# Contents

<b>Preface</b>	<b>xv</b>
<b>LOCAL ORGANIZING COMMITTEE</b>	<b>xvii</b>
<b>T1: Modelling and optimization for multi-scale integration</b>	
<b>1. An exploratory model-based design of experiments technique to aid parameters identification and reduce prediction uncertainty</b> <i>Francesca Cenci, Arun Pankajakshan, Solomon Gajere Bawa, Asterios Gavriilidis, Pierantonio Facco, Federico Galvanin</i>	<b>1</b>
<b>2. GHG emission reduction via multiple fuel options in carbon-constrained industrial clusters</b> <i>Christelle Bechara, Sabla Y. Alnouri</i>	<b>7</b>
<b>3. An optimization-free Fisher information driven approach for online design of experiment</b> <i>Andrea Friso, Federico Galvanin</i>	<b>13</b>
<b>4. A Python-based approach for thermodynamic consistency tests of binary VLE data</b> <i>Pedro Cezareth, Martina Costa Reis</i>	<b>19</b>
<b>5. Modelling building's life-cycle decarbonization in China: A multi-level and multi-region optimization approach</b> <i>Chenxi Li, Pei Liu, Zheng Li</i>	<b>25</b>
<b>6. Automated Kinetic Model Discovery – A Methodological Framework</b> <i>Miguel Ángel de Carvalho Servia, Ilya Orson Sandoval, Dongda Zhang, Klaus Hellgardt, King Kuok (Mimi) Hii, Ehecatl Antonio del Rio Chanona</i>	<b>33</b>
<b>7. Assessing process systems models for pharmaceutical development</b> <i>Margherita Geremia, Samir Diab, Charalampos Christodoulou, Gabriele Bano, Massimiliano Barolo, Fabrizio Bezzo</i>	<b>39</b>
<b>8. Simulation and optimisation of a medium scale industrial reverse osmosis desalination system</b> <i>Mudhar A. Al-Obaidi, Alanood A. Alsarayreh, and Iqbal M. Mujtaba</i>	<b>45</b>

<b>9. Modeling strategies in multi-scale food-energy-water nexus system optimization</b>	
<i>Marcello Di Martino, Patrick Linke, Efstratios N. Pistikopoulos</i>	<b>51</b>
<b>10. MULTI-FIDELITY SURROGATE MODELING FOR CHEMICAL PROCESSES WITH PHYSICS-INFORMED NEURAL NETWORKS</b>	
<i>Yu-Ting Liu, Chuan-Yu Wu, Tao Chen, Yuan Yao</i>	<b>57</b>
<b>11. A CFD-model-based approach to continuous freezing process design for human induced pluripotent stem cells</b>	
<i>Yusuke Hayashi, Benedikt X. Scholz, Hirokazu Sugiyama</i>	<b>65</b>
<b>12. Multiscale Modeling of Spatial Area-Selective Thermal Atomic Layer Deposition</b>	
<i>Matthew Tom, Sungil Yun, Henrik Wang, Feiyang Ou, Gerassimos Orkoulas, Panagiotis D. Christofides</i>	<b>71</b>
<b>13. Modeling the shrinkage effect during the drying process of a green ceramic material</b>	
<i>Achilleas L. Arvanitidis, Margaritis Kostoglou, Michael C. Georgiadis</i>	<b>77</b>
<b>14. Investigating physics-informed neural networks for bioprocess hybrid model construction</b>	
<i>Alexander William Rogers, Ilya Orson Sandoval Cardenas, Ehecatl Antonio Del Rio-Chanona, Dongda Zhang</i>	<b>83</b>
<b>15. Decision Making Approaches to Improve Resilience in Food Supply Chains and Enhance Food Security Against Climate Change Risks</b>	
<i>Bashar Hassna, Sarah Namany, Mohammad Alherbawi, Adel Elomri, Tareq Al-Ansari</i>	<b>89</b>
<b>16. Lot-sizing and Production Scheduling of a Beverage Industry</b>	
<i>Maria E. Samouilidou, Eleonora Diakoumi, Georgios P. Georgiadis, Antonios Dikaiakos, Michael C. Georgiadis</i>	<b>95</b>
<b>17. Modeling and Analysis of Clinical &amp; Municipal Waste Incineration Process using Aspen Plus</b>	
<i>Mohamad Rizza Othman, Sivanesh Kumar Anpalagam, Nur Fitriyanni Jafary</i>	<b>101</b>
<b>18. On the minimization of cycle time in periodic production scheduling</b>	
<i>Alexandros Koulouris, Georgios P. Georgiadis</i>	<b>107</b>

- 19. Non-Pareto optimal solutions as enablers for versatile heat exchanger networks**  
*David Huber, Felix Birkelbach, René Hofmann* **113**
- 20. Enhanced Automatic Initialization Method for Solving Large Nonlinear Algebraic Systems**  
*Saskia Bublitz, Erik Esche, Jens-Uwe Repke* **119**
- 21. Electroplating scheduling: Closing a research gap from an automation vendor's perspective**  
*Sophie Reimschuessel, Uwe Fuchs, Guido Sand* **125**
- 22. Real time prediction of ozone pollution using data-enabled deep learning modeling**  
*Fugui Hong, Cheng Ji, Fangyuan Ma, Chang Chen, Wei Sun* **131**
- 23. Numerical Study of a Single-Spout and Z-shaped Fluidized Bed Biomass Gasifier**  
*Fatima Ez-zahra El Hamra, and Radouan Boukharfane* **139**
- 24. Intensification of ATJ Process Using Catalytic Distillation, Optimization Considering Control and Economic Issues**  
*Gabriel Contreras-Zarazúa<sup>1</sup>, Juan José Quiroz Ramírez, Eduardo Sánchez-Ramírez,<sup>b</sup> Juan Gabriel Segovia-Hernández* **145**
- 25. Efficient physical model building algorithm using equations extracted from documents**  
*Shota Kato and Manabu Kano* **151**
- 26. Developing a rigorous chemical reaction network reduction strategy for *n*-hexadecane hydroisomerisation**  
*Fernando Vega-Ramon, Wei Wang, Wei Wu, Dongda Zhang* **157**
- 27. Troubleshooting high-pressure issues in an industrial biorefinery process by feature-oriented modeling**  
*Elia Arnese-Feffin, Pierantonio Facco, Daniele Turati, Fabrizio Bezzo, Massimiliano Barolo* **163**
- 28. Optimal Determination of the Binary Interaction Parameters for the Vapor-Liquid-Liquid Equilibrium on the Vinyl Acetate/Acetic Acid/Water System**  
*Jose Alfredo Paredes-Ortiz, Úrsula Fabiola Rodríguez-Zúñiga, Fernando Israel Gómez-Castro* **169**
- 29. Assessment of subgrid-scale models for large-eddy simulation of a gas-liquid stirred reactor**  
*Safae Elmisaoui, Radouan Boukharfane, Lhachmi Khamar, and Jean-Michel Ghidaglia* **175**

- 30. Mechanistic model for inkjet printing and applications in perovskite solar cells engineering**  
*Naveen Bhati, Mohammad Khaja Nazeeruddin, and François Maréchal* **183**
- 31. Modeling and Optimization of Low-carbon Oriented Urban Energy Systems Spatial Planning Considering Energy Networks Topology**  
*Ruiyu Zhang, Pei Liu, Zheng Li* **189**
- 32. Multi-objective optimisation for microbrewery retrofitting**  
*Ruosi Zhang, Melis Duyar, Lesley Foulkes, James Berrow, Michael Short* **197**
- 33. Thermodynamic equilibrium modelling for the optimal performance of a wood biomass downdraft gasifier for hydrogen production**  
*Anamika Kushwah, Tomas Ramirez Reina, Michael Short* **203**
- 34. A model predictive control approach for recirculating aquaculture systems integrated with sustainable hybrid energy systems**  
*Ruosi Zhang, Tao Chen, Michael Short* **209**
- 35. Multi-stage optimization for marketing industrial flexibility**  
*Martin Fischer, Karl-Wilhelm Schenzel, René Hofmann* **215**
- 36. Intelligent Process Flowsheet Synthesis and Design using Extended SFILES Representation**  
*Vipul Mann, Rafiqul Gani, Venkat Venkatasubramanian* **221**
- 37. Physics-informed Neural Network based Modeling of an Industrial Wastewater Treatment Unit**  
*Tuse Asray, Ece Serenat Koksul, Elif Ecem Esenboga, Ahmet Cosgun, Gizem Kusoglu, Duygu Aydin, Erdal Aydin* **227**
- 38. Approaches to Reduce Optimization Time for Stochastic Optimization of Complex Chemical Processes**  
*Fanyi Duanmu, Dian Ning Chia, Eva Sorensen* **235**
- 39. Design of a CO<sub>2</sub> capture plant: A sustainable approach using deep eutectic solvents**  
*Adrián Martínez-Lomovskoi, Ana-Gabriela Romero-García, Eduardo Sánchez-Ramírez, Juan-Gabriel Segovia-Hernández, Cataldo De Blasio* **241**

- 40. Optimal Retrofitting of Conventional Oil Refinery into Sustainable Bio-refinery under Uncertainty**  
*Lifeng Zhang, Ana Inés Torres, Bingzhen Chen, Zhihong Yuan, Ignacio E. Grossmann* 247
- 41. A Combined D-optimal and Estimability Model-Based Design of Experiments of a Batch Cooling Crystallization Process**  
*Xuming Yuan, Brahim Benyahia* 255
- 42. A novel mathematical formulation for short-term scheduling of multipurpose batch plants in chemical manufacturing**  
*Dan Li, Taicheng Zheng, Jie Li* 261
- 43. Heat integration and heat exchanger network design for oxyfuel cement plants**  
*Leif E. Andersson, Avinash Subramanian, Mari Voldsund, Rahul Anantharaman, Kristina Fleiger, Francisco Carrasco, Mirko Weber* 267
- 44. Technological Portfolio Optimisation for de-risking within the energy, water and food nexus**  
*Maryam Haji, Mohammad Alherbawi, Sarah Namany, Tareq Al-Ansari* 273
- 45. Prediction of Melt Flow Rate (MFR) in polymer production, with auto-regressive Machine Learning algorithms, for multivariate time-series measured in irregular timestamps**  
*Symon Doe, Christoforos Kassianides, Symeon Kassianides, Christos Christodoulou, Nikos Bakas* 279
- 46. Achieving Operational Excellence by Combining Material Tracking and On-line Polymer Analysis and Classification data in an all-in-one Integrated Decision Support System**  
*Symeon Kassianides, Symon Doe, Sanja Micunovica, Artemis Theodoropoulou, Charis Komodromos, Sofia Louloudi* 285
- 47. Markov Chain Monte Carlo simulation-based optimization for a production scale milk drying process**  
*Adrián Ferrari, Soledad Gutiérrez, Gürkan Sin* 291
- 48. Polymer Grade Transition Control via Reinforcement Learning Trained with a Physically Consistent Memory Sequence-to-Sequence Digital Twin**  
*Zhen-Feng Jiang, David Shan-Hill Wong, Jia-Lin Kang, Yuan Yao, Yao-Chen Chuang* 297

- 49. A Rolling Horizon Approach for Ethylene Production Scheduling with Daily Inventory Constraints**  
*Haoran Li, Tong Qiu* **305**
- 50. Simulation and optimization of fixed bed and moving bed TSA processes for post-combustion CO<sub>2</sub> capture**  
*Shreenath Krishnamurthy, Richard Blom, Giorgia Mondino, Schalk Cloete, John Morud, Abdelghafour Zaabout, Philip Llewelyn, Cecile Pereira, and Veronique Pugnet* **313**
- 51. AI-enhanced BoM Optimization with MILP for the EMS Industry**  
*Hossein Mostafaei, Eero Hiltunen, Antti Liski* **319**
- 52. Reduced cleaning model for highly viscous non-Newtonian fluids in pipelines**  
*Vera Liebmann, Matti Heide, Hannes Köhler, Christian Golla, Jochen Fröhlich, Frank Rüdiger* **325**
- 53. Optimal Retrofit of Simple Distillation Sequences to Thermally Coupled Side-Stream Configurations**  
*Anna S. Horsch, Andres R. Acevedo, Mirko Skiborowski* **331**
- 54. Computer aided-design of energy efficiency tools on a microalgae biorefinery scheme**  
*Araceli Guadalupe Romero-Izquierdo, Claudia Gutiérrez-Antonio, Fernando Israel Gómez-Castro, Salvador Hernández, Juan Fernando García-Trejo* **337**
- 55. Optimization of Simulated Moving Bed Chromatographic Processes using Surrogate Models**  
*Rojiar Pishkari, Marcus Fechtner, Tobias Keßler, Achim Kienle* **343**
- 56. Multi-Objective Model-based Design of Experiments of Pharmaceutical Tableting Process**  
*Ilias Bouchkira, Brahim Benyahia* **349**
- 57. Water bodies restoration as an optimal control problem with integrated internal and external strategies. The inclusion of artificial floating islands**  
*Amira Siniscalchi, Laura J. Fritz, Vanina Estrada, Maria Soledad Diaz* **355**
- 58. Developing robust hybrid-models**  
*Peter Jul-Rasmussen, Xiaodong Liang, Xiangping Zhang, Jakob Kjøbsted Huusom* **361**

- 59. A gPC-based Global Sensitivity Analysis for Phosphate Slurry Flow in Pipelines**  
*Marwane Elkarii, Radouan Boukharfane, Saad Benjelloun, Chakib Bouallou, Nabil Elmocayd* **367**
- 60. Hybrid dynamic model of monoclonal antibody production using CHO cells**  
*Mariana Monteiro, Cleo Kontoravdi* **375**
- 61. Combined Bayesian optimization and global sensitivity analysis for the optimization of simulation-based pharmaceutical processes**  
*Niki Triantafyllou, Nilay Shah, Maria M. Papathanasiou, Cleo Kontoravdi* **381**
- 62. Competitive adsorption of copper, nickel, and chromium ions onto EDTA modified SBA-15**  
*Bawornpong Pornchuti, Yuttana Phoochahan, Prarana Padma, Suchada Ruengrit, Pravit Singtothong* **387**
- 63. Auto-extractive reactive distillation for the production of fatty esters**  
*Hernán D. Muñoz, Christian Hoffmann, Markus Illner, Álvaro Orjuela, Jens-Uwe Repke* **393**
- 64. Long-term Capacity Management of Pharmaceutical Manufacturing Networks**  
*Simon B. Lindahl, Deenesh K. Babi, Gürkan Sin* **399**
- 65. Modeling of a trickle bed reactor: Study of arabinose oxidation on gold catalyst extrudates**  
*Mouad Hachhach, Vincenzo Russo, Dmitry Yu. Murzin, Tapio Salmi* **405**
- 66. Numerical simulation of flow in porous media using the SPH method and Ergun force**  
*Carlos E. Alvarado-Rodriguez, Lamberto Diaz-Damacillo, Eric Plaza* **411**
- 67. Impact of structural change in electricity and hydrogen end use on low-carbon transition of an energy system: A case study of China**  
*Nuobei Zhang, Pei Liu, Zheng Li* **417**
- 68. Optimal planning for thermal power plants with CCS under source–sink matching constraints: A case study of China**  
*Binglin Du, a Pei Liu, Zheng Li* **425**

- 69. On discrete time chemical production scheduling MILP models containing record keeping variables**  
*Amin Samadi, Nathan Adelgren, Christos T. Maravelias* **433**
- 70. ESTAN – A toolbox for global sensitivity based estimability analysis**  
*Ilias Bouchkira, Abderrazak M. Latifi, Brahim Benyahia* **439**
- 71. Multi-technology separation network synthesis**  
*Garry S.P. Taifan, Christos T. Maravelias* **445**
- 72. A Reinforcement Learning Development for The Exact Guillotine with Flexibility on Cutting Stock Problem**  
*Jie-Ying Su, Chia-Hsiang Liu, Cian-Shan Syu, Jia-Lin Kang, Shi-Shang Jang* **451**
- 73. Real-time optimization of a chemical plant with continuous flow reactors via reinforcement learning**  
*Min Wu, Furkan Elmaz, Ulderico Di Caprio, Dries De Clercq, Siegfried Mercelis, Peter Hellinckx, Leen Braeken, Florence Vermeire and M. Enis Leblebici* **457**
- 74. From problem specification to converged flowsheet simulations: Integrated workflow in an industrial context**  
*Mirko Skiborowski, Norbert Asprion, Sergej Blagov, Michael Bortz, Dennis Manuel Heim, Kai Fabian Kruber, Thulasi Rolland, Tobias Seidel* **463**
- 75. A Hybrid Modelling Framework for Dynamic Modelling of Bioprocesses**  
*Haiting Wang, Cleo Kontoravdi, Ehecatl Antonio del Rio Chanona* **469**
- 76. Simultaneous selection and optimization of reaction pathways and downstream separation network**  
*Shuang Xu, Selen Cremaschi, Mario R. Eden and Anjan K. Tula* **475**
- 77. Workflow for adaptation, analysis and application of mechanistic models for experimental planning of protein refolding processes**  
*Jan Niklas Pauk, Chika Linda Igwe, Christoph Herwig* **481**
- 78. Mechanistic modeling of product formation in recombinant *Escherichia coli* cultivations**  
*Don Fabian Müller, Philipp Pably, Daniel Wibbing, Julian Kager and Christoph Herwig* **487**

- 79. Physics-informed neural networks for optimization of polymer reactor design**  
*Yubin Ryu, Sunkyu Shin, Jay J. Liu, Wonbo Lee, Jonggeol Na* **493**
- 80. Extending the SI Decomposition to Continuous-Time Two-Stage Scheduling Problems**  
*Daniel Montes, José Luis Pitarch, César de Prada* **499**
- 81. Modelling of water vapor adsorption/desorption on hopcalite in an industrial medical air dryer**  
*Cristian Cardenas, & David Farrusseng* **505**
- 82. Multi-fidelity Bayesian Optimisation of Reactor Simulations using Deep Gaussian Processes**  
*Tom Savage, Nausheen Basha, Omar K. Matar, Antonio del Rio Chanona* **511**
- 83. Design of a sustainable biodiesel production process by a multi-objective optimization**  
*Barcia-Quimi A.F., Risco-Bravo A., Alcivar-Espinoza K., Tinoco-Caicedo D.L* **519**
- 84. Modeling of an Industrial Delayed Coker Unit**  
*Anne Firstauthor, Tim B. Secondauthor, James Q. Thirdauthora* **525**
- 85. A sustainable energy supply system in smart cities: an integrated natural gas and electricity network operation**  
*Ali Ahmadian, Ali Almansoori, Ali Elkamel* **533**
- 86. A hybrid forecasting framework for the energy sector**  
*Stefanos G. Baratsas, Funda Iseri, Efstration N. Pistikopoulos* **539**
- 87. A Chance-Constrained Programming Approach to Optimal Planning of Low-carbon Transition of a Natural Gas Supply System: A Case Study of China**  
*Jiaqi Zhang, Pei Liu, Zheng Li* **547**
- 88. Efficient 1D modelling of hot melt extrusion process for pharmaceutical applications**  
*Michaela Vasilaki, Umair Zafar, Ioannis .S. Fragkopoulos, Ioannis K. Kookos* **553**
- 89. Towards Machine Learning of Power-2-Methanol Processes**  
*Carl Julius Martensen, Christoph Plate, Tobias Kefler, Christian Kunde, Lothar Kaps, Achim Kienle, Andreas Seidel-Morgenstern, Sebastian Sager* **561**

- 90. Water resource portfolio design for optimum water productivity in agriculture**  
*Fatima-Zahra Lahlou, Rajesh Govindan, Bilal Hazrat, Hamish R. Mackey, Tareq Al-Ansari* **569**
- 91. S-GNN: State-Dependent Graph Neural Networks for Functional Molecular Properties**  
*Adem R.N. Aouichaoui, Alessandro Cogliati, Jens Abildskov, Gürkan Sin* **575**
- 92. Switching Multi-Objective Dynamic Optimization (MODO) for the Production of Value-Added Products**  
*Juan C. Acosta-Pavas, Carlos. E Robles-Rodríguez, Jérôme Morchain, David Camilo Corrales, Claire Dumas, Arnaud Cockx, César A. Aceves-Lara.* **583**
- 93. Dynamic modeling of a waste incinerator furnace in view of supervision**  
*Lionel Sergent, François Lesage, Abderrazak M. Latifi, Jean-Pierre Corriou, Alexandre Grizeau* **589**
- 94. Reinforcement learning combined with model predictive control to optimally operate a flash separation unit**  
*Dean Brandner, Torben Talis, Erik Esche, Jens-Uwe Repke, Sergio Lucia* **595**
- 95. Architecture and Design of a Modern Commercial Process Simulator**  
*Ian Boys, Jochen Steimel* **601**
- 96. High and Robust Fault Detection via Polynomial Approximated Isomap Embeddings**  
*Burak Alakent* **607**
- 97. A comparative study of distributed feedback-optimizing control strategies**  
*Vegard Aas, Risvan Dirza, Dinesh Krishnamoorthy, Sigurd Skogestad* **613**
- 98. Superstructure configuration and optimization of the biofuel production perspectives in Austria**  
*Safdar Abbas, Ada Josefina Robinson, Stavros Papadokonstantakis* **619**
- 99. Optimal operation of an industrial low pressure carburizing furnace**  
*Fatima Matamoros, Pierre-Alexandre Glaude, Roda Bounaceur, Hubert Monnier, Abderrazak Latifi* **625**

<b>100. Development of a holistic Python package for optimal selection of experimental design criteria in kinetic model discrimination</b> <i>Maerthe Theresa Tillmann, Federico Galvanin</i>	<b>631</b>
<b>101. A Model-based Computational Approach to Optimal Design of Nose-to-Brain Drug Delivery Systems</b> <i>Athina Vasileiadou, Costas Kiparissides</i>	<b>637</b>
<b>102. Global estimability analysis and model-based design of experiments in surrogate modeling</b> <i>Ilias Bouchkira, Sanae Elmisaoui, Saad Benjelloun, Abderrazak M. Latifi</i>	<b>643</b>
<b>103. Tractable Data-driven Solutions to Hierarchical Planning-scheduling-control</b> <i>Damien van de Berg, Roberto Xavier Jimenez Jimbo, Nilay Shah, Ehecatl Antonio del Rio-Chanona</i>	<b>649</b>
<b>104. A graph classification approach to determine when to decompose optimization problems</b> <i>Ilias Mitrai, Prodromos Daoutidis</i>	<b>655</b>
<b>105. An Enhanced Group-Interaction Contribution Method for the Prediction of Freezing Point and Enthalpy of Fusion for Pure Organic Compounds</b> <i>Khaled Mansour, Mourad Korichi</i>	<b>661</b>
<b>106. Single and Multi-Objective Superstructure Optimization of an Integrated Continuous Multistage Reaction-Crystallization-Filtration Process with Recycles</b> <i>Jiaxu Liu, Brahim Benyahia</i>	<b>667</b>
<b>107. Prediction of product distribution using machine learning techniques</b> <i>Praveen Kumar Bommineni, Manohar Kakunuri, Sarat Babu Anne</i>	<b>673</b>
<b>108. Architectural Design of Chemical and Biological Pathways through Parameter Sensitivity Oriented Mixed Integer Formulations</b> <i>Emir Topac, Emrullah Erturk, Ozgun Deliismail, Sahin Sarrafi, Hasan Sildir</i>	<b>679</b>
<b>109. Data-driven fouling modeling in crude oil heat exchanger</b> <i>Pelin Dologlu, Alihan Tabak, A. Eren Vedin, Gizem Kayar</i>	<b>685</b>

- 110. Explainable formation energy prediction for uncovering the relationship between the electronic structure and stability of the heterogeneous catalyst**  
*Daeun Shin, Dong Hyeon Mok, Seoin Back, Jonggeol Na* **691**
- 111. Modular stochastic optimization for optimal rainwater harvesting system design**  
*Qiao Yan Soh, Edward O'Dwyer, Salvador Acha, Nilay Shah* **697**
- 112. Knowledge-based model and simulations to support decision making in wastewater treatment processes**  
*Claire Valentin, Frédéric Lagoutière, Jean-Marc Choubert, Françoise Couenne, Christian Jallut* **703**
- 113. Homotopic Method for binodal curves computation in ternary liquid-liquid separation**  
*Nataliya Shcherbakova, Kevin Roger, Joseph Gergaud, Olivier Cots* **709**
- 114. Modelling of iron oxide reduction with hydrogen**  
*Emiliano Salucci, Snigdha Ghosh, Vincenzo Russo, Henrik Grénman, Henrik Saxén* **715**
- 115. Parameter estimation approach applied to microalgae-bacteria photobioreactor**  
*Irina Bausa-Ortiz, Raul Muñoz, Smaranda P. Cristea, Cesar de Prada* **721**
- 116. An Event-Based Continuous-Time MILP for Short-Term Crude Oil Scheduling**  
*İrem Marttin, Sena Kurban, Gizem Kuşoğlu Kaya, Özgür Kabak, Y. İlker Topcu* **727**
- 117. Modeling aqueous multi-electrolyte systems for the simulation and optimization of concentrated brine processes**  
*Wajeha Tauqir, Adaeze C. Maduako, Xi Yang, George M. Bollas* **733**
- 118. Stable two-stage scenario generation via game-theoretic optimisation**  
*Georgios L. Bounitsis, Lazaros G. Papageorgiou, Vassilis M. Charitopoulos* **739**
- 119. Global One-dimensional Root-finding Algorithm for Derivable and Continuous Functions**  
*Andrea Galeazzi, Kristiano Prifti, Flavio Manenti* **745**

- 120. A Demethanizer column Digital twin with non-conventional LSTM neural networks arrangement**  
*Marta Mandis, Roberto Baratti, Jorge Chebeir, Stefania Tronci, José A. Romagnoli* **751**
- 121. Soft modelling of spruce conversion into bio-oil through pyrolysis – Note I: steam explosion and LPMO-activated enzymatic saccharification**  
*Matteo Gilardi, Filippo Bisotti, Olaf T. Berglihn, Roman Tschentscher, Vincent G.H. Eijssink, Anikó Várnai, Bernd Wittgens* **757**
- 122. Molecular Modelling and Optimization of Diesel Hydrotreating Processes**  
*Xiaolin Bi, Nan Zhang, Robin Smith* **763**
- 123. Soft modelling of spruce conversion into bio-oil through pyrolysis – Note II: pyrolysis**  
*Filippo Bisotti, Matteo Gilardi, Olaf T. Berglihn, Roman Tschentscher, Vincent G.H. Eijssink, Anikó Várnai, Bernd Wittgens* **769**
- 124. Numerical Modeling of Gas-liquid Hydrodynamics in a U-loop Bioreactor**  
*Johan Le Nepvou De Carfort, Tiago Pinto, Ulrich Krühne* **775**
- 125. Effect of vaporisation models on the FCC riser modelling**  
*Thabang W. Selalame, Raj Patel, Iqbal M. Mujtaba, Yakubu M. John* **783**
- 126. A joint model-based design of experiments approach for the identification of Kriging models in geological exploration**  
*Philipp Deussen, Federico Galvanin* **789**
- 127. Reinforcement Learning for inventory management in multi-echelon supply chains**  
*Guoquan Wu, Miguel Ángel de Carvalho Servia, Max Mowbray* **795**
- 128. Monte Carlo Simulation of Photo Induced Atom-Transfer Radical Polymerization for Microscopic Properties**  
*Rui Liu, Xiaowen Lin, Antonios Armaou, Xi Chen* **801**
- 129. Identification of a dynamic model of the N-vinylcaprolactam-co-glycidyl methacrylate microgel synthesis**  
*Luisse F. Kaven, Thomas Nevolianis, Nadja Wolter, Adel Mhamdi, Andrij Pich, Kai Leonhard, Alexander Mitsos* **807**

- 130. A Machine Learning-assisted Hybrid Model to Predict Ribbon Solid Fraction, Granule Size Distribution and Throughput in a Dry Granulation Process**  
*Yan-Shu Huang, David Sixon, Phoebe Bailey, Rexonni B. Lagare, Marcial Gonzalez, Zoltan K. Nagy, Gintaras V. Reklaitis* **813**
- 131. A Data-driven Modeling Approach for Water Flow Dynamics in Soil**  
*Zeyuan Song, Zheyu Jiang* **819**
- 132. Numerical Simulation of No-Newtonian Fluids in Stirred-Tank with proximity impellers**  
*Alvarado-Rodriguez C. E., Martinez-Herrera G., Cortez-Gonzalez J., Murrieta-Dueñas R* **825**
- 133. Hybrid Dynamic Surrogate Modelling for a Once-Through Steam Generator**

# Preface

The 3 volumes contain papers presented at the 33<sup>rd</sup> European Symposium of Computer Aided Process Engineering (ESCAPE-33) held in Athens, Greece from 18-21 June 2023. The ESCAPE Series started in 1992 and builds on a strong foundation of 32 previous events of the European Federation of Chemical Engineers (EFCE) Working Party on Computer Aided Process Engineering (CAPE). Hosting countries to the conference have been Austria (1993, 2018), Ireland (1994), Slovenia (1995, 2016), Greece (1996, 2011), Norway (1997), Belgium (1998), Hungary (1999, 2014), Italy (2000, 2010, 2020), Denmark (1992, 2001, 2015), The Netherlands (2002, 2019), Finland (2003, 2013), Portugal (2004), Spain (2005, 2017), Germany (2016), Romania (2007), France (1992, 2008, 2022), Poland (2009), United Kingdom (2012), and Turkey (2021).

ESCAPE-33 addresses emerging and significant challenges in **Process Systems Engineering as a driver to rebuild industry with a systemic and holistic approach**. Contributions relate to the sustainable development of chemical processes, the development and the systematic evaluation of processing technologies and process innovations, and research promoting **circular economy** paradigms including social aspects and social engagement networks to incentivize and involve citizens. The conference recognizes the exceptional importance of **industrial biotechnology** as a driver and enabler for new chemistries, alongside **Artificial Intelligence and data engineering** as a technological challenge with an apparent impact on many systems technologies. Overall, ESCAPE 33 covered up-to-date topics in Process Systems Engineering and attracted a significant and diversified number of people from academia, research institutions, and industrial organizations worldwide. The themes of the conference included:

## **Modelling and optimization for multi-scale integration**

Coordinators: Antonio Espuña and Fani Boukouvala

## **Control, scheduling, and operability at the process and enterprise-level**

Coordinators: Ana Barbosa-Povoa and Chrysanthos Gounaris

## **Safe and sustainable products by design**

Coordinators: André Bardow and Fengqi You

## **Green and sustainable processes for the circular economy**

Coordinators: Seyed Mansouri and Bhavik Bakshi

## **Systems methods in industrial biotechnology and biomedical applications**

Coordinators: Joern Viell and Christos Maravelias

## **Multi-scale energy systems engineering (organized by the EFCE energy section)**

Coordinators: Francois Maréchal and Fabrizio Bezzo

**Sustainable supply chains and ecosystems**

Coordinators: Franjo Cecelja and Edwin Zondervan

**Education and knowledge transfer**

Coordinators: Ludovic Montastruc and Iqbal Mujtaba

The conference has been oversubscribed and we had to face a difficult task to review an excess of 800 submitted abstracts. The review process included reviews of abstracts, reviews of manuscripts, and the final selection of the revised manuscripts. Reviews involved 185 reviewers. They were completed primarily thanks to the generous support by members of the ESCAPE international scientific committee who contributed with evaluations, comments, and recommendations. The review process converged to 619 contributions from 57 countries. A total of 561 contributions by means of 6-page papers are included in these 3 volumes.

We hope that the books will serve as valuable reference documents to the scientific and industrial community and that they will contribute to the effective and innovative use of process systems engineering in the design, operation, and development of sustainable processes.

## Abstract

When developing mathematical models to describe reaction processes, model parameters require to be estimated from experimental data. Experiments are traditionally designed through techniques aiming at space exploration, like space-filling methods (e.g., Latin Hypercube sampling or LHS), or at information maximization, like model-based design of experiments (MBD<sub>oE</sub>). However, the former methods do not minimize parameters uncertainty, while the latter do not ensure a minimization of model prediction uncertainty in the entire experimental design space. In this work, we propose a novel exploratory MBD<sub>oE</sub> (*eMBD<sub>oE</sub>*) approach based on G-optimality calculation (*G-map eMBD<sub>oE</sub>*) to simultaneously enhance space exploration and minimize model prediction variance. The method is tested on a case study related to the identification of kinetic parameters of catalytic total methane oxidation in a flow microreactor. Results show that the method is more explorative than conventional MBD<sub>oE</sub> and more efficient than LHS and MBD<sub>oE</sub> in reducing model prediction uncertainty and parameters uncertainty.

**Keywords:** model-based design of experiments; model prediction uncertainty; parameters identification; design space exploration; total methane oxidation

## 1. Introduction

For a model to be representative of the system under study, its parameters must be estimated from experimental data. However, not all experiments are equally informative for estimating model parameters and scarce information may lead to unsatisfactory parameters precision even with a considerable amount of data. The information of each possible experiment can be estimated through the Fisher information matrix (FIM; Fisher, 1950), which depends on the sensitivity of the model response with respect to every model parameter. This is used by model-based design of experiments (MBD<sub>oE</sub>; Asprey and Macchietto, 2000), which is an optimization problem where the objective function is a scalar measure of the FIM and the result is a set of values for the manipulated variables that ensure a maximization of the information. Maximum information leads to the minimization of parameters uncertainty. However, optimal experimental design techniques are inherently exploitative and may suffer from scarce space exploration. Moreover, there is no guarantee that the minimization of parameters uncertainty leads to a minimization of model prediction uncertainty in the whole design space. In this work, we propose a modification of the MBD<sub>oE</sub> optimization framework in order to enhance

space exploration and to minimize model prediction variance in the entire domain of model utilization. The proposed procedure is based on the G-optimality (Kiefer and Wolfowitz, 1959), which estimates model prediction variance starting from the FIM, thus it does not require the acquisition of additional data. Therefore, a mapping of G-optimality values (*G-maps*) can be built for the whole design space and MBDoE optimization is performed in the regions that satisfy a user-defined requirement on the G-optimality value. This explorative MBDoE procedure based on G-map (*G-map eMBDoE*) is applied to a case study on the identification of kinetic parameters of Mars-van Krevelen reaction mechanism for total oxidation of methane. Herein, an automated flow micropacked bed catalytic reactor platform is simulated to generate in silico data. Thanks to simulated experimental campaigns G-map eMBDoE is compared against a purely information-based MBDoE and a purely exploration-based technique, namely Latin Hypercube sampling (LHS; McKay et al., 1979).

## 2. Methods

The estimation of the  $N_\theta$  model parameters  $\hat{\boldsymbol{\theta}}$  is carried out through Maximum Likelihood Estimation (MLE; Bard, 1974). The reference techniques for design of experiments are: model-based design of experiments (MBDoE), which aims at maximizing the experiments information, and Latin Hypercube sampling (LHS), which aims at an explorative design. The former can be represented by the optimization problem:

$$\boldsymbol{\varphi}_{opt} = \arg \min_{\boldsymbol{\varphi}} \psi(\mathbf{H}_{\hat{\boldsymbol{\theta}}}) \quad (1)$$

where  $\boldsymbol{\varphi}$  is the design vector, i.e. the set of control variables that determine the experimental conditions, and  $\psi(\mathbf{H}_{\hat{\boldsymbol{\theta}}})$  is a scalar measure of the FIM  $\mathbf{H}_{\hat{\boldsymbol{\theta}}}$ . Consider a general differential and algebraic model  $\mathbf{f}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{u}, t, \boldsymbol{\theta}) = \mathbf{0}$ ,  $\mathbf{y} = \mathbf{h}(\mathbf{x})$ , with  $N_y$  measurable responses ( $\hat{\mathbf{y}}$ ),  $N_\theta$  parameters ( $\hat{\boldsymbol{\theta}}$ ),  $N_u$  control variables ( $\mathbf{u}$ ),  $N_x$ -dimensional vectors of state variables and their first derivatives ( $\mathbf{x}$  and  $\dot{\mathbf{x}}$ , respectively) that change over time ( $t$ ). Then, the  $N_\theta \times N_\theta$  FIM is defined as:

$$\mathbf{H}_{\hat{\boldsymbol{\theta}}}(\hat{\boldsymbol{\theta}}, \boldsymbol{\varphi}) = [\mathbf{V}_{\hat{\boldsymbol{\theta}}}^0]^{-1} + \sum_{i=1}^{n_{sp}} \left( \frac{d\hat{\mathbf{y}}}{d\hat{\boldsymbol{\theta}}} \right)_i^T \boldsymbol{\Sigma}_y^{-1} \left( \frac{d\hat{\mathbf{y}}}{d\hat{\boldsymbol{\theta}}} \right)_i, \quad \text{with: } \mathbf{H}_{\hat{\boldsymbol{\theta}}}(\hat{\boldsymbol{\theta}}, \boldsymbol{\varphi}) \cong [\mathbf{V}_{\hat{\boldsymbol{\theta}}}]^{-1} \quad (2)$$

Thus, the FIM depends on the prior information  $[\mathbf{V}_{\hat{\boldsymbol{\theta}}}^0]^{-1}$  (related to parameters bounds; Bard, 1974), on the  $N_y \times N_y$  response variance covariance matrix  $\boldsymbol{\Sigma}_y$  and on the  $N_y \times N_\theta$  matrix of sensitivities  $\left( \frac{d\hat{\mathbf{y}}}{d\hat{\boldsymbol{\theta}}} \right)_i$  calculated at the  $i$ -th sampling point ( $n_{sp}$  is the total number of sampling points, given by the sum of the  $N_{sp}$  sampling points for every response). As shown in Eq. (2), the parameters variance covariance matrix  $\mathbf{V}_{\hat{\boldsymbol{\theta}}}$  can be approximated as the FIM inverse: therefore, the higher the experiments information content, the smaller the parameters uncertainty region. In this work, we minimize the direction of maximum variability of the uncertainty region by maximizing the minimum FIM eigenvalue  $\psi(\mathbf{H}_{\hat{\boldsymbol{\theta}}}) = -(\lambda_{\min}(\mathbf{H}_{\hat{\boldsymbol{\theta}}}))$  (E-optimal criterion).

After parameters identification, the reliability of model predictions can be assessed through the G-optimality  $V_y$ , i.e. a  $N_y N_{sp} \times N_y N_{sp}$  matrix where the  $ji$ -th diagonal element represents the prediction variance of the  $j$ -th response at the  $i$ -th time point. The  $ji$ -th element  $V_y(\hat{\boldsymbol{\theta}}, \boldsymbol{\varphi})|_{j,i}$  is calculated as:

$$V_y(\hat{\boldsymbol{\theta}}, \boldsymbol{\varphi})|_{j,i} = \left( \frac{d\hat{y}_j}{d\hat{\boldsymbol{\theta}}} \right)_i^T [\mathbf{H}_{\hat{\boldsymbol{\theta}}}]^{-1} \left( \frac{d\hat{y}_j}{d\hat{\boldsymbol{\theta}}} \right)_i \quad \text{for } j = 1, \dots, N_y; i = 1, \dots, N_{sp} \quad (3)$$

where  $\left(\frac{d\hat{y}_j}{d\hat{\theta}}\right)_i$  is the  $N_{\theta} \times 1$  vector of sensitivities.  $V_y$  depends on the current parameter estimates  $\hat{\theta}$  and it is evaluated at each condition  $\boldsymbol{\varphi}$  in the design space. For the same  $\boldsymbol{\varphi}$ ,  $N_y N_{sp}$  values of  $V_y(\hat{\theta}, \boldsymbol{\varphi})|_{j,i}$  are calculated; a scalar measure  $J_G$  summarizing them all can be defined as:

$$J_G = \sum_{j=1}^{N_y} \sum_{i=1}^{N_{sp}} V_y(\hat{\theta}, \boldsymbol{\varphi})|_{j,i} \quad (4)$$

We define *G-map* as the mapping of  $J_G$  in the whole design space and we integrate it into the MBDoE optimization seeking enhancement of space exploration and minimization of model prediction uncertainty in the whole domain of model utilization. This is done through the steps illustrated in Fig.1:

- the design space is discretized into a grid of equally spaced points (black dots in (a)) representing experimental conditions  $\boldsymbol{\varphi}$ . In the figure, two inputs are shown for sake of simplicity, but it can be extended to any number  $N_u$ ;
- every point is characterized in terms of information content  $\psi$  and total variance  $J_G$ ;
- only a subset of points is retained for the optimization of Eq. (1). These are the  $\boldsymbol{\varphi}$  satisfying the condition:  $J_G \geq J_{G,thr} J_{G,max}$  (blue circles in (b)), where  $J_{G,max}$  is the maximum  $J_G$  calculated in the grid, while  $J_{G,thr} \in [0,1]$  is a user defined threshold that allows to balance space exploration and information maximization;
- finally, the  $\boldsymbol{\varphi}_{opt}$  satisfying Eq. (1) is selected among the candidates (red star in (c)). It is used as initial guess for a subsequent constrained optimization in Python 3.9 with the Scipy optimization package.

**Figure 1.** Graphical representation of the explorative MBDoE based on *G*-maps.

This procedure is iterated until the budget of experiments ( $N_e$ ) is reached; model calibration is performed at every iteration as soon as the new experiment is designed.

### 3. Results and discussion

To test the performance of the *G*-map eMBDoE, a case study related to the identification of reaction models for catalytic total oxidation of methane over a 5% Pd/Al<sub>2</sub>O<sub>3</sub>- catalyst is considered. The mechanism is described through Mars-van Krevelen reaction kinetics in a flow microreactor system, which proved to be the most suitable kinetic model in Bawa et al. (2022). The control variables and their ranges are: temperature ( $u_1$ ), 250-350 °C; total flow rate ( $u_2$ ), 20-30 Nml min<sup>-1</sup>; inlet methane concentration ( $u_3$ ), 0.005-0.025 mol mol<sup>-1</sup>; oxygen to methane mole ratio ( $u_4$ ), 2-4 mol mol<sup>-1</sup>. The three responses  $\mathbf{y}$  are: unreacted methane, unreacted oxygen and carbon dioxide mole fractions, with measurement errors standard deviations  $\boldsymbol{\sigma}_y = [\sigma_{CH_4}, \sigma_{O_2}, \sigma_{CO_2}] = [0.00043, 0.00202, 0.00051]$ . Consider the kinetic rate of methane:

$$r_{CH_4} = k_1 k_2 P_{CH_4} P_{O_2} / (k_1 P_{O_2} + 2k_2 P_{CH_4} + (k_1 k_2 / k_3) P_{O_2} P_{CH_4}) \quad (5)$$

To aid parameters identification, Arrhenius and Van't Hoff equations are reparametrized:

$$k(T) = \exp(\log k(T_{ref}) - (E_a/R)(1/T - 1/T_{ref})) \quad (6)$$

$$K(T) = \exp(\log K(T_{ref}) - (\Delta H/R)(1/T - 1/T_{ref})) \quad (7)$$

Thus, six parameters must be estimated:  $\hat{\theta} = [(-\log k_1(T_{ref})), (\frac{E_{a,1}}{10^4}), (-\log k_2(T_{ref})), (\frac{E_{a,2}}{10^4}), (-\log k_3(T_{ref})), (\frac{E_{a,3}}{10^4})]$ . Parameters estimation is carried out with initial guesses  $\hat{\theta}_{guess} = [3, 8, 3, 10, 10, 8]$  and  $[0,15]$  as parameter Bounds. Experiments are executed in silico by simulating the flow reactor model concentration responses assuming the following set of parameters to represent the system:  $\hat{\theta}_{true} = [5.31, 6.96, 4.88, 10.49, 10.44, 7.95]$  and by adding random gaussian noise with zero mean and standard deviation  $\sigma_y$ .

A G-map eMBDoe with thresholds  $J_{G,thr} = 0.50$  and  $J_{G,thr} = 0.70$  is compared against classical MBDoe and LHS. Since LHS can change randomly the allocation of design points in the design space, three different runs are considered. Finally, 8 LHS points are used as preliminary experiments to obtain initial parameters estimates as well as to gain minimum threshold information prior to applying MBDoe; they are the same in all simulations. The results are analyzed in terms of:

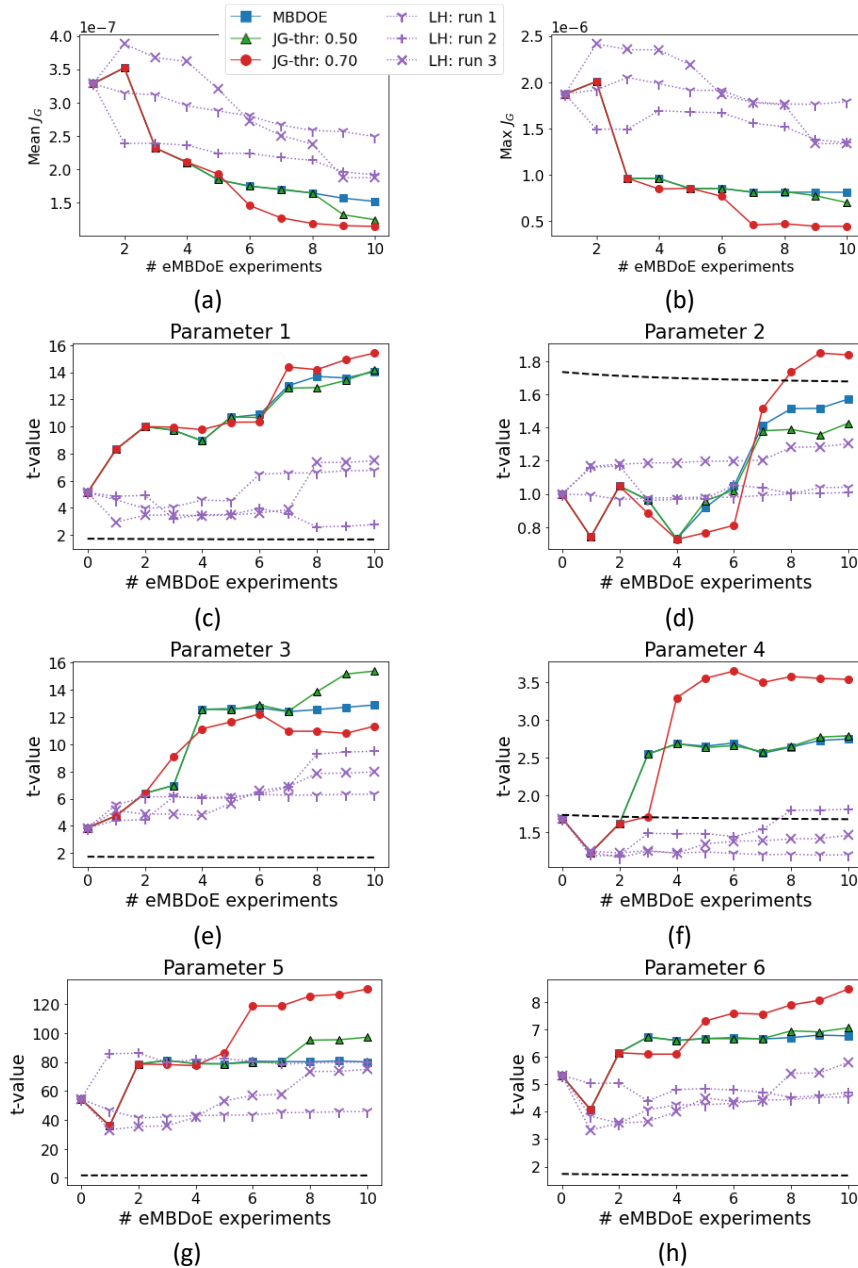

- space exploration, evaluated as deviation from the MBDoe design:  $d_i = \text{abs}(u_{i,l} - u_{i,ref})/u_{i,ref}$ , with  $i = 1,2,3,4$ ;  $l$  refers to  $J_G = \{0.50, 0.70\}$ , while the reference ref is MBDoe;
- mean and maximum  $J_G$  in the whole space; the smaller these indices, the smaller the model prediction uncertainty in the whole space of model utilization;
- parameters precision tests satisfied when  $t_{value,i} \geq t_{ref}$  (Aprey and Naka, 1999).

As seen in Fig. 2, the higher the G-optimality threshold, the greater the deviation of the optimal input values from the ones calculated through a standard MBDoe, especially at the first iterations of the experimental campaign. For instance, variable  $u_1$  with  $J_G = 0.70$  has  $d_i > 0$  starting from the 3<sup>rd</sup> iteration, while with  $J_G = 0.50$  it has  $d_i > 0$  after the 8<sup>th</sup> iteration. The results in terms of LHS are not shown since their departure from the MBDoe design is expected due to its explorative nature.

**Figure 2.** Deviation of the Gmap eMBDoe design with  $J_G = \{0.50, 0.70\}$  from the MBDoe optimal design. Only the deviations of variable 1 is shown for sake of conciseness. The x-axis shows the number of eMBDoe experiments after 8 LHS preliminary experiments.

The effect of this deviation from MBDoe conditions is assessed in terms of reduction of model prediction variance (Fig. 3 a-b) and increase of parameters precision (Fig. 3 c-h).

**Figure 3.** Results of eMBDOE compared to LHS and MBDOE: (a)-(b) mean and maximum  $J_G$  in the whole design space; (c)-(h) t-values for the full set of model parameters. In (c)-(h), the black dotted line represents the reference t-value, while the 0 in the x-axes represents the results of model calibration with the 8 LHS preliminary experiments only.

As shown in Fig.3 a-b, a purely explorative technique such as Latin Hypercube sampling has the worst performance in the reduction of model prediction uncertainty; this is true

for all the three runs considered. MBDoE is able to reduce model prediction uncertainty, but the best performance is obtained by the explorative MBDoE, particularly when a stricter threshold (namely,  $J_{G,thr} = 0.70$ ) is used.

Finally, assuming a maximum budget of 10 experiments, parameters identification is characterized by (Fig. 2 c-h):

- statistically satisfactory estimation of parameters  $\hat{\theta}_1, \hat{\theta}_3, \hat{\theta}_5$  and  $\hat{\theta}_6$  with the preliminary dataset in all scenarios;
- $\hat{\theta}_4$  estimated precisely from 3 optimal experiments for MBDoE and eMBDoE, while the estimate is more critical for LHS (estimated in one run over 3);
- the most critical parameter, e.g.  $\hat{\theta}_2$ , is sufficiently precise only when a Gmap eMBDoE is used with a strict threshold of 0.70.

This suggests that the proposed explorative MBDoE does not cause a loss of information content.

## Conclusion

A novel MBDoE technique is proposed in this paper in order to favor experimental design space exploration towards regions characterized by higher prediction uncertainty. Such regions are detected by using G-optimality maps, while the trade-off between information maximization and space exploration can be handled through a G-optimality threshold. The stricter the threshold, the higher the deviation of eMBDoE design from a conventional MBDoE. The new explorative and optimal design has benefits in terms of reduction of prediction variance as it reduces the mean and maximum G-optimality values in the entire design space with respect to MBDoE. Furthermore, G-map eMBDoE is more effective on estimating the full set of model parameters, since all t-tests are passed within 8 eMBDoE experiments. However, results show how a LHS space filling design, which is inherently explorative, can perform poorly both in terms of prediction variance minimization and increase of parameters precision. This suggests that the best experimental design performance is obtained only if a balance between space exploration and information maximization can be achieved.

## Abstract

This paper primarily investigates the effect of incorporating multiple fuel options onto carbon constrained industrial clusters. The purpose of doing so was to maximize the profit through the optimal allocation of multiple types of fuel. The cluster consists of a number of different production plants and a power plant for the processing of value-added products as well as the generation of electricity. The power plant is connected to the electric grid and constitutes the main source of electricity for the cluster. It also has the ability to produce more power and export it to the grid. The integration of additional plants that could generate new products, convert, or store carbon dioxide through CCUS technologies, and produce cleaner power through the use of renewable and/or multiple and blended fuels is assessed. It was found that the incorporation of multiple types of fuel within a single cluster resulted in the lowest post-capture emissions with 9469 t CO<sub>2</sub>/d generating a high-end profit of \$907.16 million/y, when compared to cases which relied on a single fuel option only.

**Keywords:** GHG Emissions, Industrial Clusters, Biomass, Energy, Fuel

## 1. Introduction

Fossil fuels, mainly oil, coal, and gas, have been dominating the world's energy market. In fact, they are considered to be the most commercially attractive, (Wang and Economides, 2009). Moreover, the versatile functions that are associated with such fossil fuels, such as the production of value-added products to the supply of electricity and power, has all led to a drastic increase in industrial dependence on such energy sources. The industrial sector's energy consumption has been forecasted to grow by 32% by the year 2050 (Wang, 2019), which inevitably instigates major environmental concerns. Fossil fuel utilization is associated with high CO<sub>2</sub> emissions. Recent studies have shown that 18% of global emissions are a result from the combustion of natural gas, 40% from the combustion of coal, and 31% from the combustion of oil and (Olivier and Peters, 2018). This has pushed many governments to start enforcing carbon taxes on industrial clusters and set CO<sub>2</sub> emission limits in compliance with the targets imposed by the Paris Agreement. The need to satisfy the rising energy demands, while conforming to the set emission bounds, has pushed mitigation techniques that could be implemented in industrial clusters. Bechara and Alnouri (2022) have previously assessed and compared different energy scenarios in industrial clusters. In this work, the incorporation of multiple and simultaneous fuel options within an industrial cluster is studied, and compared against single type fuel clusters.

## 2. Methodology

The generic plant in this model can have several active sinks and sources, as shown in Figure 1. The sink options include: a fuel sink, a power sink, and a CO<sub>2</sub> sink, while the source options include: a product source, a CO<sub>2</sub> source, and a power source. The plant can be of two types: a production plant or a power plant with one source of fuel allocated to it. In terms of inputs, the plant requires a fuel input either to produce a value-added product or to generate power, a power input to satisfy its electricity requirements, and/or a carbon input, as in the case of a carbon utilization plant. In terms of outputs, a plant can produce products to be exported out of the industrial cluster, generate power to either satisfy the cluster's need or to be exported as revenue to the electricity grid, and emit carbon dioxide, which in turn is either released into the atmosphere or captured, stored, or utilized by the carbon capture and utilization technologies. Moreover, each production plant contributes to the total CO<sub>2</sub> emissions of the cluster based on the number of products it produces, the quantity of fuel, and the amount of electricity it requires to meet the set production. The power plant, in turn, contributes based on the amount of electricity the cluster requires and the quantity exported to the grid as an additional revenue source. The integration of the additional plants, the option of utilizing several types of fuels as well as renewable power within the cluster serve the following functions:

- The reduced dependence of the cluster on one type of fossil fuel.
- The reduction of the total CO<sub>2</sub> footprint of the cluster through the use of carbon utilization technology with the possibility of monetizing the captured carbon.
- The production of a clean source of power to satisfy the cluster's requirement and reduce the fossil fuel requirement for power production.

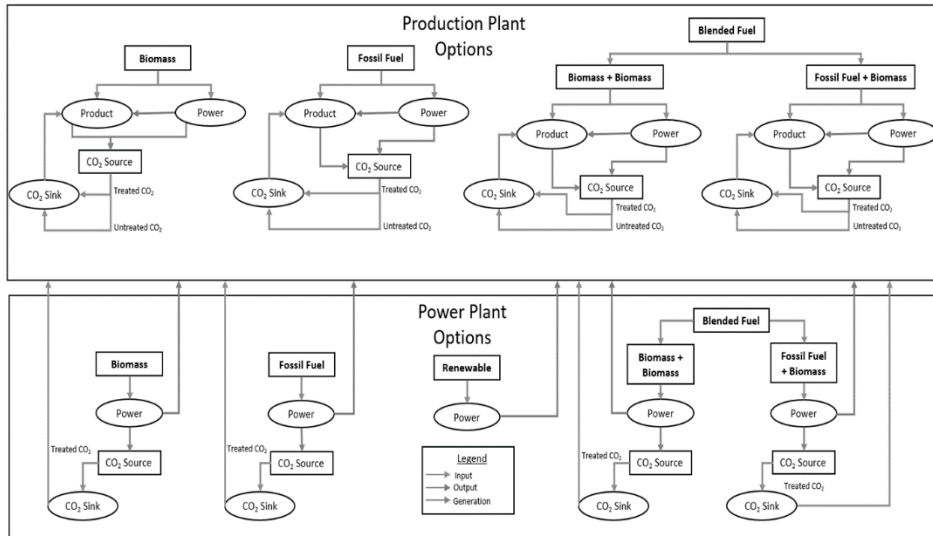

Figure 1: A generic illustration of sinks and sources within an industrial cluster

Because of the large number of variables involved in the optimization problem, from fuel allocation to CO<sub>2</sub> utilization, and power generation, a superstructure network approach is used to capture all the available configurations and determine the optimal selection. The cluster has an infrastructure suitable for the allocation and transportation of the different types of fuels that are introduced, from natural gas, to coal, to biomass, and blended fuel. All the product streams as well as the power exported to the grid are

considered as revenue streams that serve the end profit of the cluster. All active power sources are connected to the cluster's electricity grid which is supplied by the existing power plant. The CO<sub>2</sub> streams, treated and untreated, are connected to the CO<sub>2</sub> active sinks of all plants and the uncaptured CO<sub>2</sub> sources are emitted into the atmosphere. Taking all the aforesaid connections and networks into account, the optimization model was primarily designed to determine the optimal scenario that respects all constraints and results in the maximum profit for the cluster. To achieve the aforementioned, this work presents a superstructure optimization-based approach that aims at developing sustainable fuel and carbon utilization strategies to meet the environmental restrictions at a maximum end-profit. To summarise, the optimization model is able to determine:

- The selection of the production plants and the type of power plant.
- The integration of renewable energy as a replacement to the fuel-derived energy with regard to the economic and environmental aspects.
- The optimal allocation of the fuel options to the production and power plants.
- The integration of carbon capture technologies onto the cluster.
- The capturing, treating, and monetizing the captured carbon.

Moreover, the following factors are assumed to be known:

- The existing production plants, their capacities, and their locations in the cluster.
- The products that are produced in every production plant in the cluster.
- The characteristics and costs of the fuels to be allocated.
- The power requirements of the production plants in the cluster.
- The maximum renewable percentage that can replace the fuel-derived power.
- The product-to-fuel and power-to-fuel requirements.
- The parameter that describes the carbon emitted per ton of product, kWh of power produced, during the transport of solid fuels
- The revenue/cost parameter of every revenue/cost stream.
- The capital and operating costs of every plant.
- The cost of the carbon integration network (transportation, capture, treatment, compression, and pumping parameters) and the carbon capture limit.

### **3. Case Study**

The integration of different types of fuels was assessed based on both the economic and environmental feasibilities. The cluster investigated includes a set of existing and optional production plants. The existing plants were Methanol A, Aluminium, Cement and the natural gas power plant. Whereas the optional entities were Methanol B, Greenhouse, Saline storage and Enhanced Oil Recovery. Moreover, a renewable power plant with PV units has also been considered as an optional addition. Choosing between a natural gas, coal, biomass, and blended fuel power plants, and carbon utilization technologies were considered as part of the optimization problem. All process data has been obtained from Al-Mohannadi et al. (2017). The following additional assumptions were used:

- Natural gas, coal, biomass, and blended fuel are all integrated in the cluster.
- Only one type of fuel-derived power plant exists.
- Each production plant can have one type of fuel allocated to it.
- The net carbon capture rate is set to a minimum of 20%. The optimization model will select the optimal carbon capture percentage based on the set constraints.

The Mixed Integer Linear Program (MILP) involved a total of 634 variables, with a CPU

time of 3 mins and 20s using What'sBest (Lindo systems, 2006) Lindo Branch-and-Bound solver for MS-Excel 2013 via a laptop PC with Intel Core i7 Duo processor, 8 GB RAM and a 64-bit operating System. It was found that with a natural gas flow of 444.25 t natural gas/d, a coal flow of 888.35 t coal/d, a biomass flow of 585.39 t biomass/d, and a blended fuel flow of 756.14 t blended fuel/d and a carbon capture rate constraint set to a minimum of 20%, the cluster produced 5000 tMeOH(A), 10000 t Portland-cement, 1118.44 tAluminum, and 2600 tMeOH(B). The optimization selected the natural gas plant as the operating power plant, which satisfied the cluster's power requirements. The option of exporting power to the grid was not reported in the optimal solution, instead, the option of operating the renewable energy plant at the highest capacity to replace 5% (1010526.32 kWh/d) of the power supplied by the fossil fuel plant. The cluster's profit turned out to be \$907.16 million/y, slightly lower than that for the natural gas case study, but higher than the remaining case studies. However, the different fuel requirements are much lower, reducing the dependency on one type and showing the advantage of integrating more than one fuel into an industrial cluster. The activation of the renewable solar plant further shows the opportunity of gradually integrating more sources of green energy, such as green hydrogen, without being limited by capacity or by efficiency. To better understand the cluster's economics, with multiple fuels enabled, a cost distribution is presented in Figure 2. With the cluster's large product requirements, the highest costs resulted from the production sector, requiring \$1010.12 million/y, followed by the power sector, consisting of the natural gas power plant and the solar photovoltaic plant costs with \$151.53 million/y.

