}_{bt}^i = 0} y_{bt} \right) + \quad (6a)$$

$$(UB - Z^i) \left( \sum_{b \in \mathcal{B}, t \in \mathcal{T}} (\hat{y}_{bt}^i) - 1 \right) + UB, \quad i \in \mathcal{I}_O$$

$$\sum_{b \in \mathcal{B}, t \in \mathcal{T} | \hat{y}_{bt}^i = 1} (1 - y_{bt}) + \sum_{b \in \mathcal{B}, t \in \mathcal{T} | \hat{y}_{bt}^i = 0} y_{bt} \geq 1, \quad i \in \mathcal{I}_F \quad (6b)$$

where  $Z$  is the objective of the upper-level problem,  $y_{bt}$  are the binary variables associated with  $Y_{bt}$ ,  $\hat{y}_{bt}$  are the fixed values of the tank modes at the  $i^{th}$  iteration, and  $\mathcal{I}_O$  and  $\mathcal{I}_F$  contain the feasible and infeasible iteration indices, respectively. Here, Equation (6a) is added based on a feasible lower-level solution, and Equation (6b) is added based on infeasible solutions. Iterating between upper- and lower-level problems leads to convergence to a globally optimal solution of the MPBP. The gap of the decomposition is calculated between the upper and lower bounds ( $LB$  and  $UB$ ) as shown in Equation (7) where  $\epsilon$  is a small tolerance. A formal analysis is provided in (Lotero et al., 2016).

$$\text{Gap} = \frac{UB - LB}{LB + \epsilon} \quad (7)$$

### 3. Case Study

We compare the formulations in Section 2 via two case studies focused on delivering a lithium rich stream from a network of produced water sources. Case 1 is a smaller system composed by a subset of the tanks considered in Case 2. Produced water with varied lithium concentrations is produced at different wells and a source of fresh water is available. Several demand nodes are considered with their respective schedules for feed quality and quantity. We choose parameters based on those reported by Dworzanowski (2019) and Figure 1 details the topology of Case 2.

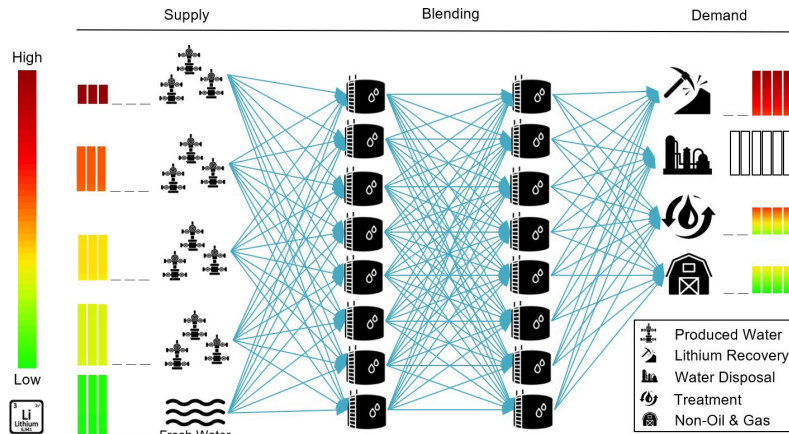

Figure 1: Topology of Case Study 2. Edges that connect sources with demands directly are considered in the case study but are not shown in the figure for simplicity.

GDP problems are often solved via big-M reformulation (BM) or Hull reformulation (HR) (Grossmann and Trespalcacios, 2013; Lee and Grossmann, 2000). Previous work conducted by Lotero et al. (2016) and Ovalle Varela et al. (2021) only use BM reformulations. We explore solving these formulations using both BM and HR to study their impact on solution performance. We implement all approaches in Pyomo.GDP on a Linux machine with 8 Intel® Xeon® Gold 6234 CPUs running at 3.30 GHz with 128 hardware threads and 1 TB of RAM with Ubuntu. We use Gurobi v9.5.1 and BARON v22.7.23 as appropriate to solve all formulations. We impose a target optimality gap of 1% and 3% for case studies 1 and 2, respectively; moreover, we set a wall-time of 3600s.

Table 1: Approach comparison for the lithium recovery case studies

Upper-level	Lower-level	Case 1		Case 2	
		Time [s]	Gap[%]	Time [s]	Gap[%]
MIQCP	-	843.87	0.77	3,600	20.02
GDP (BM)	-	3,600	61.10	3,600	47.91
GDP (HR)	-	3,600	-	3,600	-
RC (BM)	-	69.05	1.00	3,600	26.33
RC (HR)	-	3,600	1.30	3,600	-
RC (BM)	RC (BM)	160.57	<b>0.03</b>	3,600	-
RC (HR)	RC (BM)	<b>12.54</b>	0.08	<b>54.1</b>	<b>1.08</b>

Table 1 shows the solution time and final optimality gap of each solution method and case study. The columns corresponding to the levels indicate the selected formulation and GDP reformulation (BM or CH) when applicable. Rows without an entry in the lower-level column are solved directly

without the two-stage decomposition. Note that the two-stage decomposition using RC (BM) and RC (BM) was originally proposed by Lotero et al. (2016), and decomposition using RC (HR) and RC (BM) is proposed in this work. The results from Case 2 suggest that the monolithic formulations readily become intractable, which justifies the use of decomposition strategies. In fact, only our proposed decomposition is able to achieve an optimal solution for Case 2 within the wall-time. Hence, we observe that the choice of GDP reformulation strategy can significantly affect solution performance.

#### 4. Conclusions

The multiperiod blending problem is a nonconvex mixed-integer quadratically constrained program that is challenging to solve for real life applications such as lithium recovery from produced water. We observe that the previous solution approaches considered in this work are extremely expensive computationally for this problem class. Moreover, our adaptation of the two-stage decomposition approach to use hull reformulations significantly enhances scalability. These results motivate further investigation into how combinations of possible formulations, GDP solution techniques, fixing strategies, and solver tunings can accelerate the convergence of the two-stage decomposition strategy considered in this work. Future work also includes integrating these formulations within the PARETO framework (Drouven et al., 2022) for REE-CM recovery extensions.

## Abstract

In this paper, we propose the integration of a state and parameter estimation step with closed-loop dynamic real-time optimization (CL-DRTO). Different from other dynamic real-time optimization strategies, CL-DRTO uses a dynamic model that considers the closed-loop response of the plant under the action of a controller. So far, plant feedback has been incorporated into CL-DRTO using an additive noise paradigm by a bias updating strategy. In this work, we perform the feedback step in CL-DRTO updating model states and parameters via Moving Horizon Estimation. As an additional contribution, we compare CL-DRTO with two other production optimization schemes, Steady-state Real-time Optimization (SRTO) and Real-time Optimization with Persistent Parameter Adaptation (ROPA). In the latter, a dynamic model is used for only the state and parameter estimation step in SRTO, eliminating the requirement for the plant to be at steady state prior to the economic optimization execution. We show that CL-DRTO outperforms the other two schemes in terms of economic and control performance when applied to systems under control performance limitations.

**Keywords:** real-time optimization; dynamic real-time optimization; closed-loop; state estimation; parameter estimation.

## 1. Main Text

Dynamic real-time Optimization (DRTO) is a useful tool for improving plant economic performance in an increasingly dynamic market environment. DRTO computes optimal trajectories for the plant decision variables by maximizing an economic performance index subject to the system dynamics and operational/quality constraints. The optimal decisions are then sent to the plant controllers, which are responsible for implementing the computed values. In contrast to the traditional Steady-state RTO (SRTO) (Chen and Joseph, 1987), DRTO utilizes a dynamic plant model, making it better suited for systems that exhibit slow dynamics and/or frequent transitions.

The dynamic models employed at the DRTO level are often derived under a “perfect control” assumption. That is, the control response time for disturbance rejection and setpoint tracking is assumed negligible when compared to the DRTO sampling time. However, depending on the controller tuning and the system characteristics (e.g., long dead time, inverse response, etc.), this assumption may not hold. To address this issue, Jamaludin and Swartz (2017) proposed a closed-loop DRTO (CL-DRTO) scheme in which future control actions of an underlying constrained MPC system are considered. By rigorously predicting the interaction between controllers and system response, CL-DRTO improves the system performance compared to the open-loop counterpart.

One important challenge when applying CL-DRTO is how to use plant information to update the model. In the previous CL-DRTO implementations, the plant condition is represented in the model by an additive model uncertainty. Here, the difference between the measurements at the current time and the predicted output by the model is computed as a "bias", which is then added to the model outputs and kept constant over the CL-DRTO prediction horizon (similar to the typical DMC/QDMC updating scheme). Despite presenting good results for a variety of case studies, this feedback strategy is not flexible in terms of different noise structures, which is critical for the model updating step (Kolås et al. 2008). For example, if a certain parameter drifts away from its nominal value, simply adding a bias to the model outputs may not suffice to rigorously represent the plant condition in the model.

Therefore, we propose the use of a Moving Horizon Estimator (MHE) for updating the model in CL-DRTO. With this model updating formulation, we can represent the model uncertainty using time-varying parameters by augmenting the states with a parameter vector. Therefore, we are not limited to an additive noise representation, which may lead to an improper model updating depending on the nature of the model uncertainty (Kolås et al. 2008). To benchmark this new model updating strategy, we compare CL-DRTO + MHE with two other production optimization schemes that also deal with model uncertainty via online parameter estimation, namely Steady-state Real-time Optimization (SRTO) and Real-time Optimization with Persistent Parameter Adaptation (ROPA) (Matias and Le Roux, 2018). In ROPA, a dynamic model is used for only the state and parameter estimation step in a SRTO, which eliminates the requirement for the plant to be at steady state prior to an RTO execution. We show that the combination of CL-DRTO and MHE yields a superior performance over the other two schemes in terms of economic and control performance when the controllers are detuned or tuned too aggressively.

## 2. Case Study: Distillation Column

The distillation column described in Skogestad (1997) is used as the case study. The column has 40 theoretical stages and the goal is to separate an ideal binary mixture and obtain a top product with 99% purity. A diagram of the distillation column and of the

Figure 1: Distillation column diagram adapted from Skogestad (1997)

control structure is shown Figure 1. The model follows these assumptions: binary mixture; constant relative volatility; equilibrium on all stages; total condenser; constant molar flows; no vapor holdup; and linearized liquid dynamics.

For the control structure, we assume perfect pressure control, i.e. constant pressure, and we use the LV-configuration, where the reboiler and condenser levels are controlled using the bottoms (B) and distillate (D) flows, respectively. For composition control, we use the one-point control strategy, where the reflux (L) is used to control the top composition  $x_D$  and

the bottom composition is left uncontrolled. Hence, the boilup ( $V$ ) is the only degree of freedom (independent variable) of the system.

Ideally, these controllers should be tuned such that they yield a fast control loop response. However, in practice, this fast-responding tuning may lead to aggressive behavior to disturbances and setpoint changes. Consequently, the controlled variable may oscillate and overshoot before settling around the setpoint, which is undesired from a practical point of view. One alternative is to detune the controllers and change the gains to obtain a slower and smooth response, i.e., less oscillatory, and more tolerant to changes in process conditions. The problem is that this strategy goes against the “perfect control” assumption at the production optimization layer.

### 3. Simulation Setup

We tuned the sump and condenser level controllers for tight control. On the other hand, the parameters of the top composition control were chosen to achieve a smooth and slow response subject to acceptable disturbance rejection. The controller sampling time is set to  $\Delta t_{cont} = 5$  s.

The plant is affected by disturbances (Figure 2) in the feed fraction ( $z_F$ ), which we assume as unknown, and in the relative volatility ( $\alpha$ ) of the mixture. The rationale behind the disturbances is the following: the feed fraction may vary depending on the unit load and its actual value may be hard to determine exactly due to an upstream tank layering, or the variations of the raw material. The oscillation in  $\alpha$  may be connected to the vapor-liquid equilibrium and caused by changes in the column pressure setpoint.

Figure 2: Disturbance scenarios

For the economic optimization problem, we want to maximize the difference between the product revenues, considering their purity, and the utility costs (steam for the reboiler, and cooling water for the condenser). The heating and cooling costs are assumed to be proportional to the flows. The objective function can then be written as:

$$\Phi = c_1 D x_D + c_2 B x_B - (c_3 (D + L) + c_4 V) \quad (1)$$

in which,  $c_i$  are the respective prices and costs in  $[\$/\text{mol}]$ , and  $c = [1.5, 0.2, 0.03, 0.02] \frac{\$}{\text{kmol}}$ . Since the top stream contains the product of interest, we specify  $c_1 \gg c_2$ . For the economic optimization problem, we also want to consider a constraint on the top purity ( $x_D \geq 0.99$ ).

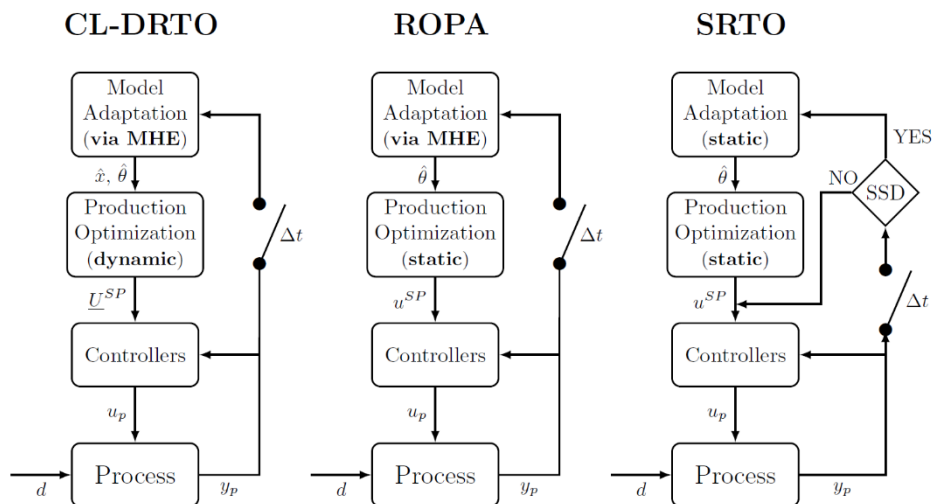

Figure 3: Block diagram of the production optimization methods

#### 4. Production Optimization Methods

The production optimization methods studied in this paper are implemented as shown in Figure 3. All methods are executed at the same rate ( $\Delta t = 15$  min), which is approximately the open-loop composition response time to changes in internal flows. Then, SRTO and ROPA optimize the future steady-state behavior of the plant and send this information to the controllers as the optimal setpoints ( $u^{SP}$ ), which are kept constant until the next cycle execution. On the other hand, CL-DRTO optimizes the behavior of the system (plant + controllers) for the next 75 minutes, discretized in intervals of 3 minutes. Next, a sequence of 5 setpoints ( $\underline{U}^{SP}$ ) is sent to the controllers. Similar to the other two methods,  $\underline{U}^{SP}$  is updated every 15 minutes.

In the SRTO case, the steady state detection (SSD) was performed based on the comparison of total variance of a signal in a fixed length window of measurements with the total variance of subsequent measurements within the same window length (see Tool A in Camara et al. (2016)). If this ratio of variances (R-statistics) is below a chosen threshold, we assume that the two variances come from the same distribution and, consequently, the process is at steady-state. We use a composition in the rectifying section as a steady-state representative measurement. The other system measurements  $y_p$  are 4 compositions along the distillation column and the sump and reboiler levels. For the formulation of the Production Optimization (dynamic and static) and Model Adaptation (static) block, please refer to Matias et al. (2022). The model adaptation via MHE is shown next.

##### 4.1. Dynamic State and Parameter Estimation via Moving Horizon Estimator (MHE)

We assume that the uncertainty structure is known, and the plant-model mismatch can be compensated by estimating the model parameters  $\theta$  (here,  $z_F$  and  $\alpha$ ), which represent the disturbances  $d$  from Figure 2. Hence, the MHE formulation can be written as:

$$\begin{aligned}
& \min_{\theta_k, x_k} \left( \begin{bmatrix} x_{t_0 - N_e} \\ \theta_{t_0 - N_e} \end{bmatrix} - \begin{bmatrix} \hat{x}_{t_0 - N_e} \\ \hat{\theta}_{t_0 - N_e} \end{bmatrix} \right)^T \Pi_{x, \theta} \left( \begin{bmatrix} x_{t_0 - N_e} \\ \theta_{t_0 - N_e} \end{bmatrix} - \begin{bmatrix} \hat{x}_{t_0 - N_e} \\ \hat{\theta}_{t_0 - N_e} \end{bmatrix} \right) + \\
& \sum_{k=t_0 - N_e}^{t_0} (y_{p,k} - y_k)^T Q_y (y_{p,k} - y_k) + \sum_{k=t_0 - N_e + 1}^{t_0} (\theta_k - \theta_{k-1})^T Q_\theta (\theta_k - \theta_{k-1}) \\
& \text{subjected to:} \\
& x_{k+1} = F(x_k, u_{p,k}, \theta_k) \quad k = \{t_0 - N_e, \dots, t_0 - 1\} \\
& y_k = Hx_k \quad k = \{t_0 - N_e, \dots, t_0\} \\
& x_k \in \mathcal{X}, \quad \theta_k \in \Theta \quad k = \{t_0 - N_e, \dots, t_0\}
\end{aligned} \tag{2}$$

where, the subscript  $k$  represents a given sampling time,  $t_0$  is the current time, and  $N_e$  is the estimation window length.  $x$  and  $y$  are the model states and outputs.  $u_p$  and  $y_p$  are the inputs implemented in the plant and plant measurements.  $F(\cdot; \cdot)$  is the discretized dynamic model, which considers the underlying PI controllers.  $H$  is a selector matrix.  $Q_y$  and  $Q_\theta$  are symmetric positive definite tuning matrices.  $\mathcal{X}$  and  $\Theta$  are the feasible state and parameter set.  $\hat{x}_{t_0 - N_e}$  and  $\hat{\theta}_{t_0 - N_e}$  are the most likely prior value of states and parameters at the beginning of the estimation window, and  $\Pi_{x, \theta}$  is the arrival cost matrix. The latter is used for summarizing the information before the estimation window and we use an extended Kalman Filter to compute it. Note that in this MHE formulation we assume that the parameters change within a sampling time following a random walk model.

## 5. Results and Discussion

The results are shown in Figure 4. Regarding the system disturbances, Figure 4a shows that MHE is able to estimate the uncertain parameters/disturbances accurately, even though they drift away from their nominal value with time. Moreover, we note that SRTO is seldom executed (executions are indicated by red circles) because the plant is at steady-state only for short periods due to the nature of the disturbances. This influences how often the boilup rate  $V$  (the free manipulated variable) is updated in the SRTO simulation. In Figure 4b, we note that  $V$  is updated only twice, which decreases SRTO economic benefits. On the other hand, the values of  $V$  computed by ROPA are a good approximation of the CL-DRTO, where the transients are rigorously optimized.

The main benefits of CL-DRTO, i.e., predicting the underlying behavior of the controllers, can be seen in Figures 4c and Figure 4d. In Figure 4c, we show the profile of the distillate rate determined by the condenser level controller, which was tuned to obtain fast level control. The consequence is the highly oscillatory behavior of the control variable  $D$  in ROPA simulations. On the other hand, CL-DRTO takes the aggressive control actions into account and the resulting behavior of  $D$  presents only minor oscillations, which are necessary to maintain the level constant due to the relatively small holdup of the condenser. For the top constraint controller (Figure 4d), we see the detrimental effect of the slow control tuning in ROPA. Even though the manipulated variable profile  $V$  is relatively well approximated as shown in Figure 4b, the slow composition control is not able to maintain  $x_D$  above 0.99. Moreover, the implementation of the setpoints computed by ROPA and SRTO overpurify the top stream, which causes a negative effect on the economic performance. The cumulative profit achieved by the methods in [\$] are  $\Phi_{cumm.SRTO} = 451$ ,  $\Phi_{cumm.ROPA} = 446$ , and  $\Phi_{cumm.CL-DRTO} = 455$ . Hence, ROPA and SRTO lead to smaller cumulative profits than CL-DRTO.

## 6. Conclusion

We explored the use of state and parameter estimation in Closed-loop Dynamic Real-time Optimization and evaluated the benefits of using this plant feedback strategy when compared to two other production optimization methods that incorporate plant information via online parameter estimation: Steady-state Real-time Optimization and Real-time Optimization with Persistent Parameter Adaptation. The simulations were conducted using a distillation system case study. The results show that the performance limitations caused by detuning or tightly tuning the controllers can be overcome by CL-DRTO, while they have a detrimental effect on the performance of the other two methods.

## Abstract

Crude oil feed instability can cause significant problems in refineries, where various types of crude oils are processed and frequent feed changes are taken place. In particular, if crude oil changes are performed in a short time, it can create various operational disruptions in the Crude Distillation Unit (CDU). In case of a sudden increase or decrease of light ends in the CDU feed, pressure fluctuation or flooding problems can occur in the atmospheric distillation column. In order to prevent potential upset cases caused by crude changes, an unsupervised machine-learning model was developed. The model which is presented in this article analyzes the high-correlated relationship between pressure of column flash zone, upper and lower diesel trays in steady-state operation. Principal Component Analysis (PCA) is performed with these three inputs. The PCA reconstruction error is calculated with new process values in every minute and the pressure profile in the column is instantly detected by the error. A soft sensor was developed by applying the unsupervised anomaly detection method to detect off-spec color.

**Keywords:** Crude oil distillation, diesel off-spec color, unsupervised anomaly detection, Principal component analysis

## 1. Introduction

The crude distillation unit separates the components in crude oil by utilizing the difference in boiling points (McCaffrey, 2021). Product yields differ depending on the choice and origin of crude oil. Due to market conditions, refineries today prefer to process crude oil from different sources. However, operational conditions like the blending of different crude oils, rapid crude-oil tank changes, or operation capacity maximization can lead to challenges for column operation. These challenges make the operation more susceptible to potential operational faults or other process disruptions. In such cases, flooding and weeping problems can be seen in the atmospheric column. In this article, diesel off-spec color change triggered by flooding prediction is submitted. Although there are other reasons causing off-spec color like pH change or preheat-train heat exchanger leaks, these conditions are not taken into account for prediction (Kister, 2006).

A flooding prediction model was developed because there is no online ASTM color analyzer system in the process that automates the color measurements (ASTM D1500-12(2017)). When a color change of the product is detected by routine laboratory samples or by visual controls, the product has already become off-spec. Therefore, an analytical

model development was considered necessary. Since flooding is a rare anomaly in normal operation, historical data obtained from the process becomes also imbalanced. Overfitting and inaccurate results can be observed in traditional supervised approaches which apply train-validation separation in the dataset, and these models can be inadequate against the problem. For this reason, an unsupervised anomaly detection model was adopted to overcome this weakness.

It is known in the literature that the temperature diagram, fraction yields, or column pump around flows can play a role in flooding identification. Since these parameters are also intervened in steady state operating conditions, flash zone pressure, diesel lower and upper stage pressures were used instead of these process parameters. An unsupervised anomaly detection model based on Principle Component Analysis (PCA) and PCA Reconstruction Error was deployed on Distributed Control System (DCS) for flooding. The model was developed by Python programming language and Python Anomaly Detection Tool Kit (ADTK) library was used for PCA method. After this study, the model detected a real diesel off-spec color case triggered by flooding 100 minutes before happening. With the early warning system, operators took action to adjust the operation to prohibit color changes in products

## 2. Methodology

### 2.1. Flooding and Off-Spec Mechanism

The objective of the crude unit (CDU) is to process a crude oil blend into its fractions by means of boiling point differences. In distillation process, flooding and weeping are common problems that can occur and cause loss of separation. The flooding problem is a complicated abnormality whose mechanism is based on liquid or excessive vapor phase accumulation and liquid-vapor separation inability. Although flooding reduces separation efficiency in the column dramatically, there can be additional and more crucial effects in the process like feed rate reduction, operational interruption, or off-spec product (Kister and Olsson, 2019). As can be seen both in the refinery incidents and in the literature, flooding causes a sudden increase in delta pressure in the column and can cause off-spec color diesel which is also called as black diesel. (Bird et al., 2018).

Figure 1: Typical Distillation Column Schema

A typical distillation column scheme was given in Figure 1, where P1 refers to flash zone pressure, P2 and P3 refer to diesel lower tray pressure and diesel upper tray pressure. In case rapid pressure difference changes between P1 and P2 or P3, product draw-off amounts from column trays are also changed. This causes heavy components to come

along with the bottom stream and turns the diesel color black (Bird et al., 2018). Fortunately, flooding and off-spec color prediction are possible by examining the pressure at these stages. This study gives a chance to the operator sufficient time to eliminate the risk of flooding.

### *2.2. PCA Analysis and Reconstruction Error*

Principle Component Analysis (PCA) is a classical statistical method that creates principle components that refer to the data set. Firstly, data is converted to a matrix, and vectors are generated by the decomposition of this matrix. As a second step, the original data is reconstructed by the first principle components, and reconstruction error is calculated with the difference between the new reconstructed data and the original data. The difference between the new matrix and the original data matrix is compared at each model run and gives an error. Calculated reconstruction error is examined by anomaly detection method, to expose at which level of error there is abnormal or not. With the increase in error, anomalies that occur in the process are detected (McCaffrey, 2021). Although there is no supervised learning included in this method, both high correlation in the dataset and strong coherence in the time series, generate a natural knowledge for the model. Therefore, the help of reconstruction error rise in value can detect anomalies in the data effectively. Unsupervised Anomaly Detection Machine Learning models based on PCA analysis are widely applied to industrial problems (Takeishi, 2019).

Another benefit that enables PCA analysis valuable in the industry is dimension reduction. Today, the management and control of any distillation unit are operated more efficiently and stable by engineers and operators with the help of transmitters and process control systems. The presence of many transmitters such as temperature, pressure, and flow, allows the system to be controlled with more assurance. However, having many measurement points, which are highly correlated to each other, makes data analysis more complicated and model data larger. The PCA algorithm eliminates this situation, which is known as multicollinearity. In PCA method, new independent orthogonal variables are created. At this point, PCA analysis is used as a rapid and efficient multivariate statistical method with ease of PCA reconstruction error that can be successfully applied in industry to detect abnormal situations or deviations in the process (Thomas et al., 1996).

### *2.3. Data Flow from Business Network to DCS and Application*

Model outputs were integrated into the Industrial control system (ICS) so that control operators can use the results. Process Data History (PHD) in PHD Historian is operated to collect and pull the live process data and the results are calculated with Python code. After calculation, results are sent to Distributed Control System (DCS) for operator control. Purdue Enterprise Reference Architecture (PERA) model by ISA-99 was used as a concept model for ICS network segmentation (ANSI/ISA-TR99.00.01-2007) Deployed anomaly model was observed to predict flooding 100 minutes in advance. By adding an alarm to the tags created in the DCS system, audible and written warnings are created for the operator to take action. When the operator receives an alarm from the system, they try to reduce the risk of flooding by interfering with the crude oil column product drafts, pump around flows, or return temperatures.

### 3. Results and Discussion

Pressure differentiation is not the only reason for product color change. Incorrect process control tunings, abnormal column temperatures, abnormal operation of condenser or furnaces, physically damaged inner-column parts, leaks in exchangers or high nitrogen levels in the crude mix may also cause darker color. Each of these parameters were examined one by one before the study. Since sudden pressure changes and sudden increase in column level was detected during off-spec product, it was estimated that the problem was caused by flooding and a pressure-induced model can help to detect off-spec color. An unsupervised anomaly detection model based on PCA analysis was studied over the pressure parameters in the CDU column to predict the flooding abnormality and off-spec diesel color. Pressure transmitters at the column flash zone, diesel stage lower tray, and upper tray were used with the help of their highly correlated interactions.

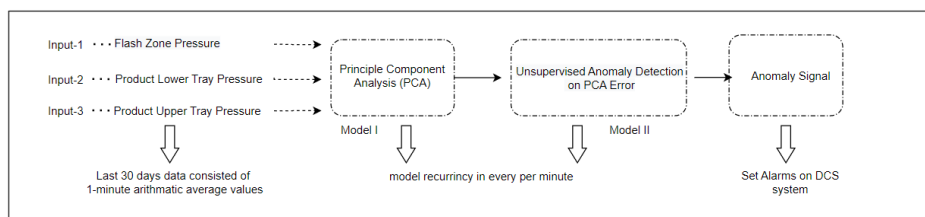

Figure 2: Data structure in the model

Not only early flooding detection but also taking fast action is significant for unit operation. Therefore, the model was scheduled to run once per minute. By processing data from the last 30 days to the model at each run, the normal fluctuation and noise level in the steady state process are understood by the model despite unsupervised learning. The data structure was created with 1-minute average values to increase sensitivity against small new changes in operation. The data architecture drawing was given in Figure 2.

A real diesel off-spec color change case, which was detected by the analytical model, is seen in Figure 3. Pressure parameters used in the model, atmospheric distillation column level, PCA reconstruction error, and delta pressure are the process parameters shown in the figure after rescaling between 0 and 1. Hairline I indicates that the model alarmed at 5:45 (see figure 3c) when incipient flooding occurred, and hairline II indicates runaway flooding occurred at 7:30 with column level increase (see figure 3 b).

Before hairline I, there was a high correlate movement of flash zone pressure, diesel lower and upper tray pressures, but the movement seems to have ceased just before the onset of the flooding initiation (see figure 3a). PCA analysis used this behavior between model parameters. The deterioration of the relationship between the parameters caused the increase in PCA error. However, it is seen that there was no increase in column level until hairline II, where flooding increased its severity. With this time difference, It was aimed to give the operator the necessary time to act.

Figure 3: Real case off-spec color triggered by flooding

In literature knowledge, delta pressure between product tray and flash zone is used as another method. In this method, delta pressure is used as a stand-alone indicator to detect flooding. (Deviation, 2009). During flooding, responses of delta pressure and PCA error can be seen as similar to each other (see figure 3d). However, this method was not preferred in the study. There are always continuous and small deviations in delta pressure (DP). Although a rapid increase of these deviations can be used to create an alarm condition, DP is usually manually controlled and changed by operators during ordinary operations too. This means, deviations coming from operational set point changes or process deviations can be confused by the flooding model and this can create false alarms.

Figure 4: Historical data prior to flooding. a) Pressure diagram, b) PCA reconstruction error, c) Delta pressure between flash zone and diesel stage

One-month pressure changes of diesel flash zone and diesel trays are given in figure 4a. The operational changes and process noises were seen to create bigger noises during both flooding case and steady-state operation period (see figure 4c). On the other hand, PCA reconstruction error seems more stable during steady-state period and started a rapid increase during only flooding (see figure 4b). For this reason, PCA analysis was preferred as an alternative model in this application. Instead of using the delta pressure alone, a PCA error-based unsupervised anomaly detection model was developed with flash zone, upper and lower diesel pressures.

Nevertheless, delta pressure calculation was also used for understanding if there was a positive or negative differentiation in the column. Inferential was developed based on PCA analysis, and DP was added as a supportive decision mechanism for the operator to see to filter flooding conditions among all abnormal conditions like weeping.

#### 4. Conclusion

Crude oil feed instabilities can create instability in atmospheric distillation column and can cause upsets like flooding and weeping. In the article unsupervised anomaly detection model based on PCA analysis was used for early flooding detection which can cause off-spec color changes. It has been seen that the developed model predicted a real flooding and color change case 100 minutes in advance. The off-spec color formation was seen by a diesel laboratory sample. The study was proven and confirmed by users. Any off-spec problem has not been observed in the refinery for one year.

# Artificial neural networks-based identification of the WWTP DO sensor types of faults

Norbert-Botond Mihály<sup>a</sup>, Alexandra-Veronica Luca<sup>a</sup>, Vasile Mircea Cristea<sup>a\*</sup>

<sup>a</sup>*Babes-Bolyai University of Cluj-Napoca, 1 Mihail Kogalniceanu Street, 400028 Cluj-Napoca, Romania*

## Abstract

Efficient and sustainable operation of the wastewater treatment plants using the activated sludge technology strongly depends on the aeration control. The role of the Dissolved Oxygen (DO) sensor for achieving the desired performance of the control loop is critical and the faults of the sensor have to be identified with promptitude. The paper presents an effective artificial neural networks (ANN)-based diagnosis and identification methodology for seven types of DO sensor faults, revealing the advantages of the proposed identification approach. The classification ANNs trained with the Bayesian regularization method showed high accuracy in identifying the fault classes, with an overall accuracy of 99.5% for the testing dataset. The developed ANNs allow the efficient and early detection of the sensor fault presence, while performing the correct identification of the sensor fault type.

**Keywords:** Artificial Neural Networks, fault type diagnosis, Dissolved Oxygen sensor.

## 1. Introduction

Increased awareness of the eutrophication negative impact on water quality and advances in environmental protection technologies have resulted in more stringent wastewater treatment requirements. Regulations developed during recent decades have followed this trend. Tightening treatment regulations are driving the addition of new processing units and renewal of existing ones in the wastewater treatment plants. The subsequent increase in operational and management investments, primarily related to energy consumption and sustainable development, encouraged modern WWTPs to meet the challenges of preserving and enhancing effluent quality while ensuring efficient and safe operation, associated to cost optimization (Haimi et al. 2013).

For comprehensive process monitoring and efficient control, accurate measurement of the composition, flow rate and temperature of the influent, effluent and process streams are obviously required. Furthermore, satisfying the needs for safety and effective process control asks for the ability to detect sensor faults as early as possible. Monitoring and control at the WWTP are focused on specific equipment, such as biological reactors, settlers, pumps, air blowers, control valves, diffusers, and the pipeline system (Morera et al. 2017). Composition measurements make use of sensors that monitor Dissolved Oxygen (DO), nitrates and nitrites, ammonia, phosphorous, suspended solids, and organic matter (Mamandipoor et al. 2020). The precise information provided by these sensors is essential for the efficient and secure operation of the entire plant.

Development of numerous methods have been aimed for fault detection. Due to their inherent detection capacity, multivariate statistical methods have the ability to reveal faults in time-varying, ill-defined, and non-linear systems (Li and Yan 2019). The role of the Dissolved Oxygen sensor for achieving the desired performance of the nitrification

control loop is critical and the faults of the sensor have to be identified with promptitude. Few studies have been conducted to investigate the issue of DO sensor failures. PCA methodology was used to detect deviations due to sensor clogging (Samuelsson et al. 2018), while another study implemented PCA for data driven detection of oxygen sensor faults (Luca et al. 2021).

Artificial intelligence (AI) techniques have been aimed to perform sensor fault detection and error type diagnosis in a variety of fields. They span over different applications, such as error diagnostic strategies for vapor compression refrigeration system (Kocyigit 2015), on-line fault detection of a sensor in a nuclear reactor core (Messai et al. 2015), fault detection and isolation in sensors of an internal combustion engine (Cervantes-Bobadilla et al. 2023), and fault diagnosis of vibration signals (Zhang et al. 2022).

AI was proven to be an effective tool, intended to target various implementations in WWTPs for: prediction of process parameters (Zaghloul and Achari 2022), prediction of plant performance indices and operation optimization by finding the control loop setpoints (Mihály et al. 2022a), optimization of aeration in the aerobic reactor (Mihály and Cristea 2022b), and optimization of recycle flowrates for better effluent quality and energy savings (Mihály et al. 2022c). One fault diagnosis using ANNs was successfully applied to sludge bulking measurements with the intention of ensuring process safety and WWTP effluent quality. The developed model could differentiate five types of sludge bulking faults (Han et al. 2019). However, artificial neural networks (ANNs) were scarcely applied to the identification of WWTP sensor faults.

The scope of the current paper is to design, train and test the performance of an ANN based tool that is capable of detection and identification of seven types of Dissolved Oxygen sensor faults. The novelty consists in the application of proposed ANN diagnosis tool for the municipal A<sup>2</sup>O WWTP, having implemented the two main control loops, one for nitrification and another for denitrification.

## 2. Methodology

### 2.1. Data generation

The data implied by the development of the ANN fault identification tool were obtained using a previously calibrated first-principle Activated Sludge Model no.1 for the Anaerobic-Anoxic-Oxic reactors configuration (Várhelyi et al. 2019) of the WWTP considered as case study. Seven types of sensor faults were simulated for the Dissolved Oxygen sensor: bias, also known as shift or off-set of the signal; complete failure, which can be maximum or minimum and occurs when the measured value is either the highest or the lowest value of the sensor calibration range; drift, which is an irregularly varying deviation in time of the measured value, compared to the true DO one; fixed value, when the DO signal value is constant; loss of accuracy, meaning that the value provided by the sensor is affected by imprecision around the true value; wrong gain, known also as a typical calibration error (Luca et al. 2021). They were denoted with class numbers ranging from two to eight, while normal fault-free case was considered as class number one.

The first 100 days of the simulations were performed in normal (nominal) operation and were considered for obtaining the regular (quasi-stationary) state of the WWTP. The simulation continued in normal operation mode until day 140, where the different types of DO sensor faults were implemented until the 160<sup>th</sup> day of operation. Data obtained during these 20 days of either normal or faulty operation periods, with a sampling time of 15 minutes, was used in the development of the classification ANNs. The same data generation approach, for a different fault identification methodology, was implemented in a previous study and where additional information can be found (Luca et al. 2021).

### 2.2. ANN development

A set of process parameters were utilized in the development of the ANNs. They were the clean effluent concentration of the variables: total nitrogen, total Kjeldahl nitrogen, chemical oxygen demand, nitrate and nitrite nitrogen, free and saline ammonia, and total suspended solids. The following concentration variables of the bottom effluent from the secondary clarifier were also taken into consideration: nitrate and nitrite nitrogen, free and saline ammonia, total suspended solids, slowly biodegradable substrate, heterotrophic biomass, autotrophic biomass, inert particulate products, particulate biodegradable organic nitrogen, soluble biodegradable organic nitrogen, Dissolved Oxygen concentration, readily biodegradable substrate, alkalinity, associated to waste flow rate, and the temperature variables. For the identification of the different DO sensor faults an ANN with two layers was considered, the first hidden layer with tangent-sigmoid transfer function, while the second (classification) layer with SoftMax as transfer function. The implementation of the first-principle model and development of ANNs were carried out in MATLAB & Simulink software environment. The hidden layer size (number of hidden neurons) was optimized by a trial-and-error process, searching around the number of ANN inputs, while the training efficiency was studied with both Levenberg-Marquardt and Bayesian regularization backpropagation training algorithms with variable learning rates.

### 3. Results and discussion

The dataset was divided in the following parts when the Levenberg-Marquardt training algorithm was employed: 70% for training, 15% for validation, and 15% for testing. The training results showed good results, with the exception of the highest obtained confusion value of 58.7%, due to the confusion between the complete failure maximum (class 3) and fixed value (class 6) fault types, characterized by comparable effects. This can be observed for the confusion matrix of the testing dataset presented in Figure 1.

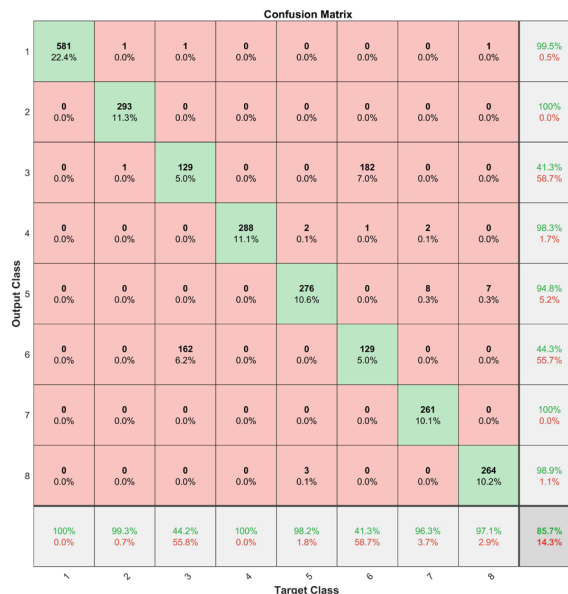

Figure 1. Confusion matrix of the testing dataset for ANN trained with Levenberg-Marquardt algorithm

However, the trained classification ANN properly detects the different fault classes, only in 0.5% of the cases classifying the faulty operation as normal (class 1). At the same time, the identification is fairly accurate except the previously mentioned confusion, while the next highest confusion percentage being of 5.2%, when loss of accuracy (class 7) and wrong gain (class 8) fault types are wrongly classified as drift faults (class 5).

In comparison to the previous training approach, the classification performed by the ANN trained with the Bayesian regularization algorithm showed better results. Results obtained for the testing data set are presented in Figure 2. This method of training did not require a validation dataset. Consequently, 85% of the data were used for training, while the remaining 15% constituted the testing dataset. In terms of training, the highest confusion value was of 1.1% in case of the wrong gain fault, where out of 1920 data points only 21 were classified as other fault classes. It is worth mentioning that neither at training, nor at testing were any of the faulty data points classified as normal (faulty-free) operation, and the previously confused complete maximum and fixed value sensor faults were correctly classified by this latter ANN.

Output Class \ Target Class	1	2	3	4	5	6	7	8	Accuracy

Overall	100% 0.0%	99.6% 0.4%	100% 0.0%	99.6% 0.4%	99.3% 0.7%	99.7% 0.3%	98.7% 1.3%	98.7% 1.3%	99.5% 0.5%

Figure 2. Confusion matrix of testing dataset for ANN trained with Bayesian regularization algorithm

Similar to the previous ANN, at the testing dataset we can observe that loss of accuracy and wrong gain fault types (classes 7 and 8) are the toughest to identify correctly, exhibiting the highest confusion percentage revealed by the reduced value of 2.1%. Regarding the training time of the two ANNs, the Levenberg-Marquardt algorithm was less time-consuming, as it required 1.3 minutes to run, while the training with Bayesian regularization lasted for 15.8 minutes. Even though there is a significant difference in computational resources needed between the two training algorithms, the superior classification accuracy offered by the second ANN leads to its ranking as the best and recommended classification model.

The classification with the second ANN for the testing data set and case of fault class 7 (loss of accuracy), which was collectively the most difficult to identify, are presented in Figure 3. The faulty operation of the WWTP is detected without time lag, from the very first failure point of the testing data (following day 140, when the sensor fault begins). The classification network quickly and correctly identified the different fault types in: 3 hours for bias, 2.5 hours in case of complete fail maximum, 2.5 hours at complete fail minimum, 3 hours for drift, 3.5 hours for fixed, 4 hours at loss of accuracy, and the longest identification of 11 hours in case of wrong gain also shown in Figure 3.

Figure 3. Classification of the testing dataset for loss of accuracy DO sensor fault

The practical implementation of the ANN based identification tools relies on the dedicated measuring instrumentation required to obtain in real time the variables used as ANN inputs. The classification offered by this ANN is of great importance for the efficient management of the WWTP and mitigation of both the environmental and economic negative impact that a faulty sensor causes by the late detection and identification of the fault. Depending on the type of the sensor fault, the CO<sub>2</sub> and N<sub>2</sub>O green House Gases emissions released during the faulty sensor operation may show increased values, characterized by factors reaching one order of magnitude higher than the values of the normal WWTP operation. They are also associated to the significant degradation of the discharged effluent water quality and harmfully affect the downstream river basin. The proposed ANN diagnosis for DO sensor fault types is useful for metrological maintenance of measuring equipment, producers of intelligent sensors and their integration in digital twins.

#### 4. Conclusions

In this study, the ANN-based sensor fault type identification method was proposed for diagnosing seven types of DO sensor faults, typical to the operation of a municipal case study WWTP. The DO measured values are of vary large importance for the aeration control loop, and they significantly influence the effluent quality, energy consumption

and sustainable operation of the plant. The investigated fault types (bias, complete failure maximum, complete failure minimum, drift, fixed value, loss of accuracy and wrong gain) were successfully identified by the classification ANN. Assessed for the testing datasets, a confidence level of 85.7% was achieved in case of the ANN trained with Levenberg-Marquardt algorithm, while this value was of 99.5% for the ANN trained with Bayesian regularization algorithm. The potential of the methodologies had been demonstrated by the efficiency of the ANN-based fault identification approach. Major practical importance can be attributed to the developed classification ANNs for the accurate monitoring and high-performing control of the WWTP complex and non-linear intrinsic processes, in support of their safe and efficient operation.

## Abstract

A major challenge faced by the chemical process industry is carrying out operations safely and safely. The proposed work entails a fault detection approach for a multivariate time series dataset by utilizing the energy scores instead of the traditional approach. This work proposes a loss function which utilizes the concept of in-distribution and out of the distribution of data. Energy scores are more theoretically aligned with the probability density of the inputs and can be used as a scoring function. For a pre-trained neural network, energy can be utilized as a scoring function and can also be used as a trainable cost function. The concept of out-of-distribution is similar to that of any outlier identification method. Similarly, for energy out of distribution, an energy value which falls below a certain threshold can be considered an outlier and is addressed as out-of-distribution. The values within the range are in-distribution. Higher energy values imply a lower likelihood of occurrence and vice versa. The proposed approach is compared with different deep learning approaches like Auto-encoders (AEs), LSTMs and LSTM-AEs that are traditionally used for anomaly detection and utilize the softmax scores. The Proposed methodology is also compared with some state-of-the-art fault detection methods, such as the PCA and DPCA and returns encouraging results. Energy based out of distribution is coupled with various deep learning methods to identify faulty and normal points. When teamed with the Auto-encoder network, energy-based scoring proved to be of significant dominance compared to other methods. The study was validated for the benchmark Tennessee Eastman data for fault detection.

**Keywords:** Fault detection, softmax score, energy score, outliers, Out-of distribution

## 1. Introduction

Anomalies or Outliers constitute a significant hindrance in the smooth functioning of the process industry. Fault detection or anomaly identification is one of the exercises that need to be carried out not only for safety purposes but also from a financial standpoint. Abnormal behaviour of the systems is a significant challenge not only for the chemical process plant but also for manufacturing, production and pharmaceutical industries. (Kodamana; 2017). Process models can be used to identify such faults, which are obtained either by first-principles-based models or data-based models. In systems with inherent non-linearity and non-Gaussianity, first-principle models are tougher to build. On the other hand, data-based models can account for all the difficulties faced by the first-principles models and can be applied due to their flexibility.

Over the years, several data-based methods have been developed for fault detection. Various machine learning approaches, such as Principal Component Analysis and Dynamic Principal Component Analysis (Rani, 2023), have been thoroughly used by the Process industries. Similarly, deep learning frameworks have also found their feet in the fault detection domain. Neural network architectures such as Auto-encoders (Sakurada, 2014), long short-term memory (LSTMs) (Nguyen, 2021; Yang, 2019) and an amalgamation of LSTM-AEs have been widely used. Deep learning architectures utilize neural networks to understand and learn a pattern for identifying faults. This work proposes an approach where the traditional neural networks are combined with the energy scores for fault classification. The loss function of the energy-based out-of-distribution is utilized for fault identification such that the problem of vanishing gradients does not occur in the system.

Various researchers have proposed out of distribution-based methods (Du, 2019) with different scoring functions. Scoring methods such as softmax score, Mahalanobis distance score, OE (Hendrycks, 2019) and ODIN (Liang, 2017) score are some of the distribution methods that the researchers have proposed. The energy-based scoring method proposed by (Liu, 2020) uses an energy-based score to identify the out-of-distribution data. In contrast, little to no work is done concerning the multi-variate time-series data for identifying faults using energy out-of-distribution methods. Compared to the softmax scores, energy scores are more theoretically aligned with the probability density of the inputs. The higher dimensional data can be mapped to a single dimension data with the help of energy scores. Based on the application, energy can be used as a trainable cost function for fine-tuning the classification model. A high energy value corresponds to a lower likelihood of occurrence and vice versa. Values exceeding a particular threshold can be considered under the umbrella of out-of-distribution and can be regarded as a fault. This serves as a classification method for faulty and normal points. The present work is carried out for Multivariate Time-series data and validated for the Tennessee Eastman Dataset benchmark. Energy-based scoring functions, when coupled with Deep learning frameworks, produced promising results. The remainder of the article is structured as follows: Section 2 contains the proposed methodology, Section 3 deals with the results and discussions, and Section 4 holds the conclusion and the significance of the proposed work.

## **2. Proposed Methodology**

### *2.1. Deep-Learning Frameworks for Fault Detection*

As discussed in the previous section, deep-learning-based fault detection methods have traditionally been used for fault detection. These architectures differ from each other in the way the neural network is designed for each of them. Different layers and number of neurons for each of the framework is used. Auto-encoder is a reconstruction-based operator. On the other hand, LSTM is not a simple feed-forward network but also has feedback connections for the neurons, and LSTM-AE utilizes the architecture of Auto-encoders in an LSTM model. The proposed methodology is presented in figure 1, where an auto-encoder network is considered, wherein an energy-based scoring method is used to detect the faults. Similarly, this methodology also considers different neural networks, as presented in the sub-sections below.

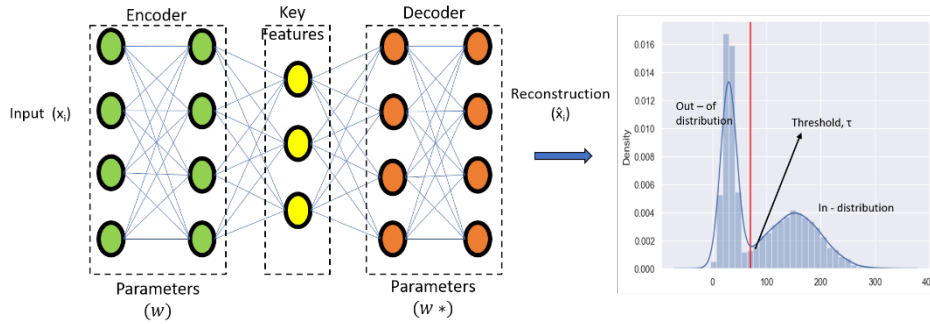

Figure 1: A schematic of the proposed Methodology.

### 2.1.2. Auto-Encoder (AE)

Auto-encoder network is a feed-forward neural network which has an encoder and decoder entailed it. The encoder tries to learn the data and converts it to a hidden space of lower dimension, and the decoder then captures the hidden space and reconstructs the original data. In a traditional auto-encoder, the mean squared error is used as a loss function, and the loss function is computed between the network output and the original input.

### 2.1.3. Long-Short Terme Memory (LSTM) Networks

LSTM networks are an extension of the Recurrent Neural networks (RNN), which can handle long-term dependencies. LSTM is not a simple feed-forward network; instead, it is a particular type of neural network that considers the previous neurons and takes inputs from them. LSTM considers sequential data and returns output for a specific window of time steps. It has three significant parts; in the first part, the model is trained to forget the irrelevant information, the second part learns the new information, and the third part returns the updated information from the current time step to the next time step.

### 2.1.4. LSTM-AE

LSTM-AE considers the encoder-decoder structure for an input sequence. The salient feature of the auto-encoder network is to reconstruct the input, and the LSTM-AE uses this to tackle the sequential data.

### 2.1.5. Energy Function

The main objective of Energy-based models is to map higher dimensional data to a single non-probabilistic scalar quantity called energy. The function  $E(x): R^D \rightarrow R$  maps each input  $x$  to a single value, and collection of these can be turned into a probability distribution function through Gibbs distribution. The probability density  $P(x)$  can be represented as:

$$P(y | x) = \frac{e^{-E(x,y)/T}}{e^{-E(x)/T}} \quad (1)$$

The parameter  $T$  is a temperature function, and its value can be considered according to the data. The energy-based model can be linked to machine learning, especially in any discriminative model where the high dimensional data, converted to a single dimensional value, called logits. Softmax function can be used to derive the categorical distribution of logits, which can be seen in equation (2).

$$P(y | x) = \frac{e^{f_y(x)/T}}{\sum_i^K e^{f_i(x)/T}} \quad (2)$$

Combining equations (1) and (2), it can be inferred that the free energy function  $E(x;f)$  can be written as:

$$E(x: f) = -T. \log \sum_i^K e^{f_i(x)/T} \quad (3)$$

In this work, energy could not serve as a sole function that could help identifying the distribution. Energy scores can then be used as trainable cost function and can be treated as a regularization term along with the cross-entropy loss function. It helps to learn better the in-distribution and out-distribution data, and an energy gap can be created where the out-of distribution data is segregated from the in-distribution data. In equation (4), the energy regularization term is added to the existing cross-entropy loss.  $F_y(x)$  is the traditional softmax scoring function and  $\alpha$  is the regularization parameter. Equation (5) which represents the cost function with two squared hinge loss terms which penalize any value exceeding the in-distribution and any value below the out-distribution margin., where are marginal values for the in-distribution and out-distribution, respectively.

$$\min_w E_{(x,y) \sim D_{in}^{train}} [-\log F_y(x)] + \alpha. L_{energy} \quad (4)$$

$$L_{energy} = E_{(x_{in},y) \sim D_{in}^{train}} (\max(0.01 * (E(x_{in}) - n_{in}), E(x_{in}) - n_{in}))^2 + E_{x_{out} \sim D_{in}^{train}} (\max(0.01 * (n_{out} - E(x_{out})), n_{out} - E(x_{out})))^2 \quad (5)$$

In this work, we have updated the regularization term in the loss function (Liu, 2020) to avoid the vanishing gradient problem. We have used a  $0.01 * (E(x_{in}) - n_{in})$  term in both the hinge losses on the lines of leaky ReLU. The loss function now penalizes the samples in energy values in the range of  $n_{in}$  and  $n_{out}$ .

### 3. Numerical Simulation

#### 3.1. Datasets

The benchmark Tennessee Eastman dataset is used for testing the proposed algorithm for fault detection. There are 41 measured and 12 controlled variables in the benchmark Tennessee Eastman dataset and twenty-one faults are available for fault detection. In particular, we have considered Faults 6, 9, 15 and 19 for this study.

#### 3.2. Simulation

For training the neural networks, we have employed the novel energy loss coupled with the cross-entropy loss. For the encoder, 64 neurons were considered in the first layer, followed by 32,16 and 8 neurons in the subsequent layers. Similarly, 16,32 and 64 neurons were considered for the decoder. Adam optimizer was used for the auto-encoder network, and the newly framed loss function was used. For the auto-encoder network, the energy threshold was found to be 0.030, and any value above the threshold value was considered a fault. Similarly, for the LSTM network, which was used for prediction in a sliding window approach, 40 neurons were used in the first layer, 20 in the second layer and the Adam optimizer was used. A dropout of 0.2 was utilized. LSTM-AE had one hundred neurons, followed by 50 neurons for the encoder section and 50, and 100 for the decoder section with a dropout of 0.5 and Equation (5) was used as the loss function. Similarly, the proposed methodology was also compared to the existing machine learning models such as the PCA and DPCA for the faults considered below.

### 3.3. Results and Discussion

From the parameters taken into consideration, it can be seen from Table 1 and Table 2 that the Auto-encoder network with energy out of distribution (EOD) performed better as compared to other fault detection methods. Table 1 represents the data for Faults 6 and 9 (average of both) for the Tennessee Eastman dataset, and Table 2 is the average of the faults 15 and 19 considered for the Tennessee Eastman dataset. Faults 6, 9, 15 and 19 were considered for the study, as they capture different types of faults in the Tennessee Eastman data. Faults 1-7 represent the step type, 8-12 are random variations, 13 is slow drift, 14 and 15 are sticking types, whereas 16-20 are unknown. Fault 21 is a constant position fault. In our work, we have tried to incorporate the step, random variations, sticking and unknown fault types.

Table 1: Performance Metrics for Faults 6 and 9 using the proposed loss function.

Methodology	Recall	Precision	F1-Score	AUC	FP	FN
<b>Auto-Encoder EOD</b>	<b>0.9405</b>	<b>0.98</b>	<b>0.9598</b>	<b>0.944</b>	<b>5</b>	<b>8</b>
<b>LSTM EOD</b>	0.8695	0.93	0.8988	0.862	12	18
<b>LSTM-AE EOD</b>	0.9008	0.921	0.9107	0.918	8	13
<b>PCA</b>	0.961	0.71	0.8166	0.831	27	3
<b>DPCA</b>	0.985	0.69	0.816	0.845	31	2

Table 2: Performance Metrics for Fault 15 and 19 of Tennessee Eastman dataset using the proposed loss function.

Methodology	Recall	Precision	F1-Score	AUC	FP	FN
<b>Auto-Encoder EOD</b>	<b>0.918</b>	<b>0.96</b>	<b>0.9385</b>	<b>0.941</b>	<b>7</b>	<b>10</b>
<b>LSTM EOD</b>	0.81	0.88	0.843	0.828	14	22
<b>LSTM-AE EOD</b>	0.87	0.92	0.8943	0.871	10	14
<b>PCA</b>	0.912	0.49	0.6374	0.656	51	7
<b>DPCA</b>	0.978	0.53	0.6928	0.765	47	3

Auto-encoder EOD, the network coupled with the proposed loss function had a higher Recall and Precision value, thus accounting to lower False Positives and False Negatives, which is a desirable result. Auto-encoder networks in the traditional environment perform better when compared to the other networks. LSTM-AE, a combination of two frameworks, turns out to be the second best as indicated in Table 1 and 2.

#### 4. Conclusion

The proposed work utilizes the concept of energy out-of-distribution for fault detection. To this extent, higher dimensional data is converted to a vector of a single dimension. This data mapping helps to formulate the energy values, which are then identified as in-distribution and out-distribution based on a suitable threshold. The energy values exceeding the threshold are classified as faults. Traditional methods such as Auto-encoders, LSTMs and LSTM-AEs were coupled with the proposed loss function for fault identification. The methodology was also validated on the benchmark Industrial Tennessee Eastman Dataset. The results indicate that the proposed approach, Auto-encoder EOD, when compared to the other deep learning and machine learning techniques yielded significant results.

## Abstract

With the current development pace of IoT technology and analytical instrumentation, the acquisition of information from devices or operations that are geographically distributed is becoming increasingly common. In some applications, these devices/operations are essentially alike but executed with slightly distinct machines/measurement systems. Such differences have been handled by constructing local models, in a fully decentralized and independent way. However, it is now possible to conceive improved centralized schemes to derive a unified model that takes advantage of the entire data lake. In this work, we demonstrate how such an endeavor can be achieved in the scope of a real case study of predicting an important property (coagulation) of waste lubricant oil (WLO) using FTIR spectra collected at different locations (laboratories). The unified classifier uses a compound mapping of Partial Least Squares for Discriminant Analysis (PLS-DA) and the Bayesian linear classifier. The best prediction models were selected by screening over 36 potential models. The best candidate models to be implemented in practice showed an accuracy greater than 98 %, while retaining less than four latent variables.

**Keywords:** Decentralized classification; Waste lubricating oil; Standardization methods; Partial Least Squares for Discriminant Analysis.

## 1. Introduction

The development of analytical solutions for decision-making and operational management using data collected from geographically distributed devices is becoming increasingly common (Marr, 2015, Qin, 2014, Reis et al., 2021). The conventional approach adopted consists of deriving local models to handle the specificities of the devices or operations. However, this poses several problems of scalability, maintenance, and comparability. Therefore, new centralized methodologies have been developed. The overarching goal is to integrate the information collected from multiple sources and derive a unified model that takes advantage of the entire data lake. A variety of model transfer approaches were developed for handling spectroscopic data (Mishra et al., 2021, Nikzad-Langerodi et al., 2021). Techniques such as Partial Least Squares (PLS) model inversion (Jaeckle et al., 2000), Joint-Y PLS (García Muñoz et al., 2005), calibration transfer (Diaz et al., 2022), and more recently transfer learning (Mishra et al., 2021, Nikzad-Langerodi et al., 2021) and domain adaptation (Pan et al., 2011), offer different paths to achieve the aforementioned goal. In general, they assume the existence of a master or reference device, whose model needs to be transferred to the remaining devices. However, we will consider here the case where there is no such master device or

operation, all of them having symmetrical roles and importance, but where a common model still needs to be found for the final classification task. We demonstrate how such an endeavor can be achieved in the scope of a real case study, briefly described below. Sogilub is the national organization that manages the entire supply chain for the regeneration of waste lubricant oil (WLO) in Portugal. WLOs are collected from different locations but should comply with certain specifications to proceed for regeneration. Currently, WLO characterization is made at four different accredited laboratories, using equipment that, even though similar (Fourier-Transform Infrared spectrometers), show some differences, that originate slightly different spectra even for the same samples. The goal of the present work is to develop a centralized classifier that all laboratories can use, despite the local differences on the devices. In other words, instead of developing a classifier for each laboratory, with much less data and representativeness of the entire population of WLO, we aim at constructing a unified, centralized classifier, that benefits from the information collected in all laboratories. The proposed centralized approach is based on a combination of data pre-processing, a projection operation to a common space (enabling data integration) and finally modeling of the projected data.

The rest of this article is organized as follows. In Sections 2 the standardization techniques, pre-processing techniques and modeling methodologies considered in this work are briefly introduced. Afterwards, in Section 3, the results are presented. Finally, a summary of the conclusions is provided in Section 4.

## 2. Methodology

The proposed methodology aims to build a centralized classifier based on FTIR spectra of WLO to predict a key property in multiple locations (laboratories). The methodology is composed by three main stages addressing (Stage 1) spectral standardization, (Stage 2) spectral pre-processing and (Stage 3) training of the unified classification model as described in the following subsections. A schematic representation of the processed procedure is presented in Figure 1.

Figure 1 Diagram of the main stages of the centralized classifier.

### 2.1. Stage 1: Spectral Standardization

In this framework, samples are collected from the same population, but present distinct correlation structures due to the use of different measurement equipment. Therefore, they must first be brought to a common space so that the spectra become source-independent. To achieve this, standardization techniques are used to relate the spectra measured in a reference equipment ( $\mathbf{S}_1 \in \mathbb{R}^{N \times M_1}$ , where  $N$  is the number of samples and  $M_i$  is the number of wavelengths measured in equipment  $i$ ) to the spectra of the same samples obtained on a secondary equipment ( $\mathbf{S}_2 \in \mathbb{R}^{N \times M_2}$ ) by a transformation matrix ( $\mathbf{F} \in \mathbb{R}^{M_2 \times M_1}$ ) composed of linear relationships, such that  $\mathbf{S}_1 = \mathbf{S}_2\mathbf{F}$ . In this work two standardization techniques were considered to determine the transformation matrix:

- Direct Standardization (DS) (Wang et al., 1991);
- Piecewise Direct Standardization (PDS) (Feudale et al., 2002).

### 2.2. Stage 2: Spectral Pre-Processing

After projecting the spectra to a common space, it is necessary to correct for undesirable artifacts and enhance the relevant features in the spectra. To this end, several pre-

processing techniques are currently available. In this work, four pre-processing techniques were considered:

- Mean Centering (MC);
- Multiplicative Scatter Correction (MSC) (Martens et al., 1983);
- Standard Normal Variate (SNV) (Barnes et al., 1989);
- Savitzky-Golay Differentiation (SGD) (Savitzky et al., 1964).