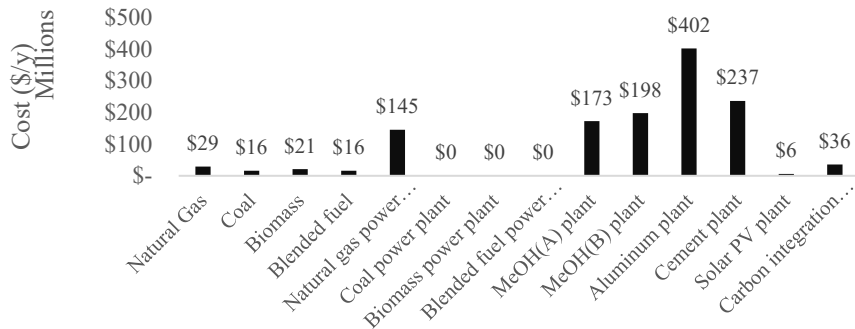

Figure 2: Optimal cost distribution attained

Analysing the carbon integration network's cost distribution, displayed in Figure 3, it can be seen that the highest cost is attributed to the treatment unit (Almohannadi and Alnouri, 2021), accounting for 65.28% of the total carbon integration costs. This high number is also associated with the fact that the optimization model selected to treat 99.91% of the carbon streams.

Figure 3: Carbon Network Cost Distribution

Regarding the carbon footprint, the total emissions of the cluster without capture was found to be 17640 t CO<sub>2</sub>/d, lower than those for the natural gas, biomass, and blended fuel cases, but slightly higher than that for the coal case study. The latter can be attributed to the higher production capacity of this cluster in comparison to the coal cluster. After applying carbon capture and utilization technologies and selecting the optimal source to sink mapping (refer to Figure 4) the carbon captured amounted to 13796 t CO<sub>2</sub>/d reducing the cluster's emissions by 47% resulting in a final footprint of 9345 t CO<sub>2</sub>/d, and a capture rate of 79%. Compared to the standalone and blended fuel case studies, the resulting emissions post capture of the multiple fuel case study turned out to be the lowest showing the great economic and environmental potentials of integrating multiple fuels into a cluster to mitigate its carbon footprint. Furthermore, the optimization chose to operate the solar photovoltaic plant at full capacity. Therefore, adding more capacity or integrating more than one type of renewable energy could result in a higher replacement of the fossil-fuel derived energy. Figure 4 summarizes the optimal source to sink mapping obtained. A treated carbon stream was allocated from aluminum to methanol (B), treated carbon from cement and a mixture of treated and untreated carbon from the natural gas power plant to the enhanced oil recovery, treated carbon from methanol (B) to the greenhouse, and treated carbon from methanol (A) and the natural gas power plant to the saline storage.

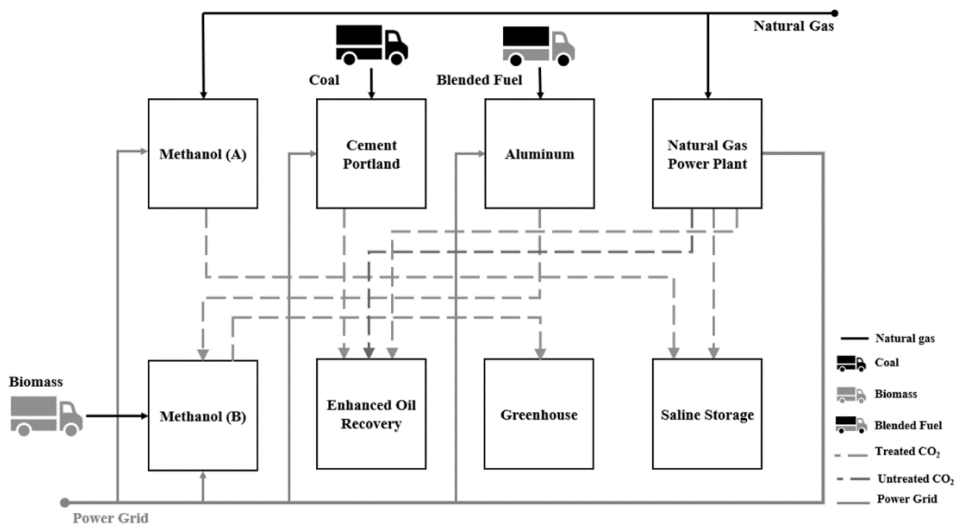

Figure 4: multiple fuel CO<sub>2</sub> network superstructure

Looking at the carbon emissions distribution in the cluster (illustrated in Figure 5) it can be seen that the production and power sector generated the highest emissions with 10780.58 t CO<sub>2</sub>/d and 6302.69 t CO<sub>2</sub>/d. Comparing the power emissions in every case study, natural gas resulted in 0.000691 tCO<sub>2</sub>/kWh, coal in 0.00077 tCO<sub>2</sub>/kWh, biomass in 0.000773 tCO<sub>2</sub>/kWh, blended fuel in 0.00077 tCO<sub>2</sub>/kWh, and finally multiple fuels in 0.000328 tCO<sub>2</sub>/kWh. The values were obtained by dividing the carbon emissions by the fuel derived power. Hence, the incorporation of multiple fuels yielded the lowest emissions per kWh, proving the advantage of adding renewable sources of energies into the power portfolio of a cluster. The flow rates of the different types of fuel are represented in Figure 6, showing the lower flow requirements needed in this analysis compared to those of the standalone and blended fuels. This further proves that integrating

different types of fuel results in a reduction in the reliance of the industry on one type. The total attained revenue for this case was found to be \$2170 million/y.

Figure 5: carbon emissions distribution in the cluster

Figure 6: Total fuel flows fuel into the multiple fuel industrial cluster

#### 4. Conclusion

A mathematical model for a systematic approach that integrates multiple types of fuels into industrial clusters was developed, by integrating the following multiple fuel options into the cluster: natural gas, coal, biomass, and blended fuel. The results obtained pertaining to fuel use, and its distribution amongst product and power sinks have been discussed. Moreover, the carbon emission footprint has analysed, and potential reduction strategies via CCUS utilization have been proposed, so as to meet the set emission target.

# An optimization-free Fisher information driven approach for online design of experiment

Andrea Friso,<sup>a</sup> Federico Galvanin,<sup>a</sup>

<sup>a</sup>*Department of Chemical Engineering University College London, Torrington Place,  
WC1E 7JE London, United Kingdom*

## Abstract

Developing mathematical models used to describe reaction kinetics is pivotal for the design, control and optimization of chemical processes. One of the most challenging tasks in the model development procedure is the identification of the unknown parameters within the model. This problem can be addressed using Model-Based Design of Experiment (MBD<sub>oE</sub>) techniques that allow experiments to be designed in such a way that parameters can be precisely estimated with the minimum number of runs and analytical resources. However, MBD<sub>oE</sub> techniques rely on an optimization procedure that is affected by the uncertainty related to the identified parameters and can be computationally expensive and prone to local optimality issues. MBD<sub>oE</sub> techniques are also applied to online procedures for faster identification of the kinetic model in autonomous platforms, and for this reason it is necessary to ensure a fast convergence and avoid numerical convergence issues during the operation. In this paper, a new optimization-free technology is proposed to tackle the above-mentioned problems.

**Keywords:** design of experiment, parameter estimation, Fisher Information matrix

## 1. Introduction

In chemical engineering, the role of kinetic models is fundamental to describe in a quantitative way the progress of chemical reactions occurring in a reaction system. These models, in the form of mathematical equations, play a key role in the design, control and optimization of chemical processes. When conventional model-building procedures are used reaction kinetics are modelled by proposing a set of candidate models based on preliminary experimental observations and hypotheses on potential reaction mechanisms. The key subsequent step is to determine the best model among the candidates to describe the system under analysis. The standard sequential methodology proposed by Franceschini and Macchietto (2000) consists of three different stages: 1) Preliminary analysis based on the identifiability and distinguishability of the model structure; 2) Model-based Design of Experiments to discriminate among the rival models that passed the first stage (MBD<sub>oE</sub>-MD); 3) Model-based Design of Experiments to improve the precision of the identified parameters for the best model selected in step 2 (MBD<sub>oE</sub>-PE). If no model passes the identifiability test of step 1 it is necessary to propose a new set of candidates. When a new experiment must be performed (either in steps 1 and 2) the new experimental conditions are optimally computed according to the expected amount of information for model discrimination (step 2) or parameter precision (step 3) the new experiments will eventually return to the experimenter. Automated model identification platforms were recently used to estimate the parameters of kinetic models online and speed up the identification procedure to reduce the costs of experimentation (Waldron et al, 2020, Pankajakshan et al, 2019). However, the parameter identification problem is often ill-conditioned and consequently the objective function of the MBD<sub>oE</sub> problem

may become difficult to compute (Quaglio et al. 2019). Moreover, optimization in these platforms can be difficult to handle in online model identification procedures for the following additional reasons: *i*) when the system under analysis is structurally very complex, and consequently requires model candidates containing a large set of variables and model parameters, numerical optimization algorithms may easily incur into infeasible solutions; *ii*) particularly for systems characterized by a high number of state variables and model parameters MBDDoE techniques can become computationally very expensive, thus reducing the benefits of online identification of kinetic models. A new MBDDoE approach to increase the precision of parameter estimation is proposed in this paper where a new optimization-free Fisher information-driven algorithm has been developed to overcome the above-mentioned problems. The method has been tested on a benchmark case study for the identification of the parameters of the Bakers yeast growth model (Asprey et al. 2000). Results show that the information-driven approach is comparable with MBDDoE methods in terms of experiments required for the precise identification of the parameters, but the information-driven approach is less computationally expensive.

## 2. Proposed framework and methodologies

The set of initial candidates used in the MBDDoE procedures are formulated as differential and algebraic equations in the form:

$$\begin{cases} f(\dot{\mathbf{x}}(\mathbf{t}), \mathbf{x}(\mathbf{t}), \mathbf{u}(\mathbf{t}), \boldsymbol{\theta}, \mathbf{t}) = 0 \\ \hat{\mathbf{y}} = \mathbf{g}(\mathbf{x}(\mathbf{t})) \end{cases} \quad (1)$$

In Eq. 1  $\mathbf{x}$  is the vector of  $N_x$  states variables,  $\dot{\mathbf{x}}$  is the vector of the derivative of the state variables,  $\mathbf{u}$  is the vector of the input of the system under analysis,  $\boldsymbol{\theta}$  is the vector of the model parameters of  $N_\theta$ -dimensions,  $t$  is the time variable,  $\hat{\mathbf{y}}$  is the vector of the measured output of the system. The objective of the proposed methodology is to reduce the number of experiments needed to estimate the parameters of the model with adequate precision, so the objective is to perform experiments that lead to estimate precisely the model parameters, i.e. with minimum uncertainty. The proposed procedure for the optimization-free Fisher Information Matrix (FIM)-driven MBDDoE algorithm is divided in 7 sequential steps, as reported in Figure 1:

1. Definition of experimental design bounds: in this step, all the control variables that can be manipulated and optimized during the process are collected in the design vector:  $\boldsymbol{\varphi} = \boldsymbol{\varphi}[\mathbf{u}(\mathbf{t}), \mathbf{y}^0, \boldsymbol{\tau}, \bar{\mathbf{w}}, \mathbf{t}_{sp}]$  where  $\mathbf{u}(t)$  is the vector of the time-varying input controls,  $\mathbf{y}^0$  is the vector of the initial conditions,  $\boldsymbol{\tau}$  is the experiment duration,  $\bar{\mathbf{w}}$  is the vector of the time-invariant input controls and  $\mathbf{t}_{sp}$  is the vector of the sampling times. In addition, the bounds on the experimental vector are defined to create the experimental space;
2. Definition of preliminary experiments using DoE techniques:  $N_{exp}$  sets of experimental conditions to test are computed using a space-filling DoE method, for example, Latin Hypercube Sampling (LHS).
3. Selection of the first experiment to run: since no information about the system is available at this stage the selection of the first experiment is random.
4. Estimation of the parameter: after collecting the experimental data, in step 4 the model parameters are estimated minimizing the loss function:

$$LOSS = \sum_{i=1}^{N_{exp}} \left( \frac{y_i - \hat{y}_i}{\sigma} \right)^2 \quad (2)$$

where  $y_i$  is the measurement of experiment  $i$ ,  $\hat{y}_i$  is the predicted output of experiment  $i$  obtained using the model and  $\sigma$  is the standard deviation. The initial guesses on model parameters are updated with the new estimation ( $\hat{\theta}$ ).

5. Statistics on model parameters and FIM evaluation: the  $t$ -test is used to evaluate the relative precision of the estimates. At this point the FIM (Zullo 1991) is evaluated using the following equation:

$$\mathbf{M}(\hat{\theta}, \boldsymbol{\varphi}) = \sum_{j=1}^{n_{\text{exp}}} \sum_{r=1}^{n_{\text{resp}}} \sum_{s=1}^{n_{\text{resp}}} \tilde{\sigma}_{rs,j} \mathbf{Q}_{r,j}^T \mathbf{Q}_{s,j} + \mathbf{M}^0 = [\mathbf{V}(\boldsymbol{\theta}, \boldsymbol{\varphi})]^{-1} \quad (3)$$

In (3)  $n_{\text{exp}}$ ,  $n_{\text{resp}}$  are respectively the number of experiments and the number of responses,  $\mathbf{Q}$  is the sensitivity matrix and  $\mathbf{M}^0$  is the prior information on the parametric system. By inverting the matrix  $\mathbf{M}$ , it is possible to obtain the variance-covariance matrix ( $\mathbf{V}$ ).

6. The evaluation of  $\mathbf{M}$  is done for each experimental design point generated in step 2 to compute the expected amount of information achievable from each experiment. Experiments are then ranked based on the computed information content using the concept of Relative Fisher information (RFI) (Galvanin et al. 2016).
7. At this point the experimental conditions with the highest expected information are selected (Eq. 4) and the corresponding experiment is performed.

$$\boldsymbol{\varphi}_{i+1} = \operatorname{argmax}(\mathbf{M}(\hat{\theta}, \boldsymbol{\varphi})) \quad (4)$$

Steps 4, 5, 6 and 7 are repeated iteratively for the fixed number of experiments set in step 2. Within this framework, it is possible to select at each iteration the most informative experiment to run in the candidate set without performing an optimization. The optimization-free approach is less prone to local optimization issues affecting the standard MBDofE approaches because an ‘exploratory part’ in the selection of the experiments is forced in step 2 as the initial selection of the experiments to perform using the LHS as preliminary DoE. In fact, since the optimal experiment is only selected based on the maximum evaluation of information from Eq. 4 there is no risk of incurring in local optima. The absence of optimization can, however, also be a limitation of the methodology, because the solution found through this procedure will always be sub-optimal. In addition, the fact that the first experiment is selected randomly (as would be done in practice if no preliminary knowledge of the system is available) can affect the computational performance and efficiency in subsequent iterations.

### 3. Case study description

The proposed framework has been tested using an in-silico case study related to a fed-batch reactor in which a fermentation reaction is carried out using baker’s yeast (Asprey et al. 2000). The model used to simulate the experiments is presented in Eq. 3.

$$\begin{cases} \frac{dx_1}{dt} = \left( \frac{\theta_1 x_2}{\theta_2 x_1 + x_2} - u_1 - \theta_4 \right) x_1 \\ \frac{dx_2}{dt} = - \frac{\theta_2 x_1 x_2}{(\theta_2 x_1 + x_2) \theta_3} + u_1 (u_2 - x_2) \end{cases} \quad (5)$$

This system has been chosen to test the method because the governing equations and their parameters are very well known. The experimenter aims to compute the dynamics of yeast concentrations  $x_1(t)$  [ $gL^{-1}$ ] and the substrate concentrations  $x_2(t)$  [ $gL^{-1}$ ] as a function

of two different inputs: the dilution factor,  $u_1 [h^{-1}]$ , and the substrate concentration in the feed  $u_2 [gL^{-1}]$ . In this model the vector of model parameters that need to be identified precisely is  $\theta = [\theta_1, \theta_2, \theta_3, \theta_4]^T$ . Parameters and constant input variables used to perform in-silico experiments are reported in Table 1.

**Table 1:** Parameter and constant input variables values used for the in-silico experiments.

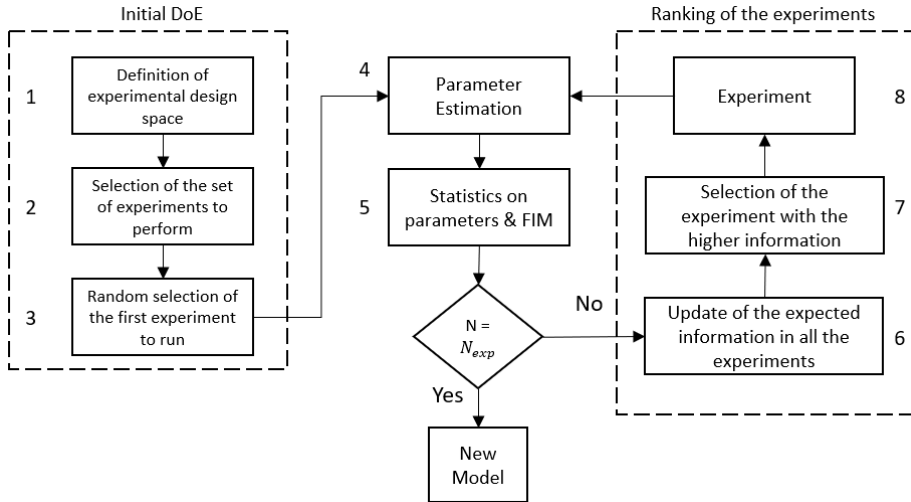

Parameter	$\theta_1$	$\theta_2$	$\theta_3$	$\theta_4$	$x_2(0)$	$u_2$
Values	0.31	0.18	0.55	0.05	0.01	5
Initial guess	5	5	5	5	-	-

The design vector is  $\phi = [x_1, u_1]$ , where  $x_2$  and  $u_2$  are kept constant. The bounds used to define the experimental space are the same used by Asprey et al. (2000) and are reported in Table 2.

**Table 2:** Bounds on the experimental conditions.

Parameter	Lower Bound	Upper Bound
$x_1(0) [gL^{-1}]$	1	10
$u_1 [h^{-1}]$	0.05	0.2

The proposed FIM-driven method is compared with a classical MBDoE approach and with a DOE LHS approach. In the MBDoE framework, the experimental conditions are selected iteratively after a sequential optimization procedure as in Asprey et al (2000). In the DOE procedure the same experiments generated for the optimization-free method in step 2 are used but randomly selected so without operating a ranking of the experiments.

**Figure 1:** Block diagram representation of the proposed methodology for the design of experiment for parameter identification.

#### 4. Results

In this section, three experimental design methodologies are compared: DOE (LHS), the proposed FIM-driven approach and a standard MBDoE. The comparison of the profiles of parameter estimates with the number of experiments is reported in Figure 2 for the full set of model parameters. The profile of estimated values and the variance of parameters

are reported to quantify the precision of the estimates during the model identification procedure.

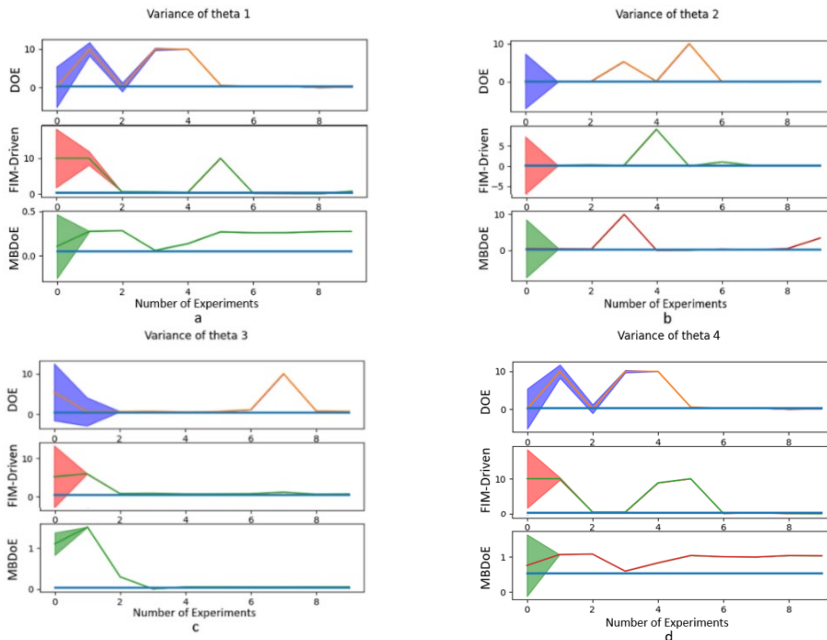

Figure 2 Profiles of  $\theta_1$  (a),  $\theta_2$  (b),  $\theta_3$  (c) and  $\theta_4$  (d) estimated values and relative variances.

From Figure 2 it is possible to observe that by using MBDoE it is possible to obtain the fastest reduction in parameter variance. Instead, the variance reduction obtained with the proposed FIM-driven approach is slower than the one obtained with MBDoE and faster than the one obtained with a conventional DOE methodology. As expected, in MBDoE the variance is generally lower and decreases faster than the variance obtained from the other two methods. This means that the precision of the estimations increases with every iteration faster than the other frameworks. The proposed methodology allows convergence to the assumed true value and negligible variance in 6 experiments. Instead, DoE requires more experiments (9) to obtain the same results. In Figure 3 the profiles of the  $t$ -values of the identified parameters are reported to evaluate and compare the relative precision of the estimates using the three methods. In Figure 2 the blue line represents the reference  $t$ -value, and the orange line represents the profile of the  $t$ -value of the parameter. If the computed  $t$ -values of the parameters are higher than the reference  $t$ -value the parameters are evaluated with good precision. From Figure 3 it is possible to notice that with a DoE method, the  $t$ -value for parameter  $\theta_3$  is lower than the reference until the sixth experiment and so the estimate is uncertain. Regarding the convergence speed of the three different procedures, the CPU time has been evaluated for all three methods. DoE is the fastest method (1.70 s) followed by FIM-driven (2.42 s) while MBDoE is the slowest method (10.47 s). These algorithms have been tested using an Intel® Core™ i9-10885H @ CPU 2.40 GHz with 16.0 GB RAM.

## 5. Conclusion

This study allows to define a new framework for the fast identification of parameters of kinetic models using an optimization-free Fisher Information Matrix-driven approach.

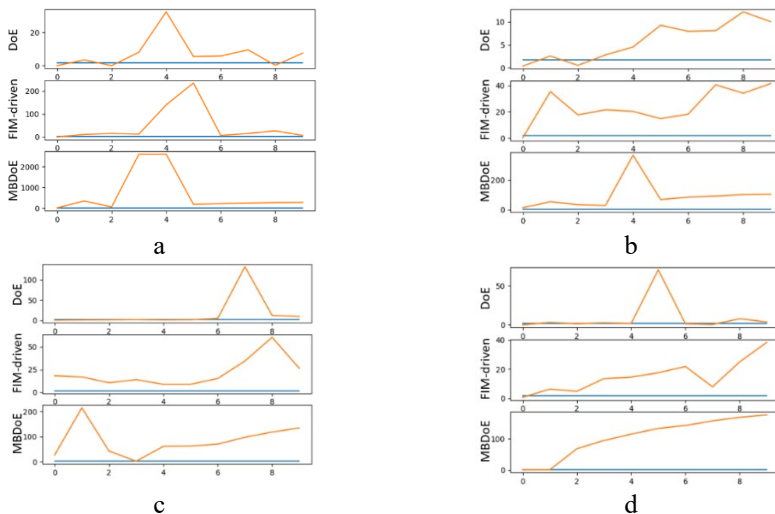

Figure 3 t-values of the parameters  $\theta_1$  (a),  $\theta_2$  (b),  $\theta_3$  (c) and  $\theta_4$  (d)

Preliminary results show how the proposed method can outperform standard space-filling design managing to identify the full set of model parameters precisely with a limited number of runs and providing results in parameter accuracy that are comparable to a standard sequential MBDoE but less computationally intensive. Future works will include re-sampling methods in the proposed procedure and the application to real chemical systems in automated platforms to test the robustness of the method and the comparison in terms of computational time required in practical lab settings.

## Acknowledgment

This project has received funding from EPSRC (EP/R032807/1). The support is gratefully acknowledged.

# A Python-based approach for thermodynamic consistency tests of binary VLE data

Pedro Cezareth,<sup>a</sup> Martina Costa Reis,<sup>a</sup>

<sup>a</sup>*University of São Paulo, School of Engineering, São Paulo 05508-000, Brazil*

## Abstract

Although reliable experimental data are fundamental in process design and optimization, critical assessment of experimental vapor-liquid equilibrium data is usually time-consuming as it requires data mining and multiple thermodynamic and statistical analyses. Given this, any initiative towards the development of computational tools that helps to speed up the assessment of experimental vapor-liquid equilibrium data is essential. Therefore, in this work, a Python-based approach for thermodynamic consistency tests of vapor-liquid equilibrium data of binary mixtures is presented. While the consistency of experimental isobaric vapor-liquid equilibrium data was checked through the L-W and Redlich-Kister tests, the thermodynamic consistency of isothermal vapor-liquid equilibrium data was analyzed through the area, Redlich-Kister, and L-W tests. The objective of this work is to introduce an open-source, efficient computational tool implemented with Python that embeds different thermodynamic consistency tests which helps chemical engineers make rational use of experimental data in process simulation and model parameterization.

**Keywords:** Thermodynamic consistency tests, vapor-liquid equilibrium, binary mixtures.

## 1. Introduction

A fundamental requirement for the design and optimization of chemical processes is the use of a reliable set of experimental data of pure component and mixture properties. Since the design and optimization of chemical processes depend on thermodynamic models whose key adjustable parameters are determined by regression of experimental data, the use of a thermodynamically consistent data set is not only desirable but also imperative. To this end, it is fundamental that the chemical engineer is familiar with the different thermodynamic consistency tests available in the literature, as well as their pitfalls and limitations. In general, it is improbable that a particular data set succeeds in all thermodynamic consistency tests. As noted by Wisniak et al. (2017), there is no unique test capable of providing an absolute answer to the question “Are the experimental data thermodynamically consistent?”. This is exactly why it is important to use a data-informed approach, where the chemical engineer can submit all data sets to several consistency tests, analyze the output, and then decide whether the experimental data set must be rejected or not.

Therefore, in this work, a Python-based approach for thermodynamic consistency tests of VLE (vapor-liquid equilibrium) data of binary mixtures is developed. For the sake of convenience, all consistency tests embedded in the Python-based approach only depend on tabulated physicochemical properties, which are easily found in compendia of physical properties. Unlike some well-known computerized systems for the retrieval, correlation, and prediction of phase equilibria data, this work presents an open-source,

efficient computational tool that helps chemical engineers to make rational use of experimental data in process simulation and model parameterization.

## 2. Theoretical background of the thermodynamic consistency tests

Overall, the Gibbs-Duhem equation plays a very important role in the development of thermodynamic consistency tests. Since one usually neglects the effect of the pressure  $p$  on the activity coefficient  $\gamma_i$ , for a binary mixture at constant temperature  $T$  the Gibbs-Duhem equation becomes

$$x_1 d \ln \gamma_1 + x_2 d \ln \gamma_2 = 0, \quad (1)$$

whose mathematical structure implies that the activity coefficients  $\gamma_i$  are coupled, that is, if one knows the value of  $\gamma_1$  at composition  $x_1$ , then the value of  $\gamma_2$  at composition  $x_2$  is known too. In practical terms, if  $\gamma_1$  and  $\gamma_2$  are determined separately, Equation (1) may be used to check the consistency of the data. Hence, if both  $\gamma_1$  and  $\gamma_2$  satisfy Equation (1) over the range  $0 \leq x_1 \leq 1$ , the data are said to be thermodynamically consistent.

Equation (1) may be rewritten as

$$x_1 \left( \frac{d \ln \gamma_1}{dx_1} \right) + x_2 \left( \frac{d \ln \gamma_2}{dx_1} \right) = 0, \quad (2)$$

which is the main equation of the slope test. Likewise, Equation (1) may be integrated over the range  $0 \leq \ln \gamma_i \leq \ln \gamma_i^\infty$  to give

$$\int_{\ln \gamma_1^\infty}^0 x_1 d \ln \gamma_1 + \int_0^{\ln \gamma_2^\infty} x_2 d \ln \gamma_2 = \underbrace{\int_0^1 \ln \gamma_1 dx_1}_{A_1} + \underbrace{\int_1^0 \ln \gamma_2 dx_2}_{A_2} = 0, \quad (3)$$

where  $\gamma_i^\infty$  is the activity coefficient at infinite dilution. Equation (3) is the basis for the area test that asserts that in a plot of  $\ln \gamma_i$  versus  $x_i$  the quantities  $|A_1|$  and  $|A_2|$  must be equal. Of course, because the measurements of isothermal VLE data are associated to an experimental error the quantities  $|A_1|$  and  $|A_2|$  are in practice not equal. Thus, it is common to assume a more lenient criterion for the thermodynamic consistency: the difference between  $|A_1|$  and  $|A_2|$  should be smaller than 2.0% of the sum  $|A_1| + |A_2|$ . Here, note that the requirement that  $|A_1|$  and  $|A_2|$  be equal is only a necessary condition for the thermodynamic consistency of the experimental data. In fact, it might be the case that some experimental data satisfy Equation (3), but not Equation (2).

Another test that may be applied to isothermal VLE data is the Redlich-Kister test. After some algebra, the Gibbs-Duhem equation gives

$$\ln \gamma_1 dx_1 + \ln \gamma_2 dx_2 = 0, \quad (4)$$

which can be integrated over the range  $0 \leq x_1 \leq 1$  to give

$$\int_0^1 \ln \left( \frac{\gamma_1}{\gamma_2} \right) dx_1 = 0. \quad (5)$$

Equation (5) indicates that in a plot of  $\ln(Y_1/\gamma_2)$  versus  $x_1$  the areas above  $A_A$  and below  $A_B$  the axis  $x_1$  must be equal. However, because of the experimental errors, this criterion is relaxed to

$$D = 100 \frac{|A_A - A_B|}{A_A + A_B} < 10. \quad (6)$$

If, however, the Redlich-Kister test is applied to isobaric VLE data, then the contribution of the excess enthalpy on the excess Gibbs energy  $g^E$  is not negligible. In this case, the criterion of thermodynamic consistency becomes

$$D = \left| 100 \frac{|A_A - A_B|}{A_A + A_B} - 150 \frac{|\Delta T^{max}|}{T^{min}} \right| < 10, \quad (7)$$

where  $\Delta T^{max}$  is the largest difference of temperature observed and  $T^{min}$  is the lowest temperature value in the data set.

A more comprehensive consistency test for VLE data is the  $L$ - $W$  test proposed by Wisniak (1993). The starting point of the  $L$ - $W$  test is the equations  $g^E = RT \sum_i x_i \ln \gamma_i$  and  $\gamma_i = y_i p / x_i p_i^*$ , where  $R$  is the gas constant,  $p_i^*$  is the vapor pressure, and  $y_i$  and  $x_i$  are the mole fraction of the species  $i$  in the vapor and liquid phase, respectively. By restricting the analysis to mixtures composed by species whose boiling points are not too different, so that the Clausius-Clapeyron equation may be used, one obtains after some algebra the following expression

$$\frac{\sum_i x_i \Delta S_i^* T_i^*}{L_i} - T = \frac{g^E - RT \sum_i x_i \ln(y_i/x_i)}{\sum_i x_i \Delta S_i^*}, \quad (8)$$

where  $\Delta S_i^*$  and  $T_i^*$  are the entropy of vaporization and the boiling point of the pure constituents at the pressure  $p$  of the solution. By integrating Equation (8) over  $0 \leq x_1 \leq 1$ , one has:

$$\int_0^1 L_i dx_1 - \int_0^1 W_i dx_1 = 0. \quad (9)$$

Equations (8) and (9) comprise the two equations that the  $L$ - $W$  test relies on. While Equation (8) may be used to check the consistency of every single point of the experimental data set, Equation (9) may be employed to test the consistency of the full data set. According to the  $L$ - $W$  test, a single experimental point is thermodynamically consistent, if the condition  $0.92 < (L_i/W_i) < 1.08$  is fulfilled. In addition, an experimental data set is said to be consistent, if the difference between  $L$  and  $W$  is smaller than 3.0% of the sum  $L + W$ .

### 3. Implementation of the thermodynamic consistency tests

The thermodynamic consistency tests herein discussed were implemented in Python by using the libraries Numpy, Pandas, Scypy, Matplotlib, and Pyplot. Once experimental phase equilibrium data have been imported as a Python dataframe, the user must specify the type of data and provide some pure component parameters. Next, the thermodynamic consistency of the experimental data set is checked and the results are exported as a

worksheet, which should be analyzed by the user. A sketch of the algorithm architecture is shown in Figure 1.

For the sake of illustration, Figure 2 shows the results of thermodynamic consistency tests for experimental VLE data retrieved from the Dortmund Data Bank (2022). In addition to the numerical results exported in the worksheet (Table 1), the results of some thermodynamic consistency tests (e.g. area test, Redlich-Kister test, and  $L$ - $W$  test) may also be analyzed through plots. This approach is particularly interesting to identify possible outliers in the data set and help the user to decide if the data set should be totally or partially rejected. In addition, note that the results of the thermodynamic consistency tests for VLE data strongly depend on the quality of the pure component parameters, the applicable temperature range of the Antoine equation parameters, the amount of available experimental data, and how large the deviations from the ideality are. Regarding this last aspect, thermodynamic consistency tests based on the Gibbs-Duhem equation tend to face some issues when dealing with VLE data of very ideal mixtures. One of the reasons for this behavior is the fact that the measured pressure and temperature values are usually the same order of magnitude as the experimental error and, as a consequence, the output of the thermodynamic consistency tests is somehow imprecise with large values for the parameter  $D$ , as illustrated in Table 1. Thus, in such cases, the results of the thermodynamic consistency tests might be dubious and should be carefully analyzed.

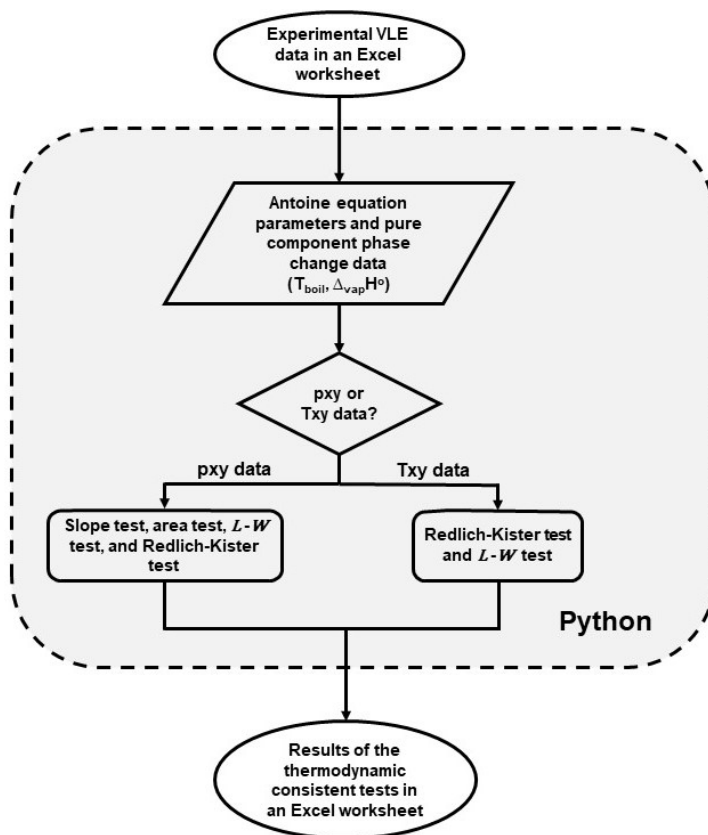

Figure 1. Structure of the proposed algorithm for thermodynamic consistency tests.

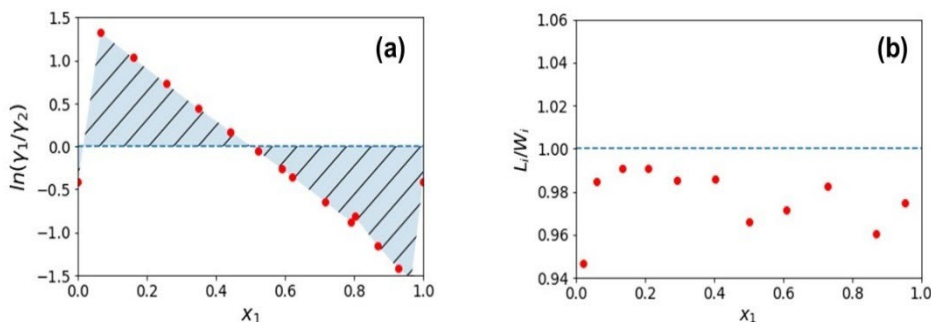

Figure 2. (a) Graphical visualization of the Redlich-Kister test ( $D= 1.48$ ) for the isothermal VLE data of the mixture acetone-hexane at 318.15 K and (b) results of the  $L$ - $W$  test for each point of the isobaric VLE data of the mixture acetone-ethanol at 101.33 kPa.

Table 1. Results of thermodynamic consistency tests for isobaric and isothermal VLE data.

			Thermodynamic Consistency Tests				
			Area	$L$ - $W$		Redlich-Kister	
			$D$	$L$	$W$	$D$	$D$
Butanol-Chlorobenzene	101.33 kPa	Txy	-	5.9	6.1	1.8	5.2
Methanol-Water	97.22 kPa	Txy	-	9.3	8.7	3.0	9.8
Acetone-Ethanol	101.33 kPa	Txy	-	4.4	4.7	3.2	7.1
Benzene-Toluene	333.15 K	pxy	1.6	35.9	2.4	87.7	14.9
Benzene-Toluene	353.15 K	pxy	13.1	16.0	2.3	75.0	11.1

Diethyl ether-Acetonitrile	293.65 K	pxy	0.2	46.2	37.5	10.3	0.5

#### 4. Conclusion and future perspectives

Although checking the reliability of experimental data is a long-established problem, the development of new thermodynamic consistency tests and computational tools for the assessment of VLE experimental data is still the motive of intensive research in chemical engineering thermodynamics. There are some commercial tools (Frenkel et al., (2005)) that were designed to dynamically evaluate the consistency of experimental data, but unfortunately, open-source codes are still non-existent. Then, since the assessment of experimental VLE data is a time-consuming and laborious task, any initiative towards the development of computational tools that help in the critical data-evaluation process is not only welcome but also necessary.

Therefore, in this work, an open-source algorithm written in Python was used to check the thermodynamic consistency of VLE data of binary mixtures. To this end, initially, experimental data are imported as a Python dataframe and then submitted to a series of thermodynamic consistency tests, according to its type. Next, the obtained results are exported as a worksheet that should be carefully analyzed by the user since passing a thermodynamic consistency test does not imply that the data set is accurate. In

fact, as observed in this work, thermodynamic consistency tests based on the Gibbs-Duhem equation seem to be not so efficient when applied to very ideal solutions. One of the reasons for this trend might be related to the fact that the measured pressure and temperature values are usually the same order of magnitude as the experimental error, which leaves room for further research in chemical thermodynamics.

Even though the open-source tool presented in this work is still under development, it may be already used to test the thermodynamic consistency of VLE data. In the near term, other consistency tests for vapor-liquid and solid-liquid equilibria data should be implemented (Kojima test, Fredenslund test, McDermott-Ellis test, Kang test, and Cunico test), as well as tests of internal and external consistency.

# Modelling building's life-cycle decarbonization in China: A multi-level and multi-region optimization approach

Chenxi Li,<sup>a</sup> Pei Liu,\* Zheng Li

*<sup>a</sup>State Key Lab of Power Systems, Department of Energy and Power Engineering, Tsinghua-BP Clean Energy Center, Tsinghua University, Beijing 100084, China  
liu\_pei@tsinghua.edu.cn*

## Abstract

The decarbonization of life-cycle emissions is a huge challenge to the building sector because it involves multiple levels. However, previous studies rarely evaluated the potential emission reduction contribution of various technologies in the life cycle, especially China, whose life-cycle CO<sub>2</sub> emissions of the building sector account for over 40 percent of the total emissions. A multi-level and multi-region optimization model is proposed to quantify the life-cycle CO<sub>2</sub> emission reduction path of China's building sector in this paper. Considering both indirect and direct emissions, this model can find the lowest-cost path of CO<sub>2</sub> emission reduction in China's building sector under specified emission scenarios. Results show that extending the building life from 30 years to 50 years has a great impact on emission reduction, leading to a CO<sub>2</sub> emission reduction of more than 50 percent if low-carbon building materials are also used. Moreover, electrification and emission reduction of the power system also have the potential of reducing the CO<sub>2</sub> emissions of buildings by nearly 40 percent, with an end-use electrification rate of more than 70 percent by 2060.

**Keywords:** building sector, decarbonization, optimization, life-cycle, China

## 1. Introduction

The building sector is an important sector which connects the upstream industries and the user terminal, leading to its high life-cycle CO<sub>2</sub> emissions. To achieve the goal of CO<sub>2</sub> mitigation in the whole society, the life-cycle emission reduction of the building sector which connects the upstream and downstream is very important, while the multi-level structure of the building sector brings great challenges to the planning of the life-cycle decarbonization.

Previous studies assessing the CO<sub>2</sub> mitigation of the building sector most focused on one level, such as the material of buildings, the operation of buildings or the reconstruction of a specific house. Li et al. (2017) and Ma et al. (2016) quantified the impacts of decarbonization in China's cement sector and steel sector by using China TIMES model separately. In order to achieve the goal of climate change, the energy demand for heating and cooling of German residential buildings was assessed comprehensively (Olonscheck et al., 2011). A multi-objective optimization model was utilized to find a building retrofit strategy to improve energy efficiency (Asadi et al., 2012). Although the above studies described the CO<sub>2</sub> mitigation pathway of the building sector or one specific house

detailedly, the research is still insufficient because of a lack of life-cycle analyzing. Each level of the building sector, material, construction, operation and demolition, affects each other, making it essential to carry out life-cycle CO<sub>2</sub> mitigation planning.

However, most life-cycle research on the building sector emphasized the accounting of historical CO<sub>2</sub> emissions instead of the mitigation potential of different low-carbon methods. Yang et al. (2018), Clabeaux et al. (2020), and Atmaca et al. (2022) counted the life-cycle emissions of a specific building or a building complex in China, USA and Turkey separately.

Overall, previous studies are rarely able to evaluate the emission reduction potential of buildings in the life cycle. Therefore, a multi-level and a multi-region optimization model is established to plan the life-cycle mitigation pathway of the building sector. The model is applied to the building sector of China, whose CO<sub>2</sub> emissions surpasses 4 billion tonnes, accounting for nearly 20 percent of the total CO<sub>2</sub> emissions all over the world.

## 2. Methodology

### 2.1. Model structure and Assumptions

The lifecycle of buildings includes material, construction, operation and demolition, which is shown in Figure 1. In this multi-level and multi-region optimization model, three main building materials and three main building structures are considered. Buildings are divided into three categories according to their use, and six energy demands are regarded. In this model, 40 technologies can be applied to the decarbonization of building sector, which are listed in Table 1.

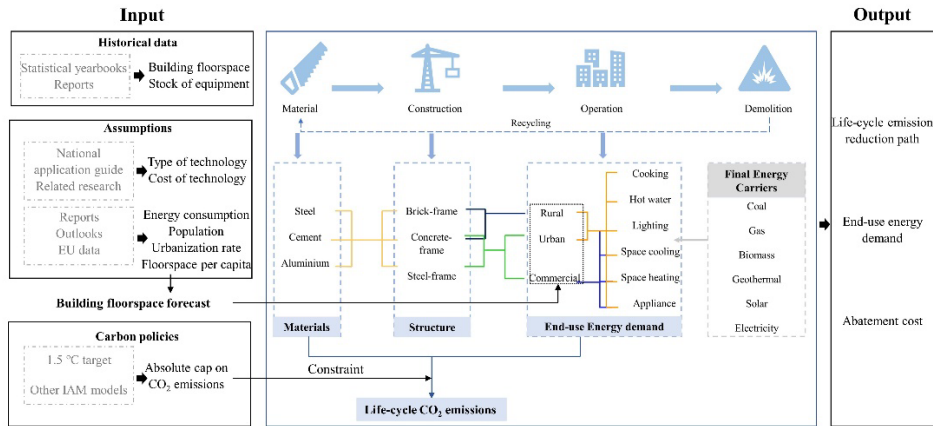

Figure 1. The structure of multi-level and multi-region optimization model of buildings

### 2.2. Mathematical formulation

Mathematical equations of the optimization model are presented in this model, including objective function and model constraints. Eight sets,  $t$ ,  $mat$ ,  $u$ ,  $str$ ,  $tech$ ,  $r$ ,  $op$ ,  $ref$  stand for time, material, type of utilization, structure, technology, region, energy demand and insulation of buildings.

#### 2.2.1. Objective function

The objective function of this model is to minimize the total cost of the building sector in its lifetime from 2020 to 2060. The total cost is composed of material costs, end-use device costs, central heating costs, insulation material costs and fuel costs, as Equations (1)-(2) shows.

$$objective = \sum_{t=2020}^{2060} \frac{sumcost_t}{(1+i)^{t-2020}} \quad (1)$$

$$sumcost_t = matc_t + devicec_t + heatc_t + refc_t + fuelc_t \quad (2)$$

Table 1. The technologies used in the model

Type of technology	Name of technology
Low carbonization of building materials	Far-infrared ceramic coating mixture, Electric arc furnace, Hydrogen steelmaking, New cement clinker, Solid regenerative fuel, Carbon capture and storage, Carbon capture and usage, 600kA potcell
Changing of building structure	Brick-frame, Concrete-frame, Steel-frame
Decarbonization of central heating	Coal-fired boiler, Gas-fired boiler, Coal-fired cogeneration, Biomass boiler, Geothermal, Solar heating, Heat pump
Insulation of buildings	Single glazing windows, 2bl glazing windows, Low-e windows, Stone wool insulation materials, Glass wool insulation materials, Expanded polystyrene, Sprayed polyurethane
	Cooking
	Electric water heater, Solar thermal water heater, Gas-fired water heater
End-use electrification	Hot water
	Lighting
	Incandescent lamp, Fluorescent lamp
	Space cooling
	AC-I, AC-II, AC-III
	Decentralized space heating
	Coal-burning fireplace, Solar heating, Heat pump

### 2.2.2. Material constrains

The demand of various materials depends on the newly-built area of different structures, which can be described by Equation (3). Although there may be demolition areas and new areas every year, it is still necessary to ensure that the total area is not less than the required area, listed as Equation (4). The CO<sub>2</sub> emissions caused by building materials are calculated by emission factors and the costs of materials are computed by unit price.

$$matd_{t,mat} = \sum_{str,u} narea_{t,u,str} * MATPRO_{str,mat} \quad (3)$$

$$\sum_{str}(area_{t-1,u,str} + narea_{t,u,str} - darea_{t,u,str}) \geq AREAD_{t,u} \quad (4)$$

$$matco2_t = \sum_{mat,tech} matp_{t,mat,tech} * TECHCO2_{t,mat,tech} \quad (5)$$

$$matc_t = \sum_{mat,tech} matp_{t,mat,tech} * MATPC_{t,mat,tech} \quad (6)$$

### 2.2.3. End-use demand constrains

The end-use demand can be divided into six categories: cooking, hot water, lighting, space cooling, space heating and electricity. Decentralized space heating and central heating constitute space heating. The decentralized equipment at the user end is supposed to meet the end-use demand, including cooking, hot water, lighting, space cooling and decentralized space heating, according to Equation (7). Due to the use of thermal insulation materials, the heating and cold demands of buildings will be reduced accordingly, as described in Equation (8). The coefficient  $COEFC_{r,ref}$  and  $COEFH_{r,ref}$  is related to the climate of the area where the building is located, and is estimated according to the average temperature. The heat provided by central heating should not be less than the demand, with the operation and heat supply of central heating boilers meeting Equation (9). The total power demand is the sum of all appliance electricity consumption, as shown in Equation (10). The consumption of fossil energy, biomass and other renewable energy is calculated according to the actual operation time of the equipment, as shown in Equation (11). The CO<sub>2</sub> emissions from fossil energy and electricity are computed by emission factors, which are described by Equation (12).

$$ENDUSED_{t,r,op} \leq \sum_{u,de,f} ndevice_{t,r,u,de} * OH_{t,r,u,de} * CONSUMPTION_{t,de,f} * CV_f \quad (7)$$

$$endused_{t,r,cooling} = ENDUSED_{t,r,op} - \sum_{ref} refarea_{t,ref} * COEFC_{r,ref} \quad (8a)$$

$$endused_{t,r,heating} = ENDUSED_{t,r,op} - \sum_{ref} refarea_{t,ref} * COEFH_{r,ref} \quad (8b)$$

$$\sum_{th} centralheat_{t,r,th} \leq CENTRALHEATD_{t,r} \quad (9a)$$

$$nbheat_{t,r,th} * OHMIN_{t,r,th} \leq heat_{t,r,th} \leq nbheat_{t,r,th} * OHMAX_{t,r,th} \quad (9b)$$

$$elec_{t,r} = ELECD_{appliance,t,r} + devicefuel_{t,elec} \quad (10)$$

$$devicefuel_{t,f} = \sum_{u,de,r} ndevice_{t,r,u,de} * OH_{t,r,u,de} * DCON_{t,de,f} \quad (11)$$

$$endco2_t = \sum_f devicef_{t,f} * FCO2_f \quad (12)$$

#### 2.2.4. CO<sub>2</sub> emissions constrains

The life-cycle CO<sub>2</sub> emissions of the building sector are composed of material emissions and end-use emissions, which can be described as Equation (13). The total emissions in the life cycle are supposed to meet the upper limit requirements of CO<sub>2</sub> emissions, as shown in Equation (14).

$$sumco2_t = matco2_t + endco2_t \quad (13)$$

$$sumco2_t \leq UPPERCO2_t \quad (14)$$

The model is implemented in General Algebraic Modelling System (GAMS) by using the CPLEX solver.

### 3. Case Study

The proposed model is implied in a case study of the building sector of China, which is divided into 9 regions according to the climate and data availability, as shown in Figure 2. The average life of buildings in China is about 30 years. It is assumed that the life of buildings are extended to 50 years to achieve the decarbonization goals. Several basic assumptions are listed in Table 2.

Table 2. Basic assumptions

Year	2030	2040	2050	2060
Floor area/100 million m <sup>2</sup> (ICCS, 2021)	806	844	861	828
Population/100 million	14.0	13.4	12.6	11.3
Emission factor of electricity /kg·kWh <sup>-1</sup> BAU	0.36	0.24	0.21	0.21
(Song et al., 2022) Decarbonization	0.34	0.13	0.06	0
Total energy demand/100 million tce (Chen et al., 2015)	7.1	8.0	8.8	8.5

#### 3.1. Decarbonization of building materials

Selecting low-carbon materials enables the building sector to lower its life cycle CO<sub>2</sub> emissions. According to the proposed model, average carbon emission factor of materials given in Figure 3 can be referred to elect low-carbon materials when new buildings are constructed in the future. In 2060, the average CO<sub>2</sub> emissions factor of steel reduces to half of that of 2020, and that of cement reduces to one-third of that of 2020. Due to the carbon neutralization of the power system, the average CO<sub>2</sub> emissions factor of aluminium is close to 0.

Figure 2 Geographic division of China

Figure 3 Emission factor of building materials

### 3.2. Decarbonization of building operation

Owing to the application of thermal insulation materials, heat loss is reduced in each region, especially after 2040, which is depicted in Figure 4. Because of the low temperature and long heating period, the application of thermal insulation materials in the northeast is significantly earlier than that in other regions. Despite rare heating demand in South China, thermal insulation materials are supposed to be used after 2050, which can reduce the demand for refrigeration, beneficial to the decarbonization.

As can be seen from Figure 5, which shows the consumption of primary energy, there is a peak both in coal and natural gas. The maximum coal consumption occurs before 2025, which is not much higher than that in 2020. The maximum gas consumption is supposed to appear between 2040 and 2045, with a peak of 250bcm. The electricity demand rises steadily until 2050. Although the electricity demand decreases after 2050 because of the shrinking population and total energy demand, the electrification rate gradually increases from 2020 to 2060, and exceeds 70% in 2060 according to Table 3.

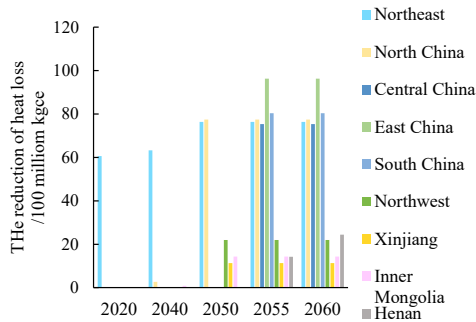

Figure 4 The reduction of heat loss

Figure 5 Fuel consumption during operation

Table 3. Proportion of clean energy

Year	2020	2030	2040	2050	2060
End-use Penetration of renewable energy	4.6%	5.0%	5.3%	12.4%	26.7%
End-use electrification rate	40.2%	27.7%	52.4%	68.2%	72.5%

### 3.3. Comparison of life cycle decarbonization potential in the building sector

Table 4 illustrates the decarbonization potential of various emission reduction methods. It is apparent from this table that extending the average lifespan of Chinese buildings from 30 years to 50 years can significantly reduce the life-cycle emissions, due to the demand for building materials being greatly reduced. This mitigation measure can be achieved by government order. Combined with low-carbon building materials, the

contribution rate of CO<sub>2</sub> reduction in non-operational processes of buildings is higher than 50%. What's more, although previous studies have implied the importance of building reconstruction (Motalebi et al., 2022), only the replacement of windows and the addition of building insulation layers contribute little to decarbonization pursuant to our study. In addition, even if there are no measures taken by the building sector, one fifth of the life-cycle CO<sub>2</sub> emissions of the building sector can be reduced by the power sector. The decarbonization of electricity and the electrification of the building contribute nearly 40% to the reduction of emissions in the building sector, meaning that support for electrification is very necessary for the Chinese government to the public to realize the low-carbon transition of the building sector at a lower cost.

#### 4. Conclusions

This paper proposes a multi-level and multi-region optimization model to analyze the life-cycle decarbonization pathway of the building sector and China is taken as a case study. It can be found that life extension plays a significant role in buildings' life-cycle CO<sub>2</sub> emissions reduction by lowering the demand for building materials. During the operation stage, natural gas becomes one of the main fuels in the next 20 years and the consumption of natural gas declines rapidly, which is consistent with the current policy of China. Although biomass-related technologies are relatively mature, the decarbonization transition of China's building sector cannot be entirely dependent on biomass due to lack of biomass resources. The improvement of end-use electrification rate is essential for the emission mitigation of buildings, which is supposed to be increased from 40% in 2020 to 70% in 2060. Therefore, to achieve life-cycle CO<sub>2</sub> reduction in the building sector in China, attention to building life extension and electrification must be paid, meaning that reasonable urban planning and electrification reform of buildings should be the major work of China's building sector in the future.

Table 4. The decarbonization potential of various emission reduction methods

Methods	CO <sub>2</sub> reduction in 2060 /100 million tonnes	Proportion	Total CO <sub>2</sub> reduction in 40 years /100 million tonnes	Proportion
Life extension	3.4	14.5%	268.7	41.3%
The use of low-carbon materials	1.7	7.2%	70.6	10.8%
Decarbonization of central heating	4.0	17.0%	62.9	9.7%
Insulation	0.2	0.9%	3.4	0.5%
Electrification of distributed heating, cooking and hot water	6.1	26.0%	109.4	16.8%
Decarbonization of electricity	8.1	34.4%	135.8	20.9%

## Abstract

The industrialization of catalytic processes benefits strongly from kinetic models for optimization and control purposes. Nevertheless, mechanistic models are difficult to construct; data-driven and hybrid models lack interpretability and the flexibility to leverage physical knowledge. Thus, a different approach called automated knowledge discovery has been recently popularized. Existing methods in literature suffer from important drawbacks: necessitating assumptions about model structures, a lack of model selection automation, and sensitivity to noise. To overcome these challenges, the present work constructs a methodological framework for the automated generation of catalytic kinetic models. We leverage symbolic regression for model generation, a hybrid optimization algorithm for parameter estimation, and a robust criterion for model selection. The framework is tested with an illustrative isomerization case study, where it showcases the ability to retrieve the underlying kinetic model with a limited amount of noisy data from the catalytic system.

**Keywords:** catalysis, kinetic model generation, automated knowledge discovery, information criteria, machine learning.

## 1. Introduction

The industrialization of catalytic processes requires kinetic models, which are a mathematical representation of the dynamical trajectories of a chemical system, typically presented in the form of ordinary differential equations. Kinetic models can be constructed using any of the three classical modelling paradigms: mechanistic (white-box), data-driven (black-box) or hybrid (grey-box). Mechanistic models are constructed by using existing fundamental laws, such as mass, energy, and momentum balances, making them interpretable and extrapolatory (Baker, 2018). However, the construction of these models can be time-consuming and experimentally expensive. Data-driven models do not use any fundamental laws for their construction. Typically, these models are constructed by solely using collected data of a system, making their construction time-efficient but experimentally expensive. Furthermore, these models generally have poor extrapolatory abilities and are uninterpretable, which may classify their usage for certain industrial scenarios as unsafe. In comparison, hybrid models aim to exploit the advantages

of mechanistic and data-driven modelling. Hybrid models are composed of two parts: a mechanistic backbone and a data-driven block which aims to improve the backbone's fit. Generally, hybrid models retain the extrapolation capabilities of a mechanistic model and the flexibility and ease of construction of a data-driven model.

Hybrid modelling offers an elegant solution to the problems posed by the other classical modelling paradigms, but not an optimal one. A better solution would be to utilize existing data to automatically generate and select mechanistic models by exploiting state-of-the-art statistical and machine learning methods. In this way, the benefits of mechanistic models are maintained, whilst some of their drawbacks are eliminated. This modelling paradigm has been coined *automated knowledge discovery* and has recently gained popularity. In current literature, many automated knowledge discovery frameworks have been developed, such as: the ALAMO approach (Wilson, 2017), the SINDy algorithm (Brunton, 2016), and symbolic regression using genetic programming (Koza, 1994). These frameworks have three drawbacks that limit their ability to retrieve underlying ground-truth models, and consequently, their real-world applicability. Firstly, they necessitate substantial structural assumptions of the underlying data-generating model. This is particularly true of ALAMO and SINDy, as a design matrix needs to be constructed for their execution (Wilson, 2017; Brunton, 2016). Secondly, they lack a motivated and rigorous model selection routine (Wilson, 2017; Brunton, 2016; Koza, 1994). Lastly, they are sensitive to noisy data (Wilson, 2017; Brunton, 2016; Koza, 1994). Hence, this work aims to overcome these obstacles by constructing a generalizable and robust methodological framework that integrates a rigorous model selection routine for the automated kinetic model discovery of catalytic systems.

The rest of the paper will be structured as follows: in Section 2, the proposed automated knowledge discovery framework is motivated and described in detail; in Section 3, the illustrative case study used to showcase the capabilities of the proposed methodology is introduced; in Section 4, the results of the study are amply discussed; in Section 5, the key findings are presented, and the outlook of the research is explored.

## 2. Methodological Framework

Given the objective of automated knowledge discovery, the proposed methodological framework constitutes three main stages: model generation, model refinement, and model selection and discrimination.

Symbolic regression using genetic programming (SR-GP) is often considered the most generalizable and reliable model generation method found in literature, as this method does not require the construction of a design matrix. In other words, assumptions regarding an underlying ground-truth model are minimal. The basic concept of SR-GP is to specify a set of state variables and operators (e.g.: '+', '/') that may be present in the underlying mechanistic model. With this, an initial population of models can be constructed, and based on Darwin's theory of evolution, the best models – based on a specified performance metric – are evolved via genetic operations (e.g.: crossover and mutation), and the worst models are discarded. This process is iterated until convergence is achieved or a termination criterion is met. As such, for the model generation stage, we propose a weak reformulation of SR-GP, where models generated represent a mapping between input and output variables in the derivative hyperspace. In other words, this reformulation generates functions dependent on the state variables that can map the output via an integration step. In this way, weak SR-GP receives the dynamic trajectories of

concentration as inputs, proposes rate models ( $r = f(C_1, C_2, \dots)$  where  $C_i$  is the concentration of species  $i \in \mathbb{Z}^+$ ) integrates the rate models with respect to time at each given time-step where concentration data is available ( $\int r dt = \int \frac{1}{v_i} \frac{dC_i}{dt} dt = \frac{1}{v_i} C_i(t)$ ), and compares the results from the integration with the original dataset.

Once promising rate models are proposed by the weak reformulation of SR-GP, model refinement needs to take place. Specifically, the model refinement comes as a parameter estimation problem, where the error between the model's response and the data are minimized by finding the best set of kinetic parameters. This optimization problem is solved by deploying a hybrid optimization algorithm composed of an explorative phase, carried out by an artificial bee colony (ABC) algorithm, and an exploitative phase carried out by a limited memory Broyden Fletcher Goldfarb Shanno (LBFGS) algorithm. The former is a stochastic optimization algorithm shown to have excellent explorative characteristics (Cho, 2021), while the latter is a gradient-based optimization algorithm shown to have excellent exploitative characteristics (Malouf, 2002). The objective function used for the parameter estimation was the negative log-likelihood (NLL), presented below:

$$f(\boldsymbol{\theta}) = \sum_{i,j,k} \left[ \frac{(C_{i,j,k} - y_i(\boldsymbol{\theta}, \mathbf{x}_0)_{j,k})^2}{2\hat{\sigma}_i^2} - \log \left( \frac{1}{\sqrt{2\pi\hat{\sigma}_i^2}} \right) \right] \quad (1)$$

where  $C_{i,j,k}$  is the simulated concentration (i.e.: in-silico data) of species  $i \in S$  for dataset  $j \in D$  at time  $k \in T$ , where  $S$ ,  $D$ , and  $T$  represent the species set, data set and time set, respectively;  $y_i(\boldsymbol{\theta}, \mathbf{x}_0)_{j,k}$  is the concentration of species  $i \in S$  for dataset  $j \in D$  at time  $k \in T$  proposed by an arbitrary model which is dependent on its parameters  $\boldsymbol{\theta}$  and the initial conditions  $\mathbf{x}_0$ ;  $\hat{\sigma}_i^2$  is the variance of the noise that we assume the concentrations of species  $i \in S$  has. Once all the promising models have been explicitly optimized, the models are ranked based on their Akaike information criterion (AIC) values. The AIC was selected after a thorough analysis of the performance of different criteria under several conditions (e.g.: different amounts of additive noise, different amounts of data). This analysis concluded that AIC has a statistically higher probability of selecting the correct data-generating rate model than the other criteria tested.

After the ranking of the optimized models has been established based on AIC values, the Akaike weights of each model,  $w_i(\boldsymbol{\theta}_i, \mathbf{x}_0)$ , (i.e.: a statistical measure that quantifies the probability of a model structure being the correct one based on AIC values) are also evaluated. Provided a user-defined tolerance  $\epsilon \in \mathbb{R}^+$ , if  $|w_1(\boldsymbol{\theta}_1, \mathbf{x}_0) - w_2(\boldsymbol{\theta}_2, \mathbf{x}_0)| \leq \epsilon$ , then the modeler cannot be confident enough of the AIC selection, extra discriminatory experiments should be performed, and the process repeated. The discriminatory experiment can be determined by solving the Hunter-Reiner criterion, which aims at finding the experimental conditions that will maximize the difference between the response of two competing models. If  $|w_1(\boldsymbol{\theta}_1, \mathbf{x}_0) - w_2(\boldsymbol{\theta}_2, \mathbf{x}_0)| > \epsilon$ , then the modeler can be confident of the AIC selection and should integrate the proposed rate model and compare it with the dynamic trajectories of the concentrations. If the results are satisfactory, the methodological framework is terminated. Otherwise, further data should be collected by applying (model-based) design of experiments – a strategy aimed at computing maximally informative experiments. For clarity and simplicity, the flowchart of the proposed methodological framework is presented in Figure 1.

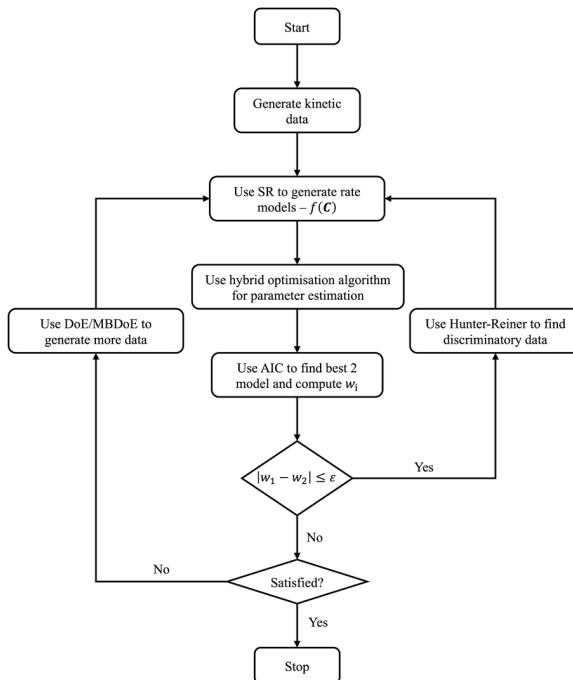

Figure 1: The flowchart of the proposed methodological framework featuring a weak reformulation of SR-GP

### 3. Kinetic Case Study

To showcase the performance of the proposed methodology, an illustrative case study of an isomerization reaction was chosen, where A is transformed to B reversibly over a catalytic active site. The reaction mechanism and the King-Altman graph of the case study are displayed in Figure 2(a).

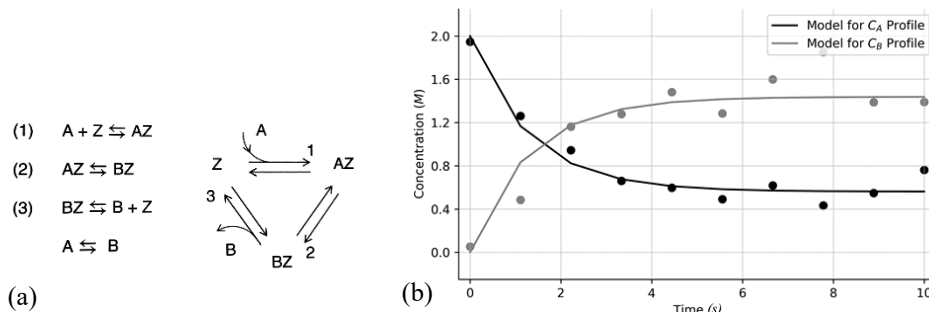

Figure 2: (a) Mechanism and King-Altman graph of illustrative isomerization reaction (Marin, 2019); (b) response of the chosen rate model for one of the three computational experiments

Given the presented mechanism, a rate model was derived and is shown in Equation 2. A detailed derivation of the rate model is found in (Marin, 2019).

$$r = -\frac{dC_A}{dt} = \frac{dC_B}{dt} = \frac{k_A C_A - k_B C_B}{k_C C_A + k_D C_B + k_E} \quad (2)$$

In Equation 2,  $C_A$  and  $C_B$  represent the concentration of reactant A and product B, respectively. The kinetic parameters of the rate model are represented by  $k_i$  where  $i \in$

$\{A, B, \dots, E\}$ . To generate the necessary data to test the proposed framework, three computational experiments were carried out, each with different initial conditions. The simulations were run with the following initial conditions (in molar units):  $(C_{A0}, C_{B0}) \in \{(2,0), (6,1), (10,2)\}$ . For each simulation, the concentration of the reactant and product are recorded at evenly spaced intervals between time  $t = 0$  s and  $t = 10$  s. For the simulations, the kinetic parameters were defined as:  $k_A = 7 \text{ M s}^{-2}$ ,  $k_B = 3 \text{ M s}^{-2}$ ,  $k_C = 4 \text{ s}^{-1}$ ,  $k_D = 2 \text{ s}^{-1}$  and  $k_E = 6 \text{ M s}^{-1}$ . To ensure that the generated data is as realistic as possible, Gaussian noise was added to the simulation results. The defined Gaussian noise had zero mean and a standard deviation of 0.13 for the concentrations of A, and 0.21 for the concentrations of B (the standard deviations represent 5% of the mean of the simulated concentrations of A and B). For the parameter estimation task, it would be futile to assume that as modellers the exact variance of the noise would be known. Thus, a conservative assumption was made by setting  $\hat{\sigma}_A = 0.26$  and  $\hat{\sigma}_B = 0.42$ , (i.e.: assuming a standard deviation of 10% of the mean of the simulated concentrations of A and B).

#### 4. Results and Discussion

As explained in Section 2, the proposed methodological framework implements a weak reformulation of SR-GP which automatically evolves rate models by integrating and comparing them with the concentration data available. Note that the law of conservation of mass is satisfied by construction under this integrating scheme. Departing from the kinetic data generated, the SR algorithm was used to generate rate models. The expression construction rules exclusively included the arithmetic operators ‘+’, ‘-’, ‘×’ and ‘/’, since rates including other operators are less common. The rate models generated were a function of the species whose concentrations were measured,  $r(C_A, C_B)$  in this case. The best expression proposed by the weak SR-GP, sorted by degree of complexity (i.e.: the number of operators and variables), are shown in Table 1.

The estimation of each kinetic parameter,  $k_i$  where  $i \in \{1, 2, \dots, 6\}$ , was carried out as explained previously: NLL was used as the objective function where the assumed variances for NLL are double of the real variances used to generate the Gaussian noise, and this is solved by using the hybrid algorithm comprised of the ABC and the LBFGS algorithms. The NLL, AIC and Akaike weight (AW) values for each of the weak SR-GP proposed and optimized models are also presented in Table 1 below. This shows that  $r_6$  and  $r_3$  are the best and second-best models for the given data, and by setting an Akaike weight tolerance of  $\epsilon = 0.05$ , we can be confident in the AIC’s choice that  $r_6$  is the best model to represent the dynamical catalytic reactive system under investigation, without requiring further discriminatory data. The response of the selected model is shown in Figure 2(b). For the sake of brevity, only one of the experiments is presented. The final rate model output by the proposed framework had a near identical structure to the data-generating one, differing only by a single parameter in the numerator. However, the hybrid optimization algorithm used for parameter estimation was able to determine that the extra parameter was practically zero, and therefore may be non-existent in the actual model. The discrepancy in other parameters may be attributed to the additive Gaussian noise in the data. Table 2 details the estimated kinetic parameter values and the original values of the true data-generating rate model.

Table 1: The NLL value, the AIC values and the Akaike weight (AW) values of all weak SR-GP proposed rate models

Model	NLL Value	AIC Value	AW Value
$r_1 = k_1$	540.410	1082.821	0.000

$r_2 = k_1 C_A$	53.857	109.715	0.000
$r_3 = \frac{k_1 C_A - k_2 C_B}{k_3 C_A}$	-0.831	4.337	0.244
$r_4 = \frac{k_1 C_A - k_2 C_B - k_3}{k_4 C_A}$	-0.988	6.025	0.105
$r_5 = \frac{k_1 C_A - k_2 C_B - k_3}{k_4 C_A + k_5}$	-2.724	4.551	0.219
$r_6 = \frac{k_1 C_A - k_2 C_B - k_3}{k_4 C_A + k_5 C_B + k_6}$	-4.275	3.450	0.380
$r_7 = \frac{k_1 C_A^2 C_B - k_2 C_A C_B^2 - k_3 C_A + k_4 C_B}{k_5 C_A^2 C_B - k_6 C_A}$	-2.289	7.422	0.052

Table 2: The estimated kinetic parameters from the chosen rate model proposed by proposed framework and the original kinetic parameter's values

Kinetic Parameter	Estimated Value	True Value
$k_1, k_A$	5.557 M s <sup>-2</sup>	7.000 M s <sup>-2</sup>
$k_2, k_B$	2.335 M s <sup>-2</sup>	3.000 M s <sup>-2</sup>
$k_3$	0.000 M <sup>2</sup> s <sup>-2</sup>	N/a
$k_4, k_C$	3.114 s <sup>-1</sup>	4.000 s <sup>-1</sup>
$k_5, k_D$	1.379 s <sup>-1</sup>	2.000 s <sup>-1</sup>
$k_6, k_E$	6.033 M s <sup>-1</sup>	6.000 M s <sup>-1</sup>

## 5. Conclusions and Outlook

In this work, we proposed an automated knowledge discovery framework for the generation of catalytic kinetic models from data. A combination of a reformulation of SR-GP, parameter estimation through hybrid optimization, and a rigorous model selection and discrimination routine alleviate drawbacks of alternative automated knowledge discovery methods in literature. The presented case study showcases the framework's ability to retrieve the underlying kinetic model of a catalytic system with a limited amount of noisy data. Future work will pursue strategies to incorporate physical constraints into the model generation, to increase its efficiency through physical guidance.

## Abstract

Quantitative models are useful tools to accelerate the development of pharmaceutical processes. The assessment of the predictive capability of such models is fundamental to enhance their usage in a systematic way, particularly when the focus is on flowsheet models. In this study, we propose a systematic procedure that combines techniques that are typically used in different modeling contexts – namely, global sensitivity analysis, model-based design of experiments, and data reduction by means of multivariate statistical methods, with the advantage of enhancing readability and interpretation. The methodology is effective for the assessment of model fidelity and can support practitioners in the development of pharmaceutical processes. A direct compression systems model for manufacturing oral solid dosage products is used as a case study. Results show that just a subset of model parameters require precise estimation to meet the target critical quality attribute, and that calibrating flowsheet models on a unit-by-unit basis may be unnecessary when the focus is on one final quality attribute.

**Keywords:** systems model, pharmaceutical development, model identifiability, parameter estimation, model fidelity, pharmaceutical engineering.

## 1. Introduction

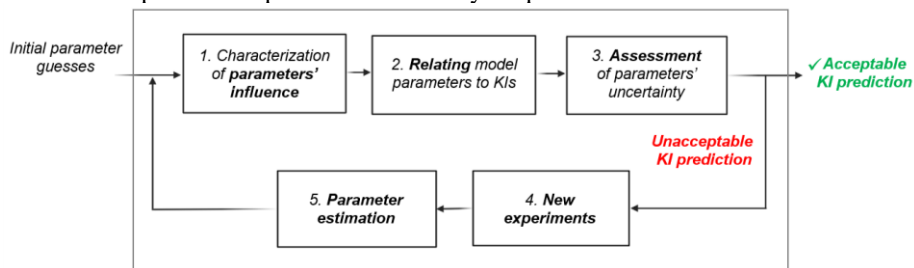

Quantitative models have been progressively adopted to accelerate the development of pharmaceutical manufacturing processes that traditionally requires time and resource-intensive experimental campaigns (Bano et al, 2022). Despite the potential benefits of modeling in pharmaceutical process development, the systematic use of these methods is not widespread, as stakeholders generally show a lack of confidence in the prediction capability of quantitative models with respect to key performance indicators (KPIs) or critical quality attributes (CQAs), which we will generically call key indicators (KIs) (Braakman et al, 2022). It is worth adding that pharmaceutical processes involve very complex phenomena, which may not be easily captured by first-principles models; therefore, high in-house expertise and resources are required (Boukouvala et al, 2011; Polak et al, 2023).

The prediction reliability of a quantitative model largely depends on the precision of model parameter estimates. A particular case is given by flowsheet models (or *systems models*, as they are often called in the pharmaceutical sector), where several unit operation models are connected, and the KIs are the outputs of some units (often the final one). It

is evident that, in general, the prediction fidelity of a KI depends not only on the parameters of the specific unit operation model, but also on the parameters of all unit operation models impacting the unit of interest. In this context, one may wonder whether *all* parameters should be estimated in a statistically satisfactory way or just a subset of them, and what parametric precision is sufficient to satisfy the prediction requirements for the KI. In this study, we propose a model evaluation framework to support the critical usage of quantitative models within pharmaceutical manufacturing process development. The methodology combines traditional tools typically adopted for parameter estimation purposes – namely global sensitivity analysis (GSA) and model-based design of experiments (MBDoE) – with techniques based on data analytics, that allow to graphically represent both model parameters and the KI onto a common space. A direct compression systems model for manufacturing oral solid dosage (OSD) products is used as a case study.

## 2. Methodology

In this section we describe the methodology for the assessment and quantification of parameters impact on the prediction reliability of quantitative models.

**Figure 1:** Schematic of the proposed methodology to quantify the model parameters' impact on the prediction reliability of quantitative models.

The workflow consists of multiple sequential steps (Fig. 1):

- **Step 1.** The objective is to characterize the parameter impacts on the prediction of the selected KI, so that the most influential parameters can be identified. We use Sobol's GSA to understand how the variability of the selected KI can be allocated to each model parameter.
- **Step 2.** The goal is quantifying the parameter impacts on the model prediction fidelity. In order to assist the interpretation of these results, here we suggest using a partial least-squares (PLS) regression model to relate the model parameters to the selected KI. Details are reported in § 2.1.
- **Step 3.** It is necessary to assess if the precision of the model parameters is sufficient. To this purpose, the estimated uncertainties of model parameters are projected onto the PLS model. If some projections fall outside the KI acceptability region, new experiments are needed to increase the parameters' precision. No improvement is required if all uncertainties fall inside the KI acceptability region (stop criterion).
- **Step 4.** If the parameters' precision requires improvement based on the output of Step 3, new experiments should be designed to collect new data. Experiments are designed through MBDoE techniques (Franceschini and Macchietto, 2008) to strengthen the precision of the most influential parameters identified at Step 1.
- **Step 5.** Once new data are available, all model parameters are estimated using a maximum likelihood estimator.

The procedure is iteratively repeated until satisfaction of the stop criterion.

### 2.1. Use of a PLS model

Let  $\mathbf{X}$  [ $N \times V$ ] be the input (regressor) matrix of  $N$  observations of  $V$  variables, and  $\mathbf{Y}$  [ $N \times L$ ] the response matrix of  $L$  variables. PLS (Geladi and Kowalski, 1986) is a multivariate regression technique that projects the regressor and response variables onto a common latent space, according to the model structure:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^T + \mathbf{E}_X ; \quad \mathbf{Y} = \mathbf{T}\mathbf{Q}^T + \mathbf{E}_Y . \quad (1)$$

First, we generate a set of parameters combinations using Monte Carlo simulations, given their initial uncertainties. These combinations of model parameters make the set of regressors  $\mathbf{X}$ , while the predicted KI is the response variable  $\mathbf{y}$ .  $\mathbf{T}$  [ $N \times V$ ] is the score matrix,  $\mathbf{P}$  [ $V \times A$ ] and  $\mathbf{Q}$  [ $L \times A$ ] are arrays of loadings,  $A$  = number of latent variables (LVs), while  $\mathbf{E}_X$  and  $\mathbf{E}_Y$  are the residuals in the inputs and responses, respectively. We fix operating conditions so that the KI is equal to the target value, given the initial parameters guesses. Then, the PLS model is used in its inverse form (Jaeckle and MacGregor, 2000) to determine the set of input combinations that yield the desired tolerance on the target KI. The quality target is described by inequality constraints (bound values for the response prediction), which in turn defines the KI acceptability region. If the dimensionality of the latent space is greater than the  $y$ -space, multiple solutions of the model inversion problem exist, and are defined by the null space:

$$W = \{(\mathbf{t}_{new} + \mathbf{t}), \mathbf{t} \in \ker(\mathbf{Q})\}, \quad (2)$$

where  $\mathbf{t}_{new} = (\mathbf{Q}^T \mathbf{Q})^{-1} \mathbf{Q}^T \mathbf{y}^{*T}$  is the score vector for the target response variable  $\mathbf{y}^*$ . The use of a PLS model to relate parameters combinations and KIs gives us the possibility to monitor the evolution of parameter uncertainties along each iteration of the methodology in Fig. 1. We obtain a clear graphical representation of both regressor and response variables onto a common latent space that can be easily interpreted.

## 3. Case Study

A direct compression systems model for manufacturing OSD products is used as a case study. The systems model comprises a tablet press unit operation and a tablet disintegration unit.

### 3.1. Tablet press unit operation

First, the variation in tablet solid fraction caused by the compaction pressure,  $P$  [MPa], exerted by the press is expressed according to Kawakita and Lüdde (1971):

$$sf = \frac{a_{sf}(1 + b_{sf}P)}{1 + a_{sf}b_{sf}P} , \quad (3)$$

where  $sf$  [-] is the attained tablet solid fraction, while  $a_{sf}$  [-] and  $b_{sf}$  [MPa<sup>-1</sup>] are model parameters to be estimated. The Kushner (2012) equation is used to relate the effect of the extent of lubrication  $K$  [dm] attained in the upstream powder blending on the tablet tensile strength:

$$TS = TS_0((1 - \beta) + \beta \exp(-\gamma K)) , \quad (4)$$

where  $TS$  [MPa] is the tensile strength,  $TS_0$  [MPa] is the tensile strength at zero porosity,  $\gamma$  [dm<sup>-1</sup>] is the lubrication rate constant, and  $\beta$  [-] is the total fraction of tensile strength that can be lost due to lubrication. The empirical model by Nassar et al. (2021) accounts for the dependence of the Kushner parameters on the attained tablet solid fraction:

$$TS_0 = a_1 \exp(b_1(1 - sf)) , \quad (5)$$

$$\beta = a_2(1 - sf) + b_2 . \quad (6)$$

The model parameters  $a_1$  [MPa],  $b_1$  [-],  $a_2$  [-] and  $b_2$  [-] need to be estimated.

### 3.2. Tablet disintegration

Both erosion and swelling (Markl et al., 2017) mechanisms are considered.

Erosion is described as:

$$V_c = (H_{coat} - \dot{\epsilon}t)A_t, \quad (7)$$

where  $V_c$  [m<sup>3</sup>] is coating volume varying with time  $t$  [s],  $H_{coat}$  [m] is the thickness of the coating layer,  $A_t$  [m<sup>2</sup>] is the tablet surface area, and  $\dot{\epsilon}$  [m s<sup>-1</sup>] is the constant erosion rate. The dynamic evolution of the penetration depth due to swelling is modelled as:

$$\frac{dP_d}{dt} = \left(\frac{P}{F_L/A_t}\right)^{n(T_{t/2}-P_d)/T_{t/2}} \left[\frac{d_h^2 \epsilon}{S_p \mathcal{T}_{or}^2 \mu P_d}\right] p_c, \quad (8)$$

where  $P_d$  [m] is the water penetration depth,  $F_L$  [MN] the tablet hardness,  $d_h$  [m] the tablet hydraulic diameter,  $\mathcal{T}_{or}$  [-] the average tablet tortuosity,  $\mu$  [Pa s] the liquid viscosity,  $p_c$  [Pa] the capillary pressure.  $S_p$  [-] and  $n$  [-] are formulation-dependent model parameters to be estimated. Parameter  $n$  can be estimated if dynamic penetration depth data are available, e.g., via terahertz (THz) spectroscopy. However, this is a relatively new technology if compared to a standard end-point disintegration time test. If

we only have end-point disintegration data, the term  $\left(\frac{P}{F_L/A_t}\right)^{n(T_{t/2}-P_d)/T_{t/2}}$  can be replaced with a lumped parameter  $\Lambda$  [-] which can be fitted.  $T_{t/2}$  [m] is the time-dependent half tablet thickness, and  $\epsilon$  [-] represents the average porosity of the swollen product. The stress due to tablet expansion from swelling is defined according to Peppas and Colombo (1989):

$$\tau = -TS + C_2 w_l + C_3 \sqrt{w_l}, \quad (9)$$

where  $\tau$  [MPa] is the total stress,  $w_l$  [-] is the liquid content in the tablet, and  $C_2$  [MPa] and  $C_3$  [MPa] are model parameters to be estimated. From  $\tau$ , we can compute  $\epsilon$  to be included in Eq. (8):

$$\tau = \frac{G_0 \exp\left(-\frac{B\epsilon}{1-\epsilon}\right) \lambda t}{T_{t/2}}, \quad (10)$$

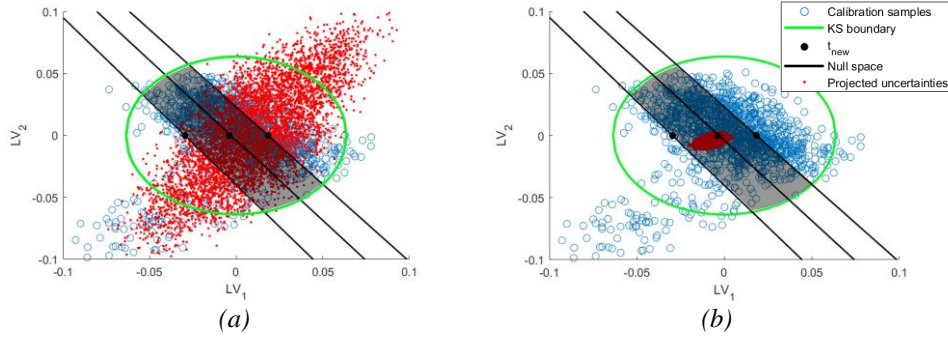

with  $G_0$  [MPa] and  $B$  [-] elastic constants from literature, and  $\lambda$  [s<sup>-1</sup>] the swelling rate (Kuentz and Leuenberger, 1998). We define the disintegration time as the time for which the tablet stops disintegrating, i.e.,  $dP_d/dt = 0$ . Five model parameters need to be estimated:  $C_2$ ,  $C_3$ ,  $\dot{\epsilon}$ ,  $n$ ,  $S_p$ .

### 3.3. Product quality assessment

We consider an immediate release product, with a target disintegration time of 4 min. According to USP <701> (2011) disintegration test specifications, the time limit for the formulation to completely disintegrate is 5 min; therefore, we set  $\pm 1$  min as the admissible tolerance with respect to the target value of the disintegration time. Results from Sobol's GSA (Step 1) are collected in two different metrics: the first-order sensitivity index  $S_i$ , which accounts for the direct effect of each parameter on the KI, and the total sensitivity index  $S_{i,TOT}$ , which also accounts for interactions with the other model parameters (Table 1). The use of both indices allows us to identify possible parameter interactions. Uniform distributions for the model parameters were assumed, and bounds were chosen on typical values that can be found in the literature (Peppas and Colombo, 1989; Nassar et al., 2021). The initial parameters' uncertainties were assumed equal to  $\pm 50\%$  of the nominal values, as reported in Table 2. The five most influential parameters, as characterized by the greatest total sensitivity indices, are:  $a_{sf}$ ,  $b_1$ ,  $b_{sf}$ ,  $n$  and  $S_p$ . Note that  $a_{sf}$ ,  $b_1$  and  $b_{sf}$  are parameters related to the tablet press model, suggesting that considering only the second unit may cause a loss of information compared to the consideration of both the tablet press and the disintegration together.

**Table 1.** Sobol's sensitivity indices for the parameters of the direct compression systems model with respect to the disintegration time. The most influential model parameters are in boldface.

Parameter	$S_i$	$S_{i,TOT}$
$a_1$	$4.767 \times 10^{-4}$	$1.925 \times 10^{-2}$
$a_2$	$3.762 \times 10^{-4}$	$5.478 \times 10^{-3}$
<b><math>a_{sf}</math></b>	<b><math>8.425 \times 10^{-2}</math></b>	<b>0.286</b>
<b><math>b_1</math></b>	<b><math>1.562 \times 10^{-3}</math></b>	<b><math>5.431 \times 10^{-2}</math></b>
$b_2$	$1.273 \times 10^{-4}$	$1.634 \times 10^{-2}$
<b><math>b_{sf}</math></b>	<b><math>2.245 \times 10^{-2}</math></b>	<b>0.139</b>
$\gamma$	$2.332 \times 10^{-4}$	$2.695 \times 10^{-4}$
$C_2$	$2.815 \times 10^{-4}$	$3.992 \times 10^{-3}$
$C_3$	$2.209 \times 10^{-4}$	$3.731 \times 10^{-3}$
$\dot{\epsilon}$	$3.603 \times 10^{-4}$	$5.042 \times 10^{-4}$
<b><math>n</math></b>	<b>0.641</b>	<b>0.881</b>
<b><math>S_p</math></b>	<b><math>1.312 \times 10^{-2}</math></b>	<b>0.101</b>

**Figure 2.** Application of the proposed methodology to the direct compression systems model for the assessment of tablet disintegration time: (a) initial iteration, (b) final iteration where all projected uncertainties expressed using new estimates CIs (red points) fall inside the KI acceptability region (black area).

The relationship between model parameters and the KI is assessed by building a PLS model (Step 2). We verified that two LVs are sufficient to capture enough variance of the data. With reference to the first iteration of the proposed workflow in Fig. 1, LV1 explains  $\sim 44\%$  the total variance, while LV2  $\sim 28\%$ . Confidence limits are considered in the latent space in the shape of an ellipse, whose semi-axis  $s_a$  along the  $a^{\text{th}}$  direction is defined as  $s_a = \sqrt{\lambda_a T_{lim}^2}$  ( $\lambda_a$  = eigenvalue of the matrix  $\mathbf{X}^T \mathbf{y} \mathbf{y}^T \mathbf{X}$ ;  $T_{lim}^2 = 95\%$  confidence limit); this region defines the knowledge space (KS) boundary. By assessing the effect of the initial model parameter uncertainty on the KI (Step 3), it can be observed that the prediction fidelity requirement for disintegration time cannot be satisfied, as many projections lie outside of the KI acceptability region (Fig. 2a). Thus, MBDoE techniques are applied to increase the precision of the five relevant parameters (Step 4); (in-silico) experimental data are used to re-estimate all parameters (Step 5). Seven iterations are required to reach the required model fidelity with respect to the KI prediction, i.e., seven experimental runs would need to be simultaneously performed for the two units. The results after the final iteration are shown in Fig. 2b: all projected uncertainties of parameter estimates fall inside the KI acceptability region. Finally, we report the estimated values of model parameters with their 95% confidence intervals (CIs) and  $t$ -values (Table 2). It can be observed that parameters  $C_2$ ,  $C_3$  and  $\dot{\epsilon}$  do not require precise estimation ( $t$ -values are lower than the reference) to meet the KI specification, and additional experimental effort can be saved.

**Table 2.** Estimated values of model parameters with their 95% CIs and *t*-values. † = 95% CI larger than  $\pm 50\%$  the parameter guess value, \* = precision is not statistically satisfactory.

Parameter	Units	Nominal	Estimated	95% CI	<i>t</i> -value

					<i>t</i> <sub>ref</sub> = 1.646

## 4. Conclusions

In this study, a systematic workflow for the development and assessment of the predictive capability of quantitative models has been proposed and assessed. The methodology combines traditional tools with techniques based on data analytics, with the advantage of graphically represent both model parameters and the KI onto a common latent space. The methodology can be applied to any model, and be used to guide practitioners in model development and the subsequent usage for pharmaceutical process development.

## Abstract

Desalination is one of the techniques used for meeting increasing water demand around the world. However, as the technology is energy intensive, the increasing energy price around the globe will force the practitioners to optimise the process from the point of minimising water production cost. The motivation of this study is to carry out simulation and optimisation of a reverse osmosis (RO) system to estimate and minimise the freshwater production cost. For this purpose, a detailed mathematical model of the process is developed using a combination of an earlier model of RO developed by the authors and a set of cost model equations collected from the open literature. The medium-scale industrial brackish water RO desalination system of Arab Potash Company in Jordan is selected as a case study. The model is first used in simulation mode which provides the detailed insight of the process and feasible operation envelope. The model is then embedded in a single objective non-linear optimisation framework to determine the best operating parameters in order to minimise the freshwater production cost while optimising several operating parameters and meeting the desired water quality specification in terms of salinity. Sensitivity of energy cost on the optimum operating conditions will also be presented in detail.

**Keywords:** Brackish water desalination; Reverse Osmosis system; Simulation; Optimisation; Water production cost.

## 1. Introduction

One of the methods being utilised to fulfil the rising water demand of the world is desalination (Mujtaba and Sowgath, 2022). However, such processes require huge amount of energy, and the rising cost of energy globally compels practitioners to optimise the process from the standpoint of reducing the freshwater production cost. Brackish Water Reverse Osmosis (BWRO) process is commonly used as a successful desalination method in many countries including Jordan and Saudi Arabia using groundwater with salinity ranging between 1,000 ppm to 10,000 ppm (Afonso et al., 2004).

According to the latest study of Pearson et al. (2021), the freshwater production cost varies between 0.39\$ to 0.66\$ per cubic meter of freshwater for water productivities ranging between 10,000 to 70,000 m<sup>3</sup>/d. However, there is still a scope of reducing the freshwater production cost further while enhancing the BWRO performance. Model based techniques can be applied to BWRO processes to identify such opportunity. Several researchers were successful in identifying optimal design and operating conditions of RO processes via simulation and optimisation leading to reduced freshwater production cost

of water. For instance, Arroyo and Shirazi (2012) evaluated the total freshwater production cost of six brackish water RO desalination facilities in Texas with productivity ranging between 5455.3 to 125017.47 m<sup>3</sup>/day and the cost ranging between 0.24 to 0.528\$ per cubic meter of freshwater. Ghaffour et al. (2013) carried out a techno-economic evaluation of the freshwater production cost considering the main influential parameters of different water desalination facilities resulting in 0.5 \$/m<sup>3</sup> of freshwater. Using simulation and optimisation, an economic study was achieved by Atab et al. (2016) to assess the specific energy consumption and freshwater production cost of brackish water RO desalination system which utilised a pressure exchanger as an energy recovery device. A specific model of RO process was used to carry out. The study resulted in 24000 m<sup>3</sup>/day of productivity at 0.11 \$/m<sup>3</sup> and freshwater salinity of 400 ppm from feed water salinity 15,000 ppm with specific energy consumption of 2.8 to 0.8 kWh/m<sup>3</sup>.

Recently, Pearson et al. (2021) attempted to obtain real cost information of seven BWRO plants in Florida, built between 2004 to 2013, for the period between 2017 and 2019. Considering the calculations of capital cost and operating cost of the plants with capacity ranging between 1364 to 56818 m<sup>3</sup>/day and brackish water salinity ranging between 2,000 to 6,000 ppm, the freshwater production cost varied between 0.23 to 0.63 \$/m<sup>3</sup> of freshwater. Using solar energy for different RO-PV designs, most recently Shalaby et al. (2022) reported the freshwater cost between 0.74-1.58 \$/m<sup>3</sup>.

The cost of desalination varies significantly depending on the location and is influenced by several factors, such as the feed water source, feed water quality, plant size, process type and design including energy recovery, intake type, pre- and post-treatment processes, concentrate disposal method, regulatory issues, land costs, and water conveyance to and from the plant. Because of these variations in water quality and quantity from site to site, and occasionally even within the same site, it is expected that the cost of RO brackish water desalination will be the same for all cases and condition. However, each case should be optimised to obtain the minimum freshwater production cost. To the best of our knowledge, there has not been any study to predict the freshwater production cost of a medium scale industrial BWRO system. This study estimates the freshwater production cost of the RO plant via simulation and optimisation using model-based technique. To carry out this task, an earlier RO model developed by the same authors and a set of cost model equations gathered from the open literature are combined to create a thorough mathematical model of the RO process comprising the estimation of freshwater production cost and associated specific energy consumption. The model is initially utilised in simulation mode, which offers an understanding of the actual freshwater production cost and a workable operational envelope. In order to reduce the cost of producing water while optimising a number of operating parameters and achieving the appropriate salinity specification, the model is then incorporated into a single objective non-linear optimisation framework.

## 2. Description of BWRO desalination system

Fig. 1 depicts the design of a brackish water RO for the APC plant with a 1200 m<sup>3</sup>/day capacity. Permeate and retentate reprocessing designs are used in two passes. Two stages of pressure vessels are arranged in the first pass in 4:2 order. Three pressure vessel stages are present in the second pass and arranged in 2:1:1 order. The permeate from the first pass is transferred to the second pass for further purification. The brine line from the first pass is drained. A high-quality water of 2 ppm is produced from the second pass. The retentate of the second pass is returned and mixed with the raw feed water to maintain a high productivity.

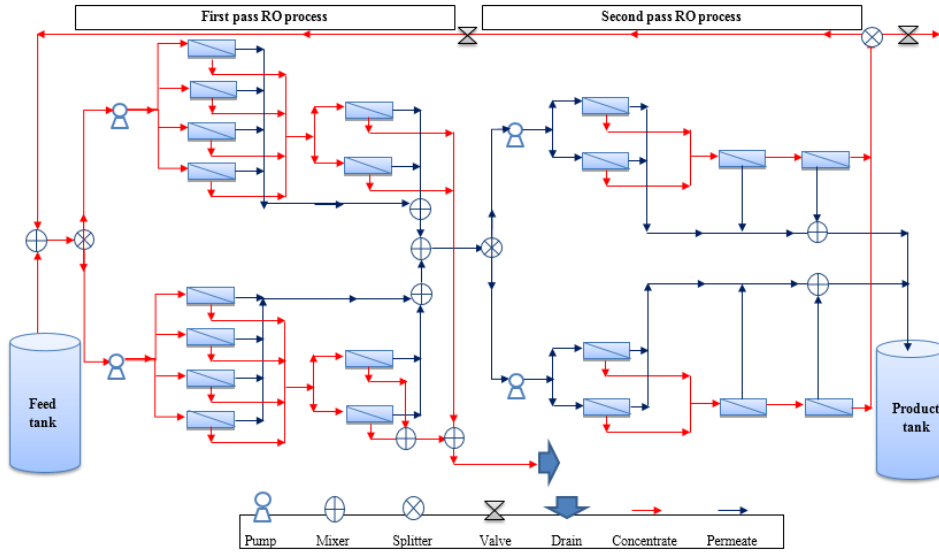

Fig. 1. A schematic representation of BWRO system of APC

### 3. Modelling of BWRO desalination system

A steady-state model was created by Al-Obaidi et al. (2018) for the APC medium-scale brackish water RO desalination plant. The model was constructed based on a number of assumptions. The most important ones are: 1) steady state operation, 2) fixed membrane features and channel geometries, 3) the film theory expresses the concentration polarisation phenomenon, 4) 1 atm in the permeate channel, 5) fixed temperature, and 6) The spacer properties are used to quantify the pressure drop in the feed channel. Before being utilised to examine the plant performance under various operating situations, the model was verified using APC plant data. In this work, this model has been improved by including a sub-model to calculate the cost of producing freshwater using data from several research (Filippini et al., 2018; Al-Obaidi et al., 2019; Malek et al., 1996). Table 1 presents a set of important equations of the RO model and the sub economic model used in this study. For further details of the model developed, parameters and variables and associated effects on the performance indicators can all be found in Al-Obaidi et al. (2018).

### 4. Simulation of BWRO desalination system

Simulation of the process is carried out to estimate the most important performance indicators including the freshwater production cost and specific energy consumption. Table 2 depicts the simulation results for the set of original inlet conditions of 988.93 ppm (salinity), 9.22 atm (pressure of 1<sup>st</sup> pass), 9.832 atm (pressure of 2<sup>nd</sup> pass), 2034.33 m<sup>3</sup>/day (feed flowrate) and 25 °C (temperature).

Furthermore, the estimation of electrical cost of pumping the brackishwater into the 1<sup>st</sup> and 2<sup>nd</sup> passes of RO system is important to be addressed. The power price (\$/day) is calculated using the following correlation:

$$\text{Power price per day} \left( \frac{\text{USD\$}}{\text{day}} \right) = \text{SEC} \left( \frac{\text{kWh}}{\text{m}^3} \right) \times \text{productivity} \left( \frac{\text{m}^3}{\text{day}} \right) \times \text{Factor} \left( \frac{\$}{\text{kWh}} \right)$$

Factor is the specific price of each kWh in Jordan which is 0.123\$/kWhr (Jordan electricity prices). Table 2 shows the energy price per day.

**Table 1.** RO model

Equation	Description	Unit
$Q_p = A_{w(r)} \left( P_f - \frac{\Delta P_{drop,E}}{2} - P_p - \pi_w - \pi_p \right) A_m$	Water flux	(m <sup>3</sup> /s)
$Q_s = B_{s(r)} (C_w - C_p)$	Solute flux	(kg/m <sup>2</sup> s)
$\Delta P_{drop,E} = \frac{9.8692 \times 10^{-6} A' \rho_b Q_b^2 L}{2 d_h R e_b^2 (W t_f \epsilon)^2}$	Pressure drop per element	(atm, -)
$\frac{(C_w - C_p)}{(C_b - C_n)} = \exp \left( \frac{Q_p / A_m}{k} \right)$	Membrane surface concentration	(-)
$k = 0.664 k_{dc} R e_b^{0.5} S c^{0.33} \left( \frac{D_b}{d_h} \right) \left( \frac{2 d_h}{L_f} \right)^{0.5}$	Mass transfer coefficient	(m/s, -)
$C_p = \frac{B_s C_f e^{\frac{J_w}{k}}}{J_w + B_s e^{\frac{J_w}{k}}}$	Permeate concentration	(kg/m <sup>3</sup> )

### 5. Optimisation of BWRO desalination system

This section intends to optimise the operation of BWRO system of APC to guarantee the lowest freshwater production cost (objective function) via determining the optimal operating condition of feed pressure of the 1<sup>st</sup> and 2<sup>nd</sup> passes and feed flowrate. The other operating conditions of groundwater salinity and temperature will be taken as fixed values of 988.93 ppm and 25 °C, respectively. Furthermore, the optimisation framework has considered several inequality constraints including the upper and lower feed flowrate for each membrane. Also, the specific energy consumption has been constrained at its simulation value. The non-linear single-objective optimisation framework can be described as:

**Given:** Feed water pressure and flowrate, RO module specifications.

**Optimise:** The optimisation variables of feed pressure, and flow rate.

**Minimise:** the freshwater production cost (*FWPC*) of RO system.

**Subject to:** Equality and inequality constraints and limits of optimisation variables.

Thus, the optimisation problem can be mathematically represented as:

$$\text{Min} \quad \text{FWPC}$$

$$Q_{f(plant)}, P_{p(plant)}$$

Subject to: Equality constraints: RO process model and fixed specific energy consumption (simulation value) ( $SEC = 0.834 \text{ kWh/m}^3$ )

Inequality constraints:

a) lower and upper limits of feed flow rate of RO system

$$(696.96 \text{ m}^3/\text{day}) \quad Q_{f(plant)}^L \leq Q_{f(plant)} \leq Q_{f(plant)}^U \quad (3707.52 \text{ m}^3/\text{day})$$

a) lower and upper limits of feed pressure of the 1<sup>st</sup> and 2<sup>nd</sup> passes of RO system

$$(5 \text{ atm}) \quad P_{f(1st \text{ pass})}^L \leq P_{f(1st \text{ pass})} \leq P_{f(1st \text{ pass})}^U \quad (12 \text{ atm})$$

$$(5 \text{ atm}) \quad P_{f(2nd \text{ pass})}^L \leq P_{f(2nd \text{ pass})} \leq P_{f(2nd \text{ pass})}^U \quad (12 \text{ atm})$$

c) lower and upper limits of feed flow rate of each membrane module

$$(87.12 \text{ m}^3/\text{day}) \quad Q_{f(membrane)}^L \leq Q_{f(membrane)} \leq Q_{f(membrane)}^U \quad (463.44 \text{ m}^3/\text{day})$$

Table 3 shows the optimisation results of several performance indicators including the freshwater production cost and the optimal feed pressure and flowrate. Note that the freshwater production cost could be reduced by 6.7% by increasing the pressure of the 1<sup>st</sup> and 2<sup>nd</sup> passes from 9.22 and 9.832 atm to 9.93 and 10.59 atm, respectively. Also, it can be noticed that the feed flowrate has been decreased from 2034.33 to 1900.8 m<sup>3</sup>/day to assure increasing the rate of permeation through the membranes due to increased residence time of the water inside the module. The productivity increases by 8% while maintaining a high-quality freshwater of 2.1 ppm (as desired). However, the electrical cost is inevitably increased (by 8%) due to increasing the productivity in cubic meter per day.

**Table 3.** Optimisation results

Optimised inlet conditions			Optimised results		
Parameter	Value	Unit	Parameter	Value	Unit
Feed pressure of 1 <sup>st</sup> pass	9.93	atm	Water recovery	66.33	%
Feed pressure of 2 <sup>nd</sup> pass	10.59	atm	Salt rejection	99.78	%
Feed flow rate	1900.8	m <sup>3</sup> /day	Salinity of product water	2.1	ppm
			Specific energy consumption	0.834	kWh/m <sup>3</sup>
			Water productivity	1260.81	m <sup>3</sup> /day
			Freshwater production cost	0.179	\$/m <sup>3</sup>
			Electricity cost	129.33	\$/day

Reduction of freshwater production cost (in comparison to simulation) = 6.7%

## 6. Conclusions

This paper attempted to reduce the overall freshwater production cost of a medium scale brackish water RO desalination system of Arab Potash Company (Jordan) via process modelling, simulation and optimisation. The simulation of the studied RO system obtained the values of performance indicators while the optimisation has obtained the minimum freshwater production cost with optimal feed pressure of the 1<sup>st</sup> and 2<sup>nd</sup> passes and inlet feed flowrate for the same specific energy consumption (as in the real plant and simulation). The freshwater production cost is reduced by 6.7% in comparison to the original simulation value while achieving a high-quality of product freshwater. Note, the actual electrical cost increases by more than 8% due to increase in the water productivity of RO system (compared to actual plant productivity). In the context of model refinement, relaxing the model assumptions would certainly provide more accurate predictions of the performance metrics. Furthermore, it should be noted that the developed model did not thoroughly incorporate the influence of fouling on the performance metrics. The enhancement of the established model is expected to introduce actual estimation of the freshwater production cost, which should be addressed in future study.

## Abstract

The modeling and optimization of multi-scale process systems is based on several interconnected process sub-systems. Due to the complexity of each individual sub-model, the resulting integrated process framework optimization formulations are computationally challenging to solve. While the richness of the multi-scale model employed is desired to maintain in order to obtain a solution with some degree of accuracy, simpler surrogate models are typically more attractive as a means to tame the underlying complexity, albeit often leading to an increase of the problem size. Here, the food-energy-water nexus (FEWN) is selected as a representative multi-scale process system, with focus on the reverse osmosis (RO) water supply sub-system. Based on a RO desalination model, two models are developed and compared in terms of accuracy, model complexity and size as well as computational efficiency, (i) a mixed-integer non-linear programming (MINLP) surrogate model, and (ii) a mixed-integer linear programming (MILP) surrogate model of reduced complexity but larger size. The results indicate that improved computational times can be obtained for a valid (lower bound) solution based on the MILP modeling strategy within the same level of accuracy, further underlying the importance of the selection of an appropriate surrogate model.

**Keywords:** optimization, surrogate modeling, food-energy-water nexus, reverse osmosis.

## 1. Introduction

The optimization of multi-scale process systems, which are composed of several interconnected sub-systems, remains challenging. Encountered challenges besides the multi-scale nature, encompass the complexity, as well as the size of the resulting optimization models. One approach to resolve these challenges is the usage of surrogate models to approximate sub-systems of the overall process systems (Kakodkar et al. 2022, Guillén-Gosálbez et al. 2019). This work evaluates in detail how changes in the employed surrogate model can have significant impact on the solution generation of the integrated process system. One of these interconnected multi-scale systems is the food-energy-water nexus (FEWN), which postulates that sustainable solutions regarding food, energy and water systems can only be obtained when all resources are considered holistically. Recently, more and more interest has been placed on the FEWN due to depleting natural resources and increasing global demands (Di Martino et al. 2019, Garcia and You 2016). FEWN models result in complex optimization programs, where surrogate models can

mitigate computational difficulties by reducing the complexity of the system. However, such systems usually increase in number of constraints and number of variables, which in turn can result in an intractable optimization model as well, especially if the surrogate is solved over a given time horizon multiple times integrated in an overarching process system (Allen et al. 2022). Thus, the scope of this work is to analyze and compare a mixed-integer linear programming (MILP) and a mixed-integer non-linear programming (MINLP) surrogate model which are representative of a sub-system in an interconnected multi-scale process model. As an example for such an interconnected system the FEWN is selected, with focus on a reverse osmosis (RO) desalination plant as the water supply system. The comparison is based on the accuracy of the obtained minimized solutions, the computational efficiency in the form of the necessary computational time to obtain solutions and the difference in the size and complexity of the optimization models. Next, the system under investigation is described. Then, the detailed modeling equations are discussed, before analyzing and discussing the results.

## 2. System Under Investigation

To analyze and compare the impact of MILP and MINLP surrogate models for the integration in a multi-scale process system the performance of RO desalination plant models is compared. As visualized in Figure 1, the goal is to integrate the RO model in a multi-scale FEWN model which in turn specifies restrictions regarding the design and operation of the RO plant. The goal is to solve this integrated model at an hourly time scale for a one-year time horizon, resulting in 8760 time points. Solutions specify the sustainable and interconnected water, energy and food supply system design and operation (Cook et al. 2022, Di Martino et al. 2022a). Thus, it is important to evaluate the model approximations in terms of accuracy and computational efficiency for the solution generation. All obtained surrogate models are based on one-and-a-half years of operational RO plant data, as presented in Di Martino et al. 2022b.

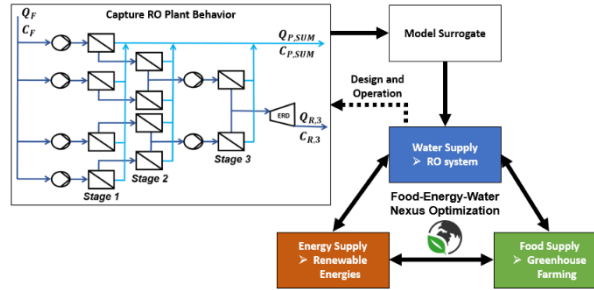

Figure 1: Schematic overview of the placement of the sub-system (RO) in the multi-scale process system (FEWN).

## 3. Modeling

The RO desalination plant is modeled and optimized according to Eq. 1 to 9 (Di Martino et al. 2022b).

$$\min SEC^* = \frac{1}{4 \cdot \eta_1} \sum_{j=1}^4 P_{f,1,j} + \frac{1}{10 \cdot \eta_1} \left( \sum_{j=1}^2 P_{f,3,j} - \frac{1}{2} \sum_{j=1}^4 P_{r,2,j} \right) - \frac{\eta_2}{20} \sum_{j=1}^2 \Delta P_{ERD,j} \quad (1)$$

s.t.

$$WR_{sys} \geq WR^{res} \leftrightarrow WR_i \geq WR_i^{res} \quad \forall i \in \{1,2,3\} \quad (2)$$

$$Q_f \geq Q_f^{res} \quad (3)$$

$$C_{p,t-1} = C_{p,t} \leq C_p^{res} \quad (4)$$

$$WR_i = WR_i^{max} \cdot \frac{\sum_j P_{i,j}}{\sum_j \max(P_{i,j})} \quad \forall i \in \{1,2,3\} \quad (5)$$

$$P_{r,i,j} = f_1(P_{f,i,j}) \quad \forall i = \{1,2\}, \forall j = \{1,2,3,4\} \quad (6)$$

$$P_{f,2,j} = P_{r,1,j} \quad \forall j \in \{1,2,3,4\} \quad (7)$$

$$\Delta P_{ERD,j} = f_2(P_{f,3,j}) \quad \forall j = \{1,2\} \quad (8)$$

$$C_{p,t} = f_3(Q_f, WR_1, WR_2, WR_3, C_{p,t-1}) \quad (9)$$

The presented objective function (Eq. 1) minimizes the linearized specific energy consumption of the system ( $SEC^*$ ) based on the feed ( $P_{f,i,j}$ ) and retentate pressures of each stage  $i$  and parallel flow  $j$  ( $P_{r,i,j}$ ).  $\eta_1$  and  $\eta_2$  denote the efficiency of the utilized pumps and energy recovery device, respectively. Eq. 2 to 9 summarize all necessary linear constraints of the system to specify the operation and design of the RO plant. The overall water recovery ( $WR_{sys} = Q_p/Q_f$ ), the feed flow ( $Q_f$ ) and the permeate concentration at the given and previous time point ( $C_{p,t}$ ,  $C_{p,t-1}$ ) are restricted to satisfy given water demand scenarios (Eq. 2 to 4). It is important to note that  $WR_{sys}$  is implicitly restricted by restricting the water recovery of each stage. The water recovery of each stage ( $WR_i \quad \forall i \in \{1,2,3\}$ ) is estimated based on the observed maximum water recovery ( $WR_i^{max} \quad \forall i \in \{1,2,3\}$ ) and pressures, according to Eq. 5. Eq. 6 and 7 summarize the pressure modeling of the system, with the linear regression ( $f_1(P_{f,i,j})$ ) used for calculating the retentate pressure of stages one and two for all parallel flows based on the respective feed pressure and the utilization of the retentate of stage one as the feed of stage 2. The pressure difference across the energy recovery device ( $\Delta P_{ERD,j} \quad \forall j = \{1,2\}$ ) as well as the overall permeate concentration ( $C_{p,t}$ ) are calculated based on the MILP reformulation of a feedforward artificial neural network (ANN) with rectified linear units (ReLU) as activation functions, as stated in Eq. 8 and 9 ( $f_2(P_{f,3,j}) \quad \forall j = \{1,2\}$ ,  $f_3(Q_f, WR_1, WR_2, WR_3, C_{p,t-1})$ ).

### 3.1. MINLP Surrogate Model

$SEC^*$  is derived by applying process specific, non-generic assumptions as described in Di Martino et al. 2022b. Therefore, obtained solutions actually specify lower bounds of the true solution. Accordingly, the non-linearized formula to calculate the exact specific energy consumption ( $SEC$ ) of the system is utilized in this study, as shown in Eq. 10. Furthermore, to obtain the energy consumption of the system ( $EC$ ),  $SEC$  has to be multiplied by  $WR_{sys}$  and  $Q_f$ , resulting in a trilinear term (Eq. 11). In addition,  $WR_{sys}$  can be derived based on  $WR_i \quad \forall i \in \{1,2,3\}$  with the nonlinear equation presented in Eq. 12. Thus, the MINLP surrogate model is given by minimizing Eq. 10 subject to the constraints summarized from Eq. 2 to 9, 11 and 12. With this modified model formulation no non-generic process specific assumptions are required.

$$SEC = \frac{1}{WR_{sys}} \cdot \left( \frac{1}{4 \cdot \eta_1} \sum_{j=1}^4 P_{f,1,j} + \frac{(1-WR_1) \cdot (1-WR_2)}{\eta_1} \left[ \frac{1}{2} \sum_{j=1}^2 P_{f,3,j} - \frac{1}{4} \sum_{j=1}^4 P_{r,2,j} \right] - \frac{(1-WR_1) \cdot (1-WR_2) \cdot (1-WR_3) \cdot \eta_2}{2} \sum_{j=1}^2 \Delta P_{ERD,j} \right) \quad (10)$$

$$EC = SEC \cdot WR_{sys} \cdot Q_f \quad (11)$$

$$WR_{sys} = WR_1 + (1 - WR_1) \cdot WR_2 + (1 - WR_1) \cdot (1 - WR_2) \cdot WR_3 \quad (12)$$

### 3.2. MILP Surrogate Model

Next, a linearized version of the nonlinear model is obtained by training ANNs with ReLUs as activation functions and reformulating them as MILPs for the calculation of  $SEC$  and  $EC$ , ultimately resulting in piecewise linear surrogate models. Here the results of the MILP approximations are specified as  $\widehat{SEC}$  (see Eq. 13 to 17) and  $\widehat{EC}$  (see Eq. 18 to 22). The obtained weights and biases together with the  $R^2$  value of both surrogate models are summarized in Table 1. The auxiliary positive variables  $(x_{SEC}^{(k_{SEC})}, s_{SEC}^{(k_{SEC})}, x_{EC}^{(k_{EC})}, s_{EC}^{(k_{EC})})$ , binary variables  $(z_{SEC}^{(k_{SEC})}, z_{EC}^{(k_{EC})})$ , together with lower and upper bounds  $(LB_{SEC}^{(k_{SEC})}, LB_{EC}^{(k_{EC})}, UB_{SEC}^{(k_{SEC})}, UB_{EC}^{(k_{EC})})$  are introduced for the MILP reformulation.

$$W_{SEC,1}^{(k_{SEC})} \cdot [WR_1 \ WR_2 \ WR_3 \ Q_f]^T + b_{SEC,1}^{(k_{SEC})} = x_{SEC}^{(k_{SEC})} - s_{SEC}^{(k_{SEC})}, \forall k_{SEC} \in \{1,2\} \quad (13)$$

$$x_{SEC}^{(k_{SEC})} - z_{SEC}^{(k_{SEC})} \cdot UB_{SEC}^{(k_{SEC})} \leq 0, \forall k_{SEC} \in \{1,2\} \quad (14)$$

$$s_{SEC}^{(k_{SEC})} - (1 - z_{SEC}^{(k_{SEC})}) \cdot LB_{SEC}^{(k_{SEC})} \leq 0, \forall k_{SEC} \in \{1,2\} \quad (15)$$

$$x_{SEC}^{(k_{SEC})}, s_{SEC}^{(k_{SEC})} \geq 0, z_{SEC}^{(k_{SEC})} \in \{0,1\}, \forall k_{SEC} \in \{1,2\} \quad (16)$$

$$\widehat{SEC} = \sum_{k_{SEC}} W_{SEC,2}^{(k_{SEC})} \cdot x_{SEC}^{(k_{SEC})} + b_{SEC,2} \quad (17)$$

$$W_{EC,1}^{(k_{EC})} \cdot [SEC \ WR_{sys} \ Q_f]^T + b_{EC,1}^{(k_{EC})} = x_{EC}^{(k_{EC})} - s_{EC}^{(k_{EC})}, \forall k_{EC} \in \{1,2,3\} \quad (18)$$

$$x_{EC}^{(k_{EC})} - z_{EC}^{(k_{EC})} \cdot UB_{EC}^{(k_{EC})} \leq 0, \forall k_{EC} \in \{1,2,3\} \quad (19)$$

$$s_{EC}^{(k_{EC})} - (1 - z_{EC}^{(k_{EC})}) \cdot LB_{EC}^{(k_{EC})} \leq 0, \forall k_{EC} \in \{1,2,3\} \quad (20)$$

$$x_{EC}^{(k_{EC})}, s_{EC}^{(k_{EC})} \geq 0, z_{EC}^{(k_{EC})} \in \{0,1\}, \forall k_{EC} \in \{1,2,3\} \quad (21)$$

$$\widehat{EC} = \sum_{k_{EC}} W_{EC,2}^{(k_{EC})} \cdot x_{EC}^{(k_{EC})} + b_{EC,2} \quad (22)$$

Table 1: Weights  $(W_{na,1}^{(k)}, W_{na,2}^{(k)})$ , biases  $(b_{na}^{(k)}, b_{na,2})$  and  $R^2$  of the surrogate models for the approximation of the specific energy consumption ( $SEC$ ) and energy consumption of the system ( $EC$ ).