Different combinations of these pre-processing techniques, as well as different parameterizations of SGD (derivative order, “D#”; window size, “W#”; and polynomial order, “O#”) were examined (see Table 2), leading to 12 distinct pre-processing variations.

### *2.3. Stage 3: Classification in the Common Space*

The final stage of the proposed procedure comprises the training of a classification model. In this framework, classification was made through a two stages procedure by application of Partial Least Squares - Discriminant Analysis (PLS-DA) (Barker et al., 2003), followed by Fisher Discriminant Analysis (FDA) (Hastie et al., 2009). In this case, the response variable of PLS-DA is an indicator variable that codifies the class labels. Afterwards, PLS is applied to extract the latent variables with greater discriminative power. Next, the extracted latent variables are fed to FDA to obtain the final classifier. As the performance of the classifier may be affected by the wavelengths included in the model, three PLS-based approaches were considered to select the relevant wavelength intervals:

- PLS (Wold et al., 2001);
- Forward interval PLS (FiPLS) (Xiaobo et al., 2007);
- Backward interval PLS (BiPLS) (Xiaobo et al., 2007).

## **3. Results**

### *3.1. Case Study*

The case study concerns the regeneration process of WLO conducted in four facilities with different geographical localizations. Before processing, the coagulation potential of the collected WLO is determined through a coagulation test using an alkaline treatment with KOH. If a certain WLO sample gives a positive result in the coagulation test, the associated lot must follow an alternative treatment other than regeneration. Otherwise, the WLO may clog the equipment, causing a premature stop of the process for cleaning and subsequent disposal of the entire production. Therefore, it is highly desirable to have a fast and reliable prediction of the coagulation potential to direct the WLO to a suitable treatment. To achieve this, it is proposed to predict the coagulation potential using the FTIR spectra of WLO samples.

This study uses two datasets: (i) a dataset composed by WLO samples (spectra) analyzed in four laboratories, which is used for selecting the standardization technique and (ii) another dataset composed by WLO samples (spectra and the respective coagulation label) used to train and test the calibration models. In all laboratories, the spectra were collected in the transmittance mode for 700 wavenumbers in the range of 4000 to 500  $\text{cm}^{-1}$  at a resolution of 5  $\text{cm}^{-1}$ .

### *3.2. Setting up the Spectral Standardization to the Common Space*

The first dataset is composed of six samples of WLO whose FTIR spectra were measured in all four laboratories with three replicates each. By applying Principal Component Analysis (PCA) (Jolliffe et al., 2016) to the spectra, the differences between laboratories can be inspected through analysis of the scatterplot of the first two principal components (explaining 92 % of the variability in the spectra) represented in Figure 2. In Figure 2 (a)

it is verified that even though the spectra are from the same set of samples, there are systematic deviations in the spectra due to the use of different equipment. This motivates the use of a standardization technique to bring the spectra to a common space. In this regard, Figure 2 (b) shows a significant improvement in homogeneity between the different laboratories after standardization.

In this work, DS and PDS were adopted using Laboratory II as the reference laboratory. To avoid overfitting, the transformation matrices of DS and PDS were obtained by PLS. To determine the best standardization technique (DS or PDS), their quality was assessed using the root mean squared error (RMSE) between the standardized and reference spectrum of each sample. These results are shown Table 1 along with a two-sided paired  $t$ -test. The results show that DS tends to produce standardized spectrum with lower RMSE. Furthermore, visual inspection of the standardized spectra shows that PDS introduced some artifacts in the transformed spectra. Thus, DS was selected as the best standardization technique for the current case study.

Figure 2 Scatterplot of the first and second principal components of samples measured in four different laboratories: (a) original spectra; (b) spectra after DS standardization.

Table 1 Comparison of the RMSE of the standardization techniques in each laboratory using a two-sided paired  $t$ -test.

Laboratory	RMSE		RMSE Comparison (DS – PDS)	
	DS	PDS	Test statistic ( $t$ )	p-value
I	0.2324	0.3814	-4.1525	<0.001
III	0.3559	0.4317	-0.5264	0.6054
IV	0.4727	0.4934	-1.8912	0.0758

### 3.3. Setting up and Selection of Calibration Model

The second dataset is used to train and test the centralized classification model. This dataset is composed of 120 samples (16 samples from Laboratory I; 58 samples from Laboratory II; 30 samples from Laboratory III; and 16 samples from Laboratory IV). Among these samples, 60 of them are from WLO that coagulate, and the other 60 samples are from WLO that do not coagulate.

Following the previous results, the samples were standardized by DS into a common space defined by Laboratory II. The samples were then used to train and select the best classification model from a pool of 36 distinct models (resulting from the combination of 12 pre-processing techniques and three modeling approaches). For FiPLS and BiPLS the spectra were divided into 15 intervals with approximately 47 wavenumbers each.

The raw dataset was randomly split into a training dataset with 80 % of the samples and a test dataset with the remaining 20 % of the samples. The models were then trained on

the training dataset using Monte Carlo Cross-Validation (MCCV) for tuning the model's hyperparameters. Afterwards, their performance was assessed on the test dataset. In both cases, the key performance indicator (KPI) to assess the model's performance was the prediction accuracy given by,

$$H = \frac{TP + TN}{n} \quad (1)$$

where  $TP$  is the number of true positives,  $TN$  is the number of true negatives and  $n$  is the number of samples in the training/test dataset. The accuracy varies from 0 to 1, where values closer to 1 relate to better classification capabilities.

The accuracy and number of retained latent variables of each model under consideration is presented in Table 2. The results show that all models attain high accuracy. However, several models also retain a considerably large number of latent variables, indicating that some overfitting may be taking place. Nevertheless, a few models present a good balance between the number of retained latent variables and accuracy. For instance, SGD-D2-W9-O2 in combination with FiPLS has an accuracy of 100 % with four latent variables, while SNV-SGD-D1-W7-O2 in combination with BiPLS has an accuracy of 98 % with only two latent variables.

Table 2 Accuracy and number of retained latent variables of each model.

Pre-Processing Technique	Accuracy			Number of Retained Latent Variables		
	FiPLS	BiPLS	PLS	FiPLS	BiPLS	PLS
MC	0.9960	1.0000	0.9710	5	9	4
SNV	0.9360	0.9757	0.9757	4	5	5
MSC	0.9998	0.9707	0.9640	5	4	4
SGD-D1-W7-O2	1.0000	1.0000	1.0000	7	8	8
SGD-D1-W15-O2	0.9452	0.9525	0.9527	7	8	8
SGD-D2-W9-O2	1.0000	0.9993	0.9400	4	7	3
SNV-SGD-D1-W7-O2	0.9843	0.9836	0.9990	6	2	2
SNV-SGD-D1-W15-O2	1.0000	0.9998	0.9827	6	5	4
SNV-SGD-D2-W9-O2	0.9683	0.9571	0.9788	6	4	4
MSC-SGD-D1-W7-O2	0.9843	1.0000	0.9610	4	7	4
MSC-SGD-D1-W15-O2	0.8866	0.8736	0.8818	5	2	2
MSC-SGD-D2-W9-O2	0.9752	0.9995	0.9948	6	5	4

#### 4. Conclusions

A centralized classification model was developed to predict the coagulation potential of WLO during the recovery process. Predictions are made from FTIR spectra collected in four laboratories, which introduces laboratory-specific variability in the data. The proposed methodology was able to handle this heterogeneity, by projecting all sources to a common space. In this regard, DS provided the best results. The best prediction model was then selected by screening over 36 potential models. The results showed that FiPLS and BiPLS in combination with Savitzky-Golay Differentiation led to prediction accuracies greater than 98 %, while retaining a low number of latent variables. Thus, these models are the best candidates to be implemented in practice. In future work, we will evaluate the performance of the centralized classifier over time and assess the impact of instrument and/or sample degradation on model quality.

### Abstract

In order to generate higher-quality products and increase process efficiency, there has been a strong push in the processing and manufacturing sectors. This has called for the creation of methods to identify and fix faults to ensure optimal performance. As a result, it is essential to develop monitoring systems that can effectively detect and identify these faults so that operators can quickly resolve them. This article proposes a novel fault detection method that adopts a deep learning approach using a Fourier neural operator (FNO) in a probabilistic way, an operator learning model that aims to learn the distribution of multivariate process data and apply them for fault detection. Herein, the historical data under normal process conditions were first utilized to construct a multivariate statistical model; after that, the model was used to monitor the process and detect faults online. The proposed FNO combines the integral kernel with Fourier transformation in a probabilistic way. As the Fourier transform helps in the time-frequency localization of time series, FNO takes advantage of them to discover the complex time-frequency characteristics underlying multivariate datasets. On the benchmark Tennessee Eastman process (TEP), a real-world chemical manufacturing dataset, the performance of the proposed method was demonstrated and compared to that of the widely used fault detection methods.

**Keywords:** Fault detection; Fourier Transform; Neural operator; Probability distribution

### 1. Introduction

A fault in industrial manufacturing processes is any anomalous deviation from normal operating conditions (NOC). Faults are a reason for concern since even minor flaws in a industrial system can set off a cascade that reduces efficiency and dependability. On the other hand, numerous cutting-edge fault detection techniques are accessible to ascertain whether the issue has occurred in the system (also known as anomaly detection in other applications). In recent decades, multivariate statistical techniques for process monitoring, especially fault detection, have developed rapidly (Kodamana et al., 2019). The principal component analysis (PCA) is mainly used in linear data processing algorithms and has proven to be highly effective in fault detection. Dynamic principal component analysis (DPCA) has been suggested in the literature to cope with serially correlated multivariate observations. Both PCA and DPCA have a linear structural model and correlation constrain while dealing with in-process dynamics (Rani et al., 2023). However, extremely non-linear and highly correlated process data pose challenges. Simultaneously, Neural network (NN) based techniques have gained considerable attention due to their flexibility and capability in modelling complex structures and temporal dynamics. Researchers have applied deep learning to the field of process monitoring, using techniques such as long short-term memory (LSTM), autoencoder (AE), Recurrent neural network (RNN), and LSTM-based AE (Lee et al., 2019). It is challenging for data-driven neural networks (NNs) to generalize beyond the training data. As an efficient and successful strategy, the trained networks should generalize to unseen inputs and predict the output precisely to

address these challenges; neural operators (NOs) have been developed recently. Since NOs only need to be trained once, they can learn the mapping among two infinite-dimensional function spaces (Kovachki et al., 2021). After being trained, they can be applied to predict the outcome of any particular input function.

The global integral operators are passed through the non-linear local activation functions via NOs, similar to NNs, to learn the complex non-linear dynamics of process data. Among the recently developed NOs, the DeepONet architecture is the first to learn such infinite-dimensional function spaces (Lu et al., 2022). Similarly, a graph neural operator (GNO) is proposed that gave new ideas for using graphs but became unstable with the increased number of hidden layers. In order to learn the network parameters in Fourier space, the Fourier neural operator (FNO) is invented, simultaneously (Li et al., 2020). The fast Fourier transform (FFT) spectral decomposition of the input and computing the integral convolution kernel in the Fourier space constitute the basis of the FNO (Li et al., 2020). The present work extends the FNO in a probabilistic sense and proposes the Fourier neural operator (FNO) for learning the distribution of finite-dimensional multivariate input. The proposed FNO is then applied for fault detection.

## 2. Methodology

### 2.1. Proposed Framework

This paper presents the FNO algorithm for learning the distribution of provided time series. To learn the distribution of the framework, the output space data was created by splitting the input data set. The input-output pairs were denoted as  $\mathbf{Y} \in \mathcal{U}$  and  $\bar{\mathbf{Y}} \in \mathcal{U}$ , where  $\mathcal{U} \in \mathbb{R}^N$  is a completely normed vector space. The distribution of the input was characterized by using the FNO, and a new channel was created by augmenting an  $m$ -dimensional random variable  $\mathbf{Z} = \{\xi_1, \dots, \xi_k, \dots, \xi_T\}$  with  $\xi_k \in \mathbb{R}^N$ . The purpose of this framework is to develop a network that can utilise the information to learn about the distribution employing the operator.

To do this, first, lift the inputs  $a(y_t) \in \mathcal{A}$  to a high-dimensional space via a local transformation  $M(a(y_t)): \mathbb{R}^{d_a} \mapsto \mathbb{R}^{d_v}$  and denote the high-dimensional space as  $v_0(y_t) = M(a(y_t))$ , where  $v_0(y_t)$  has values in  $\mathbb{R}^{d_v}$ . In a neural network framework, the local transformation  $M(a(y_t))$  can be accomplished by building a shallow, fully connected neural network (FNN). In addition, it was assumed that a total of  $n$  steps are necessary to achieve convergence. After that,  $n$  updates  $v_{j+1} = F(v_j); \forall j = 1, \dots, n$  was applied to  $v_0(y_t)$ , where the function  $F$  returns a value in  $\mathbb{R}^{d_v}$ . Once all of the  $n$ -iterations were performed, then another local transformation  $G: \{v_n(y_t) \in \mathbb{R}^{d_v}\} \rightarrow \mathbb{R}^{d_u}$  was applied using an FNN to transform the lifted space into the output space  $\bar{\mathbf{Y}} \in \mathcal{U} = G(v_n(y_t))$ . The step-wise update is given in Equation 1.

$$v_{j+1}(y_t) = Q\left(\left(\mathcal{K}(a; \phi) * v_j\right)(y_t) + \check{\partial}v_j(y_t)\right); t \in [0, T] \quad (1)$$

where  $Q(\cdot)$  denotes a non-linear activation function,  $\check{\partial}: \mathbb{R}^{d_v} \rightarrow \mathbb{R}^{d_v}$  is a linear transformation,  $*$  is the convolution operator, and  $\mathcal{K}$  denotes the wavelet integral operator parameterized by  $\phi \in \Theta_{NN}$ . The convolution in the integral kernel operator is represented as,

$$\left(\mathcal{K}(\phi \in \Theta_{NN}) * v_j\right)(y_t) = \int_T \kappa(y_t - \tau; \phi)v_j(\tau)d\tau; t \in [0, T] \quad (2)$$

where  $\kappa(\cdot, \cdot)$  is the kernel of the neural network parameterized by  $\phi \in \Theta_{NN}$  in the Fourier domain. The overarching framework of the FNO consisting of the Fourier integral layer (FIL) is illustrated in Figure 1, which is further discussed in sub-section 2.1.

Figure 1: Architecture of Probabilistic Fourier Neural Operator. It has  $M+2$  input consisting of  $M$  variables and 2-time series noise inputs. First, a higher dimensional projection of the inputs was made by utilizing an FNN space. After this, 4 Fourier internal blocks were applied to the projected data. The results from the other FNN were then used to transform the fourth Fourier integral block back to the original domain. This way, it will learn the distribution, and at the output, it will reconstruct only the  $M$  original variable without the noise.

## 2.2. Fourier Integral Block

In this section, the kernel was discovered in the frequency domain by constructing a finite-dimensional space with a Fourier transform. After that, the convolution operator was substituted in Equation 2, defined in Fourier space for the kernel integral operator. Assume  $\mathcal{W}$  represent the Fourier transform (Equation 3) of a function  $f \in \mathbb{R}^{d_v}$  and  $\mathcal{W}^{-1}$  denotes the inverse, then

$$(\mathcal{W}f)_l(\omega) = \int_D f_l(y) e^{-2i\pi(\tau, \omega)} d\tau, \quad (\mathcal{W}^{-1}f)_l(\tau) = \int_D f_l(\omega) e^{2i\pi(\tau, \omega)} d\omega \quad (3)$$

for  $l = 1, \dots, d_v$  where  $i = \sqrt{-1}$  is the imaginary unit. By letting  $\kappa_\phi(y, p, a(y), a(p)) = \kappa_\phi(y - p)$  in Equation 2 and applying the convolution theorem, the convolution was defined in the Fourier domain as Equation 4.

$$(\mathcal{K}(\phi)v_j)(\tau) = \mathcal{W}^{-1} \left( \mathcal{W}(\kappa_\phi) \cdot (\mathcal{W}v_j) \right) (\tau) \quad (4)$$

As parameterizing of  $\kappa_\phi$  occurs directly in Fourier space, so introducing a weight tensor within the Fourier domain makes better sense as  $R_\phi = \mathcal{W}(\kappa_\phi)$ . With the new information, Fourier integral layer is defined in Equation 5.

$$(\mathcal{K}(\phi)v_j)(\tau) = \mathcal{W}^{-1} \left( R_\phi \cdot (\mathcal{W}v_j) \right) (\tau) \quad (5)$$

In the frequency mode,  $\omega$  have  $(\mathcal{W}v_j)(\omega) \in \mathbb{C}^{d_v}$  and  $R_\phi(\omega) \in \mathbb{C}^{d_v \times d_v}$ , and discrete modes  $\mathbb{Z}^d$  can be used since  $\kappa$  is periodic, as it admits. Thus, a Fourier series expansion and continuous modes become more redundant and computationally costly. Therefore, a finite-dimensional parameterization was selected by truncating the Fourier series at the maximum number of modes,  $\omega_{\max} = |Z_{\omega_{\max}}| = |\{\omega \in \mathbb{Z}^d: |\omega_l| \leq \omega_{\max, l}, \text{ for } l = 1, \dots, d\}|$ . After this, the parameterization of  $R_\phi$  occurs directly as a set of complex-valued  $(\omega_{\max} \times d_v \times d_v)$ -tensors made up of truncated Fourier modes as a result. The  $\ell_1$ -norm of  $\omega \in \mathbb{Z}^d$  is typically given an upper bound in order to characterize the low-

frequency modes. Thus, computational and memory bottleneck was overcome by deciding  $Z_{\omega_{\max}}$  since it enables a practical implementation. In this work, the Fourier integral layers were constructed by using  $Z_{\omega_{\max}} = 16$ .

### 2.3. FNO-based Process Monitoring

Once the FNO model is constructed, an FNO provides a reconstructed version of the input together with the distribution mean and standard deviation. Firstly, define the likelihood distribution  $p_{\mathbf{X}|\bar{\mathbf{Y}}}(Y | \bar{Y})$  as Gaussian distribution with sample mean  $\mu_s$  and sample standard deviation  $\sigma_s$ . From the Gaussian representation of the likelihood function, a closed form for the reconstruction loss (Equation 6) was derived in terms of the log-likelihood as follows,

$$\log(p_{\mathbf{Y}|\bar{\mathbf{Y}}}(Y | \bar{Y})) = -\left(\log(\sigma_s) + \frac{1}{2}\left(\frac{y-\mu_s}{\sigma_s}\right)^2\right) \quad (6)$$

where  $\mu_s$  and  $\sigma_s$  are the mean and sample standard deviation of  $\bar{\mathbf{Y}}$ . The details steps leading to Eq. 6 are omitted for brevity. Further, a Monte Carlo framework was adopted to learn the parameters of the input distribution. For  $\bar{\mathbf{Y}}^{(l)}$  where  $l = 1, \dots, L$  were computed from the samples of  $P_{\theta}(\bar{y} | y)$ . After this, the standard deviation and mean were estimated for all variables. In the end, the presence of a fault in the data was tested using the condition standard deviation greater than the suitable threshold.

### 2.4. Datasets used in Validation Studies

Tennessee Eastman Process (TEP) dataset is a chemical simulation model based on a real-world chemical production process, and it has been widely implemented in the fields of process control, process optimization, and fault detection. There are five significant unit operations: a reactor, a product condenser, a recycle compressor, a vapor-liquid separator, and a product stripper. The TE simulator can simulate 21 different fault operation conditions in addition to the typical operating environment. Twenty-two continuous process variables, 19 composition variables, and 12 controlled variables make up the data set. In this investigation, 52 variables were monitored with fault IDs named ID1, ID6, ID7, ID8, ID16, ID18, and ID19, as all show different behaviour.

## 3. Simulation Studies

### 3.1. FNO Architecture

The four FNO layers that make up the FNO architecture were all triggered using the GeLU activation function. In order to improve the network settings, the ADAM optimizer was used. For this optimizer, the weight decay factor was set at  $10^{-6}$ , and the initial learning rate was set at 0.001. Depending on the data loader's underlying technology, the batch size ranges from 10 to 25. The numerical experiments were carried out on a Quadro RTX5000 32 GB GPU. Each dataset was normalized using Z-score and Min-Max scaling before training the models to prevent training bias toward metrics with higher values.

### 3.2. Fault Detection Results

The FNO model established in the preceding section was used in the suggested process monitoring technique. The process data under normal operating conditions were gathered and used as a training dataset after normalizing to zero mean and unit variance. Variability in data reconstruction was monitored to determine the probability that the online data have a distribution similar to that of normal data, and it was calculated by employing standard deviation. The monitoring index was computed for each process data in online monitoring, and the control limit was compared using normal data distribution. The process was declared out of control when a high abnormality occurred in the data distribution, and because the standard deviation exceeded the limit, the process was considered faulty. Firstly, compare the multivariate data samples produced by FNO to the

real samples supplied for the stable data to evaluate the model's effectiveness. As shown in Figure 2, the FNO could learn the distribution and accurately reconstruct TEP data after a sufficient number of epochs.

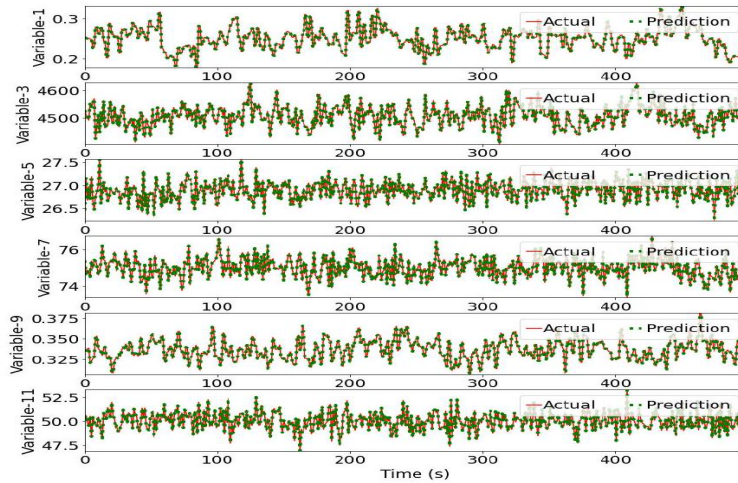

Figure 2: Reconstruction plot of TEP data for normal conditions using FNO

The standard deviation plot showed different behaviour when the fault was introduced within the dataset. The contribution plots of the factors contributing to the standard deviation at samples were computed to identify the variable responsible for any anomalous event, as shown in Figure 3. Therefore, this method aids in locating the variable also responsible for the unusual behaviour. In accordance with that, precision, recall, accuracy, and F1-score were calculated.

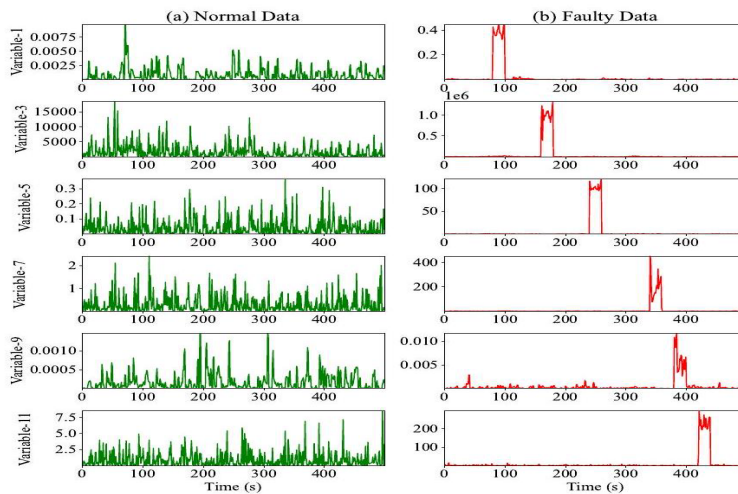

Figure 3: Standard deviation plot of normal data vs. faulty data for the Tennessee Eastman Process dataset

### 3.3. Performance Comparison of FNO with Baseline Methods

The fault detection performance of FNO was compared with other popular models such as DPCA, LSTM, and AE. When comparing the same number of noise levels among the other algorithms for each metric in Table 1, we see that the FNO has the best performance. Overall, FNO outperformed AE, LSTM, and other fault detection algorithms for the TEP dataset, as depicted in Table 1.

Table 1: Average performance metrics for Tennessee Eastman data set in the presence of the fault

Methods	Recall	Precision	F1-Score	AUC	FP	FN
AE	0.93	1.0	0.96	0.94	2	11
LSTM	0.80	0.87	0.83	0.81	11	21
LSTM-AE	0.86	0.91	0.88	0.87	7	16
DPCA	0.96	0.52	0.68	0.74	4	8
FNO	0.98	1.0	0.99	0.98	0	6

#### 4. Conclusion

In this work, a novel fault detection method using FNO architecture was developed and evaluated on an enlarged TEP dataset. A broad range of recurrent and convolutional architectures such as LSTM, AE, LSTM-based AE, and DPCA was compared to establish the baseline using F1-score and Accuracy values. The novel Fourier neural operator (FNO) technique showed its effectiveness in distribution learning and anomaly detection in multivariable time series data by showing F1 score value as 0.99, AUC value of 0.98 with no FP values which show the superiority of suggested method. The proposed model brings in threefold advantages. (i) It accurately learns the operator dynamics, (ii) the introduction of Fourier transform brings in time to frequency localization, and (iii) the probabilistic framework helps to work in a noisy environment.

## Abstract

The increasing demand of monoclonal antibodies (mAB) has been the motivation to develop methods to improve its yield of its production. The product yield for any chemical process highly depends on the fidelity of the process automation used. To this extent, deployment of model-based controllers results in heavy computational load, and its performance highly dependent on the model's accuracy. To address some of these issues, the role of model-free controllers like reinforcement learning (RL) based controllers seems to be promising. Proximal policy optimization (PPO) is one of the stochastic deep RL methods that can be used to achieve this task. In this work, we have studied the PPO algorithm for the control of mAB concentration in the bioreactor. In this process, mAB concentration is the control variable and feed flowrate is the manipulated variable. Our simulation study shows that by application of the PPO algorithm for bioreactor, we are able to track the end-point concentration of mAB, by providing the optimal flowrate strategy.

**Keywords:** Reinforcement Learning (RL), Proximal Policy Optimization (PPO), monoclonal antibodies (mAB)

## 1. Introduction

For many years monoclonal antibodies (mAB) have been used to treat several complex human diseases like arthritis, cancers, Alzheimer's, COVID-19, and HIV as they have less antagonistic effects. Due to these benefits, research has been going on to improve the yield of the mAB. Therefore, a reasonable control strategy needs to be developed for this purpose. The controller performance is highly affected even by small changes in process parameters. As stated in the literature, many model-based control strategies like iterative learning control (ILC) and model predictive control (MPC) proved to overcome these issues (Gupta et al.,2022, Kern et al.,2015, Lee et al.,2007). Model-based controllers are highly dependent on the model and moreover, they require more computational time as the optimization problem has to be performed at each time step. However, many data-driven modeling strategies for chemical processes to overcome the limitations of developing a first-principle-based model (Jiang et al.,2019). Data-driven techniques, such as model-free reinforcement learning (RL), technique tackle the major drawbacks of model-based controllers (Joshi et al.,2021, Singh et al.,2020, Nikita et al., 2021). In contrast to conventional controllers, a controller based on RL allows the agent, which is equivalent to the controller, to learn the best course of action to take in response to input from the environment (Yoo et al., 2021, Bao et al., 2021, Sutton et al., 2018). One of the promising algorithms that belong to the category of deep reinforcement learning for is

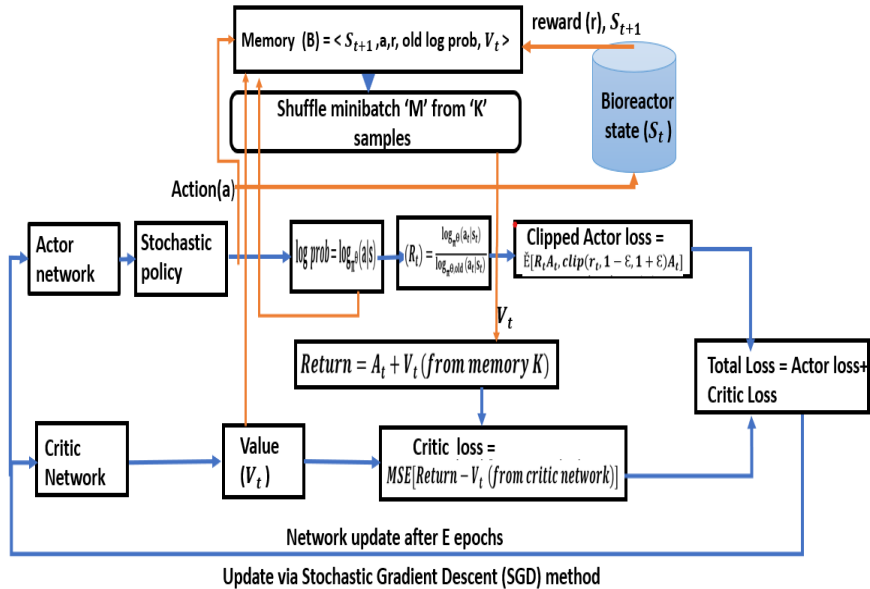

proximal policy optimization (PPO). PPO greatly reduces the complexity by adopting the clipping mechanism. The objective function uses specific clipping which prevents new policy to diverge away from the old policy (Schulman et al., 2017).

84% of all mAbs (monoclonal antibodies) are generated from hamster ovary tissue. These cells have been altered to grow in a media that has been chemically produced in order to produce the target protein of interest. The principal source of carbon and energy for cultured cells is glucose, which they primarily utilize to maintain the cell's general homeostasis (Kumar et al., 2021). That's why varying glucose concentration in media affects the growth of mammalian cell culture performance. Inlet glucose concentration can be varied by changing the inlet flow rate. Temperature also affects overall mammalian cell culture. Therefore, temperature or inlet glucose concentration or flowrate can be considered as a manipulated variable to enhance the protein (mAb) concentration, which is the control variable. But in the present work, only feed flowrate has been used as a manipulated variable for the same. In the present work, the PPO algorithm has been applied to identify the optimal operating points that enhances the antibody production in the bioreactor.

## 2. Methodology

### 2.1 Process description

The fermentation process is carried out in a bioreactor in which the inlet stream consists of feed and media having glucose as raw material. Glucose, dead cells, lactate, viable cells, and protein (monoclonal antibodies) are the constituents of the outlet stream (Kumar et al., 2021). The six states are viable cells ( $X_v$ ), monoclonal antibodies (mAB), glucose, lactate, dead cell density ( $X_d$ ) and viability. The detailed schematics of the process can be shown below:

**Figure 1: Schematic of the process**

In this process, our main objective is to maximize the concentration of monoclonal antibodies (mAB) by controlling the glucose concentration by varying the inlet flowrate.

Therefore, for this process mAB concentration is our state (S) and flowrate is our action (a). Here we have used proximal policy optimization (PPO), one of the RL techniques to obtain the optimal control policy for obtaining the desired concentration. PPO is an actor-critic method, which acts as an agent and provide optimal action ( $a_t$ ) to the bioreactor i.e., our environment at current state ( $S_t$ ) and provide us with next state ( $S_{t+1}$ ) and reward ( $r$ ). Based on the reward earned, the agent learns on continuous interaction with the environment to provide optimal control strategy as indicated in Figure 1. In this schematic, we have two networks, actor and critic network. Actor networks take state (s) as input and provide distribution of actions and one action is sampled from it. Critic network also take state (s) as input to give value function. This value function evaluates, weather the action is good or bad.  $R_t$  is evaluated as ratio of old log of probability of actions and new log probability of actions. If the value of ratio is 1, then current action policy is better but if it is between 0 and 1, then current action policy is not good. Advantage function is also a good measure of if action is good or bad. If value of advantage is positive, then probability of selecting those set of actions is good and if value of advantage is negative, then those actions are discarded. Product of ratio and advantage is very good optimization function. This ratio is clipped between a minimum and maximum value, so that new policy will not diverge much away from the old policy. This clipped function is termed as actor loss. Critic loss is evaluated using mean square error of Return and value (i.e., output from the critic network). Total loss is the sum of critic loss and actor loss, which is used to update the networks based on stochastic gradient descent method. We shuffle the minibatch size of 'M' from the 'K' samples selected from the memory 'B'. The networks are updated after every 'E' epochs, then memory 'K' is discarded. This process is repeated till the old policy weights converges with new policy weights.

## 2.2 Proximal policy optimization (PPO) algorithm

Reinforcement learning (RL) is one of the branches of machine learning (ML) in which the agent (analogous to the controller) learns to give optimal actions by maximizing the reward through interaction with the environment (bioreactor). RL-based algorithms can be divided into categories, value-based method in which agent learn action based on learned value function and policy gradient method in which policy is optimized using gradient descent method. PPO is an on-policy method that can be implemented in an actor-critic style. Here critic can be implemented as the value function approximator, and the actor can be implemented as a policy approximator. Therefore, performance of this method proved better than the plain policy gradient method (Byun et al.,2020, Wang et al.,2020).

PPO performs multiple gradient descent to update the neural network for each iteration. The stability of the system is ensured by calculating the ratio between old policy and the new policy. Here the main objective is to reduce the divergence between old and the new policy (Hämäläinen et al.,2020). The basic algorithm steps are stated below:

- 1 There are two networks i.e., actor network ( $\pi^\theta(s_t)$ ) and critic network ( $Q^\phi(s_t)$ ) with  $\theta$  and  $\phi$  as respective weights for current state ' $s_t$ '.
- 2 Initialize the memory B.
- 3 Collect set of tuples of <state ( $s_t$ ), action ( $a_t$ ), reward ( $r_t$ ), log probs, values ( $V_t$ )> at time instant 't' from memory B. Here 'log probs' is the logarithmic values of the probability of actions and values are the output from the critic network.
 
$$\log prob = \log_{\pi^\theta}(a|s) \quad (12)$$
- 4 Sample the set of 'K' samples from the memory 'B'.
- 5 Shuffle the minibatch size of 'M' from the 'K' samples collected form 'B' and perform 'E' epochs to update the network for each batch.
- 6 Calculate ratio ( $R_t$ ) =  $\frac{\log_{\pi^\theta}(a_t|s_t)}{\log_{\pi^{\theta,old}}(a_t|s_t)}$  i.e., ratio of log of probability of actions from memory and old log probabilities from the memory.

- 7 Update the actor network based on following clipped loss function:

$$L_{\pi\theta} = \mathbb{E}[R_t A_t, \text{clip}(r_t, 1 - \epsilon, 1 + \epsilon) A_t] \quad (13)$$

$$A_t = r + \beta V(s_{t+1}) - V(s_t) \quad (14)$$

Here  $A_t$  is the advantage, which considers for the goodness of state,  $\epsilon$  (epsilon) is the clipping parameter and  $\beta$  is the smoothing parameter.

- 8 Critic network is updated based on mean square error (MSE) value:

$$\text{Return} = A_t + V_t \text{ (from memory } K) \quad (15)$$

$$L_{Q\phi} = \text{MSE}[\text{Return} - V_t \text{ (from critic network)}] \quad (16)$$

- 9 Total loss = Actor loss + Critic loss

- 10 Update weights of the actor and critic networks ( $\Theta$  and  $\phi$  respectively) via stochastic gradient descent (SGD) method.

- 11 Perform iteration till the  $\Theta_{\text{old}}$  converges to  $\Theta$ .

### 3. Results and Discussions

Proximal policy optimization (PPO) based control have been applied to the bioreactor and their simulation results has been shown in this section. The efficacy of the algorithm can be shown by the root mean square error (RMSE), reward, and tracking plots. The feed flowrate mainly affects the desired protein concentration (mAB). Therefore, protein concentration is our control variable, and flowrate (ml/min) is our manipulated variable which is analogous to action. Python 3.7 version with Pytorch package has been used to train the deep neural network (DNN) for the application of the PPO algorithm. The actor and critic networks are DNN with 3 hidden layers and 256 hidden nodes each. A ReLU activation function has been used as an activation function for both actor and critic networks. Here the reference mAB concentration ( $\text{mAB}_{\text{ref}}$ ) i.e., end-point concentration is 590 mg/l. Our main objective is to reduce the error ( $e = \text{mAB} - \text{mAB}_{\text{ref}}$ ) with the help of the reward function as given below:

$$\text{Reward} = -|e| \quad (15)$$

The tracking performance of PPO can be shown in Figure 1(a) and the corresponding control policy (flowrate) can be seen in Figure 1(b). The PPO-based controller was trained for 200 episodes in presence of noise of 20 % in the input concentration of viable density. The controller performance can be evaluated with the help of average rewards (average of last 10 episodic rewards) as shown in Figure 2(a) and root mean square error (RMSE) values plot as shown in Figure 2(b). The results indicate that the proposed PPO based RL agent can effectively track the desired operating point.

Figure 1 (a) Controller tracking performance (b) Optimal control strategy (flowrate)

Figure 2 (a) Average reward plot (b) RMSE plot

#### 4. Conclusions

Proximal policy optimization (PPO), an actor-critic RL-based algorithm has been implemented for the bioreactor system (environment) to control the protein concentration (mAB) to obtain the optimal flowrate (action) to achieve the desired results. PPO can track the desired mAB concentration which is 590 mg/l. The average rewards and RMSE plot show that the controller has performed well. Therefore, PPO can be a good candidate for control the complex dynamics of the bio reactor process.

## Abstract

A palm oil-based polygeneration system (POPS) is simulated to produce the main product of high-purity green diesel as well as the liquefied petroleum gas (LPG) as a by-product. The CO<sub>2</sub>-negative design includes approaches of (i) a series of cryogenic separators for the recovery of approximately 65.5% of hydrogen feedstock, (ii) the evacuated tube solar collector (ETSC) for reducing 35% flue gas from the furnace, (iii) the amine-based CO<sub>2</sub> capture process for pursuing the high-purity CO<sub>2</sub> product. The economic analysis of POPS shows that the process becomes economically attractive if the diesel price and crude palm oil should be around 1.98 and 0.47 \$kg<sup>-1</sup>, respectively.

**Keywords:** Palm oil; Carbon capture; Polygeneration; Negative CO<sub>2</sub> emission; Economic analysis

## 1. Introduction

Oil palm is the major source of vegetable oil in the world, mainly produced in Southeast Asia. Palm oil not only contains triglycerides and many free fatty acids, but also it is a proper feedstock for green diesel production in Thailand due to Thailand being currently the third-largest palm oil producer in the world. A palm fatty acid distillate (PFAD) is a by-product generated from refining crude palm oil, so it can be treated as the feedstock of the green diesel production process. A study showed that the green diesel produced from PFAD achieved 84% GHG emissions reduction as compared to the GHG emissions of petroleum diesel (Alhajji and Demirel, 2016). In the process simulation of the production of green diesel from the hydrotreatment of vegetable oil, a model of the hydrotreatment of soybean oil for producing green diesel was validated according to experimental data, and the green diesel produced from Brazilian soybean oil could meet quality standards (Cavalcanti et al., 2022). The negative emissions technologies will become more important in the next decades due to pricing the carbon emissions. The bio-energy with carbon capture and storage technology was one of the primary negative carbon emission methods. A study showed that the process design of a biomass-based polygeneration system for power generation and ammonia synthesis could achieve negative CO<sub>2</sub> emissions (Xu et al., 2021).

## 2. Study Design

### 2.1 Palm oil-based polygeneration system (POPS)

A palm oil-based polygeneration system (POPS) named Design 1 is depicted in **Fig. 1** which mainly consists of a furnace, an FBHTR, a three-phase separator, and a series of cryogenic separators (C Sep1, C Sep2) to produce green diesel and green LPG (propane), notably the CO<sub>2</sub>-rich gases are emitted from the furnace and C Sep1, respectively. Two feedstocks of palm oil and hydrogen are heated up to 324°C by a furnace and a combination of a heater and a compressor, respectively, and they are fed into the fixed bed hydrotreating reactor (FBHTR) at the prescribed operating pressure. Notably, 65.5% of the feedstock of hydrogen is recovered through a series of cryogenic separators in Design 1, and the FBHTR is covered with a cooling jacket where the recycled water is produced from the three-phase separator. The outlet stream of FBHTR is cooled down and fed into a specific three-phase separator. The vapor-phase stream is fed into a sequence of cryogenic separators (C Sep1 and C Sep2) at the prescribed operating temperature and pressure to separate green LPG, CO<sub>2</sub>, and hydrogen, where the hydrogen flow is fully recycled and mixed with fresh hydrogen flow. The simulation results show that the purity of green diesel is up to 98.3wt% and the yield of green diesel is around 84.4%, but the purities of CO<sub>2</sub> and green LPG from C Sep1 and C Sep2 are close to 80.6% and 84.6%, respectively. Besides water and hydrogen being fully recycled, green LPG is used to meet the LPG fuel demand of the furnace.

**Figure 1** Palm oil-based polygeneration system

### 2.2 Performance evaluation

To address the performances of the POPS design, the indicators like net energy efficiency and net CO<sub>2</sub> emissions are addressed as follows.

(i) Net energy efficiency

$$\eta_{net} = \frac{E_{net}}{F_{palm\ oil} \times HHV_{palm\ oil} + F_{H_2} \times HHV_{H_2}} \quad (1)$$

and  $E_{net}$  is the net energy shown by

$$E_{net} = F_{gdiesel} \times x_{gdiesel} \times LHV_{gdiesel} + (F_{LPG} \times x_{LPG} \times LHV_{LPG} - W_{tot}) \quad (2)$$

where  $F_{palm\ oil}$  and  $F_{H_2}$  are the inlet mass flowrates of palm oil and hydrogen, respectively.  $F_{gdiesel}$  and  $F_{LPG}$  are the outlet mass flowrates of green diesel and green

LPG, respectively.  $x_{gdiesel}$  and  $x_{LPG}$  represent mass fractions of green diesel and green LPG in the outlet streams of  $F_{gdiesel}$  and  $F_{LPG}$ , respectively.

(ii) Net CO<sub>2</sub> emissions

The net CO<sub>2</sub> (equivalent) emissions ( $CO_{2,net}$ ) of each design including the total CO<sub>2</sub> emissions ( $CO_{2,tot}$ ) of all utilities are used in each design and net CO<sub>2</sub> sequestration ( $CO_{2,seque}$ ) of producing palm oil from oil palm plantations. It is noted that CO<sub>2</sub> (equivalent) emissions of equipment are evaluated by using the carbon tracking tool in Aspen Plus®. The detailed calculations have been shown by the previous work (Wu et al, 2023). **Table 1** shows that  $\eta_{net}$  is up to 68.14%, and the corresponding  $CO_{2,net}$  is negative.

**Table 1** Energy efficiency and CO<sub>2</sub> emissions

$E_{net}$	kW	8696.47
$\eta_{net}$	%	68.14
$CO_{2,net}$	kg/h	-113.39

**Fig. 2** shows the combination of the duty of each unit in the POPS, the corresponding CO<sub>2</sub> (equivalent) emissions of each equipment is shown by **Fig. 3**.

**Figure 2** POPS in terms of (a)  $E_{tot}$  and (b) CO<sub>2</sub> (e) emissions

**2.3 Economic evaluation**

The economic evaluation is based on a combination of capital expenditure, operating expenditure, and carbon revenue. Through the Aspen Process Economic Analyzer (APEA), the capital expenditure (CAPEX) and operating expenditures (OPEX) of POPS are 8.5 M\$ and 11.7M\$/year, respectively.

**Figure 3** Pie chart of POPS in terms of (a) CAPEX and (b)OPEX

**Fig. 3(a)** shows that the equipment cost of the compressor dominates the total investment cost due to high hydrogen partial pressure, and **Fig. 3(b)** shows that the palm oil price dominates the total operating cost since it takes up to 44%.

### Carbon Revenue

Referring to the emission trading scheme (ETS) for estimating CO<sub>2</sub>price, the carbon revenues ( $\Delta P_i$ ) is based on the following calculation (Wu et al., 2023)

$$\Delta P_i = D_i \times P_{t,i} + B_i \quad (3)$$

where  $D_i$  represents the amount of CO<sub>2</sub> reduction through the CO<sub>2</sub> capture and utilization (CCU) approaches.  $B_i$  represents the government incentives for the CCU, which here equals to 15000 USD. Moreover, the profile of annual carbon revenues of the POPS are shown in **Fig. 4** according to the carbon price from 2021 to 2050.

**Figure 4** Carbon revenue of the POPS

### Net present value

To evaluate the cumulative discounted cash flow of this project, it is noted (i) an interest rate of 15%, (ii) depreciation in five years, (iii) the plant construction for the first three years, and (iv) the working capital included in the third year. The cumulative discounted cash flow is shown in **Fig. 5**, notably, the net present value (NPV) remains negative until 2037. The payback period is more than 12 years from the start of plant operation.

**Figure 5** Cumulative discounted cash flow

Assuming an internal rate of return (IRR) of 15% and. The actual diesel and crude palm oil (CPO) prices are approximately 1.13 and 0.88  $\text{\$/kg}$ . In September 2019, the purchase price of CPO was set at 16.2 THB per kilogram (0.47  $\text{\$/kg}$ ). In order to make this process economically attractive, the diesel price and CPO should become 1.98 and 0.47  $\text{\$/kg}$ , respectively.

### 3. Conclusions

The process design of the green diesel produced from the hydrotreating reaction of palm oil is addressed by using Aspen Plus<sup>®</sup>. The outlet compositions of green diesel, water, propane, carbon dioxide, and hydrogen from the FBHTR are effectively separated and purified through a three-phase separator and a series of cryogenic separators. The amine-based CO<sub>2</sub> capture process integrated with two cryogenic separators in the post-separation framework not only increases two high-purity (over 99.9%) products of carbon dioxide and propane but also it ensures the maximum negative net CO<sub>2</sub> emissions. The economic scenarios show that the prices of crude palm oil and carbon revenue are key factors to promote the commercial potential of the POPS.

# Design and intensification of the production process of propylene glycol as a high value-added glycerol derivative

Jahaziel Alberto Sánchez-Gómez <sup>a</sup>, Fernando Israel Gómez-Castro <sup>a</sup>, Salvador Hernández <sup>a</sup>

<sup>a</sup> *Departamento de Ingeniería Química, División de Ciencias Naturales y Exactas, Campus Guanajuato, Universidad de Guanajuato, Noria Alta S/N, Guanajuato, Gto. 36050, Mexico. [fgomez@ugto.mx](mailto:fgomez@ugto.mx).*

## Abstract

Glycerol is a by-product obtained in the biodiesel production. Such by-product can be used as raw material to obtain high added value derivatives. However, the reduction in energy requirements and capital costs for the conversion routes is necessary to enhance the economic indicators. This can be achieved through the intensification of the conventional glycerol processing routes. This work proposes the design and intensification of processes to produce propylene glycol (PG) from crude glycerol. Four different PG production schemes are analyzed. The conversion processes are intensified by means of thermal coupling and reactive distillation systems. Each system is designed by rigorous simulation in Aspen Plus<sup>TM</sup>. As results, it has been determined that implementing a thermally coupled system in the PG purification section, a clear decrease in the required reboiler duty (37%) is obtained.

**Keywords:** process intensification, crude glycerol valorization, process simulation, propylene glycol production.

## 1. Introduction

In the biodiesel production, the transesterification reaction generates large amounts of glycerol; for instance, in 2020, 46 billion liters of biodiesel were produced worldwide, with an estimated generation of more than 4.6 billion liters of crude glycerol (REN 21, 2021). The increasing glycerol excess has motivated the development of chemical processes which employ it as the main raw material. Among the different processes for the valorization of glycerol, oxidation, hydrogenolysis, dehydration, esterification, polymerization, carboxylation and pyrolysis can be mentioned (Pagliaro and Rossi, 2010; Monteiro et al., 2018). In the oxidation reaction, the main chemical derivatives to be obtained from glycerol are glyceric acid, dihydroxyacetone, lactic acid, mesoxalic acid and oxalic acid. Some intermediate products are also obtained, such as glyceraldehyde and glycolic acid (Monteiro et al., 2018). On the other hand, the reduction of glycerol generates mainly 1,2-propylene glycol, 1,3-propylene glycol, ethylene glycol and other by-products such as propanol, methanol and carbon dioxide (Muraza, 2019).

Propylene glycol (PG) is an important chemical product that can be used as surfactant, humectant, antifreeze, solvent, and preservative. Conventionally, PG is obtained by hydrolysis of propylene oxide, which is generated from petrochemicals. Alternatively, PG can be produced by a more environmentally friendly route by using glycerol as a

carbon and hydrogen source, requiring fewer fossil sources. Although cost competitiveness remains a major constraint, the conversion of glycerol to PG is a promising route. Evidence of this is the recent announcement by ORLEN Południe about the opening by the end of 2021 of a commercial green PG plant with a production capacity of 30,000 tons per year (ORLEN Południe, n.d.).

A strategy to enhance the economic indicators on the PG production process with glycerol as raw material implies applying process intensification strategies. Process intensification (PI) is a branch of chemical engineering by means of which it is possible to obtain more efficient processes. The main objective of PI is to achieve a technological improvement in a process, so that it occupies less space, it is more efficient with energy management and is cleaner and safer (Kiss, 2019). To achieve this objective, the aims are to reduce the size of the equipment and/or the number of basic operations of the process using multifunctional equipment. In this way, PI emerges as a strategy for generating highly efficient processes.

The present work has as main objective, the simulation, intensification and assessment of the hydrodeoxygenation process to produce high purity PG (99% mol) from glycerol using thermally coupled distillation columns and reactive distillation. The performance of the conventional and intensified processes is evaluated in terms of the energy consumption and the size of the equipment, measured through the required number of stages.

## 2. Methodology

### 2.1. Thermodynamic and kinetic modelling

Considering the polar nature of glycerol, the presence of hydrogen in the reaction systems, and the presence of organic compounds in a large amount of water, the NRTL model turns out to be the most suitable approach to describe the liquid-vapor equilibrium. Also, this model has been used in the literature to describe similar mixtures (Sun et al., 2022). The binary interaction parameters for the NRTL model were obtained from the Aspen Plus database.

The production of propylene glycol ( $C_3H_8O_2$ ) from glycerol ( $C_3H_8O_3$ ) has as by-products ethylene glycol ( $C_2H_6O_2$ ), methanol ( $CH_3OH$ ) and water ( $H_2O$ ). The reactions involved in the generation of PG are shown in Eqs. 1 and 2.

The hydrodeoxygenation of glycerol to produce PG occurs in the liquid phase, using Cu/ZrO<sub>2</sub> as catalyst. For this catalytic reaction, the kinetic parameters for a first-order power-law kinetic model obtained by Gabrysch et al. (2019) have been used; such kinetic model is given by the following equations:

$$r_1 = k_1 c_{H_2} \quad (3)$$

$$r_2 = k_2 c_{H_2} \quad (4)$$

Variation of the kinetic constant ( $k_i$ ) with temperature is given by the Arrhenius equation:

$$k_I = k_{0,I} e^{-E_{A,I}/RT} \quad (3)$$

where  $k_{0,I}$  is the pre-exponential factor, and  $E_{A,I}$  is the activation energy. The parameters required for the calculation of reaction rates are summarized in Table 1.

**Table 1.-** Pre-exponential factor and activation energy for hydrodeoxygenation reactions.

<b>I</b>	<b><math>k_{0,I}</math></b>	<b><math>E_{A,I}</math> (kJ/mol)</b>
1	$2.3 \times 10^{10} \text{ L mol}^{-1} \text{ s}^{-1}$	106
2	$9 \times 10^7 \text{ L mol}^{-1} \text{ s}^{-1}$	97

## 2.2. Process design and simulation

The analyzed processing schemes for PG production from glycerol are the conventional scheme (CS), a thermally coupled scheme (TCS), a reactive distillation scheme (RDS) and a thermally coupled reactive distillation scheme (TCRDS). The studied configurations are shown in Fig 1. The conventional process scheme (CS) is considered as the base case for comparison with the proposed intensified processes. The schemes have been rigorously simulated in Aspen Plus™, and the PG production process alternatives were jointly evaluated using the energy consumption (associated with operation costs) and the number of stages (associated with capital costs) as decision criteria.

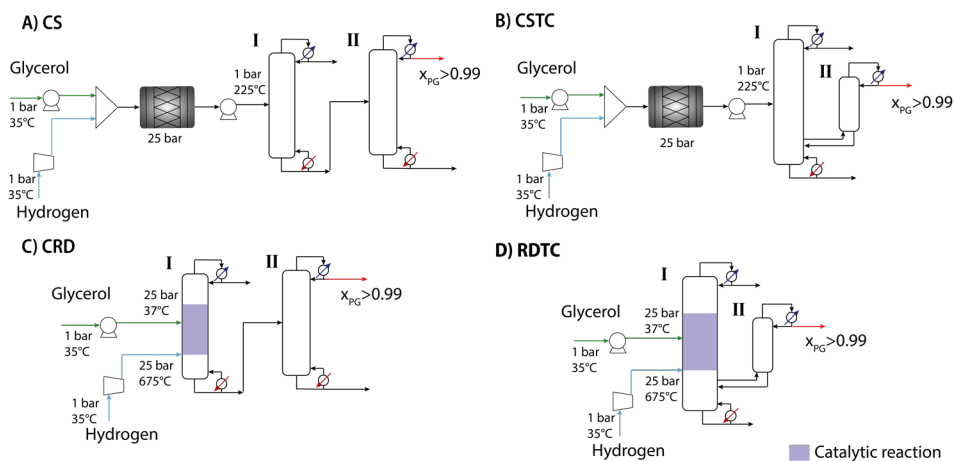

Most of the components have a very low boiling point compared to the product of interest and the rate reactions are fast, then it may be appropriate to use heuristic strategies for the design of the intensified process schemes (Keller, 2014). The feed stream has a flow rate of 100 kmol/h of glycerol and water (1:1 wt.). The distillation columns operate with a pressure drop of 10 psia (0.68 atm) and the reactions are defined in Aspen Plus™ as REAC-DIS type reactions, with residence times for the gas phase of 0.8 min for the hydrodeoxygenation reaction. The number of stages is determined through a sensitivity analysis, aiming to obtain the lowest number of stages necessary to obtain PG with a minimum purity of 99% in mol.

In the design of the thermally coupled alternatives, a sensitivity analysis in the interconnection streams was carried out. This procedure consists in the manipulation of the interconnection mole flowrate (vapor or liquid) to reduce the energy requirements of such schemes while the purity of PG is maintained at 99 % mol. Additionally, in the simulation of the proposed processing schemes, it has been necessary to fix the molar flowrate at the bottoms, since, based on a previous study, it was observed that these operating variables have a greater influence on the purity of PG in the output stream. In addition, by manipulating the reflux ratio it is possible to control the energy load in the reboiler.

### 3. Results and discussion

Figure 2 shows the required reboiler duty for the conventional and intensified processes. It is worth to mention that all the designs are still non optimal. However, all the designs satisfy the requirements in purity and recovery of PG. The results indicate that the conventional scheme (CS) have energy consumption of around 2169 kW. Additionally, the direct thermal coupling of CS to TCS represents a more significant decrease in reboiler duty than the intensification of the process using the reactive distillation system RDS. In the case of the TCS, this process shows the lowest energy consumption (1362 kW). However, the reactive distillation thermally coupled (TCRDS) has a very similar energy consumption to the TCS. The difference is only 13 kW.

**Fig 1.-** Schemes for the process of propylene glycol production from glycerol, a) conventional scheme (CS), b) thermally coupled scheme (TCS), c) reactive distillation scheme (RDS), d) thermally coupled reactive distillation scheme (TCRDS).

**Fig 2.-** Reboiler duty required in the processes for the production and purification of PG.

To complement the analysis, Table 2 presents all the design specifications, including the number of stages, the reboiler duty and the obtained savings. It has been found that for a similar value of energy requirements (1375 kW), the TCRDS requires a lower number of total stages (15) than the TCS scheme. Moreover, the TCS scheme requires a separate reactor, which would increase the equipment cost. In this sense, the TCRDS scheme would be presented as the most promissory processing scheme for PG production and purification, since it would represent the scheme associated with the lowest operating and capital costs.

**Table 2.-** Design specification for the conventional and intensified processes schemes.

<b>Scheme</b>	<b>CS</b>	<b>TCS</b>	<b>RDS</b>	<b>TCRDS</b>
Number of Stages				
Column I	20	40	20	35

#### 4. Conclusions

This work presents different alternatives to produce and purify PG using glycerol as raw material. Based on the topology of the conventional process, different intensified alternatives are proposed in the reaction and purification zones. The intensified processes have been contrasted with the conventional scheme. The results indicate that a maximum reduction of 37% in energy requirement can be achieved in comparison with the conventional scheme. The reduction in energy requirements lead to a more sustainable process and minor production costs of PG from glycerol. Additionally, the TCRDS shows important reductions in the number and size of processing equipment.

# Optimal Design of Heat Integrated Hybrid Dividing Wall Columns by Vapor Recompression

Dian Ning Chia, Fanyi Duanmu, Eva Sorensen\*

*Department of Chemical Engineering, University College London (UCL),  
Torrington Place, London WC1E 7JE, United Kingdom*

*\*e.sorensen@ucl.ac.uk*

## Abstract

A hybrid dividing wall column (HDWC) is a highly integrated design that combines a dividing wall column with a hybrid distillation-membrane process into a single process. It has previously been shown that HDWC can reduce the total annualized cost compared to its conventional DWC counterpart for the separation of an azeotropic mixture. The energy efficiency of HDWC can be further enhanced by vapor recompression, which is studied in this work. Since the HDWC has two reboilers, three different variations of heat integration are investigated, with the heat exchanger in the compression cycle replacing the reboiler in either the prefractionator, the main column, and for both columns, respectively. For the case study considered, it was found that the total annualized cost for the heat integrated HDWC can be up to 35% lower than the HDWC design, however, although heat integration always reduces operating costs, it may not always reduce total annualized costs.

**Keywords:** Process Intensification, Distillation, Hybrid Dividing Wall Column, Vapor Recompression, Optimization

## 1. Introduction

Process intensification (PI), the concept of integrating two or more processing units or methods within a single unit to enhance operation, is an important approach when designing more energy-intensified processes. Two of the most prominent examples of PI separations are the dividing wall column (DWC), where a ternary separation takes place within a single column shell, and the hybrid distillation-membrane process, where a membrane stage is incorporated into the design to help separate a close-boiling or azeotropic mixture. The DWC achieves energy savings through the reduction of mixing/remixing effects due to the central wall, while the incorporation of the membrane in a hybrid process provides savings by separating the mixture via a mechanism that is not based on VLE (e.g., solution-diffusion). Recently, Chia et al. (2022) introduced a hybrid dividing wall column (HDWC) that integrates both of these PI alternatives. In their work, the HDWC was compared with various standard hybrid distillation-pervaporation processes, and it was shown that the HDWC could separate an azeotropic mixture with a lower total annualized cost (TAC). The HDWC could be further improved by applying suitable heat integration methods to reduce energy consumption and TAC even further. It was also shown that heating and cooling requirements in the column part were about four times higher than that of the total energy required in the membrane part of the process. Therefore, further enhancement of energy efficiency is mainly dependent on the distillation column. There is no guarantee that heat integration methods will benefit the design (i.e., reduce TAC), as this depends on the process and the mixture, however,

Duanmu and Sorensen (2022) showed that vapor recompression can have great success in reducing both energy consumption and TAC for DWCs, thus vapor recompression will be considered and studied in this work. The HDWC process is here used to separate a binary minimum-boiling azeotropic mixture rather than a ternary mixture as for “regular” DWC, and the DWC has the central wall extending all the way to the bottom. The DWC is considered in a Petlyuk arrangement, i.e. a prefractionator and a main column.

## 2. Methodology

To apply vapor recompression heat integration, the condenser of the column is removed and the vapor distillate is pressurized by a compressor. A superheater before the compressor is required to maintain the vapor phase even after increasing the stream pressure. The pressurized high-temperature vapor is then utilized to vaporize the boil-up flow by replacing the reboiler with a heat exchanger. The standard hybrid dividing wall column (HDWC) is shown in Figure 1a. The design incorporates one condenser and two reboilers, which means there are a few variations that can be considered for vapor recompression-assisted HDWC. The high-temperature vapor can be used to vaporize the boil-up flow from the prefractionator (VR-HDWC-Pre; Figure 1b); from the main column (VR-HDWC-Main; Figure 1c); or from both columns (VR-HDWC-Both; Figure 1d). In the following, these three variations will be developed, optimized, and compared with the base case without heat integration (HDWC). All four structures shown in Figure 1 contain two separation units, a DWC (wall extended from the middle to the bottom) and a membrane network. For the DWC, the feed, with composition assumed to be below the azeotropic point, enters the prefractionator. A stream with composition close to the azeotropic point will leave from the top of the prefractionator (i.e., top of the wall) and enters the main column as the thermal coupling stream, while the remaining component (almost pure heavy component) will leave the system from the bottom of the prefractionator as product. The azeotropic stream will leave the DWC and pass to the membrane network. Unlike in the standard hybrid distillation-pervaporation process, where the purpose of the membrane is to purify the azeotropic mixture to achieve the product specification, here the purpose of the membrane is to assist in crossing the azeotropic point. Next, the retentate (with composition shifted to the other side of the azeotropic point compared to the feed composition) will be further separated in the main column section and almost pure light component will leave from the bottom of the main column as product.

The membrane network model proposed by Marriott and Sorensen (2003) is applied, where the membrane network contains  $n$  membrane stages connected in series, and in each membrane stage there are  $i$  membrane modules connected in parallel. It should be noted that the number of membrane modules in parallel in each membrane stage can be different and is determined through optimization. The procedure for constructing this membrane network and the overall hybrid distillation-pervaporation process can be found in Chia and Sorensen (2022). Although not shown in this work, before each membrane stage, a heater may be installed to improve the membrane separation performance and the requirement of each membrane stage heater can be optimized.