$na$	$k_{na}$	$W_{na,1}^{(k)}$	$W_{na,2}^{(k)}$	$b_{na,1}^{(k)}$	$b_{na,2}$	$R^2$
$SEC$	1	[1.1556 - 0.5436 0.4116 0.4630]	0.4638	1.0465	-0.9950	0.99
	2	[0.2843 0.1137 0.1071 1.3843]	0.5371	-0.3829		
$EC$	1	[0.7492 - 0.3236 0.4624]	0.8180	0.4966	-0.9443	0.99
	2	[-1.0350 2.5363 1.3228]	0.2926	-0.3701		
	3	[-0.1111 - 0.1307 - 0.7936]	-0.2929	-1.1133		

Lastly, Eq. 12 is linearized with a first-order Taylor expansion around the nominal operating point of the RO plant, as shown in Eq. 23 ( $\overline{WR}_{sys} = 0.6039, \overline{WR}_1 = 0.3113, \overline{WR}_2 = 0.2935, \overline{WR}_3 = 0.1860$ ). For the relevant operating range of  $0.4 \leq WR_{sys} \leq 0.85$ , the approximation results in  $R^2 = 0.98$ . Overall, the MILP surrogate model is composed of minimizing  $\widehat{SEC}$  subject to Eq. 2 to 9 and Eq. 13 to 23.

$$\begin{aligned} \widehat{WR}_{sys} \approx & \overline{WR}_{sys} + (1 - WR_2 - WR_3 + WR_2 \cdot WR_3) \cdot (WR_1 - \overline{WR}_1) \\ & + (1 - WR_1 - WR_3 + WR_1 \cdot WR_3) \cdot (WR_2 - \overline{WR}_2) \\ & + (1 - WR_1 - WR_2 + WR_1 \cdot WR_2) \cdot (WR_3 - \overline{WR}_3) \end{aligned} \quad (23)$$

The described nonlinearities are overcome by introducing piecewise linear approximations resulting in a less complex optimization model. However, the resulting

system increases in size, with an increased number of constraints (60 vs. 80) and variables (continuous 47 vs. 57; binaries 9 vs. 14). The optimization models have been solved in GAMS with the CPLEX solver for the MILP surrogate model and the BARON solver for the MINLP surrogate model. All surrogate models have been derived in MATLAB.

#### 4. Results and Discussion

To analyze the trade-offs between system complexity and system size of the presented MILP and MINLP surrogates, the monthly energy consumption of the year 2017 is minimized based on the obtained operational RO data. The results of the optimization are visualized in Figure 2. The results of both models are of the same order of magnitude, where for the same set of restrictions in terms of  $WR_{sys}$  and  $Q_f$  the MINLP surrogate results in higher energy consumptions than the MILP surrogate, as expected.

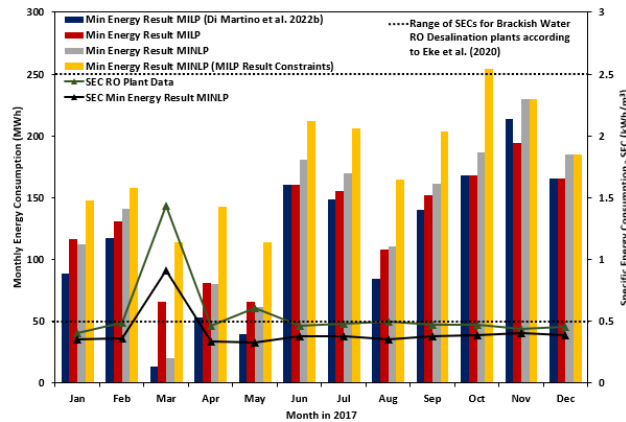

Figure 2: Comparison of the monthly energy consumption of the RO plant based on the optimization of the MILP, MINLP and MINLP with MILP result constraints.

Figure 3: Left: Pareto front of the energy consumption of the RO system dependent on the system's water recovery and feed flow; bars – results of MILP, points connected with line – results of MINLP. Right: Comparison of the necessary computational time to solve the MILP and MINLP; boxplot: {min – 1st quartile – median – 3rd quartile – max}, x – mean, outliers – 1.5 times the interquartile range larger than the third quartile.

Next, the energy consumption of the RO plant is systematically minimized for different sets of  $WR_{sys}$  and  $Q_f$  resulting in the Pareto front shown in Figure 3. Again, for all observed results, the MILP denotes the lower bound of the solution. The difference between the MINLP and MILP solution decreases with increasing water recovery. This trend is observed for all feed flows under investigation. In addition, the computational efficiency of obtained solutions was recorded, as shown in Figure 3. In all observed cases,

the computational time for the MILP solution generation is less than the MINLP one, even in extreme cases. On average, the difference between the observed computational times is 2.28s. Thus, utilizing the MILP indeed results in significant reduction of computational time (for an hourly time scale over one year, 5.55 hours) while the obtained lower bounds are good approximations of the true optimum for high water recoveries.

## 5. Conclusion

This work analyzed and compared a MILP and MINLP surrogate model for the integration in a multi-scale process system. For illustration, the surrogate modeling of a RO process for the integration in a FEWN system has been studied due to its importance for sustainable solution generation. The derived MILP surrogate provides lower bounds to the true optimum which are of the same level of accuracy as the MINLP surrogate solutions, while resulting in significant increase of computational efficiency, viz. the reduction of computational time. This trade-off between increasing the size of the optimization model to linearize it, is particularly important to consider in applications for interconnected multi-scale process systems.

## Abstract

In this study, a multi-fidelity surrogate modeling method based on physics-informed neural network (PINN) was proposed, which integrates high-fidelity simulation data and low-fidelity governing equations described by differential equations. By leveraging governing equations in the training of deep neural networks, the reliance on large amount of data has been relaxed. In the meantime, imposing physical laws ensures that the achieved surrogate models have clear physical meanings, which also improves the extrapolation performance of the models. Herein, the proposed multi-fidelity PINN surrogate modeling method was implemented to the simulation of the startup phase of a continuous stirred-tank reactor (CSTR) for illustrating its feasibility and advantages. From the computer experiment results, it is observed that the proposed method successfully reduced the sample size needed in model training and significantly improved the model extrapolation performance, facilitating its potential industrial applications.

**Keywords:** physics-informed neural network, multi-fidelity, surrogate modeling, deep learning.

## 1. Introduction

Numerical simulations, which use mathematical formulae to simulate complex physical systems, are becoming increasingly important in engineering tasks and decision-making processes (Moin and Mahesh, 1998), but the computational burden is a major practical problem limiting their applications. Surrogate models are a good solution to this problem. Nevertheless, data collection from high-fidelity simulations for training surrogate models is still computational expensive. Multi-fidelity surrogate modeling is an alternative approach, which utilizes both high-fidelity and low-fidelity data for model training (Fernández-Godino et al., 2019). A remaining problem is that, without a guidance of physical laws, the performance of surrogate models usually degrades significantly in the extrapolation applications.

In this study, we combined the strengths of data-driven and physics-based models to reduce the requirement on the amount of data for surrogate model training and improve the model extrapolation performance. In detail, we used the low-fidelity governing law described by a differential equation to constrain the training of the neural network model and obtain a multi-fidelity surrogate model based on physics-informed neuron network (PINN) (Raissi et al., 2019). With the aid of the physical law, the multi-fidelity PINN (MFPINN) surrogate model better approximates the simulated process especially in the

situation of small data or extrapolation. These advantages facilitate the potential applications of MFPINN to industries.

## 2. Numerical Simulation

In this study, a non-isothermal continuous stirred-tanked reactor (CSTR) was simulated using ANSYS Fluent to demonstrate the feasibility of proposed method. Figure 1 show a full-scale three-dimensional (3D) model of the system and Table 1 lists the system parameters and design space of input variables (Chuang et al., 2018). Here,  $C_{Ai}$  is the inlet concentrations of species A,  $T_i$  is the inlet temperature,  $V$  is the volume of the reactor,  $F_i$  is the inlet and outlet mass flow rate,  $S$  is the stirring speed of impeller, and  $\tau=V/F_i$  is the time constant of the CSTR. The physical characteristics, such as material density  $\rho$ , specific heat  $C_p$ , thermal conductivity  $\kappa$ , and dynamic viscosity  $\eta$ , are assumed to be constants with respect to temperature and compositions. This system consists of a first-order reaction,  $A \rightarrow B$ , where the activation energy is  $E_A$  and the pre-exponential Arrhenius constant is  $k_A$ .  $HR_A$  is the molar heats of the reaction. This 3D simulation provides information on product concentration and temperature as outputs, and we have selected the outlet concentration  $C_A$  as the predicted variable in presenting our results in this study due to its significance in determining product quality.

The mesh shape is tetrahedral with a minimum orthogonal quality of 0.238 and maximum skewness of 0.762 for accurate simulation results. It has 1867511 elements and 342112 nodes. The time consumption of each simulation run is about five to six hours. Consequently, this high-fidelity model is not suited for the engineering applications requiring multiple runs of simulations, such as optimization and sensitivity analysis. To deal with this problem, an MFPINN is proposed in this work, which can be implemented to build a surrogate model with a relatively small amount of simulation data.

Figure 1 Schematic diagram of 3D model of CSTR process

Table 1. System parameters and their values used in the simulation

Parameters	Values	Units	Descriptions
$k_A$	$1.4 \times 10^4$	1/sec	Physical constant
$HR_A$	$-2.12 \times 10^7$	J/kgmol	Physical constant
$E_A$	$3.64 \times 10^7$	J/kgmol	Physical constant

$\rho$	1180	Kg/m <sup>3</sup>	Physical constant
$C_p$	$3.2 \times 10^3$	J/kg/K	Physical constant
$\kappa$	0.61	W/m/K	Physical constant
$\eta$	0.0008	Kg/m/s	Physical constant
V	18.764	dm <sup>3</sup>	Physical constant
S	120	rpm	Physical constant
R	8.314	J/mol/K	Physical constant
$C_{Ai}$	2-3	M	Design variable
$F_i$	0.0167-1.67	L/s	Design variable
$T_i$	300-370	K	Design variable
$C_A$		mol/dm <sup>3</sup>	System output

### 3. Multi-Fidelity Surrogate Model base on PINN

In the course of surrogate modeling of high-fidelity simulations that are computationally expensive, the cost of simulation data acquisition for surrogate model training is prohibitive. Therefore, we are inevitably confronted with the challenge of small data. Most conventional machine learning techniques, including most deep neural networks, are not robust in such a situation, whose performance cannot be guaranteed. The state-of-the-art PINN technique proposed by Raissi et al. (2019), which aims to solve supervised learning problems while respecting physical laws described by differential equations, can be adopted to address this issue. Inspired with PINN, a multi-fidelity surrogate model named MFPINN is developed by integrating both high-fidelity simulation data and low-fidelity physical law.

The low-fidelity physical law used in the MFPINN captures the essential physics of the process by assuming that the CSTR is perfectly mixed and isothermal at 300K. The following ordinary differential equation (ODE) can be obtained according to the conservation law to the mass.

$$\tau \frac{dC_A}{dt} = C_{Ai} - C_A + r_A \tau \quad (1)$$

With a first-order reaction,  $-r_A = k C_A$  and  $\tau = \frac{V}{v}$ , where  $k$  is defined by the Arrhenius equation.

$$k = k_A e^{\frac{-E_A}{RT}} \quad (2)$$

Consequently, eq. (1) is expressed as:

$$\frac{dC_A}{dt} + \frac{1 + \tau k}{\tau} C_A - \frac{C_{Ai}}{\tau} = 0 \quad (3)$$

MFPINN can be understood as a feedforward neural network (FFNN) trained with high-fidelity data generated with the numerical simulations described in Section 2 and the low-fidelity ODE described in eq.(3), whose loss function is composed of both two terms, i.e. a prediction loss and an ODE loss as depicted in eq.(4) ~ (6).

$$\text{Loss} = \text{Prediction loss} + \text{ODE loss} \quad (4)$$

$$\text{prediction loss} = \frac{1}{N_{\text{training}}} \sum_{i=0}^{N_{\text{training}}} (\widehat{C}_A(T_i, F_i, C_{Ai}, t_i) - C_A)^2 \quad (5)$$

$$\text{ODE loss} = \frac{1}{N_{\text{collocation}} + N_{\text{training}}} \sum_{i=0}^{N_{\text{collocation}} + N_{\text{training}}} \left( \frac{d\widehat{C}_A(T_i, F_i, C_{Ai}, t_i)}{dt} + \frac{1 + \tau k}{\tau} \widehat{C}_A - \frac{C_{Ai}}{\tau} \right)^2 \quad (6)$$

where  $T_i, F_i, C_{Ai}$  are three process parameters, which represent inlet temperature, inlet volume flow rate, and inlet concentration, respectively,  $t_i$  is the time value,  $\widehat{C}_A(T_i, F_i, C_{Ai}, t_i)$  is the prediction of the system output, i.e. the outlet concentration  $C_A$ , provided by the neural network,  $N_{\text{training}}$  denotes the number of training data points, and  $N_{\text{collocation}}$  denotes the number of collocation points which are chosen by Latin hypercube sampling (LHS) (Stein, 1987) within the design space of  $C_{Ai}, F_i$ , and  $T_i$  as listed in Table 1. The utilization of collocation points reduces the requirement on the amount of training data points. The automatic differentiation techniques (Baydin et al., 2018) was adopted for calculating the differentials. The training process of the MFPINN model is illustrated in Figure 2, where  $\theta^*$  denotes the model parameters including all weights and biases.

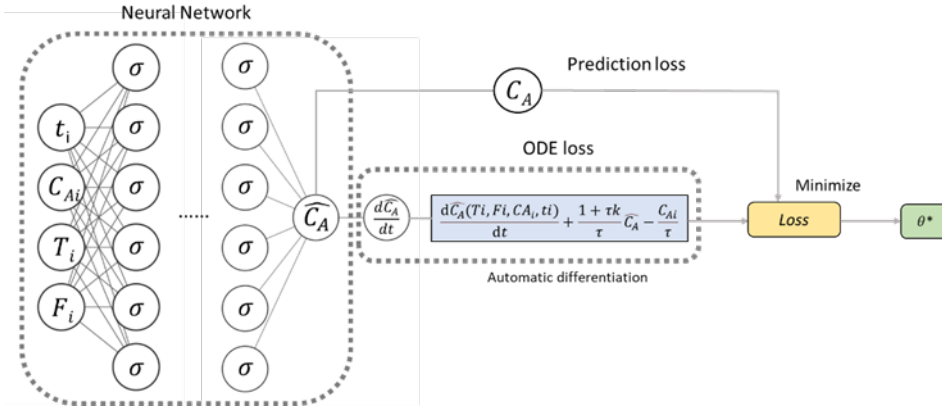

Figure 2. Training process of MFPINN

#### 4. Case Study

For the training and testing of both the proposed MFPINN model and the conventional FFNN model used for comparison, LHS was adopted to generate eight different operating conditions within the design space of  $C_{Ai}, F_i, T_i$  as listed in Table 1. The process was simulated under each operating condition for 150 seconds and the sampling time interval was set as 0.1 seconds for data generation. The hyperparameters

of the MFPINN model are given in Table 2. As shown in Table 2, the number of hidden layers and neurons per hidden layer of both the MFPINN and FFNN models are 8 and 100, respectively. Moreover, the number of collocation points collected for MFPINN is 100,000.

Table 2. Hyperparameter setup of both MFPINN and FFNN models

Number of hidden layers	8
Number of neurons per hidden layer	100
Number of collocation points	100,000

#### 4.1 Modeling with Small Data

In the first scenario, we used the simulation data collected from the 100<sup>th</sup> to 400<sup>th</sup> time intervals under each operating condition as the test set for both models. The training and validation sets with different sizes were randomly selected from the rest of the data. The ratio between the sizes of the training and validation sets was 4:1. The model test results show that, when the size of training set is relatively large, e.g. over 300, the performance of the two surrogate models are comparable. However, when the size of training set is reduced to 200, the MFPINN model is significantly better than the FFNN model, especially when applied to operating conditions 5~7. Tables 3 and 4 show the values of the coefficient of determination ( $R^2$ ) and mean squared error (MSE) of both models.

Table 3. Test results of MFPINN and FFNN when the size of training set is 300

	$R^2$ of MFPINN	$R^2$ of FFNN	MSE of MFPINN	MSE of FFNN

Condition 7	<b>0.9982</b>	0.3650	<b>0.0001</b>	0.0073
Condition 8	<b>0.9865</b>	0.9568	<b>0.0006</b>	0.0020

## 4.2 Extrapolation

In order to evaluate the extrapolation capability of the proposed model, the second scenario was designed, where all data collected under operating conditions 2 and 6 were only used for test, while the data of other operating conditions were divided to the training and validation sets under a ratio of 4:1. The test results are shown in Table 5, while Figure 3 compares the ground truth and the prediction values of different models. Obviously, the proposed MFPINN model outperforms its competitor. Because the MFPINN model is guided by the physical law during the model training process, it provides a predicted profile of  $C_A$  much closer to the high-fidelity simulation data, i.e. the ground truth. Its  $R^2$  values for operating condition 2 and 6 reach 0.967 and 0.977, respectively, although this is an extrapolation application. In contrast, although the training data is sufficient in this scenario, the FFNN model only achieves  $R^2$  values of 0.769 and 0.887 for operating condition 2 and 6, respectively. It is easy to understand that the extrapolation performance cannot be guaranteed unless the physics is taken into consideration.

Table 5 Regression analysis of MFPINN and FFNN models

	$R^2$ of MFPINN	$R^2$ of FFNN	MSE of MFPINN	MSE of FFNN
Condition 2	<b>0.9673</b>	0.7694	<b><math>7.10 \cdot 10^{-3}</math></b>	$5.03 \cdot 10^{-2}$
Condition 6	<b>0.9765</b>	0.8873	<b><math>4.80 \cdot 10^{-3}</math></b>	$2.28 \cdot 10^{-3}$

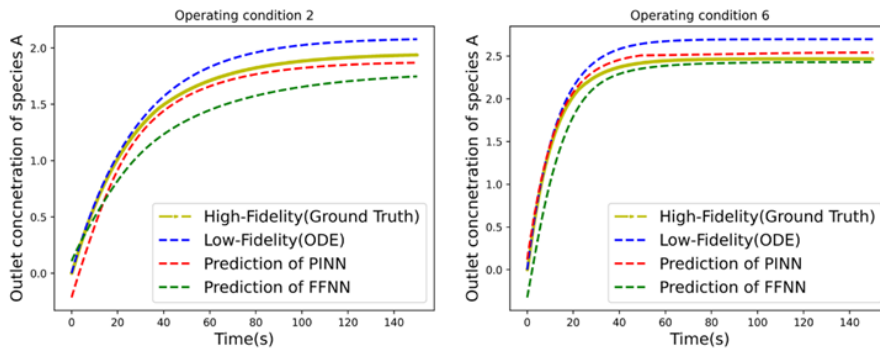

Figure 3. Predicted  $C_A$  of different models

## **5. Conclusions**

In this study, we integrate the high-fidelity simulation data and the low-fidelity physical law to build an MFPINN model for surrogate modeling. The experimental results show that, thanks to the guidance of the physical law, the proposed MFPINN outperforms the conventional FFNN when the training data is insufficient. Furthermore, the physical law comes in handy in the extrapolation. As a result, the MFPINN model predicts the outlet concentration of the CSTR system more accurately than the FFNN model. The application to the CSTR system illustrates the feasibility and potentials of the proposed MFPINN model.

## Abstract

This work presents a computer fluid dynamics (CFD)-model-based approach to continuous freezing process design for human induced pluripotent stem (hiPS) cells. A process model was developed that combined a hybrid single-cell freezing model covering the cell level with a CFD model covering the cryovial and freezer levels. Given an inlet coolant temperature, an inlet coolant velocity, and a residence time, the developed hybrid model can calculate the cell survival rate as a quality indicator. We applied the developed process model to three operating conditions of continuous freezing processes for hiPS cells. As a result, the survival rate in one of the operating conditions could achieve more than 0.90. Thus, it was demonstrated that designing the continuous freezing process could be performed with appropriate value selection of the decision parameters.

**Keywords:** Regenerative medicine, Cryopreservation, Cell therapy, Hybrid model, Optimization.

## 1. Introduction

Human induced pluripotent stem (hiPS) cells (Takahashi et al., 2007) are regarded as one of the most promising sources for regenerative medical products because of various advantages over the conventional sources, e.g., human embryonic stem cells (Narsinh et al., 2011). Along with recent successful clinical studies, e.g., Parkinson's disease (Morizane, 2019) and retinitis pigmentosa (Tagawa et al., 2021), the implementation of medical treatments using hiPS cells is in progress.

In hiPS cell manufacturing, freezing processes are one of the most critical steps because the process is needed to the transportation and preservation of the cells. Generally, two methods can be adopted for the freezing process of hiPS cells: slow freezing and vitrification. Slow freezing has been applied to many cell types, where cryovials filled with cell suspension are cooled in a freezer at a predetermined cool rate. In vitrification, the vials are immediately cooled using liquid nitrogen. At a commercial scale, vitrification is rarely adopted because of vitrification is rarely adopted in the cell therapy industry because of a scale limitation and process complexity (Vajta and Nagy, 2006). Therefore, in this work, we focus on the slow freezing option.

In general, the slow freezing of hiPS cells has been performed by a direct contact freezer that can accommodate only a limited number of cryovials. On the other hand, with the expected future commercialization, there is a need to design continuous slow freezing processes for hiPS cells that can handle many cryovials. Most recently, a computer fluid dynamics (CFD) model-based approach to scale-up batch slow freezing processes for hiPS cells using forced convection-based freezers was published by the authors' research

group (Scholz et al., 2022). However, a process design of continuous slow cell freezing was yet to be performed.

This work presents a CFD-model-based approach to continuous freezing process design for hiPS cells. A process model was developed that combined a hybrid single-cell freezing model covering the cell level with a CFD model covering the cryovial and freezer levels. The cell level model was based on our previous publications (Hayashi et al., 2021, 2020), and the cryovial and freezer level models were newly constructed. Given an inlet coolant temperate, an inlet coolant velocity, and a residence time, the developed hybrid model can calculate the cell survival rate as a quality indicator. We applied the developed model to three operating conditions of continuous freezing processes for hiPS cells.

## 2. Continuous freezing processes for hiPS cells

The continuous freezing process assumed in this work is represented in Figure 1. The freezer adopted convection-based cooling and consisted of four stations according to the three-temperature zones proposed by Hayashi et al. (2021), i.e., dehydration (Station 1), nucleation (Stations 2 and 3), and further cooling (Station 4). The decision parameters in each station were defined as the inlet coolant temperate,  $T_i^{\text{st}}$  [K], the inlet coolant velocity,  $u_i^{\text{st}}$  [ $\text{m s}^{-1}$ ], and the residence time,  $t_i^{\text{st}}$  [s] ( $i = 1, 2, 3, 4$ ).

## 3. Process model

Figure 2 shows an overview of the developed process model consisting of the freezer, cryovial, and cell levels. The inputs were defined as the decision parameters, i.e.,  $T_i^{\text{st}}$ ,  $u_i^{\text{st}}$ , and  $t_i^{\text{st}}$ , and the output was defined as the cell survival rate,  $r_{\text{surv}}$  [-]. The freezer and cryovial level models constituted of the CFD model, and the cell model was based on Hayashi et al. (2021, 2020). The process model was defined, based on the following assumptions:

- The number of rows in the freezer is one.
- The values of the decision parameters are strictly controlled.
- The flow is laminar ( $Re_{\text{max}} = 2.0 \times 10^2$ ).

### 3.1. Freezer and cryovial level models

#### 3.1.1. Flow calculation

For the fluid flow calculation, the continuity equation and the Navier-Stokes equation were adopted as follows:

**Figure 1.** Continuous freezing processes for hiPS cells.

**Figure 2.** Overview of the developed process model.

$$\nabla \cdot v_f = 0 \quad (1)$$

$$\rho_f \frac{\partial v_f}{\partial t} + \rho_f (v_f \cdot \nabla) v_f = \nabla \cdot [-pI + \mu_f (\nabla v_f + (\nabla v_f)^T)] \quad (2)$$

where  $\rho_f$  [kg m<sup>-3</sup>] is the density,  $\mu_f$  [Pa s] is the dynamic viscosity,  $v_f$  [m s<sup>-1</sup>] is the velocity,  $p$  [Pa] is the pressure, and  $t$  [s] is the time.

### 3.1.2. Heat transfer

The energy balance of the fluid in the freezer was represented using the following equation:

$$\rho_f c_{p,f} \left[ \frac{\partial T}{\partial t} + (v_f \cdot \nabla) T \right] = -\nabla q_{\text{cond}} - \frac{T}{\rho_f} \frac{\partial \rho_f}{\partial T} \bigg|_p \left( \frac{\partial p}{\partial t} + (v_f \cdot \nabla) p \right) \quad (3)$$

where  $c_{p,f}$  [J kg<sup>-1</sup> K<sup>-1</sup>] is the specific heat capacity of the fluid,  $T$  [K] is the temperature,  $q_{\text{cond}}$  [J s<sup>-1</sup> m<sup>-3</sup>] is the conductive heat flux. The energy balance of the solid was also modeled as follows:

$$\rho_s c_{p,s} \frac{\partial T}{\partial t} = -(\nabla \cdot q_{\text{cond}}) \quad (4)$$

## 3.2. Cell level model

### 3.2.1. Mass transfer

The following equation was adopted to model the mass transport of water across the cell membrane:

$$\frac{dV_{\text{cell}}}{dt} = L_p A_{\text{cell}} \Delta \Pi \quad (5)$$

where  $V$  [m<sup>3</sup>] is the volume,  $L_p$  [m s<sup>-1</sup> Pa<sup>-1</sup>] is the water permeability,  $A$  [m<sup>2</sup>] is the surface area,  $\Delta \Pi$  [Pa] is the pressure difference. The normalized maximum cell volume change,  $\overline{\Delta V}_{\text{cell}}^{\text{max}}$  [-], was calculated as follows:

$$\overline{\Delta V}_{\text{cell}}^{\text{max}} = \max \left\{ \frac{|V_{\text{cell}}^{\text{fin}} - V_{\text{cell}}^{\text{init}}|}{V_{\text{cell}}^{\text{init}}} \right\} \quad (6)$$

where the superscripts initial and final represent the initial and final state of freezing, respectively.

### 3.2.2. Crystallization

The radius at time  $t$  of an intracellular crystal that nucleated at time,  $\tau$  [s], was estimated as follows:

$$r_{ice,i} = \begin{cases} 0 & (0 \leq N_{ice} < 1) \\ \sqrt[3]{\int_{\tau_i}^t \gamma_{ice}^2 \bar{D} dt} & (N_{ice} \geq 1) \end{cases} \quad (7)$$

where  $r_{ice}$  [m] is the radius of an ice crystal,  $N_{ice}$  [-] is the number of intracellular ice crystals,  $\gamma_{ice}$  [-] is the nondimensional ice crystal growth parameter, and  $\bar{D}$  [ $m^2 s^{-1}$ ] is the average water diffusion coefficient. The number of intracellular ice crystals,  $N_{ice}$ , was calculated using the following equations:

$$N_{ice} = \text{int}[\bar{N}_{ice}] \quad (8)$$

$$\frac{d\bar{N}_{ice}}{dt} = J_{ice} \quad (9)$$

where  $\bar{N}_{ice}$  [-] is the ensemble average of the number of intracellular ice crystals and  $J_{ice}$  [ $s^{-1}$ ] is the ice nucleation rate. The total volume of intracellular ice crystals,  $V_{ice}$  [ $m^3$ ], was modeled as follows:

$$V_{ice} = \sum_{i=1}^{N_{ice}} \frac{4}{3} \pi r_{ice,i}^3 \quad (10)$$

The normalized maximum ice crystal volume,  $\bar{V}_{ice}^{max}$  [-], was calculated using the following equation:

$$\bar{V}_{ice}^{max} = \max \left[ \frac{V_{ice}^{fin}}{V_{cell}^{fin}} \right] \quad (11)$$

### 3.2.3. Cell survival rate

The cell survival rate was estimated as follows (Hayashi et al., 2021):

$$r_{surv} = \omega_1 + \omega_2 \bar{\Delta V}_{cell}^{max} + \omega_3 \bar{V}_{ice}^{max} + \omega_4 \bar{\Delta V}_{cell}^{max} \cdot \bar{V}_{ice}^{max} \quad (12)$$

where  $\omega_1$  [-],  $\omega_2$  [-],  $\omega_3$  [-], and  $\omega_4$  [-] are the fitting coefficients, for which the same values published in Hayashi et al. (2021) were used in the calculation.

## 4. Results and discussion

Three operating conditions of continuous freezing processes for hiPS cells were applied as defined in Table 1. The conditions were selected based on the results presented in Hayashi et al. (2021). Figure 3 shows (a) the temperature profiles of the vial center and (b) the cell survival rates for the three operating conditions. The cell survival rate in Condition 1 was highest, followed by Condition 2 and Condition 3. This result can be explained using the three-temperature zones proposed by Hayashi et al. (2021). Above 233 K, fast cooling would be preferred because cell dehydration mainly occurred in the temperature range. In contrast, the cooling rate between 233 K and 213 K should be slow because intracellular ice nucleation mainly happened in the temperature range. In addition, below 213 K, any cooling rates could be applied because the cooling rate would

**Table 1.** Detailed values of the inlet coolant temperature,  $T_i^{st}$ , the inlet coolant velocity,  $u_i^{st}$ , and the residence time,  $t_i^{st}$ , applied in this work

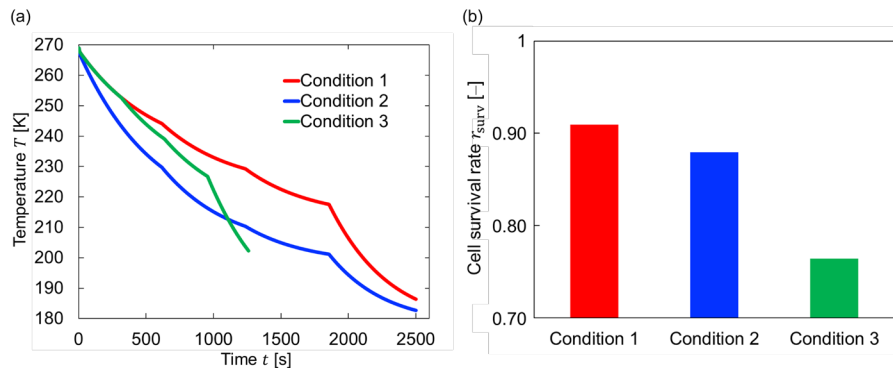

Station	Condition 1			Condition 2			Condition 3		
	$T_i^{st}$ [K]	$u_i^{st}$ [m s <sup>-1</sup> ]	$t_i^{st}$ [s]	$T_i^{st}$ [K]	$u_i^{st}$ [m s <sup>-1</sup> ]	$t_i^{st}$ [s]	$T_i^{st}$ [K]	$u_i^{st}$ [m s <sup>-1</sup> ]	$t_i^{st}$ [s]
1	233	0.100	625	213	0.100	625	233	0.100	315
2	223	0.100	625	203	0.100	625	223	0.100	315
3	213	0.100	625	198	0.100	625	213	0.100	315
4	178	0.100	625	178	0.100	625	178	0.100	315

not affect the cell survival rate. In the range of above 233 K, Condition 2 would be the best for the cell survival rate because the cooling rate was the fastest. On the other hand, in the range of between 233 K and 213 K, Condition 1 would be the most desirable for the cell survival rate because the cooling rate was the slowest. According to Mazur et al. (1972), cell damage due to intracellular ice nucleation was more critical than due to cell dehydration. Therefore, the highest survival rate (more than 0.90) was observed in Condition 1. Thus, it was demonstrated that designing continuous freezing processes for hiPS cells could be performed with appropriate value selection of the decision parameters.

The flow and heat transfer calculations were performed using COMSOL Multiphysics® version 6.1, and the calculations of mass transfer, crystallization, and cell survival rate were conducted by Python 3.9. The total CPU time that the results shown in Figure 3 were obtained was about 60 hours, using Intel® Xeon® Gold 6230 CPU @ 2.10 GHz with 512 GB RAM memory.

## 5. Conclusions and outlook

This work presented a CFD-model-based approach to continuous freezing process design for hiPS cells. A process model was developed that combined a hybrid single-cell freezing model covering the cell level with a CFD model covering the cryovial and freezer levels. The developed process model enabled calculating the cell survival rate of hiPS cells, given an inlet coolant temperature, an inlet coolant velocity, and a residence time. We

**Figure 3.** (a) Temperature profile of the vial center and (b) cell survival rate for the three operating conditions.

applied the developed process model to three operating conditions of continuous freezing processes for hiPS cells. As a result, the cell survival rate in one of the three operating conditions could achieve more than 0.90. Thus, it was demonstrated that designing the continuous freezing process could be performed with appropriate value selection of the decision parameters. In the field of computer-aided process engineering, cell therapy related studies are becoming relevant, e.g., Triantafyllou et al. (2022) and Hirono et al. (2022). Further model-based studies in this area are encouraged.

## Abstract

Area-selective atomic layer deposition (ASALD) is an advancement of conventional thin-layer deposition processes that utilizes an additional chemoselective inhibition reaction to improve nanopatterning. However, ASALD is a challenging procedure that is difficult to characterize in the surface and fluid phases. A three-dimensional (3D) multiscale model that employs an atomistic-mesoscopic density functional theory (DFT) and kinetic Monte Carlo (kMC) simulation and macroscopic computational fluid dynamics (CFD) modeling are performed for a spatial rotary reactor configuration for the ASALD of a SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> substrate *in silico*. Due to the complexity of the multiscale simulation, various reactor configurations are devised to minimize the computational requirements of the dynamic mesh of the reactor while reproducing results that are analogous to experimental data.

**Keywords:** Area-selective atomic layer deposition; multiscale modeling; computational fluid dynamics; kinetic Monte Carlo simulation; density functional theory.

## 1. Introduction

Area-selective atomic layer deposition is an attractive thin-layer deposition process that does not require subsequent processing steps (e.g., etching and lithography) to achieve effective nanopatterning and self-limiting deposition on growth areas of the substrate. In particular, semiconducting materials require thin-layer deposition processes to promote the self-aligned stacking of transistors, which is essential for producing high-performance wafers. In accordance with the predictions of Moore's Law, the stacking of the transistors is needed to improve the computational performance and efficiency of electronics; however, the lack of self-alignment introduces a fabrication challenge for wafers. Although conventional thin-layer deposition reactors are widely used, these reactors require extensive purging steps to maintain the self-limiting nature of the process. Spatial reactor configurations, including the rotary type, introduce reagent in physically isolated regions to prevent intermixing while maintaining the self-limiting tendency of the reactions (Poody et al., 2012). The stringent dimensions of these transistors require much experimentation through a tedious procedure of optimizing the reactor design such that reagent intermixing is minimized and substrate exposure to the reagents is uniformly distributed. However, multiscale modeling has emerged as a cost-effective and timely solution for relating multiphase deposition processes for various time and length scales while reproducing experimental results with high fidelity. This work will employ an atomistic-mesoscopic density

functional theory (DFT) and kinetic Monte Carlo model in conjunction with a three-dimensional (3D) macroscopic computational fluid dynamics (CFD) to simultaneously simulate surface-scale reaction kinetics comprising steric hindrance and repulsion effects and macroscopic fluid transport phenomena for a silicon wafer ( $\text{SiO}_2/\text{Al}_2\text{O}_3$ ) substrate in accordance to the ABC-type reaction kinetics proposed by Merckx et al. (2020) and Mameli et al. (2017) composed of (A) inhibition, (B) adsorption, and (C) oxidation steps. Additionally, the relation of various constraints in the design of the rotary reactor (e.g., gap distance, geometries of reaction zones, and orientations of inlets) to the surface uniformity and deposition growth rate are studied for process optimization. Such constraints provide significant insight for application to current fabrication procedures.

## 2. Multiscale Simulation

### 2.1. Atomistic-mesoscopic modeling

Area-selective atomic layer deposition (ASALD) processes integrate a variety of synergistic, chemoselective, and self-limiting reactions that deposit monolayers of substrate material. Mameli et al. (2017) proposed an ABC-type mechanism composed of three steps (Steps A, B, and C). First, an inhibition preprocessing step (Step A) to deactivate subsequent reactions in the non-growth area using a small molecule inhibitor, acetylacetone (Hacac). Next, a precursor, bis(diethylamino)silane (BDEAS), adsorbs onto the growth area to produce a modified surface layer (Step B) composed of hydrogen-terminated ligands. Finally, an oxidation step (Step C) using ozone ( $\text{O}_3$ ) oxidizes the hydrogen terminals to produce hydroxyl-ligands, thereby concluding a single monolayer of the deposition cycle. To ensure the self-limiting behavior of these reactions, each step is followed by a purging action by employing an inert gas such as nitrogen,  $\text{N}_2$ .

The abundance of reaction mechanisms and the lack of reference and experimental data would make the characterization of the kinetics difficult to quantify in the atomistic and mesoscopic phases. Thus, *ab initio* quantum mechanics that uses first principles density functional theory (DFT) is performed through the open-source software, Quantum ESPRESSO (QE) to compute the thermophysical and kinetics parameters of species and reactions, respectively. QE performs molecular structure and electronic optimization through pseudopotential data and nudged elastic band (NEB) methods to compute the minimal energy path to compute the activation energy of the reaction, to be substituted into the Arrhenius Equation. Additionally, a typical elementary reaction mechanism for rate-determining reaction steps is proposed for each step (A, B, and C) in the ASALD process to integrate transition state theory (TST) for non-adsorption reactions and collision theory (CT) for adsorption reactions.

With the kinetics mechanisms and reaction parameters defined, reaction parameters are defined into the kinetic Monte Carlo (kMC) algorithm that adopts a stochastic procedure to exemplify the behavior of realistic reactions. The kMC method, performed through the Python programming language, adopts a sequential procedure that sums probable reaction rates at a surface site to preferentially weight reactions of greater magnitude while devising a random number to arbitrarily select a reaction for the active site. Such procedure enables the computation of species generation and consumption terms from surface pressure and temperature data (from the CFD simulation), which will be integrated into the CFD simulation. Subsequently, the kMC method simulates the progression of the reaction path by calculating process time through a secondary random number described by Yun et al. (2022a). Additionally, steric hindrance effects are simulated by randomly selecting the angle of rotation for adsorption reactions encountered in Step A, and portraying the deflection of adsorption sites that are hindered by bulky molecules (Roh et al., 2022).

## 2.2. Macroscopic modeling

Computational fluid dynamics (CFD) is performed to simulate the transport phenomena in the fluid regime through the commercial multiphysics software, ANSYS Fluent. Prior to conducting the CFD simulation, a three-dimensional (3D) rotary reactor model, illustrated in Fig. 4 is constructed through ANSYS DesignModeler, which is then meshed through ANSYS Workbench's meshing software using tetrahedral cells, until an ideal mesh quality (per ANSYS standards) and minimal number of cells is obtained. An ideal mesh is composed of a minimal number of cells to lessen the dependence of robust computational power while maintaining accurate computations that are reflective of experimental results recorded in academia and ensuring convergence is obtainable. Additionally, the movement of the wafers between reaction zones are achieved through a dynamic mesh method that performs remeshing and diffusion-based smoothing methods to retain mesh quality and preserve solution convergence. In Fig. 4, the reactor design separates each wafer into 10 sections to define source generation and consumption flux terms (evaluated by the kMC simulation) on the wafer surface through user-defined functions (UDFs) in a "C++ like" script. The CFD simulation is performed using a fixed time step of 0.001 s, employing a pressure-based solver method, and adopting a first-order implicit numerical solver method that is defined through a journal file and executed through a Scheme script. Lastly, various thermophysical parameters are defined by integrating results from the atomistic *ab initio* first principles quantum mechanics simulations and through the ANSYS Fluent database of gaseous molecules.

In addition to the optimization of the reactor mesh, the chamber design of the rotary reactor and the operating conditions have a significant role in the quality and conformance of the substrate (De la Huerta et al., 2018). The reactor design must ensure that effective reagent separation is made to prevent species intermixing, which disrupts the perceived self-limiting behavior of the ASALD process. Reagent intermixing is prevented by specifying an optimal gap distance, the distance between the substrate surface and the ceiling of the reactor that separates the reaction zones, introducing output streams at precise locations to remove byproducts generated, and defining a large purge flow rate. Following the procedures to minimize reagent intermixing, the delivery of gases to the surface of the wafer and the exposure time are of paramount importance to ensure that a total surface deposition is achieved. Constraints including the reagent (Hacac, BDEAS, O<sub>3</sub>) flow rates and rotation speed have a profound impact on the deposition rate onto the substrate surface (Pan et al., 2017). Although large reagent flow rates and low rotation speeds ensure complete deposition is obtained, such quantities are also nonideal from an economics and production perspective. Lastly, the uniformity of the deposition is a qualitative parameter that discusses the effectiveness of the nanopatterning performance. This modification provides better control of the film uniformity to ensure that all regions in the wafer have the same exposure time. The aforementioned quantities provide a meaningful study for optimizing the reactor design and process operation for practical applications.

## 2.3. Multiscale modeling

The multiscale simulation allows the calculation of various time and length scale in various domains including the atomistic, mesoscopic, and macroscopic regimes (Raimondeau and Vlachos, 2002) as described in Fig. 1. Such multiscale modeling allows the relating of various phases that cannot be discerned through *ex silico* methods. The multiscale simulation is performed autonomously through a Linux cluster system through the UCLA Hoffman2 Cluster and allows the interconnection of various programming languages and application software. This work will utilize 36-core compute nodes consisting of 192 GB

of dynamic random-access memory (DRAM) that are standard for ANSYS Fluent to conduct the multiscale simulation by adopting both a parallel computation strategy in the macroscopic simulation and serial method for the microscopic simulation taking an average of 1 to 3 days, which depends on the rotation speed of the reactor. Such coding logic allows ANSYS Fluent to evaluate surface pressure ( $P$ ) and temperature ( $T$ ) data on the wafer surface to be read by the kMC coding script to evaluate the source generation and consumption terms,  $S_h$  and  $S_{m,i}$ , for the heat and mass of species  $i$  balances, which will then be defined through the UDF by ANSYS Fluent as summarized in the process diagram in Fig. 2. The simulation will conclude until the termination condition (full coverage) is obtained or if the wafer exits the reaction zone completely.

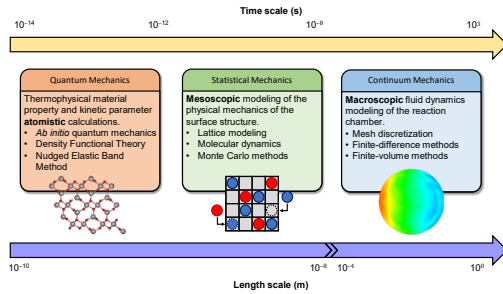

Figure 1: Multiscale model application for various phases and time and length domains.

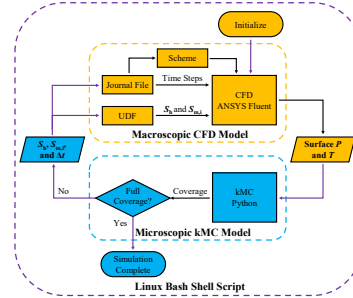

Figure 2: Multiscale model simulation process diagram.

### 3. Results

#### 3.1. Atomistic-mesoscopic simulation results

The atomistic-mesoscopic simulation is conducted for a pressure range of 10 to 500 Pa in 10 Pa intervals and a temperature range of 423 to 573 K in 10 K intervals for a total of 800 data points. The collection of a diverse data set is employed to determine the effects of the operating conditions on the total process time to obtain full coverage on the wafer surface for Steps A, B, and C on a  $100 \times 100$  lattice. Graphical results for the process times as a function of the temperature and pressure are provided in Fig. 3. Results from

Figure 3: Kinetic Monte Carlo process times for (a) Hacac inhibition, (b) BDEAS adsorption, and (c)  $O_3$  oxidation at various pressure and temperature conditions.

Step A in Fig. 3(a) demonstrates that the Hacac pulse time of 3.0 s or more above was observed for pressures below the 100 Pa, which was analogous to reported findings by Mameli et al. (2017) who reported a saturation dosage time of 5.0 s for such operating conditions. Additionally, the BDEAS adsorption in Step B displayed in Fig. 3(b) has a BDEAS dosage time of 2.3 s for a pressure of 400 Pa to reach full coverage, which is comparable to the reported findings of 2.0 s of BDEAS saturation times by Merckx et al. (2020). The aforementioned results indicate that the combined atomistic and mesoscopic simulations are reflective of experimental results; thus, the kMC simulation will have a minimal contribution to deviation of results in the multiscale simulation.

3.2. Multiscale computational fluid dynamics simulation results

The reactor mesh is fully optimized using less than 1.3 million tetrahedral cells and a gap distance of 5 mm by adopting a reactor geometry with reaction barrier zones conforming to the radial direction of the reactor as illustrated in Fig. 4. In addition to the radial separation of the vacuum ports, the wafers were also separated into 10 regions in the radial direction for the UDF specifications of the source terms. Results from the multiscale CFD simulation in Fig. 5 reveal that the dividers provide substantial reagent exposure in the radial direction when rotating with an angular velocity of 0.40 rad/s. The

Figure 4: Top view of the rotary reactor design. Inlet and outlet streams are in blue and red, respectively.

Figure 5: Multiscale CFD simulation results illustrated in N<sub>2</sub> mole fraction wafer surface contours.

contours of mole fraction of N<sub>2</sub> also illustrate that reagent intermixing is effectively minimized, thereby maintaining the self-limiting nature of the ASALD process. However, it is notable that intermixing is visible in reaction zone corners; thus, further study is needed to minimize the effects of the purge and reagents intermixing within the reaction zone by

Figure 6: Contours of N<sub>2</sub> mole fraction illustrating intermixing for a conventional rotary reactor design (a) and the mitigation of intermixing by the asymmetric design (b).

adjusting the orientation of the inlets, modifying the diameters of the outlets, and adjusting the reaction zone geometry. The optimization of the reactor configuration is illustrated in Fig. 6 to demonstrate the effects of adjusting the inlet location to an asymmetric model in Fig. 6b, which moderates the effects of purge transfer into the reaction zones for the conventional reactor configuration in Fig. 6a. Also, the process operation parameters can be considered for further study such as balancing the reagent flow rates with a proper

composition of reagent. The collection of a diverse data set is still needed to further characterize various constraints (e.g., exposure uniformity and deposition growth rate).

#### 4. Conclusion

A novel multiscale simulation of an area-selective ASALD process was performed to study the relation between various operating conditions and reactor geometry on the uniformity and deposition rate of a thin film on a  $\text{SiO}_2/\text{Al}_2\text{O}_3$  substrate in various phases. First, an atomistic-mesoscopic model was developed in conjunction with *ab initio* first principles quantum mechanics simulation to calculate kinetic parameters of rate-determining elementary reactions and thermophysical parameters of species and with a kinetic Monte Carlo (kMC) algorithm to simulate the stochastic nature of surface reactions on the wafer. The resulting mesoscopic simulation was performed with computational fluid dynamics (CFD) to study the transport phenomena of the gases. It was determined that the atomistic-mesoscopic model, when compared to experimental results found in literature, demonstrated accurate process time results in exact operating conditions. The multiscale CFD simulation illustrated that the reactor design successfully minimized the effects of reagent intermixing while improving exposure uniformity to enhance nanopatterning. Although further study is needed to characterize the relation of various reactor design and operation constraints to fully understand their effects on the deposition growth rate and film uniformity, initial results reveal that the reactor design and operation conditions determined by the model lead to improved deposition performance.

## Abstract

In this work, a 1-D diffusion model is developed to describe the drying process of a ceramic slab with respect to shrinkage. The proposed mathematical framework consists of a set of partial differential and algebraic equations along with moving boundary conditions, making it suitable for predicting the drying behavior and the physical phenomena that accompany the drying process of a green ceramic slab, such as shrinkage and porosity increase. Initially, the developed model is validated against experimental data from the open literature. Then, the drying behavior of a clay material, produced at a local factory, is investigated. This requires the characterization of the material with respect to its desorption kinetics. The parameter values of a semi-empirical desorption isotherm equation are estimated based on drying tests conducted in the lab. Finally, the drying kinetics of the porous material is studied and the shrinkage effect is discussed.

**Keywords:** Ceramic drying, shrinkage, porosity, moving boundary problem

## 1. Introduction

The drying process constitutes an essential step in the ceramic sector, which aims at removing the water from the green ceramic material before firing takes place. This is a critical production step because if the material is inserted wet into the extreme environment conditions of the firing chamber, then the probability of moisture evaporation inside the pores of the material would be high. As a consequence, this could lead to the development of intense stresses inside the porous body that can potentially lead to cracks and fracture. Cracks could also occur during the drying process itself, because of the non-uniform moisture distribution along the body and hence, non-uniform shrinkage (Kowalski and Pawłowski, 2010).

The understanding of the shrinkage mechanism during the drying procedure of a ceramic green body plays a key role for the product quality assurance and the fabrication of new drying strategies. Mancuhan et al. (2016) studied the shrinkage behavior of ceramic green bricks through Bigot curves. They proposed that during the initial stages of drying, the volume variation of the material is equal to the volume of the removed water. However, as drying proceeds, a critical moisture content is reached. This indicates that most clay particles of the solid matrix are already in direct contact and cannot move any further. At that point, shrinkage is almost complete and drying proceeds without any volume variations taking place.

It is a common practice in the open literature, to calculate the drying-induced shrinkage using mechanical interaction models which use strain – stress relationships (Hammouda and Mihoubi, 2014). Other approaches use more simplistic methods to account for the

volume variation of a porous material during drying. Barbosa de Lima et al. (2016) used polynomial expressions to correlate the moisture content of a clay material to its volumetric strain. However, this method of approaching the shrinkage calculation does not provide any physical insight for the drying process.

In this work, the drying-induced shrinkage calculation is approached by using a shrinkage velocity, which reflects the velocity at which a specific nodal point of the clay matrix recedes to the interior of the bulk body. The proposed modeling framework leads to high quality predictive results with low computational complexity and facilitates the numerical calculation of key physical quantities, such as the solid concentration and the body porosity, which are closely associated to qualitative characteristics of the green material.

## 2. Mathematical model

In this section, a mathematical model is developed to capture the drying behavior of a shrinking ceramic roof tile. Since the material aspect ratio is very small, its geometry is simplified to that of a semi-infinite tile. Consequently, the model considers that heat and mass transfer phenomena occur only on the thickness dimension of the tile.

The evolution of the water mass concentration,  $C_w$  and temperature,  $T$ , with time along the green material is given by equations. (1) and (2), respectively. Both equations also consider the shrinkage effect via a local shrinkage velocity term,  $v_{shr}$ , which determines the velocity at which a nodal point of the clay matrix moves towards the bulk body.

$$\frac{\partial C_w}{\partial t} = \frac{\partial}{\partial z} \left[ D_{eff} \frac{\partial C_w}{\partial z} - v_{shr} C_w \right] \quad , \quad z \in (0, L) \quad (1)$$

$$\rho c_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \left[ k_{eff} \frac{\partial T}{\partial z} - v_{shr} \rho c_p T \right] \quad , \quad z \in (0, L) \quad (2)$$

Where  $D_{eff}$  is the effective diffusivity of the moisture and  $k_{eff}$  is the effective thermal conductivity of the material. Both properties are constant for the present study.

Preheated air flows over the wet tile and drying is achieved through forced convection. This model assumes that moisture diffuses from the bulk body towards the air-solid interface, where it instantaneously evaporates and desorbs to the blowing air. As such the mass balance boundary equation is given by equation (3).

$$-D_{eff} \frac{\partial C_w}{\partial z} \Big|_{z=L} = h_m \frac{MW_w}{R_g} \left( \frac{P_{sat}(T_{z=L})}{T_{z=L}} RH_{eq} - \frac{P_{sat}(T_{air})}{T_{air}} RH \right) \quad (3)$$

Where,  $h_m$ , is the convective mass transfer coefficient,  $MW_w$  is the water molecular weight and  $R_g$  is the global gas constant. Also  $P_{sat}$  is the saturation pressure of water and  $RH$  is the relative humidity of the air, which is defined as  $P_w/P_{w,sat}$ .

It is assumed that at the air - solid interface, the moisture content is at chemical equilibrium with the air humidity. This is given by a desorption isotherm correlation.

$$RH_{eq} = f(X|_{z=L}, T|_{z=L}) \quad (4)$$

Where  $X$  is the moisture mass fraction (dry base) of the material and is defined as  $X = C_w/C_s$ .

As the preheated air flows over the colder wet tile surface, heat is transferred through convection. Additionally, the latent heat of vaporization,  $\Delta H_{vap}$ , is abducted from the drying surface of the material to achieve the water evaporation.

$$-k_{eff} \frac{\partial T}{\partial z} \Big|_{z=L} = h_T(T|_{z=L} - T_{air}) - \Delta H_{vap} D_{eff} \frac{\partial C_w}{\partial z} \Big|_{z=L} \quad (5)$$

The bottom surface of the green body is not in direct contact with the air.

$$\frac{\partial C_w}{\partial z} \Big|_{z=0} = 0 \quad (6)$$

$$\frac{\partial T}{\partial z} \Big|_{z=0} = 0 \quad (7)$$

The only mechanism that affects the solid concentration is the shrinkage-induced convection. Hence, the temporal evolution of the solid concentration  $C_s$ , is given by (8).

$$\frac{\partial C_s}{\partial t} = - \frac{\partial [v_{shr} C_s]}{\partial z} \quad , \quad z \in (0, L) \quad (8)$$

The local porosity,  $\varepsilon$ , is calculated from the phase volume balance.

$$1 = \varepsilon + \frac{C_s}{\rho_{intrinsic}} + \frac{C_w}{\rho_w} \quad (9)$$

Where,  $\rho_{intrinsic}$  and  $\rho_w$  are the intrinsic solid density and water density respectively. Since all heat and mass transfer phenomena are considered exclusively on the thickness direction, the tile thickness,  $L$ , evolution should be described by equation (10).

$$\frac{dL}{dt} = v_{shr} \Big|_{z=L} \quad (10)$$

The shrinkage velocity is a local term, which shows the velocity at which a nodal point recedes to the interior of the body. More specifically, the shrinkage velocity is the velocity at which a volume of water diffuses towards the air – solid interface.

$$v_{shr} = \int_0^z \alpha \frac{\partial}{\partial z} \left[ \frac{D_{eff}}{\rho_w} \frac{\partial C_w}{\partial z} \right] dz \quad , \quad z \in [0, L] \quad (11)$$

Where  $\alpha$  is a proportionality factor. Its physical meaning is that when  $\alpha$  equals to 1, the volume variation of the porous body is respective to the volume variation of the removed water (ideal shrinkage case). When  $\alpha = 0$ , no volume variation takes place as water leaves the body (no shrinkage case).

As explained earlier, during the initial stages of drying, the shrinkage is ideal (e.g.  $\alpha = 1$ ). However, when the moisture content,  $X$ , reaches a critical value,  $X_{cr}$ , almost all shrinkage phenomena are complete because most of the clay particles are already in direct contact with each other (Mançuhan et al., 2016). At that point, shrinkage stops (e.g.  $\alpha = 0$ ) and the porosity of the material starts to increase since air penetrates into the body to substitute the volume of the removed water.

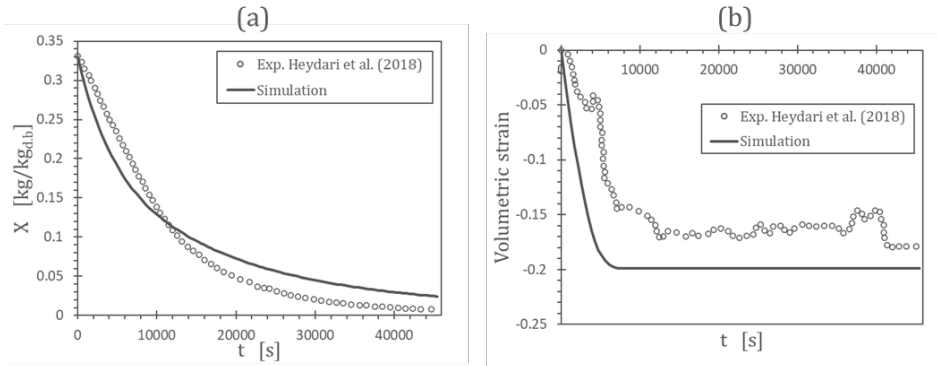

$$\alpha = \begin{cases} 1, & X \geq X_{cr} \\ 0, & X < X_{cr} \end{cases} \quad , \quad z \in [0, L] \quad (12)$$

### 3. Solution Strategy

The integration of the above system of equations on the  $(z, t)$  plane is not trivial because the boundary conditions are located on a moving boundary. The position of the  $z = L$  node must be determined as an integral part of the solution at any time. That for, a simple Lagrangean transformation is used, by introducing the spatial variable  $y = z/L$  to immobilize the moving boundary. The  $y$  spatial variable lies between 0 and 1, and enables the normal discretization of the thickness dimension. The newly transformed model is implemented into gPROMS<sup>TM</sup> modeling environment. The partial differential equations are approximated using 2<sup>nd</sup> order Central Finite Differences and the differential – algebraic solver DASOLV is used for the integration.

### 4. Model Validation

For the validation of the model, a suitable set of experimental data from the open literature was used. The experimental measurements that are presented in the work of Heydari et al. (2018) facilitate the corroboration of the model predicted shrinkage behavior of the green ceramic body. In Fig. 1, the model predicted moisture content and volumetric strain is plotted against the experimental measurements.

**Fig. 1:** Comparison of experimental data (Heydari et al., 2018) and model predictions for (a) moisture content and (b) volumetric strain.

The results indicate that a sufficiently good agreement is achieved. The deviations of the model predictions from the experimental points are ought to the fact that the studied material of Heydari et al. (2018) has much larger aspect ratio than the semi-infinite plate that is of interest in the present work. It is expected that the use of a higher order model could result to a better match between the model predictions and the experimental data.

### 5. Parameter Estimation

The material of interest in this work is a clay tile that is produced in a large-scale production plant in Greece. The simulation of the drying process of the material requires the establishment of its desorption kinetics. That for, equation (4) has to be substituted by an equation that correlates the relative humidity to the moisture content of the material and its temperature. For this reason, the GAB model is selected.

$$X_{eq} = \frac{Ckm_0RH_{eq}}{(1 - kRH_{eq})(1 - kRH_{eq} + CkRH_{eq})} \quad (13)$$

Where  $C, k, m_0$  are temperature dependent parameters and are described by Arrhenius type equations :  $C = C' e^{-\frac{\Delta H_C}{R_g T}}$ ,  $k = k' e^{-\frac{\Delta H_k}{R_g T}}$  and  $m_0 = m_0' e^{-\frac{\Delta H_{m_0}}{R_g T}}$ . The parameters  $C', k', m_0'$  and  $\Delta H_C, \Delta H_k, \Delta H_{m_0}$  are estimated based on drying tests that were conducted in the lab and their values are illustrated in Table 1.

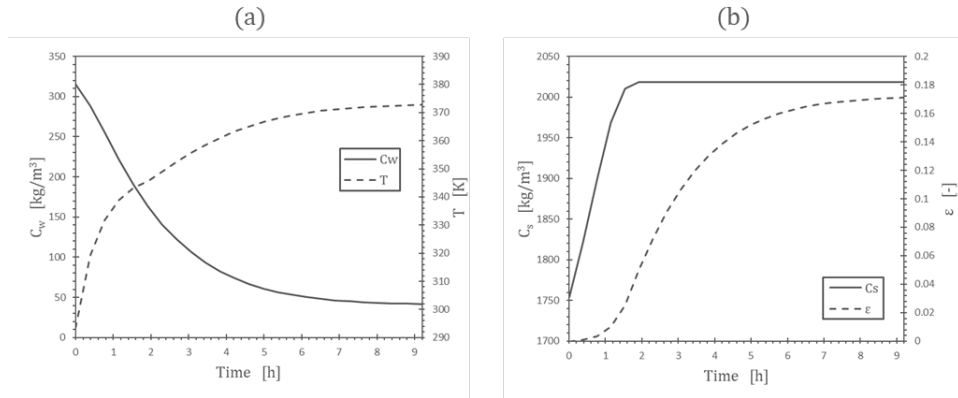

**Table 1:** GAB model parameters

GAB parameters					
$C''$	$k''$	$m_0''$	$\Delta H_{C'}$	$\Delta H_{k'}$	$\Delta H_{m_0'}$
0.195	0.0254	0.175	$-1.62 \times 10^7$	$-5.05 \times 10^6$	$2.42 \times 10^5$

## 6. Results and Discussion

Simulation results of the drying process for the studied material are summarized here, to gain insight on how the shrinkage phenomenon affects the dynamics of various quantities of the process. The model inputs required for the simulation are summarized as follows. The blowing air temperature,  $T_{air}$ , is  $100^\circ\text{C}$  and the air relative humidity,  $RH$ , is 3%. The initial water concentration and initial solid concentration are  $316 \text{ kg/m}^3$  and  $1754 \text{ kg/m}^3$  respectively. The initial tile thickness is  $1.87 \text{ cm}$  and the critical moisture content, which determines when shrinkage stops, is  $X_{cr} = 0.1 \text{ kg}_w/\text{kg}_{d.s.}$ . As for the heat and mass transfer coefficients, their values are chosen arbitrarily as  $28 \text{ W/m}^2\text{K}$  and  $0.028 \text{ m/s}$ , respectively.