For the vapor recompression assisted HDWCs shown in Figures 1b to 1d, the condenser is replaced with a series of superheater, condenser, and trim cooler. The superheater and condenser create a pressurized vapor with high temperature, which allows heat exchange between the vapor and the liquid bottom flow from the distillation column. Three VR-

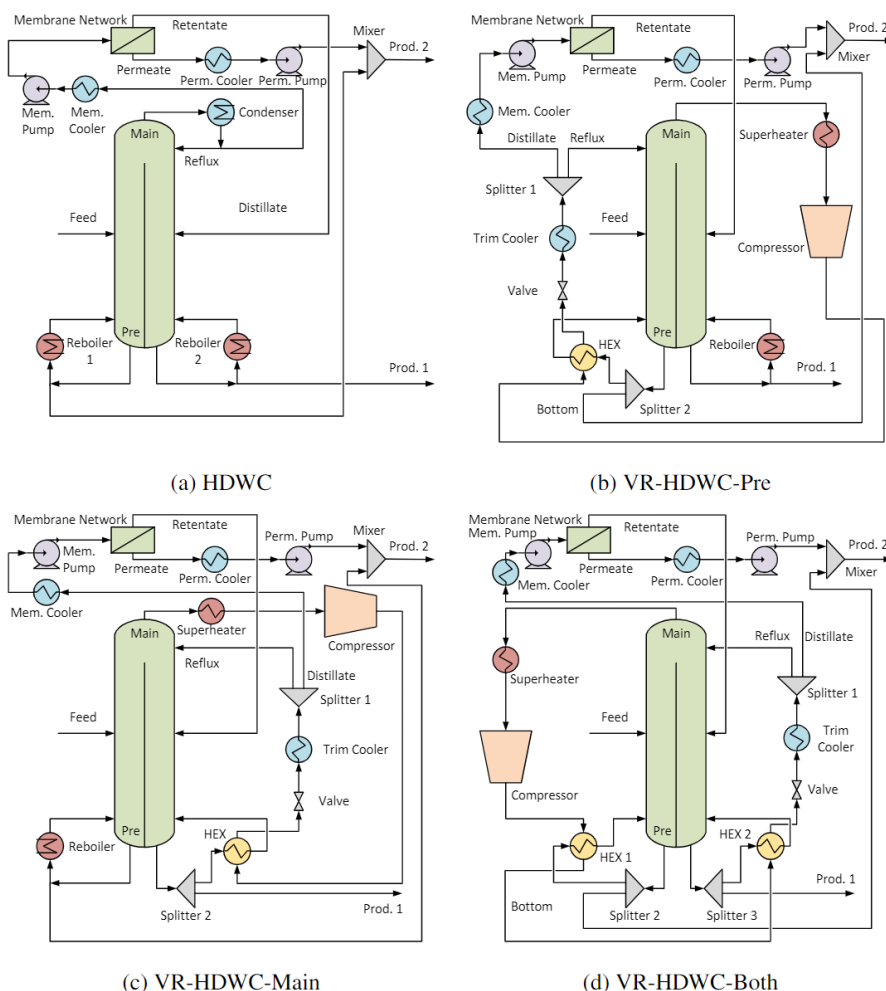

Figure 1. Flowsheets of (a) the base hybrid dividing wall column (HDWC) and vapor recompression assisted HDWCs with the heat exchanger replacing the reboiler in (b) prefractionator, (c) main column, and (d) both columns.

HDWC structures are named based on the location of the heat exchanger, i.e., VR-HDWC-Pre is the system with the reboiler in the prefractionator replaced with a heat exchanger, and VD-HDWC-Main where the heat exchanger is replacing the reboiler on the main column side. In VR-HDWC-Both, the pressurized vapor heats up the liquid bottom stream from the prefractionator first (as it has a higher boiling point compared to that of the main column), and then heats up the liquid bottom stream from the main column. For all, the hot outlet from the last heat exchanger passes through a valve to reduce its pressure back to the column operating pressure. Then, the stream is cooled down to the saturated liquid as both reflux and the feed to the pervaporation membrane need to be in the liquid phase.

### 3. Case Studies

The case study considered is the separation of  $0.2/0.8 \text{ mol mol}^{-1}$  of ethyl acetate and

ethanol. The feed is assumed to be saturated liquid at 1 atm, and is supplied at  $200 \text{ kmol h}^{-1}$ . The product purity specifications are 0.99 mol%. UNIQUAC is used to describe the liquid phase thermodynamics, while ideal gas is assumed for the vapor phase. The minimum temperature approach is set as 10 K in the heat exchangers.

All models (rigorous equilibrium-based) are built in gPROMS Process (Process Systems Enterprise, 2021). As there are no available libraries for dividing wall columns, the corresponding Petlyuk structure (not shown) is constructed using the built-in distillation column library, while the pervaporation membrane is modeled using a user-defined model. The cost equations for the distillation column can be found in Duanmu et al. (2022b), while the membrane costs can be found in González and Ortiz (2002). The optimizer chosen is the Particle Swarm Optimization (PSO), and the details of the settings can be found in Duanmu et al. (2022a). The constraints for the optimization include the product purities, using the same number of stages on both sides of the wall, a minimum approach temperature in the heat exchanger, and no phase change in the compressor (i.e., the vapor fraction in the stream after the compressor equal to one).

The key results for each optimal design are shown in Table 1. For the column design, all designs have a similar total number of stages for both the prefractionator (25-28) and the main column (27-29). The feed locations in HDWC are slightly lower compared with the VR-HDWC designs. There are no clear reasons for this, as there are no clear mixing effects observed from the liquid composition profiles in each design (not shown), indicating that the feed locations are reasonable. The changes in the feed locations may be dominated by other factors, which will be discussed later. Moving to the specifications in the main column, it is clear that the side liquid flow rate in the main column (i.e., the liquid thermal coupling stream at the top of the wall) for both VR-HDWC-Pre and VR-HDWC-Both is higher compared with the other two designs, and this is a result of the reboiler in the prefractionator being replaced with a heat exchanger. It can be seen that the trim cooler duty in both VR-HDWC-Pre and VR-HDWC-Main ( $-1164 \text{ kW}$  and  $-971 \text{ kW}$ , respectively) are large, indicating that the energy capacity of the pressurized vapor is much higher than the energy required in the heat exchanger. Therefore, increasing the side liquid flowrate will increase the flow rate of the cold liquid in the heat exchanger, which will, in turn, maximize the energy transfer between the pressurized vapor and cold liquid, and at the same time develops a better composition profile in the prefractionator (i.e., the top vapor compositions from the prefractionator are closer to the azeotropic point than the other two designs).

Next, the smaller number of membrane modules required in VR-HDWC-Main and VR-HDWC-Both can easily be explained. In order to minimize the energy wasted (i.e., to minimize the trim cooler duty), VR-HDWC-Main and VR-HDWC-Both tend to maximize the energy exchange in the heat exchanger by prioritizing the separation of the pure component from the azeotrope in the main section of the distillation column rather than in the membrane, thus the number of membrane modules required are fewer. In other words, the sloppier membrane separation will cause the heat duty required in the heat exchanger to increase, thus utilizing more of the energy from the pressurized vapor (i.e., decreasing the trim cooler duty) and, at the same time, reducing the membrane demand, which is a win-win situation for VR-HDWC-Main and VR-HDWC-Both. This is reflected in the higher boil-up flow rate and lower pure retentate composition in VR-HDWC-Main and VR-HDWC-Both when compared to the other two designs (not shown). Considering the energy consumption, it is clear that VR-HDWC-Both has the

Table 1. Optimal results for the base hybrid dividing wall column (HDWC) and the vapor recompression assisted HDWC with the heat exchanger replacing the reboiler in the prefractionator (VR-HDWC-Pre), main column (VR-HDWC-Main) and both columns (VR-HDWC-Both).

† Upper bound for the number of membrane stages is 8.

highest duty in the heat exchanger and lowest duty in the trim cooler, indicating a higher energy efficiency of the heat integration structure.

Comparing the economic performances of each design, the capital cost (CAPEX) is much lower for HDWC (about 34 % reduction compared with VR-HDWC-Pre), and the main reason is the high cost of installing the compressor in VR-HDWCs (contributing to about 40% of the CAPEX). It should be noted that the membrane cost in VR-HDWC-Main and VR-HDWC-Both on the other hand drops significantly (up to 33%) compared with HDWC due to the smaller membrane network required, as explained earlier. Considering the operating cost (OPEX), it is not surprising that all three VR-HDWCs have lower OPEX due to the energy saving in the reboiler heating cost, especially for VR-HDWC-Both. In terms of the TAC, the objective function in the optimisation, VR-HDWC-Both is the cheapest design with about 35% TAC reduction compared to HDWC. VR-HDWC-Main, however, is about 10 % more expensive than HDWC. This indicates that the VR-HDWC designs may not always yield a lower TAC, as the VR-HDWC designs are closely related to the trade-off between the capital cost of the compressor and the operating cost. The TAC is also strongly influenced by individual costs (not shown).

#### 4. Conclusions

In conclusion, this work proposed three vapor recompression assisted hybrid dividing wall column designs (VR-HDWC) to further improve energy efficiency compared to just a hybrid dividing wall column (HDWC). Compared with the base HDWC design, all VR-HDWC designs save operating costs, although not always total annualized costs (TAC) as the results of the vapor recompression assisted design relies heavily on the trade-off between the more expensive compressor capital cost vs the cheaper electricity cost.

### Abstract

In this work, we show that the systematic and simultaneous implementation of some heat integration alternatives like direct reboiler condenser heat exchange, implementation of vapor (re)compression cycles, leverage of heat in high-pressure steam utilities at lower pressure/temperatures, multiple effect distillation, etc. can eventually produce considerably reductions in energy and total annualized cost. While none of these alternatives is new, they are rarely simultaneously implemented in a distillation sequence, however, we show that there is great potential in the synergic effects of implementing simultaneously some of them. We illustrate the procedure with the separation of a mixture of acetone and chloroform using pressure swing distillation. Results show that we can get impressive reductions in energy and total annualized costs.

**Keywords:** add three to five keywords here.

### 1. Introduction

Even though in the chemical industry there are a good number of alternatives to separate components, distillation accounts for around 90-95% of all the separations and purification (Humphrey and Keller, 1997), and it seems that this situation will not change shortly. Notwithstanding, it is not uncommon the claim that distillation must be substituted by other, more efficient separation technologies (National Academies of Sciences, 2019). The main reason is based on the fact that distillation vaporizes a mixture in the reboiler and then liquifies a vapor stream in the condenser. While this is true in a single distillation column, Agrawal and Tumbalam Gooty, (2020) have shown that energy required in distillation is not necessarily proportional to the reboiler heat duty and that distillation can be much more efficient than what intuition seems to suggest. Even more, they presented an industrial separation example -separation of propylene from propane using distillation and membranes- that contradicts this believe. They showed that, in this case, distillation needs only a fraction of the energy requirement for membrane separation.

Different alternatives have been proposed to increase the energy efficiency in distillation. If we are dealing with a single separation (i.e. a single distillation column) we can consider alternatives like multi-effect distillation, and intermediate heat exchangers either in the rectifying or in the stripping section, -the optimal location, which can be done using column grand composite curves-, (Bandyopadhyay et al., 1998), pre-fractionations, internally heat integrated distillation columns (HIDiC) and heat pump assisted distillation (Vapor recompression, Mechanical or Thermal Vapor recompression -VRC- or absorption heat pumps) (Kiss et al., 2012) and combinations of some of the previous

alternatives. Kiss et al., (2012) also gave an algorithm for selecting a technology for heat integration in binary distillation.

In multicomponent distillation, the number of alternatives increases because we can integrate the alternatives for heat integration between different columns with those of a single column and the alternatives for column sequencing inherent in multi-component distillation. Therefore, if the number of possible sequences is large, the first stage must be selecting a sequence of distillation columns with inherent good energy performance and then systematically checking for the different alternatives to increase energy efficiency.

In the case of zeotropic distillation, the structural characteristics of the search space were defined by different authors around 10-15 years ago (Caballero and Grossmann, 2006; Giridhar and Agrawal, 2010) Those authors, established the basis, and the structural considerations to take into account for generating valid sequences of columns that range from sequences based on conventional distillation columns (a column with one condenser, one reboiler, and two products) to fully thermally coupled distillation sequences (a single reboiler and a single condenser for all the separation sequence). From these sequences, it is possible to systematically generate intensified alternatives like Divided Wall Columns (DWC), and Kaibel Columns – which separate 4 components in a single column-, among others. A recent review of the advances in intensification in distillation can be found in the work by Jiang and Agrawal, (2019).

In the case of separations involving azeotropes, the number of alternatives is considerably lower than that of the zeotropic counterpart, and there are other considerations to take into account. For example, in extractive distillation, the selection of the extractant is likely the decision with the highest influence on the energy consumption of the system.

In multi-component distillation, the direct heat integration between the condenser of a column and the reboiler of another, modifying the pressure(s) in the column(s) if necessary is the most obvious alternative for saving energy, and different optimization strategies have been proposed since the 70s of the last century.

However, while there are a good number of alternatives for improving the energy efficiency in distillation it is uncommon to implement two or more alternatives simultaneously. In this work, we show that the simultaneous combination of different alternatives can produce important savings in energy (and in total annual cost). Besides we present a framework to combine all those alternatives, and of course, the new ones that could eventually appear.

## **2. An algorithm for efficient energy integration in distillation.**

The implementation of an optimization model (i.e. through a superstructure) to simultaneously design/optimize the distillation sequence and each column in it together with all the considered alternatives for heat integration, is likely to produce very large and complex models, that could be, in the best case very hard to solve. Instead, we propose an approach that sequentially tries to improve efficiency in the selected configuration:

1. Select the best sequence of distillation columns. If we are considering a zeotropic mixture we can use any of the approaches based on mathematical programming to get the optimal configuration. For example, (Nallasivam et al., 2016) used an algorithm that ensures the global optimal solution. In those cases, it is also common that there are some alternatives with similar performance, so a priori we should select a sub-set of alternatives. In azeotropic (extractive, reactive...) distillation, the starting point is an optimized feasible separation sequence.

2. In the first place, we must consider the possibility of heat integration with the rest of the process. In some cases, there is a waste heat stream, that can be used in distillation and no further action is needed. (We do not consider such a case in this paper)
3. For each column in the sequence, we determine the lower and upper pressure limits. This can be based on thermodynamics, product stability, security or operational issues, etc. The pressure determines which are the highest and lowest temperatures in each column in the condenser and reboiler.
  - 3.a. The change of temperature (pressure) allows the development of strategies for direct heat integration between condensers and reboilers of different columns by manipulating the pressure of the columns if necessary. In the literature, there are different models to do this step rigorously (Caballero and Grossmann, 2006; Floudas and Paules, 1988)
  - 3.b. The limits in pressure and temperature allow for determining the possibility of multi-effect distillation which has a special interest in difficult separations.
4. When we stack two or more columns -this is the case of divided wall columns and some thermally coupled sections- it is usually necessary to increase the internal flows in some column sections with the corresponding extra energy consumption. In those cases, an intermediate heat exchanger can help to recover the system's optimal operating conditions, and in some cases, it is possible to implement a VRC that reduces, even more, the column duty (Navarro-Amorós et al., 2013)
5. If the sequence requires heat at very different temperatures, in some situations it is possible to recover energy from the exhausted high-temperature utility to use them at lower temperatures. For example, from high-pressure steam (say at 250 °C, 40 bar) that produces 100 kW when condensates in a reboiler, it is possible to recover 18.9 kW at 180 °C by expanding the exhaust water up to 10 bar and 34 kW if we expand to 1.2 bar (~120 °C).
6. The use of intermediate heat exchangers (reboilers in the stripping section and condensers in the rectifying section) can, in some cases, reduce the condenser/reboiler heat duties, which can be substituted with cheaper utilities. Besides, these new heat exchangers can eventually be used in the heat integration strategy. Column Grand Composite curves (CGCC) can be used to determine the optimal location of those heat exchangers (Bandyopadhyay et al., 1998)
7. Heat pump-assisted configurations (Kiss et al., 2012) (vapor compression, mechanical or thermal vapor recompression, absorption heat pumps, bottom flashing, etc.) can be implemented not only between the condenser and reboiler of a given column but between different heat exchangers (source and sinks of heat) whose temperature difference is not too large (typically no more than 30°C)

The systematic application of all those alternatives can yield a rich space of alternatives with an important potential for energy reduction.

Finally, considering the intensification of the sequence of columns could allow extra savings in investment. This last point is out of the scope of this work, but a review of different alternatives can be found in Jiang and Agrawal, (2019).

### 3. Discussion on Results

To illustrate some of the characteristics of the proposed algorithm we consider the separation of a mixture of Acetone and Chloroform using pressure swing distillation (PSD). The objective is to obtain each product with a purity of at least 0.995 mol fraction. Table 1 shows the data for the example.

Table 1. Data for the example.

Components	Composition (mol fraction)	Feed Flow	Pressure
Acetone	0.75	80 kmol/h (5872 kg/h)	101.3 kPa
Chloroform	0.25		
Cold Utilities	Cost (\$/kW·y)	Hot Utilities	Cost (\$/kW·y)
water (20-15 °C)	11.4	LP Steam (~2 bar 120 °C)	277.5
		HP Steam (~10 bar 180 °C)	292.18
Thermodynamics NRTL (default Aspen-HYSYS parameters)			
Electricity 0.067 \$/kWh			
interest = 10% in 10 years			
Cost estimation based on correlations by (Turton et al., 2013)			

The base case distillation sequence is shown in Figure 1. The simulation of the PSD separation was done in Aspen-Hysys V.11, including the sizing of the columns. The base case has a total module cost of k\$1,710. The total cost of utilities is 2,901.7 k\$/year with a cost of manufacturing (COM) of 3,900.3 k\$/year, which yields a TAC (total annualized cost) of 4,198.7 k\$/y. The feeds to all the columns are forced to be saturated liquids, so it is necessary to include some heat exchangers in all the streams entering the distillation columns.

Figure 1. Separation of Acetone and Chloroform by PSD. Base case for comparison. Numbers in the square brackets refer to acetone mole fractions, and numbers in brackets refer to tray number.

Even though there is some degree of freedom in the selection of the pressures of both columns, in this case, the pressures are mainly determined by the variation of the azeotrope composition, so column pressures will be fixed in all the alternatives.

It is possible to leverage part of the energy of the exhausted MPS (water around 10 bar and 180 °C) by expanding it to 1.4 bar (~110°C). If we separate the vapor fraction it is possible to recover 593.8 kW by condensing this new low-pressure steam than can be used in the low-pressure column. Figure 2a shows the resulting process. The utility cost is reduced by 5.8 %.

Figure 2a. suggests that it is possible to increase energy efficiency and the manufacturing cost by the heat integration of the different hot and cold streams (heaters, coolers, condensers, and reboilers.) The most obvious is the integration of the condenser of the high-pressure column with the reboiler of the low-pressure column -Figure 2b-. A pinch analysis shows that it is possible to reduce the cost of utilities to 1,433 k\$/year with a cost

of manufacturing of 2,094.7 k\$/year and a TAC of 2,392.8 k\$/y. This is a reduction in the cost of utilities of 50.1% and a reduction in TAC of around 43%.

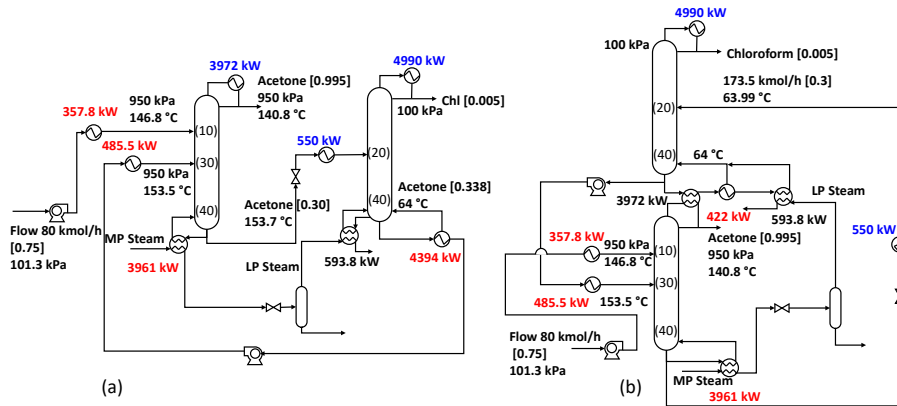

Figure 2. (a) PSD acetone and Chloroform in which the exhausted MP Steam is expanded to 1.4 bar to recover a fraction of energy in form of LP-Steam that is used in the reboiler of the LP-column. (b) include the integration between the condenser of the HP column and the reboiler of the LP column.

The temperature difference between the reboiler and condenser in the HP column is lower than 15 °C in both columns. In these conditions, a VRC usually allows for reducing energy costs, even though the capital cost can increase considerably. In this case, it is possible to implement a VRC in each column and at the same time maintain the possibility of heat integration between the condenser or HP column and the reboiler of the LP column (Figure 3).

Capital cost increases to 4,040 k\$, around 120%, but energy cost decreases also considerably. A pinch analysis shows that total energy cost is reduced to 533.0 k\$/y, which yields a COM of 1,382.8 k\$/y and a TAC of 2,037 k\$/y. Savings in energy costs and TAC are around 81% and 51.5 % respectively compared to the base case and around 63% and 14.9 % compared to the best heat-integrated sequence without VRCs.

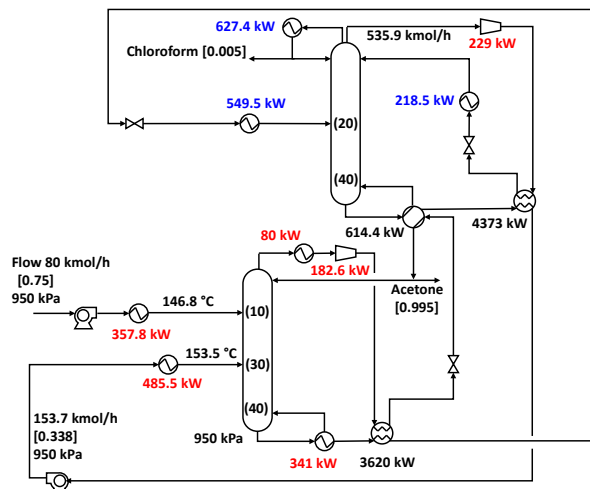

Figure 3. Integration of a Vapor Recompression Cycle in each column. Note that heat integration between the condenser in the HP column and the reboiler in the LP column is still possible.

#### 4. Conclusions

In this paper, we have shown that it is possible to increase the efficiency of distillation columns by sequentially and iteratively adding different alternatives of heat integration. While no one of those alternatives is new, the simultaneous consideration of all/some of them can produce an impressive increase in energy efficiency that is reflected in a considerable reduction in total costs.

We have illustrated the procedure with the separation of a mixture of acetone and chloroform using pressure swing distillation. The systematic consideration of different available alternatives allows for reducing the energy cost by an impressive 81% when compared with a non-heat integrated based case or 51.5% compared with a base case using only direct heat integration. In terms of TAC, reductions are around 63% and 14.9% respectively.

## Abstract

The climate changes that have occurred in recent years are modifying the characteristics of the environment. Seas and oceans swallow, each year, a part of the CO<sub>2</sub> we emit, acidifying it in consequence (*Francour and al., 2006*). To respond to this environmental alert the Dassault Systèmes Foundation launched a call for projects to UniLaSalle students to help protecting the oceans and reduce the anthropic impact. Using the Design Thinking method, the students developed solutions that links the working methods of designers and engineers. This method is a perfectly adapted approach to answer this type of problem because designers work for human beings, while engineers work for the nature. It was use in order to well understand the perimeter of the project. Its exercises allow you to ask questions about the general appearance of a project while keeping in mind how humans and/or the environment can impact it or be impacted.

**Keywords:** Artificial Reef, Design Thinking, Fluid simulation, Innovation, Modelling.

## 1. Introduction

The Dassault Systèmes Foundation had invited UniLaSalle students to participate to a call for projects. Their goal was to bring together Design and Engineering in order to mix, within the framework of science, different ways of thinking. To do that, the Foundation asked students to create a scientific project with the aim of protecting the oceans and offered them a training in Design Thinking to organize their ideas in a new way.

Climate change, which currently affects 45% of threatened marine species, is not the only stressor threatening the marine environment. It is the fifth most important factor after overfishing, transport, urban development and pollution (Wait, 2022). Therefore, it is imperative to start to focus on the preservation of the ecosystem.

During this project, Design Thinking allowed the team to highlight the importance of public awareness and the progress of research. In order to deal with this problem, the student chose to develop a project based on the creation of artificial reefs connected to sensors in order to follow the progress of the environment in which they are located. The goal was to create a database that could be used to create animations in museums or to support researchers working on specific marine environments. Step by step, the main idea switch from the development of artificial coral reefs to intelligent 'reefed' mooring posts. This change expanded the study area to regions of high anthropogenic stress and promoted the presence of fauna and flora in ports (Luff et al., 2019). On this file, it will be explained the processes of design thinking, modulization and simulation that permitted this reconversion.

## 2. Methodology

### 2.1. The Design Thinking process

*« Most people mistakenly think that design is about appearance (...)  
That's not how we define design. (...) Design is how it works»  
- Steve Jobs in 2003*

This approach, based on people, was oriented towards innovation in order to create innovative services or products. The particularity of this approach is the modification of the working method (Usabilis, 2018) by asking the right questions at the beginning of the project in order to guide its development into the right direction.

During the creation phase of the project, three workshops had been set up by the Design Studio in order to guide UniLaSalle students through the learning and use of Design Thinking. This approach made it possible to co-create projects and to determine future problems and needs by following a precise thought process (Figure 1). In this context, the supervisor prepared exercises on a remote collaboration space called Miro. This tool consists of a whiteboard that allows you to work and share your ideas with images, post-its, mind maps, tables, text boxes, and other tools.

Design Thinking exercises allow to ask questions about the general aspect of a project while keeping in mind how humans and/or the environment can impact it or be impacted. These are lighthearted questions that specify each parameter of the project, thus allowing the team to grasp most of the difficulties it will encounter in the future (Figure 2). They follow a pattern that always involves: actors, priorities, problems and proposed solutions.

Figure 1: Three steps to simplify the process (Usabilis, 2018)

**The group work on the determination of the specific part of the opportunity with the helps of the analogy of a fortress:**

- 1 **The Drawbridge:** The digital innovation possibilities.
- 2 **The Walls:** The biggest legacy we'll have to handle.
- 3 **The Towers:** Actors who can help to leverage the project.
- 4 **The Market:** External data and information needed to trigger the project.
- 5 **The Dungeon:** The core mission of the opportunity.
- 6 **The Dragon:** What can make us fail? (Competitors, business context...)

Figure 2: Exercise questions of the fortress realized by the Design Studio

To complete these exercises, the engineering students answered the questions using post-its. This method allowed everyone to express themselves and to understand the opinions of others in order to discuss the problems of the project.

Following this step, each group made a pitch explaining their project. Three meetings were held in order to answer new questions:

- What is the problem? Context, understanding of human problems, environmental impact, opportunities and trade-offs?
- What solution is proposed? To do what? At what cost? What is needed to implement it? What will be tested to verify its relevance?

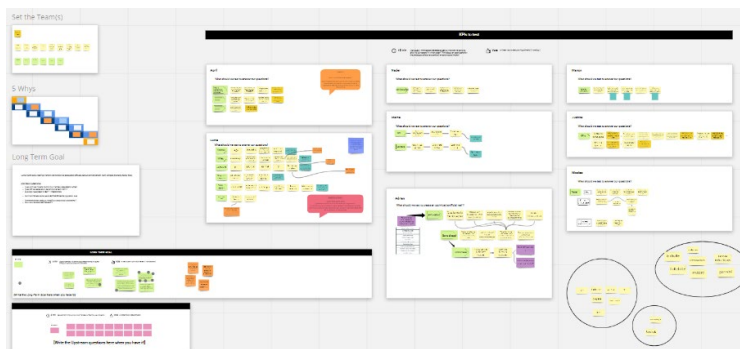

Figure 3: Example of Design Thinking work done on Miro

These pitches were used to distinguish which project would be about to be developed for an internship. The chosen subject had been the one that is presented on this paper: the "intelligent artificial reef". Therefore, the 4 members that imagined this solution constituted a team of students coming from different specialities (biology, environment, mechanics and geology) in order to develop it.

In order to create a group spirit and to communicate everyone's ideas, the new team had a formation of Design Thinking with the Design Studio supervisor. This period allowed students to bond during the important choices of the project by taking votes. Each student had post-its that they could place on whatever their choice was. The 3 choices with the most votes were then put aside to make a second round. The main objective was to make everyone agree with the development of the project by letting them discuss and debate (Figure 3).

This period also gave the students personal goals and a problem to solve. From this stage on, the students worked semi-autonomously as a small research office would. The Design Studio accompanied the group conducting weekly meetings on Friday mornings, for 30 minutes to 1 hour, to monitor the project and advise its members. These meetings began early and ended on the day of the Fondation Dassault Systèmes visit, at the end of the internship. The framing of these meetings allowed the team to refocus in this research in order to avoid misdirection and not waste time. Moreover, these project reviews allowed students to use Design Thinking by reflex, they no longer need to consult each other before a meeting because everyone follows the role of the others and knows where the project is at.

## 2.2. Digital designs and simulations

The Ocean ReGen team worked on the creation of an artificial reef and "reefed" mooring post, both composed of sensors to monitor the physico-chemical and biological criteria of the marine environment (sound, image, turbidity, temperature, pollution and population tracking). The sensors that make up the electrical system of both solutions could be modified according to the user's needs by slightly modifying the proposed system.

To carry out this project, the students used Dassault Systèmes solutions such as the 3DEXPERIENCE platform. This platform is a collaborative environment that allows the creation of innovative products using virtual experiences. It also provides a real-time view of project activity through its 3D Dashboards (Figure 4), which connect people, ideas and data.

This collaborative environment also allows the use of some Dassault Systèmes software, including Catia, Creative Experience and Drafting. The most important is the Catia software. It allowed students to model their reefs and moorings spots in 3D. These models were then used in the Drafting application to create constructions plans for each shape and then in Creative Experience to make virtual enhancement videos. In addition, these models were imported into XFlow, a fluid simulation software, also produced by Dassault Systèmes, but not included into the 3DEXPERIENCE platform. In order to optimize to the maximum their creation, numerous 3D models had been produced.

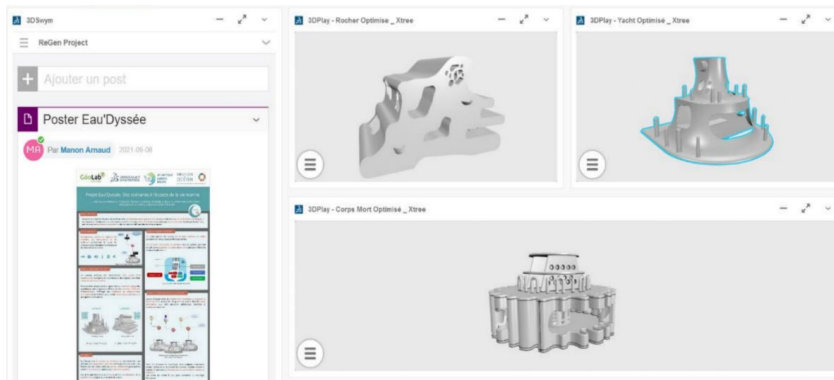

Figure 4: Example of a 3D Dashboard presenting the 3D models of the reefs made

XFlow permitted to choose the most appropriate shape for the team's needs by following some criteria... In order to attract as many species and entities as possible, reefs and moorings must have a complex shape (Charbonnel et al., 2001) and had to own shadow zones, turbidity, an upward current and a dead zone (where the current is weak or non-existent) within or behind the structure (Figure 5).

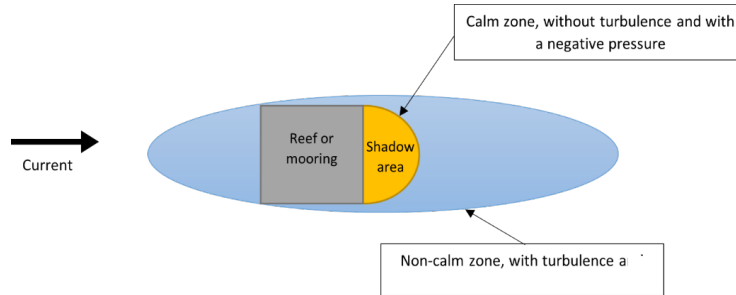

Figure 5 : Diagram of the current behavior in front of an immersed structure

Ocean ReGen students realized meetings with 6 scientists working in the domain of artificial reefs in order to have opinions on their achievements and to have new proposals. Those meetings helped the students to choose the ideal location, the shape and the materials of the reef.

Figure 6 : Deflecting the current with an artificial reef (realised on Adobe Illustrator)

This particularly form (Fig. 6) had been developed in order to correspond to the criteria previously described in figure 5.

This form can further disperse the sand like you can see with the red arrows. This allows lateral movement of the sediment which helps slow down the waves at the back of the reef. However, this also creates an acceleration of the current on each side of the shape and creates erosion which can cause the structure to bury.

Indeed, most of the structures are made of concrete and the classic concrete weighs  $250 \text{ kg/m}^2$  for 10 cm thickness (Béton, 2019). It happens that some structures are buried by 60% in only 5 years. Unfortunately, it remains one of the biggest challenges that encounter companies or researcher that try to create new reefs and the students weren't an exception. Indeed, because of this burial rate, the structures must be removed after few years.

This burial is mainly due to their weight and shape.

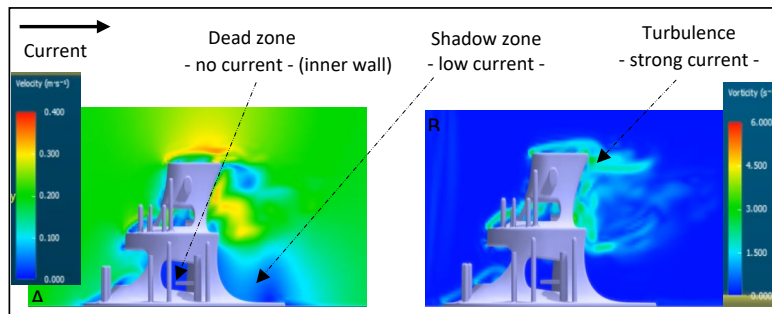

Figure 8 : Simulation of current speed (A) and turbidity (B) on XFlow® (Yacht)

Thanks to a fluid simulation software, it was possible to see that this shape respects the presence of a dead zone (without current), a shadow zone (weak current) and a zone with strong turbulences. These selection criteria were chosen because the turbulence makes noise and attracts crustaceans,

the dead zones are useful for species that like areas without current and the shadow zone at the back of the structure allows a mix between the two. The objective in gathering all these criteria is to attract as many different fish species as possible. These three 3D models are therefore the latest versions proposed by the students (Figure 7).

### 3. Analysis

#### 3.1. Project development through collaboration between Design & Engineering

The confrontation between Design & Engineering allowed the emergence of many ideas. The initial concept developed by the selected team proposed the implementation of an intelligent artificial coral reef. However, following the collective reflexion activities orchestrated by the Design Studio, the training of the different Dassault Systèmes tools and the exchanges with professionals such as Ifremer, ALR, the MIO... the project underwent many changes.

A final visit to the Fondation Dassault Systèmes permitted the Ocean ReGen project team to propose two different scenarios for the implementation of reefs. First of all, the aspect of artificial coral reefs had disappeared. Indeed, the project had split into two parts, one of which allows the implementation of an intelligent artificial reef and the other one of a reefed mooring post, also intelligent. An artificial reef would be a structure that would be voluntarily immersed in water to help the biomass to develop. A traditional mooring post is a massive concrete platform that is immersed. This structure, connected to a chain and a buoy, allows the anchoring of boats in order to avoid the ravages caused by anchors on the sea floor. The difference with the reefed mooring post would come from the shape of the structure. Unlike a massive block, the goal is to complexify its shape to create a mini reef while keeping the basic utility of a traditional mooring post. This idea came from exchanges with researchers who worked on the Port-Cros reefs immersed in 1985. Their feedback and advices guided the choices made by the group of students regarding the shape of their structures and their location.

On the other hand, the weekly design meetings also helped to guide the choice of sensors for the intelligent system while linking them to the human. To do this, the student had to answer why and to whom? In others terms: Why use these sensors and for whom would they be useful? The chosen ones are hydrophones, cameras, a tracking system, turbidity, temperature and pollution sensors. (Table 1)

Sensors		for whom?
Hydrophones	<ul style="list-style-type: none"> <li>Lack of knowledge about marine sounds.</li> <li>Identify day/night organisms.</li> <li>Locating disturbing anthropogenic sounds.</li> <li>Monitoring against illegal fishing ...</li> </ul>	<p><b>Museums:</b> diffusion of videos and aquatic sounds to show marine life to the general public</p> <p><b>Researchers:</b> ecological monitoring of the environment and scientific discoveries</p> <p><b>Authorities:</b> coastal surveillance for the protection of marine organisms by fighting against illegal fishing</p> <p><b>Swimming monitoring:</b> turbidity and pollution levels can be used to prohibit swimming and protect the public.</p>
Video cameras	<ul style="list-style-type: none"> <li>Ecological monitoring of species.</li> <li>Surveillance against illegal fishing.</li> <li>Information on the transparency of the water and the possibility of diving.</li> </ul>	
Turbidity sensors	<ul style="list-style-type: none"> <li>Detection of turbidity anomalies and thus detect certain pollutions.</li> <li>Information on the transparency of the water and the possibility of diving.</li> </ul>	
Temperature sensors	<ul style="list-style-type: none"> <li>Information on ocean warming.</li> <li>Understand the impact of temperatures on marine organisms.</li> </ul>	
Capteurs de pollution	<ul style="list-style-type: none"> <li>Monitoring of pollution levels in ports and bays.</li> <li>Monitoring the impact of pollution on marine populations</li> </ul>	
Tracing system	<ul style="list-style-type: none"> <li>Ecological monitoring of fish species (interaction and movements).</li> </ul>	

Table 1: Table of sensors use

In order to illustrate the process a little better... After a meeting with Atlantique Landes Récifs, the association expressed a need for cameras in order to obtain information on the environment around the area where their reefs are located. The usefulness would allow to know the level of transparency of the water thanks to the recordings video in order to be able to organize their diving missions. Public awareness was one of the main missions of the Ocean ReGen team. For this purpose, the data from the tracking systems, the sounds recorded by the hydrophones as well as the images from the cameras could be transmitted and used by museums or schools. The same is true for the data collected by the temperature and pollution sensors. Moreover, those sensors would also help the scientific progress and the development of nature. Human being knows little about marine sounds. It would have the possibility to increase the amount of data concerning the degradation of the biomass and the impact of the implantation of the structures that the ReGen Project team proposed.

The Design Studio's methods were reused many times by the team members. When it came to gathering everyone's ideas, Miro was the main tool used to create, deliberate and choose the best idea. This was helpful when it came to choosing the shape of the logo, the slogan phrase and the project name. The same was true for the choice of the reef shapes and mooring post. Dozens of 3D models were made and only 3 were chosen.

### 3.2. Students' feedback on the collaboration between Design & Engineering

This experience was filled with questioning, misdirection and success. The Design Thinking process allowed the group of students to see and revisit their ideas, project progress, and goals many times. Originally, the students aimed to incorporate salinity and oxygen sensors into the system in addition to temperature and turbidity... However, after a meeting with the deputy director of the MIO (Mediterranean Institute of Oceanology), instead he advised them to implement hydrophones. This technology is not very developed nowadays and marine sounds are still not well known

in the scientific world. The same is true for cameras. After discussions with ALR, the usefulness of incorporating them into the system would be beneficial to them. Consequently, after having worked for several weeks on the installation of the wrong sensor device, the mechanical pole had to radically reorient its research.

The team of 9 students managed to be quick in their decision making allowing the project to develop quickly. This was possible thanks to their motivation, the advice of external professionals and the Design Thinking methods taught by the Design Studio at the beginning of their internship. The team became more cohesive and was able to focus on the task at hand.

Design Thinking allows different domains to mix and move forward together. Indeed, this method allows to build a project link by link, by considering future problems. This way of thinking is the very source of research. Generally, the students particularly appreciated the use of Design Thinking and planned of using it for their future research projects.

#### 4. Conclusion and perspectives

Finally, the use of Design Thinking helped to direct and organize the project. The collaboration with the designers allowed the engineering students to learn a new approach to project management and the objectives of innovation. Thanks to it, the students were able to propose two scenarios that meet the needs of the environment and humans. Their work on the reefs already allows the 3D printing of the chosen shape thanks to the different construction plans made. As for the electrical system, it still needs improvements to be immersed and functional.

In order to finalize the project, UniLaSalle was considering organizing a new summer internship. This internship would focus on the development of the electronic part and would aim to realize a prototype of the reef and its intelligent system. The current team continues the exchanges with the various contacted organizations... The exchanges with ALR aimed to confirm their collaboration with the GeoLab. If this were to happen, ALR would help ReGen members with the prototyping of the electrical part and would implement it on its reefs in the Atlantic. The students were also keeping in touch with Xtree, in hopes of getting them to print the modeled reefs.

#### Acknowledgments

The authors gratefully thank the Design Studio, the educational research platform Le GéoLab and La Fondation Dassault Systèmes for the support provided for this work. The authors want to thank also Maxime Denis and Julien Duquennoy for their precious help.

# Substitution of hexane in vegetable oil extraction using Computer Aided Molecular Design

Mohamad Nehmeh,<sup>a,b</sup> Ivonne Rodriguez-Donis,<sup>a</sup> Vincent Gerbaud,<sup>b</sup> and Sophie Thiebaud-Roux.<sup>a</sup>

<sup>a</sup>*Laboratoire de Chimie Agro-Industrielle, Université de Toulouse, INRAE, INP, Toulouse (Fr)*

## Abstract

Hexane is currently the preferred solvent for the extraction of oilseed oils. Despite a good selectivity towards lipids and an easy separation from the oil by distillation, it raises toxicity and non-renewable origin issues. Hence its replacement is investigated using Reverse Engineering methodology based on Computer Aided Molecular Design (CAMD). It starts by defining target values for selected physicochemical properties (boiling point, flash point, etc.) of the existing solvents used for oil extraction (Nehmeh et al., 2022). Then molecular structures which properties match these targets are sought: thousands of solvents were evaluated by means of our CAMD tool InBioSynSolv (IBSS) (Heintz et al., 2014). Results show that hexane is not the most performant solvent, impaired by a low flash point. Further refining of the candidates generated with IBSS is done by comparing their sigma-potential using COSMO-RS. In fine, alternative and greener solvents are identified for the substitution of hexane.

**Keywords:** Computer Aided Molecular Design, Reverse Engineering, Rapeseed oil, Oil extraction.

## 1. Introduction

The use of hexane in oil extraction is a widely spread practice. It is in fact the solvent of choice for industrial processes due to its selectivity towards lipids and ease of separation (Nehmeh et al., 2022). Nevertheless, this highly flammable solvent with an unpleasant gasoline-like odour, forms an explosive mixture with air (Pohanish, 2017). Besides, hexane is toxic to the environment (hazard statement H411) and is suspected of being reprotoxic (H361f) and fatal (H304) (Regulation (EC) No 1272/2008). Hitherto, its use in the production of foodstuff is still allowed under strict regulations, i.e. a maximum residue of 1 ppm in the oil (Directive 2009/32/EC).

The time and resource consuming basic “trial and error” methodology for finding solvent substitutes is nowadays replaced by a Reverse Engineering approach based on Computer Aided Molecular Design (CAMD). The methodology starts by defining a set of physicochemical properties related to the main solvent functionalities, along with the corresponding target values for each property. It is then followed by a search or a design of solvents meeting these requirements.

In this work, CAMD is used for the substitution of hexane in the extraction process of rapeseed (canola) oil. The solubility of the oil in the alternative solvents is first assessed using Hansen Solubility Parameters. Chem21 solvent selection guide (Prat et al., 2016) is then used to evaluate the safety, health and environmental impacts of the solvents, based on the hazard statements (GHS) available to date. A second validation is done by comparing the sigma-potential profile of the solvents and the oil, using COSMO-RS.

## 2. Methodology

Reverse Engineering is a 3-phase process. The first phase, the intelligence phase, consists of identifying the problem and defining a comprehensive list of solvent functionalities, described by target physico-chemical properties (e.g. solubility power described by Hansen Solubility Parameters). Afterwards, an individual performance for each property as well as a global performance function are defined. In the second phase, the design phase, two paths can be considered: the evaluation of solvents or the design of molecular structures using a CAMD tool. The last phase is about the choice, and deals with the selection of the best candidates, either pure components or mixtures.

### 2.1. Hansen Solubility Parameters

Grounded on the “like dissolves like” rule, the interactions between a solute and a solvent can be described using the Hansen Solubility Parameters (HSP),  $\delta D$ ,  $\delta P$  and  $\delta H$  (Hansen, 2007). The cohesive energy density  $\delta_T^2$  (Hildebrand solubility parameter) is defined as the amount of energy required to break a solvent into gas molecules, divided by its molar volume. It is further approximated as the sum of the energy densities:  $\delta D^2$ ,  $\delta P^2$  and  $\delta H^2$ , for London atomic dispersion, Keesom polar forces and hydrogen bonds. This can be visualized by plotting the parameters as coordinates into a 3D-space. The HSP values for a given solute, as well as a sphere radius encompassing solvents that solubilize the solute, can be determined experimentally by a series of solubility tests in solvents with known parameters. The sphere is constructed as to include a maximum of the solvents miscible with the solute. According to the theory, similar HSP values for a solvent and a solute indicate a higher affinity between them. Furthermore, the Relative Energy Difference RED for a solvent can be calculated as the ratio of the relative distance  $D$  between the solute and the given solvent, and the sphere radius  $R$ . A solvent “inside” the sphere, thus having a  $RED < 1$ , should dissolve the solute.

### 2.2. CAMD method by using IBSS

IBSS (InBioSynSolv) is a CAMD tool developed in the Laboratoire de Génie Chimique (LGC), based on a predictive and screening process. The prediction of physicochemical properties takes place through various implemented group contribution methods. As defined in the intelligence phase step, several physicochemical properties must be matched, each having a performance function  $Perf$  (eq.1) based on the target value for the property. For a given property  $p$ , the function compares the target value  $P$  with the predicted value  $x$ . The performance is set to 1 if the predicted value meets the target value, or is computed by a Gaussian function having a tolerance  $tol$  for a deviation  $val$ . A global performance function  $GloPerf$  (eq. 2) then transforms the multi-objective problem into a single-objective problem. During the molecular design, an optimization function  $OF$  (eq. 3) subject to  $i$  inequality and  $k$  equality is used in the aim of maximizing the  $GloPerf$ . The optimization variables are the molecular graph structure  $MG_i$  of the component  $i$  and the conditions  $cond_j$  (conditions under which the properties calculated e.g. temperature, pressure) (Heintz et al., 2014).

$$Perf_p = [\ln(val)] \times \left(\frac{P-x}{tol}\right)^2 \quad (\text{eq. 1})$$

$$GloPerf = \frac{\sum_{p=1}^{np} w_p \times Perf_p}{\sum_{p=1}^{np} w_p} \quad (\text{eq. 2})$$

$$OF = \max(GloPerf(MG_i, cond_j)) \quad (\text{eq. 3})$$

$$\text{Such that } P_k(MG_i, cond_j) = P_{k, fixed}$$

$$P_{i, lowerbound} \leq P_i(MG_i, cond_j) \leq P_{i, upperbound}$$

Table 1: Solvent properties, target values and used models

Functionality	Property	Target value	Parameters	Models and individual weights
Solency power	$\delta D$	$12.6 < \delta D < 20$ Based on the values of the test solvents that solubilized the oil	$\delta D < 12.6$ Val=0.8, Tol=0.5 $\delta D > 20$ Val'=0.5, Tol'=2.0	MB2010: 1.5 HSKASG2012:1.5
	$\delta P$	$\delta P < 12$ Based on the values of the test solvents that solubilized the oil	$\delta P > 12$ Val=0.7, Tol=2	MB2010: 1.5 HSKASG2012: 1.5
	$\delta H$	$\delta H < 19$ Based on the values of the test solvents that solubilized the oil	$\delta H > 19$ Val=0.5, Tol=2.0	MB2010: 1.5 HSKASG2012:1.5
	RED	RED < 1 A solvent with a RED < 1 should theoretically solubilize the oil	RED > 1 Val=0.4, Tol=0.5	MB2010: 4
Liquid state	Melting point	Melting point = 0 °C to keep solvent in the liquid form in normal temperature conditions	MP > 0 Val=0.8, Tol=2.0	HSKASG2012: 1 JR1987: 1
	Vapor pressure	Vapor pressure < $1 \times 10^{-4}$ bar This value corresponds to the limit of what is a VOC (Directive 1999/13/EC)	VP > $1 \times 10^{-4}$ Val=0.7, Tol=0.005	Riedel1954: 0.5

### 2.3. Alternative solvents design methodology

The aforementioned three phases of Reverse Engineering methodology based on CAMD can be further refined in practice into five steps. The first step is the definition of the design problem by determining all the functionalities of the alternative solvents e.g. transport properties. The second step consists of converting the functionalities into physio-chemical properties that can be predicted e.g. volatility is converted to boiling point. For each property, a target value is determined based on the value of the existing solvents, or the process requirements (e.g. high flash point). The tolerance for each property performance function *Perf* is then defined, along with a weight for each property to compute the global performance function *GloPerf*. The third step is the identification and choice of the required property models (group contribution methods selected as to provide the smallest relative error with experimental data collected). Table 1 summarizes these three steps. The fourth step can be divided into 2 parts: (1) evaluation of solvents and (2) molecular design and structural optimization of compounds based on pre-defined chemical moieties implemented in the tool. This step provides a list of the best candidates along with their corresponding *GloPerf* values. The last step is the choice step. During this step, the best candidates are screened based on various criteria. Herein, the Chem 21 Solvent selection guide was employed for the screening of candidates based on safety, health and environment criteria. Each criterion is given a score between 1 and 10, 1 being the least impacting in the corresponding category. The safety criterion is mainly based on the flash point of the solvent, along with other properties that were ignored herein due to the lack of data (electrical conductivity, etc.). The health criterion takes into consideration the hazard statement given by REACH as well as the boiling point (as an assessment of volatility). The last criterion is also based on the environment hazard statement (H4xx) as well as the boiling point, as an estimation of VOC emissions but also the ease of recycling and separation from the product. A solvent is then classified as “recommended”, “problematic” or “hazardous” based on the three scores.

### 2.4. COSMO-RS computational method

COSMO-RS is a powerful theory based on a quantum-chemical approach, combined with statistical thermodynamics, for molecular description and thermodynamic properties prediction based on the chemical potential  $\mu$  of the molecule (Klamt, 1995; Eckert and Klamt, 2002). For molecules not found in the COSMObase, COSMO files are generated using a BP-TZVPD-FINE basis set, after geometry optimization using Turbomole V7.4 (GmbH). Statistical thermodynamics assure the transition from the microscopic molecular interactions, described by sigma ( $\sigma$ )-profile, to macroscopic thermodynamic properties, by means of the ( $\sigma$ )-potential. The latter is a measure of the system's affinity to a surface of polarity  $\sigma$ . The ( $\sigma$ )-potential similarity (SPS) is calculated as the sum of the differences between the 2 molecules using COSMOtherm (BIOVIA). It corresponds to the similarities of the compounds with respect to their properties as solvent. The smaller the compound's chemical potential profiles overlapping, the smaller the SPS. Rapeseed's bio-chemical composition varies widely depending on the seed's variety and other factors such as environmental conditions (Nehmeh et al., 2022). Triolein (OOO), is one of the main triglycerides present in the rapeseed oil with concentrations up to over 70% (Guan et al., 2016) and will be used as the base for the SPS calculations.

### 3. Results and Discussion

#### 3.1. Oil Sphere

After a series of solubility tests (25 wt% of oil) using a list of solvents carefully selected to fill and represent the Hansen space, the HSP of rapeseed oil were determined using HSPiP software. As the sphere did not have a perfect fit (around 0.9), the calculations were repeated 40 times in order to get a representative mean and standard deviation of the sphere centre coordinates as well as the radius ( $\delta D: 15.7 \pm 0.24$ ,  $\delta P: 2.8 \pm 0.44$ ,  $\delta H: 1.6 \pm 0.62$ ,  $R: 10.5 \pm 0.64$ ), as illustrated in figure 1. As can be predicted, the oil shows very low polarity and hydrogen bonding ability, mainly due to the presence of the triple ester groups ( $-\text{CH}_2\text{OOC}-$ ) on the glycerol backbone.

Figure 1: Hansen sphere for rapeseed oil.

#### 3.2. IBSS Evaluation

A list of over 3900 molecules (real and theoretical) were evaluated using IBSS. No molecular structure optimization was carried out. Over 2000 molecules showed a global performance higher than 0.8. This result is somewhat expected, as the oil sphere radius, 10.5, is quite large, and many molecules are within the solubility sphere ( $\text{RED} < 1$ : the property with the most weight). Therefore, the focus was put on the molecules that are closer to the sphere centre ( $\text{RED} < 0.5$ ), with acceptable boiling point ( $< 160^\circ\text{C}$ ), decreasing the selection down to 738 molecules. Over half of the remaining molecules were low polar hydrocarbons, like hexane, and are known to be usually toxic; they were then discarded. Special attention was given to oxygenated hydrocarbons, as their biosynthesis is generally possible, along with molecules containing heteroatoms e.g. nitrogen and fluorine. The Chem21 solvent selection guide was then applied to the 299 molecules left using all the hazard statement available to date, resulting in a list of 72 so-called “recommended” molecules, as per the same guide.

Name	Similarity	GloPerf	RED	BP (°C)	FP (°C)	Safety criteria	Health Criteria	Environment criteria	Final Criteria
Hexane	0.33	0.88	0.22	69	-24	7	7	7	Hazardous
Mol. 1	0.76	0.98	0.24	142	42	3	2	5	Recommended
Mol. 2	0.76	0.94	0.21	118	14	4	2	3	Recommended
Mol. 3	0.75	0.92	0.15	166	48	3	2	5	Recommended
Mol. 4	0.7	0.88	0.30	123	5	5	1	3	Recommended
Mol. 5	0.64	0.94	0.31	103	5	4	2	3	Recommended
Mol. 6	0.53	0.99	0.12	142	25	3	2	5	Recommended
Mol. 7	0.53	0.94	0.47	116	20	4	2	3	Recommended
Mol. 8	0.52	0.99	0.37	139	32	3	4	3	Recommended
Mol. 9	0.51	0.94	0.44		32	3	1	5	Recommended
Mol. 10	0.51	0.97	0.45	110	24	3	4	3	Recommended

Figure 2: Molecules with the highest SPS compared to hexane (BP & FP are experimental data).

Figure 3: Triolein (red) vs hexane (green) sigma-potential.

#### 3.3. Sigma Profile and solubility calculation

The sigma potential similarity of triolein with the 72 recommended molecules ( $\text{GloPerf} > 0.8$ ,  $\text{RED} < 0.5$ ) from IBSS evaluation was then calculated. Figure 2 represents the most interesting molecules along with hexane. Based on the RED value, hexane seems like a good solvent for the solubilization of oil. Nevertheless, its SPS is very low, as its  $\sigma$ -potential profile shows a quite different shape than that of the oil (figure 3). Furthermore, hexane’s global performance is low (0.88), mainly due to its very low flash point, but also its relatively high vapour pressure ( $> 0.1$  bar), and it is classified as hazardous. Meanwhile, 10 of the studied molecules had a SPS higher than 0.5, and 40 other got a SPS higher than that of hexane, meaning that they potentially have better interactions with the oil.

#### 4. Conclusion

Alternative solvents for the extraction of rapeseed oil have been evaluated and compared with the conventional hexane, using Reverse Engineering approach. The Hansen Solubility Parameters of the oil were determined experimentally. Then, an evaluation and screening of thousands of molecules was achieved using IBSS, resulting in 299 molecules with a global performance higher than 0.8, and a Relative Energy Difference lower than 0.5. Among those, 72 are thought to have no or very little impact on safety, health, and environment. The  $\sigma$ -potential of these solvents as well as that of hexane were then compared to that of triolein. It can be clearly and safely said that hexane is theoretically not the most suitable solvent for oil extraction. Further experimental validation of the performance of the evaluated molecules is essential. Moreover, further research on the availability, price, and route of production of each alternative solvent is needed. Coupling Reverse Engineering with CAMD has allowed the efficient selection of new potential candidates for the substitution of hexane.

## Abstract

Providing drug products for pediatric patients is a challenging problem for the pharmaceutical industry. Children often require flexible low-dose medication with features like taste-masking and ease of swallowing. In recent years, mini-tablets have emerged as an attractive dosing solution that can meet these requirements. They are small form oral dosages around 2-4 mm in diameter that can be dispensed individually or in combination. Conventionally, they are made using methods like direct compression and hot melt extrusion. This study introduces a new technique to make mini-tablets: drop-on-demand 3D printing. Here the active ingredient is suspended in a liquid excipient, the formulation is printed as droplets and each drop is solidified to yield a mini-tablet. An optimal solvent bath that can uniformly capture mini-tablets is designed and dosages of Atorvastatin (active ingredient) are produced as a test case. Quality of these dosages is determined by measuring their content uniformity.

**Keywords:** pharmaceuticals, mini-tablets, 3D printing, drop-on-demand, low dose high precision drug products

## 1. Introduction

Pediatric medicines make up less than 10% of the overall drug market. Serving this patient group however poses a major challenge for the pharmaceutical industry. Factors like limited excipient compatibility, prevalence of rare diseases and smaller pediatric patient populations contribute to this (Milne & Bruss, 2008). Drug products made for children must also cater to their specific needs like having low dose strengths, taste masking and ease of swallowing etc., which in-turn make their production difficult.

Currently, two categories of drug products are popular for medicating children: liquid oral dosages and compounded dosages. Liquid oral drug products are attractive as they satisfy many of these requirements: they are flexible to dose, easy to consume and can be dispensed in low dose strengths. Compounded dosages are made in special pharmacies (called compounding pharmacies) where drug products are made at non-commercial specifications, by either altering the dose or changing the ingredients, to meet the needs of the patient. Both these products, however, face some limitations: 1) many active pharmaceutical ingredients (APIs) are unstable in aqueous media and prone to degradation 2) liquids are also susceptible to inaccurate dosing leading to adverse drug reactions. 3) In compounded dosages, achieving drug content uniformity and release profile matching commercial products is difficult (Zuccari et al., 2022).

In recent years, mini-tablets have emerged as an attractive alternative for pediatric medication. These are small-size solid oral drug products (2-4 mm in diameter) that are easy to swallow and can be dispensed individually or in combination in flexible doses. Two broad categories of techniques have been used to make them: powder based and 3D printing based. Powder based techniques include conventional methods like granulation

and direct compression (Stoltenberg & Breitzkreutz, 2011). Here the API is blended with excipient powders to yield a powder formulation. In granulation this formulation is processed into coarse aggregates. Each granule aggregate is then dispensed as a mini-tablet. In direct compression the powder formulation is compacted using small dies into mini-tablets. These methods rely on existing process technology and thus are easy to implement. They also can achieve high production rates. However, manufacturing low dose drug products is challenging for poorly flowing API powders. The second category of techniques is 3D printing, this is a manufacturing process in which the product is made in a layer-wise fashion. Hot melt extrusion is the most used 3D printing method for making mini-tablets (Krause et al., 2021). Here the API-excipient blend is extruded into a thin filament which is then melted and formed into the desired shape. Drug loading in the dosage can be easily customized by varying the number of printed layers. A key limitation of this method is the need for high operating temperatures which can cause degradation of the API or change its polymorphic form.

This study introduces a new method for making mini-tablets: using a drop-on-demand (DoD) inkjet printer. DoD falls under the umbrella of 3D printing methods, it processes a liquid formulation where the API is either dissolved or suspended in an excipient carrier fluid (İçten et al., 2017). The formulation is printed as droplets onto substrates like placebo tablets or capsules to make the drug product. This study aims to manufacture mini-tablets by solidifying individual drops generated by the DoD system. Printed droplets are discharged into an inert and viscous solvent bath where they settle slowly and solidify. Solid droplets are then washed and air dried to yield ready-to-use mini-tablets. The main advantage of this technique is producing dosages having low drug loadings with high precision. To develop this manufacturing route, first an optimal solvent bath is designed to uniformly capture and solidify the printed drops and next, mini-tablets for an API called atorvastatin are printed and tested for content uniformity.

## 2. Drop-on-demand printing of mini-tablets

As discussed before, DoD is a novel pharmaceutical 3D printing technique that builds dosages by printing multiple drops of an API containing formulation onto inert substrates. It has a versatile operation and can print a variety of formulation (melts, suspension etc.) and produce dosages with broad range of drug loadings. It can also incorporate emerging developments in pharmaceutical manufacturing like continuous processing and end-to-end operation (Sundarkumar et al., 2022).

Its working principle is as follows: the formulation ink for printing is held in the reservoir with constant agitation to ensure concentration homogeneity. Then a high-precision positive displacement pump dispenses a packet of fluid with constant volume through a nozzle in the form of a drop. This drop is then deposited on the desired substrate. The central idea in this study is to capture printed droplets and process them into individual mini-tablets. To achieve this a melt formulation is used, this formulation is then printed into an inert solvent bath (silicon oil) where the droplets self-solidify at room temperature (Figure 1). These solidified drops are then washed dried and collected as ready to use mini-tablets. Details of how the bath is designed is discussed in the results section.

Drug products have many critical quality attributes, such as, content uniformity, residual solvent content, dissolution behavior etc. For 3D printed drug products, content uniformity is an important metric as precise dosing is one of its key features. Thus, to test the quality of printed mini-tablets, uniformity in shape, weight and drug loading content across dosages are measured.

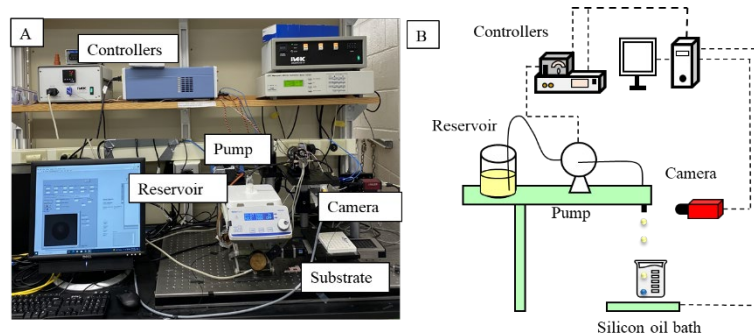

Figure 1. A) Apparatus and B) Schematic of the DoD printing system.

### 3. Materials

#### 3.1. Chemicals

Atorvastatin (Dr. Reddy's Laboratories), Polyethylene glycol 2000 (PEG) (Fisher chemicals), Silicon oil (polysiloxane, PMX 200 1000 cSt, Dow Chemical Company), Hexamethyldisiloxane (HMDSO) (Fisher chemicals). Before designing the process, the excipient material needs to be selected. PEG is an excipient widely used in drug products and acts as a dissolution enhancer. It melts at  $\sim 65$  °C and is a solid at room temperature. To solidify the printed droplets, silicon oil is used as a bath solvent as it is inert and does not interact with either the API or PEG. HMDSO is used as a washing fluid for the mini-tablets as it is a lighter inert silicon oil that can remove heavier oil adhering to the tablets.

#### 3.2. Instruments

Nikon Eclipse E600 microscope is used to image and size mini-tablets, Waters ultra-pressure liquid chromatography (UPLC) is used to measure drug loading in mini-tablets.

### 4. Results

#### 4.1. Designing the silicon oil bath

The first step in process development for this route is to design the inert solvent bath. Heat transfer (convective) due to the motion of the drop in the bath needs to be sufficient to solidify the mini-tablet. The critical process parameters here are bath viscosity and final drop temperature. Having low viscosity or high final drop temperature can lead to incomplete solidification or pooling of the droplets in the settling chamber respectively. On the other hand, high viscosities can lead to droplet aggregation (Figure 2). Optimal bath design is the one with the smallest settling chamber height (to reduce solvent amount required) and with the fastest rate of heat transfer.

To achieve this, a multi objective optimization problem can be posed with the goal of minimizing chamber height and solidification time (higher the heat transfer rate, shorter the solidification time). Decision variables here are bath viscosity  $\eta$  and final drop temperature  $T_f$ . Both variables are continuous: continuum in viscosity can be achieved by blending together base silicon oils (commercially available products) in required proportions. The bath is assumed to be at room temperature and thus temperature dependence of oil viscosity is ignored. To prevent pooling, an upper bound constraint is introduced on the final drop temperature; and to prevent drop aggregation, a minimum value is set for the distance between successive drops. Problem formulation is as follows:

$$\begin{aligned} & \min l_{\text{chamber}} \\ & \min t_{\text{solidification}} \end{aligned}$$

$$\text{st: } T_f < 35^\circ \text{C}, \quad \eta < \frac{5}{18} g d_{MT} (\rho_{MT} - \rho_{Si})$$

$$\eta \in [0.1, 10] \text{ Pas}, \quad T_f \in [23, 35]^\circ \text{C}$$

$l_{chamber}$  and  $t_{solidification}$  are calculated as follows:

1. Physical properties of the system:  $d_{MT} = 4 \text{ mm}$ ,  $\rho_{MT} = 1124 \text{ kgm}^{-3}$ ,  $C_{p_{MT}} = 2135 \text{ Jkg}^{-1}\text{K}^{-1}$ ,  $k_{MT} = 0.31 \text{ Wm}^{-1}\text{K}^{-1}$ ,  $T_i = 70^\circ \text{C}$ ,  $\rho_{Si} = 950 \text{ kgm}^{-3}$ ,  $k_{Si} = 0.15 \text{ Wm}^{-1}\text{K}^{-1}$ ,  $C_{p_{Si}} = 1250 \text{ Jmol}^{-1}\text{K}^{-1}$ ,  $T_{bath} = 23 \text{ C}$ ,  $\Delta H_{melt} = 100 \text{ kJkg}^{-1}$ ,  $T_{melting} = 45^\circ \text{C}$
2. First, calculate terminal settling velocity of the tablets.  $v_t = \frac{g d_{MT}^2}{18\eta} (\rho_{MT} - \rho_f)$ .
3. Next, compute heat transfer rate (assume convection dominated).  $h = Nu \frac{k}{d}$ ,  $Nu = 2 + \left(0.4Re^{0.5} + 0.06Re^{\frac{2}{3}}\right) Pr^{0.4}$ ,  $Re = \frac{\rho_f v_t d}{\eta}$ .
4. Finally, calculate solidification time  $t_s = \frac{\rho_{MT} V C_P}{hA} \ln\left(\frac{T_i - T_b}{T_f - T_b}\right) + \frac{\Delta H \rho V}{hA(T_m - T_b)}$  and  $l_{chamber} = v_t * t_s$ .
5. Verify if convection driven heat transfer assumption is valid, i.e., if  $\frac{hd}{k} \gg 1$ .

The first constraint acts as a variable bound,  $35^\circ \text{C}$  is chosen because it is half the initial temperature and the formulation is fully solid at this temperature. For the second constraint, we assume that for aggregation to be arrested a gap of at least one drop diameter between successive drops is necessary  $l_{inter\ drop} > d_{MT}$ . As drop generation rate is constant (one every 5 sec), the constraint can be framed in terms of settling velocity:  $v_t > \frac{d_{MT}}{5}$  which is equivalent to  $\eta < \frac{5}{18} g d_{MT} (\rho_{MT} - \rho_{Si})$ .

The problem is solved by building a Pareto front (figure 2) using the Non-dominated Sorting Genetic Algorithm II (NSGA2) available in the Python library 'pymoo'. Although this algorithm does not guarantee global optimality, it provides a quick and efficient way to generate diverse non-dominated solutions that can represent the best trade-offs between objectives. From this Pareto set, the point closest to having a bath viscosity of 0.95 Pas is chosen for operation as it is closest to the material at hand. The operating point chosen is as follows:

$$\eta = 0.95 \text{ Pas}, T_f = 34.9, l_{chamber} = 6.5 \text{ cm and } t_{solidification} = 40.8 \text{ sec.}$$

Figure 2. Design of solvent bath and settling chamber- optimization solution.

#### 4.2. Consistency measurements for the printed mini-tablets

After determining bath viscosity, mini-tablet manufacturing is carried out. Drug products with two dose levels of atorvastatin are targeted: 0.1 and 1 mg. In each case formulation drops are printed into the bath, solidified, washed with HMDSO and air dried (figure 3).

To test whether this operation yielded consistent mini-tablets, uniformity of three parameters is measured across dosages: shape, weight and drug loading. To measure variation in shape, the diameter of each mini-tablet is determined under a microscope. Drug loading in each mini-tablet is measured by dissolved it in methanol and analyzing on an offline UPLC. 25 dosages of each dose strength are used for this analysis and the results are summarized in tables 1 and 2.

The results show that for both dose strengths highly precise mini-tablets are obtained. The variation in all three parameters is very low and is well under the regulatory threshold (5% relative standard deviation for drug loading as specified by the United States Food and Drug Administration). Drop size can be altered by changing the DoD printing conditions like ejection rate, volume per drop etc. Based on concentration of the active ingredient in the formulation, drop size can be adjusted to deliver the desired dose strengths in mini-tablets. High consistency seen in the process can be explained by two reasons: 1) it is easier to disperse API in liquid excipients compared to powder excipients leading to more uniform drug loadings; and 2) each mini-tablet is made of exactly one droplet; thus, uniformity of drop formation translates into uniformity in shape and weight of mini tablets. In this study, polymorphic transformation of the API crystals is not considered. Dissolving the API in a molten polymer like PEG and solidifying it yields amorphous solid dispersions. If polymorph control is critical then the API crystals can be suspended in an inert excipient that does not dissolve it (like triglyceride oils). This method also faces some limitations: the mini-tablets produced lack hardness which would make their transportation difficult. Manufacturing high drug loading mini-tablets is also challenging, as increasing particle loading beyond a certain concentration yields a paste-like formulation that does not generate uniform droplets.

To realize the full potential of this DoD approach (flexible dosage production rate, quick product changeovers etc.), the mini-tablet manufacturing process needs to be made entirely continuous. Currently, a part of the process (up to drop solidification) is continuous while the subsequent washing and drying steps are carried out batch-wise. Continuous operation can be achieved by integrating the DoD system with a continuous filter dryer unit. To support emerging initiatives in pharmaceutical manufacturing like digitalization and quality-by-design, sensors can be installed into the platform to track drug loading in the manufactured mini-tablets in real time. This will allow for building quality into the product during the manufacturing stage itself, and thus will mitigate the need for post manufacturing quality checks.

Table 1. Consistency results for 0.1 mg mini-tablets.

Parameter	Mean	Relative stdev
Diameter	3.14 mm	1.04 %
Weight	21.27 mg	1.54 %
Drug loading	0.107 mg	2.31 %

Table 2. Consistency results for 1 mg mini-tablets.

Parameter	Mean	Relative stdev
Diameter	2.84 mm	1.22 %
Weight	16.26 mg	2.18 %

Figure 3. Printed atorvastatin mini-tablets.

Drug loading	1.01 mg	2.44 %
--------------	---------	--------

## 5. Conclusions

This study introduces a novel technique to manufacture pharmaceutical mini-tablets. API is dissolved in a molten PEG formulation and its droplets are printed and solidified in an inert silicon oil bath. These mini-tablets are seen to show a high degree of consistency in shape, weight and drug loading across dosages. To assess if these dosages are equivalent to commercial products, their dissolution behavior and long-term stability need to be determined. This technique fills an important gap in the pediatric drug market- producing high-precision low dose mini-tablets. In conjunction with the other manufacturing techniques, this method can accelerate the adoption of pharmaceutical mini-tablets.

# Process simulation coupled with life cycle assessment of an alternative polyamide precursor

Andrea Mio,<sup>a\*</sup> Maurizio Fermeglia,<sup>a</sup>

<sup>a</sup> *MolNBL@UniTS, Dipartimento di Ingegneria e Architettura, Università degli studi di Trieste, Piazzale Europa 1, 34127 Trieste, Italy*

## Abstract

A detailed process simulation for the production process of a valuable alternative reactant to produce a polyamide, *i.e.*, m-xylylenediamine (MXDA) using Aspen Plus has been performed. A comparative life cycle assessment of MXDA with an equivalent polymer precursor, *i.e.*, hexamethylenediamine (HMDA), has been carried out using the material and energy balances obtained through process simulation. Since neither of the two compounds outperformed the other in the impact assessment's environmental analysis, a general trade-off must be determined, even though slightly better performances are gained by m-xylylenediamine. The uncertainty related to the energy demand, which is one of the most influencing parameters, has been assessed to identify the implications of energy losses. The outcomes are actually reversed when the energy requirement for MXDA is increased by 25%, suggesting a general preference for HMDA. Therefore, particular care should be taken on energy optimization when implementing MXDA manufacturing process industrially.

**Keywords:** LCA, Process Simulation, Multiscale Modeling, polyamide, xylylenediamine, hexamethylenediamine

## 1. Introduction

After the pandemic, the manufacturing of polymers is facing significant challenges as a result of the enormous rise in demand, which is hardly being met by the supply. In this panorama, a major role is played by polyamide production, whose global market size for Nylon 6 and Nylon66 was estimated at 32.6 B\$ in 2022 and is expected to reach 53.04 B\$ in 2030 (Grand View Research, 2020). The tremendous growth in Nylon global market can mainly be attributed to an increasing demand of China market, along with a consistent growth of the automotive industry. The principal application of Nylon6 is in the textile industry (Deopura and Padaki, 2015), *e.g.*, carpets, fabrics and clothes, while Nylon 66, which is characterized by greater wear, thermal and structural resistances, is commonly employed in the transport sector (Ishikawa et al., 2018) and for metal replacements in advanced applications, *e.g.*, marine engine covers (Mio et al., 2021).

Due to the disruption of the supply chains, the sharp rise in the price of raw materials and the growing market demand for sustainable products, producers are being compelled to find substitute precursors. To prevent wasting time, effort, and money on a promising new synthetic route that might become more burdensome when applied at an industrial scale, the introduction of novel synthetic pathways for polyamides needs to be evaluated from an environmental standpoint already at an early-stage design. The environmental implications of a product or a manufacturing process are accurately evaluated by LCA methodology (International Standards Organisation, 2006), which allows to address the environmental impacts of the entire life cycle of goods, from raw materials extraction (cradle) to disposal at their end of life (grave). However, it is frequently challenging to

gather data on the materials and energy consumptions, the gaseous and liquid emissions, the wastes, and the by-products connected to the whole lifecycle of the substance under examination during product development in the chemical sector (Mio et al., 2018). Besides the usage of well-established databases, it is common practice to resort to process simulation for filling the gaps of life cycle inventories. Focusing on the polymer production sector, Gracida-Alvarez et al. (2019), coupled a carbon footprint analysis with a process simulation of fast pyrolysis for converting polyethylene plastic waste to monomers and aromatics, while Bello et al. (2020) conducted a life cycle assessment of a precursor of poly(ethylene furanoate), *i.e.*, 2,5-furandicarboxylic acid, using process simulation to perform sensitivity analyses and identify the major environmental hotspots. In this paper, a detailed process simulation for the production process of a valuable alternative reactant to produce a polyamide, *i.e.*, m-xylylenediamine (MXDA), has been assessed from an environmental standpoint.

## 2. Materials and Methods

Hexamethylenediamine (HMDA) and adipic acid are combined to form Nylon 66, following a polycondensation mechanism. While adipic acid is created via a multitude of syntheses that all start with benzene, industrial production of HMDA uses either butadiene or propylene via acrylonitrile. By comparing them from an economic and environmental perspective, Dros et al. (2015) have outlined and evaluated either the conventional production pathway and novel bio-based ones.

With the aim of providing a new reactant for producing a polyamide that can replace traditional Nylon 66, the production pathway for m-xylylenediamine (MXDA) has been modelled. In fact, being an aliphatic diamine with two reactive amine groups at the opposite side of the molecule, MXDA can easily replace HMDA in the polycondensation mechanism (Hugo et al., 2008a), or serve as an epoxy resin curing agent (Kutsuna and Kihara, 2008).

The production of MXDA has been described by several patented processes owned by different companies, *e.g.*, BASF (Ernst et al., 2008b, 2008a; Hugo et al., 2008a, 2008b, 2004) and Mitsubishi Gas Chemical Company (Kumano et al., 2013, 2011; Nakamura et al., 2003). As a result of a thorough investigation of the patents declared performance, the most recent process design suggested by Kumano et al. (2013) has been selected as the best available technique (BAT), due to a greater yield and lower energy consumption, as a result of the limited use of distillation columns. Moreover, this patent provides detailed information regarding the reaction duration, conditions, and, sometimes, waste by-products, which can be assumed as emissions. The published production process of MXDA follows five main steps, which have been modelled in the Aspen Plus flowsheet shown in Figure 1.

Figure 1: Flowsheet of the production of m-xylylenediamine

(i) The chain of reactions starts with an ammoxidation stage in REACT-A, where m-xylene interacts with ammonia and oxygen to produce isophthalonitrile (IPN) at 420 °C

and 2 bar. In the first separation step, m-tolunitrile (TN) is used to fill unit ABS-B to conduct a liquid-vapor absorption process that directly injects the liquid-vapor stream into the solvent at 140 °C and 0.57 bar, aiming to separate IPN from by-products and contaminants. (ii) The subsequent addition of an aqueous solution of ammonia and ammonium carbonate in REACT-C at 110 °C and 2 bar neutralizes the resultant solution. (iii) In decanter D-DECANT, the mixed solution of organic and aqueous phases is separated at atmospheric pressure. (iv) The organic phase is then further separated under vacuum (0.35 bar) in COL-E to isolate the IPN from the solvent TN and the major part of volatile components. (v) After an ammonia addition that precipitates the insoluble components, IPN is hydrogenated using a nickel catalyst under medium temperature (80 °C) and high pressure (80 bar) in REAC-H2 to produce MXDA, which is then purified in the FINAL-SEP rectifier under vacuum. Due to the formation of undesired chemicals from a partial hydrogenation, a polymerization, or cleavage of the product, ideal reaction conditions (Nakamura et al., 2003) and proper solvent (Row et al., 2007) are essential in this hydrogenation reaction to yield a high grade of MXDA.

Due to the nature of the chemicals involved, the NRTL thermodynamic model has been set, using UNIFAC group contribution method to generate missing binary interaction parameters. High-pressure hydrogenation required an Equation of State (EOS)-based model, *i.e.*, Peng-Robinson, instead. The experimental process follows a semi-batch regime and has been scaled-up considering an initial charge of 350 kg of xylene to meet the needs of an industrial scale production. Heat integration has been implemented in order to transfer the heat from outlet hot streams to inlet cold streams. Since there were no known kinetic models for the reactions involved, conversion reactors were employed in an effort to achieve the yield specified in the patent, while reactions enthalpies were calculated by means of the enthalpies of formation of the components. When the yields were not specified, a conversion of 95% of the reactants were assumed, as reported within ecoinvent guidelines for conservative scenarios (Weidema et al., 2013).

Aiming at determining the most environmentally friendly polymer precursor, openLCA was used to compare the life cycle assessments of the two alternatives, after obtaining the material and energy balances through process simulation. The functional unit was defined as *1 kg of polymer precursor in the European market*, using a cradle-to-gate approach, *i.e.*, including raw materials extraction and refining, transportations and production of the substances. For the manufacture of reactants (such as xylene, ammonia, oxygen, etc.) secondary data have been retrieved using ecoinvent v3.8, with allocation cut-off method. Moreover, the unidentified byproducts and the unreacted chemicals have been modelled as aqueous emissions of analogous substances with a characterization factor specified within ReCiPe 2016 Midpoint (H), which has also been used during the life cycle impact assessment phase.

### 3. Results and Discussion

The outcomes of the comparative LCA between the alternative precursors are shown in Figure 2 and Table 1, where the contributions from several sources (raw materials, utilities and production process) have been highlighted.

According to the results of the impact category analysis, MXDA is less burdensome than HMDA in 10 of the 18 impact categories that were analyzed, with MXDA scores ranging from 50 to 80% of HMDA's ratings. The environmental performances of MXDA are worse when considering freshwater, marine and terrestrial ecotoxicity, marine and freshwater eutrophication, water consumption, land use, ionizing radiation and human toxicity (non-carcinogenic).

Table 1: Life Cycle Impact Assessment results for HMDA and MXDA

Ozone formation, Terrestrial ecosystems	kg NOx eq	3.52E-03	4.37E-03		7.89E-03	6.13E-03	3.26E-03		7.62E-03
Stratospheric ozone depletion	kg CFC11 eq	5.97E-07	1.18E-06		1.77E-06	1.05E-06	7.06E-07		1.31E-06
Terrestrial acidification	kg SO2 eq	9.91E-03	7.42E-03		1.73E-02	9.36E-03	6.18E-03		1.20E-02
Terrestrial ecotoxicity	kg 1,4-DCB	1.88E+00	3.98E+00	2.31E-05	5.86E+00	4.86E+00	3.09E+00	4.20E-01	7.59E+00
Water consumption	m3	3.33E-02	6.49E-03		3.98E-02	9.92E-02	1.25E-02		6.19E-02

The ionizing radiation, human non-carcinogenic toxicity, marine ecotoxicity, and freshwater eutrophication are primarily influenced by the electricity consumption, which is higher for MXDA than HMDA. This is counterbalanced by a greater heat demand for HMDA, resulting in lower impacts for MXDA in terms of global warming potential, fossil resource scarcity, fine particulate matter formation, human carcinogenic toxicity and ozone-related impact categories. Freshwater ecotoxicity is affected by the m-xylylenediamine production due to the presence of a significant quantity of contaminants, primarily byproducts and impurities in wastewater, that must be further purified before being discharged into the environment. Raw materials for MXDA mainly affects marine eutrophication, due to the usage of ammonia and ammonium carbonate, as well as terrestrial ecotoxicity due to the use of m-xylene, while water consumption has been negatively impacted by both xylene and ammonia production. Raw materials for HMDA are more burdensome in terms mineral resource scarcity and terrestrial acidification, due to sulfur-based reactants. While the impacts of raw materials among the different impact categories are equally distributed between the two precursors, the impacts related to the energy consumptions are generally higher for MXDA.

Figure 2: Comparison between the Life Cycle Impact Assessment results for hexamethylenediamine (HMDA) and m-xylylenediamine (MXDA)

Even though there is a limited use of the distillation column in the MXDA process, resulting in lower heat required, the electricity consumptions of compressors and pumps is still demanding from an environmental viewpoint. Since process simulation provided

limited information due to a lack of available data for MXDA, the assumptions on energy consumptions have been subjected to a sensitivity analysis. Therefore, in order to emphasize the effects of a different energy demand from simulated data, both the heat and electricity demands have been adjusted by a factor of  $\pm 25\%$ . The results of the sensitivity analysis are reported in Figure 3.

Figure 3: Sensitivity analysis results for different MXDA energy demand scenarios ( $\pm 25\%$ )

As expected, an energy demand increment of 25% worsens the environmental performance of MXDA for a multitude of impact categories, being the most burdensome precursor for 13 out of 18 impact categories. In particular, Global warming, Human carcinogenic toxicity, Land use, and Ozone formations gained worse scores than HMDA, degrading the MXDA base case that achieved superior performances in comparison with the other monomer. The precursors' relative positions do not change when the MXDA energy demand is reduced by 25% (apart from their non-carcinogenic toxicity to humans), but their impacts do get closer in situations where the MXDA results were higher than HMDA in the base case scenario, while their difference increases in impact categories where the MXDA results were lower than HMDA for base case scenario.

#### 4. Conclusions

This paper investigated the environmental performances of a polyamide precursor, *i.e.*, *m*-xylylenediamine, generating its life cycle inventory using a publish patent coupled with process simulation. The outcomes of the study have been compared with an analogous assessment performed on a traditional polyamide precursor, *i.e.*, hexamethylenediamine. The outcomes showed how the environmental performances of the two precursors are mostly equivalent, with slightly better performances for *m*-xylylenediamine. However, the production energy demand (both heat and electricity) played an essential role to determine the most environmentally friendly precursor. Moving to an industrial scale to validate the process simulations outcomes is therefore necessary in order to determine the correct energy usage and modify the life cycle inventory accordingly.

This paper used process simulation along with life cycle assessment to fill in the existing gaps in life cycle inventories of novel materials and substances, which is a well-known example of the application of multiscale modeling for the early-design assessment of products and processes.

## Abstract

Physicochemical properties are fundamental for the design of chemical products and processes. Various approaches including cheminformatic and graph-based methods have been applied for the estimation of pure component properties. In this work, we coupled our connectivity matrix-based molecular structure representation method with a deep learning neural network to develop molecular structure-property relationship models. Molecular structure information is represented by the connectivity matrix, while substructures information is represented by the extracted submatrix. This extraction does not cause any loss of structural information, substructural information can be recovered using the stored matrix. Matrices are transferred into features and characterised based on their eigenvalues. Statistical and mathematical approaches, followed by deep learning neural network models, are developed to correlate the structure-property relationship. Results on the case studies of normal boiling point show that the accuracy of the deep neural network model improved by 9.48% over the previous neural network model.

**Keywords:** molecular descriptor, deep neural network, property estimation, connectivity matrix

## 1. Introduction

Molecular properties such as the physical, chemical, and structural properties are fundamental characteristics of molecules. Subtle structural differences may lead to significant property differences. Therefore, accurate property determination is essential for effective chemical compound design and utilisation (Katritzky et al., 1997). However, measuring molecular properties by experimental approaches is laborious and expensive. As a result, estimating molecular properties by developing mathematical models based on existing experimental data is a feasible approach (Wen et al., 2021). Generally, current approaches for property prediction include correlation-based approaches, the group contribution (GC) method, quantitative structure-activity/property relationship (QSAR/QSPR), and graph convolution methods. Correlation-based approaches are the easiest because of the concise format of correlation equations (Korsten, 1997). One of the shortcomings is that prediction accuracy is usually not guaranteed, especially for compounds with heteroatoms. The GC method is under the assumption that a molecule's properties are determined by solving a set of equations that maps the number of each group to experimental property value, a property of a molecule is then calculated through

the summation of all group contributions (Hukkerikar et al., 2012). One significant challenge of the GC method is that no method reported in the literature can be used for the systematic generation of a molecule's structural groups (or molecular fragments). The definition of groups usually has a significant effect on the performance of the prediction accuracy. It can lead to an inaccurate estimation if any of the predefined groups cannot describe one part of its molecular structure (Gani et al., 2005). Although reported GC methods predefined hundreds of groups that can represent most of the common structural characteristics of a compound, an automatic group generation approach tailored to the unique molecular pool can also improve the accuracy of structure-property correlation. Let alone the population of chemical compounds increases substantially because of the rapid progress of chemical synthesis techniques (Yoshida et al., 2011). Chemical graph theory is a branch of mathematical chemistry that models chemical topology phenomena mathematically. The basic idea of chemical graph theory is that atoms and bonds of a molecule can be thought of as nodes and edges in a graph (Randić, 2008). Therefore, topological indices representing molecular structure properties can be generated from the graph. Different to GC groups, which assume that each group contributes independently of other groups in the structure, many topological indices are a function of the entire graph and thus reflect the fundamental nature of the molecular structure. One important class of topological indices called connectivity indices considers how a graph is connected (Randic, 1975). The QSPR method correlates properties with molecular descriptors derived from molecular characteristics. Technically, molecular descriptors for QSPR models can be derived from GC groups, topological indices, and other defined descriptors (Austin et al., 2016). The major problem is that interpretation of the developed descriptors could be weak, provisional, or utterly lacking because some of the descriptors are chemically meaningless (Todeschini and Consonni, 2000). Recently, machine learning methods, especially graph neural networks (GNN), have been used to predict the structure-property relationship of molecules (Coley et al., 2019). GNN utilises a graph representation of molecules where atoms correspond to nodes and bonds to edges containing information about the molecular structure. However, the convolution process of GNN may result in the loss of information, making it difficult to trace the substructure's contribution to the property.

In this work, we applied the novel connectivity matrix-based molecular substructural descriptor generation method to normal boiling point property prediction. Different to connectivity indices which are usually derived from the adjacency matrix of a molecule, the connectivity matrix is a variant of the adjacency matrix. It includes the atomic number and actual bond type information other than the adjacency information. An extraction strategy is proposed to extract a plethora of submatrices (also called molecular structural fragments), each representing the environment of an atom/bond automatically and systematically from this connectivity matrix, rather than using predefined groups like GC methods. This extraction does not cause a loss of molecular information compared to methods with convolution steps. In addition, we increased the number of hidden layers of the neural network to increase model accuracy (Pan et al., 2023).

## 2. Methodology

### 2.1. Datasets

The normal boiling point (NBP) dataset used in this work is from the literature (Alshehri et al., 2021). As far as we know, it is the largest NBP database with molecular structural information represented in SMILES format and property values.

## 2.2. Generation of features

Our recent article describes the detailed method (Pan et al., 2023). The general idea is that the environment of an atom/bond can be represented by extracting entries in the matrix considering the connectivity information. All molecules stored in SMILES format are canonicalised before structural information extraction. Rdkit package and in-house Python scripts were implemented for the feature generation. Figure 1 shows the structure, and reference number of each atom in acetic acid, each atom in the molecule is labelled a number, which is used as row/column indexes when generating the connectivity matrix. In Table 1, a square matrix in which the number of rows equal to the number of atoms is generated. Diagonal entries store the atomic number of each corresponding atom, while off-diagonal entries store the connectivity information.

Figure 1 Structure of acetic acid and reference number of each atom

The environment of each substructure is represented by the extracted submatrix. For example, atom 1 can be represented by extracting intersections of rows 0, 1, 2, 3 and columns 0, 1, 2, 3 from the connectivity matrix. Eigenvalues and determinants of such extracted submatrices are calculated, which were used as feature names to classify the structural fragments and count the number of each feature (number of same fragments). Features were then characterised using statistical methods such as Pearson's correlation method and principal component analysis, as shown in Figure 2d and 2e. Although the determinants and eigenvalues of submatrices are chemically meaningless, substructural information can be recovered using the stored matrix, because atoms and connecting information were fully stored.

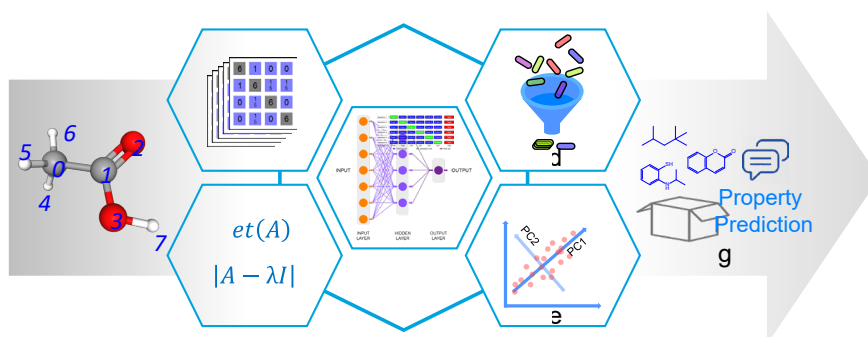

Figure 2 Flow chart of deep learning structure-property model development based on connectivity matrix

## 2.3. Development of structure-property models using DNN

Based on the previous work, we upgraded our neural network to a deep neural network (DNN) with multiple hidden layers and multiple nodes in each hidden layer. The dropout rate in each hidden layer is set as 25%. The number of neurons in the first hidden layer is

optimised, while the number of neurons in the second layer is fixed to 80. Other features of the model remain the same in as our previous work, such as the early stopping and checkpoints step of callback methods are adopted to avoid overfitting, cross-validation to evaluate model performance over different subsets of the training dataset.

Table 1 Connectivity matrix representation of acetic acid

Index	0	1	2	3	4	5	6	7
0	6	1	0	0	1	1	1	0
1	1	6	2	1	0	0	0	0
2	0	2	8	0	0	0	0	0
3	0	1	0	8	0	0	0	1
4	1	0	0	0	1	0	0	0
5	1	0	0	0	0	1	0	0
6	1	0	0	0	0	0	1	0
7	0	0	0	1	0	0	0	1

### 3. Results and discussion

Root mean squared error (RMSE) and mean absolute percentage error (MAPE) are used to evaluate the performance of the constructed model. The investigated number of the first hidden layer units varies from 10% to 130% of the number of input features with a 20 % step. The effects of hidden layer units of the DNN model on RMSE and MAPE are presented in Table 2. The DNN model with 209 neurons in the first hidden layer performs best with a minimum RMSE of 31.36 and MAPE of 4.20%. However, there is no noticeable trend regarding the number of neurons with the model performance.

Table 2 Effects of hidden layer units of the DNN model on RMSE and MAPE

Neurons	RMSE			MAPE (%)		
	training set	validation set	test set	training set	validation set	test set
41	29.66	32.56	33.73	3.63	4.45	4.83
125	24.47	27.53	31.83	2.99	3.94	4.43
209	22.69	26.29	31.36	2.76	3.80	4.20
293	23.07	26.71	32.55	2.86	3.82	4.29
377	24.12	27.49	31.88	2.94	3.92	4.25
460	23.48	26.99	31.49	2.88	3.86	4.26
544	24.98	27.83	31.93	3.12	4.00	4.43

The results of the DNN model over the previous artificial neural network (ANN) model are presented in Table 3. The average RMSE of the 6-fold cross-validation DNN model on the test set is 31.36, which is reduced by 6.50% compared to 33.54 of the ANN model. The MAPE (%) of the DNN model is reduced by 9.48%, from 4.64% to 4.20%.

Table 3 Comparison of the DNN model with the ANN model

Model	RMSE			MAPE (%)		
	training set	validation set	test set	training set	validation set	test set
ANN	30.02	39.76	33.54	3.28	4.23	4.64
DNN	22.69	36.33	31.36	2.76	3.80	4.20

The detailed RMSE and MAPE values for the DNN model generated using the 6-fold cross-validation method are presented in Table 4. The RMSEs on the test set stayed within a relatively narrow band, ranging from 28.52 to 36.71.

The parity plot (i.e., predicted values vs. experimental values) is provided in Figure 3a, where red dots represent the predicted boiling point over the practical property value in the test set (at iteration 6). It can be observed that most of the 792 data points in the test set distribute along the diagonal line, indicating that the predicted values are close to the experimental values. Figure 3b shows the distribution of relative errors (REs) between the predicted and the experimental property values at iteration 6. The number of data points with a predicted RE between (-5 %, 0) and (0, 5 %) are 330 and 325, which are higher than the ANN model (265, 217). Our previous ANN model outperformed the popular GC method, and the results suggest that the DNN model has a better prediction accuracy than the ANN model.

Table 4 RMSE and MAPE values of the DNN model using the k -fold method

Iteration	RMSE			MAPE (%)		
	training set	validation set	test set	training set	validation set	test set
1	16.63	24.28	28.56	2.17	3.29	3.75
2	18.42	70.34	31.67	2.63	3.35	4.01
3	41.07	35.00	36.71	4.39	5.17	5.35
4	14.90	28.19	30.33	2.37	3.67	4.14
5	31.29	32.68	32.35	2.98	3.72	4.31
6	13.80	27.50	28.52	2.03	3.62	3.68

#### 4. Conclusion

Structure information representation and mathematical modelling of structure-property relationships are critical factors in pure component properties prediction. In this work, based on the molecular structural features of molecules created using the novel connectivity matrix-based framework, we developed deep neural network (DNN) property prediction models. The effect of the number of hidden layer neurons was investigated. Compared to artificial neural networks, the increase in the number of hidden layers improved the accuracy of results. However, there was no apparent trend between the number of neurons and the model performance. The average RMSE of the DNN model is reduced by 6.50% compared to the ANN model (31.36 vs 33.54), while the MAPE (%) of the DNN model is reduced by 9.48% (4.20% vs 4.64%).

## Abstract

The current economic model produces large amounts of waste causing environmental problems. In contrast, circular economy focuses on the efficient utilization of resources, increasing materials' lifecycle, recycling, and decreasing environmental damage. Biorefineries are the foundation for accomplishing sustainable development goals and transitioning to the circular economy. Biomass wastes are sustainable feedstock for biorefineries and are increasing due to population growth and urbanization.

Thermochemical conversion technologies specifically supercritical water gasification, hydrothermal liquefaction, and hydrothermal carbonization are viable technologies for wet biomass feedstock. Therefore, the objective of this article is to investigate a possible biorefinery integration scenario with the mentioned processes and the feasibility of the integrated processes. A study on biorefinery processes could facilitate the transition to a circular economy and sustainability and provide a holistic view for decision-makers.

**Keywords:** Circular economy, Biomass waste, Biorefinery, Thermochemical conversion methods.

## 1. Introduction

Growing waste production due to urbanization and population growth results in several environmental risks. For instance, sewage sludge (SS) is one of the major waste streams. The generation of SS in the 27 European Union member countries, (EU-27), varies between 0.1 to 30.8 kg per population equivalent and year (Havukainen et al., 2022). SS contains organics content, inorganic compounds, various microorganisms and pathogens, nitrogen and phosphorous and toxic pollutants (Tiwari et al., 2022). Therefore, energy recovery and the disposal process of SS are quite challenging.

Different methods are applied for processing SS including supercritical water gasification (SCWG) at temperatures higher than 400 °C, hydrothermal liquefaction (HTL) at 250–400 °C, and hydrothermal carbonization (HTC) at 180–280 °C (Park et al., 2019). The superiority of these processes is the removal of costly drying pre-treatment (Özdenkçi et al., 2019). Water's physical characteristics have an important role in hydrothermal processes. The physical properties change significantly in sub-critical and critical regions: water behaves like a non-polar solvent and a catalyst in hydrothermal processes (Ghavami et al., 2021). In HTL, the organic matter is liquefied to biocrude oil and other by-products as aqueous phase (AP), bio-char, and gaseous products (Nallasivam et al., 2022). HTL process consists of three main steps: depolymerization, decomposition and recombination (Gollakota et al., 2018). HTC is a proper approach to converting wet biomass to a

carbonized solid fuel (hydrochar) with a moderately high heating value and nutrient-rich aqueous phase (Son Le et al., 2022; Xu et al., 2022). The HTC reactions include hydrolysis, dehydration, decarboxylation, aromatization, condensation, and polymerization (Ghavami et al., 2022). It is worth mentioning that the aqueous phase from HTL and HTC contains a huge amount of organic and inorganic compounds that need further processing (Merzari et al., 2019; Watson et al., 2020). SCWG is one of the effective technologies for converting biomass to hydrogen-rich gas products. Modell used it for the first time in the 1970s (Reddy et al., 2014; Wei et al., 2021). SCWG resulted in char formation being inevitable, especially with feedstocks involving unhydrolyzed large molecules, causing reactor plugging (Ghavami et al., 2021). Therefore, in order to reduce the char formation, the aqueous phase from HTL and HTC is processed in SCWG because of involving lighter and dissolved organics (Ong et al., 2020).

Integration of mentioned processes as a biorefinery concept is considered a sustainable approach to move towards a circular bioeconomy, carbon neutrality, waste management, and biofuel production (Culaba et al., 2022). Biorefineries are integrations of various processes producing multiple value-added products, in contrast with the traditional approach to a single product. Moreover, multiple products increase the rate of return on investment and protect against market uncertainties and fluctuations (Giwa et al., 2023). Designing a biorefinery requires a comprehensive understanding of integrated processes. In our previous article, we studied the integration of the HTC process into a biogas plant (Ghavami et al., 2022). Therefore, the objective of this study is to investigate the integration of hydrothermal processes with a biogas plant.

## 2. Process description and feedstock selection

Figure 1 depicts a complete view of the proposed biorefinery. SS feedstock is divided between anaerobic digestion (AD) and HTL unit operations, and the digestate from the AD process is directed to the HTC process. The aqueous phase of HTC and HTL processes enters the SCWG process for syngas production. The HTC process of SS digestate is at 200 °C and autogenous pressure with 30% solid load. The HTL process is simulated under the condition of 350 °C and autogenous pressure with 19% solid load. The aqueous phase (AP) from HTL and HTC is gasified in 600 °C and 250 bar conditions.

Figure 1. Flow diagram of the proposed biorefinery

Table 1 reports the dry basis compositions and the heating values (HHV) of the feedstocks and products based on the experiments (Parmar and Ross, 2019; Rahman et al., 2021).

Table 1. Analysis of feedstocks and products (Parmar and Ross, 2019; Rahman et al., 2021)

Sample	HHV (MJ/kg)	C	H	N	S	O	Ash	Yield
SS	14.1	33.1	5.5	5	0.7	25.9	29.8	-
SS digestate	14.9	28.7	3.1	3.4	1.5	16.4	46.9	-
Biocrude	28.3	53.3	6.01	3.9	1.1	29.9	4.7	37.1
Hydrochar	15.4	34.5	4.3	2.9	1.2	12.8	44.3	78

HTL, HTC, and SCWG processes are simulated in Aspen Plus V11.1 according to the following assumptions. The physical and chemical properties of non-conventional solids (NC solids) are estimated by 'HCOALGEN' and 'DCOALIGT'. Heating values for non-

conventional components are calculated with a unified correlation valid for a wide range of substances (Channiwala and Parikh, 2002). Gas phase in HTL contains 85.3 mol% CO<sub>2</sub>, 0.9 mol% H<sub>2</sub>, 6.4 mol% CH<sub>4</sub>, 4.4 mol% CO, and 2.9 mol% N<sub>2</sub>. The gas phase in HTC contains 90 mol% CO<sub>2</sub>, 1 mol% H<sub>2</sub>, 3 mol% CH<sub>4</sub>, and 6 mol% CO.

Prior to the simulation, it is needed to define components, thermodynamic method, and capacity. The component list is a combination of conventional and non-conventional substances including water, hydrogen, oxygen, carbon dioxide, carbon monoxide, methane, and nitrogen as conventional besides SS, digestate, hydrochar, biocrude oil, dissolved organics, and ash as non-conventional. The thermodynamic method is selected as PSRK for HTC and HTL sections because of accuracy at close-to-critical temperatures. Meanwhile, Peng-Robinson is used for the reactor and separation units in the SCWG section when converting non-conventional components to conventional ones and simulating the phase separation. In addition, mass balance is required to define yields on a non-inert basis for the RYIELD reactors in HTC and HTL processes. Yield reactors are used due to the non-conventional substances in the feedstocks. The HTC yields are calculated as 0.15, 0.81, 0.04, 0.005, 2.64e-6, 4.22e-5, and 0.00015 for hydrochar, water, organics, CO<sub>2</sub>, H<sub>2</sub>, CH<sub>4</sub>, and CO, respectively. Similarly, the HTL yields are 0.05, 0.02, 0.83, 0.02, 0.06, 3.14e-5, 0.0016, 0.0019, and 0.0013 for biocrude oil, solid, water, organics, CO<sub>2</sub>, H<sub>2</sub>, CH<sub>4</sub>, CO, and N<sub>2</sub>, respectively. The SCWG process is simulated as a yield reactor decomposing the non-conventional components into stable elemental components, separating ash, and a RGIBBS as an equilibrium reactor minimizing Gibbs free energy. Figure 2 depicts the process simulation of the proposed biorefinery.

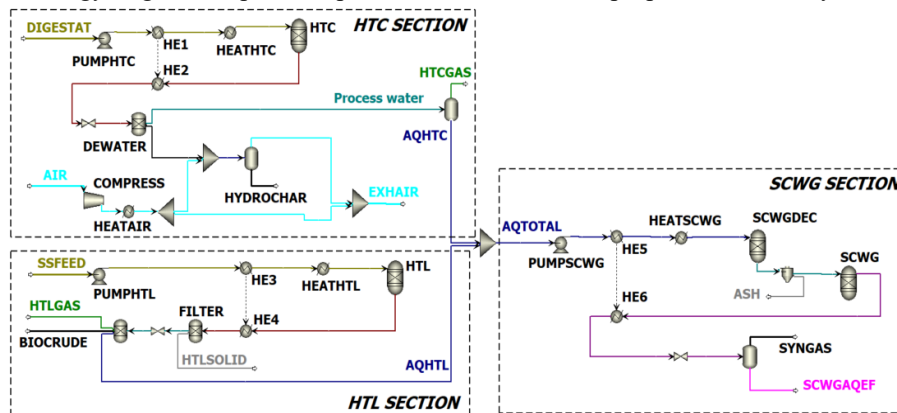

Figure 2. Process simulation of the proposed biorefinery

In the HTC section, the digestate feedstock (DIGESTAT) is pumped to 45 bars and is heated to 200 °C to reach the conditions in the HTC reactor. The stream exchanges heat with the reactor downstream by units 'HE1' and 'HE2' up to 180 °C and then reach the temperature of 196 °C by the external source in the HEATHTC heater. The product mixture goes through expansion and separation after heat exchange with the feedstock. Hydrochar is separated from the process water in the dewatering section and is dried down to 20% moisture by compressed air at 110 °C and 1.2 bars as described more in detail by Ghavami et al. (Ghavami et al., 2022). The HTC process water is conducted to a flash separation for removing gas products and then mixed with the HTL process water. In the HTL section, SS feedstock (SSFEED) is pumped to 170 bars and is heated to 350 °C to be prepared for the reaction condition, and same as the HTC part the reactor product exchange heat with the feedstock by units 'HE3' and 'HE4', then it reaches reaction condition by HEATHTL. The product mixture is passed through a filter to remove the

HTLSOLID after heat exchange with the SS feedstock. HTL products (gas, biocrude oil, and aqueous phase) are separated via a drum after expansion. The mixture of aqueous effluents (AQTOTAL) is pumped and heated with the same procedure as HTC and HTL to 250 bars and 720 °C. After the heat exchange with the aqueous mixture (units ‘HE5’ and ‘HE6’) and expansion, the syngas is separated in a flash unit.

### 3. Result and discussion

#### 3.1. Mass balance

Different methodologies are applied for mass balance calculations due to using various feedstock and data availability for each process. For the HTC and HTL sections, mass balance calculations were conducted by hydrochar, biocrude oil, liquid, and gas yields as well as proximate and ultimate analysis. Moreover, oxygen and hydrogen in organics are calculated by experimental chemical oxygen demand (COD) and biochemical methane potential (BMP). Ash content in biocrude oil is assumed as 4.72% based on error bars of the dry-ash-free elemental composition. In the SCWG section, mass balance calculations in the decomposition reactor were based on elemental compositions. Figure 3 depicts mass balances for HTC, HTL, and SCWG reactors.

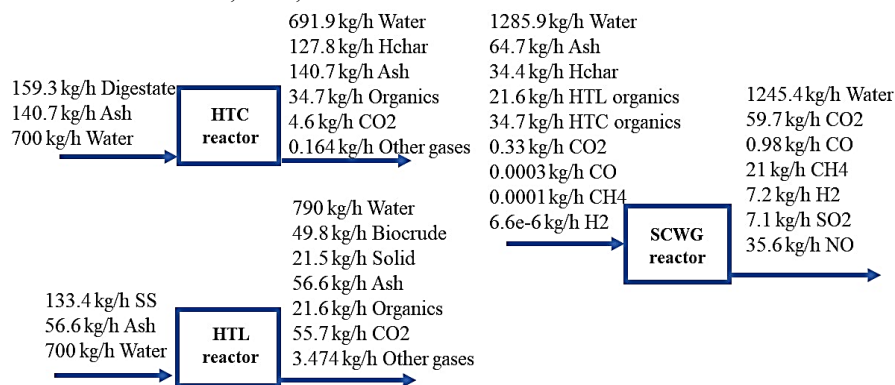

Figure 3. Mass balance in HTC, HTL, and SCWG reactors

#### 3.2. Energy balance

Table 2 reports the power and heat requirements for the proposed biorefinery as well as energy obtained from HTL solid and syngas.

Table 2. Power and heat requirement for the biorefinery

Electricity requirement (kW)		Heat requirement (kW)	
PUMPHTC	1.7	HEATHTC	16.1
PUMPHTL	7.8	HEATHTL	50.2
PUMPSCWG	15.1	HEATAIR	162.1
COMPRESS	56.4	DEWATER	5.9
0.25 x HEATSCWG	41.9	0.75 x HEATSCWG	125.6
<b>Total</b>	<b>122.9</b>	<b>Total</b>	<b>359.9</b>
Electricity outcome (kW)		Heat outcome (kW)	
Syngas	152.8	Syngas	458.3
HTL solid	38.5	HTL solid	115.5
<b>Total</b>	<b>191.3</b>	<b>Total</b>	<b>573.8</b>

The electricity requirement results from the pumps and the compressor while heat requirement results from the external heat supplied to air and HTC and HTL reactor inlets. Since the SCWG inlet is at a high temperature, it is compromising the combined heat and power (CHP) production. Therefore, the duty of the “HEATSCWG” unit is considered as

25 % electricity and 75 % heat requirement. Similarly, the CHP obtained from the combustion of syngas and HTL solid is also assumed as 25 % electricity and 75 % heat. Biocrude oil can also be used as a fuel in the process or be upgraded to a transportation fuel. Meanwhile, the hydrochar can be used as a fertilizer, benefiting from nutrients and minerals. In addition, the remaining fertilizer elements can be recovered from the SCWG process as the solid outlet.

### 3.3. Feasibility and future aspects

The proposed biorefinery process is applicable to biogas plants with various feedstocks. Hydrothermal processes are suitable for converting wet biomass. In addition, the nutrients and minerals can be recovered on the solid downstream regarding the usage as a fertilizer. The proposed process leads to the generation of 68.4 kW of electricity and 213.9 kW of heat as the net amounts.

The proposed process has high potential in terms of feasibility since the combination improves economic performance and overcomes the operational issues of each conversion method. HTC is industrially applied for sewage sludge (Buttmann, 2017). Meanwhile, HTC alone requires energy, e.g. 58 kW electricity and 61 kW heat consumption to process 1000 kg/h of agricultural residue digestate with 30 % moisture (Ghavami et al., 2022). Similarly, HTL alone also requires energy, despite being stated as a feasible process for large-scale (Seiple et al., 2020). Moreover, SCWG was stated to be feasible for a more challenging feedstock (black liquor) provided that the operational issues are addressed well (Özdenkçi et al., 2019). The proposed process provides net CHP production via SCWG of aqueous effluents while producing hydrochar and bio-oil as well as addressing the aqueous discharge issues and char formation in SCWG.

## 4. Conclusion

The scheme of a biorefinery is proposed in this article and integrated processes including HTC, HTL, and SCWG are simulated in Aspen Plus. Moreover, the process is able to produce CHP, especially via syngas after covering the energy requirements as well as the biocrude oil product and solids to be used as fertilizers.

## Abstract

The water-energy nexus is an important topic nowadays. Within it, the wastewater treatment plants (WWTPs) energy consumption is becoming an issue. WWTPs typically consume more energy than the one that can be obtained from the biogas produced from sludge anaerobic digestion. In this work, a process-level analysis is presented to study the feasibility of integrating both wastewater and municipal solid waste (MSW) treatment to achieve an energetically self-sustainable operation of a WWTP. The influence of the climate of different regions across the Iberian Peninsula on the energy requirements has also been evaluated. Mesophilic and thermophilic digestion is compared in Salamanca as a case base. Next, the optimal digestion temperature of 30 °C is found. Moreover, in all cities it is necessary for MSW to provide between 37-40% of the facility energy consumption. From an economic point of view, an investment between 0.09-0.16 €/kg of sewage sludge is obtained for the integrated process. Therefore, this techno-economic assessment demonstrates the feasibility of integrating these two treatments for a fully self-sufficient and sustainable process.

**Keywords:** energy, wastewater, municipal solid waste.

## 1. Introduction

Wastewater treatment plants are crucial facilities for reducing the potential environmental impact of wastewater discharges into receiving water bodies. However, they consume large amounts of energy. Until recently, energy was relatively affordable internationally, and many wastewater treatment facilities were not designed and operated with the goal of minimizing energy consumption, only to satisfy certain effluent quality requirements. Nowadays, rapid population growth and urbanization have led to an increase in wastewater production, so the number of WWTPs has also increased and effluent quality requirements have also become more demanding. This fact has resulted in a large energy consumption devoted to the operation of WWTPs, and the water-energy nexus has started to attract increasing attention from both environmental and economic points of view. On the one hand, WWTPs can represent 15–20% of the total energy consumption of municipal public structures and facilities, with energy also constituting anywhere 25-40% of the total operating costs in a conventional WWTP (Yang, et al., 2020). On the other hand, the operation of WWTPs involves greenhouse emissions due to the need for non-renewable energy sources; moreover, they have grown in recent years due to the increase in the volume of waste treated and the implementation of new processes aimed at achieving higher effluent quality. This water-energy nexus is promoting a series of studies on the relationship between energy and water for sustainable development, in particular,

the potential for energy self-sufficient WWTPs has become an area of increasing research and innovation.

Anaerobic digestion (AD) is a common technology for sludge treatment at WWTPs and allows the production of biogas, which is the main energy source in a WWTP. The use of biogas for digester heating and electricity generation is a sustainable way to recover energy from WWTPs, as it could replace fossil fuels, with consequent sludge reduction. However, while the use of AD for sludge processing and biogas production is widely reported in the literature (Bin Khawer, et al., 2022), in most cases, the biogas cannot cover the energy requirements, thermal and electrical, of the plant. Even in developed countries, there is still a large gap for the energy self-sufficient WWTPs, so it is necessary to investigate and apply new trends in energy production (renewables) and new technologies to achieve it. An alternative to generate clean energy that has gained importance in recent years is its production from waste, known as waste-to-energy (WTE). MSW can be used to provide such energy helping manage this residue at the same time. Several waste-to-energy technologies, both conventional and non-conventional, have been described in recent literature (Munir, et al., 2021). Conventional waste treatment or disposal techniques include composting, anaerobic digestion, and landfilling, while incineration, pyrolysis, gasification, and hydrothermal processing are considered non-conventional waste-to-energy technologies. Among all of them, incineration is regarded as the most mature.

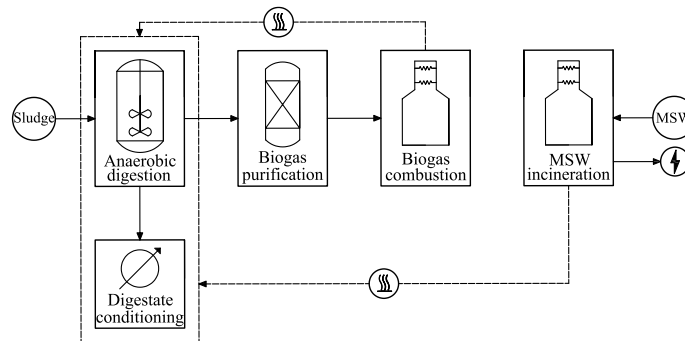

This work proposes the integration of sludge and MSW treatment for self-sufficient operation. The incineration of MSW produces steam to provide the thermal energy requirements in the AD process of the sewage sludge that cannot be covered by the biogas generated, and, also, to produce the total electricity requirements of the WWTP.

## 2. Process description and modeling

The integration of wastewater and MSW treatment combines two sections: sewage sludge treatment, that is the main thermal energy consumer within wastewater treatment, and the incineration of MSW, that is the provider of additional thermal energy and supplies power to the complete wastewater treatment, aiming at an energetically self-sufficient operation. The sewage sludge treatment is divided into four sections: biogas production, biogas purification, digestate conditioning and energy production (biogas combustion) (Figure 1). First, the sewage sludge is heated up and fed into a bioreactor where it is anaerobically digested to produce biogas, which contains methane, carbon dioxide, nitrogen, hydrogen sulfide, ammonia and moisture, and a decomposed substrate (digestate). The two main anaerobic digestion conditions are considered, mesophilic and thermophilic, which operate between 30-37°C and 50-55°C, respectively. Then, the digestate produced is conditioned in a reboiler, removing the excess of water and ammonia. This step is included so that the digestate can later be used as a fertilizer. The third step consists of the biogas purification by removing the CO<sub>2</sub> (and traces of NH<sub>3</sub>) and the H<sub>2</sub>S in a Pressure Swing Adsorption (PSA) system and in a fixed-bed reactor, respectively. Once the biogas is mainly methane, it is burned with air in a furnace to provide the thermal energy requirements of the process. They include heating up the combustion air and the sludge feed, and to produce steam to heat up the bioreactor and the heat exchanger of the sludge conditioning step.

The incineration of MSW is used to produce the additional thermal energy needed in the anaerobic digestion and the power requirements of the WWTP. A fraction of the MSW is burned in a furnace to produce the steam to heat the bioreactor and the heat exchanger of sludge conditioning, and the rest is used to produce steam to feed a Rankine cycle to

generate power. In the Rankine cycle, three different sections of the steam turbine are considered (high, medium and low-pressure turbines). The treatment of the combustion

gases generated in the incineration is not considered in this work.

Figure 1. Process diagram of the integrated process of sewage sludge and MSW treatment.

Both processes, stand-alone digestion in Salamanca and the integrated process in all cities, have been modelled using an equation-based approach. These models are formulated using mass and energy balances, thermodynamics, chemical and vapor-liquid equilibria, etc., to evaluate their performance and are based on the work of León and Martín (2016). The entire superstructure is formulated as a non-linear programming problem and is implemented in GAMS using CONOPT 3.0 as preferred solver in a multistart optimization approach. The objective function is the minimization of the external energy requirements, given by (Eq.(1)):

$$Z = (E_{\text{dig}} - E_{\text{biogas}}) - E_{\text{MSW}} \quad \text{Eq.1}$$

where  $E_{\text{dig}}$  is the total thermal energy required in the digestion process,  $E_{\text{biogas}}$  is the thermal energy supply by the generated biogas and  $E_{\text{MSW}}$  is the external thermal energy that needs to be provided by MSW.

This study is divided into two stages:

1) The evaluation of the operating conditions and the optimization of the operating temperature of the AD, minimizing in both cases the external supply of thermal energy. Firstly, mesophilic (35°C) and thermophilic (55°C) operation are compared. The variation of the water and air temperature that exists along the year in the city of Salamanca is considered, as a case base, because the thermal energy requirements depend on these temperatures. And, secondly, the operating temperature of the sludge digestion over a year has also been optimized, due to its effect on the amount of biogas produced and the energy consumption to heat up the sludge and dewatering step.

2) The study of the influence of the location on the thermal energy requirements of the optimized process. Different regions of the Iberian Peninsula have been evaluated considering the different climates that influence the air and water temperature each month, particularly: Oceanic in La Coruña (population: 244850, hab.eq.: 600000), Coastal Mediterranean in Barcelona (population: 1637000, hab.eq.: 1706250), Continental Mediterranean in Salamanca (population: 144000, hab.eq.: 260042) and Madrid (population: 3266000, hab.eq.: 1335000), and Oceanic Mediterranean in Sevilla (population: 689000, hab.eq.: 950000). The size of each WWTP is related to the amount of organic matter that is treated, considering that a person produces 26.9 kg of dry matter per year (Bianchini, et al., 2016). Also, it conditions its electricity consumption, considering that the average consumption of a WWTP in Spain is 5.6 kW/hab.eq. (IDEA, 2010).

### 3. Results

For the base case, the city of Salamanca, first, the operating conditions of the two different main types of AD have been studied. For the mesophilic and thermophilic digestion modes, the most energy intensive processes are the digestion itself and the digestate dewatering. The digester consumes 914.5 kW in both cases because it is considered as an isothermal process, so it only depends on the enthalpy of reaction. Nevertheless, the digestate dewatering consumes more energy in the mesophilic case, 467 kW vs. 358 kW, because the outlet temperature of the heat exchanger has always the maximum value (150°C), so the gradient temperature of the thermophilic case is lower. The other two duties are the sludge heating before digestion and the air heating before combustion and these values change over the months. The sum of these energy requirements goes from 103.5 kW in warm months to 175.4 kW in the coldest ones, in the case of mesophilic digestion, and, from 215.9 kW to 288.0 kW for thermophilic digestion. Obviously, they are higher as the digestion temperature increases. The amount of additional thermal energy is higher in the case of mesophilic digestion, although the digestion temperature is lower, an average of 39% vs. 37%. This fact is due to the significant contribution of digestate dewatering to the total thermal energy requirements of the process, that is higher in the mesophilic digestion (30% vs. 23%). In fact, the extra thermal energy without considering digestate conditioning is higher in the thermophilic case.

Then, digestion temperature has been optimized within the range of 30-55°C. The optimal operating temperature is 30°C, although it is shown that the additional thermal energy requirements is reduced with the increasing of digestion temperature, the problem tends to choose the lowest digestion temperature of the range to reduce the thermal energy involved in the process since the additional yield of biogas is not enough to mitigate the difference. This optimal temperature is the value used to study the influence of the climate, because it determines the value of the energy that heats up the sludge before digestion and the air before combustion. The change over the months and the different contribution on the total energy are shown in next section, where they are compared to other climates.

Once optimized the digestion temperature, the integrated process of wastewater a MSW treatment is modeled to make the process self-sufficient in terms of energy. The influence of the climate on the energy requirements has been studied for different cities (Salamanca, Madrid, Barcelona, La Coruña and Sevilla). The value of energy required in the digester and the one required to dehydrate the digestate per kilogram of sludge is the same in all cities, 680 kJ/kg, and 364 kJ/kg, respectively. In Figure 2, the energy requirements to heat sludge and air for each city over the months are shown. For all cases, June, July, and August present the lowest values because are the warmest months. Salamanca presents the maximum values, around 110 kJ/kg, because the winter in the Continental Mediterranean climate is the coldest one; nevertheless, in the warmest months, La Coruña exceeds the energy requirements of Salamanca, because the Oceanic climate tends to present mild summers, so water and air temperatures are lower, around 61-70 kJ/kg vs. 56-66 kJ/kg. The minimum values are obtained in Sevilla, from 37 kJ/kg to 86 kJ/kg, because the city is located in the most southern part of the Iberian Peninsula and the Continental Mediterranean climate presents the warmest temperatures, both air and water. The largest difference between the maximum and minimum value is shown in Madrid, 58%, because it presents the highest gradient temperature over the months and the minimum in La Coruña, 32%, where the thermal amplitude is lower due to ambient humidity; while, in Salamanca, this difference is 49%, in Sevilla, 56%, and, in Barcelona, 50%. This difference can also be seen in the shape of the curve presenting the data for the

extra energy (Figure 2), which is more pronounced in the case of Madrid. The amount of additional energy to be provided by the MSW slightly varies between the different cities and is between 37% and 40% of the total energy required for the digestion process for all of them. This percentage is similar because the main contributor to the total energy required in the process is the energy for the digestion and for the digestate conditioning, which represent around 91% of the total thermal energy. Its value increases as thermal energy requirements increase, so the same trend is observed as in the case of energy needs throughout the year between cities. Therefore, the extremes are Seville, with the lowest percentage of additional energy, and Salamanca, with the highest, except in summer, when it is surpassed by La Coruña. From January to April, between Madrid, Barcelona and La Coruña, the first one is the major consumer, and the same occurs from October to December; however, this trend changes between April and October, where the energy requirements of La Coruña increase, becoming even higher than those of Salamanca. The average amount of MSW that is fed to the integrated process is higher as the size of the WWTP increases because the energy and ranges from 0.26 kg/s in Salamanca to 1.67 kg/s in Barcelona. However, the amount of MSW per kilogram of sludge is almost the same for all cities, around 0.19 kg/kg, with a very slight difference between cities, being lower as the average of extra thermal energy decreases. Around 12% of the total MSW fed is devoted to the production of thermal energy, and the rest goes to the production of electricity. The databases show that there is enough MSW in each city to cover the energy requirements of the WWTP, considering that, a person produces 455 kg of MSW per year (Eurostat, 2022).

Figure 2. Energy contribution of sludge and air heating to digestion and percentage of extra energy needed in Salamanca, La Coruña, Sevilla, Madrid, and Barcelona per month.

An economic analysis of the integrated process has also been carried out for the different cities. Capital and production cost are obtained. Figure 3 shows the breakdown of the capital and the production cost for the different cities. The digester is the main item in the distribution of the capital cost in all cities, with around 51% of the total investment, followed by the steam turbines, with 25%. Regarding production costs, the main item is capital charges, with about 60% in all cities, followed by maintenance, with 20%. There is a slight difference in these percentages between cities, so they are higher as the size of the WWTP increases. Although, both capital and operating cost are higher in the larger WWTP, they benefit from economies of scale. The investment for the integrated process goes from 0.16 €/kg of sewage sludge in Salamanca, the smallest WWTP, to 0.09 €/kg in

Barcelona, which is the largest. The same is true for the investment per kilogram of MSW fed, which ranges from 0.86 €/kg in Salamanca to 0.46 €/kg in Barcelona.

Figure 3. Capital and production cost for the different cities

#### 4. Conclusions

In this work, the energy requirements of the WWTP have been studied. The thermal energy requirements in sewage sludge treatment are a challenging problem because the anaerobic digestion of sludge does not produce enough biogas to cover them. Therefore, an integrated wastewater and municipal solid waste treatment process has been evaluated to make the WWT self-sufficient in terms of energy. Moreover, the influence of the climate in different region of the Iberian Peninsula has been studied. The results show that it is feasible to integrate the treatment processes because there is enough MSW to provide energy to the WWTP in all cities. An amount of MSW per kilogram of sludge is around 0.19 kg/kg, with a very slight difference between cities, being lower as the average of extra thermal energy decreases. The investment cost ranges from 0.09 €/kg to 0.16 €/kg of sewage sludge, depending on the size of the WWTP. This analysis allows the successful integration of these treatment processes with the aim of a fully self-sufficient and sustainable system.