Fig. 2 illustrates the water concentration and body temperature time profiles. It is observed that the water concentration inside the body decreases with time as its temperature rises. Finally, a steady state is reached and the drying procedure is complete.

**Fig. 2:** (a) Mean water concentration and temperature vs time and (b) Mean solid concentration and body porosity vs time

The solid concentration and porosity temporal evolutions are illustrated in Fig. 2(b). At the beginning of the process, the body porosity remains unchanged and the solid concentration rises abruptly. This is justified by the fact that during these times shrinkage is ideal and  $\alpha = 1$ . When the critical moisture content,  $X_{cr}$ , is achieved, a transition to the no-shrinkage state occurs and shrinkage stops. Consequently, the solid concentration stops to vary and air starts to replace the removed water volume, which leads to the porosity increase.

In Fig. 3, the shrinkage parameter on the moving boundary and the tile thickness are plotted against time. It is observed that the body shrinks for some time despite that the shrinkage parameter  $\alpha|_{z=L}$  obtains the zero value. This is because even if  $X < X_{cr}$  at the

boundary,  $z = L$ , shrinkage continues to take place to the interior of the body, as long as  $X > X_{cr}$ .

**Fig. 3:**  $\alpha$  parameter on the boundary  $z = L$  and slab thickness vs time

## 7. Conclusions

A 1-dimensional model is developed to predict the drying behavior of a green ceramic tile with respect to shrinkage. The proposed model facilitates the calculation of key physical quantities that have not been studied extensively in the literature. Such quantities are the local solid concentration and porosity. The prediction of the transient evolution of these quantities is crucial because they are severely associated to most qualitative characteristics of the green product.

## Abstract

Integrating physical knowledge and machine learning is a cost-efficient solution to modelling complex biochemical processes when the underlying mechanisms are not fully understood. However, hybrid model structure identification is still time-consuming for new processes, requiring iteration over different hypotheses to explain the observed process dynamics while minimizing over-parameterization. Unfortunately, conventional approaches to automatic model structure identification do not always converge for highly nonlinear models and cannot estimate time-varying model parameters. To address this and accelerate the design of new biochemical processes, a Reinforcement Learning (RL) based framework recently reformulated synchronous hybrid model structure-parameter identification into a process optimal control problem. To further investigate other possible solutions, in this study, a novel Physics Informed Neural Network (PINN) based framework was proposed for the first time to infer time-varying kinetic parameters. This framework first combines possible kinetic structures from phenomenological knowledge, then simultaneously identifies the most likely hybrid model structure and time-varying parameter trajectories. To demonstrate the performance of the PINN based framework, several in-silico case studies were conducted using a known ground truth bioprocess. We thoroughly examined the advantages and limitations of the framework, elucidating its potential for high-fidelity hybrid model construction in biochemical engineering research.

**Keywords:** automatic model structure identification, time-varying parameter estimation, physics-informed neural network, hybrid modelling, machine learning.

## 1. Introduction

Mathematical modelling is pivotal to understanding and designing biochemical processes. A thoroughly validated dynamic model can predict biomass growth and product synthesis under different operating conditions, reducing the number of experiments required to characterize and optimize novel biochemical processes. Kinetic and data-driven models have been proposed to describe biological processes. However, identifying a suitable kinetic model structure is time-consuming, and they are often overparameterized (i.e., multiple structures and many parameters) in an effort to capture the complex dynamics, leading to high parameter and propagated state uncertainties. On the other hand, data-driven models risk overfitting without enough experimental data – which is time-consuming to generate – and poor generalization to new operating conditions.

Integrating physical knowledge and machine learning is a cost-efficient solution to modelling complex biochemical processes when the underlying mechanisms are not fully understood. Hybrid models either use a data-driven model to correct the discrepancy between a kinetic model and the observed process dynamics or update selected time-varying kinetic model parameters. A properly validated hybrid model can effectively resolve the issue of incomplete physical knowledge and low-quality-quantity data (Zhang et al., 2020) while improving prediction accuracy and confidence compared with pure kinetic models (Vega-Ramon et al., 2021). However, hybrid models inherit the risk of over-parameterizing the kinetics and overfitting the data-driven model, which can lead to high uncertainty and poor generalization. Consequently, it is essential to identify the kinetic model structure that best represents the underlying mechanisms to reduce the burden on the data-driven model to compensate and risk overfitting. This is no trivial task since the current bioprocess kinetics depend on the present culture conditions and microenvironmental history due to stochastic effects on the controlling mechanisms or metabolic stores and systematic intracellular metabolic regulation mechanisms. As a result, the kinetic model parameters and structure will evolve with time and history.

Despite this challenge, there are few attempts outside case-specific studies to resolve automatic model structure identification for complex combinatorial, history-dependent or time-varying kinetics. Conventional approaches such as mixed integer nonlinear programming (MINLP) do not always converge for highly nonlinear models and cannot estimate time-varying model parameters. To address this, we recently proposed a novel Reinforcement Learning (RL) based framework to reformulate synchronous hybrid model structure-parameter identification into a process optimal control problem (Wu et al., 2022). The RL-based framework proved promising for recovering the correct kinetic model structure or time-varying kinetic parameters, but the combined case with more combinatorial options and time-varying kinetic parameters remains unexplored. In recent years, Physics-Informed Neural Networks (PINNs) (Raissi et al., 2019) have emerged as a novel approach to discovering underlying governing equations; however, they have not been applied before to infer time-varying physical parameters. Therefore, in this work we aim to propose a novel PINN-based framework for hybrid bioprocess model construction. Several in-silico case studies will thoroughly examine the advantages and limitations of this technique for synchronous hybrid model structure-parameter identification.

## 2. Problem Statement

The PINN-based framework first combines several possible kinetic structures from phenomenological knowledge, then simultaneously identifies the most likely hybrid model structure and time-varying parameter trajectories. To demonstrate the performance of this framework, several in-silico case studies were conducted using a known ground truth model, shown in Equation 1, that we developed in our previous work (Rogers et al., 2022). This high-fidelity hybrid model can predict the temperature-dependent biomass growth, glucose consumption and  $\gamma$ -linolenic acid (GLA) accumulation rates during fermentation of the fungus *Cunninghamella echinulata*. In Equation 1,  $X$ ,  $F$ ,  $S$  and  $P$  are the total biomass, fat-free biomass, glucose and GLA concentration, respectively, while  $T$  is temperature. The half-saturation  $K_S$  and maintenance  $k_S$  coefficients, the total  $k_X$  and fat-free  $k_F$  biomass decay rates and specific GLA decay rate  $k_P$  are all constants, while the total  $Y_X$  and fat-free  $Y_F$  biomass growth rates, the glucose-to-biomass yield coefficient  $Y_S$  and growth-dependent GLA yield coefficient  $Y_P$  are all time-varying parameters. In

our previous work, we estimated the constants and built the Gaussian Process (GP) model mapping the states and temperature to the time-varying parameters (Rogers et al., 2022).

$$\frac{dX}{dt} = Y_X(X, F, S, P, T) \cdot \frac{S}{S + K_S \cdot X} \cdot X - k_X \cdot X \quad (1a)$$

$$\frac{dF}{dt} = Y_F(X, F, S, P, T) \cdot \frac{S}{S + K_S \cdot X} \cdot X - k_F \cdot X \quad (1b)$$

$$\frac{dS}{dt} = Y_S(X, F, S, P, T) \cdot \frac{S}{S + K_S \cdot X} \cdot X - k_S \cdot X \cdot \frac{S}{S + 0.1} \quad (1c)$$

$$\frac{dP}{dt} = Y_P(X, F, S, P, T) \cdot \frac{S}{S + K_S \cdot X} \cdot X - k_P \cdot X \quad (1d)$$

Now the ground-truth model was used to generate six in-silico batches from low ( $S_0 = 60 \text{ g L}^{-1}$ ) and high ( $S_0 = 100 \text{ g L}^{-1}$ ) initial glucose concentrations under three different temperatures ( $T = 14^\circ\text{C}$ ,  $T = 28^\circ\text{C}$ ,  $T = 37^\circ\text{C}$ ). The four GP models updated the four time-varying parameters every 24 hours while the constants were fixed. Each batch was ‘fermented’ for 408 hours, and the four state variables ‘measured’ every 24 hours.

### 3. Methodology

#### 3.1. Physics-Informed Neural Network Structure

The PINN aims to learn the solution to the system of ordinary differential equations (ODEs) presented in Equation 1 by reformulating the parameter estimation and numerical integration problem into a single nonlinear optimization problem. The ANN aims to learn the concentration profile and kinetic parameters that satisfy the measured states and the system of ODEs of the form:  $d\mathbf{x}/dt = \mathcal{N}(\mathbf{x}, \boldsymbol{\phi}, \boldsymbol{\theta})$ , where  $\mathbf{x} = [X, F, S, P]^T$ , while  $\boldsymbol{\phi}$  and  $\boldsymbol{\theta}$  are vectors of time-varying and time-constant parameters, respectively. The unknown solution to the concentration profile  $\mathbf{u}_x(\boldsymbol{\lambda}, t, \mathbf{x}_0)$  and kinetic parameters  $\mathbf{u}_\phi(\boldsymbol{\lambda}, t, \mathbf{x}_0)$  was represented by a single ANN as a function of batch time  $t \in [0, 408 \text{ hours}]$  and the initial state  $\mathbf{x}_0 = [X_0, F_0, S_0, P_0]^T$ , where  $\boldsymbol{\lambda}$  denotes the tunable weights and biases.

$$\boldsymbol{\lambda}^* = \min_{\boldsymbol{\lambda}} \mathcal{L}(\boldsymbol{\lambda}) = \min_{\boldsymbol{\lambda}} [\omega_0 \mathcal{L}_0(\boldsymbol{\lambda}) + \omega_d \mathcal{L}_d(\boldsymbol{\lambda}) + \omega_c \mathcal{L}_c(\boldsymbol{\lambda})] \quad (2a)$$

$$\mathcal{L}_0(\boldsymbol{\lambda}) = \frac{1}{N_0} \sum_{i=1}^{N_0} |\hat{\mathbf{x}}_0^i - \mathbf{x}_0^i|^2 \quad (2b)$$

$$\mathcal{L}_d(\boldsymbol{\lambda}) = \frac{1}{N_d} \sum_{i=1}^{N_d} |\hat{\mathbf{x}}_d^i - \mathbf{x}_d^i|^2 \quad (2c)$$

$$\mathcal{L}_c(\boldsymbol{\lambda}) = \frac{1}{N_c} \sum_{i=1}^{N_c} \left| \frac{\partial \hat{\mathbf{x}}_c^i}{\partial t} - \mathcal{N}(\hat{\mathbf{x}}_c^i, \hat{\boldsymbol{\phi}}_d^i, \hat{\boldsymbol{\theta}}) \right|^2 \quad (2d)$$

The PINN was trained by minimizing the composite loss function in Equation 2, where  $\omega_0$ ,  $\omega_d$  and  $\omega_c$  balance the interplay between the different loss terms during training. Here  $\{\mathbf{x}_0^i\}_{i=1}^{N_0}$ ,  $\{t_d^i, \mathbf{x}_d^i\}_{i=1}^{N_d}$  and  $\{t_c^i, \mathbf{x}_c^i\}_{i=1}^{N_c}$  are the time-state value pairs for the initial conditions,

measured data points and collocation points, respectively. Each batch is divided into  $N$  intervals of  $\Delta t = 24$  hours, where  $t_d \in \{0, \Delta t, 2\Delta t, 3\Delta t \dots N\Delta t\}$ , while each interval is subdivided into  $\Delta t/\delta t = 5$  collocation points, such that  $t_c \in \{0, \delta t, 2\delta t, 3\delta t \dots n\delta t\}$  is on the same timescale. The terms  $\hat{\mathbf{x}}_d = \mathbf{u}_x(\boldsymbol{\lambda}, t_d, \mathbf{x}_0)$  and  $\mathbf{x}_d$  denote the predicted and measured states, respectively, at the known data points, while  $\hat{\mathbf{x}}_c = \mathbf{u}_x(\boldsymbol{\lambda}, t_c, \mathbf{x}_0)$  denotes the predicted state at the collocation points for which the states were not measured. Once  $\hat{\mathbf{x}}_c$  is evaluated, the gradients with respect to time  $\partial \hat{\mathbf{x}}_c / dt$  were computed by reverse automatic differentiation. The time-constant  $\hat{\boldsymbol{\theta}} = \mathbf{u}_\phi(\boldsymbol{\lambda}, 0, 0)$  and time-varying  $\hat{\boldsymbol{\phi}}_d = \mathbf{u}_\phi(\boldsymbol{\lambda}, t_d, \mathbf{x}_0)$  kinetic parameters were both predicted by the ANN, implicitly coupling them to the same network parameters for more stable training. However, unlike the continuous state variables,  $\hat{\boldsymbol{\theta}}$  is a fixed constant, while  $\hat{\boldsymbol{\phi}}$  is a piecewise constant. To represent this behaviour,  $\hat{\boldsymbol{\theta}}$  was evaluated at a fixed input while  $\hat{\boldsymbol{\phi}}_d$  was evaluated at each data sampling point  $t_d$  and the result used over  $t_d \leq t_c < t_d + \Delta t$  when computing  $\mathcal{N}(\hat{\mathbf{x}}_c, \hat{\boldsymbol{\phi}}_d, \hat{\boldsymbol{\theta}})$ . The network was built from a single hidden layer of 40 neurons with a hyperbolic tangent activation function in the hidden layer and a linear output layer. This combination mirrors the typical bioprocesses sigmoid-like growth and parameter profiles.

### 3.2. Physics-Informed Neural Network Training and Simulation

The PINN was fitted simultaneously to all six in-silico batches. The PINN was trained in two stages: first (i) the network was trained for 6000 epochs with  $\{\omega_0 = 5, \omega_d = 1, \omega_c = 0\}$  and a learning rate of  $5 \times 10^{-2}$  until  $\mathcal{L}_d(\boldsymbol{\lambda})$  converged, then (ii) the network was trained for 10000 epochs with  $\{\omega_0 = 5, \omega_d = 1, \omega_c = 5 \times 10^3\}$  and a learning rate of  $5 \times 10^{-4}$  until  $\mathcal{L}_c(\boldsymbol{\lambda})$  converged. Fitting the state profile before the kinetic parameters approximates the initial gradients  $\partial \hat{\mathbf{x}}_c / dt$  and was found empirically to be more robust to becoming trapped within low-quality local optima than single-stage training.

Once the PINN was constructed, the multistep-ahead state trajectory was re-simulated using Equation 3 from  $\mathbf{x}_0 = [X_0, F_0, S_0, P_0]^T$  using the predicted time-constant parameters  $\hat{\boldsymbol{\theta}}^* = \mathbf{u}_\phi(\boldsymbol{\lambda}^*, 0, 0)$  and the predicted time-varying parameters  $\hat{\boldsymbol{\phi}}_d^* = \mathbf{u}_\phi(\boldsymbol{\lambda}^*, t_d, \mathbf{x}_0)$  updated once every 24 hours.

$$\hat{\mathbf{x}}'_{d+1} = \hat{\mathbf{x}}'_d + \int_{t_d}^{t_{d+1}} \mathcal{N}(\mathbf{x}', \hat{\boldsymbol{\phi}}_d^*, \hat{\boldsymbol{\theta}}^*) dt \quad (3)$$

## 4. Results and Discussion

Once the PINN was fitted to the six in-silico batches, the fitted state  $\hat{\mathbf{x}}_d^* = \mathbf{u}_x(\boldsymbol{\lambda}^*, t_d, \mathbf{x}_0)$  trajectory, the time-constant parameters  $\hat{\boldsymbol{\theta}}^* = \mathbf{u}_\phi(\boldsymbol{\lambda}^*, 0, 0)$  and the time-varying kinetic parameter  $\hat{\boldsymbol{\phi}}_d^* = \mathbf{u}_\phi(\boldsymbol{\lambda}^*, t_d, \mathbf{x}_0)$  trajectory was retrieved. In addition, the fitted PINN was used to re-simulate the multistep-ahead state trajectory  $\hat{\mathbf{x}}'_d$  for the six in-silico batches from their different initial states and operating temperatures, as described in Section 3.2. Figure 1 compares the fitted (i.e.,  $\hat{\mathbf{x}}_d^*$ ) and the re-simulated (i.e.,  $\hat{\mathbf{x}}'_d$ ) state trajectories for one of the six in-silico batches, showing that the PINN could fit and re-simulate the state trajectory with very high accuracy, with a mean absolute percentage error (MAPE) of 1% and 5%, respectively. Since  $\mathbf{x}_0$  is satisfied (MAPE of 1%) by strong regularization (i.e.,  $\omega_0 > \omega_d$ ) the mismatch between the fitted and re-simulated trajectories is due to the PINN not being strictly required to satisfy the system of ODEs during PINN training.

Figure 1: Fitted and re-simulated state trajectory for one of the six in-silico training batches for total biomass (a), fat-free biomass (b), glucose (c) and GLA (d) concentration.

Figure 2: Ground truth and estimated time-varying parameters for one of the six in-silico batches for the specific growth rate  $Y_X$  (a) and  $Y_F$  (b),  $Y_S$  (c) and  $Y_P$  (d) yield coefficients.

Table 1 compares the PINN estimated and ground-truth constants, demonstrating that the PINN can accurately recover (MAPE of 8%) the correct constants when there is no measurement uncertainty. The residual between the ground truth and estimated values can likely be attributed to the practical identifiability of the parameters given only six in-silico batches. Figure 2 compares the PINN estimated and ground-truth time-varying parameter trajectories, demonstrating that the PINN can recover  $Y_F$ ,  $Y_S$  and  $Y_P$  well (MAPE of 15%), particularly considering the time-varying parameters (i.e.,  $Y_X$ ,  $Y_F$ ,  $Y_S$  and  $Y_P$ ) become non-identifiable as  $S \rightarrow 0$  at the end of the batch, as their influence becomes negligible compared to the specific decay constants (i.e.,  $k_X$ ,  $k_F$ ,  $k_S$  and  $k_P$ ). However, the PINN could not recover well  $Y_X$  (MAPE of 150%). Given the excellent fit in Figure 1,

there could be two reasons for this: either (i) the PINN cannot converge to the globally optimum ground-truth parameters, and the model is insensitive to the exact parameter values, or (ii)  $K_S$  is partially non-identifiable, and extra regularization is required.

Table 1: Comparison of ground-truth and estimated time-constant parameters.

Parameter	$K_S$	$k_X$	$k_F$	$k_S$	$k_P$
Ground-Truth	48.64	1.70E-03	1.35E-03	3.10E-03	3.23E-05
Estimated	49.60	1.50E-03	1.32E-03	2.57E-03	2.96E-05
Absolute Error (%)	2.0	11.8	2.2	17.1	8.4

## 5. Conclusion

The PINN-based approach has potential for kinetic parameter estimation and for providing a way to understand real bioprocess underlying system dynamics. At present, embedded hybrid model construction follows a two-step procedure: (i) simultaneous time-constant and time-varying parameter estimation, then (ii) data-driven model construction to correlate the time-varying parameters with the state and operating conditions for predictive simulation. This novel PINN-based framework has the potential to accelerate hybrid model construction by directly building the predictive data-driven model. However, there remains the challenge of identifying a high-quality solution to the PINN network parameters. Therefore, future work will explore more advanced techniques, such as adaptive time-sampling, self-attenuation, time-marching and causal training (Wang et al., 2022). In addition, the PINN-based framework is currently only employed to estimate the kinetic parameters for a pre-defined kinetic model structure. Therefore, future work will also explore synchronous parameter-structure identification and compare the performance of the PINN-based framework against an extended RL-based framework (Wu et al., 2022) when multiple possible structures are possible.

### **Abstract**

As far as food security is concerned, the world is challenged by growing resource scarcity, changing diets, environmental challenges, volatile prices, and supply chain disruptions. Various technological, political, economic, and social factors drive food system dynamics that fluctuate in terms of their impact on food security. Many studies have attempted to alleviate risks governing food systems as means to achieve food security by suggesting numerous modelling approaches and decision-making tools. The purpose of this paper is to design a composite indicator analysing the risk status of a set of trade partners supplying Qatar with a predetermined food basket. The latter involves perishable fruits and vegetables. To design risk indicators, a set of individual factors reflecting the impact of climate change, inclusive of seasonality and sudden risks, are considered. The evaluation of these risks is performed based on their impact on Qatar's demand satisfaction. Whereas the assessment is conducted using the Analytical Hierarchy Process (AHP). The second stage of this work formulates a multi-objective optimization model in MATLAB that determines the optimal network of suppliers to satisfy the local need of Qatar, considering their climate risk profiles and their production capacities. The purpose of the optimization framework is to identify the contribution percentage of each trading partner to the total demand for the predetermined food basket while minimizing economic costs and risk composite factors. Results of the study assert that diversifying trade partners is the most resilient option to satisfy local demands yet with a high economic cost.

**Keywords:** food imports, climate change, risks, AHP, multi-objective optimisation.

### **1. Introduction**

One of the most pressing issues in today's world is climate change, which has significantly impacted the earth's ecosystems. Although the world has always experienced some degree of climate change in the last 100 years, the rate of this variation has multiplied in recent decades. Since the nineteenth century, anthropogenic activities have caused an increase in average temperature of 0.9 °C, primarily as a result of greenhouse gas (GHG) releases into the atmosphere. This rise is anticipated to reach 1.5 °C by 2050 due to continuous deforestation and the contamination of air, soil, and water bodies (Roe et al., 2019).

Long-term variations in temperature and precipitation patterns contribute to changing the comparative advantage of food production around the world and may even slow the expansion of agricultural productivity in areas with high rates of hunger. As a result, global agriculture and food systems may be altered, causing an inter-annual volatility in food supplies. If the current climate change patterns continue to evolve, crop losses may

rise in the very near future at an unprecedented rate; significantly reducing production, driving up food costs, and making it difficult to meet the rising demands of a growing population. Therefore, future food security must be strengthened by considering the inter-annual and inter-decadal effects of climate change.

Considering food systems are susceptible to climate change and natural disasters. The effect of these factors either can be sudden or can be slow, resulting in a positive or negative change (Gomez-Zavaglia, 2020), noting that it mainly affects the production stages, which have been found to only contribute to around 20% of the value chain (Cucagna & Goldsmith, 2018). Whereas the complexity of the global agricultural markets has increased due to more focus on food standards that are related to food safety, food quality, and technological advances, which creates changes in the industry along the value chain. These considerations make the task of creating a robust and resilient food supply system even more challenging.

Therefore, it is imperative to adopt a holistic value chain to enhance resilience rather than considering the production stage alone (Ringsberg, 2014). Consequently, there is a need to increase the efforts related to identifying and classifying risks related to food systems considering data from different parts of the value chain.

Hence, the main aim of this study is to develop a clearer understanding of the food system, influencing factors, and respective risk management tools, with a focus on climate change as an external and unpredictable risk to food systems.

In this study, food system's associated risks are evaluated considering their impact on the demand satisfaction for the State of Qatar. While the Analytical Hierarchy Process (AHP) tool is utilised to evaluate the relative weight of these risk factors based on quantitative and qualitative measures.

A multi-objective optimization model is then developed and solved using MATLAB's Genetic Algorithm. The goal of the optimization framework is to select optimal suppliers and define their contribution percentage towards the food basket of Qatar, while ensuring the local demand is satisfied within the suppliers' capacities, with reduced costs and minimal associated risks. The model in hand may provide insights on possible enhancement to global food systems considering economic, social, and environmental aspects.

## **2. Methodology**

### **2.1. The Analytical Hierarchy Process to design a climate risk indicator**

The Analytical Hierarchy Process (AHP) was used to develop a composite risk index which involves five different climate change risk related indicators counting, surface temperature change, water stress, arable land, sea level rise and natural disasters management in addition to agriculture policy adoption. Four countries were selected which are USA, India, China, and Iran. The AHP is used to quantify the level of risk of each trade partner through determining its priority rank and following the decision tree described in figure 1. Priorities were selected based on the situation of the country in each of the indicators and was based on historical data and grey literature (Dahlman, (n.d); EEA(2021) Level of Water Stress (2023); The Economist Group (2018)).

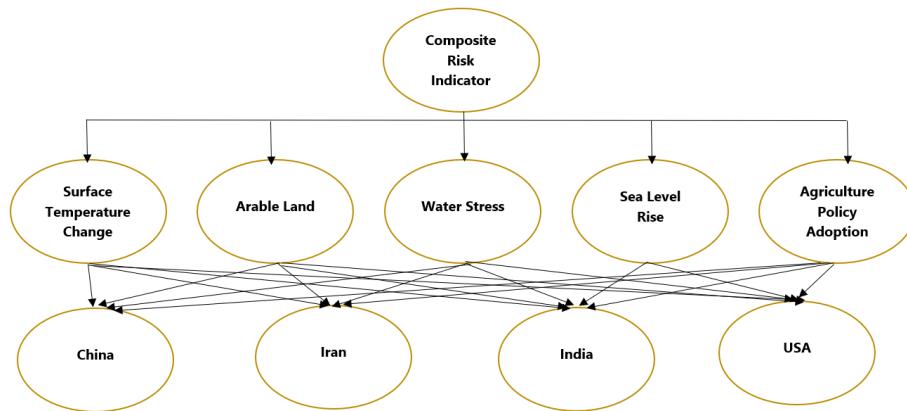

Figure 1. The hierarchical decision tree

## 2.2. Optimization model

The purpose of this part of the methodology is to design a multi-objective optimisation model that determines the optimal network of suppliers that can satisfy the local need of Qatar, considering their climate risk profiles and their production capacities. The purpose of the optimization framework is to identify the per cent contribution of each trading partner to the total demand for the predetermined food basket while minimizing economic costs, and risk composite indicators. The following table 1 presents the mathematical formulation of the suggested optimisation model. Considering the variable used,  $x_i$  presents the decision variable of the model which is the percent contribution of each country to the food basket.  $Q$  is the yearly local demand for food in kg. As for  $c_i$ , it represents the food basket average overall unit cost in \$/kg.  $r_i$  is the overall risk indicator generated from the AHP model. As for the  $cap_i$ , it represents the allowable exportable quantities in kg that can be supplied by each trade partner.

Table 1. The mathematical formulation of the optimisation model

	Equation	Connotation
<b>Objective function 1</b>	$\min \sum_{i=1}^5 Qc_i x_i$	Identifies the optimal set of trade partners that supply Qatar’s food basket while minimising the overall cost.
<b>Objective Function 2</b>	$\min \sum_{i=1}^5 r_i x_i$	Identifies the optimal set of trade partners that supply Qatar’s food basket while minimising the overall composite risk indicators.
<b>Constraint 1</b>	$\sum_{i=1}^5 x_i = 100\%$	Logical constraint implies that the sum of all contributions per cent of water technologies must be 100%.
<b>Constraint 2</b>	$Qx_i < cap_i$	The imported quantity from each trading partner should not exceed their individual exportable capacity.

### 3. Results and discussion

After conducting the AHP, 4 composite risks factors were generated for each country describing its overall risk performance (table 4). Those risks factors were derived from the composite indicators involving the set of climate risks sub-indicators as highlighted in table 3.

Composite risk factors were later used in the optimisation framework as parameters to select the optimal mix of exporting countries that can supply the market with food products.

**Table 3.** Results of the AHP priority score for each exporting country

	China	USA	India	Iran
<b>Disaster Risk Management</b>	0.0611	0.0614	0.0656	0.0738
<b>Surface Temperature Change</b>	0.14065	0.1484	0.1322	0.1264
<b>Arable land</b>	0.1612	0.1738	0.3004	0.2546
<b>Water Stress</b>	0.1388	0.1921	0.2432	0.2726
<b>Sea level rise</b>	0.4522	0.3755	0.2116	0.2255
<b>Agricultural Policy Adoption</b>	0.0459	0.0482	0.0467	0.0466

**Table 4.** Composite risk factors for each exporting country ((Namany et al., 2019)

	China	USA	India	Iran
<b>Unit cost (\$/kg)</b>	1.22	7.08	1.45	0.81
<b>Composite Risk Factor</b>	0.2222	0.2155	0.2114	0.2088

Results of the optimisation model are summarised in Figure 2 and 3. The optimal solution suggests a slightly diversified network of exporting countries with a large dominance of Iran with around 90%, while the remaining 10% is distributed between China and India. As for USA, its contribution is below the 1%. This can be explained by the large unit costs of products originating from the USA and the relatively low risk factors and costs of the other trade partners. Taking the graphical average from the Pareto front, the average optimal solution, generates an average total cost of \$672M.

Figure 2. The average optimal trade partners' network

Figure 3. The Pareto front.

#### 4. Conclusion

In this paper a multi-objective optimization model was developed to identify the ideal network of suppliers that can meet Qatar's local demand while taking into account their production capacities and risk profiles related to the climate. The optimization framework's goal was to calculate each trade partner's percentage contribution to the overall demand for the predefined food basket while minimizing composite risk factors and economic costs four different countries. According to study findings, diversifying trade partners is the most durable way to meet local wants, however it can come at a high financial cost.

## Abstract

In this work, the lot-sizing and production scheduling problem of a real-life beverage industry is addressed. In particular, a Big bucket-Small bucket Mixed-Integer Linear Programming (MILP) framework is proposed for the optimal scheduling of a Greek soft-drink production facility. The production process consists of two main stages, a batch syrup preparation stage and a continuous bottling stage. The synchronization between the syrup tanks and filling lines is of key importance for the feasibility and efficiency of the production schedules. The main goal is the generation of an optimal weekly production schedule which satisfies a given demand. A rigorous scheduling formulation for the lot-sizing and production scheduling of an industrial facility including both batch and continuous processes is presented. The derived optimal schedules lead to an increased plant productivity while reducing the utilization and cost of labor resources.

**Keywords:** production scheduling, optimization, beverage industries, MILP

## 1. Introduction

Nowadays, process industries operate in a challenging economic environment with low profit margins, where the demands they have to meet significantly increase and competition is rapidly intensifying. The ever-increasing number and diversity of products, as well as the complexity of production processes, especially in the food and beverage industry, render production scheduling an essential procedure for acquiring efficient production plans and ensuring the plant's viability and profitability. The main challenge regarding these industries is the integrated modelling of all the production stages (Toledo et al., 2015). In the beverage industry, a few scheduling techniques have been proposed in the literature, with even fewer addressing complex real-life industrial applications (Georgiadis et al., 2021). Baldo et al. (2014) proposed an MILP model, combined with MIP-based heuristics for the production lot-sizing and scheduling problem of a brewery industry with long lead times and unfixed bottleneck. Mediouni et al. (2022) studied the lot-sizing and scheduling problem in a dairy soft-drink production process, considering the limited shelf life of intermediate products and utilizing a relax-and-fix heuristic. Ferreira et al. (2009) presented an MILP model that integrates production lot-sizing and scheduling decisions of beverage plants with sequence-dependent setup costs and times and applied it to a real life instance generating improved results. The efficient lot-sizing and scheduling problem of a real-life soft-drink production facility is examined in this

work, including the integrated modelling of all production stages. The proposed mathematical framework tackles the existing production restrictions and provides optimal results regarding the productivity and the production costs of the plant.

## 2. Problem Statement

The plant includes both batch and continuous processes. More than 60 final products are produced over a 5-day time horizon. A daily 8-hour shift is used, while overnight and weekend shifts can take place if needed. It is noted that more than one product can be produced from the same syrup. A brief layout of the production process is shown in Figure 1.

Figure 1. Production process layout

According to the production recipe, initially, a primary flavored syrup is prepared. There are two tanks available for the preparation of syrups. At the same time, water is treated and deaerated so as to be suitable for mixing with the primary syrup. Inline mixing takes place between the primary syrup, the treated water and  $\text{CO}_2$  and the final mixture reaches the filling lines. In the meanwhile, empty cans/bottles are also transferred to the appropriate packing lines, where they are rinsed. There is a total of three packing lines in the facility, one for cans, one for PET bottles and one for glass bottles, but according to the company's policy only two of them can operate per day. Then, the cans/bottles are filled with the final mixture and before they finally form a multipack, labels and other messages are printed on them. Additionally, a brief quality check happens at this point. Finally, the final products are transferred to the warehouse, where they are stored until they are later distributed according to customer demand. It can be considered that the production process consists of two main stages, a batch syrup preparation stage and a continuous packing stage. The production of soft-drinks requires the synchronization between these two stages, in order to secure feasible schedules and to minimize overtime costs. Furthermore, time consuming changeovers take place in both stages depending on factors such as flavor, packing size and label. Taking into account all of these limitations while satisfying a given demand is quite challenging in real life industrial environments. Therefore, the production scheduling of a facility presenting the aforementioned characteristics is examined in this work.

## 3. Mathematical framework

This model constitutes an extension of the mathematical frameworks previously developed by Ferreira et al. (2009) and Mediouni et al. (2022). It is a Big bucket-Small bucket Mixed-Integer Linear Programming (MILP) framework extended in such a way that up to three products can be produced in the same Small Bucket (micro-period) from a single syrup and additionally the option of overtime production is considered. The planning horizon is divided in  $T$  macro-periods with the duration of a day and each macro-period is further divided into  $S$  micro-periods with flexible lengths. In each micro-period

only one syrup can be prepared in each tank. A brief description of the mathematical model follows below.

**1<sup>st</sup> stage constraints**

$$\sum_{l \in LU_{l,u}} Yl_{u,l,s} \leq 1 \quad \forall u, s \quad (1)$$

$$\sum_m Yum_{u,m,l,s} = Yl_{u,l,s} \quad \forall u, s, l \in LU_{l,u} \quad (2)$$

$$\sum_{l, u \in UL_{u,l}} Yum_{u,m,l,s} \leq 1 \quad \forall m, s \quad (3)$$

$$Zl_{u,k,l,s} \geq Yl_{u,k,s-1} + Yl_{u,l,s} - 1 \quad \forall u, t, s \in St_{s,t}, k \in LU_{k,u}, l \in LU_{l,u}, k \neq l \quad (4)$$

$$\sum_{u \in UL_{u,l}} q_{l,u} \cdot Yum_{u,m,l,s} \leq \sum_{j \in JML_{j,l} \cap JM_{j,m}} r_{j,l} \cdot x_{m,j,s} \leq \sum_{u \in UL_{u,l}} Ku_u \cdot Yum_{u,m,l,s} \quad \forall m, s, l \quad (5)$$

**2<sup>nd</sup> stage constraints**

$$In_{j,t-1} + \sum_{m \in JM_{j,m}, s \in St_{s,t}} x_{m,j,s} = In_{j,t} + d_{j,t} \quad \forall j, t \quad (6)$$

$$\sum_{s \in St_{s,t}} TSm_{m,s} \leq w_{m,t} + Ov_t \quad \forall m, t \quad (7)$$

$$TSm_s \geq \sum_{j \in JM_{j,m}} a_{m,j} \cdot x_{m,j,s} + \sum_{i \in JM_{i,m}, j \in JM_{j,m}, i \neq j} bb_{i,j} \cdot Zij_{m,i,j,s} + \sum_{u,k \in LU_{k,u}, l \in LU_{l,u}, k \neq l} b_{k,l} \cdot Zum_{u,m,k,l,s} \quad (8)$$

$$+ tr \cdot \sum_{u,l \in UL_{u,l}} Yum_{u,m,l,s} \quad \forall m, s$$

$$TSm_s \geq \sum_{j \in JM_{j,m}} a_{m,j} \cdot x_{m,j,s} + \sum_{i \in JM_{i,m}, j \in JM_{j,m}, i \neq j} bb_{i,j} \cdot Zij_{m,i,j,s} + \sum_{i \in JM_{i,m}, j \in JM_{j,m}, i \neq j} bb_{i,j} \cdot Zjm_{i,j,s} \quad \forall m, s \quad (9)$$

$$\sum_{i \in JM_{i,m}, i \neq j} Zij_{m,i,j,s} + \sum_{ii \in JM_{ii,m}, ii \neq j} Zij_{m,j,ii,s} + 1 \geq Yjm_{j,s} + Yjm_{j,j,s}, \quad (10)$$

$\forall m, j \in JM_{j,m}, jj \in JM_{jj,m}, j \neq jj, s$

$$\sum_{i \in JM_{i,m}, j \in JM_{j,m}} Zij_{m,i,j,s} + V_{m,s} = \sum_{j \in JM_{j,m}} Yjm_{j,s} \quad \forall m, s \quad (11)$$

$$G \leq Zjm_{i,j,s} \leq 0.5 + \frac{G}{2} \quad \forall m, i \in JM_{i,m}, j \in JM_{j,m}, i \neq j, t, s, \text{ where} \quad (12)$$

$$G = Yjm_{i,s-1} + Yjm_{j,s} - 1 - \sum_{jj \in JM_{jj,m}, i \neq jj} Zij_{m,i,jj,s-1} - \sum_{ii \in JM_{ii,m}, j \neq ii} Zij_{m,ii,j,s} \leq Zjm_{i,j,s}$$

**Objective function**

$$\min \sum_{m,t,s \in St_{s,t}} TSm_{m,s} \quad (13)$$

Constraint set (1) imposes that in each micro-period  $s$ , each tank  $u$  can prepare at most one syrup  $l$ , using the binary allocation variable  $Yl_{u,l,s}$ . Constraints (2) and (3) express that if a syrup  $l$  is prepared in tank  $u$  in micro-period  $s$ , then it must be transferred to a single packing line  $m$  and this packing line cannot receive another syrup from another tank. The binary variable  $Yum_{u,m,l,s}$  indicates that the tank  $u$  prepares syrup  $l$  in micro-period  $s$  for the line  $m$ . Constraints (4) define the changeover of syrups in a tank using the immediate precedence binary variable  $Zl_{u,k,l,s}$ . With constraints (5) it is ensured that the amount of final products produced from the same syrup in a micro-period  $s$  (where  $r_{j,l}$  is the required amount of syrup  $l$  to produce one unit of product  $j$  and  $x_{m,j,s}$  represents the produced units of product  $j$  on packing line  $m$  in micro-period  $s$ ), is bounded by the minimum quantity of filling  $q_{l,u}$  and the maximum capacity  $Ku_u$  of the tank. Constraints (6) demonstrate that the inventory of product  $j$  in macro-period  $t$ ,  $In_{j,t}$ , equals the inventory of the previous macro-period plus the produced amount in the current macro-period, minus the customer demand  $d_{j,t}$ . Constraint set (7) guarantees that the total production time in macro-period  $t$ ,  $\sum_{s \in St,s,t} Ts_{m,s}$ , does not exceed the daily production time horizon  $w_{m,t}$  including any possible overtime shifts  $Ov_t$ . Constraints (8) and (9) establish that the functioning time of line  $m$  in micro-period  $s$ ,  $Ts_{m,s}$ , must be equal to or greater than the packing time (with  $a_{m,j}$  being the required production time of one unit of product  $j$  on line  $m$ ), plus the changeover time between products from the same syrup  $bb_{i,j}$ , plus the line's waiting time. The line's waiting time in a micro-period is either equal to the time needed for the tank's changeover  $b_{k,l}$  and preparation of syrup  $tr$  or to the line's changeover  $bb_{i,j}$  regarding the previous micro-period, depending on which one lasts longer. Constraints (10) and (11) monitor the changeover between products in the same micro-period  $Zij_{m,i,j,s}$  while constraints (12) define the changeover between products in consecutive micro-periods  $Zj_{m,i,j,s}$ . The binary variable  $Yj_{m,j,s}$  specifies whether product  $j$  is being packed in line  $m$  in micro-period  $s$  and the binary variable  $V_{m,s}$  is activated if line  $m$  functions at micro-period  $s$ . The objective of the model, described by constraint (13), is the minimization of the total production time.

#### 4. Results & Discussion

An industrial case study concerning the production plant of Green Cola Hellas is demonstrated. The MILP model was implemented in GAMS and solved using CPLEX 12.0. Optimality was reached in acceptable computational times by the company in all cases, as shown in Table 1. Figures 2 and 3 illustrate the generated schedules for two given weekly demands. According to the company's policy two of the three available packing lines operate per week. Figure 4 depicts the plant's weekly schedule if all three packing lines were to operate in a week. Moreover, Figure 5 shows the percentage of functioning time each machine devotes to different kinds of operations in this case. It is noted that in the following Gantt charts only the syrup preparation and changeover time are illustrated with colors for the tanks, whereas the time dedicated to feeding the packing lines is not. The different syrup flavors prepared are annotated as RX while the final products are annotated as PX.

Table 1. Solution report for the satisfaction of three weekly product demands

	CPU (s)	GAP (%)	Overtime (hrs)	Weekly functioning time (hrs)				
				Tank 1	Tank 2	Can line	PET line	Glass line
Demand 1	28	0	16.3	40.3	38.1	30.6	-	23.8
Demand 2	900	0.4	12.6	36.1	47.0	25.9	21.3	-
Demand 3	900	0.3	16.3	46.4	38.0	31.7	12.8	23.8

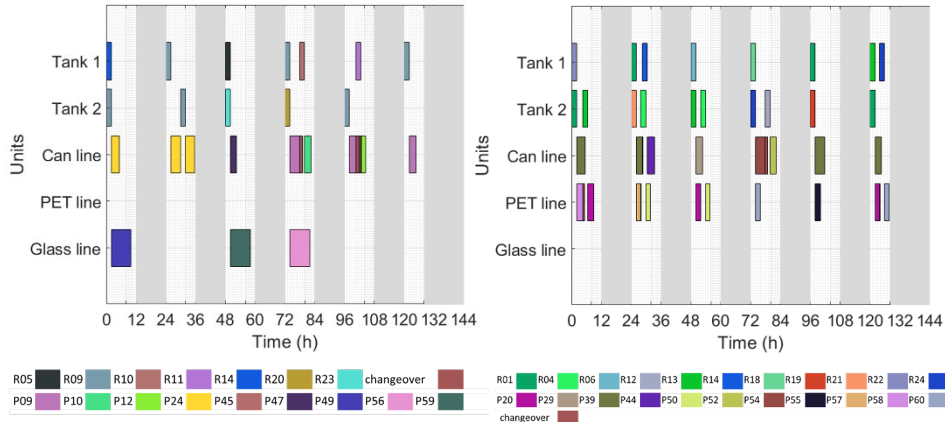

Figure 2. Weekly schedule for Demand 1

Figure 3. Weekly schedule for Demand 2

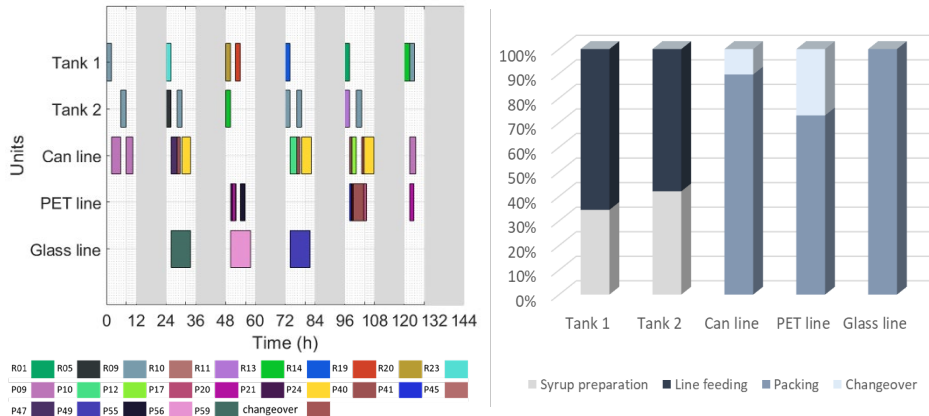

Figure 4. Weekly operation of all three lines

Figure 5. Functioning time allocation for each machine (Demand 3)

In all cases, overtime is required to satisfy the given demand. In Figures 2 and 4, it is observed that multiple products are produced from a single syrup, a flexibility given by the extended mathematical model presented in this work. Furthermore, the correct synchronization of the various units is achieved. The syrup tanks are identified as the production’s bottleneck since they are utilized during the whole production horizon, either preparing syrups or feeding the packing lines. Syrup preparation requires only a little time, nevertheless a tank cannot start preparing a new syrup unless it is empty. In

fact, significantly more time is dedicated to line feeding compared to the time dedicated to syrup preparation, as shown in Figure 5. The operation of all three available packing lines in a week gives flexibility to the production while larger product demands can be satisfied. However, this leads to an increased inventory.

## 5. Conclusions

The lot-sizing and production scheduling problem of a real-life beverage industry is presented in this work. The production facility under consideration can be identified as multiproduct and multistage, with each stage including both batch and continuous processes, making the problem particularly complex. Furthermore, the synchronization between these stages is important for the feasibility and efficiency of the production schedules, an issue often met in food and beverage industries. For the optimal scheduling of the facility, an MILP framework is proposed. To the best of our knowledge this study is the first to allow multiple products to be produced in the same Small Bucket from a single syrup, thus significantly improving the facility's productivity. This work's novelty is further extended by the inclusion of overtime production if necessary, for the timely satisfaction of the given weekly demand. Optimal production schedules are generated in short computational times leading to an increased plant productivity and reduced cost of labor resources. Moreover, the syrup tanks are identified as the production's bottleneck. Future work focuses on the short-term storage of the intermediate syrups in the preparation tanks while taking into account their shelf life and also on the introduction of buffer tanks between the preparation stage and the packing lines so that the syrup tanks can function at their full capacity.

## Abstract

Modeling and analyzing the solid waste incineration process is a salient study for future advanced waste disposal technology and optimizing process efficiency. However, the development of a mechanistic model that describes the process deal with several challenges and has yet to be extensively explored. Thus, this paper aims to develop a mechanistic model for clinical and municipal solid waste incineration in Aspen Plus. The waste was modeled using customized non-conventional (NC) solid properties, and a general coal enthalpy model with heat correlations to calculate the heating value. The model results accurately depict the waste heating values found in the literature. Further analysis reveals the ability of the model to describe the effect of waste feed quality on incinerator performance.

**Keywords:** Clinical and municipal waste, incineration, Aspen Plus.

## 1. Introduction

The generation of municipal solid waste (MSW) has been increasing globally owing, primarily due to an increase in global population, urbanization, and economic growth, as well as changes in production and consumption behavior (Lohri et al., 2017). On the other hand, the amount of clinical waste (CW) has increased over the past two years due to a high number of COVID-19 infections. Studies found that the weight of CW has increased by 27% due to higher cases of COVID-19 being recorded. In 2013 about 50 metric tons of CW was generated; however, for now, it is estimated that about 90 metric tons of CW are generated each day, and about 25 metric tons of it is due to COVID-19 (Agamuthu & Barasarathi, 2021). Various solid waste management treatments exist, including conventional sanitary landfill treatment, biological treatment, and thermal treatment. Predominantly, landfill is the primary method of waste disposal in most countries around the world. However, such a common method is ineffective in managing the increasing volume of solid waste apart from its drawback towards land, air, ground, and surface water pollution. Hence, this combustible waste may be incinerated or combusted as an alternative to landfill.

The advantages of waste incineration over landfilling are the reduction in waste volume, waste stabilization, waste-to-energy (WtE) conversion, and sanitization of waste, especially clinical waste. Besides, it also runs stably for a long period. In the incinerator, waste is burned at 850 to 1000°C, where CO<sub>2</sub>, SO<sub>2</sub>, NO, NO<sub>2</sub>, HCl, HF, CO, dioxins, and furans are released during incineration. The government law has mandated that waste incineration facilities use gas purification technologies to reduce volume and hazardous characteristics and capture or destroy potentially harmful substances that may be released

during incineration. As a result, atmospheric gas emission limits are typically set to minimize health and environmental impacts. According to Williams (2005), the combustion properties and emissions produced by the combustion system will be influenced by the waste's composition and characteristics. The solid waste's fuel properties and the proximate and ultimate analyses play an important role in how the waste will burn in the incinerator and the emissions that are likely to result. The composition and heating value were the most important parameters governing thermal processing (Zhou et al., 2014). Heating values measure the chemical energy bound in a feedstock where this energy is released during combustion (Erol et al., 2010) and categorized into two, namely higher heating value (HHV) and lower heating value (LHV). The former involves the heat of condensation of water vapor produced in the heat of combustion, while the latter is related to the HHV via the heat of vaporization of water. In some instances, the HHV and LHV are associated with the heat of vaporization of both HCl and water if the waste contains chlorine and produces HCl as one of the products.

There are two methods for experimentally determining the heating values: a full-scale boiler as a calorimeter and a laboratory bomb calorimeter. Heating values can also be determined by calculation using empirical models, and several models have been developed by researchers (Ogwueleka, 2010). To this day, the most popular method for predicting heating value is linear regression. Using regression analysis to develop an empirical model to predict the heat value is thought to be easier and more cost-effective (Khuriati et al., 2017). A model that describes the oxidation, pyrolysis, and incineration process is useful to provide insights into the incineration performance and operations. However, the development of such a model deal with several challenges and has yet to be extensively explored. Therefore, the focus of this study was to develop a working model by employing Aspen Plus simulation software. The establishment of such a model is useful to describe the solid waste incineration process, determine the factors impacting its performance, and predict incineration performance under various operating conditions.

## 2. Methodology

### 2.1. Calculation of heating value

The solid waste was modeled in Aspen Plus as a non-conventional (NC) solid. The NC component models for enthalpy and density properties calculations were empirical correlations that require solid material characterization information derived from constituent ultimate and proximate analyses. The estimates were based on the general coal enthalpy model, including several correlations to compute the heat of combustion, heat of formation, and heat capacity. In this work, the heat of combustion in dry, mineral-matter-free basis,  $\Delta_c h_i^{dm}$ , was calculated using the Boie correlation according to the following equation,

$$\Delta_c h_i^{dm} = (a_{1i}w_{C,i}^{dm} + a_{2i}w_{H,i}^{dm} + a_{3i}w_{St,i}^{dm} + a_{4i}w_{O,i}^{dm} + a_{5i}w_{N,i}^{dm})10^2 + a_{6i} \quad (1)$$

Where  $w$  is the weight fraction and the constant terms,  $a_{1i}$  to  $a_{6i}$  were obtained from the Institute of Gas (IGT) study. Products were in the form of ash, liquid water, and gaseous CO<sub>2</sub>, SO<sub>2</sub>, and NO<sub>2</sub>. The heat of formation,  $\Delta_f h_i^d$  was based on the standard heat of combustion-based correlation. The numerical coefficients were combinations of stoichiometric coefficients and heat of formation for CO<sub>2</sub>, H<sub>2</sub>O, HCl, and NO<sub>2</sub> at 298.15K represented by,

$$\Delta_f h_i^d = \Delta_c h_i^d - (1.418 \times 10^6 w_{H,i}^d + 3.278 \times 10^5 w_{C,i}^d + 9.264 \times 10^4 w_{S,i}^d - 2.418 \times 10^4 w_{N,i}^d - 1.426 \times 10^4 w_{Cl,i}^d) 10^2 \quad (2)$$

Whereas the heat capacity calculations were based on Kirov Correlations (Kirov, 1965), which treats the heat capacity as a weighted sum of the heat capacities of the constituents, which include moisture, fixed carbon, volatile matter, and ash.

### 2.2. Aspen Plus flowsheet for CW incineration

Modeling and simulation for solid waste incineration were performed in Aspen Plus V12.1. The solid waste was fed constantly, and the combustion chamber's process was adiabatic. Gaseous equilibrium is achieved between the primary and secondary chambers. Heat transfer occurs within the chamber via the mixing of hot gases as well as radiation. The flowsheet comprised two reactor blocks, RYIELD and RSTOIC. The former was used to convert non-conventional components into conventional components and the heat of formation required, while the latter was used to simulate the combustion process. In addition, two calculator blocks were added to convert the ultimate analysis element into a wet basis component for the RYIELD reactor block, while the second calculator block was used to calculate the heating value. The IDEAL base method was used as the property method. The thermophysical properties (enthalpy, density, and specific heat) of solid waste were calculated using the built-in coal property models HCOALGEN and DCOALIGT based on their proximate and ultimate analysis. For calculating heating values, all unit operations use 25°C and 1 bar as the reference state. Excess air with 78% nitrogen and 21% oxygen was used as the oxidizing agent.

### 2.3. Case study

Table 1 shows the proximate and ultimate analysis and its heating values of several municipal and clinical samples found in the literature. Each sample's proximate and ultimate values were inserted into the model to calculate the heating values. The calculated results were then compared. For all cases, the waste fed rate was assumed to be 500 kg/h. To ensure excess air between a stoichiometric ratio of 1.5 to 2.0, the combustion air fed rate used was 7000 kg/h.

Table 1: Proximate and ultimate analysis of municipal and clinical waste samples

	CW (Erdogan & Yilmazoglu, 2021)			MSW (Gebreslassie et al., 2020)

<sup>a</sup> LHV, <sup>b</sup> HHV

### 2.4. Statistical analysis

To determine the accuracy of the proposed model, mean absolute percentage error (MAPE) was used to denote the closeness of the calculated heating value to the actual

value. MAPE is mainly used to determine model accuracy and is calculated using the following equation,

$$MAPE = \left( \frac{1}{n} \sum_{i=1}^n \frac{|E_i - P_i|}{E_i} \right) \times 100\% \quad (3)$$

where  $n$  is the sample number,  $E_i$  is the actual value, and  $P_i$  is the calculated value. Based on Lewis (1982), a MAPE value of less than 10% gives a highly accurate prediction.

### 2.5. Model analysis

Analysis of the model was performed to illustrate the effect of process parameters on the incineration performance of CW and MSW. Two parameters were studied for each type: moisture and VM content. Moisture content, in CW, for example, could consist of up to 38% (Li & Jeng, 1993), and for some biomedical compositions, VM values were from 30% (Olanrewaju, 2019). These two values were varied, and the corresponding normalized proximate and ultimate analyses were then used in the model to determine the heating value and combustion temperature. Furthermore, some waste, i.e., CW, must be incinerated to around 1000 C due to regulatory requirements. Therefore, additional heat duty was calculated to determine the combustion heat duty required to achieve the desired decomposition temperature. Typically, the extra heat duty was supplied by auxiliary fuel i.e., diesel and natural gas.

## 3. Result & Discussion

### 3.1. Model validation

In Table 2, the model calculated Sample 1 to have the highest heating values, whereas Sample 6 had the lowest. Moreover, each sample's descending pattern of calculated heating values was consistent with the experimental heating values. In general, carbon elements have a direct impact on heating value and the results were coherent with the carbon composition in Table 1. Table 2 also shows the percentage difference between the calculated value and the experimental data. The percent MAPE range for all samples were between 3-12%. On average, the percentage error was 7%. This implies that the simulation model estimated the heating value of the CW and MSW samples with an excellent range of accuracy.

Table 2: Heating values comparison and simulated combustion temperature results.

Category	Sample #	Experiment, kJ/kg	Simulation, kJ/kg	Simulated comb. temp, C	MAPE, %
Clinical waste	1	42650 <sup>a</sup>	39042	1075	8

### 3.2. Model analysis

The results for variation in moisture and VM content of CW and MSW feed to heating value, and combustion temperature is shown in Figure 1. Figure 1a shows that when the moisture content is increased, the heating value decreases. These findings are intuitive

and agree with Liang et al. (2008). Higher moisture content typically leads to lower calorific value as various moisture content levels in mass burning affect combustion performance. Furthermore, the higher moisture content also reduces reaction temperature and results in poor ignition (Johari et al., 2012). This, in return, lowers the combustion temperature, as shown by the decreasing combustion temperature. On the other hand, the increase in VM had an inverse effect on heating values. As shown in Figure 1b, the heating values increase upon increasing VM content. High VM content contributes to easy fuel ignition, where a lower minimum ignition temperature is needed. The impact, however was less significant compared to moisture content. Nevertheless, the result ties well with theoretical data wherein VM significantly impacts thermal decomposition.

Specifically for CW, an additional heat duty is required to increase the temperature to around 1000 C for complete disintegration. Figure 2 shows the additional heat duty required with variation in moisture content. This is typically achieved through burning of fuel i.e., diesel and natural gas. Obviously, a larger temperature difference needs more heat or fuel. Therefore, proper handling, segregation, sorting, waste volume, and size and feed time of the waste are detrimental to reducing the interference with reaction product combustion, increasing combustion quality, and consequently decreasing the fuel cost.

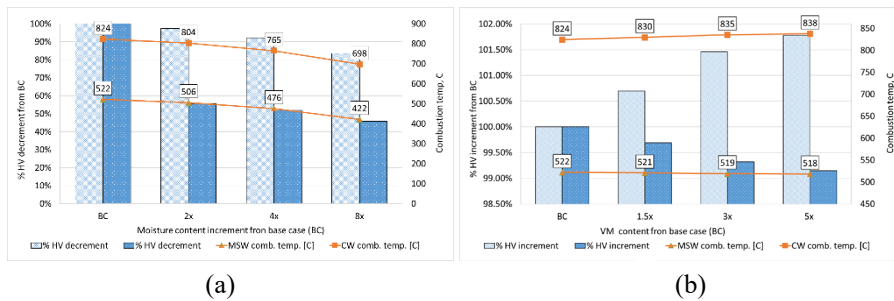

Figure 1: Effect on LHV and combustion temperature of CW and MSW for variation in (a) moisture and (b) VM content.

Figure 2: Additional heat required and temperature difference to achieve the CW decomposition temperature of 1000 C.

#### 4. Conclusion

The objective of this study to develop a mechanistic model of the CW and MSW incineration process was achieved. Using customized NC solid properties, flowsheet, and a general coal enthalpy model with heat correlations in Aspen Plus, the model demonstrates excellent agreement with experimental data with a mean absolute

percentage error of 7%. Model analysis of waste feed content agrees well with results found in the literature. The model shows that lower moisture and higher VM content contribute to higher heating values. However, the effect of moisture content is much more significant than VM content. The model was also extended to predict combustion temperature and the additional heat required to achieve decomposition temperature. The model reveals that waste feed quality is detrimental to the incinerator's performance. In future work, we will expand the model to other applications, such as optimization, air pollution control, and waste-to-energy systems.

## Abstract

Periodic scheduling (commonly implemented in batch processing) is characterized by the process cycle time. Minimizing the cycle time maximizes throughput. This paper proposes two approaches for the calculation of the minimum cycle time for batch processes with resource sharing among tasks: an algorithmic and an MILP-based. The first approach implements an exact, exhaustive algorithm which also allows the calculation of all feasible cycle time ranges. The second approach is optimization-based, yields only the minimum cycle time but is more flexible than the algorithmic in the type of problems it can handle. Both approaches are demonstrated with illustrative examples.

**Keywords:** periodic scheduling, cycle time minimization, MILP.

## 1. Introduction

Cyclic, and more specifically, periodic scheduling is preferred by many batch industries because of the simplified shop floor control, the easily implementable schedules and easier shift decisions for the staff. Furthermore, studies show that cyclic schedules tend to be more robust compared to non-cyclic ones. Despite those facts, cyclic scheduling has not attracted much attention from the PSE research community.

Periodic scheduling is characterized by the process cycle time, i.e. the constant time interval between the start (or end) of two consecutive batches. The cycle time is directly related to throughput; minimizing the cycle time is essential in the operation of a plant and in capacity studies. Many researchers proposed exact algorithmic polynomial solvable methods for cyclic scheduling problems, where tasks do not share resources (Hanan, 1994). However, the methods available in the literature cannot optimize cases with sharable resources. Few researchers developed novel mathematical optimization approaches for cyclic scheduling (Pinto and Grossmann, 1994; Wu and Maravelias, 2019). In most of these formulations, each task can only be processed in exactly one unit throughout the cyclic schedule. Moreover, they do not address the cycle time minimization problem.

The objective of this paper is to present solutions to the minimization of cycle time in the presence of tasks sharing multiple resources. Two approaches are presented: an algorithmic and an MILP-based. In the algorithmic case, the non-overlapping constraint between tasks on the same resource yields bounds on the feasible cycle time between any pair of tasks under the assumption that all available resources are used periodically by all tasks. The developed MILP model is based on the general precedence framework (Kopanos et al., 2011) and takes into account the cyclic nature of batch scheduling through the introduction of a new set of constraints. In comparison to the solutions

found in literature, the model relaxes the requirement of using a single resource for each task throughout the schedule allowing for a better utilization of the available resources. The proposed model is relatively general and can be easily extended to consider any specific operational constraint, thus providing a basis for tackling realistic large-scale problems. Two case studies are presented, demonstrating the applicability of the proposed solutions in real-life industrial scenarios and highlighting their differences. The case studies have been modeled and scheduled within the scheduling software SchedulePro (by Intelligen, Inc., Scotch Plains, NJ, USA, [www.intelligen.com](http://www.intelligen.com)) where the algorithms have also been implemented. The MILP models have been solved using the HiGHS open-source solver (Huangfu and Hall, 2018).

## 2. Periodic Scheduling Set-up

Let  $T = \{1, 2, \dots, n\}$  be a set of  $n$  tasks corresponding to a batch that is to be executed indefinitely often. Let  $p_i > 0$  be the duration of task  $i$ . The batches must be executed periodically with a fixed cycle time,  $a$ . Let  $t(i, k)$  denote the start of the execution of task  $i$  in batch  $k$  and  $t_i$  denote the start of task  $i$  for the (randomly selected) reference batch 0. Then,

$$t(i, k) = t_i + ak \quad (1)$$

Within each iteration, the tasks are to be executed at a specific order with fixed time intervals between their starts. Let  $D_{i,j} \forall i, j \in T$  be the fixed time distance between the start of task  $j$  and the start of task  $i$  within the same batch. Then,

$$\begin{aligned} D_{ij} &= t(j, k) - t(i, k) \Rightarrow D_{ij} = t_j - t_i \\ D_{ji} &= -D_{ij}, \quad D_{ii} = 0 \end{aligned} \quad (2)$$

It is assumed that all tasks within  $T$  are ordered in ascending start times. Each task uses a pool of available resources to be used for its execution. Different tasks may use the same resources, therefore, the resource pools may overlap (partially or fully) between tasks. Feasible cycle times are those that do not create overlaps of tasks (in the same or different batches) on the same resource. Under this setting, a unique schedule can be generated with the assignment of the cycle time,  $a$ , and the allocation of resources for each task in every batch.

## 3. Algorithmic Approach

To obtain the minimum and feasible cycle time ranges in an algorithmic way, it is assumed that each task uses exclusively its own resource pool, or, if tasks are to share resources, the resource pools are identical. It is further assumed that if common resources are available, they are used in a rotation mode. As a result, all tasks will eventually "meet" on each resource but it is not known a priori to what batch these tasks will belong. Under these assumptions, a periodic schedule is completely determined by setting the value of the cycle time and the resource used for every task at the first batch. To find the minimum cycle time, it is possible to split the task set into subsets composed of either a single task (using its own resources) or of a group of tasks sharing a common resource pool. If a task uses exclusively one or multiple resources, then its feasible cycle time range is simply  $[p_i/m_i, \infty)$  where  $m_i$  is the number of resources available for task  $i$ . The analysis below will deal with tasks sharing a pool of multiple resources.

Due to the periodicity and the cyclic rotation between all resources, each task  $i$  is executed on the same resource every  $m$  batches (where  $m$  is the number of common

resources). The indices of repetitions of the same task  $i$  on the same resource can therefore be represented by  $mk_i + s_i$ , where  $k_i, s_i \in Z$  and  $s_i$  ( $0 \leq s_i < m$ ) is an integer representing the index of the batch (with respect to reference batch 0) for the first occurrence of task  $i$  in a specific resource. Note that  $s_i$  is not the same for all resources. The non-overlap constraints between two tasks  $i, j$  on a given resource can be written as:

$$\begin{aligned}
 t(i, mk_i + s_i) + p_i &\leq t(j, mk_j + s_j) \quad \text{or,} \quad t(j, mk_j + s_j) + p_j \leq t(i, mk_i + s_i) \\
 t_i + amk_i + as_i + p_i &\leq t_j + amk_j + as_j \quad \text{or,} \quad t_j + amk_j + as_j + p_j \leq t_i + amk_i + as_i \\
 t_j - t_i &\geq p_i - \alpha(mK_{ij} + S_{ij}) \quad \text{or,} \quad t_j - t_i \leq -p_j - \alpha(mK_{ij} + S_{ij}) \\
 D_{ij} &\geq p_i - \alpha(mK_{ij} + S_{ij}) \quad \text{or,} \quad D_{ij} \leq -p_j - \alpha(mK_{ij} + S_{ij})
 \end{aligned} \tag{3}$$

where  $K_{ij} = k_j - k_i$ , and  $S_{ij} = s_j - s_i$ ,  $K_{ij}, S_{ij} \in Z, -m < S_{ij} < m$ . Note that because of the cyclical rotation over all resources, and despite the fact that  $s_i$  and  $s_j$  are resource-dependent, their difference  $S_{ij}$  is not.

For a feasible schedule to exist, for every pair of tasks  $i, j$  executed on the same resource with given value of  $S_{ij}$ , there must exist an integer value of  $K_{ij}$  so that  $D_{ij}$  belongs to one of the allowed intervals, namely  $[p_i - \alpha(mK_{ij} + S_{ij}), -p_j - \alpha(m(K_{ij} - 1) + S_{ij})]$ . In other words, the non-overlapping constraints can be re-written as:

$$p_i - \alpha(mK_{ij} + S_{ij}) \leq D_{ij} \leq -p_j - \alpha(m(K_{ij} - 1) + S_{ij}) \tag{4}$$

or, if the two inequalities are separated,

$$\begin{aligned}
 D_{ij} &\geq p_i - \alpha(mK_{ij} + S_{ij}) \\
 D_{ij} \leq -p_j - \alpha(m(K_{ij} - 1) + S_{ij}) &\Rightarrow D_{ij} \geq p_j - \alpha(m(1 - K_{ij}) - S_{ij})
 \end{aligned} \tag{5}$$

These two constraints are, in fact, symmetrical provided that in the second inequality we use:  $K_{ji} = 1 - K_{ij}$  and  $S_{ji} = -S_{ij}$ . The feasible values of the cycle time,  $\alpha$ , should therefore satisfy the following constraints:

$$\begin{aligned}
 D_{ij} &\geq p_i - \alpha(mK_{ij} + S_{ij}) \quad \forall i, j \in T \\
 K_{ij} + K_{ji} &= 1 \\
 S_{ji} &= -S_{ij}
 \end{aligned} \tag{6}$$

Depending on the sign of the term  $p_i - D_{ij}$ , Eq. (6) provides upper or lower bounds on  $\alpha$  for different values of  $K_{ij}, S_{ij}$ . After a few algebraic steps (outlined in Koulouris and Georgiadis, 2022), these bounds can be calculated as follows:

$$\begin{aligned}
 a &\geq \frac{p_i + p_j}{m} \\
 \text{if } p_i - D_{ij} > 0 \text{ then,} \\
 a &\geq \max \left\{ \frac{p_j + D_{ij}}{m - S_{ij}}, \frac{p_i - D_{ij}}{S_{ij}} \right\} \text{ for } S_{ij} \neq 0 \\
 \text{if } p_i - D_{ij} = 0 \text{ then,}
 \end{aligned} \tag{7}$$

$$a \geq \frac{p_j + D_{ij}}{m - S_{ij}}$$

if  $p_i - D_{ij} < 0$  then,

$$\frac{p_j + D_{ij}}{m(1 - K_{ij}) - S_{ij}} \leq a \leq \frac{p_i - D_{ij}}{mK_{ij} + S_{ij}} \text{ for } \frac{p_i - D_{ij}}{p_i + p_j} - \frac{S_{ij}}{m} \leq K_{ij} < -\frac{S_{ij}}{m} \text{ and } K_{ij} \neq 0$$

$$a \geq \frac{p_j + D_{ij}}{m - S_{ij}} \text{ for } K_{ij} = 0$$

As seen in Eq. (7), the values of  $K_{ij}$  are either fixed or bounded on both sides and that means that the search of feasible ranges is also bounded. Using different values of  $K_{ij}, S_{ij}$  within their admissible ranges, bounds on cycle time are calculated. The union of all these feasible ranges provides the values of the cycle time that, for a given pair of tasks, guarantee repetitive execution of these tasks with no overlaps. This calculation process must be repeated for all task pairs; the intersection of all pair-wise feasible ranges will result in the feasible cycle time ranges for all tasks sharing common resources. The lower bound of these ranges is the minimum process cycle time.

#### 4. MILP Approach

While computationally efficient, the previously described exact method is based on a heuristic of utilizing the resources in a cyclical manner that could affect the output resulting to very good but potentially suboptimal solutions. Therefore, an MILP-based approach, that can ensure the optimality of the generated solutions and can tackle problems with non-identical resource pools, is also developed. The model is based on the known general precedence framework, which has been extended to address periodic scheduling optimization problems. Given a specific number of batches  $B$  of tasks  $T$  to be processed in the available resources  $R$ , the optimization model generates a complete optimal schedule with minimum cycle time. A set of binary allocation variables ( $Y_{i,b,r}$ ) and binary sequencing variables ( $X_{i,b,i',b'}$ ) are employed. The first are enabled when a batch  $b$  of task  $i$  is processed by resource  $r$ , while the latter when a batch  $b$  of task  $i$  is processed prior to batch  $b'$  of task  $i'$  using the same resource. The proposed model consists of constraints (8)-(15) and the objective function (16), which are described below.

$$\sum_{r \in IR_{i,r}} Y_{i,b,r} = 1 \quad \forall i \in T, b \in IN_b \quad (8)$$

$$L_{i,b} + \sum_{r \in IR_{i,r}} (Y_{i,b,r} \cdot p_i) = C_{i,b} \quad \forall i \in T, b \in B \quad (9)$$

$$L_{i,b} = t_i + (b - 1) \cdot \alpha \quad \forall i \in T, b \in B \quad (10)$$

$$L_{i',b'} \geq C_{i,b} - M \cdot (1 - X_{i,b,i',b'}) - M \cdot (2 - Y_{i,b,r} - Y_{i',b',r}) \quad \forall i, i' \in T, i < i', b, b' \in B, r \in (IR_{i,r} \cap IR_{i',r}) \quad (11)$$

$$L_{i,b} \geq C_{i',b'} - M \cdot X_{i,b,i',b'} - M \cdot (2 - Y_{i,b,r} - Y_{i',b',r}) \quad \forall i, i' \in T, i < i', b, b' \in B, r \in (IR_{i,r} \cap IR_{i',r}) \quad (12)$$

$$L_{i,b'} \geq C_{i,b} - M \cdot (2 - Y_{i,b,r} - Y_{i,b',r}) \quad \forall i \in T, b, b' \in IN_b, b < b', r \in IR_{i,r} \quad (13)$$

$$Y_{i,b,r} = Y_{i,b+NB,r} \quad \forall i \in R, b \leq |B| - NB, r \in IR_{i,r} \quad (14)$$

$$L_{i,b+NB} \geq C_{i,b} \quad \forall i \in T, b \leq |B| - NB \quad (15)$$

$$\text{Min } \alpha \quad (16)$$

Constraint set (8) ensures that each batch  $b$  of a task  $i$  will be processed by exactly one resource  $r$ . Notice that in order to reduce the model's size, we only consider the batches in the set  $IN_b$ . This set denotes the batches for which we optimize the allocation decisions. Let us assume that we want to create an optimal schedule for a set of batches  $B=\{b0, b1, \dots, b10\}$  and decide that  $IN_b=\{b0, b1\}$ , then the allocation of the tasks in the available resources is repeated every two batches. For example, if task  $i1$  is allocated to resource  $r2$  and  $r3$  in batches  $b0$  and  $b1$ , then the allocation for the upcoming batches will be  $b2 \rightarrow r2, b3 \rightarrow r3$  etc. The size of set  $IN_b$  is a user-defined parameter depending on the needs and wants of the production engineer using the model. A larger size means potentially lower cycle times but requires more CPU time. Next, constraint set (9) guarantees the proper connection between the starting and completion times of every batch of each task. In particular, the completion time  $C_{i,b}$  must equal the starting time  $L_{i,b}$  plus the required processing time  $p_i$ . Constraints (10) are essential since they define the problem as a cyclic scheduling problem. More specifically, we define that the starting time of a batch  $b$  of task  $i$  must be equal to the start time of the first batch  $t_i$ , plus the cycle time times the batch number minus 1. For example, let us assume a task with starting time 5 hours, if the optimal cycle time is calculated to be 2 hours, then the starting time of the first batch will be 5 hours, of the second 7 hours, the third 9 hours and so on. Constraints (11) and (12) are the precedence constraints that are necessary in order to respect the disjunctive constraints (any resource can only process one task at a time). Constraints (11) and (12) are complementary. If a batch  $b$  of a task  $i$  is processed prior to a batch  $b'$  of task  $i'$  ( $X_{i,b,i',b'}=1$ ) and both of them are processed on the same resource ( $Y_{i,b,r}=Y_{i',b',r}=1$ ), then the batch  $b'$  of task  $i'$  must start after the completion of batch  $b$  of task  $i$ .  $M$  is a large number (big-M parameter), which is necessary in order to relax the constraints, in case the previously mentioned conditions are not valid. Constraint set (13) states that a batch  $b'$  of task  $i$  must start after the completion of a batch  $b < b'$  of the same task in case both are processed by the same resource. Again, to reduce the model's size we only consider this constraint for the subset  $IN_b$ . The next two constraints ensure that the generated schedule will be a cyclic one.  $NB$  is the number of batches in the subset  $IN_b$ . Constraints (14) guarantee that a batch  $b+NB$  of a task  $i$  will be processed in the same resource with batch  $b$ , since the schedule must be cyclic. Similarly, for the same couple of batches, batch  $b+NB$  must start after the completion of batch  $b$ . Goal is the minimization of the cycle time  $\alpha$ .

## 5. Examples

To demonstrate the use of the above approaches, two examples are presented here. The first example refers to a process producing a small molecule API. It consists of 11 tasks: 4 tasks sharing 3 reactors, 5 tasks sharing 2 tanks and two tasks using exclusive equipment (1 filter and 3 dryers, respectively). Details about the start time and duration of these tasks can be extracted from Intelligen, Inc. (2022) where this process is presented as a SchedulePro case study. As an extension to this example, it was assumed that 2 transfer panels are used as auxiliary equipment for all material transfers (11 in total). Their duration and start times in hours are  $\{4, 1, 1, 1, 1.5, 1, 1, 1, 1, 8, 2\}$  and  $\{0, 11, 15, 16, 17, 19.5, 20.5, 24, 25, 43, 51\}$ , respectively. Both the algorithmic and the MILP approaches yield instantaneously the same minimum cycle time of 17.67 hours. The bottleneck resources are the transfer panels. A Gantt chart showing the bottleneck equipment in a sequence of 15 batches scheduled at the minimum cycle time is shown in Figure 1. The algorithmic approach yields also all feasible cycle time ranges which are:  $\{[17.67, 18.5], [19.5, 20], [27, 27.75], 29.25, [31.5, 32.5], [33.5, \infty)\}$ .

Figure 1. Gantt chart of 15 batches for the small molecule API case study.

Knowledge of the feasible ranges is useful if the plant wants to operate at specific cycle time which is not necessarily the minimum.

The second case is an example process where the algorithmic approach yields a suboptimal solution as a result of the resource rotation assumption. The process has 3 tasks with durations and start times  $\{6, 2, 11\}$  and  $\{0, 2, 5\}$  hours, respectively. It is assumed that 3 equipment resources (Eq1-3) are available. In this case, the algorithmic approach yields a minimum cycle time of 8 hours while the optimal value calculated by the MILP approach ( $IN_b=3$ ) is 7 hours. As shown in Figure 2, unlike the algorithmic approach, the optimal policy assigns an exclusive resource (Eq1) to the first task.

Figure 2. Gantt chart of 15 batches for the example process.

## 6. Conclusions

Two approaches are presented in this paper for the calculation of the minimum cycle time in periodic batch process scheduling with resource sharing. The algorithmic approach is an exact, exhaustive method that yields the minimum cycle time and all feasible cycle time ranges for an infinite scheduling horizon under the assumption that all common resources are used in rotation. The MILP approach is more general since it makes no a priori assumption on resource assignments and generates optimal solutions for predefined scheduling horizons in short computational times.

## Abstract

Assessing a heat exchanger network (HEN) based on total annual costs (TAC) alone is no longer appropriate. Climate-damaging emissions must also be considered. Thus, we use CO<sub>2</sub> emissions and TAC as objectives in the fully linearized heat exchanger network synthesis (HENS). Due to uncertainties concerning emissions and equipment costs, a refurbishment of the HEN may become necessary even before its life cycle has been reached. Since a significant share of the system costs is related to the piping, it is economical to change only the heat exchanger (HEX) areas. To assess the potential for the refurbishment of a given HEN in the future, we constrain the Pareto optimal HEN configurations and recompute sub-Pareto fronts. Our results show that there are obviously superior configurations regarding distance and coverage of the sub-Pareto front concerning the initial Pareto front. The hypervolume indicator (HVI) and the coverage were used as quantitative indicators to evaluate different configurations. However, these characteristic parameters do not correlate with empirically determined high-quality configurations. This contribution has laid an essential foundation towards developing versatile and optimal HEN.

**Keywords:** MILP, multi-objective optimization, non-dominated solutions, locked HEN configuration

## 1. Introduction

To save energy and costs, industrial energy systems can connect hot and cold process streams using a HEN. The optimal interconnection of the HEN can be calculated using HENS. If we look at various literature on HENS, the aim is almost entirely to achieve a cost minimum. The single-objective approach cannot consider environmental impacts. To produce a holistic set of choices for decision-makers, multi-objective optimization (MOO) with CO<sub>2</sub> emissions and costs is the way to go.

Many optimal HEN can provide a comprehensive basis for decision-making. However, determining which HEN to choose is a significant challenge for decision-makers. The selected HEN should meet the current conditions and be reasonable in case of unforeseen developments. For example, political or economic changes such as increased CO<sub>2</sub> certificate costs or energy costs can adversely influence the selected HEN's performance. Since such changes can never be fully considered, it is more effective to present decision-makers with fewer but more robust solutions.

According to Peters et al. (2003), the piping costs in fluid processing plants can be up to 80 % of equipment costs. This corresponds to about 25 % of the total investment costs. The costs associated with adjusting the operating point of the HEN can be reduced

significantly when keeping the piping configuration as it is. With an unchanged HEN, the operating point, respectively the load on the utilities can be influenced by varying the HEX areas.

In this paper, we use HENS to propose a method to assess the versatility of Pareto-optimal configurations and to identify the ones that can be refurbished economically in the future if necessary. To determine the versatility of a configuration, we compute sub-Pareto fronts from the Pareto optimal configurations. Investigation of the Pareto front has shown that only a few unique configurations of HEN exist as non-dominated solutions. Sub-Pareto fronts can be generated using those unique configurations, which differ only in the utility load and HEX areas. The results show that the sub-Pareto fronts cover large areas of the initial Pareto front while containing a variety of only weakly dominated solutions.

## 2. Methods

The HENS formulation used in this paper is based on the stage-wise superstructure formulation according to Yee and Grossmann (1990). With this formulation, heat exchange can occur in counterflow between streams in  $k$  stages with stream splits. The hot and cold utilities are located at the ends of the streams, respectively.

### 2.1. Objectives

The first of the two objectives describes the TAC and was adopted from Yee and Grossmann (1990). The second objective represents the CO<sub>2</sub> emissions due to the operation and manufacturing of the HEN, according to Pintarič et al. (2019). This method evaluates CO<sub>2</sub> emissions based on hot utility consumption and economic activity level according to the economic input-output life cycle assessment (EIO-LCA). In contrast to Pintarič et al. (2019), we also consider emissions from the circulation pumps power consumption.

### 2.2. Linearization

To apply highly efficient mixed integer linear programming (MILP) solvers, all non-linear terms (reduced stream HEX area, reduced utility HEX area and logarithmic mean temperature difference (LMTD)) are linearized. The non-linear reduced stream HEX area is tightened to the feasible solution space according to Beck and Hofmann (2018) and approximated with super positioned planes. The convex approximation allows the efficient transfer to MILP without using binary variables. Analogously, the reduced utility HEX area is tightened. In contrast to Beck and Hofmann (2018), the non-linear relation is approximated with several straight lines. The function of LMTD is approximated using plane triangles on a regular grid. The transformation to MILP is done using a highly efficient logarithmic coding of the binary variables introduced by Vielma and Nemhauser (2011). With this method,  $T$  Simplices require only  $\lceil \log_2(T) \rceil$ , instead of  $T$  binary variables.

### 2.3. Optimization Approach

The developed method can be divided into the following main steps:

1. Calculate Pareto optimal solutions
2. Constrain incidence matrix in Pareto optimal HEN configuration
3. Calculate Pareto optimal solutions of subproblems

The Pareto front is calculated using the adaptive weighted sum method from Kim and de Weck (2005). Compared to the weighted sum method, the Pareto front can also be solved in non-convex regions and with well-distributed solutions. In the remainder of this paper, we will refer to this Pareto front as an initial Pareto front.

In the second step, the unique configurations of the initial Pareto front are identified. From the resulting set of unique configurations, new subproblems are created. The incidence matrix representing the HEN configuration is blocked with constraints. Therefore, the degree of freedom and thus, the complexity can be reduced significantly, leading to short computation time.

In the final step, a new Pareto front is calculated for each subproblem with the adaptive weighted sum method. Note that the Pareto optimal solutions of the subproblems are not optimal regarding the initial problem. The sub-Pareto fronts always contain at least one non-dominated Pareto optimal solution concerning the initial problem.

### 3. Use Case

The method presented in the previous section was applied to a representative use case with four hot and five cold process streams, according to Linnhoff and Flower (1978). The stream data, HEX, and utility costs are summarized in Table 1. The CO<sub>2</sub> emissions factor for hot utilities  $\omega_{HU}$  and investment costs  $\omega_{INV}$  were taken from Pintarič et al. (2019). The emission factor for the cold utilities is calculated assuming that 10 % of the cooling load must be supplied as electrical energy. With 8000 h full load hours and an average electricity mix,  $\omega_{CU}$  results in 0.0016 t/kWy. The minimum allowed approach temperature was set to  $\Delta T_{\min} = 20^\circ\text{C}$  and heat transfer is possible in two stages.

Table 1: Case-study: stream and cost data according to Linnhoff and Flower (1978).

Stream	$T_{\text{in}} / ^\circ\text{C}$	$T_{\text{out}} / ^\circ\text{C}$	$F / \text{kW/K}$	$H / \text{kW/m}^2\text{K}$
H1	327	40	100	0.50
H2	220	160	160	0.40
H3	220	60	60	0.14
H4	160	45	400	0.30
C1	100	300	100	0.35
C2	35	164	70	0.70
C3	85	138	350	0.50
C4	60	170	60	0.14
C5	140	300	200	0.60
HU	330	250	-	0.50
CU	15	30	-	0.50

HEX data:  $c_f = 2000 \text{ \$/y}$ ,  $c_v = 70 \text{ \$/m}^2\beta\text{y}$ ,  $\beta = 1$ ,  $\omega_{INV} = 399 \cdot 10^{-6} \text{ t/\$y}$

Utility data:  $c_{HU} = 60 \text{ \$/kW}_y$ ,  $c_{CU} = 6 \text{ \$/kW}_y$

CO<sub>2</sub> emissions:  $\omega_{HU} = 1.436 \text{ t/kW}_y$ ,  $\omega_{CU} = 0.0016 \text{ t/kW}_y$

#### 3.1. Optimization Framework

The optimization problem has been modeled using *Yalmip* R20210331 Lofberg (2004) in *MATLAB* R2022a. The optimization problem was solved with the state-of-the-art solver *Gurobi* 9.5.2 on a 128-core system (AMD EPYC 7702P) with 128 GB RAM.

#### 3.2. Linearization Settings

The reduced stream HEX areas were approximated with as many planes as necessary to obtain a root mean square error (RMSE) of less than 1.0 %. In most cases, this was achieved with four planes. The LMTD was approximated with 32 plane triangles resulting in an RMSE of 1.0 %. The reduced HEX areas of the utilities were approximated with two straight lines resulting in an RMSE below 2.0 %.

### 3.3. Pareto Front Settings

The problem was normalized between the nadir and utopia point to calculate the Pareto front. The solutions were estimated to have a minimum relative distance of 2.5 %. Below that, solutions are considered overlapping and excluded. Within the adapted weighted sum method, iteration was performed until a maximum relative point distance of 5.0 % was met. If larger distances occur in the Pareto front, no solution exists.

The normalization of the problem with locked HEN configurations is done based on the respective nadir and utopia points. Each subproblem was thus normalized with respect to its nadir and utopia point, different from the initial solution.

## 4. Results

Figure 1 shows the calculated Pareto fronts of the use case with 27 different solutions. Out of  $2^{49}$  possible HEN configurations, only 13 are identified as a solution to the problem. Identical configurations are shown in the same color.

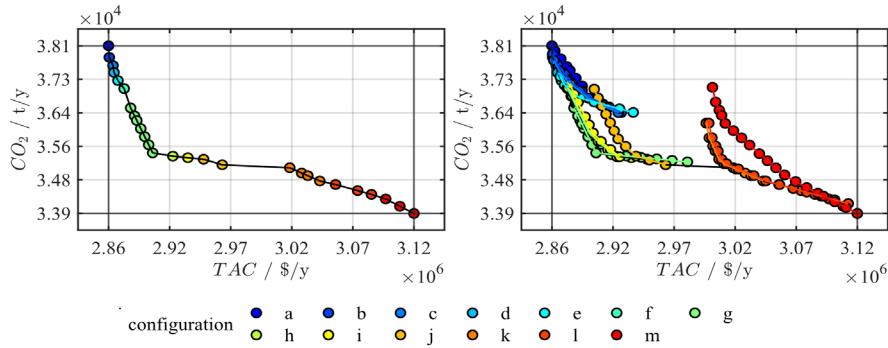

Figure 1: Left: initial Pareto front with 27 non-dominant solutions and 13 different HEN configurations. Right: initial Pareto front with 27 non-dominant, sub-Pareto fronts with 125 dominated solutions and 13 different HEN configurations.

The resulting 13 sub-Pareto fronts with locked HEN configuration are shown in Figure 1 (right). Obviously, some solutions are closer to the initial Pareto front and cover a broader range than others. The hypervolume indicator (HVI) according to Guerreiro et al. (2021) was calculated for each Pareto front to evaluate the quality of the different configurations. The reference point is always the nadir point of the initial Pareto front. The ratio of the HVI between a sub-Pareto front and the initial Pareto front can be interpreted as a dimensionless area ratio. The closer the HVI ratio is to 100 %, the closer the sub-Pareto front is to the initial Pareto front. The results are summarized in Table 2. Since the single-criterion evaluation of the different configurations considers versatility only to a limited extent, the coverage is also evaluated and listed in Table 2. The coverage quantifies the overlap of the sub-Pareto front concerning the initial Pareto front.

Since there is no direct correlation between coverage and HVI ratio, it is up to the decision-maker to find a trade-off between these two indicators.

Table 2: Characteristic values of subproblems with locked HEN configuration.

config.	# of solutions	HVI ratio		coverage	
		/ %		annual CO <sub>2</sub> emissions	TAC
/ -	/ -			/ %	/ %
a	7	32.42		9.90	23.95
b	9	52.23		22.49	34.91
c	8	52.64		21.12	31.14

d	2	33.46	3.67	8.16
e	7	52.51	23.90	21.39
f	8	85.60	16.92	40.99
g	12	88.57	37.13	32.21
h	9	85.56	15.94	41.01
i	9	84.74	16.20	43.33
j	11	54.16	23.39	45.11
k	9	55.93	18.67	34.49
l	15	55.93	45.67	48.00
m	19	48.46	47.44	75.22

Configurations f-i (light green to orange in Figure 1) have a high HVI ratio of over 80 % but cover only small areas of the Pareto front. The peripheral areas are not covered at all. Configuration g offers the best trade-off between HVI ratio and coverage. However, configurations l and m (red and dark red in Figure 1) cover at least the peripheral area with low CO<sub>2</sub> emissions well. Due to the higher HVI ratio, configuration l is preferable. The second configuration (blue in Figure 1) covers a substantial area in the low TAC region. Based on this empirical analysis, the obviously relevant solutions can be reduced to the three configurations b, g and l. The stream plots of the three configurations can be found in the Appendix. As can be seen in Figure 2, these solutions cover almost the entire Pareto front. Remarkably, all solutions have large areas with only weakly dominated solutions.

Figure 2: Pareto front with three non-dominant solutions and 33 weakly-dominated solutions of configuration b (blue), g (light green) and l (red).

## 5. Conclusion

In this paper, we used MOO to incorporate TAC and CO<sub>2</sub> emissions into the design optimization process of a HEN. Our results show that some sub-Pareto fronts cover the initial Pareto front to a large extent. Although each sub-Pareto front contains at least one Pareto optimal solution, some HEN configurations are obviously superior to others. We argue that a desirable configuration is one whose solutions are as close as possible to the initial Pareto front and at the same time provide high coverage and therefore versatility. In this paper, we attempted to quantify the trade-off between versatility and optimality of a given configuration. HVI and coverage were considered, but results were not satisfactory. The analysis of Pareto-optimal configurations, which we proposed in this paper, can be a useful tool to identify the most versatile HEN. More research on quantitative measures for the optimality of these configurations is still required.

## Abstract

New aspects of an interval-arithmetic (IA) based automatic initialization scheme for root-finding algorithms to efficiently solve nonlinear algebraic equation systems (NLEs) are presented. Using the model of a partial condenser, it is demonstrated how additional constraints may eliminate non-physical solutions by the help of interval arithmetic for initialization. Finally, the number of stages of a multicomponent distillation column is varied to investigate the required time of the approach to obtain initial values and solutions by root-finding as a function of the system size. The overall method finds a physically feasible solution for the distillation column with 20 stages without any initial values required.

**Keywords:** NLE, initialization, interval arithmetic, numerical iteration

## 1. Motivation

Chemical processes can become quite complex so that corresponding mathematical models are frequently hard to solve. Newton-based methods guarantee convergence in Lipschitz continuous areas, but fail, in case functions or derivatives are not defined at individual iteration points. In our study, we present further developments of an already introduced hybrid approach (Bublitz et al., 2021) that can automatically initialize nonlinear algebraic systems for root-finding algorithms using IA-based iteration methods. Its aim is to ease the challenging task of finding a converging initial point. The approach is designed to solve square problems of the form

$$f(\mathbf{x}) = \mathbf{0} \quad . \quad (1)$$

## 2. Notation

Throughout this work, multidimensional quantities are printed in bold. An interval  $\bar{x}$  is a convex set of real numerical values delimited by the lower bound  $\underline{x}$  and the upper bound  $\bar{x}$ . Intervals of multiple variables span a convex variable space, which we term a box  $\bar{x}$ . The midpoint  $m(\bar{x})$ , width  $w(\bar{x})$  and magnitude  $|\bar{x}|$  of an interval are defined as

$$m(\bar{x}) := \frac{\underline{x} + \bar{x}}{2}; \quad w(\bar{x}) := \bar{x} - \underline{x}; \quad |\bar{x}| = \max\{|\underline{x}|; |\bar{x}|\} \quad (2)$$

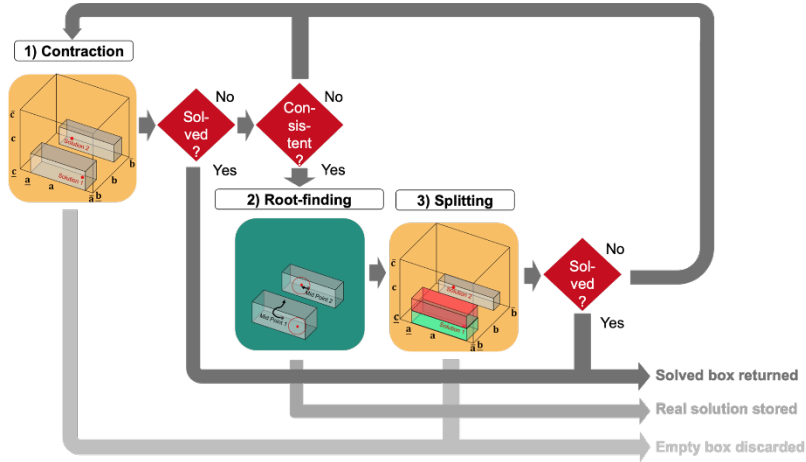

Figure 1. Three steps of the hybrid approach: 1) Contractions; 2) Root-finding; 3) Splitting

### 3. Hybrid Approach

The hybrid approach applied, consists of three steps, which are shown in Figure 1. As input, the user must provide initial intervals for all iteration variables. They span the initial box, which is reduced in the first step via IA-based contraction methods to one or more boxes (see section 3.1). A box  $\bar{x}$  is termed solved when all its intervals  $\bar{x}$  satisfy the condition

$$\Delta_{Abs} + \Delta_{Rel} \cdot |\bar{x}| \geq w(\bar{x}) . \quad (3)$$

The absolute and relative tolerances,  $\Delta_{Abs}$  and  $\Delta_{Rel}$ , must be specified. Unsolved boxes are reduced until they are consistent, i.e., their intervals no longer change from reduction step  $k - 1$  to  $k$  and both conditions,

$$\Delta_{Abs} + \Delta_{Rel} \cdot \max\{|\underline{x}^{(k-1)}|; |\underline{x}^{(k)}|\} \geq w(|\underline{x}^{(k)} - \underline{x}^{(k-1)}|), \quad (4)$$

$$\Delta_{Abs} + \Delta_{Rel} \cdot \max\{|\bar{x}^{(k-1)}|; |\bar{x}^{(k)}|\} \geq w(|\bar{x}^{(k)} - \bar{x}^{(k-1)}|) \quad (5)$$

hold for all of them. In the second step, a consistent, unresolved box is passed on to a Newton-based solver that starts from the center of the box to potentially find a root in its interior. A solution  $x^*$  to Eq. (1) in a set tolerance  $\Delta_{FTOL}$  is found when

$$\|f(x^*)\|_2 \leq \Delta_{FTOL} \quad (6)$$

holds, and is immediately returned to the user. If only one numerical solution is of interest, the procedure can be configured so that it terminates after a successful numerical iteration. Otherwise, the consistent box is split in step 3 (see section 3.3), and then further processed in contraction.

#### 3.1. Contraction

Contraction methods can reduce an initial variable space  $\bar{x}$  based on the given constraints from Eq. (1). This can be generalized by the introduction of the contracting operator  $\Gamma(f(x), \bar{x})$  (Granvilliers, 2020):

$$\Gamma(\mathbf{f}(\mathbf{x}), \bar{\mathbf{x}}) \subseteq \bar{\mathbf{x}} \quad . \quad (7)$$

While removing inconsistent variable domains, contraction methods never lose any solution within the initial box. A general contraction step is defined as

$$\{\bar{\mathbf{x}}^{(c+1)}\} := \bar{\mathbf{x}}^{(c)} \cap \Gamma(\mathbf{f}(\mathbf{x}), \bar{\mathbf{x}}^{(c)}) \quad . \quad (8)$$

Eq. (8) either breaks a box into one or more sub-boxes, verifies that the box cannot contain any solution, or proves that the box has a unique solution (Moore et al., 2009). For contraction, we use a combination of our own method Bnormal, presented in Bublitz et al. (2021), as well as the method HC4revise from Benhamou & Puget (1998). Both contracting operators have different requirements and capabilities. Details of which can be found in the respective publications. The latter method is particularly fast in reducing wide intervals. Our method on the other hand can find tighter enclosures for variable domains in equations with many instances of the same variable. For example, the equation

$$0 = x^3 - x^2 + x + y \quad (9)$$

can be used to reduce the initial interval  $[-10; 10]$  of  $x$  to  $[-1.37; 1.57]$  by HC4revise in 17 ms<sup>1</sup> through the given variable interval  $[0; 10]$  of  $y$ . Bnormal needs 29 ms but the reduced interval of  $x$  is  $[-0.55; 0]$ . Besides, Bnormal can filter infeasible regions within variable intervals to pave the way for the upcoming root-finding step. However, to use the advantages of both methods, a combination of them is also tested, in which HC4revise is applied first due to its speed. It continues until a box becomes consistent and forwards the box subsequently to Bnormal. When Bnormal could further contract the box, it returns it to HC4revise, and the alternation continues until the box does not change anymore according to Eq. (4) and (5). This alternation is denoted as a box reduction step. One box reduction step usually encompasses many contraction steps to reach consistency.

### 3.2. Root-finding

The root-finding problem is reformulated to a minimization problem of the sum of the quadratic function residuals of Eq. (1)

$$\min_x \frac{0.5}{\Delta_{FTOL}} \cdot \sum f(\mathbf{x})^2 \quad (10)$$

and can be solved by any nonlinear optimization solver, e.g., ipopt (Wächter & Biegler, 2006). The reduced variable bounds from the contraction are directly considered here. To avoid an early termination of ipopt at a point with a low curvature of the objective, Eq. (10) is scaled by the hyperparameter  $\Delta_{FTOL}$ . In addition, a Newton method is started on the root-finding problem at the local minimum in case it does not fulfill Eq. (6), to find the root of Eq (1) with the required tolerance.

### 3.3. Splitting

The applied splitting scheme bisects the variable interval, which has changed the least since the last split. If no split has occurred yet, it refers to the initial box. If there are several variable intervals that were reduced equally little, the interval is taken that causes

Table 1. Initial bounding of 36 iteration variables of the partial condenser.

Iteration Variables	Symbol	Initial Interval	Unit
Mole fractions	$x_i; y_i$	[0; 1]	-
Outlet flow rates	$F^L; F^V$	[0; 75]	kmol/h
Compressibility factors	$Z^L; Z^V$	[0; $10^2$ ]	-
Cohesion pressure	$a^L; a^V$	[0; $10^4$ ]	Pa
First derivative (EoS)	$\delta_{d1}^L; \delta_{d1}^V$	[0; $10^9$ ]	-
Second derivative (EoS, Liquid)	$\delta_{d2}^L$	$[-10^9; 0]$	-
Second derivative (EoS, Vapor)	$\delta_{d2}^V$	[0; $10^9$ ]	-
Other iteration variables		$[-10^9; 10^9]$	various

the greatest box reduction in a subsequent contraction. Ideally, one of the bisected boxes can be identified as empty and is directly discarded.

#### 4. Computer Experiments

We apply the hybrid approach on two NLEs: a partial condenser and a distillation column. The hybrid procedure stops as soon as ipopt finds a solution. The tolerances of the box reduction  $\Delta_{Abs}$  and  $\Delta_{Rel}$  are set to  $10^{-12}$  and  $10^{-10}$ . These values ensure that no solution near an infeasibility is filtered accidentally. This could otherwise be the case due to low mole fractions in the order of  $10^{-6}$ . For root-finding,  $\Delta_{FTOL}$  is set to  $10^{-8}$  to ensure that all state variables are sufficiently converged. A maximum of 10 box reduction steps and 50,000 iteration steps during root-finding are applied. Each test run is repeated three times and the averaged CPU time is presented in the results<sup>i</sup>. The success of the box reduction at reduction step  $k$  is measured by parameter  $\varepsilon$ :

$$\varepsilon^{(k)} := \sum_{b=1}^{n_{box}} \left( \sum_{v=1}^{n_{var}} \frac{w(\bar{x}_v^{(k)})}{w(\bar{x}_v^{(0)})} \cdot \frac{1}{n_{var}} \right) \cdot \frac{1}{n_{box}} . \quad (11)$$

After reduction step  $k$ , the contraction methods might have split the initial variable space into  $n_{box}$  reduced boxes. A value of  $\varepsilon = 1$  corresponds to no reduction of the initial box, while a value of  $\varepsilon = 0$  equals tight enclosures of all real valued solution(s), which fulfill the required tolerances, i.e., all solutions have been found.

##### 4.1. Partial Condenser

In this unit, a gas mixture of Toluene, Biphenyl, Benzene, Methane and Hydrogen is partially condensed to separate the low-boiling components Methane and Hydrogen at a given pressure and temperature of 35 bar and 298.15 K. The inlet flow rate is 75 kmol/h. Thermodynamic equilibrium between the ideally mixed liquid and vapor phases prevails in the unit. The chemical equilibrium according to the  $\phi$ - $\phi$  approach as well as the enthalpies rates are calculated using the cubic equation of state of Soave-Redlich-Kwong (SRK) (Soave, 1972). The full model consists of 36 equations and can be found in MOSAICmodeling<sup>ii</sup>. Table 1 summarizes its coarse initialization.

For each phase, a dimensionless equation of state is implemented (Rao, 1997) to determine the compressibility factor  $Z$

$$0 = Z^3 - Z^2 + (A - B - B^2) \cdot Z - A \cdot B . \quad (12)$$

Figure 2. Number of real valued roots of a cubic equation  $y = f(Z)$  depending on its distance to the origin.

Figure 3. CPU time and convergence results after one box reduction step for different number of trays of the distillation column<sup>1</sup>.

According to Figure 2, such a cubic equation has one up to three real roots for  $Z$ . Physically interesting, however, are only the smallest root for the liquid phase and the largest one for the vapor phase. A potential third solution in between can be filtered by requiring the first order derivative of Eq. (12) with respect to  $Z$  to be greater than or equal to zero

$$\delta_{d1} = 3 \cdot Z^2 - 2 \cdot Z + (A - B - B^2), \quad \delta_{d1} \geq 0 \quad (13)$$

The compressibility factors of the liquid and the vapor phases differ in their second order derivatives. To obtain the compressibility factor of the liquid phase  $Z^L$  the condition

$$\delta_{d2}^L = 6 \cdot Z^L - 2, \quad \delta_{d2} \leq 0 \quad (14)$$

must be fulfilled, while for  $Z^V$  the condition

$$\delta_{d2}^V = 6 \cdot Z^V - 2, \quad \delta_{d2} \geq 0 \quad (15)$$

holds. To avoid interval dependency during contraction, Eq. (12) und Eq. (13) are reformulated to become

$$0 = Z^3 - Z^2 + (A - (B - 0.5)^2 + 0.25) \cdot Z - A \cdot B, \quad (16)$$

$$\delta_{d1} = \left( \sqrt{3} \cdot Z - \frac{1}{\sqrt{3}} \right)^2 - \frac{1}{3} + (A - (B - 0.5)^2 + 0.25) \quad (17)$$

This ensures that, e.g.,  $\overline{\delta_{d1}}$  can be further tightened. Let us assume  $\overline{A} = [0; 5]$ ,  $\overline{B} = [-1; 1]$ , and  $\overline{Z} = [0; 1]$ : Evaluating the righthand side of Eq. (13) by IA can only reduce  $\overline{\delta_{d1}}$  to  $[-4; 9]$ , while its reformulation according to Eq. (17) achieves  $[-2. \overline{3}; 6.25]$ . Eq. (14) to (17) have been implemented to limit the variable space to the desired solution without having to make any case differentiation.

Table 2 shows the results of the tested contraction schemes. While Bnormal finds a physical solution after one box reduction step, HC4revise has not solved the system numerically even after 10 reduction steps. The combination of both finds a solution. It is slower than Bnormal but has a better box reduction performance in terms of  $\epsilon$ .

Table 2. Results after one box reduction step applied on the partial condenser<sup>i</sup>.

Method	Solved	CPU (s)	$\epsilon$ (-)
Bnormal	yes	4.63	0.60
HC4revise	no	2.13	0.59
HC4revise + Bnormal	yes	4.82	0.57

#### 4.2. Distillation Column

A mixed liquid stream of the same components as in the previous example is thermally separated in a distillation column. The unit removes the byproduct Biphenyl from the hydrodealkylation process. Its model was originally implemented by Rajes (2020) and includes equilibrium trays, a total condenser and a total reboiler. The number of trays is varied from 5, 10, 15 to 20 which corresponds to 241, 416, 591, and 766 state variables. The processing time in dependence of the problem size is of interest in this investigation. The vapor liquid equilibrium and the enthalpies are also calculated via SRK. The initialized NLEs can be found in MOSAICmodeling<sup>iii</sup>. According to Figure 3 the combination of Bnormal and HC4revise outperforms the single methods in most cases regarding its run time. Unlike the other two methods, it always finds a solution for all NLEs after one box reduction step.

### 5. Conclusion

Without a laborious search for suitable initial values, just one box reduction step of our IA-based initialization approach suffices to reduce the initial variable space to such an extent that the applied root-finder determines feasible solutions for both test examples. Nevertheless, it should be noted that overly wide variable intervals, e.g., of  $[-10^9; 10^9]$ , may slow down the method due to extreme box splitting. Hence, process knowledge remains indispensable to narrow the operating range. The more precise this estimation is, the faster also the hybrid approach becomes.

## Abstract

The production scheduling of batch operated electroplating plants gives rise to hoist scheduling problems. A literature review and real-world case studies reveal that a broad spectrum of electroplating scheduling problems can be modeled as mixed integer programs. Since problems of real-world size cannot be solved by state-of-the-art standard solvers in reasonable times, problem-specific simplification heuristics can be manually applied. An automation vendor strives for an automated solution for a wide spectrum of hoist scheduling problems to reduce the engineering effort. Therefore, the selection and parameterization of models and heuristics need to be automated. This paper argues for an approach which combines mixed integer programming with hyper-heuristics to close this research gap.

**Keywords:** Hoist Scheduling, Electroplating Plants, Mixed Integer Programming, Hyper-Heuristics

## 1. Electroplating scheduling

In batch-operated electroplating plants, piece or bulk material is coated with thin layers of metal using electrolysis. Such a plant, schematically shown in Figure 1, consists of several tanks arranged in one or more coupled rows, which are filled with liquids for coating as well as for pre- and post-treatment of the products.

Figure 1 Schematic representation of a batch operated electroplating plant (left) and different recipes with their production sequence (right)

Items to be coated are mounted on racks or filled into barrels (in general carriers) and dipped into specific tanks in a sequence given by recipes. The processing times may vary for some stages within a given range (see Figure 1). The carriers are automatically picked up, transported and lowered by hoists, moving above the tanks on a rail. Multiple hoists operate on one rail, so they cannot pass each other and must not collide. The plant operation constitutes Hoist Scheduling Problems (HSPs), which can be thought of as Flexible Job Shop Problems (FJSP) with additional consideration of hoists. The dominating degrees of freedom are the movements of the hoists, which also determine the occupancy of the tanks. The carriers usually move back and forth and must be returned to the start of the line, as shown in Figure 1. The most common scheduling objectives are the minimization of the makespan or cycle time. In the HSPs of the electroplating processes at hand, no-wait conditions as well as time intervals for process durations must be satisfied, so that the hoists arrive at the tanks in time. The reachability combined with the collision avoidance of the hoists increase the complexity of the HSPs compared to FJSPs and simplification strategies become necessary to solve real-world problems. Multiple aspects like the combination of products, their geometrical shape, base and coating material, layer-thickness or the required space for the plant determines the plant structure and the recipes of the products. Virtually each electroplating plant is designed individually for a specific application according to these requirements. Consequently, a broad spectrum of scheduling problems exists, which differ from application to application and require different simplification strategies.

## 2. State of research and technology

### 2.1. MIP-based methods

For the HSP, different Mixed Integer Programming (MIP) models for different plant and process structures exist. The HSP belongs to the class of NP-hard problems (Lei et al., 1989) and, depending on the size of the problem instance, cannot be solved in reasonable time with a standard solver like CPLEX ([ibm.com/de-de/analytics/cplex-optimizer](http://ibm.com/de-de/analytics/cplex-optimizer)). Therefore, often simplification strategies are applied to compute a feasible schedule for one or a few days. A first distinction of simplification strategies is made between cyclic and acyclic scheduling. Cyclic scheduling is suitable for plants processing few product types in large quantities. Each cyclic schedule covers one or a few products and is executed several times in succession (Feng et al., 2018). There also exist MIP-models to switch from one cyclic schedule to another in an optimal way (Steneberg, 2013). Acyclic scheduling is suitable for plants processing many product types in small quantities. To compute an acyclic schedule in reasonable times, a rolling horizon approach can be applied, where the entire scheduling horizon is decomposed into smaller time segments (Ramin et al., 2022). If cyclic or acyclic scheduling with rolling horizons does not reduce the solution time sufficiently additional simplification heuristics become necessary.

The simplification heuristics can be classified as follows: (1) decomposition, (2) fixing variables, (3) adding constraints, (4) aggregation, (5) relaxation of constraints and (6) algorithm tuning. Cyclic scheduling (decomposition by products) and rolling horizon (decomposition by time) can be assigned to class (1). Furthermore, there are different zone partitioning approaches, in which the electroplating line is decomposed into zones which are assigned to the hoists (Li et al., 2015). A further decomposition can be done by the choice of the cycle degree (decomposition by batches). A higher degree leads to an equal or shorter cycle time but to a longer scheduling horizon and thus to a longer solution time (Feng et al., 2018). Simplification heuristics from class (2) are the assignment of certain transport operations to hoists (Fröhlich et al., 2009) or the fixed assignment of

stages to identical tanks (Reimschüssel et al., 2022). Simplification strategies from class (3) include fixed processing times (Che et al., 2010), restriction of the transport direction (Chtourou et al., 2013), and prevention of a cycle transition during a transport operation (Leung et al., 2004). The aggregation of picking up, transporting, and lowering a carrier is a simplification from class (4) (Mao et al., 2018). Different approaches exist for relaxing constraints (5) and dealing with infeasible schedules caused by this simplification. For instance, Yan et al. (2018) check whether the solution violates relaxed constraints and reinserts them into the model. Algorithm tuning (6) can be done by tighter model formulations (Leung et al., 2004) or passing a warmstart solution (Ramin et al., 2022) or lower/upper bounds on variables to the solver (Che et al., 2007).

### *2.2. Metaheuristics, constructive heuristics and hyper-heuristics*

In addition to MIP, some metaheuristics are applied to solve the HSP, such as evolutionary algorithms (Amraoui et al., 2013), variable neighborhood search (Laajili et al., 2021) or tabu search (Wang et al., 2019). There are also various constructive heuristics like variations of the earliest starting time heuristic (Amraoui et al., 2016) or the adaptive time window heuristic (Paul et al., 2007). Hyper-heuristics are used to automate the selection and parameterization of metaheuristics or constructive heuristics. For a given problem instance, a hyper-heuristic (often a metaheuristic itself or a neural network) selects a suitable metaheuristic/constructive heuristic from a pool of low-level heuristics and determines an appropriate parameterization (Burke et al., 2019).

### *2.3. Commercial solutions*

Generic production planning systems are usually not applicable for the electroplating scheduling since they neglect the hoists. Scheduling without hoists and adding them to an existing schedule later is usually infeasible due to collisions of hoists or hoists not reaching transport operations in time. Specific software solutions for scheduling batch-operated electroplating plants exist, such as GALVATEK ([galvatek.eu](http://galvatek.eu)), DiTEC ([ditec-gmbh.com](http://ditec-gmbh.com)) or ICOM Automation ([icom-automation.de](http://icom-automation.de)), but their market penetration is limited due to complex manual adjustments required for the specific problem instances.

## **3. Automation vendor's perspective**

In practice the scheduling is typically done individually for each plant through the manual application of different types of heuristics by experienced experts. Sometimes the scheduling procedure is split between the automation vendor and the plant operator. However, this manual heuristic procedure suffers from long response times, a lack of experienced experts and a considerable loss of optimization potential – in particular for plants processing many product types in small quantities.

To overcome the mentioned drawbacks of the manual heuristic procedure, automated MIP-based scheduling services are proposed. In order to exploit economy of scale effects, they should be offered by automation vendors. However, a key requirement for an automated scheduling procedure for a broad spectrum of problem instances is an efficient and widely automated engineering process. The engineering process is meant to adapt the generic scheduling procedure to individual problems.

## **4. Research gap**

This chapter outlines the gap between an automation vendor's requirements for an automated solution to schedule individual electroplating plants as described in chapter 3 and existing approaches.

#### *4.1. MIP-based solution*

Mathematical programming methods offer a high modeling flexibility and standard solvers that are independent of the model. The applicability of MIP methods to real-world electroplating scheduling problems depends on two prerequisites: The models need to represent the real-world problems sufficiently well and the computational limits of the standard solvers need to be overcome.

##### *4.1.1. Case studies*

Three real-world use cases were examined: (a) a medium-scale manually operated plant, (b) a small- and (c) a large-scale automatically operated plant. Their key properties can be adequately reflected by MIP models. To solve them by CPLEX, (a) was simplified by an aggregation approach and (b) and (c) by a product-decomposition approach. For (b), the optimized schedule was computed within 2 min CPU-time and with a 14,9 % shorter cycle time than the manually created schedule. Further it was shown that varying problem instances require different models and simplification heuristics. The model for (a) cannot be used for (b) and (c) because the hoists are not covered and depending on the problem size, certain combinations of simplifications are no longer sufficient to compute a schedule in reasonable time. For (c) for example, a schedule could be computed within 48 hours only for small recipes. The selection of a suitable model and suitable heuristics for a given problem instance is based on an educated guess.

##### *4.1.2. Literature analysis*

A complementary literature analysis revealed, that according to the classification scheme by Manier (2003), nearly the full spectrum of HSPs can be modelled as MIPs. However, an analysis of the papers also showed that different problems require different models and heuristics, as well as different parameterizations of the heuristics. A typical approach in the literature for selecting models and heuristics and parameterizing heuristics for MIP is also an educated guess.

#### *4.2. Automated model and heuristic selection*

The models existing in literature collectively represent almost the entire spectrum of the HSPs. Considered individually, the models as well as the heuristics are suitable for a small subset of problem instances and are usually applied to individual selected or benchmark instances. However, an automation vendor needs a solution that can be applied to a spectrum of real-world problem instances automatically. Which model and heuristics should be applied for a given problem instance to compute a solution in a short solution time with high quality is still not considered in the state of research and not yet automated. Manually selecting the models and the simplification heuristics for each instance takes much time and requires a lot of knowledge. From an automation vendor's perspective an automated engineering process i.e. an automated selection, parameterization and solution of models and heuristics for specific instances is crucial.

## **5. Approach**

Studies on real-world instances show that MIP can be used in practice for hoist scheduling in electroplating plants if simplification heuristics are applied. As described in section 4.2, an automated selection and parameterization is needed. According to literature the application of hyper-heuristics is limited to metaheuristics and constructive heuristics. Methods to select and parameterize simplification heuristics used to solve MIP models are not known to the authors. The authors propose to combine the principles of hyper-heuristics with MIP as follows. The real-world problem instances as well as the models are classified according to the scheme of Manier. Based on the classification, a preselection of models suitable for the problem is possible. The suitable models are

parameterized for the problem instance and a pool of suitable heuristics is chosen. The preselection of the models already decides which low-level heuristics are to be added to the pool, since only a subset of heuristics is applicable to each model. In the research phase, a parameterized model with a suitable heuristic and its parameterizations is to be determined with an evolutionary algorithm. A possible criterion to evaluate the fitness of individuals could be the objective value after a given solution time. This process is performed for multiple problem instances, resulting in pairs of scheduling problems with model-heuristic combinations. These will be used to train a neural network to avoid selecting a model and heuristic each time again with the evolutionary algorithm during the application phase.

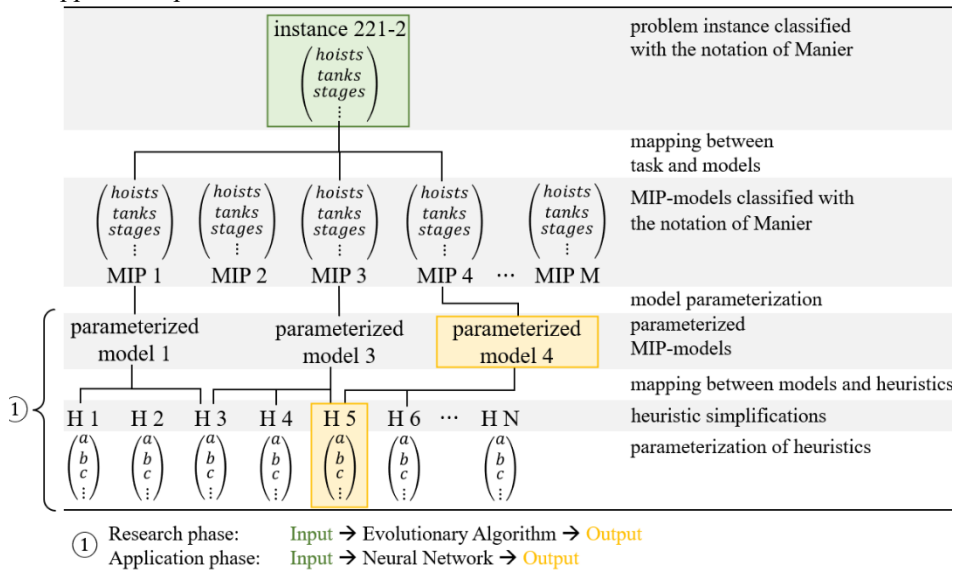

Figure 2 Procedure to select and parameterize a model and a heuristic for a scheduling problem

## 6. Outlook

Young research areas like hyper-heuristics deal with automated algorithm selection and parameterization but have not yet been applied to simplification heuristics for solving MIP models. The approach presented in this paper combines hyper-heuristics with MIP to compute good schedules in reasonable time for new, unknown problem instances. The study of this approach shall provide a deeper insight into the problem as well as knowledge about the relationships between the scheduling problem and suitable models-heuristic combinations. It is expected that the research will reveal the potentials of an intelligent, automated model and heuristic selection, regarding solution time and scheduling quality, compared to the educated guesses applied in literature and at the automation vendor. Furthermore, information on suitable structures for hyper-heuristics for selecting MIP models and heuristics as well as their essential differences compared to classical hyper-heuristics shall be obtained. The results can not only be transferred to further applications in the field of HSPs such as robotic cells or cluster tools, but also to optimization problems for which many models and heuristics exist which are differently suited for different problem instances. The expected overall goal is to bring the theoretical results in the form of MIP models and simplification heuristics into practice through the approach presented here.

## Abstract

Tropospheric ozone pollution is one of the most harmful secondary air pollutants that could have brought challenges to air pollution prevention. Therefore, early prediction and warning of high-level tropospheric ozone concentration plays an important role in the management of ambient air pollution. Deep learning methods have been widely applied for their powerful data fitting ability, but nonstationary characteristic is exhibited in ozone concentration data owing to the instability of the atmosphere, which pose a challenge to the prediction of data with high-level ozone concentration. Considering the effectiveness of difference in handling nonstationary sequence, a nonstationary modeling method called single difference-embedded long short-term neural network (SDELSTM) is applied to realize the prediction of high-level tropospheric ozone concentration. Case study on an ozone dataset between 2013 and 2017 in Los Angeles is used to verify the effectiveness of the SDELSTM.

**Keywords:** SDELSTM, high-level tropospheric ozone concentration, nonstationary characteristics

## 1. Introduction

Tropospheric ozone pollution is a secondary pollutant produced by nitrogen oxides (NO<sub>x</sub>) and volatile organic compounds (VOCs) under solar radiation (Jenkin and Clemitshaw, 2000). The long-term exposure to tropospheric ozone contributes to the risk of respiratory and circulatory mortality, and is potentially associated with cardiovascular disease risk and premature death (Jerrett et al., 2009, Turner et al., 2016). The real time prediction of tropospheric ozone pollution can realize the early alarm and prevention of ozone pollution and reduce the risk of human health. Generally, data-driven methods are widely used to achieve this task. Among them, LSTM is widely used in ozone prediction since it could model long-term time dependence (Cabaneros et al., 2019). However, the air quality data show short-term nonstationary characteristics due to the unstable atmospheric composition and the complexity in the formation mechanism of pollutants. Under this circumstance, traditional data-driven models show poor performance in the field of ozone prediction. Zakaria et al. (Zakaria et al., 2021) introduced stationary and nonstationary model to forecast high ground-level concentrations and found that nonstationary models showed better performance in ozone prediction. Therefore, the consideration of nonstationary characteristics of data can enhance the performance of ozone prediction model. Difference is widely used in statistics to deal with nonstationary time series, which could eliminate the impact of random fluctuations in data, so as to improve the performance of the model. It is reported that several difference methods have been combined with deep learning methods for time series prediction. Zhou et al. (Zhou et al., 2022) proposed difference-LSTM (DLSTM) in which the difference of input variables was seen as a dynamic input, and the method was verified by the prediction of key variables in complex industrial process. Wang et al. (Wang et al., 2019) proposed the memory in memory (MIM) networks. Then the MIM module was utilized to replace the

forgotten gate and retain more nonstationary characteristics. In this study, a model called SDELSTM is introduced to perform ozone prediction from the perspective of nonstationary characteristics of data. In this model, an additional network layer including a differential module is embedded into LSTM neural network to capture the nonstationary characteristics of data under the premise of avoiding the loss of original data information (Ji et al., 2023). The effectiveness of the SDELSTM model is validated by performing ozone prediction using the historical tropospheric data from Los Angeles.