## Abstract

Continuous manufacturing has been incorporated in the pharmaceutical industry to achieve a beneficial production system for scale-up or scale-out, flexibility of demand response, and sustainability of material utilization (Yu, 2008). This paper proposes a rapid prototyping approach based on a mathematical model that integrates experiment and simulation. It is important to segregate the parameter identified for new manufacturing items from the parameter applied to common items based on the accumulation of experimental data. As an example case of rapid prototyping, a trickle bed reactor (TBR) as a multiphase heterogeneous catalytic reactor with complex interdependencies is presented. This design approach enables a rapid prototyping of production system supporting multiphase catalytic reaction. Both the hardware design, such as catalysts and filling systems in the equipment in multi-stage reactors, and the design of operating conditions can be decided considering the constraints of the equipment, materials and reagents. The cycle of data acquisition and model evaluation in laboratory scale can accelerate the actual manufacturing system establishment.

**Keywords:** Continuous pharmaceutical manufacturing, Modeling and simulation, Optimization, Process design and Trickle bed reactor

## 1. Introduction

TBR is used for applications ranging from large-scale manufacturing centered on petrochemicals to small-scale manufacturing, including pharmaceutical manufacturing. When compared to other types of reactors such as bubble column, fluidized bed, slurry type reactor, and so on, TBR is preferable as a multiphase catalytic reactor because of the simple separation process and an easy replacement of catalyst (Duduković et. al., 1999). In conventional large-scale production, a robust design of the wetting efficiency of the catalyst is essential for the prevention of catalyst and equipment burnout, owing to localized severe temperature fluctuations. Process modeling is often applied to TBR design in various industrial fields, as shown in Fig.1 (Al-Dahhan et. al., 1997).

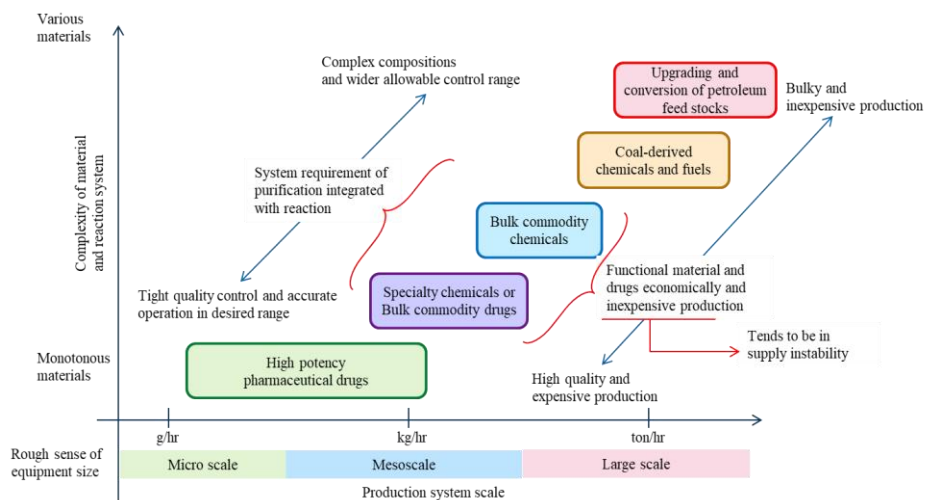

Fig.1 Conceptual map of a TBR application in various industrial fields

In the mesoscale region, engineering technology is required to establish a rapid and high-quality manufacturing system. It is necessary to determine the characteristics of the target product and establish a new database about the thermodynamic and transport properties (Masson et al., 2022). The mesoscale production system tends to be in supply instability of the functional material and drugs because of the inexpensive production considering the complicated manufacturing process. Frequently consumed mesoscale products need to be manufactured economically and inexpensively in robust facilities designed with process integration. In a mesoscale TBR design, it is necessary to select a good catalyst size to compensate for its deterioration during transport ability in the laminar flow area, to suppress the pressure drop, and to enhance the reaction rate at a high solid-liquid ratio during transport of the reactants. Furthermore, the target material must be recovered at high purity when compared to the conventional production of petroleum products, where the amount of impurities should be small. The other motivation is to increase the synthetic route of organic synthesis through applying continuous manufacturing. The reductive amination and removal of benzyl-type protecting groups are two major examples of reduction reactions that frequently use catalytic hydrogenation over precious metal catalysts (Carey et al., 2006). The basic concept of the proposed method is to utilize the pre-determined information about the process and equipment and to incorporate the reaction kinetics. It can reduce the experimental work for the preparation of the TBR system, concerning the characteristics of the reaction and catalysts.

## 2. Concept of rapid prototyping

The rapid prototyping approach consists of three steps: 1) parameter adjustment of the reaction kinetics through laboratory experiments; 2) verification of the integrated model parameters through bench-scale experiments under suppressed material consumption; and 3) determination of production scale and system specifications.

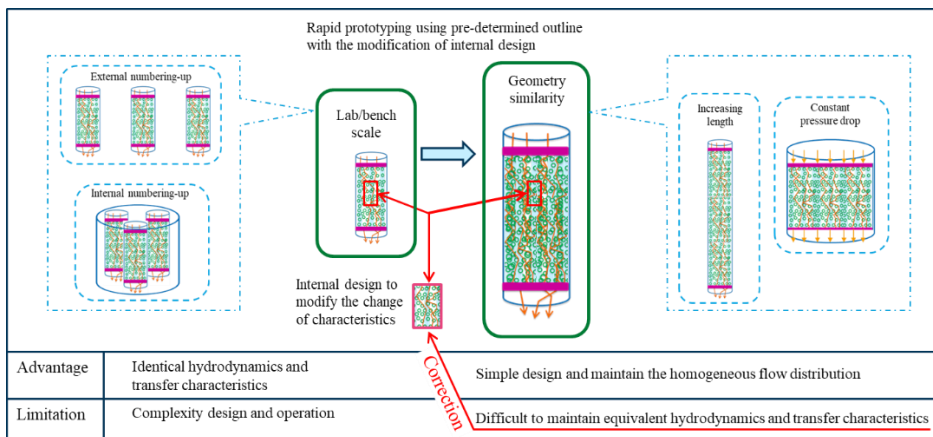

Fig.2 Concept of rapid prototyping of fixed bed multiphase catalytic reactor

With the pre-determined models in Sections 2 and 3, we can focus on the exploration of reactions and material properties characteristic, and quickly determine the required design prototypes for different manufactured products. Figure 2 shows the morphology of the scale-up policy (Dong, et. al., 2021). Numbering-up has the advantage of retaining the production conditions established from the lab/bench scale. However, there are disadvantages that it is difficult to establish design, operation and control philosophy for multiple reactors. On contrary, scaling up has the advantage concerning simple configuration and more flexible design space of internal packed features and operating condition, although the homogeneity of flow and transport phenomena are required to modify. However, it can adjust the reaction performance, heat and mass transport characteristics to the desired condition that is similar to the condition of the lab/bench scale. The navigation system consisted of segregating data base both material features and transport phenomenon can help to determine the appropriate process design. Fig.3 shows the concept of navigation system. New material features need to be created for the new target production repeatedly, although a data base of transport phenomenon is usually to provide the best route to achieve a high-quality production. The experience of development cycle will enhance this navigation system according to the accumulated properties.

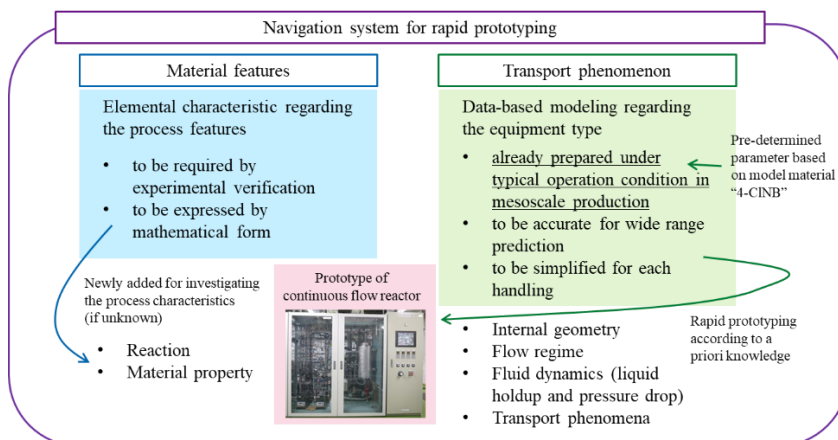

Fig.3 The concept of navigation system for rapid prototyping

### 3. Integrated modeling of trickle bed reactor

The modeling of TBR can be separated into three sections: 1) reaction kinetics; 2) the size of the equipment and catalyst; and 3) transport phenomena. If the model parameters in sections 2 and 3 are pre-determined, the reaction model with different fixed bed catalysts can be applied in a simple and rapid way. The parameters of the process model are adjusted considering the reaction kinetics, catalyst properties (size and metal loading), flow regime, axial dispersion, pressure drop, transport phenomena, and liquid holdup. Establishment of the TBR system requires the comprehension of complex independent phenomena by conducting careful experimentation and deconvolution of various parameters (Azarpour et al., 2021). The hydrogenation reaction of 4-chloronitrobenzene using a Pd/TiO<sub>2</sub> catalyst is adopted as a mockup substance and reaction system. The intermediate 4-chloronitroaniline is set as the product for the evaluation of reaction pathways by overreaction, by-products (nitrobenzene), and impurities (nitrosamines). To build this integrated model, 300 experimental data points were used under the following conditions:

Table 1 The reference data for providing mockup integrated model of TBR

Process conditions	Filling conditions	Equipment size
Substrate concentration: 50 mol/m <sup>3</sup> , 100 mol/m <sup>3</sup>	Catalyst amount: 1~50 g (based on Pd/TiO <sub>2</sub> )	Catalyst filling length: 10~320 mm
Liquid flow rate: 0.2~80 mL/min.	Metal content: 0.2~5 wt%	Diameter (I.D.): 12.2mm, 30mm
G/L ratio: 16.7~100 (volume ratio)		
Temperature: 35~60 °C		
Pressure: 0~0.5 MPaG		

Fig. 4 shows an overview of the integrated simulation model.

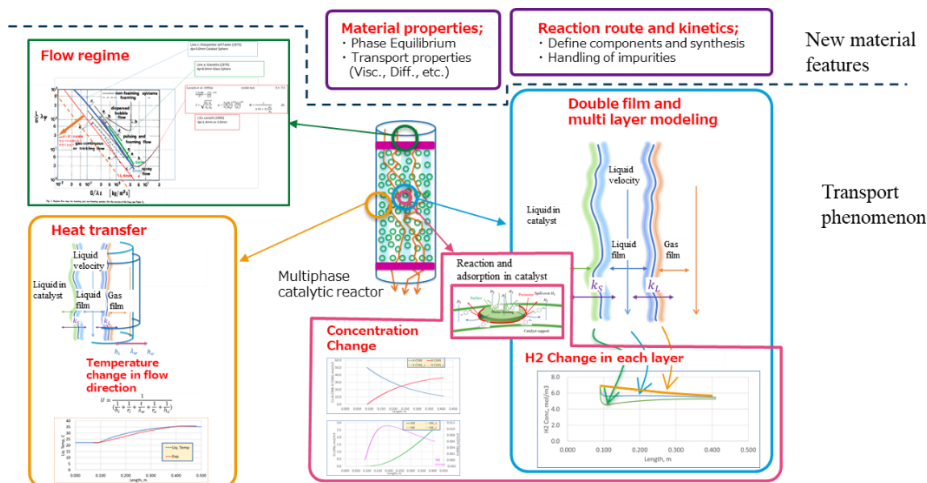

Fig.4 Integrated modeling of interdependency phenomenon

Based on the formula determined for the flow regime in a TBR (Gianetto et al., 1978), the formula is modified to adapt the process conditions to the packing size applied in the mesoscale region. As a result, the liquid holdup and pressure drop change, which affects the heat and mass transport phenomena and reaction conditions in the integrated simulation model.

#### **4. Model-based design approach**

To provide an accurate integrated model, the acquisition of high-quality experimental data is important to provide a map constituting the accuracy of process characteristics. On the other hand, scale design experiences will update a compass to predict the right reactor scale with the interior design. The integrated model can aim to design the following aspects;

##### *4.1. The internal design*

The size of the catalyst is set at a few hundred  $\mu\text{m}$ , which does not change significantly from the viewpoint of reactor pressure loss and liquid holdup capacity. However, the catalyst amount and metal loading are deemed the design parameters that affect the balance between the reaction heat generation and heat removal by the jacket coolant. The different combinations of catalyst amount and metal loading are evaluated for reaction performance. Fig. 5 shows the conversion of starting material (SM) and Fig.6 shows the selectivity of target material (TM). It can be confirmed that both Fig.5 and Fig.6 give a good estimation. In other words, it is possible to predict the desired conditions using the integrated model and to determine design conditions rapidly.

##### *4.2. The reactor scale design*

The reactor scale is an important design parameter. Higher velocity makes the transport ability better, but it makes the pressure drop worse. The liquid flow and Gas/Liquid ratio also have a significant impact on liquid holdup. Therefore, different sets of catalyst packing heights are verified. Fig.7 shows the conversion of SM, and Fig.8 shows the selectivity of TM, respectively. It can be confirmed that both Fig.7 and Fig.8 give good estimations. The integrated model can predict the TBR performance for different diameters and catalyst packing heights; therefore, the desired operating condition can be determined by the selection of the appropriate size of reactor. By combining equipment size selection and internal design, it is possible to rapidly prepare a multiphase catalytic reactor system that satisfies the required manufacturing scale and specifications.

#### **5. Conclusion**

This paper introduces a rapid prototyping method, which is a conceptual model based on a comparison between mesoscale experimental data and simulation. In the design of multiphase catalytic reactors in the mesoscale region, the basic data on transport phenomena is still insufficient. Therefore, the fluid parameter and transport phenomena are incorporated into the integrated TBR mathematical model. Improvement of the integrated TBR database can be achieved through repeated experiments and simulation.

Fig.5 Prediction of conversion change based on the internal design

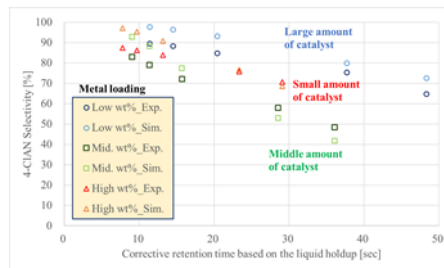

Fig.6 Prediction of yield change based on the internal design

Fig.7 Prediction of conversion change based on reactor scale design

Fig.8 Prediction of yield change based on reactor scale design

This study has made it possible to evaluate the catalytic reaction performance and to quickly identify the parameters for the reaction characteristics. According to the reaction parameter incorporation into the integrated model, which can help the determination of reactor internal and scale design. This method can be used as a common platform to combine chemical and catalytic reactions, which can help researchers with the chemist and process engineer. This design approach can also make the frequent change of production items possible. Following that, while establishing the mesoscale continuous pharmaceutical manufacturing system, this approach can be used to study other processes such as synthesis and separation.

## Abstract

MOF membranes have shown high productivity in CO<sub>2</sub> removal from gas mixtures. In this work, we present a new integrated framework for reliable prediction of the process performance of MOF-based membranes (e.g. IRMOF-1). Firstly, molecular simulations are conducted to investigate the adsorption isotherms, self-diffusivity, activation energy, permeability and selectivity of IRMOF-1 for CO<sub>2</sub>/CH<sub>4</sub> separation under different operating conditions. The simulated isotherms at 298 K are in good agreement with the experimental results. As the operating conditions vary, the permeability of CO<sub>2</sub> can scale from 40898 to 381776 barrer. A similar observation is made regarding selectivity, highlighting the dramatic effect of operating conditions on membrane performance. Further, predictive models are developed with machine learning, allowing the calculation of permeability and selectivity. As the mean squared error is 0.0086 and the R-Square is 0.9822, the predictive models are shown high reliability. The predictive models integrated with the tanks-in-series model of a hollow fiber membrane separation process are simulated by the finite-volume method. The feasibility and competence of the proposed framework are illustrated in three case studies.

**Keywords:** Metal-organic framework (MOF), CO<sub>2</sub>/CH<sub>4</sub> separation, Molecular simulation, Machine learning, Membrane separation.

## 1. Introduction

As energy consumption increases due to large-scale industrial production, more and more greenhouse gases (mainly CO<sub>2</sub> and CH<sub>4</sub>) are released, leading to serious greenhouse effects such as global warming. In the meantime, the extraction of raw natural gas fields is increasing where the separation of CO<sub>2</sub> and CH<sub>4</sub> is becoming particularly crucial. For industrial applications of CO<sub>2</sub>/CH<sub>4</sub> gas mixture separation, the feed composition of CO<sub>2</sub> is widely distributed, covering a range of 30 to 90%. This makes it urgent to develop technologies for the efficient CO<sub>2</sub> removal. In order to reduce energy costs, membrane separation techniques are employed for the enrichment of lean feed gas. Membrane separation takes advantage of the selective separation function of materials. Therefore, operating conditions are typically moderate, leading to much lower energy consumption.

Furthermore, the membrane separation is generally easy to operate, control and scale up with high separation efficiency.

There are two parameters that characterize the efficiency of membrane separations, including permeability and selectivity. Conventional polymer membranes typically have a trade-off relationship between permeability and selectivity, failing to achieve high permeability and high selectivity simultaneously. Porous membranes are considered to be the alternative to polymer membranes due to their adsorption behavior and pore size sieving effect, which allow them to break through the limitation of Robeson trade-off upper bound of the polymer membrane (Robeson 2008). MOF stands for a new type of porous materials which have shown high productivity in CO<sub>2</sub> removal from gas mixtures. Various MOF materials have been synthesized experimentally, however, unfortunately their properties are generally evaluated at ambient temperature and 1 bar pressure (Erucar and Keskin 2013). Due to the fact that these properties can vary significantly depending on the operating conditions, this evaluation is no longer sufficient for industrial applications under varying operating conditions. On one hand, experimental studies are usually complex and expensive because of the uncertainty of uncontrollable errors and the variability of samples with impurities and defects. On the other hand, some MOF membrane performance have been evaluated by molecular simulations, most of these are carried out at ambient temperature and a fixed pressure (Li, Kresse et al. 2001). Therefore, existing work is insufficient to support a process optimization approach to identify the optimal design for CO<sub>2</sub>/CH<sub>4</sub> membrane separation.

Although molecular simulation is extensively applied to study gas separation in MOFs, it is computationally expensive in terms of resources and time costs (Pronk, Pall et al. 2013). For this reason, it is a challenge to integrate molecular simulations with process simulations. Through molecular simulation it is possible to generate the big dataset on the performance of MOFs under different operating conditions. A prediction model can be developed based on this big dataset by machine learning. This incorporation shows great potential as it can efficiently realize integration design. To the best of our knowledge, there is currently no framework developed for the integration of molecular simulation into membrane process simulation via machine learning. Consequently, the main objective of this study is to develop a novel multi-scale design framework via the integration of molecular and process simulation through machine learning, which is evaluated by exploring the potential of a MOF-based membrane for the separation of CO<sub>2</sub>/CH<sub>4</sub> mixture.

## 2. Methodology

### 2.1. Molecular Simulation

In this work, we firstly apply grand canonical Monte Carlo (GCMC) and molecular dynamics (MD) simulation to investigate the adsorption, diffusion, and permeation of a MOF-based membrane (e.g. IRMOF-1) for CO<sub>2</sub>/CH<sub>4</sub> mixtures separation under different operating conditions. We choose IRMOF-1 as the MOF-based membrane material because it is one of the earliest MOFs that can be stably synthesized and industrialized and has been successfully fabricated as film. It is also the parent of the classical IRMOF series with a large number of available literature and experimental data. The CO<sub>2</sub>/CH<sub>4</sub> binary mixtures with varied feed CO<sub>2</sub> compositions from natural gas is used in this work. The molecular simulation is carried out at temperatures of 273, 298, 323, 348, 373 and 423 K under pressure range of 0–20 bar. The adsorption isotherms of pure CO<sub>2</sub>, CH<sub>4</sub> and their mixtures in IRMOF-1 are evaluated by GCMC simulation. MD simulation is then performed in NVT ensemble to investigate the self-diffusivity and diffusion activation

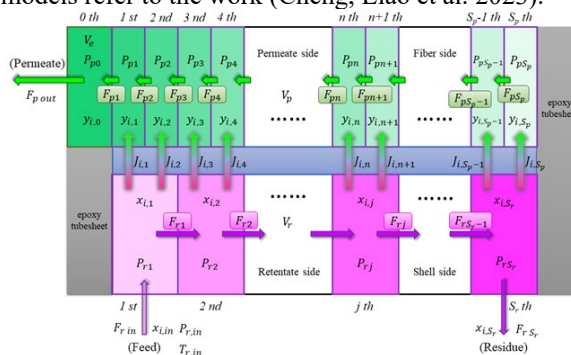

energy. The permeability and membrane selectivity of IRMOF-1 are also calculated based on the solution-diffusion model. For detailed parameters and validation refer to the work (Cheng, Liao et al. 2023).

### 2.2. Machine Learning (e.g. Artificial Neural Network)

Based on the GCMC & MD simulation for the CO<sub>2</sub>/CH<sub>4</sub> mixture separated in IRMOF-1 membrane under different operating conditions, two ANN models are developed and trained to describe the adsorption capacity and self-diffusivity, respectively. There are approximately 70% of the data selected randomly from dataset (1340 points) for model training, 15% of the data for validation and 15% of the data for testing. The ANN models use the feed CO<sub>2</sub> composition, temperature, and partial pressure as the input layer to create the input vector. The output layer of the network is a four-dimensional output vector containing adsorption capacity and self-diffusivity of each component. For detailed configuration of ANN refer to the work (Cheng, Liao et al. 2023).

### 2.3. Mathematical Modeling of Hollow Fiber Membrane

This work adopts a tanks-in-series model (Katoh, Tokumura et al. 2011) of the hollow fiber membrane as shown in Fig. 1, feeding from the shell side, capturing permeate CO<sub>2</sub> from the inside of fibers and yielding a product from the residue side. The tanks-in-series model consists of a series of equal sized and well-mixed tanks which are numbered in both sides from the feed end to the residue end. The number of tanks in the permeate side is set to double of that in the residue side. The mathematical model includes the relationship governing transport across the membrane, mass balance equations, pressure drop equation for permeate/feed sides and boundary and initial conditions that reflect the configuration and operation of the hollow fiber membrane module. For detailed expressions and models refer to the work (Cheng, Liao et al. 2023).

**Figure 1** Schematic of tanks-in-series model for a counter-current hollow-fiber

### 2.4. Implementation

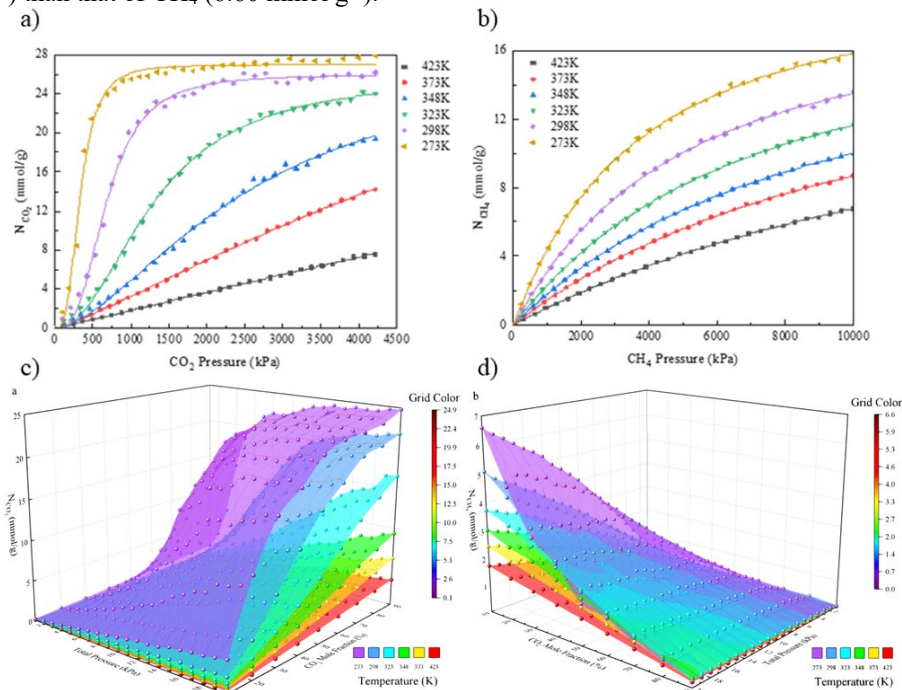

The GCMC and MD simulations are conducted in Materials Studio software. The ANN training, validation and testing are conducted in MATLAB providing early stopping applied in this work. The mathematical model of hollow fiber membrane separation process is simulated using the finite volume method implemented in MATLAB.

## 3. Results

### 3.1. GCMC & MD Simulation

Fig. 2a-b show the adsorption isotherms of pure CO<sub>2</sub> and CH<sub>4</sub> while Fig. 2c-d show adsorption isothermal surfaces of mixed CO<sub>2</sub> and mixed CH<sub>4</sub> in varied composition binary mixtures in IRMOF-1 from the GCMC simulation. On one hand, the pure gas GCMC results show that the maximum adsorption capacity of CO<sub>2</sub> is as high as 27.91

mmol g<sup>-1</sup>, while the maximum adsorption capacity of CH<sub>4</sub> reaches 15.86 mmol g<sup>-1</sup>. On the other hand, the mixture GCMC results demonstrate that CO<sub>2</sub> plays a dominant role in the mixed gas adsorption behavior, with a much larger adsorption capacity (24.80 mmol g<sup>-1</sup>) than that of CH<sub>4</sub> (6.60 mmol g<sup>-1</sup>).

**Figure 2** Adsorption isotherms of pure CO<sub>2</sub>, CH<sub>4</sub> and CO<sub>2</sub>/CH<sub>4</sub> binary mixture at different temperatures: a) pure CO<sub>2</sub> b) pure CH<sub>4</sub> c) mixed CO<sub>2</sub> d) mixed CH<sub>4</sub>

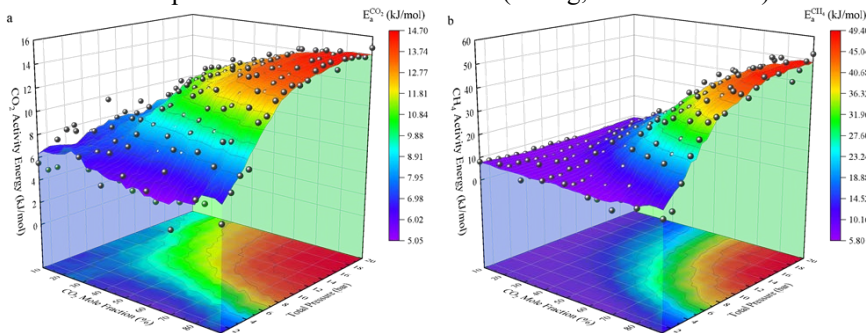

**Table 1** Diffusion activation energy of pure CO<sub>2</sub> and CH<sub>4</sub> at 1, 5, 10 bar

p (bar)	Pure CO <sub>2</sub> E <sub>a</sub> (kJ mol <sup>-1</sup> )	Pure CH <sub>4</sub> E <sub>a</sub> (kJ mol <sup>-1</sup> )
1	9.2	6.6
5	11.6	5.6
10	15.0	5.4

As observed from Table 1, the MD results for pure gases suggests that the activation energy of CO<sub>2</sub> diffusion in IRMOF-1 is greater than that of CH<sub>4</sub> under the same operating conditions, indicating that the diffusion of CO<sub>2</sub> is more difficult. This conclusion is consistent with the fact that the self-diffusivity of CO<sub>2</sub> is smaller than that of CH<sub>4</sub>. On the other hand, the mixture MD results are completely opposite to the pure gas results, which can be seen from Fig. 3. The activation energy of CO<sub>2</sub> diffusion in IRMOF-1 is much lower than that of CH<sub>4</sub> in the mixture, which is also confirmed by experimental phenomena of CO<sub>2</sub>/CH<sub>4</sub> binary mixture diffusion in other porous materials (Zhao, Feng et al. 2016). The combined effect of competitive adsorption and synergistic diffusion leads to a significant reduction in activation energy of mixed CO<sub>2</sub> diffusion. CH<sub>4</sub> carries CO<sub>2</sub> along with it through the membrane, while large amounts of CO<sub>2</sub> get stuck in the pores of membrane, blocking the pathway and making the diffusion of CH<sub>4</sub> difficult.

Based on the solution-diffusion model, permeability and selectivity could be calculated. The mixture results show that CO<sub>2</sub> permeability in IRMOF-1 is ranging from

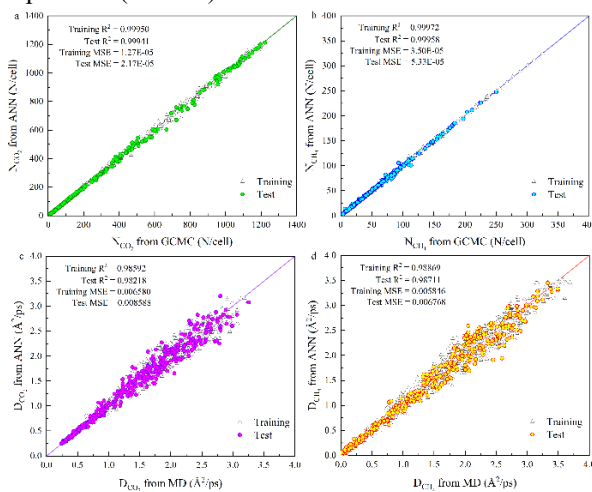

40898 to 381776 barrer with the variation in operating conditions, the same phenomenon is also reflected in the selectivity. These indicate the great effect of operating conditions on the performance of MOF membrane. The rest of available data and analysis of GCMC and MD results are presented in detail in the work (Cheng, Liao et al. 2023).

**Figure 3** Diffusion activation energy of CO<sub>2</sub>/CH<sub>4</sub> mixtures: a)  $E_a$  of mixed CO<sub>2</sub>, b)  $E_a$  of mixed CH<sub>4</sub>

### 3.2. ANN Prediction

Prediction models for adsorption and diffusion are developed through ANN. The MSE of prediction test is 0.0086, and R<sup>2</sup> is 0.9822, which indicate the high prediction accuracy of the developed ANN models. Fig. 4 reveals the parity plot for adsorption capacity and self-diffusivity of CO<sub>2</sub> and CH<sub>4</sub> in mixtures from ANN prediction and GCMC & MD results under various operating conditions such as temperature (273–423 K), pressure (0–20 bar), and feed CO<sub>2</sub> composition (0.1–0.9).

**Figure 4** Parity plot for prediction from ANN vs. GCMC & MD

### 3.3. Integrated Process Simulation

Three case studies by process integration and simulation of membrane separation of CO<sub>2</sub>/CH<sub>4</sub> mixture from raw natural gas, landfill gas and shale gas indicate that IRMOF-1 membrane can produce greater recovery with significantly smaller membrane area than the polymer PTMSP membrane from Ref. (Robeson 2008) to achieve the desired target purity. The computational results using IRMOF-1 membrane with the developed ANN model and using PTMSP membrane are provided in Table 2. All these demonstrate the proposed multi-scale design framework is feasible, practical, and superior. It integrates

the variation of permeability with operating conditions into the dynamic simulation of membrane separation process. The rest of available data and analysis of integration results are presented in detail in the work (Cheng, Liao et al. 2023).

**Table 2** Computational results of case study

Criterion	Case 1		Case 2		Case 3	
	This work	Reference work [9]	This work	Reference work [9]	This work	Reference work [9]

$F_{residue-product}$ (Nm <sup>3</sup> /h)	1348	1284	1314	1200	814	518
<b>Fiber number</b>	6062	45600	7408	40500	17964	50480
<b>Membrane area</b> $A_m$ (m <sup>2</sup> )	<b>14.47</b>	108.9	<b>17.69</b>	96.70	<b>42.89</b>	120.5
<b>Purity<sub>CH<sub>4</sub></sub></b> (mole %)	90	90	80	80	65	65
<b>Recovery<sub>CH<sub>4</sub></sub></b> (%)	<b>76</b>	72	<b>81</b>	74	<b>88</b>	56

#### 4. Conclusion

In this paper, the integrated design framework we initially proposed is well demonstrated in the gas separation hollow fiber membrane process with the example of IRMOF-1, which provides an integration idea for future optimization of process conditions and innovative design of optimal MOF membrane material.

## Abstract

The design of formulated chemical products such as cosmetic emulsions is normally carried out by interdisciplinary teams that need versatile and reliable tools to support them in the decision-making process. In view of this, this article presents a tool to support product designers during the conceptual design of emulsified cosmetic products. The tool is based on a previously developed ontology for cosmetic product design. It integrates concepts from emulsion science, cosmetic formulation, expert knowledge, and design heuristics in a systematic and flexible way. Additionally, it has a modern architecture based on mobile applications which makes it easy to use. The tool support three types of decisions: screening of ingredients, selection of ingredients considering multiple criteria (ingredient performance, origin, price, etc.), and evaluation of a formulation according to design heuristic. As a result, the tool allows the visualization of ingredient properties and a better selection of ingredients, as well as an early evaluation of formulations prior to experimentation.

**Keywords:** Product design, Cosmetic emulsions, Software application, Ontology

## 1. Introduction

The design of cosmetic products is a complex task that involves the management of multiple and heterogeneous information: raw material data, mathematical models, design heuristics, emulsions science principles, experimental data, among others (Zhang et al., 2020) (Kontogeorgis et al., 2022). Thereby, tools capable of handling varied information and comprehensively representing the solution space of design options are needed. They would have the potential to assist product designers in making decisions to seek original and context-specific solutions. Those tools should be flexible to be adapted to different design problems, easy to use and understand to help rather than hinder the design process, and reliable to be effective in supporting decision making.

There have been extensive contributions from the academy to produce tools for chemical product design. Some of the most notable are ProCAPD with an emphasis on the prediction of physicochemical properties for product optimization (Kalakul et al., 2018) and the virtual process-product design laboratory (VPPD-Lab) which contains a wide

database of property and molecular design models to support design decisions (Kontogeorgis et al., 2022). Previously mentioned tools are generic and not specific for cosmetic design. They are mostly applicable for the definition and resolution of optimization design problems, i.e., they can be used when the design problem is or can be well and explicitly defined. Additional examples of practical tools to support formulators in the design of cosmetics are the app-based resources from Abbott (2022), which shows how scientific principles of colloidal science can be used to explore design solutions for different formulated products, mainly paints, and the commercial software Ansys Granta MI for material design and selection (Ansys, 2022).

However, the drawbacks of the contributions are their complexity, their lack of specificity for cosmetics and their low accessibility and ease of use. In view of the above, this article presents a cross platform decision-making tool for the design of emulsion-based cosmetics at early stages. It is called Formultools. Its architecture was inspired by the OntoCosmetic ontology (Serna et al., 2022), whose scope is the formulation of emulsion-based cosmetic products.

## 2. Design methodology

Considering the premise that the tool must be accessible, a great importance was given to the interaction with the user/formulator. The design process was inspired by the 5-plans user-centered design approach (Garrett, 2011). It involved cosmetics experts and computer scientists in co-design. The development was done iteratively with intermediate usability tests with non-expert users. Each experience was assessed through a questionnaire using the method AttrakDiff (Lallemand et al., 2015) to follow usability improvement at each iteration. The problems encountered were progressively corrected until the current version was released.

### 2.1. Tool scope and functionality

The decision-making tool targets cosmetic product designers (the user). It is to be implemented at the early design stages. Three purposes were defined: the exploration of ingredients according to their properties; the selection of ingredients considering specific criteria, the evaluation of a possible formulation according to design heuristics.

## 3. Formultools: an application for the design of cosmetic products

### 3.1. Ontology as a foundation

The ontology OntoCosmetic is a knowledge representation containing all the concepts used for the development of the application. The ontology scope is the formulation of emulsion based cosmetic products. It is based on four main concepts: ingredients, formulations (list of ingredients with composition), properties, design heuristics, and their interrelations. Figure 1 presents an overview of the ontology:

- **Ingredients and formulation (dosage):** These concepts correspond to the variables that designers can select to achieve expected product properties, i.e., they are the independent variables because designers can select ingredients and their composition (dosage). Ingredients can be emollients, surfactants, thickeners, actives, other ingredients (stabilizers, preservatives, etc.).
- **Properties:** There are product properties and ingredients properties, and they characterize the behavior of the product and of the different ingredients respectively. Some properties are specific to a category of ingredient such as the HLB for surfactants. Some properties are quantitative (as the HLB) or qualitative (as the origin of ingredients, which can be natural or synthetic). As an example, Table 1 presents a list of the properties of emollients and their characteristics.

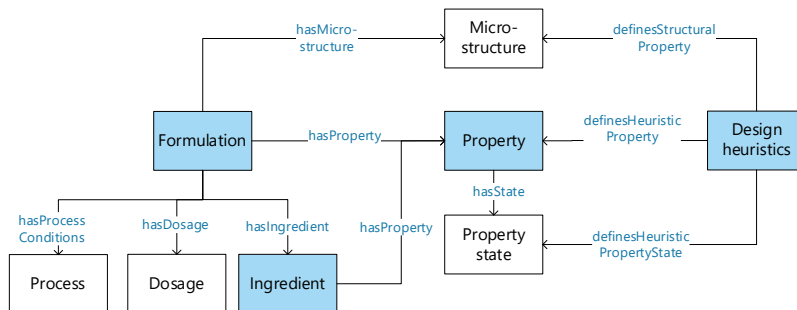

Figure 1. Overview of OntoCosmetic

Table 1. Main emollient properties in OntoCosmetic

CAS	Meaning	Range
INCI name	Abbreviation for International Nomenclature of Cosmetic Ingredients	String
Chemical class	chemical nature of an emollients: ester, fatty alcohol, hydrocarbons, silicones, triglyceride, fatty acid	String
Polarity (qualitative)	It determines the types of inter-molecular forces of the substance.	
Viscosity (qualitative)	Resistance of a fluid to the deformation	
Spreading (qualitative)	It identifies the easy of a fluid to spread on a surface	
Emollience (qualitative)	It indicates if an emollient produces a light skin feel or a rich skin feel	
After feeling (qualitative)	It indicates if an emollient leaves an oily residue after application	
State	indicates if the substance is liquid or solid.	
Biodegradability	It is the capacity for biological degradation of organic materials by living organisms	
Origin	It makes refer to the source of the substance: if it is of petrochemical origin or natural origin.	
Price	Ingredient cost	Float
HLBr	It represents the HLB needed by an oil or a mixture of oils to be more likely to be incorporated in a stable O/W emulsion.	Float
MW	Mass of a compound divided by the number of moles	Float

- **Design heuristics:** They are design rules based on expert knowledge and they relate ingredients, ingredients properties and the formulation with product properties and their values. They enable to predict the effects of design decisions in product properties. As an example, Table 2 presents a list containing some of the design heuristics.

Table 2. Example of design heuristics in OntoCosmetic

Product property	Heuristic
Stability	An emulsion tends to be more stable using a suitable combination of surfactants with a HLB equivalent to the HLB required by the emollients
Stability	It is recommended to use more than one surfactant
Stability	The quantity of surfactant should be between 14 to 20% of the total oily phase
Viscosity	Viscosity is low (lotion texture) if a low proportion of thickener is used
Viscosity	Viscosity is high (cream to gel texture) if a high proportion of thickener is used
Viscosity	Viscosity increases if the content of one of the following fatty alcohol increases: cetearyl alcohol, stearyl alcohol or cetyl alcohol
Viscosity	Viscosity is decreasing if a branched-chain higher alcohol is added

### 3.2. Formultools: a cross platform tool based on OntoCosmetic

Ontologies are great for formalizing knowledge but they are not intended for end users. Formultools aims to provide user-friendly interface to product designers who wants to

explore the design space at early design stages looking for product concepts to be tested. It was developed to be simple, accessible, useful, and versatile. Its data architecture is directly inspired by the OntoCosmetic ontology as the knowledge graph used is an instantiated version of OntoCosmetic with ingredients, heuristics, and properties. The structure of the application is split into two main sections as represented in **Error! Reference source not found.**. An exploration section, which is focused on ingredients searching within a collection, visualization, and ranking. And a formulation section calculating product properties based on heuristics for their verification. Its interface is inspired on mobile applications.

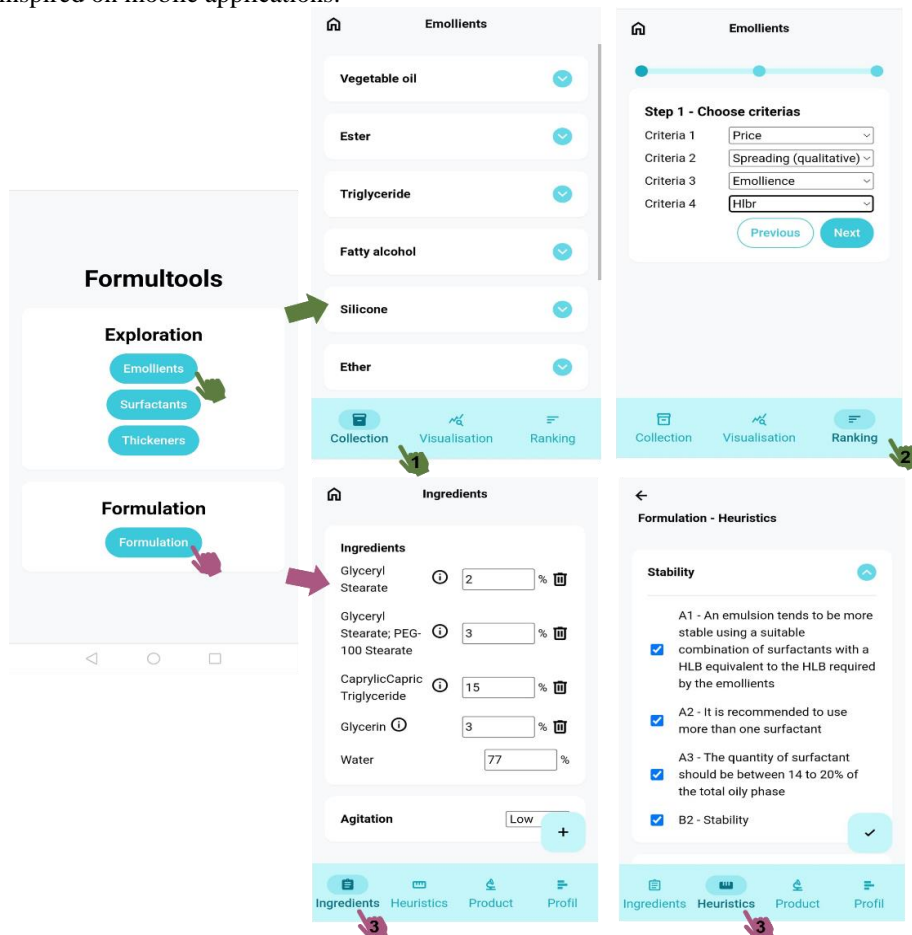

Figure 2. General interface of Formultools

The main functions of Formultools are explained below:

- **Ingredient searching and visualization:** The application has three categories of ingredients according to their functions in cosmetic products: emollients, surfactants, and thickeners, which can be accessed in the home page. Subsequently, the collection of ingredients of each category are listed and presented according to their chemical class. Ingredients can be explored in the following two ways: they can be viewed with their individual properties on the collection tap, they can be explored based on the

values of their properties and compared graphically on the visualization tap. The latter also presents the filter option, where ingredients can be screened according to their properties.

- Figure 3 presents the exploration options.

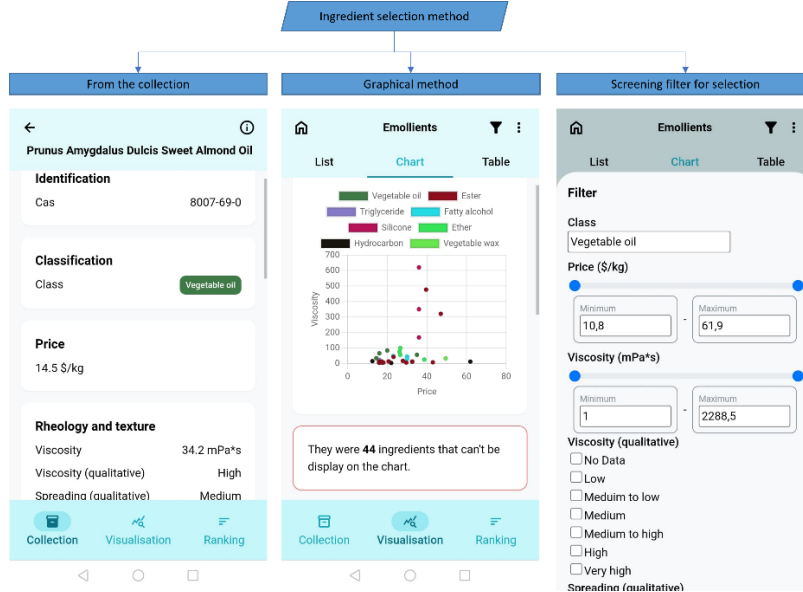

Figure 3. Exploring emollients using Formultools (collection, visualization, filter)

- Ingredient selection: The application enables the ranking of ingredients considering the properties that the designer wants to optimize. For this, the method Analytic Hierarchy Process (AHP) (Saaty, 1987) is used. With the aid of the tool, the formulator first defines the proprieties considered as criteria of selection in the first tap. Then, he defines which proprieties must be minimized and maximized in the second tap. Thirdly, he makes a pairwise comparison of proprieties to calculate their weights. The AHP method implies the calculation of a consistency ratio to evaluate the pairwise comparison, which can be also visualized. The last step is the visualization of the ranking. The four steps of ingredient selection are illustrated in Figure 4.

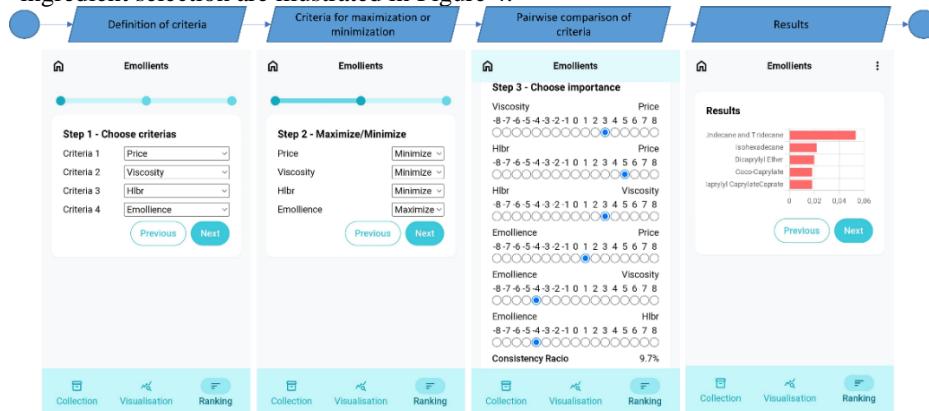

Figure 4. Ranking process of cosmetic ingredients using Formultools

- Formulation evaluation: FormulTools enables the evaluation of formulations suggested by designers according to design heuristic and recommendations contained in the data base. He defines a formulation (ingredients and composition), select design heuristics from the data base and based on the heuristics, the tool calculate product properties. In this way, the designer can propose solutions to design specifications and check if those solutions would correspond to specifications according to heuristics before testing them experimentally.

#### 4. Conclusions and perspectives

The article presents Formultools, a tool to support decision-making process for the design of cosmetic emulsions at early stages. Currently, the tool can perform three functions: exploration and selection of ingredients and verification of cosmetic formulations. It was designed to make it as practical as possible which is why it has the form of a mobile application. In a near future, it will be tested with experts and improved for its subsequently application in real design cases.

Formultools was developed in co-design between experts on cosmetic formulation and computer science. Additionally, it was continuously tested with users and iteratively improved. As a result, the tool was developed in a very agile process.

In the long term, the tool will be enhanced to assist the design process in a more holistic way. This will require the implementation of new features to enable information management, learning from each successful design, use by various design agents, among others, while maintaining its simplicity and usability.

## Abstract

Liquefied Petroleum Gas (LPG) is a product made from crude oil and has several domestic and industrial applications. Continuous increases in energy demand around the world and strict environmental regulations require clean fuel for various applications. This requires the cleaning of liquid hydrocarbons from acid gases which are toxic to human health and disastrous to industrial equipment. Currently, most of the liquid hydrocarbon treatment is done using caustic solutions to remove acid gases. However, depending on the concentration of impurities in the feed and the amount of feed to be processed, a large amount of caustic solution is required which poses another disposal issue. This study proposes to replace the conventional caustic cleaning process with the amine process for liquid hydrocarbon treatment. The process consists of a liquid-liquid contactor where impurities are removed using the amine and then rich amine is regenerated in the stripper column. This study's goal is to assess various amine types for removing acid gases from liquid hydrocarbon feeds. The study is conducted using commercial simulation software ASPEN HYSYS<sup>®</sup> for the design and analysis of process performance. The studied variables include the concentration of the amine, the amine circulation rate, the effect of LPG feed temperature, and the lean amine temperature. The outcomes demonstrate that the removal of acid contaminants from the hydrocarbons can be a competitive process to achieve the required product purities.

**Keywords:** LPG sweetening; acid gases; process design; amines.

## 1. Introduction

LPG is typically a mixture of propane and butane in various proportions derived from the processing of crude oil or natural gas. LPG has a wide range of domestic and industrial usage. The global demand for LPG has been raised over the past decades due to the need for clean energy. Additionally, a compound annual growth rate (CAGR) of 2.2% is anticipated from 2021 to 2026 (*Global Five-Year LPG Demand Fuelled by New Petchems Plants, Res-Com; Supply to Overwhelm*, n.d.). Moreover, at the same time, strict environmental policies are in place to curtail environmental and health issues, therefore the demand for liquid hydrocarbon sweetening facilities has increased. The most common impurities present in LPG are carbon dioxide (CO<sub>2</sub>), hydrogen sulfide (H<sub>2</sub>S), carbon sulfides (COS), and mercaptans (RSH). These impurities, if not removed, can cause corrosion, operational inefficiencies, and other personnel health issues. Currently, many industries are using caustic solutions to treat the contaminants. However, usually, a large amount of caustic solution is required for the hydrocarbon sweetening which poses another environmental issue. Another method to remove impurities from the liquid hydrocarbon is to treat it with the amine solution. The typical amine process consists of

contactor-stripper columns in series where the acid impurities are removed with amine solvent in a liquid-liquid extractor (LLE) (Jayakumar et al., 2017).

Amines have been used for many years in the natural gas industry for the sweetening of natural gas (Zahid et al., 2020). However, the application of amines for the treatment of liquid hydrocarbon is rarely studied. Most of the existing studies have focused on hydrocarbon treatment using caustic solutions and various ways how the process efficiency can be improved. However, in the literature, there are only a few studies that have investigated the use of amines for liquid hydrocarbon treatment. Qeshta et al. (Qeshta et al., 2015) studied the LPG sweetening process using MDEA for the Takreer refinery in Abu Dhabi, UAE where the current LPG sweetening process is the MEROX process. They concluded that amine can be a good alternative process for the treatment of LPG which can reduce significant losses in the caustic process. Zoghi et al. (Zoghi et al., 2022) investigated the effect of 30 wt.% DEA solution for the treatment of liquid propane containing both  $H_2S$  and  $CO_2$ .

The primary purpose of this research work is to focus on the design and simulation of the liquid hydrocarbon sweetening process using different amines in a liquid-liquid extractor (LLE). Three amine solvents namely methyl diethanolamine (MDEA), diglycolamine (DGA), and diethanolamine (DEA) are evaluated to analyze the sweetening performance. The goal is to keep  $H_2S$  and  $CO_2$  in the sweet hydrocarbon stream leaving at the top of the contactor below 5 ppm. Finally, a parametric analysis has been performed to study the effect of various operational parameters.

## 2. Process Details

### 2.1. Thermodynamic

Aspen HYSYS was used to build the steady-state simulation model. For the calculation of the properties of the gas phase, the Peng-Robinson (PR) equation of state has been employed while the E-NRTL model for electrolytic thermodynamics with binary and electrolyte pair parameters optimized for liquid-liquid applications has been selected. Aspen HYSYS has a built-in library for all the equilibrium and kinetic reactions taking place in the acid gas removal (AGR) system which has been utilized from the acid gas-liquid treatment package. The available acid gas-liquid treatment thermodynamic package has been validated over a wide range of operating conditions with good accuracy, it can be used with confidence (Zahid et al., 2020).

### 2.2. Process Description

Figure 1 shows a typical LPG sweetening unit. Initially, LPG is fed at the bottom of the liquid-liquid extractor. As the amine solution flows countercurrent to the sour LPG, the components of the acid gas react with the amine to produce regenerable salts. The rich amine leaves at the bottom of the LLE, while the sweet LPG leaves at the top. Following this, any absorbed hydrocarbons are removed in a flash drum. The rich amine is then fed to the top of the stripper column after being heated in the rich/lean amine heat exchanger.  $H_2S$  and  $CO_2$  are stripped from the rich amine as it flows down the column, leaving the lean amine at the bottom. It is then recycled to the top of the absorber where it passes through a lean/rich exchanger and repeats the cycle.

### 2.3. Process Simulation

This study explored three simulation cases with different impurities in the sour LPG feed as shown in Table 1. The first one has both  $H_2S$  and  $CO_2$ , while the second and the third have only either  $CO_2$  or  $H_2S$  respectively. For each sour feed, three different amine solutions have been tested MDEA (35 wt.%), DGA (50 wt.%), and DEA (30 wt.%). The input variables to the simulation models are listed in Table 2. Trayed columns have been

used to model the absorber and stripper due to high solvent circulation flow. For towers with a low-pressure drop requirement and a diameter of fewer than 2.5 feet, packed columns are typically advised. For single amines, the circulation rate is adjusted according to the required product purity, which is not more than 5 ppm of H<sub>2</sub>S in the sweet gas. The stripper column's vent rate and reflux ratio have been specified to achieve column convergence, whereas the absorber column has a degree of freedom equal to zero.

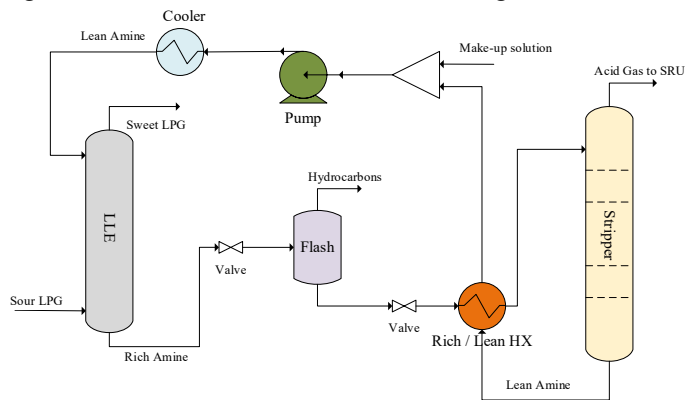

Figure 1: Process flow diagram of LPG sweetening unit.

Table 1: Sour LPG stream composition.

Component	<i>Mole fraction</i>		
	Case 1	Case 2	Case 3
Methane	0.009	0.006	0.011
Ethane	0.028	0.443	0.132
Propane	0.839	0.218	0.267
i-Butane	0.009	0.000	0.414
n-Butane	0.001	0.129	0.168
n-Pentane	0.001	0.068	0.005
n-hexane	0.000	0.060	0.000
CO <sub>2</sub>	0.019	0.077	0.000
H <sub>2</sub> S	0.093	0.000	0.002

Table 2: Input specifications used in the simulation for each LPG feed.

<i>Parameter</i>		<i>Case 1</i>	<i>Case 2</i>	<i>Case 3</i>
<b>LPG Temperature</b>	° C	38	15.6	51
<b>LPG Pressure</b>	bar	34.5	55.2	40.2
<b>LPG flow rate</b>	m <sup>3</sup> /h	20.9	159	24.4
<b>LLE Number of stages</b>		20	20	10
<b>Amine Temperature</b>	° C	54.44	45	51
<b>Amine Pressure</b>	bar	28.3	55.2	40.2
<b>Rich amine Reg. Feed Temp.</b>	° C	110	100	100
<b>Regeneration column number of stages</b>		10	10	20

### 3. Results

The simulation results such as rich loading, lean loading, and circulation rate have been summarized in table 3. Since each scenario has different lean loading and rich loading that reflect to have different circulation rates for the amine. For case 1 and case 3, DGA shows promising results while for case 2 MDEA was the best as illustrated in the next section.

Table 3: Main simulation results for the three cases.

	Case 1	Case 2	Case 3
<b>MDEA 35 wt. %</b>	Rich Loading: 0.45	Rich Loading: 0.249	Rich Loading: 0.273
	Lean loading: 0.01	Lean loading: 0.01	Lean loading: 0.002
	Circulation rate: 825 kmol/h	Circulation rate: 543 kmol/h	Circulation rate: 25 kmol/h
<b>DGA 50 wt. %</b>	Rich Loading: 0.35	Rich Loading: 0.35,	Rich Loading: 0.35
	Lean loading: 0.035	Lean loading: 0.01	Lean loading: 0.02
	Circulation rate: 600 kmol/h	Circulation rate: 263 kmol/h	Circulation rate: 12.3 kmol/h
<b>DEA 30 wt. %</b>	Rich Loading: 0.35	Rich Loading: 0.43	Rich Loading: 0.35
	Lean loading: 0.015	Lean loading: 0.03	Lean loading: 0.015
	Circulation rate: 1210 kmol/h	Circulation rate: 355 kmol/h	Circulation rate: 26 kmol/h

#### 3.1. Regeneration energy requirements

Energy analysis for the regeneration process has been studied, the results show that the developed simulation models are in good agreement with the available literature data. The result shows that the DGA is preferred in the presence of  $H_2S$  and  $CO_2$ , with 62% and 38% less energy compared to MDEA and DEA, respectively. However, for case 2 in the presence of  $CO_2$  only, MDEA has lower energy requirements with a slight improvement of approximately 3% and 11% compared to DEA and DGA. While in the case of  $H_2S$  only (Case 3), DGA has a lower energy requirement similar to case 1. Figure 2 illustrates the energy requirement of three cases for amine regeneration.

Figure 2: Energy required for the regeneration process.

### 3.2. Effect amine concentration

Acid gas removal in the LLE depends directly on amine concentrations. Figure 3 shows the effect of different amine concentrations on the acid gas in the sweet LPG and the energy required for the regeneration. It was observed that as the amine concentration increased, the acid gas in the sweet LPG decreased while there is an increase in the energy required for the regeneration. Similar trends were observed for Cases 2 and 3.

Figure 3: Effect of amines concentration

### 3.3. Effect of lean amine temperature

As shown in figure 4, the lean amine temperature influences both acid gas concentration in the sweet LPG and regeneration duty. As the lean amine temperature increased, the acid gas in the sweet LPG gradually increased due to the exothermic nature of the extraction of the acid gas with amines. However, the regeneration duty slightly decreases with the increase in the lean amine temperature. Similar trends were observed in other cases.

Figure 4: Effect of lean amine temperature

### 3.4. Effect of Lean amine circulation rate

One of the major parameters that directly affect the extraction of the acid gas from the LPG is the lean amine circulation rate. Figure 5 shows the effect of circulation rate on acid gas concentration and regeneration energy requirement. As the circulation rate increased, the acid gas concentration increased because of the lower residence time. On the other hand, the duty of the regeneration is also increased due to the high flow rate.

Moreover, the effect of the LPG feed temperature has been studied for Case 3. LPG feed temperature has been changed in temperature between 10 °C to 50 °C while keeping the difference between the lean amine temperature and the sour LPG feed fixed at 5 °C. The results show that the H<sub>2</sub>S concentration in the sweet LPG increases as the temperature of the feed increases while the regeneration duty slightly decreases.

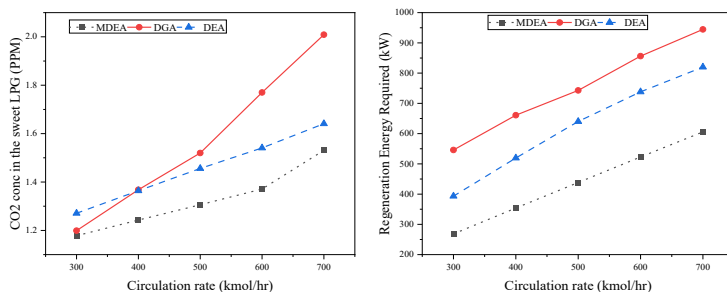

Figure 5: Effect of lean amine circulation rate

#### 4. Conclusion

In conclusion, the design specification of the sweetening of the sour LPG should be maintained in such a way that the concentration of the acid gas in the sweet LPG achieved the product specification. Sensitivity analyses have been conducted for a few of the significant process variables that could have an impact on the process performance. The results show that the acid contaminants removal from the hydrocarbons can be a competitive process to achieve the required product purities

# Embedding Operating Flexibility in Process Design

Steven Sachio, Cleo Kontoravdi, Maria M. Papathanasiou

*Sargent Centre for Process Systems Engineering, Department of Chemical Engineering,  
Imperial College London, London, United Kingdom SW72AZ*

## Abstract

Inherently flexible processes are able to handle disturbances better than point-specific designed processes. However, there is a lack of systematic framework to embed operating flexibility in process design. In this work, we propose a model-based framework for integrated analysis of process flexibility and performance based on the identification and assessment of process design spaces. The proposed framework enables the identification of operating regions, quantification, within which the product and process meet the specifications. The operational flexibility and sensitivity of the process to design and operating parameters is also quantified. We demonstrate the capabilities of the framework on a Protein A chromatographic separation, used in biopharmaceutical manufacturing. We identify the feed flow rate as the most influential process parameter, while we quantify an acceptable range for the feed stream variability (concentration: 0.37 – 0.43 mg ml<sup>-1</sup> and flowrate: 0.72 – 0.88 ml min<sup>-1</sup>) for a fixed process design.