## 2. Description of the model

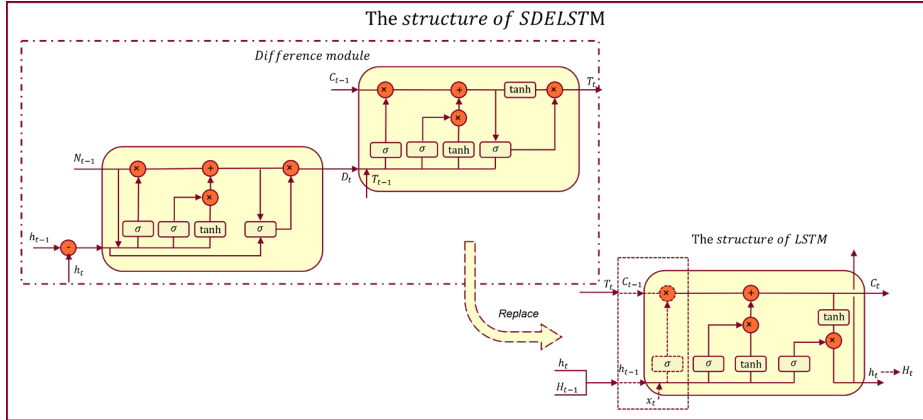

Figure 1 The structure of LSTM and SDELSTM

### 2.1. long short-term memory neural network

The LSTM neural network is a special recurrent neural network which contains many neurons in the hidden layer. The structure of LSTM is shown in Figure 1. The initial input  $h_{t-1}$  and  $x_t$  represent the state of the previous hidden layer and input of current time respectively.  $C_t$  and  $C_{t-1}$  record the cell state which is the key value to LSTM.  $h_t$  represents the output of the current layer. The neurons in hidden layer contains three gates including a forget gate, an input gate and an output gate which could control the transmission of information. The unique structure helps LSTM learn the long-term characteristics of the data. The forget gate control which part of information should be retained. Then the input gate determines the information to be added to cell state and the output gate control the output of the cell state. However, the short-term nonstationary characteristics cannot be obtained by a single forget gate and some measures have been adopted to make LSTM become nonstationary model.

### 2.2. The structure of single difference-embedded long short-term neural network

To address this problem, the SDELSTM model is improved from LSTM where an additional layer including a differential module is embedded into the hidden layer. The dashed box indicates the replacement of the forget gate by the differential module. The input of difference module is states of hidden layers of the current and previous moment ( $h_t$  and  $h_{t-1}$ ) which is regarded as difference information.  $N_{t-1}$  represents cell state of the previous difference layer. The output of difference layer is a new cell state  $D_t$  which contains difference information. The next layer combines  $D_t$  and  $C_{t-1}$  whose purpose is selective retain difference characteristics and long-term characteristics of the original sequence.  $T_t$  represents cell state which records both short-term and long-term information. Eventually, in order to avoid the loss of original information,  $h_t$  and  $H_{t-1}$  which represents the state of SDELSTM are utilized as the input of LSTM neural network

and  $H_t$  represents the output of SDELSTM. Then, the short-term nonstationary characteristics can be obtained by the unique forget gate module. In summary, the proposed SDELSTM model could learn short-term nonstationary characteristics and long-term dependence at the same time by a difference module, and therefore the performance of ozone concentration prediction can be improved.

### 2.3. Implementation procedure of SDELSTM

The implementation procedure of SDELSTM is shown in Figure 2 which contains three parts: data processing, stationary analysis and modelling. The procedures can be summarized as follows,

Step 1: The missing values are filled by K-Nearest Neighbor (KNN).

Step 2: The datasets are divided into training data and test data in a ratio of 4:1 and 20 percent of training data are grouped into validation data.

Step 3: The stationarity of time series is tested by the ADF test.

Step 4: The SDELSTM model is set up by training data and the hyperparameters of the model are determined by validation data.

Step 5: The performance of the model is verified by test data.

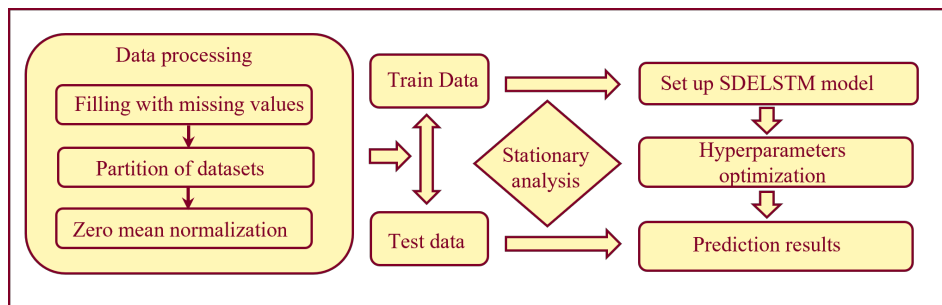

Figure 2. The training process of SDELSTM model

## 3. Results and discussions

### 3.1. Data preparation

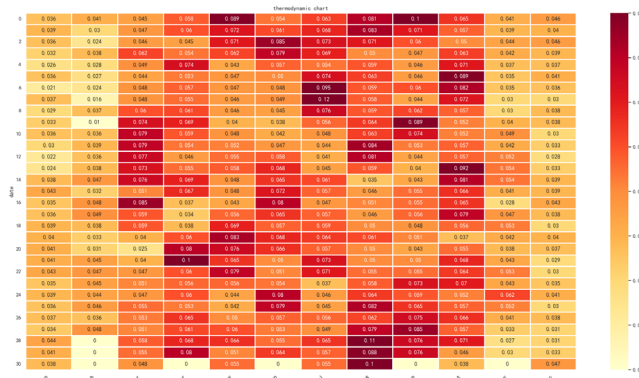

Figure 3 Daily Maximum ozone distribution thermal map of Los Angeles in 2017  
 Due to the special geographical location of Los Angeles and the year-round high temperature and little rain characteristics, ozone pollution is serious. In 2017, more than 100 million people in the United States were exposed to tropospheric ozone pollution,

especially in Los Angeles (Zhang et al., 2019). Figure 3 shows that the thermal map of daily maximum ozone of Los Angeles in 2017. The national ambient air quality standards from EPA for ozone concentration is 0.070 parts per million (ppm). In addition, according to world health organization (WHO) air quality guidelines, the standard for ozone concentration is 0.05ppm which suggests more people are exposed to tropospheric ozone pollution. It is found that the darker the color, the more ozone pollution there is and most ozone pollution is concentrated during the warmer months. Besides the dataset mentioned above, the Los Angeles air quality datasets between 2013 and 2017 are obtained from the air quality system of environment protection agency (EPA) which were collected from the monitoring site at N main St in Los Angeles. Datasets from 2013 to 2016 are used as training sets and the data of 2017 is selected as the test set. Considering that there are missing values in the data, KNN is utilized to fill missing data. After data preprocessing, twelve air monitoring variables are selected, including SO<sub>2</sub>, NO<sub>2</sub>, PM<sub>2.5</sub>, PM<sub>10</sub>, RH\_DP, TEMP, CO<sub>0</sub>, CO<sub>1</sub>, NO<sub>x</sub>, NO<sub>y</sub>, NO<sub>0</sub>, and NO<sub>1</sub>.

### 3.2. Case study

#### 3.2.1. Stationary analysis

Since the complexity of atmospheric environment, the air quality monitoring data obtained from monitoring stations would fluctuate randomly within a certain range, which is easy to be ignored from a long-term perspective, and the nonstationary characteristics generated by random fluctuations will affect the performance of ozone prediction model. The Augmented Dickey-Fuller (ADF) test was widely used to test the stationary of the time series and conducted for monthly tropospheric ozone concentration to demonstrate the non-stationary characteristics of the data. It is shown in Table 1 that 8 months ozone concentration data are nonstationary at 1% confidence. Therefore, the nonstationary characteristics of the data cannot be ignored while traditional LSTM models do not take these characteristics into account. To address this issue, the SDELSTM model is introduced to learn the nonstationary characteristics within the air quality data, which could enhance the performance of ozone prediction.

Table 1 Los Angeles monthly data ADF statistics in 2017

Months	Test statistics	1%	5%	10%
January	<b>-2.97</b>	-3.71	-2.98	-2.63
February	<b>-2.44</b>	-3.66	-2.96	-2.62
March	-4.79	-3.67	-2.96	-2.62
April	-4.97	-3.78	-3.01	-2.64
May	<b>-3.34</b>	-3.66	-2.96	-2.62
June	<b>-2.53</b>	-3.66	-2.96	-2.62
July	-4.07	-3.75	-2.99	-2.63
August	-4.92	-3.67	-2.96	-2.62
September	<b>-3.27</b>	-3.66	-2.96	-2.62
October	<b>-3.43</b>	-3.66	-2.96	-2.62
November	<b>-1.75</b>	-3.71	-2.98	-2.63
December	<b>-2.99</b>	-3.66	-2.96	-2.62

#### 3.2.2. Performance of SDELSTM on ozone concentration

With the current air quality data fed in, the model is able to predict ozone concentration for the next hour. It is shown in Figure 4 that the prediction results of the model for different months. The model makes accurate predictions of the concentration data where there is a health risk while the model performed poorly in the prediction of low concentration data. It is found that ozone data show successive near-zero values at regular

intervals after the analysis of actual hourly ozone data. Then we speculate that it is caused by artificial manipulation which leads to the deviation in the predicted result graph. However, only high concentrations of ozone (>0.05ppm) pose a huge threaten to human health. Therefore, when evaluating the predictive performance of the model, the prediction results of low concentration values will not greatly affect the predictive performance of the model.

Figure 4 Comparison of true and predicted values for different months

In order to evaluate the prediction effect of the model more scientifically and objectively, it is necessary to use quantitative indicators to further evaluate the model, coefficient ( $R^2$ ), root mean square error (RMSE) are widely used to evaluate the performance of prediction models. The indicators are defined as follows,

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_j - \hat{y}_j)^2} \quad (1)$$

$$R^2 = 1 - \frac{\sum_{i=1}^N (y_j - \hat{y}_j)^2}{\sum_{i=1}^N (y_j - \bar{y}_j)^2} \quad (2)$$

where  $N$  is the number of test samples.  $y_j$  and  $\hat{y}_j$  indicate the actual and predicted values at time  $j$ .  $\bar{y}_j$  indicates the mean of the predicted values over all times. The specific calculation results are presented in the next section along with the comparison of other models.

### 3.2.3. Model comparison

In order to demonstrated the performance of the SDELSTM model in ozone prediction, the related models including artificial neural network (ANN), LSTM, gate recurrent unit

(GRU) are utilized to compare the results with the SDELSTM model. The specific model comparison results are shown in Table 3. It is shown in Table 2 that the SDELSTM model performs better than other models in all indicators. The  $R^2$  of the model is 13.4% higher than that of the traditional LSTM and RMSE is 34.6% lower than other models. The SDELSTM model shows more accuracy on the tropospheric ozone concentration because nonstationary characteristics of the ozone data cannot be considered by traditional predictive models.

Table 2 Comparison of different models

	RMSE	$R^2$
ANN	0.0120	0.6119
GRU	0.0110	0.6869
LSTM	0.0104	0.7265
SDELSTM	0.0068	0.8237

#### 4. Conclusions

In this work, a model called SDELSTM is introduced to perform ozone prediction from the perspective of nonstationary characteristics of data. An additional network layer including a differential module is embedded into LSTM neural network to capture the nonstationary characteristics of data under the premise of avoiding the loss of original data information. Based on literature research, the ADF stability test was conducted on the ozone data of Los Angeles in 2017, which confirmed the nonstationary characteristics of the ozone data. Then the effectiveness of SDELSTM model is validated by performing ozone prediction using the historical tropospheric data from Los Angeles. The results demonstrates that the SDELSTM model shows better performance in hourly troposphere ozone prediction than other related models, indicating its application prospect in preventing ozone pollution.

# Numerical Study of a Single-Spout and Z-shaped Fluidized Bed Biomass Gasifier

Fatima Ez-zahra El Hamra,<sup>a</sup> and Radouan Boukharfane<sup>a,\*</sup>

<sup>a</sup>*Mohammed VI Polytechnic University (UM6P), MSDA Group, Benguerir, Morocco  
radouan.boukharfane@um6p.ma*

## Abstract

Gas-solid multiphase systems are ubiquitous in several applications such as pharmaceutical, mining, and petrochemical industry (Geldart, 1986). The vigorous interaction between gas and solid particles involves complex dynamics in the determination of mass and heat transfer. Most simulations and experiments use fluidized beds with simple geometries, but industrial multiphase reactors generally have complex configurations (Zhao et al., 2020). The aim of this work is to study the gas–solid flow characteristics of a Z-shaped gas-solid fluidized bed by means of an in-house solver DEM-LES solver. The fluid phase is computed through solving the volume-averaged four-way coupling Navier–Stokes equations in which the Smagorinsky sub-grid scale tensor model is used. Results show that particles and fluid phases are not uniformly distributed, and a core-annulus structure is observed. These findings provide valuable insight into the development and optimization of particle purification appliances in multiphase reactors.

**Keywords:** Fluidized bed, Computational fluid dynamics, DEM-LES, Biomass particles, Particle sorting.

## 1. Introduction

Finding sustainable, clean, and low-carbon alternatives to traditional fossil fuels is becoming crucial given the world's rising energy needs and the severity of global warming. The many inherent benefits of biomass for bioenergy, such as its global availability, renewability, and carbon neutrality, make it one of the most attractive possibilities. Torrefaction, pyrolysis, gasification, and catalytic conversion are among the thermochemical conversion processes that may turn raw biomass feedstocks into high-quality energy products. Because it can transform biomass into three different products-biogas, bio-oil, and biochar, pyrolysis has drawn the most attention among these processes. The fluidized-bed pyrolyzer is one of the most popular reactors for biomass pyrolysis because of its excellent particle mixing capability, high heat transfer efficiency, and operational flexibility. The fluidized-bed reactor, however, typically presents a complicated system in which the hydrodynamics of dense gas-solid flow, heat/mass transfer, chemical reactions, and turbulence are intimately inter-coupled, making it challenging to fully comprehend the mechanics of biomass pyrolysis.

In order to develop and scale-up fluidized systems, it is necessary to understand the flow characteristics between particles and gas but doing so through experiments is challenging. The usage of numerical simulation as an alternate tool for engineering analysis has increased with the advancement of numerical methods and processing power.

Particle-resolved direct numerical simulation (PR-DNS), two-fluid model (TFM), and CFD-DEM are the three categories into which numerical methods of particle fluidization can be categorized. PR-DNS is only useful for flow systems with no more than 1000 particles due to its high computing requirements. The TFM technique treats fluid and solid as two distinct continuous phases. The CFD-DEM model uses Newton's second law to monitor particles, which is why a good match was obtained between simulations and experiments.

Numerous studies have concentrated on how operating parameters affect the particle flow characteristics. Ejim et al., (2017) investigated how the inner geometry of mesoscale tubes with baffles affected the axial dispersion and suspension of materials. Hu et al. (2019) assessed how collisional characteristics affected the hydrodynamics and heat transport in a spouted bed. In a full-loop circulating fluidized bed at varied surface gas velocities, Xu et al. (2018) computationally and empirically examined the particle movements, proving that solid behaviors (such as residence duration, dispersion, and mixing) are connected to the fluidization regions. Particle size and gas velocity effects on tar yield in rapid pyrolysis reactors were discussed by Xue et al. (2012). Wang et al. (2018) also thoroughly investigated the particle behaviors, including the particle force and velocity. The effectiveness of chemical reactions is impacted by the fact that biomass is made up of heterogeneous particles of various densities, sizes, and forms. Consequently, a number of separation and purification techniques were suggested.

Konrath et al. (2014) investigated the circumstances of fine particle separation in centrifugal classification. The influence of particle organization and spigot widths on the enhancement of separation of the hydrocyclone was numerically modeled by Vega-Garcia et al. (2020). Further discussion was made regarding the impact of dipleg shape on the functionality of gas-solid cyclones.

Lv et al. (2018) investigated the motion and separation behavior of coal in a fluidized bed for gas-solid separation.

Since most previous research places emphasis on the effects of operating conditions but gives the reactor structure relatively little attention, the current work aims to investigate the influence of the reactor structure on biomass fluidized-bed pyrolysis behavior. The separation of two-component suspension has typically been shown to be improved by the fluidized bed structure's inclination (Masliyah et al., 1989). In the present study, multiple inclination cross-sections that make up a Z--shaped channel, which has considerable potential for the fluidization and separation of mixed biomass particles, is investigated.

## 2. Mathematical modeling

The single-spout fluidized bed is simulated in the current study using a coupled Computational Fluid Dynamics and Discrete Element Method (CFD-DEM). The Newtonian laws of motion control the dynamics of the particles suspended in the bed. To describe the fluid phase, the locally volume-filtered Navier-Stokes equations are solved. The whole momentum exchange between the solid and fluid phases is then included in these sets of equations (two-way coupling).

$$\left\{ \begin{aligned} \partial_t(\theta_f \bar{\rho}_f) + \partial_i(\theta_f \bar{\rho}_f \tilde{u}_{f,i}) &= 0, \end{aligned} \right. \quad (1a)$$

$$\left\{ \begin{aligned} \partial_t(\theta_f \bar{\rho}_f \tilde{u}_{f,i}) + \partial_j(\theta_f \bar{\rho}_f \tilde{u}_{f,i} \tilde{u}_{f,j}) &= -\partial_j \bar{p} + \partial_j(\bar{\tau}_{ij} + \bar{\tau}_{ij}^{SGS}) + \theta_f \bar{\rho}_f g_i + \mathcal{F}_i^{inter}, \end{aligned} \right. \quad (1b)$$

Where  $\theta_f$ ,  $\rho_f$ ,  $p$ , and  $u_f$  are the fluid-phase volume fraction, density, dynamic pressure, and velocity, respectively. In Eq.(1b),  $g$  stands for the acceleration due to gravity and  $F^{inter}$  for the inter-phase exchange term that arises from filtering the divergence of the stress tensor. The volume-filtered stress tensor,  $\tau$ , is expressed as  $\overline{\tau_{ij}} = \mu \left[ \partial_i \overline{u_{f,j}} + \partial_j \overline{u_{f,i}} - \frac{2}{3} \partial_i \overline{u_{f,i}} \delta_{ij} \right] + \mathcal{R}_{\mu,ij}$ , where  $\mu$  is the dynamic viscosity and  $\delta_{ij}$  is the Kronecker function. The SGS stress tensor  $\overline{\tau_{ij}}^{SGS} = \overline{\rho_f u_{f,i} u_{f,j}} - \overline{\rho_f} \widetilde{u_{f,i}} \widetilde{u_{f,j}}$  is modeled within the Boussinesq's framework evaluated using the classical Smagorinsky (Smagorinsky, 1963) model.

A Lagrangian particle-tracking approach is used for the solid phase. The displacement of an individual solid particle indicated by the subscript  $p$  is calculated using Newton-Euler equations for rigid body motion as follows:

$$\left\{ m_p \frac{du_{p,i}}{dt} = f_{p,i}^{inter} + f_{p,i}^{col} + m_p g_i, \text{ with } \frac{dx_{p,i}}{dt} = u_{p,i} \right\} \quad (2a)$$

$$\left\{ \mathcal{J}_p \frac{d\omega_{p,i}}{dt} = \mathcal{M}_{p,i}^{drag} + \mathcal{M}_{p,i}^{col} \right\} \quad (2b)$$

where the particle mass is defined by  $m_p = \pi \rho_p d_p^3 / 6$  and  $u_p$  is the centroid particle velocity. The force  $f_p^{col}$  accounts for the particle-particle and particle-wall repulsion modeled using a soft-sphere model (Cundall & Strack, 1979). The force  $f_p^{inter}$  exerted on a single particle  $p$  by the surrounding fluid is related to the inter-phase exchange term in Eq.(1b) by  $\mathcal{F}^{inter} = \sum_{p=1}^{N_p} \xi(|x - x_p|) f_p^{inter}$ , where  $N_p$  is the total number of particles,  $\xi$  is the filtering kernel used to volume filter the Navier-Stokes equations,  $x_p$  is the position of the  $p^{th}$  particle, and  $f_p^{inter}$  is approximated by  $f_{p,i}^{inter} \approx \mathcal{V}_p \partial_j \tau_{ij} + f_{p,i}^{drag} \approx -\mathcal{V}_p \partial_i p^\circ + f_{p,i}^{drag}$ , where  $\mathcal{V}_p$  is the volume of the  $p^{th}$  particle given by  $\pi d_p^3 / 6$  and  $\partial_i p^\circ$  is the local pressure gradient interpolated at the center of the particle. The drag force is computed using the drag force coefficient of Tennesi et al. (2011). Particle-particle and particle-wall collisions are modeled using the adaptive collision time model ACTM proposed by Kempe & Fröhlich (2012), which is a variation of the classical soft-sphere model. In this work, a fourth-order central scheme is used for the spatial integration, and a third-order accurate semi-implicit Crank-Nicolson scheme is employed for time integration. The reader is referred to (el Hamra et al., 2022) for further information on the current CFD-DEM solver as well as to review the numerical validation.

### 3. Single-spout and Z-shaped fluidized bed system

In our study, three spouted-fluidized beds with a single orifice with the same cross-section are considered as schematically depicted in Fig. 1. The difference between the second and third configuration is the angle between the two sections, which is equal to  $155^\circ$  in the Case 2, while it is equal to  $132^\circ$  in the Case 3. In all base case simulations carried out for this work, the spouted-fluidized bed height (BH) and depth are 400 mm and 14 mm, respectively. There are two portions

Figure 1: Different geometric models of Z-shaped particle fluidized system.

across the bed's width (shown as  $W_0 = 0.007$  mm and  $W_1 = 0.007$  mm in Fig. 1).

The computational domain is divided into  $82 \times 12 \times 370$  quad grids. In the spouted region, 12 grids are considered. Gas flows upwards through  $W_0$ , which induces three distinct regions: a dilute central core, where the solid phase is entrained in the concurrent jetting gas flow, a fountain region in the uppermost part, and a dense annular region with a counter-current flow between both phases. Simulation settings of the validation cases are summarized in Table 1.

Fluid phase	
Fluid density $\rho_f$ [kg/m <sup>3</sup> ]	1.165
Fluid viscosity $\mu$ [Pa · s]	$2.0 \times 10^{-5}$
Superficial mass flow rate at the injection [kg/s]	$2.0 \times 10^{-3}$
Solid phase	
Number of particles	93808
Bed mass $m_{bed}$ [kg]	0.122
Particle diameter $d_p$ [mm]	1.0
Particle density $\rho_p$ [kg/m <sup>3</sup> ]	2500
Inter-particle & Particle-wall restitution coefficient	0.97
Inter-particle & Particle-wall friction coefficient	0.1

Table 1: Simulation settings of the validation case for the three spouted bubbling fluidized configurations.

A typical illustration of particle velocity distribution for the three cases at  $t=25$  s can be seen in Fig. 2, where the mesoscopic bubble formed in the mixture with different sizes is observed. During this process, the particles are impulsed into the bubbles and scattered to the freeboard and fall back to bed due to the gravitational force. As the angle between the two sections in the Z-shaped fluidized bed, the bed height is higher. A higher bed expansion rate and an intense particle motion is therefore caused by applying the change of lateral wall's shape compared to the flat wall case.

The time-averaged fluid volume fraction and gas velocity at the midplane of the fluidized bed is portrayed in Fig. 3 for three configurations.

A large velocity gradient is observed around the irregular wall. The Z-shaped fluidized bed breaks the flow symmetry, thus allowing the mixed particles to achieve effective screening in each section. Furthermore, in the corners, heaps of unfluidized particles accumulate in much larger quantities in the case of flat walls. While less unfluidized zones are obtained when the angle between the two sections of the Z-shaped fluidized bed gets smaller. Note that due to these corners actually act as dead zones and create more resistance to bubble movement.

Because gas and solids transfer mass at slower rates in dead zones than they do in a fully fluidized bed, mixing rates may be lowered as a result. Dead zones in corners thereby reduce the cross section available for bubble passage, which in turn reduces bubble size and/or speed.

Figure 2: Instantaneous distribution characteristic of particles colored by particle velocity in the three cases.

The mixing rate in case 1 bed is lower than in case 3 bed because dead zone particles move into the active zone of the bed extremely slowly. In other words, Z-shaped fluidized beds remove dead zones and enhance the movement, homogeneous mixing, and subsequent fluidization of the solids.

Figure 3: Time-averaged (a) fluid volume fraction and (b) gas velocity at the midplane for the three studied cases.

Solid flow rate is a key parameter for the operation and optimization of fluidized beds. To quantify this parameter, the  $x_2$ -direction of the bed, and mainly the interval  $x_2 \in [0, 0.35]$  m, is subdivided into seven equal sections, and the mean number of particles within each section is computed for  $t \in [5, 25]$  s as can be seen in Fig. 4. The section #1 is the lowest one (at the injection) and the section #7 is the highest one. It is confirmed that the Z-shaped beds tend to provide sufficient space compared to flat walls for the separation and purification of particles as they occupy more space in the  $x_2$ -direction.

Figure 4: Mean number of particles in different sections for three studied cases.

Due to collisions and energy loss, many particles congregate near the corners of flat walls. However, in cases 2 and 3, where zigzag patterns are present, larger flocules form, break, and then slide down the wall.

#### 4. Conclusion

This work presented a preliminary attempt to use single-spout and Z-shaped fluidized beds as fluidized bed gasifiers of mixed biomass particles. A numerical study based on a large-eddy Simulation (LES) solver coupled with Discrete Element Method (DEM) was employed to study the effect of zigzagging the lateral walls with two angles. The Z-shaped fluidized bed was found to modify the uniformity of the flow domain and to allow an enhanced particle's mixing. These results offer an important direction for

designing clean particle products and can be expanded to include research into environmental chemical and process engineering.

## Abstract

In this work the design and simultaneous optimization of an intensified process for jet fuel production by the ATJ process was developed. The intensified process consists of a catalytic reactive distillation column. The process integrates the oligomerization, hydrogenation and purification stages in a single unit. The design and simultaneous optimization process were performed using the differential evolution with tabu list (DETL) algorithm. Total annual cost and condition number were considered as objective functions to evaluate cost issues and control properties, respectively. The optimized process was contrasted against the original intensified process. The results indicate that the optimized process reduces energy consumption by 30% and total annual cost by up to 80%, due to reductions in energy consumption and equipment size. Regarding the control properties, it is observed that the optimized process has a condition number of 82.52 against 915,000 of the original process. This means that the optimized process withstands disturbances better, which facilitates control and ensures the quality of the bioturbosine in a more reliable way.

**Keywords:** Biojet-fuel, reactive distillation, process intensification.

## 1. Introduction

The world is currently facing increasing energy demands. This growth in energy is associated with an increase in the production of goods and services, increase in the quality of life, among others. Unfortunately, most of the energy produced by humans derives from the burning of fossil fuels such as coal, natural gas, gasoline, etc., which generates severe environmental problems by the emission of greenhouse gases such as CO<sub>2</sub>. Carbon dioxide is the main greenhouse gas, recent studies reveal that by 2018 its concentration in the atmosphere had gone from 280 to 408ppm, taking the year 1900 as a reference. This increase means a 0.8°C increase in the earth's global temperature and it is expected that by the year 2100 the temperature increase will reach 5°C (Bains et al., 2017).

In order to reduce their emissions, various industries such as the aviation sector have started to develop technologies to reduce their CO<sub>2</sub> emissions. The aircraft industry is responsible for 2.6% of CO<sub>2</sub> emissions and it is expected that by mid-century this industry will emit 20.2% of CO<sub>2</sub> emissions. An interesting alternative to reduce polluting emissions is to replace jet fuel (also called biojet-fuel), which comes from fossil sources,

with biojet-fuel, which is a renewable fuel derived from biomass residues, vegetable oils, etc. Several processes and biomasses have been proposed to produce biojet-fuel, however, a little explored alternative is the ATJ (Alcohol to Jet fuel) process, which consists of converting lignocellulosic residues into sugars, which are transformed into hydrocarbons (Wang and Tao, 2016). As with other alternatives to produce biojet-fuel or even other biofuels, economic viability remains the main challenge for this type of technology. In the case of the ATJ process, a critical and energy-intensive stage is the oligomerization and hydrogenation stage, since it is at this stage that hydrocarbons are produced and separated. In this sense, process intensification coupled with rigorous optimization techniques can help to reduce energy consumption and process operating costs, in order to increase the profitability and adoption of these processes. In this work, an intensified process based on catalytic reactive distillation is proposed to replace the current oligomerization and hydrogenation steps in the ATJ process. This column is simultaneously designed and optimized using the differential evolution stochastic optimization method with tabu list (DETL). The minimization of the total annual cost is proposed as the economic objective function. On the other hand, because the catalytic column is notably more complex and in order to ensure a viable operation of this equipment, the minimization of the condition number is proposed as the second objective function in order to evaluate the control properties.

## 2. Methodology

First, the intensified catalytic reactive distillation process is generated from the conventional process. As shown in Figure 1, the conventional process consists of 2 reactive zones, the first one is the oligomerization stage, where ethylene is fed to a fixed bed reactor, then the reactor products which are light compounds (C2- C5) and oligomers (C6-C17) are fed to a distillation column, where the light compounds are recirculated, while the heavy oligomers are sent to the hydrogenation zone. In this second reaction zone, the oligomers are transformed to alkanes by hydrogenation reactions, which are carried out in a second fixed-bed reactor. Finally, the products of the hydrogenation reactor are separated into three main fractions, light, jet-fuel and diesel (Wang and Tao, 2016).

The catalytic column integrates these separation and reaction stages in a single equipment, the oligomerization zone is located at the top of the column, it is in this zone where the proper distribution of hydrocarbons is obtained. The compounds that descend from this zone are transformed into olefins (alkanes), which at the same time as they are produced are separated into the 3 main fractions. The mathematical modeling of this intensified process was performed in Aspen Plus software, considering an ethylene input flow of 2100kg/hr. The kinetic models were taken from (Goortani et al., 2015). NRTL-RK (Interan, 2021) was selected as thermodynamic model. It is important to mention that the original design of the intensified column was obtained through a sensitivity analysis of some important design parameters, such as hold ups, number of hold ups, feed stages, etc.

The preliminary design of the catalytic column will be used as the starting point for the optimization algorithm. As mentioned earlier, the total annual cost (TAC) and the condition number were the objective functions to be minimized. The total annual cost consists of the sum of the annualized capital costs, plus the operating costs. As shown below:

$$TAC = \frac{\text{Capital cost}}{\text{Payback period}} + \text{Operating cost} \quad (1)$$

**Figure 1.** Intensification of ATJ process using catalytic distillation

The capital cost is associated to the construction cost of process equipment, such as condensers, reboilers, distillation columns, trays, process vessels and compressors; whereas the operating cost corresponds to the cost of use of electricity, cooling water, steam and solvents. The Guthrie method is used to calculate the total annual cost. The parameters and equations required to estimate the cost of equipment and utilities were taken from Turton et al., 2018. Carbon steel is the construction material considered, and a payback period of ten years is used, which corresponds to an average payback time of a chemical plant according to (Turton et al., 2018). Trays type Sieve with 0.61m spacing were considered for distillation columns. The utilities costs are calculated considering 8,500 hours of operation per year. Cooling water (0.355USD/GJ), electricity (16.8 USD/kwh) and Fired heat (20.92 USD/GJ) were the utilities considered (Turton et al., 2018).

The condition number is a common index used to determine in a qualitative way the controllability of a specific process. It has proven be a powerful tool as it analyzes the control properties of a process in order to detect potential operational problems. Mathematically, the condition number is calculated through a singular value decomposition of the gain matrix according to equation 2:

$$K = W \cdot S \cdot V^T \quad (2)$$

Where K is the relative gains matrix, W and V are unitary matrices and S is the singular value matrix. From the matrix S we take the maximum singular value ( $\sigma^*$ ) and the minimum singular value, to calculate the condition number as shown below:

$$\gamma = \frac{\sigma^*}{\sigma_*} \quad (3)$$

The condition number represents the sensitivity of a system to assimilate a disturbance without process destabilization. indicate that the processes could be susceptible to destabilization by small perturbations. Furthermore, low condition numbers represent a robust process that is resistant to perturbations

Based on the above, the optimization problem can be stated mathematically as equation 4.

$$\begin{aligned} \min Z &= [TAC, \gamma] \\ \text{Subject to } & y_i \geq TE_i \\ & w_i \geq u_i \end{aligned} \quad (4)$$

The objective functions are constrained to meet the minimum boiling point specifications ( $TE_i$ ) for each of the products which are 220°C for jet fuel and 300°C for diesel. On the other hand, the optimization problem is also subject to meet minimum production quantities ( $u_i$ ) which were 1000kg/hr for jet fuel and 100kg for diesel. As decision variables, the number of stages, feed stages, number of reactive stages, hold up values, reflux ratio and thermal load were taken.

Differential evolution with tabu list (DETL), the mathematical method used to solve the optimization problem. DETL is a direct population-based search method, specially designed for non-continuous and highly non-linear functions. This method consists of the 4 stages: generation of the initial population, mutation, crossover and selection. Its main feature is its ability to avoid or revisit areas with bad values of objective functions, by tracking previous searches using the tabu list, improving its computational efficiency (Srinivas and Rangaiah, 2007). The parameters used for the algorithm are: population size: 120, number of generations: 1250, Tabu list size 60, crossover factor: 0.8, mutation factor: 0.3 and tabu radius of 0.01. The algorithm parameters were taken from (Contreras-Zarazúa et al., 2017). Finally, the implementation of the optimization strategy involves a hybrid platform, where, the optimization algorithm is programmed in Excel and the mathematical model of the process and equation solving is in Aspen Plus.

### 3. Results

This section presents the results obtained during the design and simultaneous optimization stage of the catalytic column. In order to determine the solution with the best balance between both objective functions, the utopia point methodology was used to determine the solution, which requires the Pareto front analysis. The Pareto front of the solution is shown in Figure 2.

As can be seen in Figure 2, the range of condition numbers for the different solutions is quite wide, ranging from 11.34 to 2,500 000, indicating that the design of the column design parameters has a strong impact on the process accounting. Note the presence of a red dot in the Pareto, this dot corresponds to the solution with the best trade-off between the two objectives. Table 1 shows the comparison of the original intensified process versus the process obtained by the optimization technique.

Figure 2. Pareto front for catalytic distillation

Table 1. Design parameters for the original process and intensified process

Process variable	Original process	Optimized process
Number of stages	80	29
Ethylene feed stage	15	21
Hydrogen feed stage	59	26
Reactive stages (oligomerization)	2-29	12-16
Reactive stages (Hydrogenation)	30-59	17-25
Reflux ratio	100	51.55
Reboiler duty (kW)	170	117.642
Hydrogen mass flowrate (kg/hr)	22	20.6417
Diameter(m)	4	1.39
Condition number	915, 000	82.58
Total annual cost (USD/yr)	1,028,914	215,553

As can be seen in Table 1, the intensified process shows remarkable improvements over its original counterpart. It can be seen that the optimized process presents energy savings of 30% while the cost savings are almost 80%. As for the control properties, the optimized process has a condition number of 82.58 against 915,000 of the original process. This means that the optimized process is less sensitive to changes and disturbances. This is due

to the reactive stages and column diameters. The oligomerization and hydrogenation reactions are very sensitive to temperature changes, so having many reactive stages for these areas means that it is easier for the process to have a temperature perturbation, which dramatically affects hydrocarbon conversion. In contrast, the optimized process has determined that it is not necessary to have many reactive stages for these zones, and the optimization process has identified the optimal location of the column temperature reactive zones, thus avoiding the process to be sensitive to disturbances.

#### 4. Conclusions

In this work, the design and simultaneous optimization of a reactive distillation column for jet fuel production by the ATJ process was developed. The objective functions, total annual cost and condition number were used to evaluate the cost and control properties. The results indicate that the optimization algorithm is able to generate a design that has 30% energy savings and 80% cost savings over the original process. Also, the optimized process has a condition number of 82.58 which is a notably lower value than the original process. The results indicate that the design of a process using robust optimization techniques generates a significantly cheaper and more efficient process. Future work proposes the optimization of the conventional process and a rigorous control analysis in order to have a broader picture of the improvements of the optimized process.

# Efficient physical model building algorithm using equations extracted from documents

Shota Kato and Manabu Kano

*Department of Systems Science, Kyoto University, Yoshida-honmachi, Sakyo-ku, Kyoto 606-8501, Japan*

## Abstract

To facilitate arduous physical model building tasks, we aim to develop automated physical model builder, AutoPMoB, which automatically builds physical models from multiple documents. This study focuses on a method for building desired models from equations, a fundamental technology for realizing AutoPMoB. We defined two requirements desired models must fulfill and proposed a gradual method. The gradual method obtains combinations of input equations satisfying one requirement and then modifies the combinations to fulfill the other. For comparison, we used an exhaustive method, which obtains all possible combinations of the equations and checks whether each combination fulfills the requirements. We compared the models built by the two methods and their computational time in four cases. In all cases, both methods built models including all correct models. The gradual method and exhaustive method took  $1.0 \times 10^{-4}$  s and 30 s, respectively, to build models from 23 equations.

**Keywords:** Physical model building, Modeling algorithm, Process systems engineering.

## 1. Introduction

In the process industry, a digital twin, which is a model that mimics the behavior of a real process like a twin, is expected to yield significant benefits. Digital twins should be based on physical models derived from scientific principles rather than statistical models derived only from data since data collection through experiments under various conditions, especially abnormal ones, in the manufacturing process is difficult from cost and safety perspectives. However, the physical model building requires a deep understanding of the process and trial-and-error improvements in the model's accuracy. To facilitate the arduous task, we aim to develop automated physical model builder, AutoPMoB, which automatically builds physical models from multiple documents [Kato and Kano (2022)]. AutoPMoB 1) retrieves documents related to the target process from literature databases, 2) unifies the documents' formats, 3) extracts information vital for model building from the documents, 4) unifies the expression of the extracted information, and 5) combines the information to build physical models and presents the models with their rankings. Users of AutoPMoB decide which model to use based on the rankings.

This study focuses on how to build models by combining equations extracted from documents to perform task 5. We assume that users give input variables (IVs) and output variables (OVs) of the models. For example, when a user builds a model to predict a variable, the variable is an OV, and the other measurable variables are IVs.

The present study proposes a gradual method and uses an exhaustive method as a baseline. We compare the models built by the two methods and the required computational time.

## 2. Methods

The number of degrees of freedom (DoF)  $N_{DF}$  of a model calculating the OVs from the IVs must be equal to the number of the IVs  $N_{IV}$ . We propose a gradual method for building such desired models from a set of  $N_e$  equations  $S_e = \{e_1, \dots, e_{N_e}\}$ . Each desired model is an equation group (EG) that meets the following requirements: 1) the EG includes the IVs and OVs, and 2)  $N_{DF}$  of the EG is equal to  $N_{IV}$ . Here, the given set of IVs and that of OVs are denoted by  $S_{IV} = \{v_1, \dots, v_{N_{IV}}\}$  and  $S_{OV} = \{v'_1, \dots, v'_{N_{OV}}\}$ , respectively. Since there has not existed any method for comparison, we use an exhaustive method, which obtains all combinations of  $N_e$  equations and checks whether each combination fulfills the requirements, as a baseline.

### 2.1. Exhaustive method

The exhaustive method is shown in Algorithm 1. The method obtains all possible combinations of  $N_e$  equations (ll. 3–6) and checks whether each combination fulfills the requirements above (ll. 7–13). The total number of the combinations is

$$\sum_{n=1}^{N_e} C_n = 2^{N_e} - 1. \quad (1)$$

This method checks whether each of the  $2^{N_e} - 1$  EGs satisfies the requirements and outputs EGs that meet the requirements. The time complexity of this exhaustive method is  $O(2^{N_e})$ .

---

#### Algorithm 1: Exhaustive method for building model

---

**Input:** set of equations  $S_e = \{e_1, \dots, e_{N_e}\}$   
 set of input variables  $S_{IV} = \{v_1, \dots, v_{N_{IV}}\}$   
 set of output variables  $S_{OV} = \{v'_1, \dots, v'_{N_{OV}}\}$

**Output:** set of equation groups  $S_{EG}$

- 1:  $S_{EG} \leftarrow \emptyset$
- 2:  $S'_{EG} \leftarrow \emptyset$
- 3: **for**  $n_e = 1$  to  $N_e$  **do**
- 4:      $S''_{EG} \leftarrow n_e$  combinations of  $S_e$
- 5:     add  $S''_{EG}$  to  $S'_{EG}$
- 6: **end for**
- 7: **for**  $G'$  in  $S'_{EG}$  **do**
- 8:      $S_{v,G'} \leftarrow$  set of variables in  $G'$
- 9:      $N_{DF,G'} \leftarrow$  the number of degrees of freedom of  $G'$
- 10:     **if**  $(S_{IV} \cup S_{OV}) \subseteq S_{v,G'}$  **and**  $N_{DF,G'}$  is equal to  $N_{IV}$  **then**
- 11:         add  $G'$  to  $S_{EG}$
- 12:     **end if**
- 13: **end for**
- 14: **return**  $S_{EG}$

---

## 2.2. Gradual Method

Algorithm 2 shows the pseudocode of the gradual method. The method first obtains sets of variables contained in each formula (ll. 2–4), sets of equations containing each of the IVs and OVs (ll. 5–8), and sets of EGs that include both IVs and OVs (l. 9). Then, the method checks each of the obtained EGs,  $G'$ . If the number of DoF of  $G'$ ,  $N_{DF,G'}$ , is equal to  $N_{IV}$ ,  $G'$  is judged desired (ll. 10–13). If not, to change  $N_{DF,G'}$ , the method searches the remaining equations for the equations containing the variables that appear in  $G'$  (ll. 14–17). If such equations exist, one or more of the equations are combined with  $G'$ , and the combined EGs whose number of DoF is equal to  $N_{IV}$  are decided desired (ll. 18–24). Finally, the method outputs all the desired EGs.

---

### Algorithm 2: Gradual method for building model

---

**Input:** set of equations  $S_e = \{e_1, \dots, e_{N_e}\}$   
 set of input variables  $S_{IV} = \{v_1, \dots, v_{N_{IV}}\}$   
 set of output variables  $S_{OV} = \{v'_1, \dots, v'_{N_{OV}}\}$

**Output:** set of equation groups  $S_{EG}$

- 1:  $S_{EG} \leftarrow \emptyset$
- 2: **for**  $n = 1$  to  $N_e$  **do**
- 3:      $S_{v,e_n} \leftarrow$  set of variables in  $e_n$
- 4: **end for**
- 5:  $N_{IOV} = N_{IV} + N_{OV}$
- 6: **for**  $n = 1$  to  $N_{IOV}$  **do**
- 7:      $S_{e,v''_n} \leftarrow$  set of equations including  $v''_n$  in  $S_e$ , where  $v''_n \in (S_{IV} \cup S_{OV})$
- 8: **end for**
- 9:  $S'_{EG} \leftarrow \{\{e'_1, \dots, e'_{N_{IOV}}\} \mid e'_n \in S_{e,v''_n} \text{ for every } n \in \{1, \dots, N_{IOV}\}\}$
- 10: **for**  $G'$  in  $S'_{EG}$  **do**
- 11:      $N_{DF,G'} \leftarrow$  the number of degrees of freedom of  $G'$
- 12:     **if**  $N_{DF,G'}$  is equal to  $N_{IV}$  **then**
- 13:         add  $G'$  to  $S_{EG}$
- 14:     **else**

The time complexity of the gradual method is

$$O(N_e N_{IOV}) + O\left(\prod_{n=1}^{N_{IOV}} |S_{e,v'_n}|\right) + \sum_{i=1}^{|S'_{EG}|} O\left(\prod_{n=1}^{|S_{v,G'}(G'_i)|} |S_{e,\bar{v}_n}(G'_i)| + |S''_{EG}(G'_i)|\right), \quad (2)$$

where  $G'_i$  denotes the  $i$ th element of  $S'_{EG}$  and  $S(G'_i)$  indicates that  $S$  depends on  $G'_i$ . The first, second, and third terms indicate the time complexities at lines 1–8, 9, and 10–26, respectively. The gradual method obtains combinations focusing on IVs and OV and judges whether each combination satisfies the requirements; hence, the time complexity is smaller than the exhaustive method.

### 3. Experiments

#### 3.1. Datasets

We generated datasets consisting of  $S_e$ ,  $S_{IV}$ , and  $S_{OV}$  shown in Table 1 based on the textbook about process control [Seborg et al. (2010)] and defined correct models, which can calculate the values of the OVs by substituting values into IVs. Then, we used these  $S_e$ ,  $S_{IV}$ , and  $S_{OV}$  as the input of the model building methods and checked whether the correct models could be obtained.

#### 3.2. Results and Discussion

The model building results of the exhausted method and the gradual method are summarized in Table 2. In Case 1, the two methods obtained the same correct models. In Case 2, where equations with only variables not included in IVs and OVs exist, the gradual method built the same models as in Case 1, while the exhaustive method built 2,097,152 models, most of which were incorrect. Since adding unnecessary equations does not change the number of DoF, the exhaustive method outputs much more models than the gradual method. In Case 3, similar to Case 1, the same models were obtained by the two methods. In Case 4, similar to Case 2, the models obtained by the two methods comprised all the correct models, and the number of models built by the gradual method is less than that by the exhaustive method.

All the built models in Table 2 meet the predefined requirements, but some models, such as those built by only the exhaustive method in Case 2 and the second model in Case 3, are impractical because the values of the OVs cannot be obtained. This is because the two methods judged only the necessary conditions. To remove such impractical models and obtain only practical ones, we need to judge whether the values of OVs can be obtained. If all the equations in one model are linear, the additional check can be done using the coefficient matrix. However, built models usually include nonlinear equations, as shown in Case 3. We must develop a method for selecting practical models.

Equations (1) and (2) indicate that the gradual method can build models within a shorter time than the exhaustive method, even when the number of equations is large. In Case 2, which took the longest computational time among the four cases, the computational time of the exhaustive method was 30 s, and that of the gradual method was  $1.0 \times 10^{-4}$  s. We used MacBook Pro with an Apple M1 Max processor, 10 Cores, 64GB RAM, and macOS 13.0.1.

Table 1 Equation set, input variable (IV) set, and output variable (OV) set used in experiments.

Case	Equation set $S_e$	IV set $S_{IV}$	OV set $S_{OV}$
1	$y = x_1 + x_2$ $x_2 = 0.1$ $x_2 = 1$	$x_1$	$y$
2	$y = x_1 + x_2$ $x_2 = 0.1$ $x_2 = 1$ $a_i = i (i = 1, \dots, 20)$	$x_1$	$y$
3	$V \frac{dC_A}{dt} = v_0 C_{A0} - v_0 C_A + r_A V$ $-r_A = k C_A^n (n = 0, 1, 2)$ $k = k_0 \exp(a/T)$ $k_0 = 0.1$ $a = 10$	$v_0$ $C_{A0}$ $T$ $V$ $C_A$	$\frac{dC_A}{dt}$
4	$V \frac{dC_A}{dt} = v_0 C_{A0} - v_0 C_A + r_A V$ $-r_A = k C_A^n (n = 0, 1, 2)$ $k = k_0 \exp(a/T)$ $k_0 = 0.1$ $a = 10$ $Q = UA(T_c - T)$ $V\rho \frac{dT}{dt} = wC(T_i - T) + H_r V r_A + Q$	$v_0$ $C_{A0}$ $T$ $V$ $C_A$ $T_c$ $U$ $A$ $\rho$ $w$ $C$ $T_i$ $H_r$	$\frac{dC_A}{dt}$     $\frac{dT}{dt}$

#### 4. Conclusion

We proposed a gradual method to build desired models from equations extracted from documents. We used an exhaustive method for comparison and compared the model building results of the two methods in four cases where the equations, IVs, and OVs were generated based on the textbook about process control [Seborg et al. (2010)]. Both methods built models including all correct models in all cases. In terms of the computational time, the gradual method took  $1.0 \times 10^{-4}$  s while the exhaustive method took 30 s when the number of equations was 23. However, the models built by the two methods sometimes had unnecessary ones. We will develop a method for filtering the obtained models to only correct models in our future work.

Table 2 Model building results of exhaustive method and gradual method.

Case	Method	#built models	Examples of built models
1	Exhaustive	2	$\begin{cases} y = x_1 + x_2 \\ x_2 = 1 \end{cases} \quad \begin{cases} y = x_1 + x_2 \\ x_2 = 0.1 \end{cases}$
	Gradual	2	
2	Exhaustive	2,097,152	$\begin{cases} y = x_1 + x_2 \\ x_2 = 1 \\ a_1 = 1 \\ a_2 = 2 \end{cases}$
	Gradual	2

## Abstract

The hydroisomerisation of long-chain alkanes on bifunctional zeolite catalysts is a promising synthetic route for the sustainable production of diesel fuel derived from vegetable oils. Significant efforts have been made in literature to propose potential reaction mechanisms and materials with improved catalytic activity, but the development of a kinetic model remains a challenge due to the complexity of the reaction network. In this study a microkinetic model was initially constructed to simulate both observable and non-observable states in the reaction mechanism. Upon fitting the model against packed bed reactor experimental data, two rigorous model simplification strategies were proposed and adopted to guide reaction network reduction. In the physics-based approach the ratios of the fitted microkinetic rate constants are evaluated against a threshold to identify irreversible reactions, whereas in the mathematics-based approach an additional penalty term is introduced during microkinetic parameter estimation to penalise the number of active chemical pathways. The reaction network reduction results were similar under both strategies and provided valuable insight on the irreversibility of isomerisation, cracking and desorption reactions, as also supported by observations in literature. Finally, simplified kinetic models that are only capable of simulating observable states based on the steady-state assumption were also constructed using the two reduced reaction networks. Through comparison, it is concluded that both simplified kinetic models can yield satisfactory fitting result of the process; however, their model structures and parameter values are highly sensitive to the mechanism reduction strategy adopted. This strongly indicates the impact of different reaction network reduction strategies on kinetic model construction, and that directly building a steady-state kinetic model may not be the best approach to investigate intrinsic reaction mechanisms. The kinetic modelling and reaction network reduction frameworks proposed in this work, therefore, provide a new avenue to infer mechanistic knowledge from kinetic data in a more efficient manner than traditional steady-state approaches.

**Keywords:** Hydroisomerisation, kinetic model, reaction network reduction, catalytic reaction, intrinsic mechanisms.

## 1. Introduction

### 1.1. Background and motivation

The hydroisomerisation of *n*-alkanes found in waxy feedstock is considered a promising sustainable route for diesel synthesis. Recent research in this area has mainly focused on

novel catalyst development in an attempt to minimize the yield toward cracking by-products and improve isomerization selectivities. This sets the motivation behind microkinetic modelling approaches, which can help elucidate potential reaction mechanisms, streamline the design of catalysts with improved performance, and provide guidelines for model-based design of experiments and process optimisation (Motagamwala & Dumesic, 2021). In this work, a microkinetic modelling and reaction network simplification framework was proposed to analyse experimental data of *n*-hexadecane hydrosiomerisation and cracking over a Pd/ZSM-12 catalyst.

## 2. Methodology

### 2.1. Kinetic model construction

#### 2.1.1. Base-case reaction mechanism

To construct a microkinetic model comprising equations for the rate of change of reactants, products and intermediate species, the reaction network presented in Fig. 1 was proposed by considering the plausible elementary steps occurring at the catalyst surface.

Figure 1: Proposed reaction mechanism. *n*-C<sub>16</sub>, Mo-C<sub>16</sub> and Mul-C<sub>16</sub> refer to unbranched, monobranched and multibranched hexadecane isomers, Cracked refers to cracking by-products. Their respective carbenium ion intermediates are denoted by the subscript <sup>+</sup>, while \* represents an active site. *k<sub>i</sub>* and *k<sub>i</sub><sup>-</sup>* are the forward and reverse reaction rates of elementary step *i*, respectively.

In the classical mechanism of *n*-alkane hydrosiomerisation described by Weitkamp (2012), the unbranched alkane reactant is first adsorbed at the metallic sites of the bifunctional catalyst, where it is dehydrogenated into its corresponding *n*-alkene. The *n*-alkene intermediate is then readily protonated at the acid catalytic sites, forming a primary alkylcarbenium ion intermediate. This intermediate then undergoes successive skeletal rearrangement reactions into more stable monobranched, dibranched and tribranched isomers. The carbenium isomers desorb from the acid sites as their corresponding branched alkenes, which are then hydrogenated at the metallic sites to yield branched isomers of the starting *n*-alkane. The branched isomers may also crack due to β-scission reactions, resulting in shorter-chain alkenes and carbenium ions which can also participate in further cracking reactions.

In this study, the packed-bed reactor (PBR) experimental data lumped dibranched and tribranched isomer products into a single multibranched species. Similarly, the by-products of the cracking side-reactions were lumped into a single species for convenience. The mechanism proposed in this study was therefore modified accordingly such that it was in line with the measured states, as seen in Fig. 1. Furthermore, the fractional site coverage of surface species is not observable during practical applications, and so including all the reaction intermediates and active site balances in the kinetic analysis

would lead to non-identifiable model structures. Coonradt and Garwood (1964) suggested that if there are sufficiently high concentrations of metallic sites for hydrogenation/dehydrogenation, the alkene intermediates assume their equilibrium concentrations. This, in turn, means that the acid site-catalysed isomerisation and cracking reactions become selectivity- and rate-determining for the overall reaction (Vandegehuchte et al., 2014). Thus, the metal-catalysed surface reactions were neglected in the present study, and it was assumed that the gas-phase species directly adsorb to (or desorb from) their corresponding alkylcarbenium ion intermediates at the acidic sites. For this reason, the alkene intermediates and the metallic active site balance were not considered during kinetic model construction.

### 2.1.2. Microkinetic model construction

The microkinetic model developed in this work consists of balance equations for both the gas-phase species as well as the non-observable intermediate states in the proposed reaction network (Fig. 1). These are presented in Eq. 1(a) – Eq 1(i), where  $x_i$  refers to the mass fraction of gas-phase species  $i$ ,  $\tau$  is the weight-based spacetime (h),  $\theta_i$  is the fractional coverage of the alkylcarbenium intermediate  $i$ , the subscripts “r”, “mo”, “mul”, and “cr” refer to unbranched, monobranched, multibranched, and cracked species, respectively. Forward and backward reaction constants ( $\text{g}_c \text{ mol}^{-1} \text{ h}^{-1}$ ) of the  $j^{\text{th}}$  elementary step are denoted by  $k_j$  and  $k_j^-$ , respectively.  $c_{\theta_T}$  is the total active site concentration of the catalyst ( $\text{mol g}_c^{-1}$ ),  $\rho_b$  is the catalyst bulk density ( $\text{g}_c \text{ m}^{-3}$ ) and  $c_{r,0}$  is the initial concentration of the reactant ( $\text{mol m}^{-3}$ ). In addition, the model assumes 1:1 overall reaction stoichiometry (this is exact for the isomerisation reactions but clearly an approximation for the cracking reactions) and isothermal reactor operation, such that the total pressure of the reacting mixture can be assumed constant.

$$\frac{dx_r}{d\tau} = c_{\theta_T} \cdot (-k_1 \cdot x_r \cdot \theta_V + k_1^- \cdot \theta_r) \quad \text{Eq. 1(a)}$$

$$\frac{d\theta_r}{d\tau} = \frac{c_{r_0}}{\rho_b} \cdot [k_1 \cdot x_r \cdot \theta_V + k_2^- \cdot \theta_{Mo} - (k_1^- + k_2) \cdot \theta_r] \quad \text{Eq. 1(b)}$$

$$\frac{dx_{Mo}}{d\tau} = c_{\theta_T} \cdot (k_3 \cdot \theta_{Mo} - k_3^- \cdot x_{Mo} \cdot \theta_V) \quad \text{Eq. 1(c)}$$

$$\frac{d\theta_{Mo}}{d\tau} = \frac{c_{r_0}}{\rho_b} \cdot [k_3^- \cdot x_{Mo} \cdot \theta_V + k_2 \cdot \theta_r + k_4^- \cdot \theta_{Mul} + k_8^- \cdot \theta_{Cr} - (k_2^- + k_3 + k_4 + k_8) \cdot \theta_{Mo}] \quad \text{Eq. 1(d)}$$

$$\frac{dx_{Mul}}{d\tau} = c_{\theta_T} \cdot (k_6 \cdot \theta_{Mul} - k_6^- \cdot x_{Mul} \cdot \theta_V) \quad \text{Eq. 1(e)}$$

$$\frac{d\theta_{Mul}}{d\tau} = \frac{c_{r_0}}{\rho_b} \cdot [k_6^- \cdot x_{Mul} \cdot \theta_V + k_4 \cdot \theta_{Mo} + k_5^- \cdot \theta_{Cr} - (k_4^- + k_5 + k_6) \cdot \theta_{Mul}] \quad \text{Eq. 1(f)}$$

$$\frac{dx_{Cr}}{d\tau} = c_{\theta_T} \cdot (k_7 \cdot \theta_{Cr} - k_7^- \cdot x_{Cr} \cdot \theta_V) \quad \text{Eq. 1(g)}$$

$$\frac{d\theta_{Cr}}{d\tau} = \frac{c_{r_0}}{\rho_b} \cdot [k_7^- \cdot x_{Cr} \cdot \theta_V + k_5 \cdot \theta_{Mul} + k_8 \cdot \theta_{Mo} - (k_5^- + k_7 + k_8^-) \cdot \theta_{Cr}] \quad \text{Eq. 1(h)}$$

$$\theta_V = 1 - \theta_r - \theta_{Mo} - \theta_{Mul} - \theta_{Cr} \quad \text{Eq. 1(i)}$$

### 2.1.3. Kinetic parameter estimation

The kinetic models were fitted against the PBR data; the parameter estimation problem was formulated as a weighted least squares objective function (Eq. 4(a)), subject to nonlinear process constraints and parameter bound constraints (Eq. 4(b)):

$$\min \sum_j (x_{j,E} - x_{j,M})^T \Lambda (x_{j,E} - x_{j,M}) \quad \text{Eq. 4(a)}$$

$$\text{st. } \frac{dx}{d\tau} = f(x, \theta, k), \quad \frac{d\theta}{d\tau} = g(x, \theta, k), \quad \mathbf{k}_{lb} < \mathbf{k} < \mathbf{k}_{ub} \quad \text{Eq. 4(b)}$$

where  $\mathbf{x}_{j,E}$  and  $\mathbf{x}_{j,M}$  are the experimental and model estimates of the state variables, respectively.  $f(x, \theta, k)$  and  $g(x, \theta, k)$  refer to the kinetic model differential equations for the gas-phase and surface species, respectively.  $\mathbf{k}_{lb}$  and  $\mathbf{k}_{ub}$  are the lower and upper bounds of the optimization variables  $\mathbf{k}$ . The weighting matrix  $\Lambda$  is used to normalise the residuals. The differential process constraints were fully discretised into algebraic profiles by applying orthogonal collocation on finite elements. The arising nonlinear programming problem was then solved via interior-point optimization (IPOPT) algorithms. Both the numerical discretization and IPOPT procedures were implemented via the *Pyomo* modelling environment in *Python* programming language.

## 2.2. Reaction network simplification

### 2.2.1. Physics-based network reduction

The physics-based reduction approach aims to identify kinetically negligible reactions by comparison of the forward and backward reaction rates of each elementary step. Similar rate-based procedures have been applied in literature to automatically discriminate elementary steps in complex reaction mechanisms (Goldsmith & West, 2017). In this study, the estimated equilibrium constants were compared against an upper and lower threshold:

- If  $\frac{k_i}{k_i^-} > 10$ , then the backward reaction is negligible ( $k_i^- \approx 0$ )
- If  $\frac{k_i}{k_i} < 0.1$ , then the forward reaction is negligible ( $k_i \approx 0$ )

These thresholds have been chosen on the basis that most of the estimated rate constants in the proposed mechanism were 1 order of magnitude apart ( $10^5$ -  $10^6$ ), and that both observable and non-observable states in the kinetic model were expressed in normalised units (mass fractions and fractional surface coverages, respectively). Upon identifying negligible steps, the microkinetic model was reconstructed in accordance with the physics-reduced mechanism and subsequently fitted against experimental data.