**Keywords:** computing and systems engineering, process design, chromatography

## 1. Introduction

Embedding flexibility into process design can enable more agile and sustainable processes. This is particularly true in the case of (bio-) pharmaceutical production processes, where disturbances resulting from variability in processing streams are dominant. For example, in the case of monoclonal antibodies (mAbs), an increase in the impurity content (e.g., concentration of host cell proteins, antibody aggregates or fragments) may lead to additional separation columns and/or purification cycles required to reach the desired product purity. Subsequently, this can increase the overall downstream cost and processing times, leading to less economically and environmentally efficient processes (Papathanasiou et al, 2020; Narayanan et al, 2020). In addition to this, manufacturers need to demonstrate that the processes can meet consistently product quality criteria with respect to functionality and purity for regulatory authorities to grant market authorization. For this, there is an imminent need to design processes that are adaptive to mixture variabilities and can guarantee eco-efficient, sustainable production within specifications.

Traditionally, product quality is confirmed through a Quality by Testing (QbT) approach before batch release, which incurs high experimentation costs and waiting times, delaying market release. Furthermore, manufacturers are not able to take in-process corrective actions with this approach leading to ‘off-spec’ products and hence lost batches. To this end, the Quality by Design (QbD) initiative aims to shift the focus in process development to revolve around product quality (ICH, 2011) moving away from QbT. A key step in QbD-supported initiatives is the identification of a design space defined by good candidate condition sets where the process is guaranteed to satisfy the target specifications. This approach offers greater operational flexibility, in contrast to point-

specific operation (Ding et al, 2021; Laky et al, 2022). Nonetheless, identification of a design space can lead to time- and cost- intensive exhaustive wet-lab experimentation. For this reason, computer-aided modelling tools are exploited for the pre-identification of good candidate operating condition sets (Kotidis et al, 2019; Diab et al, 2020; Kusumo et al, 2020). Here, we present a machine learning-aided design space identification framework that harnesses the potential of Sobol sequences for single-pass parallelizable sampling, allowing for rapid determination of acceptable operating conditions and space-specific sensitivity analysis.

## 2. Framework

The framework comprises of three main steps: 1) model development and problem formulation, 2) design space identification and 3) design space analysis.

### 2.1. Model Development and Problem Formulation

The process of interest is characterized using mathematical models, which can be mechanistic, hybrid, or fully data driven and are validated through experimental data. Following that, the manipulated variables (MVs), the KPIs and their associated bounds are identified. Finally, the KPIs of interest are selected and constraints with respect to both MVs and KPIs are defined.

### 2.2. Design Space Identification

First, virtual experimentation using Sobol sequence based on the formulated problem is performed to collect the dataset. Then, the constraints defined are applied to screen the dataset separating the satisfied and violated points. A collection of satisfied points, also known as a point cloud, is then set as the basis for the design space identification. The identification of the design space relies on geometrical hulls, known as alpha shapes which are a generalization of convex hulls with a parameter (alpha radius,  $\alpha_r$ ), determining the non-convexity of the resulting hull. As  $\alpha_r \rightarrow \infty$ , the formed hull is the convex hull, while as  $\alpha_r \rightarrow 0$ , the hull becomes increasingly non-convex until it reduces to the set of points at alpha radius equal to zero. The value of the alpha radius is critical for the identification of a continuous design space and is proportional to the number of points available in the space. In the case of non-linear problems, the design space shape is often non-convex and therefore at large alpha values, violated points may be found lying inside of the design space. However, at small alpha radius values, disjointed spaces start to be formed. To mitigate this, we propose two methods: namely the tolerance and the resolution support method.

#### 2.2.1. Tolerance Method

Here, we allow for a percentage of violated points to be included in the design space to allow for the identification of a design space at low resolution with less disjointed spaces. To do this, we set a tolerance value for the allowed number of violations inside the design space is set. The alpha radius should not be too small so that the hull does not reduce to thin disjointed spaces, but not too large either as this would result in many points inside the design space violating the constraints. Here, a bisection search is used to find the alpha radius. In each iteration, a check for how many violations lie inside of the design space is performed and the iteration is terminated once the number of violations tolerance is met. This method allows for the rapid identification of the design space which can be useful provided that the resulting violations in the space are analyzed further to ensure that the violation of the KPIs meets the required accuracy.

### 2.2.2. Resolution Support Method

An alternative to the tolerance method is the resolution support method. For this, we train artificial neural networks (ANNs) using the manipulated variables as inputs and the KPIs as outputs. The trained ANN is used as an interpolator to increase the resolution of the dataset. Provided that it is accurate enough, this allows for small alpha radius values to be used, resulting in very fine design spaces which capture non-convexity well.

### 2.3. Design Space Analysis

The space defined in 2.2 is used for process flexibility analysis typically based on a nominal operating point (NOP) of interest. Starting from the NOP, a uniform cube with respect to the parameter axes is formed and expanded until one of its vertices intersects the design space boundary. The resulting region is defined as the uniform acceptable operating region (AOR). This allows for the extraction of multivariate proven acceptable ranges (MPARs) of the operating parameters with respect to the NOP used, which is an underpinning element for analyzing process flexibility and controllability. This analysis is highly dependent on the number of data points used to construct the design space. Therefore, design spaces formed using low-resolution datasets are coarser. Comparing the tolerance based and resolution support design spaces, the latter results in a larger AOR, owing to the richer dataset.

### 2.4. Sobol Sensitivity Indices

In addition to the systematic flexibility analysis, the framework also offers information on the sensitivity of the monitored KPIs with respect to the manipulated variables. For this, the obtained dataset within the framework can be directly used to calculate Sobol sensitivity indices (Sobol, 2001). With the resolution support method, where ANNs are trained for interpolation, the sensitivity analysis can also be performed in any acceptable operating region without further simulation of the original model. This allows for the identification of the most impactful manipulated variables and their second order interactions.

## 3. Case Study: Protein A Chromatography

### 3.1. The System

The framework presented in section 2 is applied to the semi-continuous multicolumn capture process presented by Steinebach et al (2016). The process considers two chromatography columns operated in a semi-continuous cyclic manner. Figure 1 shows the process schematic. In step A, both columns are interconnected, and fresh feed is introduced into column I. While the breakthrough from column I is fed into column 2. Next (step B), column I is washed while column

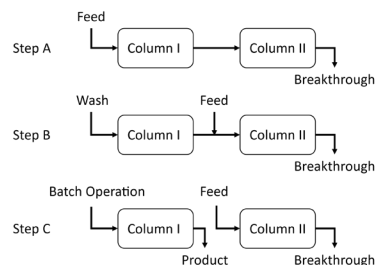

Figure 1. Process schematic adapted from Steinebach et al (2016).

II is fed the breakthrough from column I and the fresh feed simultaneously. In step C, the columns operate in batch mode with column I eluting the products and regenerating while column II is fed with the fresh feed. The process is repeated with the columns position switched. The process is modelled with Partial Differential and Algebraic Equations (PDAEs) with 50 discretization points over the column length. This results in a total of 808 ordinary differential equations (ODEs) and 812 algebraic equations. The process was validated by Steinebach et al (2016) for feed mAb concentration of 0.2 – 0.77 mg/ml and

feed flowrate of 0.5 – 1.5 ml/min. Both the process modelling and post-modelling analysis are carried out in Python.

### 3.2. Problem Formulation & Data Sampling

In this study, the objective is to investigate the process performance and flexibility of the process under the influence of feed concentration variations. The variables considered in this study are feed mAb concentration ( $c_{\text{feed}}$ ) [disturbance], feed volumetric flowrate ( $Q_{\text{feed}}$ ) [control variable], and the column switching time ( $T_{\text{switch}}$ ) [design variable]. The mAb concentration is considered as a disturbance due to variability in the performance of the upstream bioreactor. On the other hand, the volumetric flowrate is a control variable while the column switching time is a design variable. The manipulated variable bounds for the study are based on the model validation range (Table 1). The KPIs considered are yield and productivity. Following standard practice, minimum constraints of 99% and 4 mg ml<sup>-1</sup> h<sup>-1</sup> are assumed for yield and productivity, respectively. The formulated problem is used to collect a total of 4096 points via quasi-random Sobol sampling.

Table 1. Manipulated variable bounds used in the study based on the validated model range (Steinebach et al., 2019).

Manipulated Variable	Lower Bound	Upper Bound
$c_{\text{feed}}$ (mg ml <sup>-1</sup> )	0.21	0.63
$Q_{\text{feed}}$ (ml min <sup>-1</sup> )	0.5	1.5
$T_{\text{switch}}$ (min)	40	120

## 4. Results and Discussion

### 4.1. Design Space Identification

The collected dataset is screened using the constraints (> 99% yield and > 4 mg ml<sup>-1</sup> h<sup>-1</sup> productivity) specified to classify satisfied and violated points. Figures 2 (A), (B) and (C) illustrate the knowledge space (unconstrained), and design spaces (constrained) using the tolerance and the resolution support method, respectively. The proposed framework enables quantification of the volume of the design space including good candidate operating points. As discussed previously, in nonlinear problems as the one presented here, the design space may include points that violate one or more of the predefined constraints. A tolerance of 1% resulted in 12 out of 1281 points (0.94%) (large blue crosses) which violated the constraints inside of the design space. On the other hand, the resolution support method arrives at a zero-violation design space with a smoother surface. The framework also allows for the quantification of the size of the design space for exact comparison. In this case, the size is the volume of the space defined by the manipulated variables, hence the units are in mg ( $\frac{\text{mg}}{\text{ml}} \times \frac{\text{ml}}{\text{min}} \times \text{min} = \text{mg}$ ). The design space size of the tolerance-based method is 5.98 mg, while that of the resolution support method is 8.43 mg (41% larger). This is due to

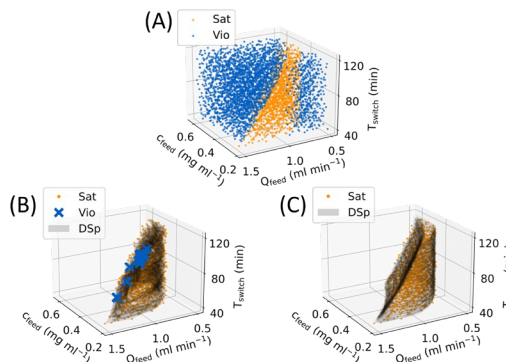

Figure 2. (A) Point cloud classification by applying constraints, (B) tolerance-based method, (C) resolution support method.

the higher resolution allowing for the use of a finer alpha radius which can capture the non-convexity of the problem better.

4.2. Design Space Analysis

The operational flexibility is then assessed by analyzing the identified design space. For this, we use the resolution support method (Figure 2 A(C)) as it provides the design space without any violated points. For the analysis, we choose two arbitrary nominal points of interest, as shown in Figure 3. The first nominal point lies in the center of the design space, while the second point is in the higher productivity region of the design space. The comparison between the two designs is detailed in Table 2.

Figure 3. Good candidate operating point analysis with resolution support.

Table 2. Detailed comparison of NOP1 & NOP2

	NOP1	NOP2
AOR size (mg)	0.134	0.116
MPAR $c_{feed}$ (mg ml <sup>-1</sup> )	0.40 ± 0.033	0.55 ± 0.032
MPAR $Q_{feed}$ (ml min <sup>-1</sup> )	0.80 ± 0.080	0.75 ± 0.076
MPAR $T_{switch}$ (min)	70.0 ± 6.34	50.0 ± 6.05
Average Productivity (mg ml <sup>-1</sup> h <sup>-1</sup> )	5.91	7.54

The size of NOP1 is 15% larger than that of NOP2 indicating greater flexibility. This is further expressed in the respective MPARs of the manipulated variables which reduce by 5% going from NOP1 to NOP2. The average expected productivity when operating at NOP2 is 27% larger than that of NOP1. Using this framework, such trade-offs between flexibility and performance gain can be quantified systematically. Quantification of such metrics is essential for the design of robust and controllable processes that are crucial in biopharmaceutical manufacturing, bounded by stringent regulations.

4.3. Sobol Sensitivity Indices

We further investigate and quantify the impact of the studied variables and disturbances on the chosen KPIs. This is achieved through calculation of the Sobol sensitivity indices. For this, we use the dataset as generated in section 2. The Sobol sensitivity indices highly depends on the chosen bounds of the manipulated variables and the non-linearity of input output relationship within the chosen bounds. Hence, it is vital to be able to identify the sensitivity indices at different spaces especially for integration process units and process control. Figure 4 illustrates the Sobol sensitivity indices calculated for the acceptable

Figure 4. Sobol indices in (A): AOR1 & (B): AOR2.

operating region of NOP1 (AOR1) and NOP2 (AOR2). Whereby first order interactions are observed by looking at the main diagonals and second order interactions on the off-diagonal elements. First order indices refer to how the fractional contribution of a variable

on the variance of the KPI while the second order indices show the contribution of variable-variable interactions to the variance of the KPI. We assume that any interaction with an index below 10% is non-significant. There is a significant difference in the indices within AOR1 and AOR2 (Figure 4 (A) & (B)). The results indicate that for AOR1, the feed flowrate has the largest impact on both KPIs with indices larger than 0.70. AOR2 illustrates a different trend, where the switching time plays a bigger role in determining the yield of the product (from  $S_i = 0.00$  in AOR1 to  $S_i = 0.37$  in AOR2). On the other hand, the second order interactions observed between the feed concentration and flowrate in productivity of AOR1 ( $S_{ij} = 0.20$ ) are not present in AOR2 ( $S_{ij} = 0.02$ ). This is due to the nonlinear relationship between the KPIs and the manipulated variables which is a challenge for identifying the design space with zero violations. This framework allows for the unravelling of such complex relationships in a computationally efficient manner.

## 5. Conclusion

We presented a novel framework for the identification and analysis of process design spaces. The capabilities of the presented framework were illustrated through its application on a downstream purification unit used in biopharmaceutical production. We considered design (switching time) and operating decisions (flow rate), as well as disturbances (feed composition) simultaneously. Based on the process feasibility constraints and the target KPIs, we identified and quantified a design space that includes good candidate condition sets, predicted to meet the KPIs of interest. We further demonstrated how this space can be used for the evaluation and quantitative comparison of different operating conditions and their flexibility. This can assist manufacturers by offering a measurable estimate of the variability that a process at hand can handle without any further mediation and remaining within spec. In addition to this, we demonstrated how the framework enables space-specific sensitivity analyses without additional high-fidelity model simulation which is crucial for process control and integration. Importantly, the presented framework is generic, owing itself to the assistance of simultaneous design and flexibility assessment of different processes. In the future, the advantages of the framework will be further enhanced to incorporate formal optimization and control methodologies that can benefit from the process knowledge and good candidate initial guesses generated by the presented methodology.

## Abstract

Process design is a creative task that is currently performed manually by engineers. Artificial intelligence provides new potential to facilitate process design. Specifically, reinforcement learning (RL) has shown some success in automating process design by integrating data-driven models that learn to build process flowsheets with process simulation in an iterative design process. However, one major challenge in the learning process is that the RL agent demands numerous process simulations in rigorous process simulators, thereby requiring long simulation times and expensive computational power. Therefore, typically short-cut simulation methods are employed to accelerate the learning process. Short-cut methods can, however, lead to inaccurate results. We thus propose to utilize transfer learning for process design with RL in combination with rigorous simulation methods. Transfer learning is an established approach from machine learning that stores knowledge gained while solving one problem and reuses this information on a different target domain. We integrate transfer learning in our RL framework for process design and apply it to an illustrative case study comprising equilibrium reactions, azeotropic separation, and recycles, our method can design economically feasible flowsheets with stable interaction with DWSIM. Our results show that transfer learning enables RL to economically design feasible flowsheets with DWSIM, resulting in a flowsheet with an 8% higher revenue. And the learning time can be reduced by a factor of 2.

**Keywords:** Reinforcement learning, process design, transfer learning

## 1. Introduction

The transition of chemical engineering to a sustainable and circular future requires new methods of process design (Fantke et al., 2021). Currently, methods for process design are mainly manual work with long development times and superstructure methods are also limited to predefined process configurations (Chen et al. 2017, Mitsos et al. 2018). Recently, reinforcement learning (RL), a branch of machine learning (ML), has shown promising results in process design (Midgley et al., 2020, Khan et al., 2020, Göttl et al., 2021, Stops et al., 2022, Kalmthout et al., 2022). One major challenge in RL for process design is the training process as it is trial-and-error based. Thereby, the learning process typically requires a large number of process simulations, which demands expensive computational power. Previous work (Khan et al., 2020, Göttl et al., 2021, Stops et al., 2022) mostly leverages short-cut process simulation methods to simulate the processes efficiently, which can lead to inaccurate results. Recent works employ rigorous process simulators such as COCO and Aspen Plus with rigorous models (Midgley et al., 2020, Kalmthout et al., 2022). Nevertheless, the problem of long simulation times hinders further developments (Kalmthout et al., 2022).

We propose to utilize transfer learning in process design with RL to facilitate the effectiveness and efficiency of the learning process. Transfer learning is a technique to improve learning performance by transferring knowledge from different but relevant domains to the target domain (Zhu et al., 2020). Adapting the concept of transfer learning for process design with RL, we first pre-train our recently proposed RL agent on a short-cut process simulation from our previous work (Stops et al., 2022). Then, we transfer the pre-trained agent to a rigorous process simulator DWSIM for further training. Finally, we illustrate the impact of transfer learning through one case study.

## 2. Methods

The RL problem can be formulated as a Markov decision process (MDP):  $M = \{S, A, T, R\}$ , which includes states  $s \in S$ , actions  $a \in A$ , transitions  $T: S \times A$ , and reward functions  $R$ . The agent aims to maximize the reward in the environment by iteratively taking action, evaluating the current reward, and updating the states. Specifically, in process synthesis tasks, states correspond to flowsheets. Actions are composed of two parts: Discrete and continuous actions. The discrete actions include the selections of a unit operation and its location in the flowsheet. The continuous actions define the design and operation variables of the corresponding unit operation. After the agent has performed actions, the states are updated. Based on the current state, a reward is calculated by the environment, e.g., the process simulation software, and returned to the agent as feedback on its actions. For process design, this reward is typically a design goal such as the process revenue. By repeating the process of performing actions and receiving rewards multiple times, the agent is trained to perform actions that result in a higher reward, corresponding to flowsheets with higher revenue.

### 2.1. Agent and environment

We adapt the RL framework from our previous work (Stops et al., 2022), where the states are presented as directed flowsheet graphs. Within the directed flowsheet graphs, nodes represent the unit operations and edges correspond to the process streams. Each node and edge is assigned a feature vector, respectively, storing information about the unit operation, e.g., type or size, and stream, e.g., thermodynamic data or flow rate of the stream. Furthermore, the agent architecture consists of three major parts: Graph encoder, actor networks, and critic networks. The graph encoder takes current flowsheet graphs as input and utilizes graph convolution in GNNs to learn information about the flowsheet graphs, in form of a vector representation, also referred to as flowsheet fingerprint. Actor networks are responsible for taking actions during the training process. There are three action levels: Selecting an open stream, selecting a unit operation, and selecting a corresponding design variable. Moreover, taking the flowsheet fingerprint as input, critic networks are used to estimate the reward of actions, and then actor networks will learn to take actions with the highest estimated reward. Specifically, the reward is calculated by using the DWSIM process simulator (Medeiros et al., 2018). The RL framework is implemented in Python including an interface for the agent to actively interact with DWSIM.

### 2.2. Transfer learning

We extend our RL framework by transfer learning. Specifically, we add a pre-training phase to the training of the agent. In the pre-training phase, we use a short-cut process simulation environment (Stops et al., 2022) and train the agent over 10000 episodes. Then, we transfer the pre-trained agent to a fine-tuning phase in which the agent is trained against a rigorous process simulator DWSIM for further 15000 training episodes. For the comparison, we directly train another agent with DWSIM environment over 15000

episodes. Note that in each episode, the agent generates a complete flowsheet. Both pre-training and fine-tuning processes are adapted from Proximal Policy Optimization (PPO) by OpenAI (Schulman et al., 2017). Then, the agent architecture is updated by gradient descent for the total loss function derived from summing up losses of actor networks, loss of critic networks, and corresponding entropies.

The agents are trained on a Windows server with a 3.5 GHz 24 cores Intel(R) Xeon(R) W-2265 CPU, NVIDIA GeForce RTX 3090 GPU and 64 GB memory.

### 3. Illustrative case study

The production of methyl acetate (MeOAc) is chosen as an illustrative case study.

#### 3.1. Process simulation

The short-cut process methods for pre-training are illustrated in our previous work (Stops et al., 2022). Here, the process simulation with DWSIM is introduced. In this case study, the agent can choose reactors, distillation columns, and heat exchangers as unit operations. Besides, the agent can also decide to add recycles or claim open streams as products. The types of unit operations and corresponding design variables are defined as follows.

**Reactor** is deployed to convert reactants to the desired product (MeOAc). The reactor is modeled as a plug flow reactor (PFR) where the following reversible reaction takes place:

For operational simplicity, the reactor is simulated isothermally, in which the temperature is kept constant regarding the inlet stream temperature. Besides, catalyst loading is not considered. The reaction kinetics are obtained from (Xu et al, 1996), with the equilibrium being related to temperature. The reactor cross-sectional area is determined by the relation:  $N/10$ , where  $N$  is the inlet molar flow (Stops et al., 2022). The design variable is the reactor length, which will be determined by the agent in the third-level continuous decision process. The range is from 3 to 10 m.

**Distillation column** is applied to separate MeOAc from the quaternary system. Rigorous distillation columns are used instead of shortcut columns in the previous work (Stops et al., 2022) to account for more realistic factors such as intermolecular interactions. The rigorous column models provide multiple possible choices of design parameters, from which the distillate to feed ratio (D/F) is selected as the third-level decision. Other adjustable parameters such as the number of stages and reflux ratio are set as fixed values (35 and 1.5, respectively). The D/F ratio can range from 0.4 to 0.6.

**Heat exchanger** is a DWSIM heater model. In the proposed framework, the heat exchanger is simulated based on the outlet temperature which is determined by the third-level decision. A temperature range from 278.15 K to 330.05 K is applied, where the upper limit refers to the lowest boiling point of the components which is MeOAc.

**Recycle** action consists of additional units including a splitter and a mixer. Firstly, the process stream is split into a recycle stream and a purge. Secondly, the recycled stream is merged with the selected feed with a mixer. Thereby, the split ratio is the third-level decision of the agent, which lies in the range of 0.1 to 0.9 for pragmatic consideration.

#### 3.2. Reward

The reward determines the economic viability of generated flowsheets and teaches the agent to take feasible actions. First, a reward of 0 € is given when the incomplete flowsheets can converge after every single action, because the economic value is difficult to assess for an incomplete flowsheet. Second, whenever the agent fails the simulation by taking infeasible actions, the episode will be terminated immediately and a negative

reward -10M€ is given. Finally, when a flowsheet is completed, we calculate the reward according to Equation 2:

$$r = \sum P_{product} - \sum C_{feed} - \sum (C_{operation} + 0.15 \cdot C_{invest})_{units} \quad (2)$$

where  $P_{product}$  is the revenue of the sold product (Seider et al., 2008),  $C_{feed}$  is the costs of feeds,  $C_{operation}$  is the operation costs (Smith, 2016) and  $C_{invest}$  is the total capital investment which is multiplied by factor 0.15 (Seider et al., 2008). In the case of negative rewards, a reduction factor 10 is applied to encourage the exploration of the agent.

#### 4. Results and discussion

Figure 1 shows the learning curves for the agents with and without transfer learning. The scores represent the moving average rewards, i.e., the economic viability of the flowsheets, over 100 episodes. The training for the agent without transfer learning took 72 hours over 10000 episodes. For the agent with transfer learning, the pre-training took 2 hours over 10000 episodes and the further training took 72 hours over 10000 episodes. During the first 3500 episodes, the agent without transfer learning generates predominantly infeasible lengthy flowsheets, resulting in the learning curves rising slowly. In fact, due to the complexity of the design space, the agent has difficulty in learning from the previous failed flowsheets, leading to negative scores. After 3500 episodes, the agent mainly produces flowsheets with positive scores, which indicates that the designed processes are economically viable. Besides, within the training episodes, the learning curve slowly converges and reaches maximally to about 42. In comparison, the agent with transfer learning shows a quicker learning process. At the beginning of the learning process, the agent is able to mostly produce positive scores, and then the learning curve rises steeply. This demonstrates that the agents successfully leverage the pre-trained information from a short-cut process environment to make favorable decisions even in the early training stages. After about 4500 episodes, the score begins to fluctuate between 30 and 40 and maximumly reaches 46 which is higher than the agent without transfer learning.

Figure 1: Learning curves of the agent with and without transfer learning. The blue line depicts the learning curve with transfer learning and the orange line indicates the learning curves without transfer learning. The scores are moving average rewards over 100 episodes and each learning curve runs over 10000 episodes.

Figure 2 displays the best flowsheet generated by the transfer learning agent and the continuous design variables are shown in Table 1. First, the feed (F1) is fed directly into three consecutive reactors (R1, R2, and R3) where the MeOAC and H<sub>2</sub>O are produced by

the esterification of HOAC and MeOH. Then, the resulting quaternary mixture is split up in a column (C1). The mixture is distilled from the top part of the column and sent to one heat exchanger (Hex1) to get the product (P1), containing enriched MeOAc and residues of HOAC and H<sub>2</sub>O. The bottom product of the first column is further split up into the second column (C2) to produce pure H<sub>2</sub>O in the distillate (P2) and a mixture of MeOH and H<sub>2</sub>O in the third product stream (P3). And 90 % of the bottom product is recycled and mixed back into the feed.

While the resulting flowsheet has a positive reward, it is still far from a realistic engineering solution and future research is required. In particular, there are three major issues observed in the optimal flowsheet solution: (1) In industrial applications, MeOAc is primarily produced in reactive distillation (Huss et al., 2003). As our agent does not include reactive distillation as a unit operation, this cannot be identified. In future work, intensified unit operations can be added to our framework or the agent could operate on a phenomena level rather than a unit operation level. (2) The best flowsheet generated by the agent in this work contains three consecutive PFRs. The reason is that the length of a single PFR is limited to 10 m, which is not sufficient to finish the reaction. Therefore, the agent learns to choose multiple PFRs to fulfill the reaction and maximize the product. (3) One unnecessary heat exchanger is added after the distillation column C1 and before the product P1. We believe this is due to the small operations cost of the heat exchangers and the minor impact on the overall reward. Future research should further investigate possible mitigation strategies such as longer training or further hyperparameter tuning.

Figure 2: Best flowsheet generated by the transfer learning agent. First, MeOAc and H<sub>2</sub>O are produced from the feed (F1) in three consecutive reactors (R1, R2, and R3). Then the mixture is separated in the first column (C1). The first product (P1) is enriched with MeOAc but also contains residues of HOAC and H<sub>2</sub>O after one heat exchanger (Hex1). Then the bottom mixture of MeOH and H<sub>2</sub>O is further separated in the second column (C2). Pure H<sub>2</sub>O is in the distillate (P2) and the third product (P3) is the mixture of MeOH and H<sub>2</sub>O. And 90% of P3 is recycled and mixed with the feed stream.

Table 1. Design variables selected by the agent with transfer learning in the best flowsheet.

Unit operation	Design variable	Unit	Best run
Reactor 1 (R1)	Length	m	9.42
Reactor 2 (R2)	Length	m	9.25
Reactor 3 (R3)	Length	m	8.38
Column 1 (C1)	Distillate to feed ratio	-	0.58
Column 2 (C2)	Distillate to feed ratio	-	0.4
Heat exchanger 1 (Hex1)	Outlet temperature	K	315
Recycle	Recycled ratio	-	0.9

## 5. Conclusion

We propose to deploy the transfer learning for process design in RL to accelerate the learning process of the agent. The GNNs-based agent is first pre-trained with a short-cut simulation environment and then transferred to the rigorous process simulator environment for further training. In the illustrative case study, the agent is able to design economically feasible flowsheets in the process simulator DWSIM environment. Furthermore, the learning curves demonstrate that transfer learning indeed improves the efficiency of the learning process significantly and thus can be used to reduce the overall training time significantly. This work thus demonstrates that transfer learning can accelerate the learning process of graph-based RL with rigorous process simulator environments.

## Abstract

Artificial intelligence has great potential for accelerating the design and engineering of chemical processes. Recently, we have shown that transformer-based language models can learn to auto-complete chemical process flowsheets using the SFILES 2.0 string notation. Also, we showed that language translation models can be used to translate Process Flow Diagrams (PFDs) into Process and Instrumentation Diagrams (P&IDs). However, artificial intelligence methods require big data and flowsheet data is currently limited. To mitigate this challenge of limited data, we propose a new data augmentation methodology for flowsheet data that is represented in the SFILES 2.0 notation. We show that the proposed data augmentation improves the performance of artificial intelligence-based process design models. In our case study flowsheet data augmentation improved the prediction uncertainty of the flowsheet autocompletion model by 14.7%. In the future, our flowsheet data augmentation can be used for other machine learning algorithms on chemical process flowsheets that are based on SFILES notation.

**Keywords:** Data Augmentation, Flowsheet Autocompletion, SFILES, Transformers

## 1. Introduction

The design of a flowsheet topology is an important step in early process synthesis. This step consists of selecting and arranging unit operations for a chemical process. Artificial intelligence (AI) methods have the potential to learn from previous flowsheets and support engineers in process development (Hirtreiter et al., 2022; Oeing et al., 2022; Schweidtmann, 2022; Vogel et al., 2023). For instance, Vogel et al. (2023) proposed an algorithm for the autocompletion of flowsheets. This autocompletion algorithm is inspired by text-autocompletion from natural language processing (NLP) that is based on generative transformer models (Radford et al., 2019). In addition, Hirtreiter et al. (2022) showed that the prediction of control structure elements from Process Flow Diagrams (PFDs) can be interpreted as a translation task between PFDs and Process and Instrumentation Diagrams (P&IDs). Hence, they deployed a sequence-to-sequence transformer architecture which is commonly used for translation of text between different languages. These flowsheet transformers rely on machine-readable flowsheet representations.

To represent flowsheets in a machine-readable format, we depict them as graphs or as text using unique, i.e., canonical, SFILES 2.0 strings (Vogel et al., 2022b). In general, flowsheets are drawings of chemical processes. Chemical engineers use flowsheets for the communication, planning, operation, simulation, and construction of these processes. An example flowsheet is given in Figure 1.

An intuitive way to represent flowsheets is via graphs with unit operations as nodes and stream connections as directed edges. Besides the graph representation, flowsheets can also be represented as strings. D’Anterrosches (2005) introduced the Simplified Flowsheet Input-Line Entry-System (SFILES) notation, which we recently extended to include control structures and other features in (Vogel et al., 2022b). When creating the SFILES, we traverse the graph by starting at an input node and following the stream direction until we reach a product node or a recycle. In case the stream branches at a node, i.e., a splitter, we need to decide which stream to follow first. To determine the order of the branches in the linear string, the SFILES algorithm assigns each node a unique rank. The SFILES string for the flowsheet from Figure 1 is given by:

$$(\text{raw})(\text{hex})\{1\}(\text{r})<\&|(\text{raw})(\text{pp})\&|(\text{mix})<1(\text{v})(\text{dist})[\{\text{tout}\}(\text{prod})]\{\text{bout}\}(\text{splt})1(\text{prod})\text{n}|(\text{raw})(\text{hex})\{1\}(\text{prod}).$$

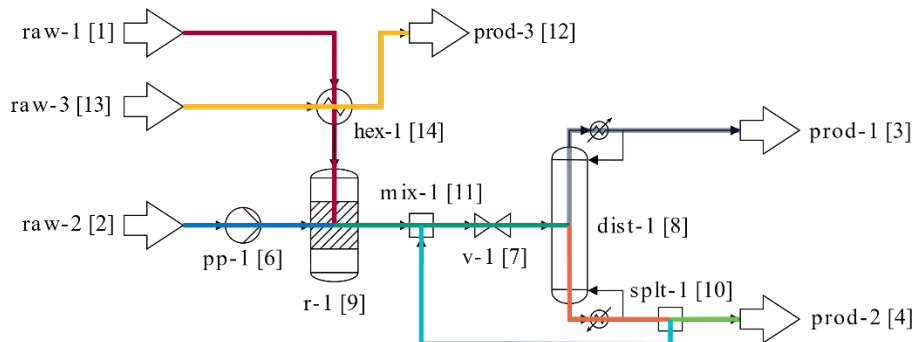

While AI models require big training data, machine-readable flowsheet data is typically limited. The reason for limited data is that flowsheets are mainly depicted as images and therefore not machine-readable (Schweidtmann, 2022). Recently, we propose to automatically find flowsheet images in literature (Schulze Balhorn et al., 2022) and to make them machine-readable via computer vision (Theisen et al., 2023). However, these methods need to be implemented at a large scale. In addition, the majority of flowsheets are not publicly available due to company’s intellectual property protection. Chemical process datasets with machine-readable flowsheets are rare and often contain only dozens of flowsheets (Hirtreiter et al., 2022; Oeing et al., 2022; Vogel et al., 2023; Zhang et al., 2018; Zheng et al., 2022). However, AI methods like transformers usually require big training data.

One promising approach to overcome limited training data for artificial intelligence is data augmentation. Data augmentation builds on the idea to generate additional artificial training data by masking, modifying, perturbing the available original training data at hand. For example, in computer vision, data augmentation is an established method to improve the model performance by adding modified copies of already existing images (Shorten & Khoshgoftaar, 2019). However, no data augmentation method for flowsheets exists yet. Thus, a data augmentation method is needed which adds modified copies of already existing flowsheets to mitigate the issue of limited available flowsheet data.

We propose a novel data augmentation method for process flowsheets. Specifically, we use a text-based augmentation method for SFILES which is inspired by the augmentation of SMILES strings for molecules (Bjerrum, 2017). Our approach is to randomize the branching decisions in the SFILES generation. We demonstrate the proposed flowsheet augmentation method in the context of a flowsheet autocompletion model from (Vogel et al., 2023).

## 2. Data augmentation methodology

To augment the flowsheet data sets, we modify the branching decision in the SFILES generation algorithm to create multiple SFILES strings representing the same flowsheet. In the case of determining canonical SFILES the branching decisions are made by assigning every node of the graph to a unique rank. Hence, canonical SFILES are a unique mapping of a flowsheet graph to a string. When generating augmented SFILES, the branching decisions are made randomly, resulting in a non-canonical form. The difference lies in the order of branches in the linear string. The resulting augmented SFILES contain the identical information as the canonical SFILES, thus describing the same process flowsheet. Hence, all augmentations can be translated back to the original canonical SFILES. In Figure 1 we show the augmentation of the example flowsheet.

### canonical SFILES

```
(raw)(hex){1};(r)-&(raw)(pp)&(mix)<1(v)(dist)[{tout};(prod)]{bout}(spl)1(prod)n(raw)(hex){1};(prod)
```

### augmentation SFILES

```
(raw)(hex){1};(r)-&(raw)(pp)&(mix)<1(v)(dist)[{bout}(spl)1(prod)]{tout}(prod)n(raw)(hex){1};(prod)
```

```
(raw)(hex){1};(r)-&(raw)(pp)&(mix)<1(v)(dist)[{bout}(spl)1[(prod)]]{tout}(prod)n(raw)(hex){1};(prod)
```

```
(raw)(hex){1};(r)-&(raw)(pp)&(mix)<1(v)(dist)[{tout}(prod)]{bout}(spl)1[(prod)n(raw)(hex){1};(prod)
```

Figure 1: Augmentation example for the flowsheet from Figure 1. The node rank is given in square brackets after the node name.

During augmentation, only the uniqueness of the SFILES representation is lost while the full flowsheet topology information is preserved. Notably, we do not change the order of the input branches during data augmentation. Otherwise, flowsheets with disconnected sub-graphs cannot be translated back to the original canonical form. This is for example important for independent processes with heat integration, such as  $(raw)(hex)\{1\}(prod)$  in the example flowsheet from Figure 1.

The number of augmented SFILES that can be derived from a single flowsheet graph is limited. Specifically, the number of potential augmented SFILES depends on the number of available branching points for a given flowsheet, with more branching points leading to an exponential increase of augmentation possibilities. For example, the flowsheet in Figure 1 contains two branching points. This results in three augmented SFILES representations and four SFILES representations in total.

The two branching points in this case are the distillation column  $dist-1$  and the splitter after the distillation column  $spl-1$ . At the first branching point, we switch the order of the top and bottom outlet streams. The second augmentation affects only the bottom product stream  $prod-2$ . Recycles without unit operations always appear directly after the splitting unit, here that leads to  $(spl-1)1$  in all cases. In case the product branch is visited before the recycle branch, additional squared brackets around  $prod-2$  are used. To make the methodology for flowsheet augmentation openly accessible, we include it in our public SFILES 2.0 Github repository (Vogel et al., 2022a).

## 3. Case study and Results

### 3.1. Data and Data augmentation

We use two SFILES datasets which were created by (Vogel et al., 2023). Firstly, we use their proposed flowsheet generator to generate a large-scale dataset of about 8,000

artificial flowsheets. Here, we can flexibly scale the dataset size. Secondly, we use a dataset made from 223 Aspen and DWSIM chemical process simulations. We call this the real dataset. Before starting the training runs, we split each dataset into a training dataset, a validation dataset, and a test dataset. For the two training datasets we created a maximum of five augmentations for each SFILES, which roughly increases the dataset five-fold. By limiting the number of augmentations to five, we ensure that larger flowsheets are not over-represented.

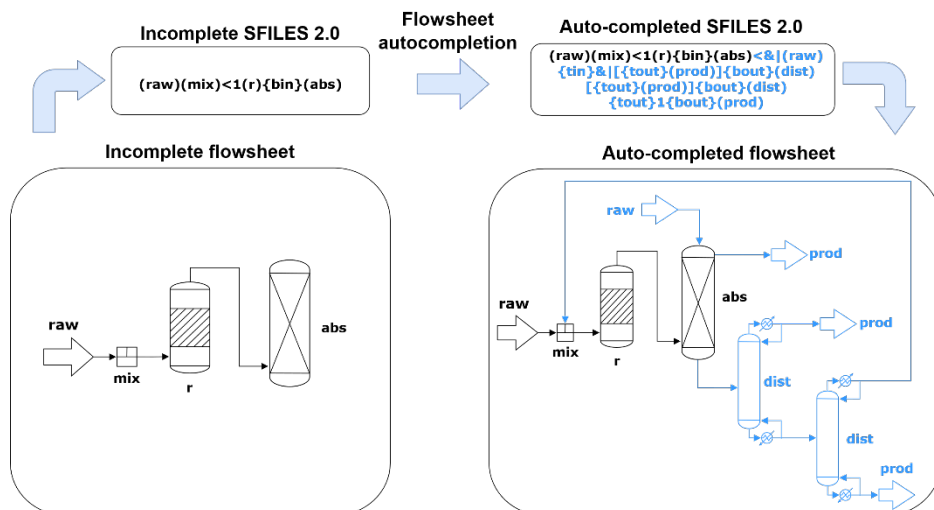

Figure 2: Example prediction of the flowsheet autocompletion model. Figure adapted from (Vogel et al., 2023).

### 3.2. Flowsheet autocompletion

We consider a process design case study and use the flowsheet autocompletion model from (Vogel et al., 2023). The objective of the model is to support chemical engineers in the design of a new process topology. It can suggest the following unit operation for an incomplete flowsheet, similar to sentence completion in messenger apps. Specifically, the start of a SFILES is given and the autocompletion model predicts how the sequence ends by iteratively predicting the following building block, token, of the SFILES (Figure 2). It should be highlighted that the prediction is only based on the process topology and does not consider operating points, components, and material flows. The autocompletion model is built on the transformer architecture in a decoder-only approach (Radford et al., 2019). Because transformer models are very data-intensive, the generated dataset is used to pretrain the flowsheet autocompletion. The real dataset is then used to fine tune the flowsheet autocompletion. For a more detailed description of the model we refer to (Vogel et al., 2023).

To study the effectiveness of data augmentation we retrain the model for flowsheet autocompletion from (Vogel et al., 2023). Specifically, we train the model both with augmented and non-augmented flowsheet data. Overall, we consider three different training scenarios. First, we train the model with the non-augmented generated dataset and fine-tune this model with the real dataset (i). This model is used to reproduce the results from (Vogel et al., 2023). Secondly, we augment the real data and use them to fine-tune the pretraining model, resulting in model (ii). We thus only alter the fine-tuning. Finally, we train the flowsheet autocompletion with augmented data for both pretraining

and fine-tuning, yielding model (iii). For a fair comparison of training runs with and without data augmentation, we use the same hyperparameters.

### 3.3. Results

We use perplexity to measure the model performance. Perplexity describes the uncertainty of a model in its predictions. Therefore, a low perplexity is desirable. Here, a lower perplexity means that the model is more confident that the suggested unit operation is reasonable. Perplexity is the exponential of the negative average log-likelihood of the next token prediction. It is also equivalent to the exponential of the cross-entropy loss obtained during model training. The perplexity is computed as

$$PP(T) = \exp\left(-\frac{1}{n} \sum_i^n \log P(t_i | t_{1:i-1})\right), \quad (1)$$

where  $T = (t_1, \dots, t_n)$  is a sequence of  $n$  tokens and  $P(t_i | t_{1:i-1})$  describes the predicted probability for the next token  $t_i$  given the sequence  $t_{1:i-1}$ .

Table 1: Perplexity  $PP$  results of data augmentation. Best test result in bold font. The column "Augm." shows whether the training data were augmented or not. Pretraining and fine-tuning test perplexity are both evaluated after the model training is completed with the fine-tuning dataset.

Model	$PP$ pretraining		$PP$ fine-tuning			Training Time	
	Augm.	Test	Augm.	Train	Val		Test
(i)	No	5.38	No	3.13	4.23	5.02	51 min
(ii)	No	6.33	Yes	3.32	4.12	4.69	57 min
(iii)	Yes	<b>5.16</b>	Yes	3.07	3.80	<b>4.28</b>	1 h 31 min

The results of the different training runs are shown in Table 1. For the fine-tuning, model (ii) performs slightly better than model (i) on the test set. We explain this improvement by the fact that the fine-tuning data are limited in size (i) and with the data augmentation we can make the model more robust (ii). Even though the test perplexity is lower with data augmentation, the training perplexity is higher. This shows that the model trained with data augmentation is less prone to overfitting and generalizes better to unseen data. With data augmentation also applied to the pretraining (model (iii)), we see the best performance in all categories, improving the fine-tuning perplexity by 14.7% compared to model (i). We conclude that data augmentation can also improve the pretraining with a relatively large, generated dataset, resulting in a better fine-tuning performance.

In general, we see that the augmented SFILES are valid flowsheet representations and that they help the flowsheet autocompletion to learn the SFILES grammar and chemical process structure. For future work it would be interesting to investigate if it is more favorable for pretraining to generate more artificial data, to increase the dataset with data augmentation, or to combine both methods. It is worth noticing, that the training and test perplexity are in every case more similar for the models trained with augmented data. Due to the higher variance in the training data, these models are less prone to overfitting.

## 4. Conclusions

We propose a data augmentation of chemical flowsheet data by randomizing the branching decisions in the graph traversal for producing SFILES. We thereby demonstrate a way to increase the available flowsheet data for subsequent training of AI models. We apply augmented SFILES to the problem of flowsheet autocompletion and show that the augmentation improves the model performance in low data regimes. In

future research, we aim to apply the data augmentation methodology to further NLP models to improve their performance. The long-term goal should be to increase the flowsheet dataset size by mining additional flowsheets from literature (Schweidtmann, 2022; Schulze Balhorn et al., 2022) and companies and, if necessary, digitizing them (Theisen et al., 2023). A combination of both, data augmentation and increased dataset, size will be necessary and most beneficial.

## Abstract

Search for a good catalyst to catalyse surface reactions with high product selectivity has always been an important aspect of heterogeneous catalyst design. To this end, detailed insights into the mechanism of a reaction need to be developed, which is at times difficult for heterogeneous reactions. Efficient techniques are required which accurately provide all possible pathways over a heterogeneous catalytic surface given a set of chemically plausible species present. Linear algebra along with graph theoretical techniques can be used for identifying different possible reaction pathways from a set of elementary reactions. This study demonstrates the use of one such technique resulting in a reaction route diagram for acetylene hydrogenation-hydrogenolysis reaction system. A systematic protocol for the identification of all possible pathways is presented. Multitude of reaction pathways influencing the product selectivity of the reaction was observed with the possibility of existence of pathways with the desired selectivity.

**Keywords:** elementary reactions; surface species; reaction graph; incidence matrix; reaction route diagram.

## 1. Introduction

Rational design of a heterogeneous catalytic reactor requires a detailed understanding of the surface chemistry of the associated reaction. An important issue in the engineering of heterogeneous catalytic reactions is the identification of all possible reaction pathways leading to a specified product given an initial set of reactants. This problem can be quite challenging even for macroscopically simple reactions like acetylene hydrogenation, as has been highlighted in this study. Due to the possibility of existence of a large number of surface species on catalytic surfaces and their simultaneous interactions, on-surface synthesis has been reported by several investigators to yield a range of products based on the reaction and surface conditions. All these observations motivate the necessity of knowledge of all possible reaction pathways which can be observed over a heterogeneous surface. Recent developments in theoretical and computational frameworks for the analysis of reactive systems have proved to be helpful in gaining insights into on-surface systems. Such methods for the systematic reaction pathway search for the automated generation of reaction mechanisms work efficiently for small molecules only, and are time intensive for large molecules. Theoretical techniques reported till date require an efficient technique for the synthesis of reaction pathways. This work provides an efficient approach towards the systematic

search of reaction pathways considering as the test case acetylene hydrogenation and hydrogenolysis. Since the reactions are carried out heterogeneously, as mentioned earlier, the possibility of existence of a large number of surface intermediates exists leading to varied macroscopically observed products. Apart from the desired reaction, namely the selective hydrogenation, complete hydrogenation to  $C_2H_6$  is a possibility. Further, conversion of all three forms of  $C_2$  gases to  $CH_4$  by hydrogenolysis cannot be ruled out. Therefore, it is desirable to obtain all possible pathways during the aforementioned conversions. This remains the central issue addressed in this study.

With an aim of addressing the aforementioned issues, we propose a combination of mathematical techniques involving linear algebra and graph theory to get the correct picture. For acetylene- $H_2$  surface reactions, attempts have been made in the past to implement graph theory to complex reaction systems. Christiansen [1] and Temkin et al. [2] introduced the use of reaction graph for catalytic and noncatalytic reactions. Fishtik et al. [3] confirmed the use of this graph theory approach to be suitable for linear as well nonlinear kinetic mechanisms for single and multiple overall reactions. The success of such methods, however, depends on the identification of reaction pathways. In this study, we demonstrate a novel and generic approach for the analysis of surface catalytic systems which is capable of handling systems with a large number of surface species and macroscopic parallel reactions. Our approach considers the presence and influence of every possible surface species contributing towards the overall reaction. We demonstrate its applicability using hydrogenation and hydrogenolysis of  $C_2H_2$  as the test case.

## 2. Problem formulation and methodology

Macroscopically observable chemical species involved in the system under consideration are  $C_2H_2$ ,  $C_2H_4$ ,  $C_2H_6$ ,  $CH_4$  and  $H_2$ . These five chemical species in different adsorbed states over a catalytic surface can give rise to three categories of macroscopically observable chemical reactions given below in the scheme of Figure 1. Application of linear algebra tells us that in the above system of six series-parallel reactions with five chemical species, only three reactions are independent. This can be arrived at by finding the rank of the stoichiometric matrix with reactions as rows and chemical species as columns. However, chemical insights invoke some fundamental questions to consider all six reactions for further analysis. Analysis of the sub-set consisting of reactions (1-3) will show one of equations (2) and (3) to be redundant. This means that  $C_2H_6$  formation can take place by sequential hydrogenation of  $C_2H_2$  via  $C_2H_4$ . However, reaction (2) chemically means that  $C_2H_6$  formation takes place from  $C_2H_2$  and we ask this question: is it possible to obtain  $C_2H_6$  from  $C_2H_2$  without observing  $C_2H_4$  in any of the intermediate steps. For this, it is required to identify a pathway from  $C_2H_2$  to  $C_2H_6$  such that no intermediate species is  $C_2H_4$ . Similar analysis is required for hydrogenolysis reactions also.

The proposed algorithm for synthesis of pathways given an initial reactant and a final product is shown in Fig. 1.

Selective hydrogenation:

Complete hydrogenation:

Hydrogenolysis:

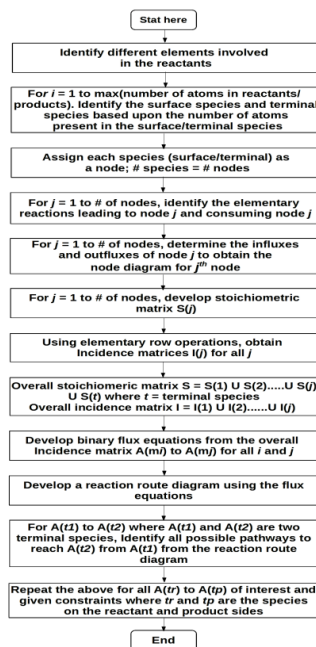

Fig. 1: Reactions involving the hydrogenation and hydrogenolysis are shown in left and the flowchart depicting the algorithm developed for systematic synthesis of pathways for a heterogeneously catalysed surface reactions is shown in right.

### 3. Results and discussion

The incidence matrix is a vital tool for the development of reaction route diagram as it gives a precise way of converting a set of reactants into a set of products. To obtain the stoichiometric sub-matrices,  $S(i)$  ( $i= 1$  to 33), the elementary reactions are written in the mathematical form as

$$\sum_{n=1}^{33} [a_n n_j] = 0 \forall r; r = 1 \text{ to } 119 \dots \dots \dots (7)$$

where  $n_j$  in Eq. 7 represents the chemical species. We identified a total of thirty-three surface species and five terminal species for the system under consideration. Correspondingly, thirty-three node diagrams were developed. We have prepared predefined pathways before analysing them and this process of synthesis of pathways can be automated. A sample node diagram for one of the surface species is shown in Figure 2a. Based on the surface species and node diagrams, a hundred and nineteen elementary reactions were identified which would explain hydrogenation and hydrogenolysis of acetylene over a catalytic surface. We have verified that no other possible surface species and elementary reaction exists.

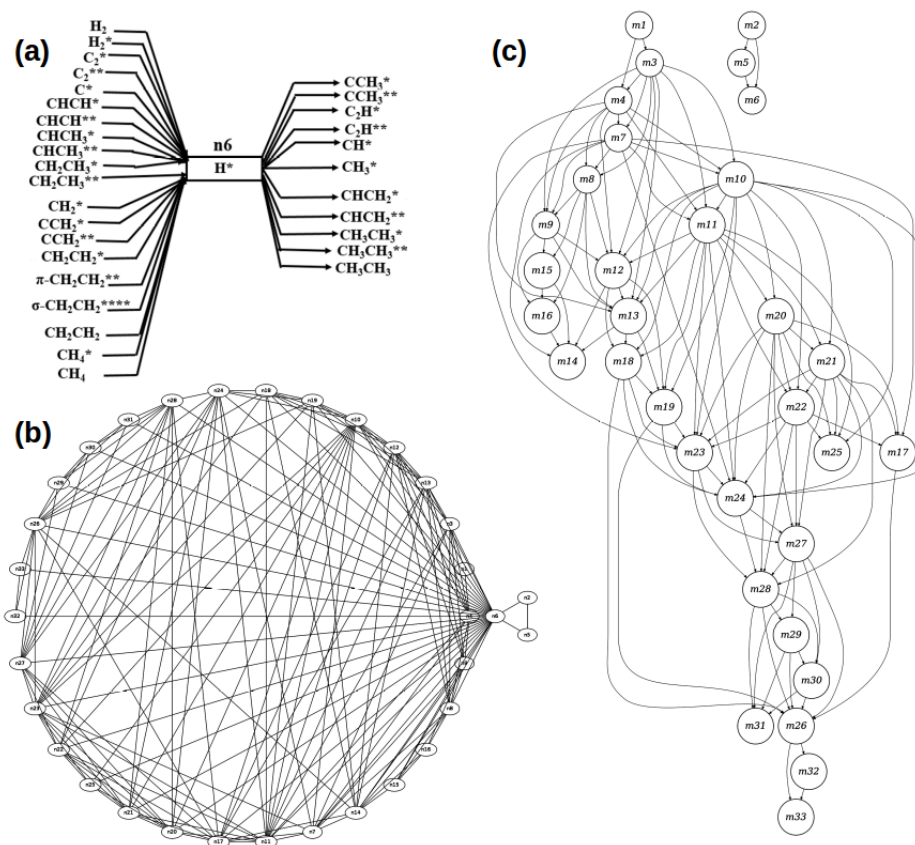

Fig. 2: Catalytic hydrogenation and hydrogenolysis of  $C_2H_2$ . Fig.2a: Node diagrams for the different chemical species identified. Fig. 2b: Reaction network diagram. Nodes  $n_i$  represent species connected by an undirected arrow, Fig. 2c: Reaction route graph.

A node appearing in the reaction scheme as a result of a surface reaction can be characterised distinctly by the appearance of both influxes and outfluxes in its node diagram. This can be seen in the node diagram of ( $H^*$ ), for example. The conversion of the given species to other species and its formation from other species can be seen from the influxes and outfluxes of this node. It is to be noted that it is possible to obtain a given species from a combination of other species resulting in treatment of such interactions as influxes while the same species can as well be treated to be resulting into a combination of other species resulting in the appearance of such species as outfluxes. This happens because of the inherent reversibility of surface reactions. This, however, does not affect our analysis in any manner as we define the interconnections in the reaction network diagram as direction-less and the appearance of a given species as influx or outflux in a given node results in the same network. The set of all node diagrams indicating individual influxes and outfluxes can be collated as a reaction network diagram which has no directionality (Figure 2b) and further as a reaction route graph which has directionality (Figure 2c). The reaction route diagram can be used to obtain the reaction pathway diagram, as shown in Fig. 3. The two pathways for  $C_2H_2$  hydrogenation to  $C_2H_4$ , for example, can be observed to involve two different modes of

adsorption of  $C_2H_2$ , one being the single site adsorption ( $C_2H_2^*$ ) while the other being the two site adsorption mode ( $C_2H_2^{**}$ ). The intermediates following the adsorption steps can also be seen to be distinct. Both of these pathways have been reported previously for  $C_2H_2$  hydrogenation to  $C_2H_4$  [4, 5]. This shows the success of our method in capturing different pathways. Pathways for further hydrogenation of  $C_2H_4$  to  $C_2H_6$  were also identified, the conversion of  $C_2H_2$  to  $C_2H_6$  via  $C_2H_4$  is shown in Fig. 3.

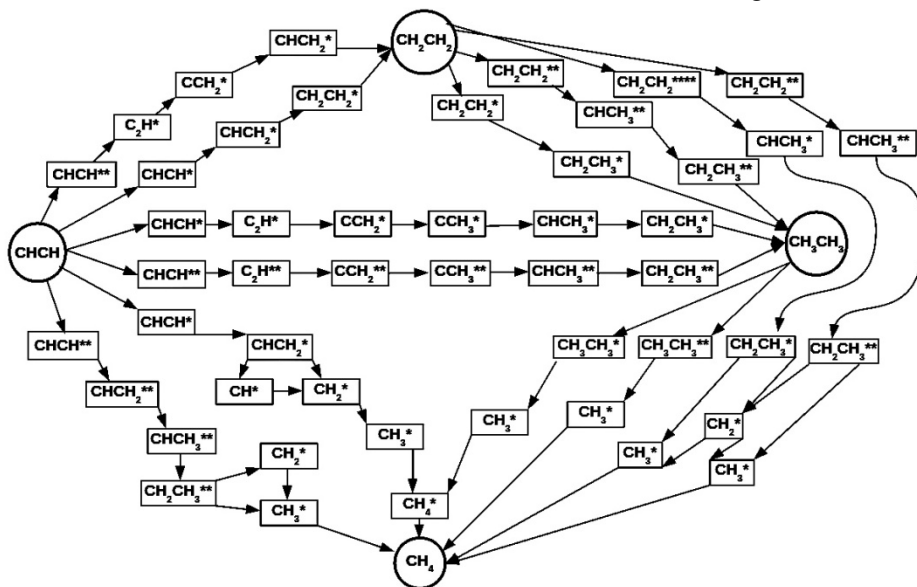

Fig. 3: Two sample pathways between any two terminal specified

Another important observation from the figure is the existence of distinct pathways for  $C_2H_2$  hydrogenation to  $C_2H_6$  without observing  $C_2H_4$ . These pathways have never been discussed in the literature and the existence of such pathways shown by our study signifies the importance of our systematic synthesis protocol in identification of pathways. Identification of hydrogenolysis of different  $C_2$  gases with the aforementioned constraints of observing or not observing a particular species can similarly be done, three instances for example are given in Fig. 3.

## Conclusions

A novel and efficient technique utilising linear algebra and graph theory was developed for the identification of all possible pathways for heterogeneously catalysed surface reactions. The applicability of the method was demonstrated successfully for  $C_2H_2$  hydrogenation-hydrogenolysis reaction. The macroscopically simple reactions involving  $C_2H_2$ ,  $C_2H_4$ ,  $C_2H_6$ ,  $CH_4$  and  $H_2$  were found to have complex surface interactions resulting in thirty-three chemical species and a hundred and nineteen elementary surface reactions. A reaction route graph, developed from elementary reactions via the stoichiometric matrix and the incidence matrix, demonstrated complex surface interactions among the surface species and a multitude of reaction pathways for partial hydrogenation, complete hydrogenation and hydrogenolysis with existence of direct reaction routes from  $C_2H_2$  to rest all terminal species. This method is capable of determining all possible pathways in short time frame compared to other expensive methods, for example techniques like quantum chemical calculations. Although the

presented model has demonstrated for hydrogenation of ethylene, the same can be explored for other surface reactions as well.

# New Methodology Integrating Tray Efficiency Predictions with Internals Design for Valve-Tray Distillation Columns

Chenguang Zhu,<sup>a</sup> Megan Jobson,<sup>a</sup> Nan Zhang<sup>a</sup>

<sup>a</sup>*Centre for Process Integration, Department of Chemical Engineering, The University of Manchester, Manchester, M13 9PL, United Kingdom*

## Abstract

Column internals design is a complex problem with many degrees of freedom and hydraulic constraints. This work proposes a new automatic design methodology for the internal design of valve-tray columns, iteratively applying results from rigorous distillation simulations, hydraulic correlations and tray efficiency predictions for valve trays. The feasibility of the proposed internals is checked against hydraulic constraints, including jet flooding, downcomer flooding and weir loading. The methodology is applied to an existing industrial valve-tray column separating C4 hydrocarbons; the results show the impact of the internals design approach on column hydraulics and tray efficiency. The proposed design can reduce the column diameter while avoiding hydraulic bottlenecks. Future work aims to implement the methodology for column design optimisation.

**Keywords:** Hydraulic analysis; Hydraulic Design; Tray efficiency;

## 1. Introduction

Distillation is a widely used, effective fluid separation process in industrial practice but requires substantial energy input and capital investment. Several published papers have addressed the optimal design of distillation columns, i.e. the column diameter, and number of trays in each section, to meet given separation specifications with minimum total annualised cost (TAC). However, these optimal column designs are still conceptual designs; details of column internals are not accounted for. The traditional approach to dimensioning column internals is to use trial and error: Kister et al., 1992; Chuang and Nandakumar, 2000; Towler and Sinnott, 2021. No definitive procedure to guide the design of column internals is available in the open literature. Typically, assigning hardware to a conceptual design depends on the designer's experience using the trial-and-error method, without a comprehensive search for internals that meets hydraulic limits and operating constraints and targets with the lowest capital cost. As a result, the design is time-consuming and a new column is excessively conservative and the effect of the column's internal design on the column efficiency and sizing has not been considered.

Valve tray is used in this study as valve tray columns are the most popular choice for trayed distillation column internals in the industry since lower pressure drop than bubble cap trays and have a wide range of applicability (Kister et al., 1992). The capital cost of a valve-tray column depends on column or section diameter, the number of trays, and the column internals – namely, type of tray; type, dimensions and layout of valves; tray spacing, pass configuration, downcomer dimensions, etc. At the same time, the column

internal dimensions affect the stage efficiency, and hence the theoretical number of stages, and thus the reflux ratio. The reflux ratio will in turn affect the required dimensions of the internals, which implies that design optimisation should consider column internal dimensions and stage efficiency iteratively (or simultaneously).

Due to the development of computer-aided process engineering, limited research in the open literature has developed optimisation approaches for internals design for sieve-tray columns (Ogboja and Kuye (1990); Lahiri, 2014; Souza et al., 2022). However, these papers optimised the sieve tray column internals dimension by giving fluid information. Interaction between tray efficiency and column internals dimensions are ignored.

Lahiri (2014) used particle swarm optimisation and the Aspen Plus simulator to optimise the design of sieve-tray distillation columns, including tray specifications. The continuous design variables considered are: downcomer dimensions, tray dimensions and tray spacing, while the discrete variables are the number of stages, feed location and pass configuration. The objective function is the total annualised cost; the constraints are hydraulic limits and pressure drop. Lahiri (2014) only considers the continuous variables during the optimisation, while the discrete variables are specified manually. Significantly, tray efficiency is not evaluated within the optimisation. In practice, neglecting the tray efficiency could lead to different internal flows, and violation of hydraulic constraints.

Souza et al. (2022) formulated a mixed-integer nonlinear problem for optimising the internals dimensions (diameter, tray spacing, hole diameter, weir length, etc.) of sieve-trayed columns using column capital cost or the mass of shell and trays as an objective function, applying hydraulic (including jet flooding, downcomer flooding) and pressure drop constraints. Souza et al. (2022) first obtain the flow rate and physical properties from the Aspen Plus simulator with operating conditions and overall efficiency specified manually without any updating.

Ogboja and Kuye (1990) developed a formulation considering tray efficiency for sieve tray optimisation. Chan and Fair's (1984) correlation was used to calculate tray efficiency; the objective is then to maximise the tray efficiency with rigorous consideration of hydraulic limits and pressure drop. However, Ogboja and Kuye (1990) used a set of flow rates and fluid properties presented by literature to conduct the design, which means flow rate, fluid properties and the total number of stages are fixed in the optimisation. Although this work uses an exhaustive method to analyse all sets of variables (internal dimensions) to determine tray efficiencies, the effect of tray efficiency on the flow rate and fluid properties was not considered during the iteration of the tray efficiency evaluation.

Meanwhile, published research has not explored details of the hydraulic evaluation of valve-tray columns with cost as a design criterion, and the impact of the tray efficiency of the key tray in each section on the flow rate, and fluid properties should be assessed.

This work develops a systematic and automatic column design methodology for valve-tray columns considering column internals dimensions design, hydraulic performance of the trays, pressure drop and tray efficiency, with a focus on minimising column internals dimensions with the consideration of tray efficiency, where the operating limits (jet flooding, downcomer flooding and downcomer backup) in the column should be avoided.

## 2. Valve-trayed column design methodology

Figure 1 represents the proposed methodology which employed converged simulation of a simple distillation column (using Aspen Plus V11) and Python code which can exchange inputs and outputs with the process simulator automatically.

This work proposes a design methodology including an equilibrium-based 'rigorous' simulation of a column considering section efficiency (Murphree efficiency) to achieve a

specified separation of a given feed; calculation of column internal dimensions (diameter, deck thickness, downcomer sizing, tray spacing, valve dimensions, tray spacing) under specified flooding limits and fractional hole area; and prediction of section efficiency of mean stage efficiencies within the section. The column is simulated using an established process simulation software assuming the stage efficiencies (as input variables), tray spacing, and the number of passes. The simulation results (stage-flow rates and fluid properties) are used as inputs for column hydraulic analysis and tray and downcomer calculations for every stage. The feasibility of the design is checked in terms of hydraulic limits and pressure drop, and the internal dimensions are then modified to avoid hydraulic limits. Next, the corresponding internal dimensions (active area, deck thickness, fractional hole area) and fluid properties are input to the stage efficiency prediction model of Chen and Chuang (1993). The calculated section efficiencies are re-input to the process simulator to recalculate the material and the energy flows and thus update the internal dimensions and section efficiencies, which means the column simulation and internal dimensions calculation are repeated until converged. The three steps are repeated until the calculated and assumed efficiencies are equal.

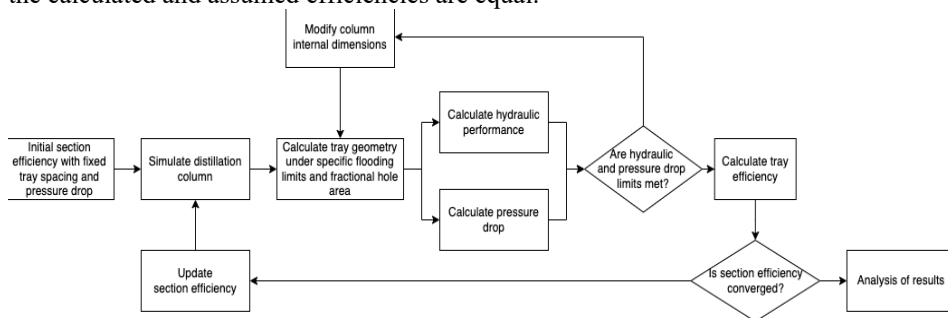

Figure 1. Proposed design methodology for valve-tray distillation column

### 2.1. Hydraulic analysis: methodology

Distillation columns can only operate efficiently with containing trays within certain hydraulic limits. A smaller diameter means a smaller active area or downcomer area for vapour-liquid pass-through, which will cause jet flooding or downcomer flooding. Thus, the selection of jet flooding and downcomer flooding upper limits have a significant effect on the diameter.

A maximum value of 80% is assumed since this figure is widely used in design textbooks. Jet flooding is predicted using the Glitsch correlation, also known as the ‘Equation 13’ (Branan, 2005) for conventional floating valve trays. Downcomer choke flooding is evaluated in terms of the volumetric flow rate at the downcomer entrance following the Glitsch correlation (Kister et al., 1992). Another typical constraint weir loading, the ratio of liquid volume flow rate to weir length, is assumed to limit 107 m<sup>3</sup>m<sup>-1</sup>h<sup>-1</sup>, as the value is typically applied in the practice (Kister et al., 1992). The clear liquid height, downcomer backup and pressure drop analysis are evaluated following correlations of Koch-Glitsch (2013); the vapour capacity factor and approximate tower diameter are calculated using the correlations of Branan (2005).

Downcomer backup is evaluated knowing the aerated liquid height in the downcomer, which is calculated by an aerated factor, the ratio of the clear liquid height to the aerated liquid height. A correlation is proposed, regressed from the aerated factor chart for valve trays of Klein (cited by Kister et al., 1992). The regressed model is shown in Eq. (1), where  $F_{va}$  is the superficial F-factor based on the active area.

$$\beta = -1.31F_{va} + 2.07F_{va}^2 - 1.71F_{va}^3 + 0.72F_{va}^4 - 0.15F_{va}^5 + 0.01F_{va}^6 + 0.97 \quad (1)$$

Eq. (1) is only valid between the  $F_{va}$  from 0 to  $3.05 \text{ kg}^{0.5}\text{s}^{-1}\text{m}^{-0.5}$ .

### 2.2. Tray efficiency evaluation: methodology

The correlation of Chen and Chuang (1993) was developed based on a sieve tray in the hydrocarbon systems. However, Vennavelli et al. (2014) validated this correlation using FRI valve tray efficiency data (hydrocarbon test data) and showed that Chen and Chuang's (1993) model predicted the FRI valve tray efficiency better than the four existing valve tray efficiency models presented in published literature. Vennavelli et al. (2014) suggested that the sieve tray models present reasonable alternatives if they are developed from a wide range of data and operating conditions. Thus, there is good evidence that the Chen and Chuang (1993) model is valid for valve-tray columns in hydrocarbon systems.

## 3. Case study: separation of i-butane/n-butane mixture

The distillation system to demonstrate the proposed methodology is an industrial-scale valve-tray column separating the i-butane and n-butane mixture. However, the composition of distillate and bottom stream, and the section efficiency presented by Ilme et al. (2001) are not self-consistent. Thus, a self-consistent distillate and bottom stream composition, and section efficiency simulated and calculated following the methodology above are used instead of the results presented by Ilme et al. (2001), while the rest of the operating conditions and column internals dimensions are the same as that presented by Ilme et al. (2001). Thus, the i-butane/n-butane column based on the modified distillate and bottom stream composition, and section efficiency is used as a base case. The detailed operating conditions, stage distribution and product specifications are shown in Figure 2. Standard valve trays (Koch-Glitsch Ballast V-1 trays) are assumed for both sections. Section efficiency is applied instead of the tray efficiency of each tray, which is the average value of the tray efficiency of each tray in rectifying or stripping section predicted using Chen and Chuang (1993) model. The design methodology was applied automatically via the Python code to meet different flooding limits (jet flooding and downcomer flooding). The fractional hole area, which is the ratio between the hole area and the active area, was also varied. The impact of different flooding conditions and fractional hole area on the column diameter, section efficiency, pressure drop, and heat duty of the condenser and reboiler were analysed. The feed conditions, light key component purity in the distillate stream and distillate rate were maintained throughout the study. Table 1 presents the details of column internal dimensions and operating conditions under different flooding conditions (from 70% to 80%) and fractional hole area (from 16.6% to the lower limit).

The percentage of jet and downcomer flooding calculated based on the base case internal dimensions given by Ilme et al. (2001) are 69% and 52%. It is found that the diameter can reduce by 10% when the column operates under 80% of both jet and downcomer flooding and the fractional hole area is 16.6%. However, higher flooding condition means higher froth liquid height on the tray, leading to a slightly higher pressure drop than the base case, while section efficiencies are almost the same as the base case.

It is also found that the section efficiency is mainly dominated by the fractional hole area. The section efficiency can increase by around 7 to 10% in both rectifying and stripping sections under the same flooding condition. However, it shows that the lower limits of fractional hole areas are different under different flooding conditions due to downcomer backup constraints. Thanks to the increasing of section efficiency, the reflux ratio is smaller than the base case, leading to a low heat duty demand in both the condenser and reboiler.

Figure 2. Flowsheet and operating data for an i-butane/n-butane column

Table 1. Column internal dimensions, hydraulic performance and pressure drop performance under different flooding limits and fractional hole area.

Flooding condition	base case	70%			80%		
		16.6%	13.0%	8.7%	16.6%	13.0%	10.1%
% hole area	16.6%	16.6%	13.0%	8.7%	16.6%	13.0%	10.1%
Diameter	2,900 mm	2,796 mm	2,765 mm	2,721 mm	2,593 mm	2,564 mm	2,539 mm
Pressure drop	0.48 kPa	0.51 kPa	0.55 kPa	0.73 kPa	0.54 kPa	0.64 kPa	0.89 kPa
Heat duty	10.60MW; 10.22 MW	10.59MW; 10.21 MW	10.38MW; 10.00 MW	10.09MW; 9.71 MW	10.52MW; 10.15 MW	10.31MW; 9.94 MW	10.13MW; 9.76 MW
Section efficiency	110%, 115%	110%, 115%	114%, 119%	121%, 124%	112%, 116%	115%, 120%	119%, 123%

Since the section efficiency is integrated into the column internals design, the column diameter can reduce an extra 2% than only changing the flooding condition. However, the reduction of fractional hole area allows the vapour velocity through the valve tray to be increased, which results in a significant increase in pressure drop. As shown in the table, the pressure drop can be increased by up to 60%, from 0.54 kPa to 0.89 kPa, under the same flooding conditions.

#### 4. Discussion

In this work, the complex tray internals design and tray efficiency prediction can be integrated automatically by computer-aided design. Thus, the size of the distillation column no longer needs to be too conservative based on the designers' experience, and the separation efficiency is also improved, resulting in substantial savings in capital investment. At the same time, it helps engineers clearly understand the current production capacity and the potential to increase production, which is also important for safe production.

#### 5. Conclusion

The case study illustrates the benefit of the proposed automatic design methodology to design and evaluate design results to reduce the column diameter while satisfying the hydraulic limits (jet flooding, downcomer flooding, downcomer backup, and weir loading).

The methodology can be applied to trayed distillation columns and accounts for the impact of the change of hydraulic limits and fractional hole area on the pressure drop, downcomer backup and section efficiencies. In this case study, the distillation column diameter could be reduced by up to 12%, compared to the base case, by increasing the flooding conditions, without violating hydraulic constraints. Since the tray efficiency is integrated into the internal design, additional benefits can be obtained while the fractional hole area is changed. For the tray column, the fractional hole area is contributed by many variables, including valve leg length or hole diameter, deck thickness, and pitch of the hole, which will also affect the tray efficiency according to Chen and Chuang (1993) correlation. Thus, there is still a wide range to explore an optimal design.

However, the feed location and the number of actual stages are fixed in this work; these may not be optimal for the total annual cost. Cost-benefit analysis would be needed to further evaluate the design solutions.

## Abstract

The catalytic oxidative coupling of methane (OCM) process has received intense interest in the literature due to the potential to directly convert natural gas or methane to value-added chemicals at a reduced cost, energy consumption and carbon emissions when compared to conventional processes. However, major challenges such as low yield, catalyst deactivation, and reactor scale-up still challenge the commercialization of this process. A promising solution to address these challenges is to develop innovative OCM reactor designs leveraging the recent advances in modular process intensification, e.g. membrane reactors. The aim of this work is to design an optimal OCM process at commercial scale leveraging the concept of modular process intensification. We investigate an intensified fluidized bed membrane reactor (FBMR) catalyzed by  $\text{La}_2\text{O}_3/\text{CaO}$  and compare its performance to a conventional fluidized bed reactor (FBR). The use of membrane for oxygen feed distribution has been reported to result in better  $\text{C}_2+$  yield and selectivity by selectively enhancing the desired reactions.

**Keywords:** OCM, Process Intensification, Fluidized Bed Membrane Reactors

## 1. Introduction

The oxidative coupling of methane has been the target of intense scientific and commercial interest for more than forty years due to the tremendous potential of the technology to reduce costs, energy, and environmental emissions in the production of ethylene. In OCM, methane ( $\text{CH}_4$ ) and oxygen ( $\text{O}_2$ ) react over a catalyst exothermically to form ethylene ( $\text{C}_2\text{H}_4$ ), ethane ( $\text{C}_2\text{H}_6$ ), water ( $\text{H}_2\text{O}$ ) and heat, according to the following reactions (1 to 4) (Penteado et al., 2016). While the benefits of OCM have been known since the early 1980s, past efforts did not result in a viable process design with acceptable performance needed for commercialization. Despite the pioneering work in the catalysis of OCM that has managed to bring the commercialization realization of OCM (Galadima & Muraza, 2016; Onoja et al., 2019), there is need for a novel reactor design to achieve highly economically and environmentally relevant optimal OCM process design with optimal  $\text{C}_2+$  yield, selectivity and  $\text{CH}_4$  conversion (Bartreau, 2022). These catalysts, while at times achieving promising yield and selectivity, were hampered by very high operating temperatures, low activities, and short lifetimes on the order of hours to days.

The paper by (Cruellas et al., 2017) outlined that there are more than 20 types of reactors that were designed for experiments or only modeled for the optimized OCM production. In the aforementioned paper, it outlined that the most popular and widely applied reactors that, produce the highest  $C_2+$  selectivity%,  $CH_4$  conversion%, and the highest  $C_2+$  yield%. The most common types of conventional reactors used were the packed bed reactors and fluidized bed reactors. The advantages of fluidized bed reactors (FBR) are: (i) Perform almost isothermally and (ii) Stable and efficient performance especially concerning the reactor operability and the safety aspects (Chen et al., 2020; Schwarz et al., 2014; Yaghobi & Ghoreishy, 2008). Concerning the packed bed reactors (PBR), issues associated with the performance of the reactor were identified. In the application of OCM, the reactor suffers from the following: (i) Hot spot formations on the catalyst causing the reduction of  $C_2+$  formation drastically due to high operation temperatures. (ii) Fast degradation of catalyst. This in fact leads to low yield of  $C_2+$ . While fluidized bed reactors overcame the catalyst deactivation and high heat management issues, still FBR showed that only low yield of 19% could be achieved (Jašo et al., 2011). Several works have tried to overcome some of the bottlenecks in both conventional reactors such as reducing the operating temperatures while improving the yield and for better conversion, however, the highest yield% reached was approximately 20% (Chen et al., 2020; Yaghobi & Ghoreishy, 2008). Membrane reactors offer a great advantage to overcome those issues, however, the overall conversion, yield and selectivity were relatively low. The maximum methane conversion  $C_2+$  yield and selectivity achieved from membrane reactors were 24%, 20% and 47% respectively (Onoja et al., 2019). Although membrane reactors demonstrated an improved selectivity of  $C_2+$ , those systems suffered from low methane conversion due to the low flux of oxygen throughout the membrane which hindered the overall performance. While this issue could be avoided by raising the operating temperature, it negatively affected the selectivity of  $C_2+$  (Farrell & Linic, 2016). Cruellas et al., 2020 introduced the concept of bubbling fluidized bed reactor with a membrane installed and loaded with catalyst of interest. The advantages behind this system are the following (Cruellas et al., 2017): (i) Distributed oxygen feeding results in a local lower  $O_2$  concentration, which allows to obtain higher yields, (ii) Stability of the catalyst particles. Typically, the advantages of traditional fluidized beds and use of membranes are combined. Thus, the objective of this paper is to design a novel intensified circulating Fluidized Bed Membrane Reactor (FMBR) for the application of OCM to overcome all the above-mentioned issues leveraging the use of membrane for better oxygen distribution and the internal catalyst circulation to achieve higher  $C_2+$  yield. This paper summarizes the main findings behind the oxidative coupling of methane (OCM) system, main key elements to model an intensified OCM Circulating Fluidized Bed Membrane Reactor system. This rest of the paper is organized as follows: section 2 covers the kinetics of oxidative coupling of methane. Section 3 presents the design and validation of the conventional Fluidized Bed Reactor (FBR). Section 4 showcases the design and intensification of circulating Fluidized Bed Membrane Reactor followed by results and technical insights.

## 2. Kinetics of Oxidative Coupling of Methane

The reported kinetic model is considered the most used kinetic OCM model for the development of an OCM reactor (Ching et al., 2002; Cruellas et al., 2020). A comprehensive 10-step kinetic model of the oxidative coupling of methane to  $C_2+$  hydrocarbons over a 10 %  $La_2O_3/CaO$  catalyst was developed on the basis of kinetic measurements in a micro catalytic fixed bed reactor covering a wide range of reaction conditions by Stansch et al., 1997. The reaction scheme shown in Figure 1 contains three primary and seven consecutive steps that involves many species. The conversion of hydrocarbons and of carbon monoxide with oxygen were described by applying Hougen-Watson type rate equations. For the remaining reaction, power law equations were applied. The kinetics model's parameters were reported by (Ching et al., 2002; Stansch et al., 1997)

Figure 1: Reaction scheme of the kinetic model proposed by (Stansch et al., 1997)

## 3. Modeling of Conventional Fluidized Bed Reactor (FBR)

To systematically identify the optimal design solution, 2D high fidelity conventional Fluidized Bed Reactor (FBR) was adapted from (Cruellas et al., 2020a; Cruellas et al., 2020b) and modeled utilizing gPROMS ModelBuilder (PSE, 2020), which comprise partial differential algebraic equations accounting for mass balances, hydrodynamics, catalyst solid distribution and radial velocities across the reactor. The model is a core-annulus system which describes the two reactor regions that are characterized by different fluid dynamic conditions and catalyst concentrations. Figure 2 illustrates the hydrodynamic mechanistic of the 7 meters length and 0.6 meters diameter adapted reactor design. The model assumes that gas is transported upward in the core section, and it is stagnant in the outer region and accounts for radial gas mass transfer between the two sections. It was assumed that undiluted catalyst particles are fed to the reactor. The reactor is operated at 800 °C and 2 bar with methane to oxygen feed of 4:1. The reactor was simulated with a terminal velocity of 2 m/s and the value of mass transfer coefficient was fixed at 0.05 m/s. Results shows that  $C_2+$  yield was found to be 15% with a selectivity of 50% and a methane conversion of 26% which matches the adapted model from (Cruellas et al., 2020a). The validation of FBR hydrodynamics is shown in Figure 3.

## 4. Design and Intensification of Circulating Fluidized Bed Membrane Reactor (FBMR)

Oxygen permeation only membranes are integrated in the circulating FBR design to investigate the performance the proposed intensified FBMR design. A configuration had been selected where the membrane tube is placed in middle of the reactor along the axial direction and the catalyst bed is positioned around the membrane tubes. Due to the high

operating temperature of the process,  $\text{Ba}_{1-x}\text{Sr}_x\text{Co}_{1-y}\text{Fe}_y\text{O}_{3-\delta}$  (BSCF) perovskite membrane is selected to be integrated with the conventional fluidized bed reactor with a diameter of 0.01 meters, whereas the membrane length is equal to the reactor length to maximize the oxygen distribution (Spallina et al., 2015).

Figure 2: FBR Hydrodynamics Mechanism

Figure 3: Hydrodynamics Validation - FBR Design

This membrane can withstand high temperature ranges up to 1000 °C. In addition, the selected membrane is an  $\text{O}_2$  permeation only meaning that air could be used as inlet along with methane for better economics (CAPEX and OPEX). The utilization of membrane along the axial distribution in the reaction offers a uniform distribution of  $\text{O}_2$  thus, it helps to better control  $\text{O}_2$  concentration along the reactor, and eventually improves  $\text{C}_2+$  selectivity%, yield% and an increase in the  $\text{CH}_4$  conversion%. The equations were modified to accommodate the placement of the membranes in the FBR design. The model includes the membrane characteristics, governing equations of both fuel and air sides, hydrodynamics, catalyst solid distribution and radial velocities across the reactor. The membrane characteristics including permeabilities, mass and heat coefficients were adapted from (Spallina et al., 2015; Xu & Thomson, 1999). The Fluidized Bed Membrane Reactor (FBMR) governing equations are presented in table 1.

Table 1: Fluidized Bed Membrane Reactor (FBMR) Governing Equations	
Mass Balance in the core	$\frac{dc_i^c v^c}{dx} = r_i(c_j^c, \gamma^c) - K_i^{ca}(c_i^c - c_i^a) + h_i^f a^f (c_i^c - c_i^f)$
Mass Balance in the annulus	$r_i(c_j^a, \gamma^a) + \frac{V^c}{V^a} K_i^{ca}(c_i^c - c_i^a) = 0$
Air Side Equations	$\frac{dc_i^{air} v^{air}}{dx} = -h_i^{air} a^{air} (c_i^{air} - c_i^{m,air})$
Total Mass Balance	$c^c = \sum_{i=1}^N c_i^c$
Average Solid Fraction	$\gamma^c = 1 - \varepsilon^c = \frac{1}{r_c^2} \int_0^{r_c} 2r\varepsilon(r) dr$
	$\gamma^a = 1 - \varepsilon^a = \frac{1}{r_a^2 - r_c^2} \int_{r_c}^{r_a} 2r\varepsilon(r) dr$
	$\varepsilon(r) = 1 - \frac{G(r)}{\rho_s V_p(r)}$
Radial Velocity Profile – Solid reflux	$\frac{G(r)}{G_s} = a \left( 1 - \left( \frac{r}{r_a} \right)^5 \right) + 1 - \frac{5a}{7}$
Radial Velocity Profile – Particle velocity	$V_p(r) = \left( 1.5 \frac{U_{g,c}}{\varepsilon^c} - V_t \right) \left( 1 - \left( \frac{r}{r_c} \right)^2 \right)$

### 5. FBMR Results and Technical Insights

The fluidized bed membrane reactor was simulated with the same conditions selected for the conventional fluidized bed reactor with catalyst particle size of  $70\ \mu\text{m}$  and net solids flux of  $100\ \text{kg m}^{-2}\text{s}^{-1}$ . The amount of oxygen has been varied from 10% to 30% whereas the catalyst concentration was fixed at 10%. The results showed that the optimal feed ratio  $\text{CH}_4/\text{O}_2$  of 4 with a bed temperature of 800 and pressure of 2 bar. The computed axial mole fraction profiles of methane and  $\text{C}_2^+$  are given in Figure 4. The overall process performance resulted in a  $\text{C}_2^+$  yield of 35%,  $\text{C}_2^+$  selectivity of 67% and methane conversion of 67%. The axial  $\text{C}_2^+$  selectivity,  $\text{C}_2^+$  yield and conversion profiles are presented in Figure 5. The integration of membrane in the FBR design along with the catalyst distribution offered feeding the oxygen along the axial direction. While this integration helps in keeping the oxygen partial pressure low, it does consequently help in enhancing the reactor's performance towards the yield of more  $\text{C}_2^+$ . At the entrance of the reactor, the kinetics dominates over mass transfer allowing all the reaction to take place in the core only. It is important to note that both the kinetics resistance and mass transfer resistance are comparable as the reactions progress along the axial direction in both the core and annulus. This in fact could help protecting the  $\text{C}_2^+$  formed inside the intensified FBMR. Finally, one of the drawbacks of the OCM kinetics is the enormous production of carbon dioxide. It is one of most critical issues faced as it has a significant impact on the energy consumption, the environment and the product's purity (Galadima & Muraza, 2016). As the implementation of the membrane in the intensified FBMR design shifted the kinetics towards the production of more  $\text{C}_2^+$ , a  $\text{CO}_2$  reduction was achieved from 6.8% in the FBR configuration to 1.3% in the intensified FBMR design.

Figure 4: FBMR molar fraction profile of  $\text{CH}_4$  and  $\text{C}_2^+$

Figure 5:  $\text{C}_2^+$  Selectivity, Yield and  $\text{CH}_4$  Conversion of FBMR

### Conclusion

In this paper, we present the new intensified reactor design system for the simulation of oxidative coupling of methane. The conventional fluidized bed reactor was simulated and validated with a  $\text{C}_2^+$  yield, selectivity, and methane conversion of 15%, 54% and 26% respectively. A membrane was integrated with the conventional reactor coupling a perovskite oxygen selective membrane along the axial direction to improve on the three parameters mentioned above. The reactor's design shows a noticeable improvement with a  $\text{C}_2^+$  yield of 35%,  $\text{C}_2^+$  selectivity of 67% and improved conversion of methane up to 50% with a reduced  $\text{CO}_2$  production by almost 81%. Finally, the intensified fluidized bed membrane reactors could be a solution to improve the  $\text{C}_2^+$  yield%,  $\text{C}_2^+$  selectivity% and

CH<sub>4</sub> conversion%. Through this paper, it has been demonstrated that the concept of the intensified FMBR design can outperform the conventional FBR design.

## 6. Future Work

Although the new proposed intensified FMBR design solves some of the limitation for the OCM reaction to take place, it opened few research questions to uncover the role of membrane in achieving high C<sub>2</sub><sup>+</sup> selectivity%, C<sub>2</sub><sup>+</sup> yield% and CH<sub>4</sub> conversion%. The effect of these parameters (e.g. oxygen vacancy dilution coefficient (D<sub>v</sub>), species diffusion coefficient (D<sub>i</sub>) and perovskite membrane mass transfer coefficients (k<sub>f</sub> & k<sub>a</sub>)) will be investigated to enhance the economics of the OCM reactions and performance of FMBR. While the investigation of OCM reaction systems has mostly been focused on steady-state conceptual designs, ignoring the process dynamics limits the applicability of evaluating the implementation for commercial use.

## Abstract

When selecting candidate solvents for extractive distillation, activity coefficients at infinite dilution are commonly employed. With them, the selectivity of different solvents for a given mixture can be estimated, and the solvents can be ranked accordingly. However, given the large chemical space of potential solvents and the limited experimental data for activity coefficients at infinite dilution, predictive methods become necessary to perform a solvent pre-selection process across a broad solvent space. In this work, a method for selecting solvents using the Gibbs-Helmholtz Graph Neural Network as predictive model for infinite dilution activity coefficients is presented. Different case-studies are given to illustrate the efficacy of this methodology ranging from aliphatic-aromatic separations to the separation of olefin-paraffin mixtures. The extended Margules equation is employed to estimate the vapor-liquid equilibria of the system of interest allowing the minimum solvent-to-feed ratio to be estimated. The results show that industrially relevant solvents are selected for different type of mixtures while exploring a much larger solvent space compared to the one delimited by the available experimental data. Also, it is shown that the pre-selection of solvents based on infinite dilution conditions differs from the one performed using the minimum solvent-to-feed ratio criterion. The latter is recommended because it approximates the conditions usually encountered in a real extractive distillation column.

**Keywords:** Graph Neural Network, Activity coefficient, Extractive distillation, Solvent selection.

## 1. Introduction

Separation processes in general, and distillation in particular, account for a significant part of the whole world's energy consumption (Sholl et al., 2016). Despite the efforts in alternative separation technologies, distillation is envisioned to remain as the predominant separation technology in practice during the coming decades. When dealing with close-boiling or azeotropic mixtures, extractive distillation is of particular interest. The reason is that by using an external agent, the entrainer, the thermodynamic equilibrium of the original mixture is conveniently modified, and the separation becomes possible or much more energy-efficient. However, the process of selecting the most appropriate solvent to enhance the separation is far from being straightforward. The

solvent not only has to be thermodynamically powerful, but also economically viable and environmentally responsible.

The process of selecting the best solvent for a given mixture is particularly difficult because, typically, a large number of solvents need to be screened or novel solvents need to be designed from the vast chemical space. Therefore, an efficient pre-selection methodology that reduces the number of candidate solvents which need to be considered for more detailed evaluation is valuable. Brouwer et al. (2021) recently proposed a simple methodology for solvent pre-selection that does not rely on specialized software (e.g., COSMO-RS). Instead, it only uses experimental infinite dilution activity coefficients and the extended Margules equation. This makes it accessible to a broader range of engineers and researchers around the globe that might not have access to specialized software. However, its application is limited by the availability of experimental values for activity coefficients which in turn limits the number of solvents that are considered during the screening. Here, we extend this methodology by using our recently proposed Gibbs-Helmholtz Graph Neural Network approach (GH-GNN) (Sanchez Medina et al., 2022b) as a predictive method for enlarging the solvent search space. This removes the limitation of experimental activity coefficients availability and increases the number of solvents that can be considered during early-stage process design. Moreover, the original method's assumption of partly symmetric Margules parameters is here removed given that all binary mixtures can be potentially calculated by the GH-GNN.

## 2. Background

The relative volatility of the key components  $i$ ,  $j$  in a mixture indicates its ease of separation. At low or moderate pressures, it is defined as the ratio of the pure component vapor pressures  $P^\circ$  multiplied by their activity coefficients  $\gamma$ . Since the ratio of the vapor pressures ( $P_i^\circ/P_j^\circ$ ) within a small temperature range is constant, the modification of the relative volatility, at the same operating pressure, can only be accomplished by the introduction of a solvent that effectively modifies the ratio of the activity coefficients ( $\gamma_i/\gamma_j$ ). This ratio in the presence of a solvent is called selectivity. The maximum impact that a solvent has on the mixture's relative volatility occurs at infinite dilution conditions where the original mixture is infinitely diluted in the solvent. As a result, it is a common practice to rank the efficiency of different solvents according to the value of the selectivity at infinite dilution achieved by such solvents.

Recently, graph neural networks (GNNs) have shown promising performance on predicting activity coefficients at infinite dilution (Sanchez Medina et al. 2022a, Sanchez Medina et al., 2022b, Rittig et al. 2022). In this context, molecular graphs are constructed that contain atomic information (such as the type and hybridization of the atom) in their nodes and chemical bond information (such as the type of bond) in their edges. This information is then processed via a message-passing scheme. Moreover, in the GH-GNN model, global-level features (molecular descriptors describing the polarity and polarizability) are used as part of the learning process of activity coefficients at infinite dilution (Sanchez Medina et al. 2022b). First, the GH-GNN model uses two molecular graphs (corresponding to the solute and solvent in the mixture) that are passed through a molecular-level GNN. Then, a two-node mixture graph is constructed in which each node is defined by the solute and solvent embeddings learned by the first GNN. Intermolecular interaction information is gathered in the mixture graph using hydrogen-bonding information and the global-level embeddings of the solute and solvent graphs. This mixture graph is passed through a second GNN which learns the molecular interactions. Finally, an integrated Gibbs-Helmholtz expression is used to model the temperature-

dependent activity coefficients at infinite dilution. This GH-GNN model is here used to estimate the necessary activity coefficients to perform the solvent pre-selection.

### 3. Methodology

#### 3.1. Pseudo-binary relative volatility at infinite dilution (*inf-RV*)

The relative volatility between the key components  $i$  and  $j$  in the presence of the solvent is called pseudo-binary relative volatility and, at infinite dilution conditions, it is defined as

$$\alpha_{ij}^{\infty} = \frac{P_i^{\circ}}{P_j^{\circ}} \left( \frac{\gamma_i^{\infty}}{\gamma_j^{\infty}} \right)_s \quad (2)$$

where the activity coefficients at infinite dilution  $\gamma^{\infty}$  refer to the solute (i.e., key component  $i$  or  $j$ ) infinitely diluted in the solvent. These coefficients were calculated using the GH-GNN model. The pure component vapor pressures were calculated using the Antoine equation with parameters available from the NIST Chemistry WebBook (2022). The screening was performed over 911 molecular solvents obtained from the original GH-GNN work (Sanchez Medina et al. 2022b) which contrasts with the screening performed by Brouwer et al. (2021) where only 69 molecular solvents were screened due to the restrictions of limited experimental data availability. The pseudo-binary relative volatility at infinite dilution (*inf-RV*) with respect to all solvents was calculated at different temperatures of industrial relevance, and the solvents were ranked according to the mean value across all utilized temperatures. The applicability domain prediction of the GH-GNN model based on chemical classes and Tanimoto similarity was used to only consider predictions within the applicability domain of the model.

#### 3.2. Minimum solvent to feed ratio (*min-SF*)

As pointed out by Brouwer et al. (2021), the selection of solvents based on the pseudo-binary relative volatility at infinite dilution corresponds to situations where the solvent-to-feed ratio is very large. However, often much smaller solvent-to-feed ratios are used in practice. Therefore, the pre-selection of solvents was also carried out according to the minimum solvent-to-feed ratio (*min-SF*) that is necessary to have a pseudo-binary relative volatility equal to 3. This relative volatility value has been recommended as a threshold for which the energy savings due to employing extractive distillation are still considered attractive (Blahušiak, et al. 2018). Typically, if the relative volatility is increased beyond 3 the energy-savings are not as significant and extractive distillation becomes less attractive from an energetic perspective.

The extended Margules model (Eqs. 3-7) (Mukhopadhyay et al., 1993) is here used to estimate the activity coefficients at finite dilution. If one assumes that the ternary interaction parameter  $A_{123}$  is equal to zero, this equation has as its only parameters the activity coefficients at infinite dilution of the species involved which are here predicted by the GH-GNN model.

$$\ln(\gamma_1) = 2(x_1x_2A_{21} + x_1x_3A_{31}) + x_2^2A_{12} + x_3^2A_{13} + x_2x_3B_{123} - 2G^E \quad (3)$$

$$\ln(\gamma_2) = 2(x_2x_3A_{32} + x_2x_1A_{12}) + x_3^2A_{23} + x_1^2A_{21} + x_3x_1B_{123} - 2G^E \quad (4)$$

$$\ln(\gamma_3) = 2(x_3x_1A_{13} + x_3x_2A_{23}) + x_1^2A_{31} + x_2^2A_{32} + x_1x_2B_{123} - 2G^E \quad (5)$$

$$G^E = x_1x_2(x_2A_{12} + x_1A_{21}) + x_1x_3(x_3A_{13} + x_1A_{31}) + x_2x_3(x_3A_{23} + x_2A_{32}) + x_1x_2x_3B_{123} \quad (6)$$

$$B_{123} = 0.5(A_{12} + A_{21} + A_{13} + A_{31} + A_{23} + A_{32}) - A_{123} \text{ with} \quad (7)$$

$$A_{ik} = \ln(\gamma_{ik}^{\infty})$$

Therefore, by employing only the infinite dilution activity coefficients together with the extended Margules model, the vapor-liquid equilibrium behavior of a given mixture, in the presence of a solvent, can be estimated. And the minimum solvent-to-feed ratio (*min-SF*) to reach a relative volatility of 3 can be used as the ranking criteria for pre-selecting solvents.

## 4. Results

### 4.1. Aliphatic-aromatic separations

We studied a collection of binary systems composed of benzene and one of the following alkanes: n-hexane, n-heptane, n-octane, n-nonane and n-decane. The above mentioned two metrics (i.e., *inf-RV* and *min-SF*) were used to rank the set of solvents considered during the screening. It is possible that, these two metrics lead to different solvents during the selection process depending on how the solvent's impact varies at the finite dilution. For instance, Figure 1 shows the top 10 solvents selected by each metric for the n-heptane-benzene system. While some solvents were selected by both metrics (indicated with "(Both)"), most solvents differ depending on the metric used for the selection.

Figure 1. Pseudo-binary relative volatility of the top 10 solvents selected for the mixture n-heptane-benzene using *min-SF* and *inf-RV*. The horizontal red dotted line indicates a pseudo-relative volatility of 3. The star markers denote the corresponding pseudo-binary relative volatilities at infinite dilution.

Table 1. Top 5 solvents selected for the binary mixture benzene and the indicated alkane based on the minimum solvent-to-feed ratio (*min-SF*) to reach a pseudo-binary relative volatility of 3. The range of *min-SF* for the selected solvents is also indicated for each mixture.

Rank	n-hexane <i>min-SF</i> : 0.3	n-heptane <i>min-SF</i> : 1.0-1.2	n-octane <i>min-SF</i> : 2.3-3.7	n-nonane <i>min-SF</i> : 3.3-8.4
1	1,2,3-Tris(2-cyanoethoxy)propane	(2Z)-2-Butenedinitrile	(2Z)-2-Butenedinitrile	Water
2	1,3-Propane sultone	Succinonitrile	Succinonitrile	(2Z)-2-Butenedinitrile
3	(Methylsulfonyl)ethane	Ethylene carbonate	Water	Succinonitrile

4	3,3'-(oxybis(ethyleneoxy))dipropionitrile	Sulfolane	3,3'-Iminodipropanenitrile	Carbamoyl
5	Sulfolane	1,3-Propane sultone	Carbamoyl	(2E)-2-Butenedinitrile

The above occurs whenever the intersection of the pseudo-binary relative volatility trajectory of one solvent intersects the one of another solvent above the threshold of relative volatility equal to 3. For this reason, even though water was selected as the best solvent for this system based on *inf-RV*, it is actually the worst among the 17 solvents depicted on Figure 1 based on *min-SF* (i.e., its impact decays more rapidly as the solvent-to-feed ratio decreases compared to the other solvents). Given that in practice very large solvent-to-feed ratios are not plausible, a better pre-selection criterion should be *min-SF*. Table 1 shows the top 5 solvents selected for each of the considered aromatic-aliphatic binary systems.

As can be seen in Table 1, industrially relevant solvents are often selected which strongly indicates that the proposed methodology is able to pre-select promising candidates. For example, sulfolane (Tilstam, 2012), ethylene carbonate (Mohsen-Nia et al., 2010) and succinonitrile (Tan et al., 2022) are often reported as promising solvents for aliphatic-aromatic separations. For the mixture n-decane/benzene the top 5 selected solvents are similar to the ones for the system with n-nonane with a *min-SF* ranging from 5.6 for the top solvent to 30.5 for 1,4-Butynediol.

#### 4.2. Olefin-paraffin separations

To exemplify olefin-paraffin separations the separation of the following binary mixtures was studied: n-hexane/1-hexene, n-butane/2-butene, n-heptane/1-heptene and n-propane/propene. Table 2 contains the top 5 performing solvents based on the *min-SF* metric along with the ranges needed to achieve a pseudo-binary relative volatility of 3. In the case of the n-heptane/1-heptene mixture only three solvents were found to increase the relative volatility up to 3 (corresponding to the top 3 solvents for the mixture n-hexane/1-hexene). This shows the difficulty of separating olefin-paraffin mixtures. Dimethyl sulfoxide stands out from the selected solvents for the n-propane/propene mixture agreeing with an extractive process already patented (Carter, 1981).

Table 2. Top 5 solvents selected for the shown olefin/paraffin mixtures based on the minimum solvent-to-feed ratio (*min-SF*) to reach a pseudo-binary relative volatility of 3. The range of *min-SF* for the selected solvents is also indicated for each mixture.

Rank	n-hexane/1-hexene <i>min-SF</i> : 5.2-439	n-butane/2-butene <i>min-SF</i> : 1.0-1.3	n-propane/propene <i>min-SF</i> : 1.0-2.5
1	Fumaronitrile	Carbamoyl	Glycerin
2	(2Z)-2-Butenedinitrile	Cyanogen	Dimethyl sulfoxide
3	Succinonitrile	Fumaronitrile	Carbamoyl
4	m-Phenylenediamine	2,4-Dinitrobenzaldehyde	Cyanogen
5	Morpholine	Succinonitrile	1,3-Benzenediamine

## 5. Conclusions and future work

The pre-selection of good candidate solvents for extractive distillation is an important step during chemical process development. Obtaining experimental data for all potential solvents in a large chemical space is practically impossible given the limitations of time and resources to which the exploration is bounded. Therefore, accurate and efficient predictive methods that assist experts in selecting suitable solvents are necessary. Here, we extend the methodology proposed by Brouwer et al. (2021) by using the Gibbs-

Helmholtz Graph Neural Network (GH-GNN) (Sanchez Medina et al., 2022b) together with the extended Margules equation to estimate the activity coefficients of all chemical species in the mixture of interest. With this, the minimum solvent-to-feed ratio needed to increase the relative volatility of the mixture to a certain point can be estimated. The impact of assuming an infinite solvent-to-feed ratio is also discussed by comparing the solvent selection obtained by the relative volatility at infinite dilution to the one obtained by using the minimum solvent-to-feed ratio metric. The latter is recommended because it approximates the real conditions of an extractive distillation column better. Industrially relevant solvents were selected using the proposed methodology for both aliphatic/aromatic and olefin/paraffin separations showing the validity of the proposed framework. The proposed methodology has been made open-source at [https://github.com/edgarsmdn/SolvSelect\\_GHGNN](https://github.com/edgarsmdn/SolvSelect_GHGNN).

## **Abstract**

Operator performance is key to ensuring safety in process industries. Therefore, a comprehensive assessment of their performance is critical for smooth and efficient plant operation. Traditional performance assessments are not comprehensive as these ignore cognitive aspects of performance. On the other hand, while eye-tracking-based approaches do provide a cognitive assessment during operating training, their applicability in a real-time real setting is limited. Existing eye-tracking systems come with many constraints affecting users' mobility (restricted movement in all directions) in their environment. In addition, it is beyond the scope of current eye trackers to track multiple users working in an environment, such as in control rooms. Satisfying the above requirements makes these eye-trackers expensive. In this work, we demonstrate the capabilities of an in-house developed cost-effective eye-tracking system to track users' eye movement in an unconstrained environment while giving freedom of head movement. Human subject studies are conducted to compare operators' gaze patterns and the quality of data with that obtained using commercial eye trackers. The results generally agree with data quality obtained using commercial eye trackers. Hence, the performance of the developed eye-tracking system is comparable to existing commercial eye-trackers while overcoming their limitations, such as restricted user movement, single-user tracking, and high cost.

**Keywords:** Operator performance, Eye-tracking, Cognitive behavior, Human error, Safety

## **1. Introduction**

The use of innovative automation methods and safety management systems has helped the process industries become safer. Nonetheless, accidents of varying severity continue to occur. Studies indicate that human error is the primary cause of 75% of industrial accidents (Jung et al., 2020). The safe running of the plant is guaranteed by cooperation between the human and automation system. Operators must constantly keep track of the functioning of several control mechanisms and step in when the automation fails to provide as expected. However, the rise of digitization and the complexity of automation

have changed the operator's role and added new difficulties (Nazir et al., 2014). To ensure optimum operating conditions, operators must collect, prioritize, and utilize data from several information sources. This adds to their cognitive workload and worsens if the operators are not well trained. Therefore, keeping track of the operator's performance is crucial to ensure safe plant operation.

Addressing operators' performance issues involves improving their competency and continuously observing their behavior in the field (Dai et al., 2016). There are hardly any studies focusing on monitoring operator performance in real time. For operators to become more competent, research has largely focused on providing them with the proper feedback based on their performance. Most performance assessment methods depend on subjective expert opinion that disregards the operators' cognitive behavior (Nazir et al., 2015). There is widespread agreement that cognitive behavior plays a significant role in unusual circumstances and accident causation.

In recent years, researchers have used eye-tracking to get insights into human cognitive behavior. It has been extensively used in understanding human cognitive processes such as situation awareness, expert level, learning ability, and mental state of the operator in several safety-critical domains such as healthcare, aviation, automobile driving, and nuclear power plant (Srinivasan et al., 2019). This work shows the potential of an in-house developed eye-tracker (Dhrushti-AI) capable of monitoring human performance in an unconstrained environment. Human subject studies were conducted to compare the quality of data obtained from Dhrushti-AI and commercial eye trackers.

Dhrushti-AI can enhance safety by addressing the challenges associated with operator performance during training and in real-time plant operation. Firstly, it can be used along with operator training simulators to identify flaws in the operator's understanding of the process during training. Secondly, it can be deployed in real control room settings to monitor the operator's performance in real-time. In addition, we can enhance operators' situational awareness based on the insights from eye-tracking data. For instance, if operators miss any critical information from HMI (Human Machine Interface) appropriate feedback can be provided. Adequate situational awareness and skills are crucial, especially when dealing with abnormal situations (Bhavsar et al., 2017).

## 2. Literature Review

Eye tracking is a technique to record a person's eye movement. It provides eye gaze coordinates (where the person is looking) and pupil size. There are two primary categories of eye trackers in the market: remote and wearable. The latter must be worn, whilst the former may be positioned close to the test screen. Wearable eye trackers are appropriate when the scenario is not constrained to a narrow space and the test participants are allowed to walk about the test setting. However, it may create discomfort for the user to wear a device for a long time, such as in a control room setting where operators work for long hours. On the other hand, a remote eye-tracker is set up in the user environment and it doesn't hinder the subject. Current key market players are Tobii, Smart Eye, SMI (SensoMotoric Instruments), and SR Research (Hermens et al., 2013).

Eye-tracking measures have been found to correlate with various aspects of human performance in safety-critical domains. An eye-tracking study using SMI Eye-tracking Glasses was conducted with air traffic controllers to capture their mental workload (Rodríguez et al., 2015). The study reveals that increased pupil diameter is associated with an increased mental workload. Another study found that changes in mental workload

can be measured using frequency domain analysis of pupil size measurements. An increase in workload is connected with an increase in power level at low frequencies (Peysakhovich et al., 2015). The experiments are conducted by using a single-screen setup. During the whole experiment, participants' gaze position and pupil diameter were recorded with a remote SMI RED eye-tracker (SensoMotoric Instruments GmbH, Germany) at a sampling rate of 120 Hz. Wu et al. (2020) used eye-tracking to analyze the difference in cognitive behavior of 32 novices and 7 expert operators when doing activities involving standard operating procedures of accident scenarios in nuclear power plants (NPPs). The study uses iView X head-mounted eye tracking device (SMI, Germany) at a sampling rate of 50 Hz to capture the eye movements of operators. It was found that novice operators had a greater fixation rate, illustrating their intense search in various places and inexperience in tackling process disturbances.

Our previous studies with control room operators reveal distinct mental models of expert and novice operators (Shahab et al., 2021). During an abnormal situation, expert operators have higher dwell time on important regions of HMI than novices (Sharma et al., 2016). Further, operators who failed to complete a disturbance task have higher gaze entropy indicating that their eye gaze is distributed in several regions on the HMI unrelated to the disturbance (Bhavsar et al., 2017). These approaches provide interesting insights into operators' cognition and help identify the reason behind human failure. These eye-tracking studies were conducted using Tobii TX300 eye tracker to record participant eye movements at sampling rates of 120 Hz.

In summary, existing commercial eye-tracking systems support single-user and single-screen HMI with limited user movement. However, this is not the case in real control rooms where the operator needs to gather information displayed on multiple screens and involves a lot of head movements. In addition, satisfying the above requirements makes these eye-trackers expensive. In this work, we demonstrate the potential of an in-house developed cost-effective eye-tracker system (Dhrushti-AI) to record multiple users' eye movements from an unconstrained environment.

### 3. Methodology

In this work, we demonstrate the capabilities of an eye-tracker (Dhrushti-AI) developed to track users' gazes in the presence of head movements in unconstrained environments. The eye-tracker comprises an array of cameras fitted with lenses and filters, illuminators, an optics controller, power sources, and a computing unit. The camera array observes a region of the environment to detect users' faces and track their gazes, referred to as the headbox. The eye-tracking system illuminates the headbox with light in the near-infrared region using the illuminators. The optics controller generates the trigger signals to control the camera exposure and the illuminators. The compute unit detects the faces in the images obtained from the camera array using Histogram of Oriented Gradients (HOGs) based face detectors. Face recognition algorithms are utilized to identify faces and enable

Fig. 1. Steps involved in the proposed eye-tracking system

the application of user-specific calibrated gaze models. Key landmarks in the faces (such as corners of the eyes, nose, etc.) are extracted and are used to estimate the users' head orientation. The pupils from these images are detected using several image processing techniques, such as thresholding, closing, and contour extraction. The eye-tracker utilizes the head orientation, pupil center locations, and the user-specific calibrated gaze model to estimate the gaze direction. The output of the developed eye-tracker is the user's gaze location (coordinates on screen) and pupil size variation. The overall methodology to get the output is shown in Fig. 1. The raw gaze data from Dhrushti-AI is processed further to obtain fixation and saccades using the Velocity-Threshold Identification (I-VT) filter.

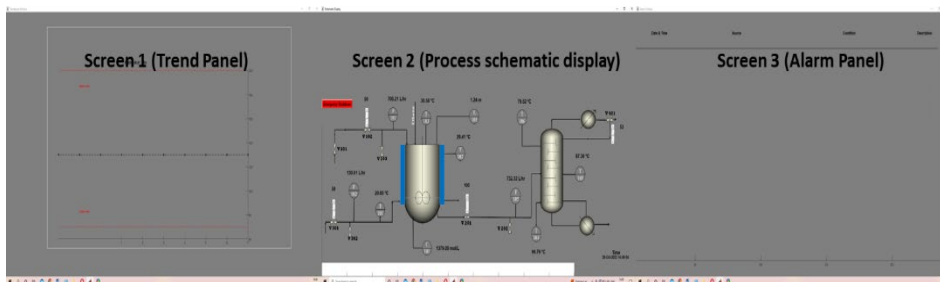

Fig. 2. HMI with the schematic and display units for three screens.

To demonstrate the applicability of the developed multi-screen eye-tracker (Dhrushti-AI), we used a simulated chemical process plant with which operators interacted via HMI. The HMI is presented to the operator on a display comprising three screens. Eight participants volunteered to play the role of the control room operator. They were asked to monitor and intervene during abnormalities. The participants first interacted with the process via a single-screen HMI of the chemical process displayed on the center screen. During this period, the other two screens were blank. In the next study, we displayed the HMI on all three screens. A typical task involves bringing a process variable(s) to within the acceptable limits as specified by the region between the upper limit and lower limit in Fig. 2. Eye-tracker calibration for each participant was performed at the beginning of the experiment. Next, we compare the results obtained from Dhrushti-AI and a commercial eye-tracker.

#### 4. Result & Discussion

In this section, we illustrate the potential of Dhrushti-AI in capturing user eye movements in an unconstrained environment (typical control room setup) without restricting their head movements. The eye-tracker was set up to monitor user head movements at a distance of 45-60 cm from the center camera while allowing 25 cm horizontal movement and 35 cm vertical movement. Initial results have been obtained with image capture rates of 30 frames per second (FPS), while the hardware capabilities allow image capture at rates higher than 120 FPS. Gaze angle errors of less than  $1.5^\circ$  were obtained.

As discussed earlier, we conducted experiments with human subjects using Dhrushti-AI and commercial eye-tracker Smart-eye Aurora. We compared the quality of data obtained from the eye-tracker using data loss (proportion of missing gaze samples including blinks; (Holmqvist, 2017) and proportion of all fixation durations (dwell time) outside of various information sources, i.e. AOI's (Areas of interest) on the HMI. When dealing with abnormal situations operators primarily focus on various information sources which are relevant to the situation at hand (Sharma et al., 2016). Therefore, it is expected that the

proportion of fixation on non-information sources obtained from Dhrushti-AI should be minimum and comparable to commercial eye trackers.

Fig. 3. Comparison of results obtained from Eye-trackers (Dhrushti-AI and Smart Eye Aurora): based on (a) Fixation on non-information sources, (b) Data loss

The results for both Dhrushti-AI and Smart Eye Aurora obtained from eight participants are shown in Fig. 3a and 3b. As observed from Fig. 3, the data loss for Dhrushti-AI is lesser compared to the smart-eye aurora (Fig.3b). This signifies that even with a significant head movement of participants, Dhrushti-AI is able to capture the operator's gaze position from all three screens. Similarly, the proportion of time on non-information sources obtained from Dhrushti-AI is also similar to that of Smart Eye Aurora (Fig.3b). It is important to note that few of the AOIs on the HMI were smaller and even with such lower size, Dhrushti-AI indicates that operators were looking at the AOIs most of the time.

In addition to the data quality, we also compare the distribution of dwell time on AOIs for operators who successfully completed the task and those who failed. The results indicate that experts have higher dwell time on key variables and exhibit lower gaze entropy than novices. These results are in general agreement with earlier works (Sharma et al., 2016; Bhavsar et al., 2017; Shahab et al., 2021) conducted using commercial eye trackers. In light of these results, the performance of the developed eye-tracking system (Dhrushti-AI) is comparable to existing commercial eye-trackers while overcoming their limitations such as restricted head movement, single screen setup, and high cost. Thus, the developed eye tracker has the potential to be deployed in control rooms for assessing operator performance.

## 5. Conclusion

In this work, we demonstrated the potential of a multi-screen- multi-user eye tracking system (Dhrushti-AI) in capturing operator cognitive behavior in a process plant setting. There is widespread agreement that cognitive behavior plays a substantial role in the causes of abnormal situations and accidents. The capabilities of Dhrushti-AI are demonstrated with a 3- screen workstation as the HMI. We conducted experimental studies to validate the quality of the developed eye tracker with that of the commercially available eye-trackers. Results indicate that the performance of the Dhrushti-AI is lesser than the existing commercial eye trackers, in terms of data loss. The operator's cognitive

behavior obtained from Dhrushti-AI is also in general agreement with our earlier works (Sharma et al., 2016) with research-grade eye trackers (smart eye Aurora). Thus, the developed multi-screen eye-tracker can be deployed in actual control rooms to infer the cognitive behavior of operators previously confined to controlled environments. Additionally, it can identify flaws in the thought process of novice operators during training and help them in acquiring knowledge about the process dynamics. In the future, we can increase the system's potential to meet the requirements of large-scale industrial studies.

## Abstract

An Operator Training System (OTS) is a digital twin of a process plant, that enables to study the plant before it really exists. That does not just give an opportunity to train the operators of the plant, before plant startup, but it also helps to get a better understanding of the process.

In this work, an OTS of a novel process to produce biochemicals from wood was developed. Aiming to train the staff while the plant is still under construction and to gain a deep knowledge of this plant, a digital twin of the plant was built. According to the requirements for the training, a mid-fidelity process model was combined with a high-fidelity model.

To finalize the OTS, the process model was connected to the original Distributed Control System (DCS) environment.

It can be shown that the development of a process plant digital twin is highly effective in accelerating the commissioning of a new plant. On the one hand, the operators are enabled to gain a deep knowledge of the process and the operation of the plant even before the plant is finalized. On the other hand, the detailed simulation gives valuable insights to the process, which help to understand the process, the conditions, and the regulation concept.

**Keywords:** Digital Twin, Operator Training System, dynamic Simulation.

## 1. Introduction

In the recent years, Digital Twins became omnipresent in a huge variety of applications. They are of major contribution to the digitalization of the industries, still one of the actual megatrends. Of course, also the process industry applies Digital Twins over the life cycle of a production plant like described by Labisch (2019). An Operator Training System (OTS) is a digital twin of a process plant, that enables to study the plant even before it really exists. That does not just give an opportunity to train the designated operators of the plant, before plant startup, but it also helps to get a better understanding of the process and the plants functionalities as investigated by NAMUR (2006).

The aim of an OTS as a Digital Twin is, to reproduce the physical plant as well as the real drive and control mechanisms, the automation and operation. Both, the real plant and the virtual plant, i.e. the Digital Twin are compared in Figure 1.

The overall plant including the automation can be separated in five layers. For the real plant the first layer is the real process plant. The process plant contains all units like columns, reactors, vessels pumps, valves, pipes and so on.

The second layer of the real system contains all actuators and sensors. Actuators are typically pump motors and valve drives. The sensors measure all relevant process data like temperature, pressure, flow, and composition.

The third layer with the remote IOs (Input/Output) describes the operations or assets, transferring the data from the second layer (sensors and actuators) to the automation system (AS), the fourth layer.

Finally, the automation system is connected to the human machine interface (HMI). The fifth layer. By means of the HMI the state of the process and the plant is visualized, and the operator can control the plant.

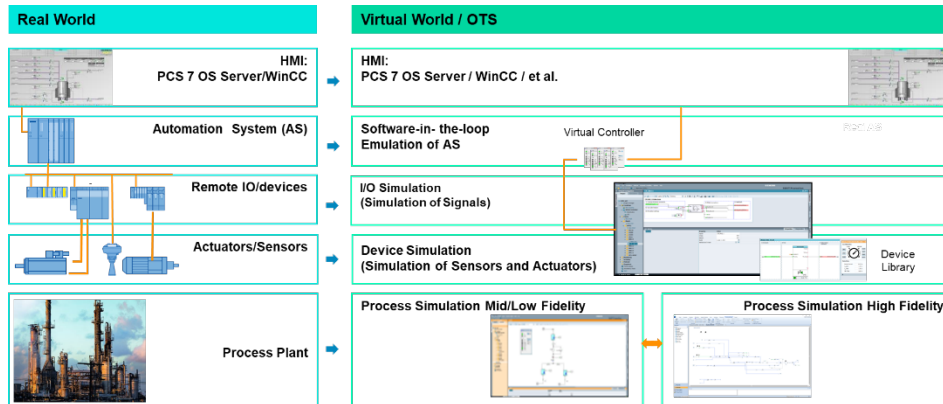

Figure 1: structure of a real plant and an OTS

Analogue to the overall real plant, an operator training system as a digital twin of a real plant has the same five layers. But in contrast to the real plant, most of the five layers are virtualized in an operator training system.

The basis for an operator training system is the process simulation. This virtual plant represents the real process plant (layer one). By means of the process model the behavior of the plant is simulated. For an operator training system mainly dynamic process models are used. With a dynamic process model the transient behavior of the process can be described. Dynamic simulations can be quite computationally intensive. Thus, it is aimed, to model as accurate as possible but only as accurate as needed, to save time and resources. Based on the needs for the training and considering the computational effort the fidelity of the process model can be selected. Even the combination of low or mid fidelity models with high fidelity models is possible. Within the process model all necessary process measurements are calculated and transferred to the next layer.

In this layer, the device simulation, the behavior of the measurement devices and actuators is simulated. The time dependent behavior of valve drives and motors as well as all necessary feedback signals for the automation system are calculated. Based on a library containing the necessary device modules, the relevant device simulation model can be composed.

The device Simulation is connected to the IO simulation (third level). In this level the signals from the device simulation are transferred to the fourth level, the emulation of the automation system and vice versa. The IO-level can also be used without the first two layers (process simulation and device simulation) to generate signals for testing the automation system.

The automation system itself is emulated in the fourth layer. With virtual controllers running on standard personal computers (PCs) the behavior of the automation system is simulated. The configuration of the automation system of the real plant can be loaded to the virtual controller without any change. The automation is executed and behaves like the real automation system.

Finally, as in the real plant control, the automation system of the Digital Twin is connected to the original human machine interface (HMI) of the distributed control system (DCS). In this fifth layer the process can be controlled with the very same operating screens like in the control room. Thus, with the OTS, the operator will not realize the differences between the Digital Twin and the real plant. Neither the operating system, i.e. the HMI, nor the effect of operating actions differ from the real plant. The only difference might be the actual surrounding of the operator, which might be anywhere but is not limited to the real control room.

In the current work, an example of an OTS is given as develop and implemented for a real process. The process itself is described, the proceeding of the development and the benefits are shown.

We think the correct split of model fidelity is an essential decision in the design of an OTS. Furthermore the use of tools that can direct reuse the original data of the automation system reduces the effort of design.

## 2. Development of the Operator Training System.

In this work, an OTS was realized, representing a novel process to produce biochemicals from wood. Aiming to train the staff while the plant is still under construction and to gain a deep knowledge of this plant and the corresponding process, a digital twin of the plant was built. According to the requirements for the training, to reproduce the real process and to consider the complexity of the process, a mid-fidelity process model was combined with a high-fidelity model. To finalize the OTS, the process model was connected to the original DCS environment. Thus, including the sensor and actor level, virtual controllers are applied to train the effect of interferences while the process is running, but also to train the startup, shutdown, disturbances, and an emergency case.

In the next section the process itself is briefly presented. Furthermore, the modeling of the process and it challenges are described.

### 2.1. Biochemical Process

The biochemical process is divided in several main steps (see Figure 2). In a first step the tree trunks are grinded into chips. These chips are washed and prepared for the next process steps. The wood is then enzymatically converted into intermediate products. These intermediate products are separated from the slurry and purified. Further, these intermediate products are chemically converted to the final product. In a last step the biochemicals are purified in a distillation train to achieve the required purities. The final purified products are stored in several tanks.

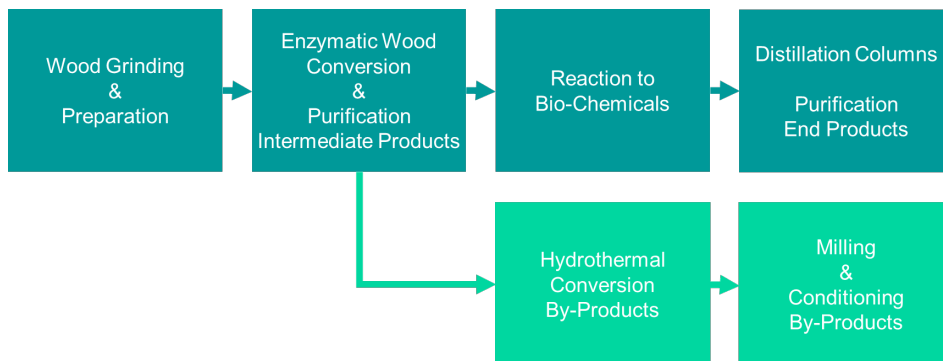

Figure 2: Block flow diagram of the process

The residual components separated from the slurry after the enzymatic conversion are further processed. This complex mixture is converted hydrothermally. These side products are further conditioned by drying and milling and the final byproducts are stored in tanks for further distribution.

## 2.2. Process modelling

To create a detailed but economic OTS, the process was divided in many individual process steps. Some of the process steps require an intensive, high-fidelity simulation, while others can be represented by less intensive mid-fidelity models. Some process steps were not considered at all, since their complexity is very low, the operation is well known and the benefit of a Digital Twin is comparatively low.

Therefore, the wood unloading, storage and coarse chopping are not represented in the Digital Twin. Furthermore, since the process model is focused on the main operation of the plant, cleaning facilities (cleaning in place (CIP) systems) and safety relief valves, sampling points and drain valves were neglected.

Simple models, thus, a mid-fidelity simulation was chosen for plant components such as tank farms, truck unloading stations and storage. Furthermore, utility systems, if relevant for the process simulation, are also simulated with simple models. Complex chemical processes such as reactions or phase changes typically do not take place in these parts of the plant, so that it is reasonable, to apply the simpler models in these cases.

In contrast, plant sections with reactions and apparatuses in which the phase equilibrium plays a decisive role (e.g. distillation columns) are simulated with high fidelity models. But not only the necessary complexity was decisive for the division into mid fidelity or high-fidelity models, but also that there are not too many interfaces between the two simulators.

### 2.2.1. High fidelity process model

Decisive for each process model is the application of reliable and evaluated physical properties of the participating components. Within this work, property packages adjusted to the requirements of the single process steps were defined for the high-fidelity models. On the one hand, all the necessary components for the various process steps had to be available. On the other hand, the number of components should be kept low, to keep the simulation simple and therefore not too slow. Some of the physical property packages contain up to about 50 different components. This is necessary to consider all the relevant educts and products of a reaction as well as solvents and components effecting the equilibrium or the reaction conditions like pH value and so on. Especially the many different materials, which are part of the natural raw material wood behave differently throughout the single process steps and must be accounted for individually. Nevertheless, the component list was simplified, wherever possible, to keep the simulation as simple as possible. In any case, the property packages were optimized to reduce the simulation effort, but precisely describe the phase behavior and the heat and mass balance at the same time. This was achieved by using the non-random-two-liquid model (NRTL model). Another challenge beside the large number of components was to get all the necessary parameters in the NRTL model. For well-known components like water these parameters are known. For other components like the components of wood these parameter, not only the pure component parameters but also the binary interaction parameters, must be adapted to the existing measurements.

An accurate simulation also requires a detailed description of the reaction kinetics in dependence of time and conditions (e.g. temperature, pressure or pH value). In the described process, several conversions (enzymatical, chemical, and hydrothermal) need

to be considered. All of the reactions are complex and depend on the detailed composition of the raw material, which cannot be assumed to be constant. Accordingly, the detailed mechanism for these very complex reactions is not yet investigated in such a detail, as the input for the simulation requires. Thus, based on lab trials and data from pilot plans, the key influencing parameters for each conversion step was identified. In simplified descriptions, the effect of those parameters on the conversion rate was defined and the respective kinetics was implemented into the simulation.

Beside a reliable physical property package and adequate reaction mechanisms, models for the simulation of the single unit operations are required. For many parts of the plant, the model could be created with the standard elements from the simulation library. The library contains, for example, devices such as pumps, valves, tanks, heat exchangers and distillation columns.

However, there are also devices/plant parts that could not be created directly with devices from the library. For example, a model for a filter press had to be developed in-house. The filter press runs continuously, operating in different steps. Thus, the filling with suspension, dehumidifying by pressing, washing with fresh water, repeated pressing, and eventually further drying with compressed air need to be covered by the developed model. All these steps were implemented with a simplified substitute model, using the available library models like component splitters, pumps, and tanks, linked, controlled, and coordinated with an adjusted logic.

A tailor-made model also had to be implemented in case of the reactors. Although different reactors are available in the library, the kinetics derived for the reactions could not simply be integrated into them. In most cases the reactor was represented by a simple tank. The reaction is then calculated in a spreadsheet, taking the current state of the influencing reaction conditions into account. The actual material conversion and heat of reaction is then implemented by a virtual recirculated material stream.

In total, the entire high fidelity dynamic process model includes about 200 process and instrumentation diagrams (PIDs) with the corresponding devices. The total process model has been divided into around 15 individual models, so that the complete model can also be calculated in real time during the transitions from one state to the other with sufficient accuracy and with sufficiently small simulation steps. These individual models are simulated in parallel. The individual models are connected to each other so that the streams are transmitted from one model to the other at the interfaces.

### *2.2.2. Mid fidelity process model*

Compared to the simulation with the high-fidelity model, the mid-fidelity model uses simplified approaches. A maximum of 20 different components are taken into account in the mid fidelity model, only. In addition, ideal gases or ideal liquids are assumed for the physical properties. Phase changes are not taken into account. These simplified assumptions are sufficient for the plant parts to be modeled like storage tanks, truck unloading and loading stations. All of the used models are part of the available libraries.

### *2.2.3. Model integration*

The individual sub models of the high-fidelity process model are connected to the mid fidelity simulation. The corresponding information for the streams is exchanged at the transitions. The entire plant is thus simulated with the two types of process models. In addition, the process models are linked to the device level (layer two). In the device level the manipulated variable for the actuators in the process model is calculated, such as the valve position or the engine speed. In the same way, the corresponding signals for the control technology are calculated from the measured values of the process model.

### 3. Benefits of the OTS

The aim of developing the OTS for the described process, was to be able to train the future operators already while the plant is still under construction. Nevertheless, additional benefits were generated also on the way to develop the OTS. Important insights into the process could already be gained in the first phases of the project. On the one hand, the process design was improved for the distillation columns. The column design was based on the heat and mass balance generated from the steady state simulation, fitted to lab experiments and pilot plant data. Since manual adjustments, applied in the steady state simulation, cannot be used for dynamic simulation, a more general and robust approach was chosen. With improved physical properties, the simulation could be better adapted to the existing measurement results. However, it turns out that the required purities could not be achieved in one separation step with the chosen design of the column. Based on this knowledge, the design of the column could be adjusted just before ordering and a potentially expensive redesign during commissioning could be avoided. Normally such a redesign is not done, and the equipment is specified based on the heat and mass balance. In addition, the control concept could be adapted and improved based on the dynamic simulation, especially in the area of the distillation columns. Based on the dynamic behavior of the system, the control concepts could be optimized. Above all, the interactions between several columns in a row could be considered. Furthermore, it was possible to define the necessary number and position of complex online measurement methods to determine the purity.

### 4. Conclusion

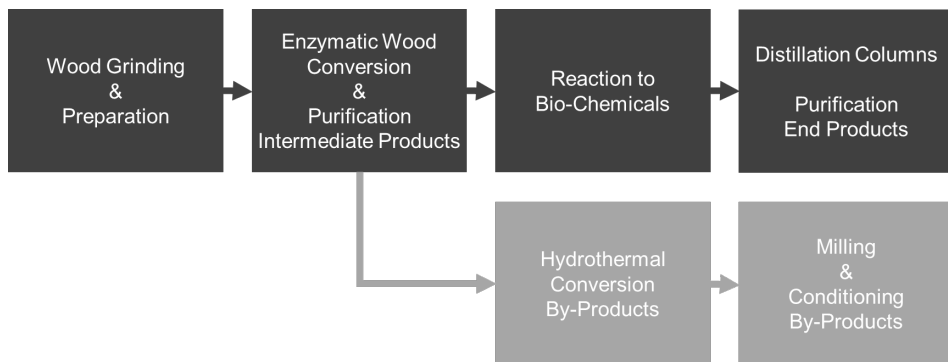

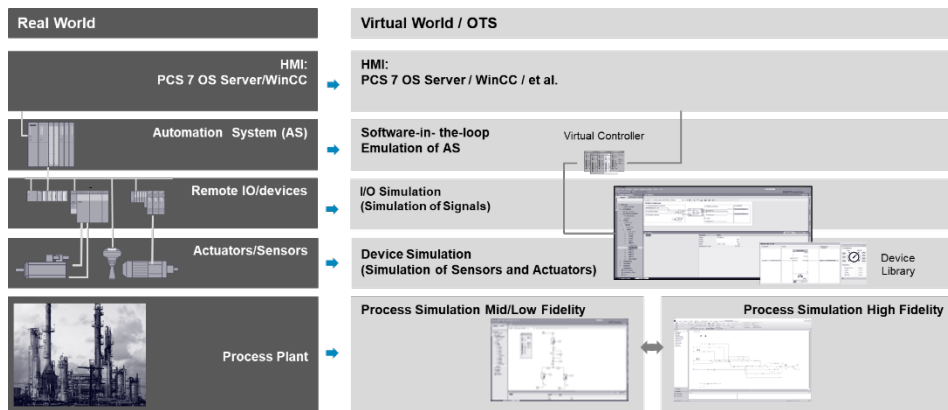

In this work, an example for a successful development of an OTS is given. By the combination of mid- and high-fidelity models, an accurate, fast simulation of a novel, high complex and comprehensive process was realized. The OTS was successfully applied, to train the operators prior to the commissioning.

Furthermore, it was shown, that a digital twin in the form of an operator training system (OTS) can not only be used to train the plant operator. The normal operation of the plant as well as the start-up and shutdown of the plant can be practiced without risk. In addition, a wide variety of malfunctions and emergency situations can be simulated and the optimal behavior in these cases can be practiced again and again. All of this can also be done before the system is actually put into operation.

In addition, however, the dynamic simulation for an operator training system also provides valuable information in relation to system design and control concepts. In this way, knowledge about the later operation of the system can be gained in the early phases and can be incorporated into the construction of the system.

## Abstract

Modular plants built from process equipment assemblies (PEAs) provide a promising solution to challenges like increasing requirements of flexibility and faster time to market. To leverage the potential in processes under good manufacturing practice (GMP) conditions new methods are required to support the process validation in modular plants. In this paper, we present an integrated approach to Quality by Design and Process Performance Qualification between lab and production scale in modular plants applying the Product-Process-Resource model by Bamberg et al. (2021). Furthermore, we reformulate the Extended Flexibility Analysis by Ochoa et al. (2021) adapting the terminology to the Quality by Design context and adding the control inputs in the form of the CPPs to the optimization problem. The problem is solved by means of a grid search algorithm. The approach is studied and illustrated in a simulation-based case study with a simple reaction system.

**Keywords:** Modular Plant, Quality by Design, Design Space, Process Performance Qualification, Scale-Up

## 1. Introduction

Modular Plants, in accordance with VDI 2776 (VDI, 2020) and VDI/VDE/NAMUR 2658 (VDI/VDE/NAMUR, 2019) consist of Process Equipment Assemblies (PEAs) enabling increased flexibility and faster time to market. These properties make this concept attractive to industry sectors which often operate under the good manufacturing practice (GMP) conditions. Although aspects like PEA selection (Schindel et al., 2021) and orchestration (Klose et al., 2022) have been considered in literature before, process validation and quality by design in modular plants remain rather underdeveloped. However, Mädler et al. (2022) did present a digital twin-concept for smart process equipment assemblies supporting process validation in modular plants. This concept aims to make prior knowledge Findable, Accessible, Interoperable, and Reusable (FAIR) and relates different kinds of information to a set of methods for process validation in modular plants. In this paper we build upon these results and propose a method for Quality by Design (QbD) and Process Performance Qualification (PPQ) in the production scale based on knowledge gained in process development with lab scale PEAs. The remainder of this paper is structured as follows: section 2 provides background information about Process Validation, Quality by Design, and the Product-Process-Resource model. In section 3, a method for the Design Space Identification and Design of Experiments in the

PPQ is introduced. This method is researched in a simulation-based case study with a reactor PEA in section 4. Section 5 provides a conclusion and an outlook.

## 2. Background

### 2.1. Process Validation

According to the FDA Guidance (FDA, 2011), Process Validation consists of the (1) Process Design, the (2) Process Qualification (PQ), and the (3) Continued Process Verification stage. In the Process Design stage, the process development takes place which is frequently carried out according to the Quality by Design (QbD) paradigm. Furthermore, the scale-up of the process from lab scale to production scale must be achieved. The Process Qualification stage consists of two parts: the “Design of Facilities & Qualification of Equipment and Utilities” and the Process Performance Qualification (PPQ) (Katz and Campbell, 2012). The PPQ aims to confirm the capability of the process and plant for reproducible production of sufficient quality (Katz and Campbell, 2012). The Continued Process Verification aims to assure that the process is kept under control and to facilitate continued process optimization (Katz and Campbell, 2012).

### 2.2. Quality by Design and Process Performance Qualification

The Quality by Design paradigm proclaims the application of scientific methodologies and risk management in order to assure product quality. An important sub-concept is the Design Space (DS), which can be interpreted as a mathematical model relating the Critical Process Parameters (CPPs), the Critical Material Attributes (CMAs) of the feed streams, and sufficient values for the Critical Quality Attributes (CQAs) of the product. The Design Space is enclosed by the Knowledge Space (KS), which “contains all the information about all regions of the process that have been investigated” (Boukouvala et al., 2017) in the process development. To assure product quality under disturbances, usually a Normal Operating Range (NOR) is chosen within - but smaller than - the Design Space (cf. Boukouvala et al., 2017). The identification of the Design Space frequently requires extensive experimentation which is often very expensive at the production scale. In such cases, the identification of the Design Space is done using lab scale experiments. Afterwards, the results are scaled to production scale and tested in the PPQ.

### 2.3. Product-Process-Resource Model

The Product-Process-Resource model outlines the distribution of knowledge (Bamberg et al., 2021). The Capability Model (CM) is a product-independent description of the PEA capabilities like e.g., cooling capacity. The Transformation Model (TM) is a plant-independent description of the process. Combining these two models yields the Operation Model which can be used to characterize, identify, or predict the Design Space.

## 3. Methodology

The method presented in this paper is based on a scale-down concept employing behavioral models of PEAs in lab scale and production scale. Experiments for the identification of the Design Space are carried out utilizing a lab scale PEA which mimics the capabilities of the production scale PEA (e.g., Services with related Process Parameters). The gained knowledge is then used to derive an Operation Model for the production scale which is applied to estimate the Design Space in the production scale PEA and plan experiments for the PPQ.

### 3.1. A behavioral model for the Knowledge Space

In this paper, we consider a system of nonlinear algebraic equations (NAEs) for behavioral models of Knowledge Space

$$\mathbf{0} = \mathbf{h}(\mathbf{x}, \mathbf{u}_{\text{CMA}}, \mathbf{u}_{\text{CPP}}, \boldsymbol{\theta}_{\text{TM}}, \boldsymbol{\theta}_{\text{CM}}) \quad (1)$$

where  $\mathbf{x}$  denotes the states of the system,  $\mathbf{u}_{\text{CMA}}$  the independent inputs related to the CMAs,  $\mathbf{u}_{\text{CPP}}$  the independent inputs related to the CPPs,  $\boldsymbol{\theta}_{\text{TM}}$  the parameter values related to the Transformation Model of the material system, and  $\boldsymbol{\theta}_{\text{CM}}$  the parameters related to the Capability Model of a PEA in lab scale or in production scale.

### 3.2. Identification of a Knowledge Space in Lab Scale

In the lab scale, a Knowledge Space can be identified applying prior knowledge from Product Development and the Capability Model of the lab scale PEA. This Capability Model provides one or multiple potential behavioral models according to equation (1). Furthermore, it does provide the parameters  $\boldsymbol{\theta}_{\text{CM}}$  including their values which have been captured during a separate characterization of the PEA and/or through other previous experimental data. In addition, it provides information about  $\mathbf{u}_{\text{CPP}}$  of the PEA, which relate to the services of the PEA and their service parameters. Furthermore, the characteristics of the educts ( $\mathbf{u}_{\text{CMA}}$ ) are assumed to be controllable during lab experiments. The Knowledge Space is identified by applying statistical DoE to obtain initial parameter estimates and afterwards model-based design of experiment (MBDoe) for parameter estimation and for model discrimination. The results of these experiments are used to identify the parameter values  $\boldsymbol{\theta}_{\text{TM}}$  including uncertainty estimates, applying e.g., the maximum likelihood method and confidence intervals.

### 3.3. Identification of the Design Space and Process Performance Qualification in the Production Scale

The Transformation Model and its parameters  $\boldsymbol{\theta}_{\text{TM}}$  are extracted from the Operation Model of the lab scale PEA and combined with the Capability Model of the characterized production scale PEA. The resulting Operation Model is used to identify the Design Space in the production scale and optimally design experiments for the PPQ.

For the identification of the Design Space from a Knowledge Space described based on a behavioral model according to equation (1), the Extended Flexibility Analysis approach by Ochoa et al. (2021) is adopted. In contrast to this publication, we consider the control inputs in our approach, which relate to the Critical Process Parameters  $\mathbf{u}_{\text{CPP}}$  (or  $z$  in Ochoa et al. (2021)). In the Flexibility Analysis, the permitted ranges of the CQAs are described by the feasibility functions

$$g_j(\mathbf{x}, \mathbf{u}_{\text{CMA}}, \mathbf{u}_{\text{CPP}}, \boldsymbol{\theta}_{\text{TM}}, \boldsymbol{\theta}_{\text{CM}}) \leq 0 \quad (2)$$

These functions are combined with the behavioral model from equation (1) and constraints to the independent inputs and parameters. The following formulation the flexibility index can be calculated

$$\begin{aligned} F &= \max_{\delta_{\text{CMA}} \in \mathbb{R}^+} \delta_{\text{CMA}} \\ \text{s.t. } \chi(\boldsymbol{\theta}_{\text{CM}}) &= \max_{\mathbf{u}_{\text{CMA}} \in \mathcal{I}_{\text{CMA}}} \min_{\mathbf{u}_{\text{CPP}} \in \mathcal{I}_{\text{CPP}}} \max_{\boldsymbol{\theta}_{\text{TM}} \in \mathcal{I}_{\text{TM}}} \max_{j \in \mathcal{J}} g_j(\mathbf{x}, \mathbf{u}_{\text{CMA}}, \mathbf{u}_{\text{CPP}}, \boldsymbol{\theta}_{\text{TM}}, \boldsymbol{\theta}_{\text{CM}}) \leq 0 \\ \mathbf{h}(\mathbf{x}, \mathbf{u}_{\text{CMA}}, \mathbf{u}_{\text{CPP}}, \boldsymbol{\theta}_{\text{TM}}, \boldsymbol{\theta}_{\text{CM}}) &= \mathbf{0} \\ T_{\text{CMA}}(\mathbf{u}_{\text{CMA}}) &= \left\{ \mathbf{u}_{\text{CMA}} : \mathbf{u}_{\text{CMA}}^{\text{N}} - \delta_{\text{CMA}} \Delta \mathbf{u}_{\text{CMA}}^- \leq \mathbf{u}_{\text{CMA}} \leq \mathbf{u}_{\text{CMA}}^{\text{N}} + \delta_{\text{CMA}} \Delta \mathbf{u}_{\text{CMA}}^+ \right\} \\ T_{\text{CPP}}(\mathbf{u}_{\text{CPP}}) &= \left\{ \mathbf{u}_{\text{CPP}} : \mathbf{u}_{\text{CPP}}^{\text{LB}} \leq \mathbf{u}_{\text{CPP}} \leq \mathbf{u}_{\text{CPP}}^{\text{UB}} \right\} \\ T_{\text{TM}}(\boldsymbol{\theta}_{\text{TM}}) &= \left\{ \boldsymbol{\theta}_{\text{TM}} : \boldsymbol{\theta}_{\text{TM}}^{\text{LB}} \leq \boldsymbol{\theta}_{\text{TM}} \leq \boldsymbol{\theta}_{\text{TM}}^{\text{UB}} \right\} \end{aligned} \quad (3)$$

where  $\delta_{\text{CMA}}$  denotes the scalar flexibility index of a CMA and the superscripts LB and UB denote lower and upper bounds respectively. The optimization problem reads as follows: the maximum among the feasibility functions  $g_j$  is maximized based on the range of the uncertain transformation variables  $\boldsymbol{\theta}_{\text{TM}}$ , which have been identified within the lab

scale. Hence, the multistage optimization problem generates the worst-case scenario in terms of the CQA values. The CPPs are then used to derive minimized values for the feasibility functions in the worst-case. Afterwards, the feasibility function values are again maximized based on the allowed range of CMA values. If the feasibility function values remain below 0, the range of CMAs is feasible, and the flexibility test is passed. Finally, the range of CMAs is maximized by maximizing the flexibility index  $\delta_{\text{CMA}}$ . This multistage optimization problem is known to be very computationally expensive (cf. Ochoa and Grossmann, 2020). Thus, Ochoa and Grossmann (2020) list two reformulations for special cases like e.g., the vertex enumeration approach for cases with 1-D quasi-convex feasibility functions, and two general reformulations.

For this publication, we use a similar algorithm to the vertex enumeration approach according to Ochoa and Grossmann (2020), but instead of only considering the vertices, a grid of points is used which is spanned by the CMAs and Transformation Model parameters. This is done to get an approximation to the global solution in cases of non-convex feasibility functions. This approach is computationally very expensive, but easy to implement and therefore suits the demonstration of the approach.

The result of this Extended Flexibility Analysis is a hyperrectangle formed by the CMAs. In PPQ, the vertexes of this hyperrectangle with some safety margin should be tested in combination with the corresponding CPPs to span a Normal Operating Range. Furthermore, the Operational Model can be used to search for an optimal operation point.

## 4. Case Study

### 4.1. Example case

Let us assume that an owner/operator aims to scale-up a synthesis of a product B in an exothermic, homogeneous second order reaction from educt A, but B degrades in another reaction to C:

Two stirred tank reactor (STR) PEAs (one in lab scale and one in production scale) are available to the owner/operator. Both PEAs can be operated in a continuous STR (CSTR) operation mode, but their minimal residence times and cooling capacities may differ. The behavioral models under sufficient homogenization can be described as follows

$$0 = \frac{1}{\tau} (c_{i,\text{in}} - c_i) + \sum_{j=1}^{\text{NR}} \left[ \nu_{i,j} k_{0,j} \exp\left(-\frac{E_{A,j}}{RT}\right) \prod_{i=1}^{\text{NC}} c_i^{\gamma_{i,j}} \right] \quad (4)$$

where the subscripts  $i$  and  $j$  denote the species and the reactions with the number of components NC and the number of reactions NR respectively,  $c$  are the molar concentrations,  $\nu$  the stoichiometric coefficients,  $k_{0,j}$  the Arrhenius constants,  $E_{A,j}$  the activation energies,  $R$  the universal gas constant,  $T$  and  $\gamma$  the reaction orders regarding a species. Assuming a dosing and tempering service of ideal behavior, the residence time  $\tau$  and the temperature  $T$  can usually be classified as CPPs. The concentration of species A in the feed  $c_{A,\text{in}}$  is a CMA. The owner operator aims to achieve the following CQAs:

$$\text{Profit} = \frac{100c_B - 25c_{A,\text{in}}}{\tau} \geq 2 \quad (5)$$

$$\text{Purity} = \frac{c_B}{c_A + c_B + c_C} \geq 0.8 \quad (6)$$

### 4.2. Identification of a Knowledge Space in Lab Scale

For the sake of simplicity, we assume that the Transformation Model parameter values including uncertainties in Table 1 have been identified in lab scale applying MBDoE.

Table 1: Assumed parameter values including uncertainty measures identified in lab scale

Parameter	Unit	Nominal value	Minimum	Maximum
$k_{0,1}$	L/(mol×min)	3.2e+06	3.19e+06	3.21e+06
$k_{0,2}$	1/min	5.2e+06	5.19e+06	5.21e+06
$E_{A,1}$	J/mol	4.0e+04	3.99e+04	4.01e+04
$E_{A,2}$	J/mol	5.5e+04	5.49e+04	5.51e+04

### 4.3. Identification of the Design Space in Production Scale

Figure 1 visualizes the CQAs (Profit, Purity) in dependence of the CMA ( $c_{A,in}$ ) and the CPPs ( $\tau, T$ ) for the nominal parameter values  $\theta_{TM}$  according to Table 1. Applying the Flexibility Analysis formulation in equation (3), the relation for the flexibility index according to Figure 2 is calculated. A conservative estimate of the flexibility index can be derived to be 0.175 assuming a  $\Delta u_{CMA}$  value of 1 mol/L for  $c_{A,in}$ . This can also be seen in the Figure 2 on the right side, where it can be recognized that the Profit and Purity values barely reach the sufficient level for combination of CPPs ( $\tau = 44$  min,  $T = 300$  K).

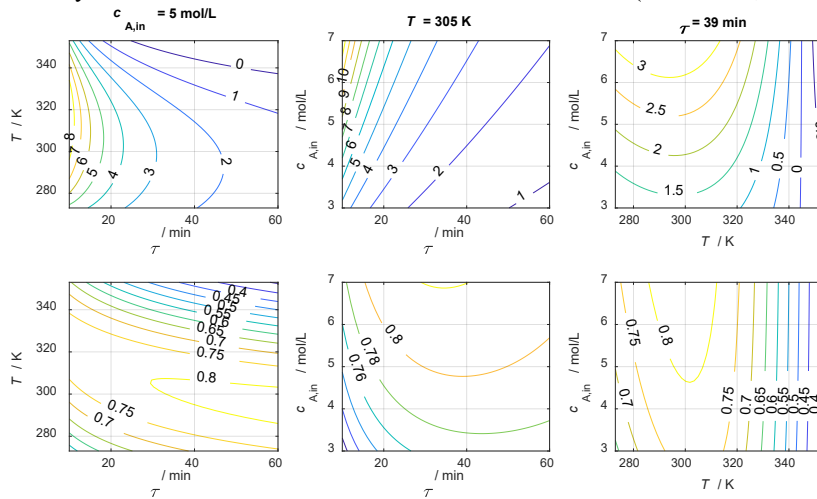

Figure 1: Profit (top row) and Purity (bottom row) in dependence of the CMA (molar concentration of species A in the feed  $c_{A,in}$ ) and the CPPs (residence time  $\tau$ , temperature  $T$ )

Figure 2: Maximum value of the feasibility functions  $u_{max}$  in dependence of the flexibility index  $\delta_{CMA}$  (left); and the corresponding the Profit (central) and Purity (right) at  $c_{A,in} = 4.825$  mol/L

## 5. Conclusions

In this paper, we introduced a methodology for Quality by Design and Process Performance Qualification in modular plants. This approach is based on similar PEAs in lab scale and production scale, which are integrated with Capability Models including behavioral models and Capability Model parameters. To avoid expensive experimentation in the production scale, experiments are carried out in the lab scale PEA initially based on statistical design of experiments and afterwards based on MBDoE. The identified Transformation Model including the Transformation Model parameter values with uncertainty measures are then integrated with the Capability Model of the production scale PEA. The resulting Operation Model is used to identify the Design Space and plan experiments for the PPQ. Furthermore, we suggested a reformulation of the Extended Flexibility Analysis problem proposed by Ochoa et al. (2021) by adding the CPPs (or control inputs) to the optimization problem. This allows the consideration of control actions based on measured deviation of the CMAs in the operation phase.

In future work, the approach should be applied to more complex and real-world problems. In addition, the design of experiments, experimentation and identification in lab scale should be further elaborated. Furthermore, the solution algorithm for the Extended Flexibility Analysis should be reworked adopting the general formulations by Ochoa and Grossmann (2020), or surrogate-based formulations.

## Abstract

The application of Digital Twins for scale-up in Modular Plants is envisioned to significantly reduce the necessary time-to-process for new-to-market products and address scale-up challenges. To identify application specific requirements of a Digital Twin for scale-up in Modular Plants, expert interviews were conducted. The spectrum of identified requirements as well as plant life cycle aspects are incorporated into a workflow concept which illustrates the partial models of Digital Twins, as well as the interfaces for the exchange of information. Also presented is a roadmap illustrating the cluster-specific development pathways for Digital Twins for scale-up in Modular Plants.

**Keywords:** Digital Twin, Modular Plants, process development, scale-up

## 1. Introduction

In order to maintain a competitive edge within dynamic markets, such as pharmaceuticals and specialty chemicals, Modular Plants (MP) must address the following requirements: (1) reduce the time-to-market, (2) provide increased flexibility, and (3) have increased efficiency (Bernshausen et al., 2019). An additional hurdle is the scale-up from laboratory to production. The integration of Digital Twins (DT) into process development workflows could potentially significantly speed up the equipment selection of a manufacturing process. For this purpose, the combination of standardized, predesigned equipment such as Process Equipment Assemblies (PEA) with DTs is poised to be an integral tool to facilitate rapid time-to-process (Mädler et al., 2022a; Mädler et al., 2022b).

## 2. Background

### 2.1. Digital Twins

According to Rosen et al. (2019), a Digital Twin is a semantically linked collection of all digital artefacts, including design and engineering data as well as operational data and behavior descriptions. Moreover, a Digital Twin is intended for a specific purpose (Rosen et al, 2019). Bamberg et al. (2021) view the Digital Twin as consisting of different partial models which can be structured in the **Product-Process-Resource-Model** (Bamberg et al., 2021). The model of Bamberg et al. (2021) was applied to Modular Plants by Mädler et al. (2022b) to illustrate how the knowledge distribution in a Digital Twin is divided between the PEA manufacturers and the owners/operators (O/O). The **capability model** is a product independent description of a PEA containing structural, operational, and behavioral information about the PEA, independent of a concrete process. The

**transformation model** is a plant independent and product specific description of the process used to derive information for a concrete PEA such as residence times. Combining the capability model and the transformation model yields the **operation model**, which is used for recipes and optimization of process parameters (Mädler et al., 2022b).

### 2.2. Modular Plants

The structure of Modular Plants is outlined in the VDI 2776 Part 1. Modular Plants (MPs) consist of functional equipment assemblies (FEAs), which are combined into process equipment assemblies (PEAs) (VDI, 2020). PEAs can be further characterized as intelligent modules which are computerized and (static) self-describing (Mädler et al., 2022a). Automation in Modular Plants is described in VDI/VDE/NAMUR 2658 (VDI/VDE/NAMUR, 2019). The operation of multiple PEAs in a modular plant is carried out via the process orchestration layer (POL). Here, the Module Type Package (MTP) serves to integrate PEA into the POL, yielding a standardized and non-proprietary means to describe the automation in a PEA (Klose et al., 2019).

### 2.3. Process Design in Modular Plants

Applying modular-based plant design methodology results in decreased planning and construction times by incorporating predefined modules and devoting time to the selection process instead of to individual design of each piece of equipment (Bramsiepe et al., 2012). Methodologies for matching PEAs in process design can be found in literature. One example is Schindel et al. (2021), who utilize Matching Matrices to match the technical attributes of a PEA with the process requirements (Schindel et al., 2021).

## 3. Methodology: Expert Interviews

In order to delineate the task-specific requirements of a Digital Twin for Modular Plants for process development and scale-up, semi structured interview questionnaires based on a set of working hypotheses were conducted with experts from industry and academia with experience ranging from 3 to 45 years (cf. Koch, 2022). To elicit requirements, the interview transcripts were then analyzed using the coding agenda methodology of Mayring (Mayring, 2021). The coded requirements were grouped into five clusters, which were adapted from Oppelt (2016). These clusters, shown in Figure 1, are defined as follows:

- (1) **Acceptance:** demonstrate DT and gain acceptance by Owners/Operators (O/O)
- (2) **Efficiency:** address bottlenecks in process development workflows with DTs
- (3) **Integration:** exchange of information using interfaces
- (4) **Reusability:** reusability of models and information for new products
- (5) **Usability:** accessibility and ease of use of DT by O/O

To illustrate how these requirements are applied to the DT workflow concept and roadmap, four selected requirements from the integration cluster are discussed: interfaces, semantically linked models, CAE System, and DEXPI. These requirements are well suited to describe the DT workflow in Section 5. A detailed explanation of all requirements can be found in Koch (2022). The requirement of a CAE System serves as a tool to store the digital artefacts including design and engineering data (cf. Rosen et al. (2019)), which are part of the essential information contained in a DT. The requirement of interfaces refers to the interfaces, which are needed as part of a DT in order to transfer information between engineering tools, such as a simulation tool and a CAE system. Interface also refers to interfaces between a simulation tool and operating data contained in a POL. One specific identified bottleneck in the process development workflow is the difficulty in transferring information between engineering tools.

Figure 1: Clustered, expert identified requirements of Digital Twin for scale-up (Koch, 2022).

The integration of interfaces to support the obligatory semantic linkage between CAE tools could address this specific bottleneck, resulting in a DT concept that is in line with Rosen et al. (2019). The last requirement explained here, is DEXPI (Wiedau et al., 2019), which refers to a specific, openly available information model which could be used to transfer data between engineering tools and should be integrated into a DT concept.

## 4. RoadMap: Vision for Digital Twins in Scale-Up

### 4.1. Background and Prerequisites

In order to create a DT concept, the requirement catalog (see Figure 1) was workshopped and refined with software experts from industry. The final requirements catalog was used to create a Roadmap, shown in Figure 2, which outlines the necessary steps to enable this Digital Twin Vision for scale-up in Modular Plants. As a starting point for this specific Digital Twin, a minimum baseline was defined with two prerequisites: (1) MTP is integrated into both the lab and production PEAs and (2) the lab and production PEA setup makes both scale-up and scale-down possible.

### 4.2. Explanation

The roadmap depicts five different pathway lines with a series of different symbols. Each pathway line aligns with a requirement cluster explained in Section 3, and each symbol refers to a different requirement identified from the expert interviews shown in Figure 1. Additionally, each requirement was allocated to a specific tool or interface, which are categorized as follows: simulation tool (circle), plant engineering tool (triangle), interface (star), both simulation tool and plant engineering tool (diamond), and undefined/other (square). Moreover, each requirement is allocated to a specific time frame represented by the background color: short term (dark grey), medium term (medium grey), and long term (light grey).

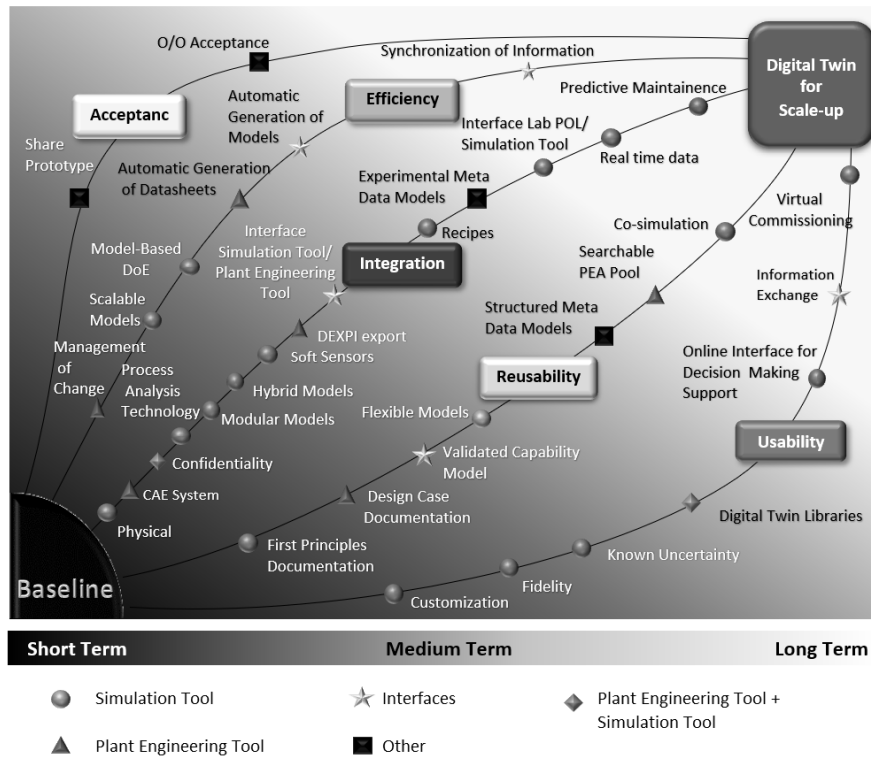

Figure 2: Roadmap for a Digital Twin for Scale-up using Modular Plants. Adapted from Koch (2022).

The requirements are ordered along each cluster pathway and allocated to a time frame based on both the importance to experts as well as the feasibility of the required technology needed to implement a requirement. Addressing each of these requirements yields the vision of a Digital Twin for scale-up potentially facilitating faster time-to-process.

## 5. Digital Twin Concept

### 5.1. Workflow Concept

Short- and medium-term requirements illustrated in the roadmap in Figure 2 are addressed with a concept workflow for a Digital Twin for scale-up, which is shown in Figure 3. This presented DT concept workflow assumes that information such as design and engineering data is contained in a Plant Engineering Tool, behavior descriptions in a simulation tool, operational data from the production PEA in the Production POL, and experimental data in the Lab POL. The partial models within the simulation tool are aligned with Bamberg et al. (2021). Here, the operation model for the Lab PEA consists of a capability model, representing the characterized capability of the Lab PEA resource and a transformation model for a specific product. This transformation model is shared with the production PEA and also contains relevant information from product development. This product specific transformation model is combined with the capability model from the production PEA into an operation model. Operational data from the Production PEA is used to improve the Operation Model for the Production PEA, illustrating the semantic linkage between models. The result of this workflow is an in-spec product for the supply chain.

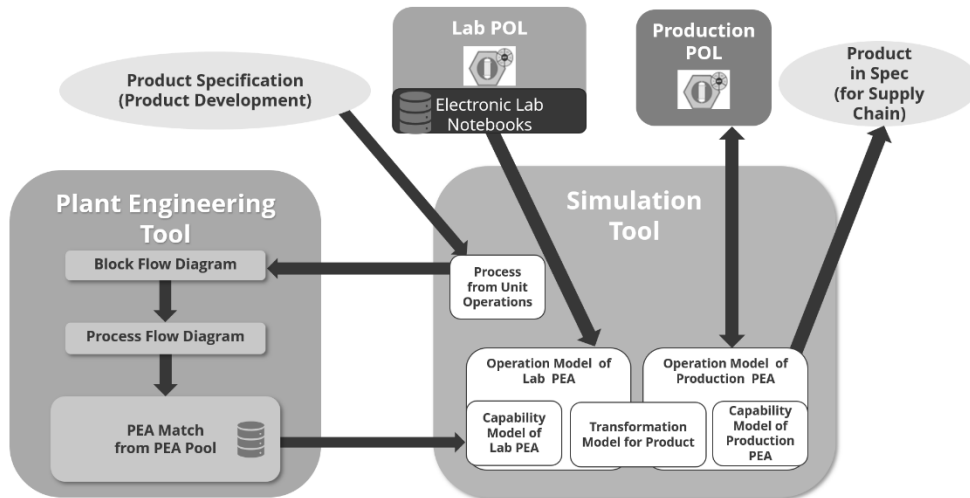

Figure 3: Workflow for a Digital Twin for Scale-up. Adapted from Koch (2022).

### 5.2. Requirements of an Interface to Support PEA Matching

To demonstrate how the expert requirements were integrated into the workflow shown in Figure 2, the interface between the simulation tool and plant engineering tool is explained. This Digital Twin concept centers around having a repository of resource models, or PEA Pool, stored in a searchable databank of a plant engineering tool containing design and engineering data. This addresses the requirement of structured and searchable information as well as CAE system. Here, the PEA matching methodology of Schindel et al. (2021) is referenced to identify the requirements of an interface that supports matching process models (from a simulation with unit operations) to resource models in a PEA Pool. This workflow begins with a resource independent simulation of a process for a new product based on a simulation created from unit operations (reaction, distillation, etc.). Schindel et al. (2021) assume that the information about a process provided by a simulation for matching PEAs to processes is low. Moreover, technical criteria (e.g., temperature, pressure, and viscosity) are identified as the most important information for successful matching. These technical criteria are found to be unit operation and material flow specific; thus, important technical criteria for the selection of a heat exchanger are not the same as the criteria for the selection of a distillation column. Hence, for a match to be successful it is essential that the simulation tool propagates these necessary technical criteria through an interface to a plant engineering tool. The exchange of this information across this interface could be supported by an information model such as DEXPI (Wiedau et al., 2019). A detailed explanation of this workflow concept, interfaces, and partial models as well as how the requirements were used to create this concept can be found in Koch (2022).

## 6. Discussion and Conclusion

In this paper, expert interview derived requirements of Digital Twins for scale-up in Modular Plants are presented and discussed. The expert interviews yielded purpose specific requirements that must be integrated into a Digital Twin for scale-up, thereby supporting process development and potentially facilitating faster time-to-process. Considering these requirements and challenges along with plant life cycle aspects, a concept DT workflow was presented. This DT concept was used to illustrate the linkage

of the capability models and transformation models of a Digital Twin as well as the integration of information contained in the plant engineering tool, Lab POL, and Production POLs. This semantic linkage enables efficient engineering workflows, resulting in faster time-to-process and ultimately model reuse when PEAs are integrated into new processes. These interfaces support PEA matching, which is critical in order to support faster time-to-process. Moreover, the presented roadmap illustrates clear pathways to enable this vision of a Digital Twin and the necessary steps which must be taken to achieve this goal. Using this DT concept and roadmap, the next step is to develop prototypical implementations demonstrating the added benefit of a Digital Twin, resulting in owner/operator acceptance of a Digital Twin and integration into existing engineering workflows within process development. Moreover, prototypes should address the uncertainty and challenges in scale-up, specifically focusing on the linkage between scalable simulation models and information models. Here, alliance with existing standards is necessary to support the exchange of essential and potentially proprietary information between the partial models of the Digital Twin.

## Abstract

This work aims to model and simulate a pressure swing adsorption (PSA) unit for CO<sub>2</sub>/syngas separation using rigorous multi-bed and single-bed approaches. The PSA unit was designed to purify syngas from reverse water-gas shift (RWGS) reaction to application in the Fischer-Tropsch synthesis. Process simulations were performed in Aspen Adsorption® v10 software, using the Peng-Robinson equation of state. The association of 7 adsorption beds was considered, allowing the continuous production of purified streams, in a concept of cyclic steady-state operation. The single-bed approach reduces the system complexity and improves the processing power/time without losing precision. A sensitivity analysis showed that integrated RWGS and PSA processes can produce syngas with purity above 94.65% with an H<sub>2</sub>/CO molar ratio of 1.50. The total recovery was around 99.98% and 99.57% for H<sub>2</sub> and CO, respectively, for an adsorption pressure of 20.00 bar, and a desorption pressure of 1.50 bar.

**Keywords:** Pressure swing adsorption, Syngas purification, Adsorption of CO<sub>2</sub>, Process simulation.

## 1. Introduction

Syngas is a mixture composed mainly of carbon monoxide (CO) and hydrogen (H<sub>2</sub>), whose importance as a building block for oxygenates production and Fischer-Tropsch (FT) synthesis to hydrocarbons (Theampetch et al., 2021) has increased. Syngas composition depends on its production technology, which includes methane reforming processes and reverse water-gas shift (RWGS) reaction (Dasireddy et al., 2021), which converts CO<sub>2</sub> and H<sub>2</sub> into CO. For the syngas to achieve the specification of the desired derivative, for instance, FT synthesis, major impurities such as CO<sub>2</sub> must be removed from the gas stream. Methods such as membranes, absorption, and adsorption have been used to separate CO<sub>2</sub> from syngas. Among these, adsorption is a well-established purification technology due to its efficiency, operational flexibility, low costs, and absence of by-products when combined with an effective regeneration process (Wibowo et al., 2021). In parallel adsorbent beds, alternated adsorption/desorption steps are used to maintain continuous feeding and high productivity. Adsorption performances depend on the operation parameters, such as gas type, mixture properties, temperature, and pressure (Kacem et al., 2015). The CO<sub>2</sub>/syngas separation can potentially be carried out,

at moderate temperatures and pressures, using adsorbent materials, such as zeolites and activated carbon (Wilson *et al.*, 2020), which affects the unit process design. These processes may be categorized according to the desorption technique employed, such as temperature swing adsorption (TSA), vacuum swing adsorption (VSA), pressure swing adsorption (PSA), and combined options. Only a few applications of TSA to CO<sub>2</sub> capture have been found and large-scale VSA is highly electricity-demanding, which seriously impacts the electrical system. PSA is widely used in gas separation applications (Golmakani *et al.*, 2017). This work aims to model and simulate a PSA unit for CO<sub>2</sub>/syngas separation using rigorous multi-bed and single-bed approaches. The PSA unit was designed to purify syngas from the RWGS reaction to application in the FT synthesis. The novelty of the proposal lies in the application of PSA technology with a new arrangement of adsorption beds and operational stages to separate large amounts of impurities (~64% wt of CO<sub>2</sub>).

## 2. Methods and Modeling

PSA is a separation process whereby the gaseous components with weak physical interaction with the considered fixed phase, a solid material of high porosity, are separated from other substances. Highly interactive substances are adsorbed at higher pressures, and, after an adequate interval, the adsorption bed is intermittently depressurized to recover the product and regenerate the fixed phase at lower pressures (Durán *et al.*, 2022). In this proposal, CO<sub>2</sub> must be adsorbed, allowing syngas to pass through the adsorbent bed. The desorbed gas mixture, rich in CO<sub>2</sub>, is recycled to the RWGS reactor previously evaluated by Santos *et al.* (2022), considering a purge of 1% (Figure 1).

Figure 1. Process Flow Diagram of the general topology of the process.

### 2.1. Model implementation and parameters

Aspen Adsorption® v10 software was used to simulate the PSA unit. The Peng-Robinson equation of state was used for simulation. The extended Langmuir adsorption isotherms (Equation 1) and adsorbent parameters by Liu *et al.* (2020), and linear driving force adsorption kinetics (Equation 2) by Xiao *et al.* (2016) were used to predict the adsorption equilibrium behavior on a packed bed of activated carbon as the fixed phase. The same H<sub>2</sub> adsorption isotherms were used for H<sub>2</sub>O. This assumption is justified by the fact that H<sub>2</sub>O does not significantly affect the CO<sub>2</sub>/syngas separation, similar to H<sub>2</sub>, due to the hydrophobic character of activated carbon (Kumita *et al.*, 1994).

$$n_i^* = \frac{IP_{1,i} e^{\frac{IP_{2,i}}{T}} p_i}{1 + (\sum_{i=1}^N IP_{3,i} e^{\frac{IP_{4,i}}{T}} p_i)}, i = 1, \dots, N \quad (1)$$

$$\frac{\partial n_i}{\partial t} = k_i(n_i^* - n_i), i = 1, \dots, N \quad (2)$$

where  $n_i^*$  is the equilibrium adsorption amount of species  $i$  (mol/kg);  $IP_{k,i}$  are parameter  $k$  ( $k=1,4$ ) of the Extended Langmuir model of species  $i$ , (mol/kg bar), (K), (1/bar), (K);  $n_i$  is the dynamic adsorption amount coefficient of species  $i$  (mol/kg),  $k_i$  is the mass transfer coefficient of species  $i$  (1/s).

2.2. PSA unit simulation

The association of 7 adsorption beds was considered for the PSA unit, allowing the continuous production of purified streams, in a concept of cyclic steady-state operation. The operational phases considered were: 1- Adsorption (A): Retention of higher adsorbent affinity species; 2- Equalizations (depressurizations) (EnD): Sequential bed depressurization to recovery product; 3- Proving purge (PP): Product utilization to clean adsorption bed interstitial spaces; 4- Blowdown (B): Depressurization for regeneration; 5- Purge (P): Bed interstitial clean-up for regeneration; 6- Equalizations (pressurizations) (EnP): Product recovery through sequential bed pressurization; and 7- Final pressurization (FP) with the clean product. Figure 2 brings the time-dependent diagram, showing the integration of each adsorption bed during a complete operating cycle.

Bed	Steps																													
1	A											E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP									
2	E1P	FP	A										E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP								
3	E3P	E2P	E1P	FP	A										E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP						
4	B	P	E3P	E2P	E1P	FP	A										E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP				
5	E3D	PP	B	P	E3P	E2P	E1P	FP	A										E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP		
6	E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP	A										E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP
7	A		E1D	E2D	E3D	PP	B	P	E3P	E2P	E1P	FP	A																	

Figure 2. Integration of adsorption beds during a complete operating cycle.

To simulate the multi-bed column adsorption, rigorous multi-bed and single-bed approaches were used. In the first approach, all existing beds were added to the simulation and connected via material streams by interaction valves and holdup tanks. In the single-bed approach, only one bed was modeled, and an interaction block was used. This block records the material profile from the rigorously modeled column and reruns it at user-defined points to simulate returning material. To make this approach possible, each adsorbent bed must be identical and undergoes the same steps in a given cycle.

Since the adsorption process is exothermic, the enthalpy variation is small, and the simulations were considered isothermal. The temperature of the adsorbent bed was kept constant at 298.15 K during the complete operating cycle. The pressure of the adsorption step was set at 20.00 bar for integration with the FT synthesis. The pressure of the purge step was set at 1.50 bar to avoid vacuum operation. Identical dead volumes before and after the adsorbent bed were considered. Table 1 summarizes the pressure and duration of the steps of an operating cycle.

Table 1. Conditions of the PSA process operation cycle.

Step	Pressure (bar)	Time (s)
A	20.00	360
E1D	20.00 → 15.42	60
E2D	15.42 → 8.57	120
E3D	8.57 → 5.58	60
PP	5.58 → 3.82	120
B	3.82 → 1.50	60
P	1.50	120
E3P	1.50 → 3.60	60
E2P	3.60 → 7.71	120
E1P	7.71 → 10.26	60
FP	10.26 → 20.00	120

A sensitivity analysis was performed to find the appropriate residence time for the syngas production respecting the length/diameter ratio of 4 for the adsorbent bed. To assess the performance of the operating cycle when the system reaches the steady state, the process performance indicators were estimated: syngas (CO + H<sub>2</sub>) purity (Equation 3), H<sub>2</sub>/CO molar ratio in the product, and CO, H<sub>2</sub>, CO<sub>2</sub>, CH<sub>4</sub> and H<sub>2</sub>O recovery per pass (Equation 4) and global recovery (Equation 5).

$$Pur_s = \frac{M_{p,s}}{M_p} \quad (3)$$

$$Rec_{i,pp} = \frac{M_{p,i,pp}}{M_{p,pp}} \quad (4)$$

$$Rec_{i,o} = \frac{M_{p,i}}{M_p} \quad (5)$$

where  $Pur_s$  is the syngas purity (%),  $M_{p,s}$  is the syngas in the product (kmol),  $M_p$  is the total product (kmol),  $Rec_{i,pp}$  is the recovery per pass of species  $i$  (%),  $M_{p,i,pp}$  is species  $i$  in the product per pass (kmol),  $M_{p,pp}$  is the total product per pass (kmol),  $Rec_o$  is the overall recovery (%),  $M_{p,i}$  is species  $i$  in the product (kmol).

### 3. Results and Discussion

#### 3.1. Rigorous multi-bed approach

The rigorous multi-bed approach allows the accurate calculation of column interaction and the more precise inclusion of advanced control systems. However, systems with over two beds are extremely complex. The system initialization is extremely detailed, and convergence is slow and hard. Each element of each bed must be independently included in the cycle manager, generating huge data tables with exact specifications. In this approach, when two different pressure streams are separated by a block, the simulator

automatically and instantly equalizes the pressures, preventing the step-by-step pressure reduction. For instance, if the top of two columns, at 1.50 bar and 20.00 bar, respectively, are separated by a closed valve, the calculation proceeds as normal. The moment the valve is slightly opened, both columns tops instantly go to around 15.00 bar. This creates unrealistic pressure profiles with huge increases in pressure. Thus, the modeling of each interaction is not recommended for multi-bed/column adsorption, since it is very time-consuming, a hard-to-converge system, and a power demanding processing.

### 3.2. Single-bed approach

The single-bed approach reduces the system complexity and improves the processing power/time without losing precision. Table 2 shows the effect of the residence time on the outcome of the PSA cycles with the single-bed approach. As expected, an opposite trend is observed in the pattern of syngas purity and CO and H<sub>2</sub> recovery per pass. Therefore, it is usually necessary to reach a compromise when selecting the optimum cyclic configuration. CO<sub>2</sub>/syngas separation also depends on the requirements of the intended application.

Table 2. Simulation results in terms of process performance indicators.

Residence time (s)	27	37	47	57
Adsorbent bed diameter (m)	1.83	2.03	2.20	2.34
Adsorbent bed length (m)	7.31	8.12	8.79	9.38
Syngas purity (%)	74.33	84.66	95.50	97.86
H <sub>2</sub> /CO molar ratio	1.51	1.67	2.14	8.91
CO recovery (%)	81.45	73.12	56.74	13.48
H <sub>2</sub> recovery (%)	99.02	98.61	97.97	96.65
CO <sub>2</sub> recovery (%)	40.14	20.13	5.96	1.66
CH <sub>4</sub> recovery (%)	60.10	43.93	18.47	2.10
H <sub>2</sub> O recovery (%)	99.02	98.61	97.97	96.65

The results of the sensitivity analysis showed that in the residence time of 47 s the purified syngas presented the molar composition of 0.03% CH<sub>4</sub>, 30.04% CO<sub>2</sub>, 5.53% CO, 64.39% H<sub>2</sub>, and 0.32% H<sub>2</sub>O. This composition is similar to that presented by Graciano et al. (2018) for FT synthesis in a slurry bubble column reactor. After the recycle convergence of the CO<sub>2</sub>-rich stream to the RWGS reactor, the proposed system to treat 50 tons/h of CO<sub>2</sub> was able to produce syngas with 94.65% purity and an H<sub>2</sub>/CO molar ratio of 1.50. The overall recovery was 99.98% and 99.57% for H<sub>2</sub> and CO, respectively. Table 3 shows the main streams of the proposed system shown in Figure 1. Each adsorbent bed in the PSA unit is 13.08 and 3.27 m in length and diameter, respectively.

Table 3. Component mass flow rate (ton/h).

Parameter	CO <sub>2</sub> + H <sub>2</sub>	RWGS product	PSA feed	Syngas	Recycle
Total	54.99	163.05	145.20	36.04	108.06
CO <sub>2</sub>	50.00	93.04	93.03	5.45	86.70
H <sub>2</sub>	4.99	3.00	3.00	2.95	0.05
CO	-	48.46	48.46	27.39	20.86
H <sub>2</sub> O	-	18.00	0.15	0.15	0.00
CH <sub>4</sub>	-	0.55	0.55	0.10	0.45

## 4. Conclusion

A PSA unit for CO<sub>2</sub>/syngas separation integrated into the RWGS process was studied. The single-bed approach was the best option for a multi-bed/column system, capable of

reducing the system complexity and improving processing power/time without losing precision. Considering syngas purity and CO recovery, a residence time of 47s was in good agreement with the literature data. After integrating RWGS and PSA units, the proposed system can properly treat and separate the RWGS reaction products for a CO<sub>2</sub> load of 50 tons/h to produce 94.65% pure syngas. The total recovery was 99.98% and 99.57% for H<sub>2</sub> and CO, respectively, at adsorption and desorption pressures of 20 bar and 1.5 bar. Thus, PSA units using activated carbon as adsorbent material for CO<sub>2</sub>/syngas separation is a technically feasible process.

## 5. Acknowledgment

The authors gratefully acknowledge Repsol Sinopec Brazil for its financial and technical support and ANP (Brazilian National Oil, Natural Gas, and Biofuels Agency) for the strategic importance of its support through the R&D levy regulation. The authors also thank the National Council for Scientific and Technological Development - CNPq (#314598/2021-9). ## Abstract

In this work we propose a mixed integer nonlinear programming (MINLP) model for the optimal design of an integrated cyanobacteria-based biorefinery and its heat exchanger network (HEN), considering alternative *in-vivo* and *in-silico* *Synechocystis* sp. PCC 6803 strains, designed in our previous work. The objective is to potentially produce pigments, biopolymers, bioethanol, biogas and biofertilizers. The production process includes different alternatives embedded within a superstructure. To assess the feasibility of the biorefinery, we considered the Sustainability Profit (SP), a monetary-based sustainability metric as the objective function. The Net Present Value (NPV) was also calculated. Both indexes give positive values and numerical results provides useful insights on advanced biofuels production with metabolic engineered cyanobacteria. Comparison with suboptimal solutions using *in-vivo* strains is also provided.

**Keywords:** MINLP, *Synechocystis* sp. PCC 6803, Cyanobacteria-based biorefinery, *In-silico* cyanobacteria

## 1. Introduction

Cyanobacteria are promising candidates to become cell factories, as these photoautotrophic microorganisms are capable of growing on atmospheric and/or industrial carbon dioxide, inorganic phosphorus (P) and nitrogen (N) as macronutrients, and solar and/or artificial light as energy source. One interesting high added-value product for food and nutraceutical industries produced by cyanobacteria is the photosynthetic pigment phycocyanin, which possesses an intense blue color. Also, some cyanobacteria are able to store carbon as poly- $\beta$ -hydroxybutyrate (PHB), a biopolymer similar to polypropylene with a wide range of applications. On the other hand, photoautotrophic fourth generation bioethanol production by cyanobacteria has been widely studied *in-vivo* (Dienst *et al.*, 2014) and *in-silico* (Lasry Testa *et al.* 2019, 2022) with mutant strains of *Synechocystis* sp. PCC6803 (*Synechocystis*).

In this work, we aim to assess the efficiency of *in-silico* strains of *Synechocystis* sp. PCC6803, developed in previous work (Lasry Testa *et al.* 2019, 2022), in a large scale biorefinery. We propose a mixed-integer nonlinear programming (MINLP) model for the simultaneous optimal plant design and heat exchanger network synthesis (HEN) of a cyanobacteria-based integrated biorefinery for pigments (phycocyanin and zeaxanthin), PHB, biofuels (bioethanol and biogas) and biofertilizers. To enhance cyanobacterial biomass valorization and biofuels production, and to close the nutrient (N and P) cycle in

the integrated biorefinery, an anaerobic digester (AD) is included in the superstructure. Four *Synechocystis* strains are considered as production options: three *in-silico* strains previously developed by our group (Lasry Testa *et al.* 2019, 2022) and one *in-vivo* strain (Vidal Vidal, 2009; Delpino *et al.* 2014). The idea behind evaluating the performance of the developed *in-silico* strains is to determine if it is worth the effort to design them, based on metabolic engineering in the laboratory. The objective function is the sustainability profit (Zore *et al.*, 2017) for the assessment of economic, environmental and social benefits

## 2. Process Description

### 2.1 *Synechocystis* strains

In this work, four different *Synechocystis* strains constitute the main “cell factories” for this biorefinery superstructure, as we aim at assessing *in-silico* developed strains efficiency within the frame of an integrated biorefinery. S1 (Vidal Vidal, 2009; Delpino *et al.*, 2014) is an *in-vivo* genetically engineered strain that harvests the insertion of *pdh* and *adh* genes from *Zymomonas mobilis*, to create an ethanol production pathway (as *Synechocystis* do not naturally produce ethanol). The remaining strains are *in-silico* ones, we have designed in previous work. S2 is a wild type strain (no ethanol production) represented by its genome scale model. It comprises 784 reactions and 535 metabolites, with 80 exchange reactions that include cytoplasm, carboxisome, thylacoidal lumen, thylacoidal membrane, cytoplasmic membrane, periplasm, extracellular space (Lasry Testa *et al.*, 2019). S3 includes the reactions codified by the genes *pdh* and *adh* and produces ethanol coupled to growth (Lasry Testa *et al.*, 2019), and S4 produces PHB coupled to growth (Lasry Testa *et al.*, 2022). The coupled strains were designed by formulating a bilevel optimization problem that identifies gene deletions to achieve the desired coupling. Coupling production to growth has the objective of turning the desired product production into a subproduct of growth, so that it becomes necessary to the microorganism’s metabolic function. In the bilevel optimization problem, the outer objective function is to maximize product production rate, while setting an upper bound to the number of gene deletions (represented through binary variables), and the inner optimization problem minimizes product production rate subject to the metabolic network model (LP). The problem has been reformulated as a single level optimization problem by applying dual theory; i.e., replacing the inner LP by a set of equations comprising the primal LP constraints, its dual problem constraints and the strong duality condition (primal LP objective function equal to dual problem objective function). In this case, the dual problem objective function has bilinear continuous-discrete terms, which have been replaced by exact linearizations (Glover, 1975). The resulting Mixed Integer Linear Programming (MILP) model renders a genetically engineered strain that couples ethanol production to cell growth through fourteen genetic intervention in the case of S3 (Lasry Testa *et al.*, 2019) and with sixteen genetic interventions for PHB production in the case of S4.

### 2.2 Process Superstructure

The proposed superstructure of a cyanobacteria-based biorefinery for the potential production of pigments (phycocyanin and zeaxanthin), PHB, bioethanol, biogas and

biofertilizers is shown in Fig. 1. It includes three main processing stages: production, separation and purification.

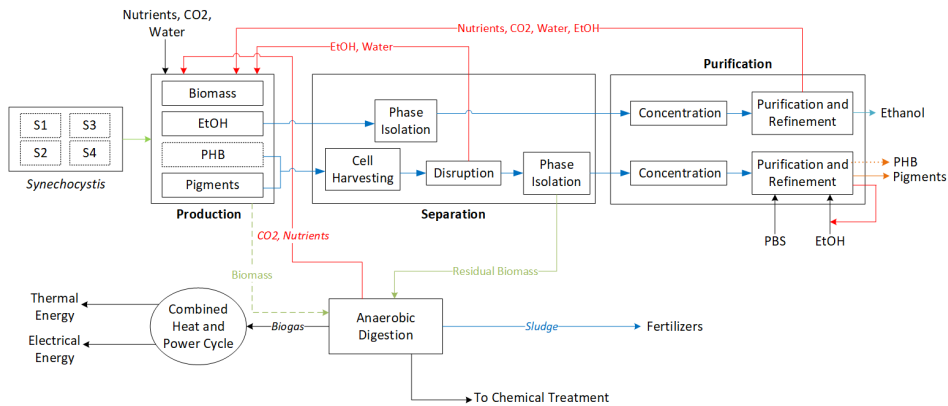

Figure 1. Cyanobacteria-based biorefinery simplified superstructure

The process begins with the production stage, where the four *Synechocystis* strains are considered for cultivation in open ponds at 30 °C, using CO<sub>2</sub> as carbon source, water, and N and P as nutrients. If S1 or S3 are chosen for cultivation, the harvesting process is carried out by microfiltration membranes to separate ethanol and culture media from the biomass. On the other hand, if S2 or S4 are selected, a centrifugation step is required to remove and recycle the culture media from the biomass.

A fraction of the harvested ethanol and water mixture (containing CO<sub>2</sub> and nutrients) from the microfiltration membranes (S1 or S3), is recycled to the open ponds in order to reach a minimal ethanol concentration threshold of 5 g/L, to attain an efficient performance of pervaporation membrane units in the subsequent ethanol separation and purification stages. The stream fed to the ethanol separation section is pre-heated to 50 °C in a heat exchanger before entering the polydimethylsiloxane membrane (PDMS) for pervaporation (where a concentration of 55 g ethanol/L is achieved). Next, ethanol is fed to a vapor compression distillation system where it reaches a concentration of 76%. The compressed vapor (ethanol/water mixture) is sent to a ceramic membrane followed by a cooling exchanger (25 °C) in order to obtain bioethanol fuel-grade concentration of 99.5% (Lopes *et al.*, 2019). Removed culture media streams from PDMS, ceramic membranes and vapor compression distillation system are also recycled to the cultivation system in order to enhance the sustainability feature of the proposed cyanobacterial biorefinery. For the four strains, the main stream of harvested biomass can be directly fed to an anaerobic digester for the production of fertilizers and biogas, and to recycle nutrient streams to the cultivation stage (García Prieto *et al.*, 2017). Also, it can be led to the separation section for pigments or PHB (S4 strain only) extraction. At the pigment separation stage, the wet biomass is dried in a spray drier with hot air (110 °C) in a 5.03 air-to-water ratio. In this step, most of the water and ethanol remnants are removed and recycled to the production stage after a cooling (40 °C) and flash operation. The dried biomass is disrupted in a bed mill, and then, a phosphate buffer solution (PBS) in a 17.25 PBS-to-phycoerythrin ratio is used in a diafiltration system to separate phycoerythrin from the residual biomass and zeaxanthin. In order to obtain commercial phycoerythrin, the purification of this pigment is conducted by freeze drying, removing mostly all of the water containing phosphates. For the case of the hydrophobic pigment, zeaxanthin, it is

extracted in a solid mixer-settler extractor, using ethanol as solvent in a 7.43 ethanol-to-zeaxanthin ratio. Finally, the residual biomass is sent to the anaerobic digester and the zeaxanthin is purified by chromatographic columns where the removed ethanol is reused in the solvent-extractor. The separation and purification stage for PHB, when strain S4 is cultivated, is described in detail in Ramos *et al.* (2019).

### 3. Mathematical Model