### 2.2.2. Mathematics-based network reduction

In the mathematics-based network reduction strategy, an additional penalty term is included in the parameter estimation objective function to penalise the number of non-zero reaction rate constants:

$$\min \sum_j (\mathbf{x}_{j,E} - \mathbf{x}_{j,M})^T \Lambda (\mathbf{x}_{j,E} - \mathbf{x}_{j,M}) + \omega \sum_i \left( \frac{k_i}{k_i + 1} + \frac{k_i^-}{k_i^- + 1} \right) \quad \text{Eq. 5}$$

For non-negligible microkinetic parameters, we have  $k_i \gg 1$  and the corresponding penalty term  $\frac{k_i}{k_i + 1} \approx 1$ , whereas for negligible reactions we obtain  $\frac{k_i}{k_i + 1} \approx 0$ . This, in turn, allows for the identification of kinetically redundant reactions without the introduction of binary variables and mixed-integer programming. The penalty weight  $\omega$  must be manually tuned so the sparsity of the model does not compromise its fitting accuracy.

## 3. Results

### 3.1. Microkinetic model results

The microkinetic model for the proposed mechanism exhibited good fitting performance, with an overall mean percentage error of 6.94%; the simulated process trajectories for the Pd/ZSM-12 catalyst with 0.5 Pd wt% composition are presented in Fig. 2 below. The

estimated microkinetic constants not only allow for the simulation of the process, but also provide mechanistic insight on the underlying reaction network. For example, comparison of the estimated rate constants  $k_3 = 8.02 \times 10^5$ ,  $k_6 = 5.99 \times 10^5$  and  $k_7 = 1.45 \times 10^6$   $\text{g}_c \text{ mol}^{-1} \text{ h}^{-1}$  indicate that the monobranched and cracking intermediates are more readily desorbed to the gas-phase than their multibranched counterpart. This trend can be justified with reference to the higher diffusional energy barriers of multibranched paraffins in zeolite catalysts (Oenema et al., 2020), recalling that the desorption step involves the diffusion of an alkene intermediate from the acid sites to the metallic sites. Similarly, the estimated multibranched cracking rate constant ( $k_5 = 3.44 \times 10^6$   $\text{g}_c \text{ mol}^{-1} \text{ h}^{-1}$ ) is much larger than its desorption rate constant ( $k_6 = 5.99 \times 10^5$   $\text{g}_c \text{ mol}^{-1} \text{ h}^{-1}$ ), thus providing a mechanistic justification for the high yield towards cracking by-products and the comparatively low yield towards the multibranched hexadecane isomers. Previous microkinetic studies of *n*-alkane hydroconversion have reached similar conclusions regarding the cracking affinity of multibranched alkanes and its effect on the product distribution (Vandegehuchte et al., 2014).

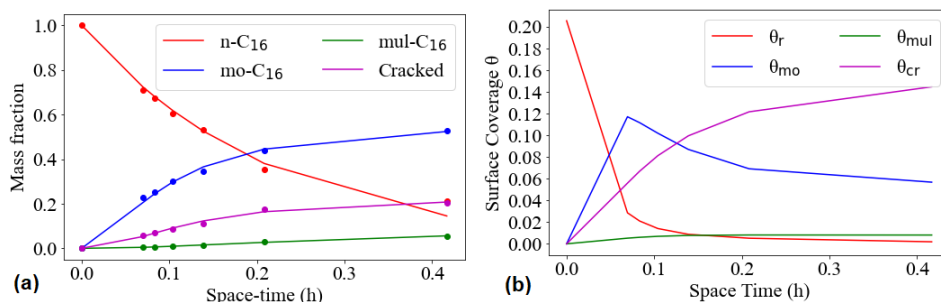

Figure 2: (a) Microkinetic model fitting results for gas-phase species profiles. Dots indicate experimental data while solid lines are model predictions; (b) Simulated coverages of surface species.

### 3.2. Reaction network simplification results

Physics- and mathematics-based network reduction analysis were conducted upon fitting the microkinetic model for the proposed mechanism; in either case five elementary steps were deemed to be irreversible, as seen in the simplified reaction networks presented in Fig. 3(a) and 3(b). The microkinetic model was also reconstructed in accordance with the simplified mechanisms, yielding fitting results (6.22% and 6.98% overall MAPE) of similar accuracy as the original model (6.15%) despite having 5 less parameters. This indicates that the neglected reactions were indeed kinetically insignificant.

Figure 3: (a) Physics-reduced reaction network, (b) mathematics-reduced network. Red arrows indicate elementary steps that have been identified as irreversible.

Both simplification approaches identified the isomerization reactions (steps 2 and 4 in Fig. 3(a) and Fig. 3(b)) as irreversible. The irreversibility of these skeletal rearrangements has been previously analysed in literature and may be attributed to operating conditions and reactant conversions far away from thermodynamic equilibrium, such that the rates of the reverse isomerization reaction are negligible (Steijns & Froment, 1981). The main dissimilarity between the two reduced networks concerns the reversibility of the two cracking reactions in the mechanism (steps 5 and 8). The relative stabilities of the alkylcarbenium intermediates suggest that the cracking products would re-alkylate more readily into the multibranched species (i.e.  $k_5^- > k_8^-$ ). This is indeed what is observed in the mathematics-reduced network ( $k_8^- = 0$ ), but not in the physics-reduced network ( $k_5^- = 0$ ). This suggests that the reduced microkinetic mechanisms identified by different model reduction strategies should be further evaluated before finally applying them.

#### 4. Conclusion

In this work, a microkinetic modelling approach was adopted to simulate observable gas-phase species and non-observable intermediate states in the proposed *n*-hexadecane hydroisomerisation network. Upon parameter estimation, the model provided accurate fitting of the packed bed reactor data and mechanistic insight was gained through evaluation of the estimated microkinetic constants. Mathematics and physics-based network reduction strategies were then applied to identify kinetically insignificant reactions in the mechanism. The microkinetic model was modified in accordance with the network reduction results, also yielding satisfactory fitting of the experimental data. This study suggests that the two proposed reaction network reduction strategies have great potentials to be applied to generic processes for reaction mechanism investigation.

## Abstract

Biorefinery plants manufacture chemicals by conversion of sustainable raw materials. Membrane separation processes are commonly used to separate cells from fermentation broths, and account for most of the operating costs of a biorefinery process. Membrane fouling can disrupt normal operation, increasing cleaning costs and process downtime (hence, overall manufacturing costs). Whereas investigating the causes of fouling through mechanistic models can be challenging in an industrial environment, information in process data historians can be leveraged through data-driven modeling. In this study, principal component analysis and feature-oriented modeling are combined to identify potential causes of fouling in a semi-continuous membrane separation process of an industrial biorefinery. This approach can effectively address batch duration variability issues, while exploiting process knowledge to enhance information on effects of fouling. Membrane age and operating temperature were found to be the major variables related to fouling.

**Keywords:** biorefinery; membrane separation processes; process understanding; feature-oriented models; data analytics

## 1. Introduction

Biorefineries are facilities that integrate biomass conversion processes and equipment to sustainably produce fuels, power, and chemicals from biomass (Martín *et al.*, 2013). Process operations typically include: media preparation, production of microorganisms, and large-scale fermentation in the upstream section; broth sterilization, cell separation, and product recovery and purification in the downstream section (Bähner *et al.*, 2021). Operating costs of downstream in biorefineries usually range between 40% and 60% of the total processing cost. Energy is the main cost, as typical downstream operations are evaporation, distillation, and, recently, membrane separation processes (Bähner *et al.*, 2021). Membranes are becoming common in biorefineries to separate cells and/or large molecules from the fermentation broth (Ables *et al.*, 2013), for examples by ultrafiltration and nanofiltration operated (semi-)continuously. Such membrane separation processes can determine the major operating cost of a biorefinery (Satam *et al.*, 2019). Pressure-driven membranes separation processes (i.e., membrane filtration) are the most

widely used, especially to remove cells from the fermentation broth. However, this operation can greatly suffer from membrane fouling, as highlighted in many studies. Ables *et al.* (2013) highlighted a permeate flux decrease in constant pressure filtration, while Klimkiewicz *et al.* (2016) recorded remarkable pressure build-up in constant flow-rate separation. The latter case is particularly relevant as, besides obvious disruption of operation and increase in cleaning costs, it also implies an increase in energy expenditure.

Mathematical modelling is a valuable tool to analyze this problem. Membrane fouling mechanisms are well known for some membrane separation processes, and models are available (Meindersma *et al.*, 1997) to help diagnosing the root-causes of fouling and support decision making to mitigate its effect. However, reliable fouling models often feature remarkable complexity and require high quality data for parameter estimation (Bolton *et al.*, 2016). Although modern biorefineries are heavily sensorized and provide a wealth of data recorded online, data usually regard the history of process operation, and might not be adequate for estimation of parameters of fouling models.

Data historians contain valuable information on process operation and can be leveraged to enhance performance (Cuellar *et al.*, 2020). To this end, data-driven models such as principal component analysis (PCA; Wold *et al.*, 1987), proved valuable when applied to membrane separation processes, as shown by Klimkiewicz *et al.* (2016) and Naessens *et al.* (2017). Applying such methods to membrane separation processes requires some extra care, mostly because of the semi-continuous nature of the process. This implies frequent process downtimes for membrane cleaning and strong variability in the duration of operating periods (runs), in the process variables within runs, and in the profiles of process variables between runs. Variable batch duration entails a lack-of-synchronization issue when process datasets are explored by data analytics.

Feature-oriented modeling (Yoon *et al.*, 2001; Rendall, 2019) offers an elegant way to address the lack-of-synchronization issue, while also emphasizing the phenomena one wants to model by properly defining features (Rendall *et al.*, 2017). In this study, knowledge-driven feature-oriented PCA (Wold *et al.*, 2009) is used to investigate the observable effects of fouling, i.e., high-pressure issues, in the membrane separation section of an industrial biorefinery process. The analysis of features summarizing time-profiles of process variables can highlight potential causes of fouling, thus paving the way for targeted experimental investigations.

## 2. Materials and methods

### 2.1. The membrane separation process

The focus of this study is membrane filtration of a fermentation broth, aimed at separating cells and large molecules from the stream containing the product. The operation is performed as a part of the downstream processing of an industrial biorefinery process where a biopolymer is manufactured. Sensible details on process and data are not disclosed for confidentiality.

The sterilized fermentation broth is accumulated in two parallel tanks, and, during operation, is fed to the first membrane module of the sequence at a constant flow-rate. Part of the retentate of each module gets discharged to the retentate manifold, while the remainder is fed to the following module. The first modules perform a standard filtration, while last ones operate in diafiltration: part of the permeate of each module is sent to the permeate manifold, and the remainder is fed back to the preceding module; water is fed to the very last one. A simplified scheme of the process and sensors is shown in Figure 1. The process runs in semi-continuous mode. The membrane modules are initially filled with water, which is displaced by the fermentation broth during the startup phase. In the

steady-state phase, the pressure on the feed/retentate side of the membranes is manipulated to keep flow-rates constant. When the feed tanks are almost empty, the flushing phase begins, and the modules are filled again with water before cleaning-in-place takes place. However, premature interruption of the process occurs frequently due to excessive pressure build-up following membrane fouling. Investigating the potential causes of this issue is the objective of this study.

Production data over a seven-month timespan are available for this investigation. Namely, online measurements from all sensors are available; offline measurements from the upstream process are available as well, to characterize the broth being processed.

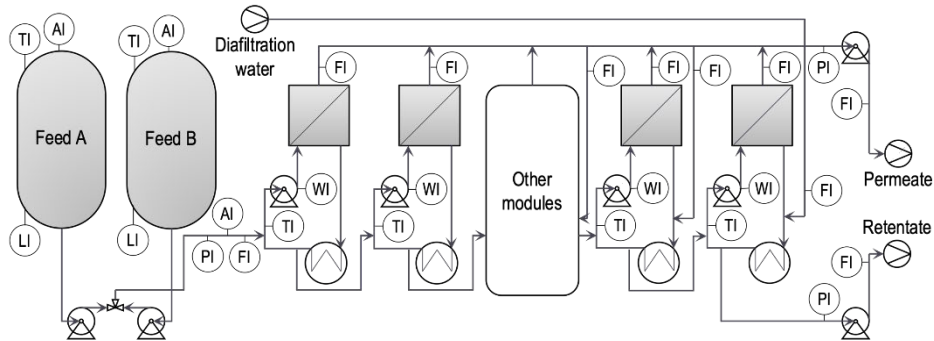

Figure 1. Simplified diagram of the membrane separation process under analysis. Analyzers on feed tanks measure pH, while the one on feed manifold measures conductivity.

## 2.2. Principal component analysis

PCA (Wold *et al.*, 1987) is a multivariate statistical method that allows extracting a sequence of orthogonal variables, called principal components (PCs), from a data matrix  $\mathbf{X} \in \mathbb{R}^N \times \mathbb{R}^V$  collecting  $N$  observations of  $V$  variables. Assuming that  $\mathbf{X}$  is mean-centered (and possibly scaled to unit variance), the PCA model is provided as a matrix decomposition in the form  $\mathbf{X} = \mathbf{T} \cdot \mathbf{P}^T + \mathbf{E}$ , where  $\mathbf{T} \in \mathbb{R}^N \times \mathbb{R}^A$  is the score matrix,  $\mathbf{P} \in \mathbb{R}^V \times \mathbb{R}^A$  is the loading matrix,  $A$  is the number of PCs of the model (to be set prior to model calibration), and  $\mathbf{E} \in \mathbb{R}^N \times \mathbb{R}^V$  is the residual matrix. The scores are projections of observations in  $\mathbf{X}$  onto the PC space and describe the relation among observations. The loadings describe the correlation among variables in  $\mathbf{X}$ , and the relation between the original space and the PC space. The columns of  $\mathbf{P}$  are set as to maximize the variance of data explained by the PCs (while respecting orthogonality constraints) and can be obtained by truncated singular value decomposition of the sample covariance matrix of data.

## 2.3. Feature-oriented modelling of membrane separation processes

PCA requires operating onto two-dimensional data arrays. However, the available data on the membrane separation process under investigation are a sequence  $\{\mathbf{X}_1, \dots, \mathbf{X}_B\}$ , where  $\mathbf{X}_b \in \mathbb{R}^{N_b} \times \mathbb{R}^V$  is a matrix collecting  $N_b$  observations of the  $V$  process variables during the  $b$ -th run of the process, with  $b = 1, 2, \dots, B$ , and  $B$  is the total number of runs (i.e., batches). To apply PCA to this process, one would need to concatenate all  $\mathbf{X}_b$  matrices as a single matrix. However, if the aim is to investigate on runs that suffered from high-pressure issues, this approach may be inadequate due to observations representing single time instants rather than entire runs. In this study, we tackle the problem by means of feature-oriented modeling (Yoon *et al.*, 2001; Rendall *et al.*, 2019). The rationale is to summarize profiles of variables into numerical indexes called features. This approach offers an elegant solution to the lack-of-synchronization issue, while also allowing to emphasize the phenomena one is interested in by properly defining features. To this end,

knowledge-driven features (Wold *et al.*, 2009; Rendall *et al.*, 2017) can be derived from time profiles, such as integrals, averages, slopes, minima, and maxima of measured variables in a run (note that all these operations are independent of  $N_b$ ). Furthermore, the available process knowledge can be used to improve such “standard” features. An example is splitting time-profiles into phases to better characterize the process (e.g., startup, steady operation, and washing). Process knowledge can also be used to design special features.

Feature synthesis can be interpreted as an operator  $\mathcal{F}: \mathbb{R}^{N_b} \times \mathbb{R}^V \rightarrow \mathbb{R}^F \mid \mathbf{X}_b \mapsto \mathbf{h}_b$ , where  $\mathbf{h}_b \in \mathbb{R}^F$  is a vector containing  $F$  features. As one vector of features is obtained from each run, a matrix  $\mathbf{H} \in \mathbb{R}^B \times \mathbb{R}^F$  is obtained, whose rows characterize single runs. Such a matrix can be analyzed by PCA for process understanding and troubleshooting purposes.

### 3. Results

After preliminary screening, data for  $B = 176$  runs were selected for analysis. Concerning data from process sensors, only the steady-state phase was used, as the startup and flushing phases usually feature excessive/unstructured variability and significant nonlinearities. Sensor measurements were first augmented with additional variables (e.g., pressure profile slope) to detect occurrence of fouling. Some engineering variables were added as performance indexes, for instance average energy consumption and volume conversion ratio (VCR, ratio of retentate flow-rate and feed flow-rate). A total of  $V = 61$  online variables was obtained. These variables, together with data from upstream process (characteristics of the broth being processed), were used to compute  $F = 179$  features for PCA analysis. Some of the most important features are collected in Table 1. Note that some features were also computed on sub-phases of the steady-state phase, whenever that seemed meaningful.

*Table 1. Examples of features extracted from profiles of online variables. Features marked with a star are encoded as binary variables.*

Average flow-rates in manifolds	Average VCR
Average feed conductivity	Energy consumed
Slope of feed conductivity	Processed volume
Max/min of pressures	Run duration
Average slope of pressures	Feed tanks average temperature
Max/min of pressure slopes	Feed tanks average pH
Average trans-membrane pressure	Concentration of cells in the feed
Average flow-rates of module permeates	Concentration of organic acids in the feed
Average temperatures of modules	Concentration of ions in the feed
Durations of pump steps	Concentration of product in the feed
Average pump power over steps	Contamination of upstream fermenter*
Pressure features computed over pump steps	Chemicals used in cleaning*

A preliminary PCA model including all variables featured limited interpretability. Therefore, a stepwise approach was adopted. Features were first grouped in subsets according to their “origin”, such as upstream, cleaning, single modules. The most important subset is the one of global features characterizing the membrane filtration, which are basically the ones regarding manifolds: flow-rates, pressures, and performance indexes. A first PCA model is developed on global features alone. Pressure-related features were identified as the main drivers of variability (first PC), as expected; the second source of variability (second PC) regards average flow-rates and some of the performance indexes, among which VCR. The explained variances of the other PCs were far lower than the

ones of the first two, and loadings appeared to model random variability. Therefore, the features modelled by the first two PCs were selected as the reference set of features; cell concentration in the feed was added to this set, as it was expected to be an important factor for fouling. A PCA model developed on these selected features proved to properly identify runs that suffered from high pressure issues, which are separated from the bulk of the runs in the score plot reported in Figure 2 (triangles).

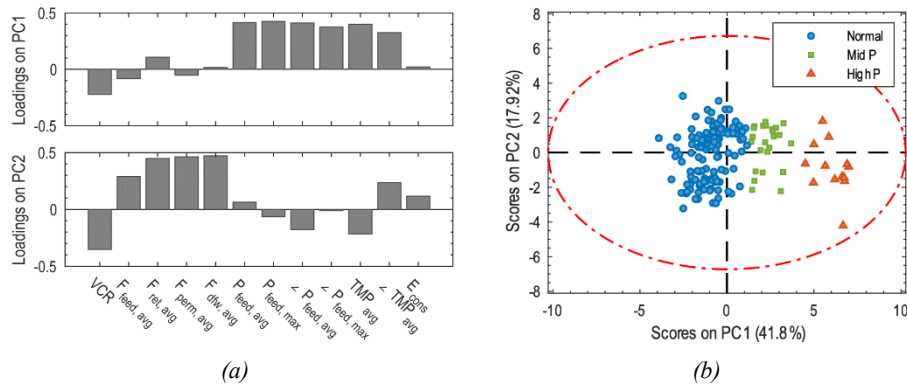

Figure 2. (a) Loadings and (b) scores of the PCA model developed on the set of global features. Runs suffering from high pressure clearly group along PC1.

More features were then added to the data matrix for PCA modelling, in a group-by-group fashion, to assess the occurrence of correlation with the pressure-related features. When such a correlation was found and was physically meaningful, newly added features correlating with pressure were regarded as potential causes of fouling.

The most important factor for high pressure issues was found to be membrane age. This is highlighted by features regarding permeates of single modules, which are proxies for membrane age (i.e., permeate flux decreases run after run). The second most important factor was found to be temperature: more precisely, runs featuring a high temperature of flows entering membrane modules suffered from high-pressures more frequently than runs with low inlet temperature. Such conclusions were verified by targeted analysis of raw data (see Figure 3) and make engineering sense. Therefore, they were deemed as potential causes of fouling, and are currently being verified by designed experiments.

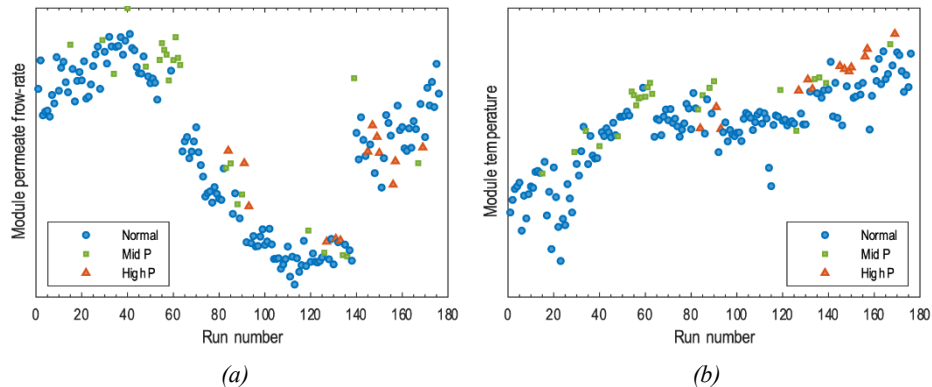

Figure 3. (a) Average permeate flow-rate and (b) temperature of a selected module. Pressure issues are more frequent for old membranes (flow-rate is a proxy for membrane age) and when modules operate at high temperature.

#### 4. Conclusions

Interpretable data-driven models are valuable tools to investigate issues in membrane separation processes, such as membrane fouling, relying solely on data collected during process operation. This study proved how principal component analysis can identify potential causes of fouling by analysis of data concerning the observable effect of this complex phenomenon, namely, pressure increase in membrane filtration. A feature-oriented approach was adopted: instead of using process data directly, numerical values characterizing each operating period were obtained so as to summarize time profiles into time-independent numerical features. This allowed addressing issues (e.g. lack of synchronization and uneven batch duration) that can complicate the use of other approaches. Process knowledge was exploited to design features that enhanced the phenomenon under investigation, thus maximizing the dataset information content and enhancing interpretability with respect to other methods. Incorporation of process knowledge into the data analysis workflow proved essential to identify potential causes of fouling, which are currently being verified by targeted experimental studies.

## Abstract

The design of the vinyl acetate purification process requires modelling the vapor-liquid-liquid equilibrium (VLLE) of the mixture vinyl acetate/acetic acid/water. In this work, the equilibrium of the system is represented through the gamma-phi formulation using the Hayden O'Connell (HOC) model for the vapor phase and the universal quasi-chemical (UNIQUAC) model for the liquid phases. The parameters for the model are estimated through optimization tools, using the BARON global optimization algorithm. The objective function to be minimized was the least-squares function. The results show a good correlation for the LLE and VLE of vinyl acetate with water with errors less than 2%. In the case of the VLE equilibrium of water with acetic acid the error is close to 5% with a larger deviation at acid mole fractions above 0.4. The parameters determined allow a proper modeling of the VLLE for the analyzed mixture.

**Keywords:** Binary interaction parameters, vapor-liquid-liquid equilibrium, deterministic optimization

## 1. Introduction

Vinyl acetate is one of the most widely produced chemicals in the world. It is used in the production of polyvinyl acetate and polyvinyl alcohol. At present, the main route for vinyl acetate synthesis is via the acetoxylation reaction of ethylene in the presence of oxygen and palladium catalysts. During the vinyl acetate synthesis process, the mixture vinyl acetate/acetic acid/water is generated; this mixture is commonly separated by distillation. Over the last few years, several authors have conducted research related to the improvement of the vinyl acetate process focusing on both the design and control areas, with particular emphasis on the purification of the mixture. Nevertheless, the mixture presents two liquid phases, which may difficult the separation. On the last years, authors such as Li et al. (2022) and Xie et al. (2020) point to the use of intensified separation operations such as extractive distillation or azeotropic distillation to achieve the purification task.

The vinyl acetate purification by intensified processes involves modelling the VLLE of the mixture. However, this implies that the binary interaction parameters of the equilibrium models must properly predict both vapor-liquid equilibrium (VLE) and liquid-liquid equilibrium (LLE). Unfortunately, the currently available binary interaction parameters accurately describing the VLE show inaccurate predictions for the LLE, and vice versa. The data fitting of these models for the representation of vapor-liquid-liquid equilibrium is a complex task with a high probability for the solution to get stuck in a local optimum. Some authors propose global optimization strategies based on minimization of squares to solve this problem (e.g., Wyczesany, 2014). Therefore, in the present work, a least-squares optimization was performed using the BARON global optimization algorithm to obtain the binary interaction parameters that properly represent VLE and LLE for the mixture vinyl acetate/acetic acid/water.

## 2. Methodology

For mixtures with carboxylic acids, as is the case due to the presence of acetic acid, the HOC model describes the behavior quite well since the carboxylic acid interacts with itself or with other compounds in vapor phase due to dimerization. In addition to this model, the NRTL or UNIQUAC models proposed by Hsieh et al. (2008) are often used for this type of mixtures due to the presence of non-ideal solutions. Thus, in this work, the UNIQUAC-HOC combination has been used.

The Gamma-Phi approach is used to model the vapor-liquid equilibrium, as represented in equation 1.

$$\phi_i^V y_i P = x_i \gamma_i \phi_i^S P_i^S \quad (1)$$

Where the left-hand terms are the vapor phase fugacity of the component, the mole fraction of the component in vapor phase, and the pressure. On the right-hand side the terms appearing are the liquid phase mole fraction, the activity coefficient, the saturation fugacity, and the saturation pressure, all for the respective component  $i$ .

For the calculations of the vapor phase, the relationship between the apparent fugacity coefficients and the real fugacity coefficients is used, as well as the true mole fraction of the vapor phase, based on the chemical theory that also complements and uses the equation of state HOC, equation 2.

$$\phi_i^V y_i = z_i \phi_i^\# \quad (2)$$

Equation 2 corrects for the deviation generated due to dimer formation. In this case it is used because acetic acid has a predominance in dimer formation.

The Gamma-Gamma representation has been used for the liquid-liquid equilibrium, this is shown in equation 3, where the upper indices refer to each of the liquid phases.

$$x_i^I \gamma_i^I = x_i^{II} \gamma_i^{II} \quad (3)$$

The binary interaction parameters of the UNIQUAC model are represented with an independent and a temperature-dependent parameter (equation 4).

$$\tau_{ij} = \exp\left(a_{ij} + \frac{b_{ij}}{T}\right) \quad (4)$$

For the correction of the binary interaction parameters, the experimental data reported by Shanghai College Chemical Engineering (1976) and Zhang et al. (2011) has been used for the liquid-vapor equilibrium modeling. Complementarily, the data reported by Gao et al. (2017) has been employed for the liquid-liquid equilibrium correlation.

The least squares ratio for the experimental and the estimated data is established as the objective function, equation 5.

$$F = \sum_{i=1}^{N_{LLE}} \sum_{j=1}^{N_C} \sum_{k=1}^2 (x_{e_{k,j,i}} - x_{t_{k,j,i}})^2 + \sum_{i=1}^{N_{VLE}} \sum_{j=1}^{N_C} (y_{e_{j,i}} - x_{t_{j,i}})^2 + \sum_{i=1}^{N_{VLE}} (T_{e_i} - x_{t_i})^2 \quad (5)$$

The objective function refers to the number of experimental points reported ( $i$ ), the number of components ( $j$ ) and the number of phases ( $k$ ), organic and aqueous.

The model was run through the GAMS interface using the Global BARON optimization algorithm created by Sahinidis (1996) through the NEOS server, Hosted by the Wisconsin Institute for Discovery at the University of Wisconsin in Madison.

### 3. Results and Discussion

Based on the experimental data reported by Shanghai College Chemical Engineering (1976), Zhang et al. (2011) and Gao et al. (2017), and the adjustment of the interaction parameters, the following results have been obtained.

#### 3.1. LLE Vinyl Acetate/Acetic Acid/Water

As shown in Figure 1, favorable results have been obtained with respect to the liquid-liquid equilibrium of the mixture. The curve fit with the model is very close to the data reported by Gao et al. (2017), as observed from the deviation data shown in Table 1.

Fig 1. LLE for the ternary system vinyl acetate/ acetic acid / water: (red) experimental data at 298.15 K, (blue) estimated values.

Table 1. Deviation of the liquid-liquid equilibrium of the Vinyl Acetate (1) / Acetic Acid (2)/ Water (3) mixture at 298 K y 1 atm.

### 3.2. VLE Vinyl Acetate/Acetic Acid

A good correlation has been obtained between the model and the experimental data for the mixture of vinyl acetate with acetic acid (Figure 2), obtaining an adequate prediction, as shown in Table 2 in terms of the deviations.

### 3.3. VLE Acetic Acid/Water

The fit between the model and the experimental data in Figure 3 is good. However, the results presented in Figures 1 and 2 present a better fit to the data. The higher the acetic acid composition, the larger the deviation. The error with respect to the experimental points is detailed in Table 3. Finally, the computed parameters are presented in Table 4.

Table 4. UNIQUAC binary interaction parameters of the Vinyl Acetate (1) / Acetic Acid (2)/ Water (3) mixture.

		$A_{IJ}$	$B_{IJ}$	$A_{JI}$	$B_{JI}$
(1)	(2)	-4.118	936.916	-0.554	416.761
(1)	(3)	-10.000	2469.161	7.513	-2500.000
(2)	(3)	5.724	-2500.000	-3.855	1675.908

#### 4. Conclusions

The results of the methodology employed show that the UNIQUAC equation, combined with the HOC equation of state, can properly describe the LLE and VLE of the ternary mixture vinyl acetate/acetic acid/water with adequate accuracy if the parameters are simultaneously fitted for both equilibria. The VLE of acetic acid with water has a higher deviation, up to  $3.13 \times 10^{-2}$  for the vapor composition of acetic acid. Nevertheless, the parameters obtained allow to adequately represent the ELLV of the evaluated mixture. This data will be useful for the simulation and analysis of intensified processes for the separation of the mixture vinyl acetate/acetic acid/water in the vinyl acetate production process.

## Abstract

The LES-SGS simulations of a three-dimensional multiphase flow in an industrial preneutralizer reactor is performed, and the Multiple Reference Frame (MRF) approach is used. The effectiveness of the three SGS turbulent closures (Smagorinsky–Lilly model, Wall Adapting Local Eddy Viscosity (WALE) model, and the Algebraic Wall Modeled LES (WMLES) model) to predict the flow hydrodynamics and to capture the eddies near to high turbulent zones (in liquid injection point and in the turbine rotation zone) is assessed. The results show that the SGS model has a significant impact not only on the instantaneous flow field, but also on the time-average velocity magnitude, therefore the hydrodynamics of unsteady behaviour in turbulent chemical reactors is found to be significantly influenced by the choice of the SGS closure model.

**Keywords:** CFD, LES- SGS, turbulence model, hydrodynamics, multiphase flow

## 1. Introduction

In the phosphate industry, Di–Ammonium Phosphate (DAP) is considered to be a very efficient chemical fertilizers that is used to provide the required nutrients to the plants and soil. The DAP manufacturing processes begin with a preneutralizer reactor that consists of the production of homogeneous slurry produced by mixing the Ammonia gas and Phosphoric acid (ACP), under specific conditions. The preneutralizer reactor is a non-standard stirred tank reactor, equipped with a pitched blades turbine agitator that (i) promotes mass and heat transfer, (ii) reduces foaming, and (iii) improves ammonia dispersion in the liquid phase. This unit operation represents the masterpiece that conducts the physicochemical phenomenon called "preneutralization" chemical reaction (Elmisaoui et al., 2020).

The reaction between ammonia and ACP in the reactor leads to MAP or DAP depending on the ratio of N (Nitrogen) and P (Phosphorus) ratio N/P. Other species are formed but in small quantities in such a way that they do not significantly affect the total nitrogen or P<sub>2</sub>O<sub>5</sub> in the final product (Campbell et al., 2006). When the ratio N/P is greater than unity,

the produced MAP in the first reaction is converted to DAP in the second one (Campbell et al., 2006). The overall reactions are listed as follows

These reactions occur immediately after Ammonia gas  $\text{NH}_3$  and ACP( $\text{H}_3\text{PO}_4$ ) are mixed. Produced slurry feeds the granulator, to be sprayed onto the granular fertilizer bed existing in the granulator, and granule growth occurs. Granules leaving the granulator are first dried and then screened to separate out the product size.

For the CFD modeling studies of multiphase flows in stirred reactors, different turbulence models have been developed to predict the hydrodynamics of the flow, each one of them demonstrating its effectiveness and robustness in each particular application (Derksen, 2001). The age-old CFD modeling method based on the Reynolds Averaged Navier-Stokes (RANS) approach is still considered the most employed turbulence modeling approach due to its acceptable accuracy and affordable computational cost for predicting the hydrodynamics involving complex geometries, but with the development of the HPC capabilities, the employment of the hybrid Detached Eddy Simulation (DES) model, which blends the RANS approach with LES finds its applications. The DES methodology shows its increasing potential and accuracy in flow prediction more than the RANS models. Especially for its informative ability to predict the flow regimes in the moving zone characterizing the impeller rotation. This work aims at evaluating the performance of three main Large-Eddy Simulation (LES) subgrid-scale (SGS) turbulence models in a stirred reactor.

## 2. Physical model of the preneutralizer

In this study, numerical simulations have been carried out using the workbench of the CFD commercial software ANSYS Fluent 2021-R2. The physical model tailored in this work is based on the actual size of a preneutralization chemical reactor (PN) with a working volume of  $47 \text{ m}^3$  to ensure throughput of around  $120 \text{ m}^3/\text{hr}$ . The ACP is injected from the top, and eight uniform Ammonia inlet nozzles are arranged in the bottom, which are 3m away from it. The rotational agitator is equipped with a Pitch Blade Turbine (PBT), consisting of four impellers slanted with an angle of  $45^\circ$  from the horizontal plane. Detailed characteristics of the CAD file (cf. Fig. 1) are based on the original preneutralizer geometry and are previously described in Elmisaoui et al. (2022).

Figure 1: Mesh grid of the simulation domain, with zoom in shaft axis and gas spargers

### 3. Mathematical modeling and numerical schemes

LES comes in between the Direct Numerical Simulation (DNS) and the Reynolds Averaged Navier-Stokes (RANS) approaches in terms of turbulent scale resolution. Large eddies are directly resolved in LES, whereas small eddies are modeled. The time-dependent Navier-Stokes equations are filtered. The space-filtered equations for the conservation of mass and momentum of an incompressible Newtonian fluid can be written as:

$$\begin{cases} \frac{\partial \bar{u}_i}{\partial x_i} = 0 & (2a) \\ \frac{\partial \bar{u}_i}{\partial t} + \bar{u}_i \frac{\partial \bar{u}_j}{\partial x_i} = -\frac{\partial \bar{P}}{\partial x_i} + \nu \frac{\partial^2 \bar{u}_i}{\partial x_j^2} - \frac{\partial \tau_{ij}}{\partial x_j} & (2b) \\ \tau_{ij} = \bar{u}_i \bar{u}_j - \bar{u}_i \bar{u}_j & (2c) \end{cases}$$

where  $\tau_{ij}$  is the sub-grid scale stress tensor, which reflects the effect of the unresolved scales on the resolved scales. Subgrid-scale stresses resulting from the filtering operation are unknown, and require modeling. The subgrid-scale turbulence models employ the Boussinesq hypothesis as in the RANS models, computing subgrid-scale turbulent stresses from:

$$\tau_{ij} = \frac{1}{3} \tau_{kk} \delta_{ij} - 2\mu_t \bar{S}_{ij} \quad (3)$$

Three SGS turbulence models are considered in this work:

- Smagorinsky-Lilly model
 
$$\mu_t = \rho L_s^2 |\bar{S}| \quad (4)$$
- Wall Adapting Local Eddy Viscosity (WALE) model

$$\mu_t = \rho L_s^2 \frac{(s_{ij}^d s_{ij}^d)^{3/2}}{(s_{ij}^d s_{ij}^d)^{5/2} + (s_{ij}^d s_{ij}^d)^{5/4}} \quad (5)$$

- Algebraic Wall-Modeled LES Model

$$\mu_t = \rho m [(\kappa d_{\text{wall}})^2, (C_k \Delta)^2] \cdot S \cdot \{1 - \exp(-(y^+ / 25))\} \quad (6)$$

where  $d_{\text{wall}}$  is the wall distance,  $S$  is the strain rate,  $\kappa = 0.41$ , and  $C_k = 0.2$  are constants.

To consider chemical species transport, the previous system of equations is coupled to the species transport equation, as described in Elmisaoui et al. (2022).

### 3.1 Numerical simulation conditions

As previously stated in many CFD simulations of stirred reactors, a variety approaches may be used to cope with the movement of the impeller blades. The Multiple Reference Frame (MRF) approach was employed in this investigation Elmisaoui et al. (2022), and the SIMPLE algorithm was employed for pressure-velocity coupling.

### 3.1 Computational domain

The computational domain grid is composed of two parts: an inner spinning cylindrical volume holding the turbine and an outer, stationary volume containing the remainder of the tank. In both portions, structured grids of non-uniformly distributed hexahedral cells are utilized. To provide a more precise description of the impeller, the grid employed in the impeller region is refined. In the tank, there are a total of 970997 grid nodes.

It is worth noting that a grid-dependency study is carried out using ANSYS Mesher to evaluate mesh suitability for the present configuration. A three-dimensional mesh grid of the computational domain is discretized into unstructured cells with specific refined zones (cf. Fig. 1). Three mesh featuring grids are generated and defined as coarse, medium, and fine meshes, respectively. Refinements are carried out in the shaft region, near to the nozzles, at the inlets, and at the outlet of the domain, allowing for a minimum and maximum mesh size of 25 mm and 15 mm for the medium mesh grid. The last refinement level is retained based on a mesh grid sensitivity, as the grid allows for an accurate numerical solution at acceptable time costs.

## 4. Results and analysis

To evaluate the flow hydrodynamics in a three-dimensional multiphase turbulent flow, the identification of coherent structures is crucial, which allows a better understanding of the real space dynamics of turbulent flows. One of the most commonly used methods for categorizing three-dimensional flow structures is the Q-criterion proposed by Hunt et al. (1988). It is defined in terms of the instantaneous velocity gradient tensor as:

$$\mathbf{Q} = \mathbf{1}/2((\nabla \cdot \mathbf{u})^2 - \nabla \mathbf{u} : \nabla \mathbf{u}^T) = \mathbf{1}/2((\nabla \cdot \mathbf{u})^2 + \|\boldsymbol{\Omega}\|_2^2 - \|\mathbf{S}\|_2^2) \quad (7)$$

Here,  $S$  is the strain rate tensor and  $\Omega$  is the rotation rate tensor. The turbulence associated with the flow through the inlet and across the stirred reactor is visualized at two different instants  $t = 100$  s and  $t = 190$  s in Figs. 2 and 3. As can be noted for the three SGS-

models and as the flow is introduced from the nozzles into the tank, it is clear to have higher velocities near the inlet pipes. In addition, there is a velocity difference between the nozzle stream and the rotating flow in the tank, which creates local shear zones. As a consequence, inlet nozzles become the inherent turbulence generators. The intensity of the generated turbulence is less pronounced in the classical Smagorinsky model, while it seems to be more pronounced in the WALE and WMLES models.

Figure 2: Turbulence structures for (left to right) Smagorinsky–Lilly model, WALE model, and WMLES model, respectively at  $t = 100$  s

Furthermore, for the latter models, the instantaneous flow seems to be characterized by nearly concentric streamlines in a circular fluid motion, which is due to tangential inflow. The resulting vortex column around the central outlet structure is wrapped by the external turbulent filaments, leading to intensive momentum transport.

Figure 3: Turbulence structures for (left to right) Smagorinsky–Lilly model, WALE model and WMLES model, respectively at  $t = 190$  s

Figure 5 presents the profiles of instantaneous magnitude velocities in two locations of the domain (denoted by P1 and P2 in Fig. 4).

Figure 4: Axial projection plan in the middle of the domain

As a considerable throughput of liquid is injected near to position P2, a high velocity peak is observed in a short time. Then, as the mixing gets enhanced, the velocity decreases gradually until  $t = 150$  s and a considerable flow amount of Ammonia gas achieves the top of the domain. This explains the emergence of new turbulent eddies in the P2 location.

LES models were able to capture the generated eddies coming from the liquid injection and from the mixing zone. WALE model gives higher values of the velocity magnitude than WMLES and Smagorinsky-Lilly models.

Figure 5: (a) & (b) Temporal evolution of velocity magnitude profiles in probes P1 and P2, respectively

However, based on the P2 probe position near to the shaft wall, the WALE is more appreciated to be used for near to the wall turbulence eddies prediction. As shown in Fig. 5b, the predicted velocity magnitude profiles fastly increase in the rotation zone (P2 probe). Strong eddies are developed by mixing, and interesting redistribution of the reactants is ensured by the circulation loop, which amplifies the magnitude of velocity. The occurrence of the gas flow from the nozzles with a considerable injection velocity considerably enhances the eddies and amplifies the circulation loops. The Smagorinsky-

Lilly model seems to capture the flow hydrodynamics with a good precision compared to WMLES and WALE models.

## **5. Conclusion**

In this paper, the large eddy simulation method based on an Eulerian–Eulerian CFD model is used to simulate hydrodynamics of the gas–liquid reacting flow in the preneutralizer stirred reactor. The liquid and gas phase flow fields in the stirred tank simulated by the LES approach are more asymmetric in the case of WMLES and WALE models. Overall, each of the three models has its own specific ability for the flow prediction. However, the choice of an LES Turbulence model should be done carefully, for a good physical flow prediction.

## Abstract

Perovskite solar cells (PSCs) are the most exciting third-generation PV technology, which has shown an unprecedented increase in power conversion efficiencies from < 4% to > 25% in just over a decade. However, most of the research results indicating efficiencies of more than 20% are based on spin coating techniques with small cells with an active area < 20mm<sup>2</sup>. With efficiency already been on par with established silicon solar cells, there is a need to upscale the technology to production scale and parallelly work on other facets of the technology like stability and toxicity. Among such techniques for mass production of PSCs is well-established inkjet printing, which has been explored to achieve PSC printing and can be used with various substrates and solvents. However, there is not much effort in modelling the inkjet printing process and understanding the impacts of different decision variables related to the process. Here, this article presents a mechanistic model to achieve perovskite printing (or entire stack of layers) using this technique and analyzing the influence of solvent selection and process parameters on film characteristic.

**Keywords:** Perovskite solar cells, inkjet printing, fabrication techniques, modelling.

## 1. Introduction

Inkjet printing is an attractive technology not only for research level but also for scaling the perovskite solar cells fabrication because of low cost, high production throughput and high material efficiency. Further, the non-contact nature of printing helps in depositing solutions on variety of materials. The technique has been discussed in literature with focus on droplet formation mechanism, travel to substrate and droplet interaction with substrate (Derby, 2010; Kang et al., 2020; Soltman and Subramanian, 2008). However, most of the studies in simulation regime were based on computational fluid dynamics which is time-consuming and resource intensive (Tofan et al., 2021; van der Bos et al., 2014) with less focus on process dynamics of the process. With the ever-increasing applications of inkjet printing in printable energy technologies like organic solar cells, polymer solar cells, fuel cells, energy storage devices, etc., it is important to understand the effect of different variables involved in the process on the final film quality.

Perovskite solar cells have shown unparalleled improvement in their efficiency over the last decade and have reached the levels of the established Si cells. Solution-based deposition methods have shown better results compared to their vacuum-based counterparts not only in efficiency but also provides cost effective, easily controllable, and scalable solutions. Among these solution-based deposition methods, inkjet printing

has gained significant interest in the community where drop-by-drop printing leads to complete formation of film with control over droplet spacing and morphology via solvent engineering (Yang et al., 2022). The power conversion efficiency (PCE) of inkjet-printed devices has risen from 11.6% (Wei et al., 2014) to 21.6% (Abzieher et al., 2019) since its first application. Moreover, many researchers have also shown the complete fabrication of PSCs except the transparent conducting oxide layer using inkjet printing technique which shows the potential of complete fabrication of perovskite solar cells based on inkjet printing (Gao et al., 2021). However, the dynamics of inkjet printing is more complex as compared to other solution-based techniques like spin-coating (0-D) or slot-die coating (1-D) processes. Therefore, it is crucial to understand the influence of different parameters on the inkjet printing process to obtain homogeneous liquid films and to control the morphology of the final dry film (Huckaba et al. 2019, Mathies et al., 2016).

## 2. Model Description

The entire process of inkjet printing can be divided into four stages:

### 2.1. Droplet generation

Inkjet printing technique can be used only with certain solvents or solutions depending on the solution properties and is governed by coating window which can be represented in terms on non-dimensional numbers Eq. 1-3 (Derby, 2010).

$$0.1 \leq Oh (= 1/Z) \leq 1; \quad Oh\text{-Ohnesorge number} \dots \dots \dots \text{Eq. 1}$$

$$We > 4; \quad We\text{-Weber number} \dots \dots \dots \text{Eq. 2}$$

$$We^{1/2} Re^{1/4} \leq 50; \quad Re\text{-Reynolds number} \dots \dots \dots \text{Eq. 3}$$

### 2.2. Droplet travel to substrate

Once the drop is generated and leaves the nozzle, the set of differential equations describing the system in second stage include Eq. 4-7 where  $C_D$  is based on Kunii and Levenspiel(1991), velocity,  $v$  is based on Sloth(2007) and  $k_m$  is mass transfer coefficient.

$$\frac{dv}{dt} = \left(1 - \frac{\rho_a}{\rho_d}\right) g - \frac{C_D \rho_a v^2 \pi r_d^2}{2m_d} + \frac{F_t}{m_d}; \quad C_D\text{-Drag coefficient, } m_d\text{:drop mass} \dots \dots \dots \text{Eq. 4}$$

$$\frac{dm_{\text{solvent}}}{dt} = \left(-k_m 4\pi r_d^2 \frac{M_{\text{solvent}} P_{\text{amb}}}{RT_{\text{avg}}}\right) (y_{v,\text{surface}} - y_{v,\text{amb}}); y_{v,\text{mole fraction in vapor}} \text{Eq. 5}$$

$$\frac{dr_d}{dt} = \frac{1}{4\pi r_d^2 \rho_{\text{solvent}}} \frac{dm_{\text{solvent}}}{dt}; \quad r_d\text{-droplet radius, } t\text{-time, } \rho\text{-density} \dots \dots \dots \text{Eq. 6}$$

$$\frac{dT_d}{dt} = \frac{h_c [4\pi r_d^2 (T_{\text{amb}} - T_d)] + \Delta H_v \frac{dm_{\text{solvent}}}{dt}}{m_{\text{solute}} c_{p,\text{solute}} + m_{\text{solvent}} c_{p,\text{solvent}}}; \quad T\text{-temperature, } h_c\text{-heat transfer coefficient} \dots \dots \text{Eq. 7}$$

The thermophoretic force component,  $F_t$  is a dominant force especially close to the surface when the temperature of substrate is very high (Filipovic et al., 2013).

### 2.3. Droplet impingement and positioning

Based on Stringer and Derby (2010), once the droplet reaches the surface, the equilibrium diameter of the droplet ( $D_{\text{eq,d}}$ ) can be expressed in terms of diameter of droplet at impingement and the equilibrium contact angle ( $\theta_{\text{eqb}}$ ). For stable line formation without any defects like waviness or bulging, criteria for maximum and minimum droplet spacing is used. Further, width of the bead is deduced based on Stringer and Derby (2010). Afterwards, the line formed is assumed to be a flat rectangle with height depending on the width and total volume of the bead from initial state of flat cylinder for single droplet.

### 2.4. Film formation

The system of differential equations for tracking the solution parameters during line/film stages can be expressed as given in Eq. 8-10 where  $\Delta H_v$  is enthalpy of vaporization.

$$\frac{dm_{\text{solvent}}}{dt} = \left[ -k_m(A_{\text{eff}}) \frac{M_{\text{solvent}} P_{\text{amb}}}{RT_{\text{avg}}} \right] (y_{v,\text{surface}} - y_{v,\text{amb}}); A_{\text{eff}} \text{ -mass transfer area...Eq. 8}$$

$$\frac{dH_{\text{bead}}}{dt} = \frac{1}{A_{\text{eff}} \rho_{\text{solvent}}} \frac{dm_{\text{solvent}}}{dt}; H_{\text{bead}} \text{ -bead height, } A_{\text{eff}} \text{ -heat transfer area from substrate.Eq. 9}$$

$$\frac{dT_{\text{bead}}}{dt} = \frac{h_c[A_{\text{eff}}(T_{\text{amb}} - T_{\text{bead}})] + \Delta H_v \frac{dm_{\text{solvent}}}{dt} + \frac{A_{\text{eff}}(T_{\text{subs}} - T_{\text{bead}})(\kappa_{\text{sol}})}{H_{\text{bead}}/2}}{m_{\text{solute}}c_{p,\text{solute}} + m_{\text{solvent}}c_{p,\text{solvent}}}; \kappa \text{ -thermal cond.. Eq. 10}$$

The total time of the deposition process,  $t_{\text{dp}}$  can be calculated based on Eq. 11-12.

$$t_{\text{dp}} = \frac{\text{cell}_{x\text{-dim}} \text{cell}_{y\text{-dim}} \text{dpi}_{\text{target-y}}}{v_{\text{ph}} \text{dpi}_{\text{native}} \text{width}_{\text{ph}}}; \text{cell}_{x\text{-dim}}, \text{cell}_{y\text{-dim}} \text{ -x and y-dimension of cell.....Eq. 11}$$

$$v_{\text{ph}} = \frac{25.4 f_{\text{DOD}}}{1000 \text{dpi}_{\text{target-x}}}; v_{\text{ph}} \text{ -printhead velocity, } f_{\text{DOD}} \text{ -drop ejection frequency .....Eq. 12}$$

During film formation stage, line width ( $W_{\text{line}}$ ) during multiple repetition ( $N_{\text{rep-y}}$ ) is based on the lateral spacing (based on  $1/\text{dpi}_{\text{target-y}}$ ), equilibrium diameter of droplet and initial line width ( $W_{\text{ini-line}}$ ) (Eq. 13). When merging of line happens, the width ( $W_{\text{rem-bead}}$ ) and length ( $L_{\text{rem-bead}}$ ) of the new bead is expressed based on Eq. 14-15.

$$W_{\text{line}} = \frac{W_{\text{ini-line}}}{2} + \max\left(\frac{W_{\text{ini-line}}}{2}, (N_{\text{rep-y}} - 1) * \frac{0.0254}{\text{dpi}_{\text{target-y}}} + \frac{D_{\text{eq,d}}}{2}\right) \dots \dots \dots \text{Eq. 13}$$

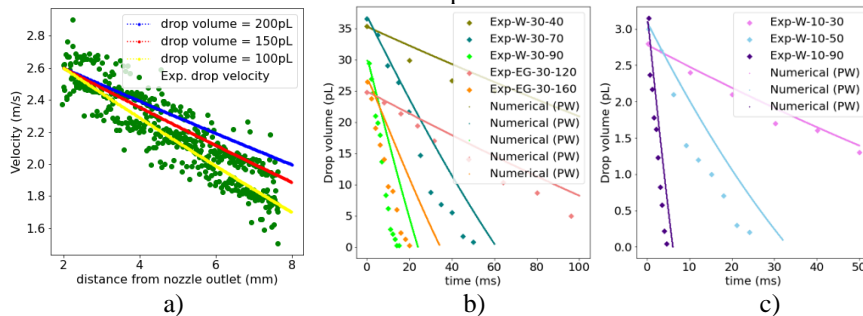

$$L_{\text{rem-bead}} = N_d * D_{\text{eq,d}} - (N_d - 1) * \frac{0.0254}{\text{dpi}_{\text{target-x}}}; N_d \text{ -number of drops deposited....Eq. 14}$$

$$W_{\text{rem-bead}} = \frac{0.0254}{\text{dpi}_{\text{native}}} - W_{\text{line}}; \text{dpi}_{\text{native}} \text{ - nozzles per inch.....Eq. 15}$$

### 3. Results

#### 3.1. Validation

In this section, model is validated based on existing experimental data before extending it to elucidate film formation dynamics. Figure 1 a) shows the droplet velocity as a function of distance from nozzle which lies in the range of data collected by Kang et al. (2020). Further, Figure 1 b) and c) shows the evolution of droplet volume based on present model and comparison with experimental results obtained by Lim et al. (2009) which shows very good agreement in all range of initial droplet volume and substrate temperature with water (W) and ethylene glycol (EG) as solvents. Since, the analytical expression for equilibrium droplet diameter and first bead/line width were directly used, they are not validated here. With these validation results, the model can be used for further understanding of the process dynamics involved in the inkjet printing process including line formation and film formation and the impact of different decision variables.

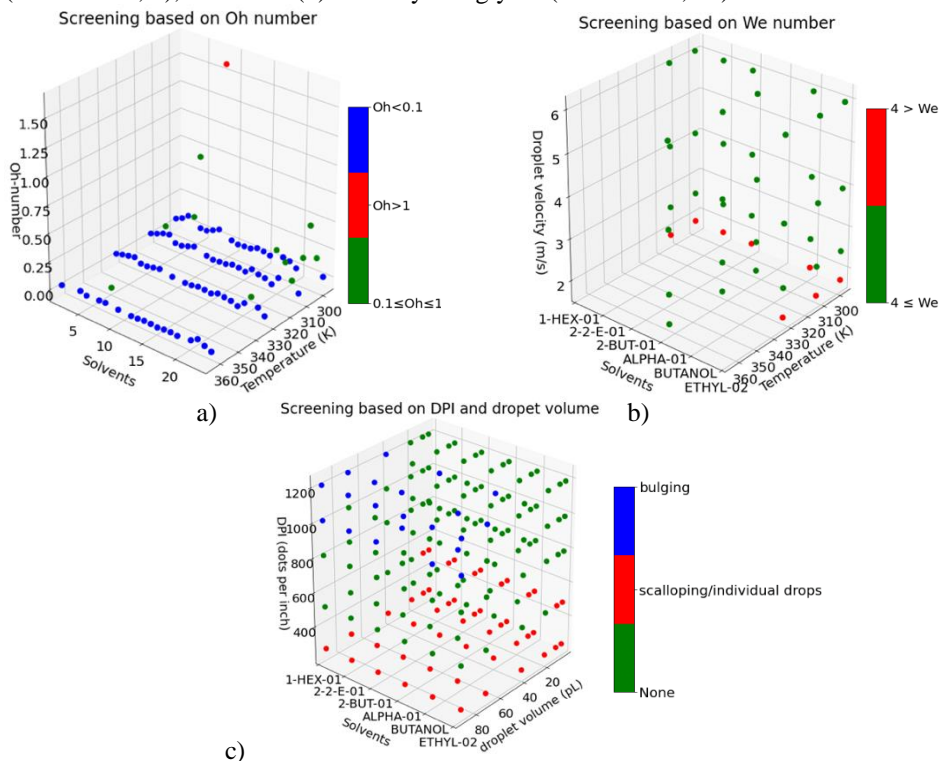

**Figure 1:** Validation results for a) droplet velocity, and b) and c) droplet volume during evaporation on substrate (PW-present work)

#### 3.2. Screening decision variables space

In the first part, the screening of parameter space based on coating window available for the process can be investigated. The result shows that out of 84000 cases only 12600 fall

within the coating window. Further, with constraints on the size of droplets with respect to nozzle and boiling point of solvents only 6480 cases remain feasible. Finally, with constraints on minimum spacing and maximum spacing between droplets only 4568 cases remain feasible for the inkjet printing process. Out of the 24 solvents commonly used in perovskite layer deposition, only 6 solvents have required properties with the given parameters selected for the analysis which include hexanol (1-HEX-01, 23), 2-2-ethoxyethoxy-ethanol (2-2-E-01, 21), 2-butoxyethanol (2-BUT-01, 17), alpha terpineol (ALPHA-01, 9), n-butanol (4) and ethylene glycol (ETHYL-02, 22).

**Figure 2:** Screening results based on a) Oh-number b) We number and c) line defects. Ethanol (2) and IPA (3) are on the edges of the applicability window. Further DMSO (14), DMF (13), gamma-butyrolactone (15), o/m-Dichlorobenzene (24, 10) and NMP (19) are also lying close to the edges of the application window at low temperature. Other solvents used include water (1), chlorobenzene (5), methanol (6), 2-methoxyethanol (7), propanol (8), acetone (11), toluene (12), Methyl-phenyl-ether (16), tetrahydronaphthalene (18) and acetonitrile (20). Ambient conditions are 25°C and 40% RH.

**Figure 3:** Influence of solvent properties a) within and b) outside coating window

3.3. Effect of solvent ( $T_{subs}=55^{\circ}C$ ,  $DPI=847$ ,  $LPI=635$ ,  $\theta_{eqb} = 1^{\circ}$ ,  $V_d=10pL$ ,  $f_{DOD}=5000$ )

Figure 3 shows the influence of different solvents on the wet film characteristics. IPA shows maximum change (>20%) in mass fraction over printing time (<100 ms). However, the solvents lying within the coating window don't show more than 5% change in the mass fraction over time with maximum change shown by Butanol. Therefore, mixing solvents with different properties can be used to influence the final film characteristics.

3.4. Effect of substrate temperature ( $T_{subs}$ )

Figure 4 shows the effect of substrate temperature on film properties with Dimethyl-sulfoxide (DMSO) as solvent (for all remaining cases). The effect of temperature becomes more dominant at high temperature resulting in >10% difference in film height with progressive increase in mass fraction of solute. Here, the maximum temperature cannot be more than boiling point of solvent to avoid pin-hole formation in the deposited film.

Figure 4: Influence of substrate temperature on a) mass fraction and b) film height

3.5. Effect of Target DPI ( $dpi_{target-x}$ ) ( $LPI=51$ )

Figure 5 shows the effect of DPI (dots per inch, relates to spacing in direction of printing) for DMSO at substrate temperature of  $55^{\circ}C$ . Depending on the frequency the total time for printing changes with dpi. With increase in DPI, the total time increases, however, the change in mass fraction is very less. Further, with increase in DPI, film height increase as more droplets are deposited on the same area of substrate. With increase in dpi, the morphology of wet film changes from individual lines (from different nozzles) to merged film as closer droplets leads to broader lines which become greater than nozzle spacing.

Figure 5: Influence of target DPI on a) mass fraction b) film height and c) film width

3.6. Effect of Target LPI ( $DPI=254$ )

In this subsection, influence of droplet spacing in lateral direction (lines per inch, lpi or  $dpi_{target-y}$ ) is shown. With LPI increase, total time of process increases resulting in more solution deposited on the same area thus leading to thicker wet films. Further, change in mass fraction decreases and time for film formation increase with increase in LPI(Fig. 6).

4. Conclusions

Here a mechanistic model for inkjet printing is presented which can be used to understand the impact of different decision variables involved in the process of inkjet printing.

**Figure 6:** Influence of target LPI on a) mass fraction b) film height and c) film width

Screening solvents based on existing literature should be done with more lenient conditions. Most of the solvents show similar behavior during the printing process except a few which have high vapor pressure. Substrate temperature can have significant impact of final mass fraction of film. DPI and LPI have direct influence on the film thickness, processing time and film morphology with less impact on change in mass fraction.

## Abstract

Spatial dimension planning of an energy system is critical at an urban scale due to the strong spatial heterogeneity of load levels and categories at different spots of a city and the high complexity of pipeline networks extension and connection topology. External requirements of low-carbon transition of a city may make its urban energy systems planning further complicated. In this paper we propose a novel urban energy systems spatial planning modeling and optimization approach considering energy systems form and topology. Coupling with integrated energy systems modeling and multiple energy pipeline networks topology modeling, the processes of energy generation, conversion, storage, and transmission are depicted synthetically. A case area is employed to illustrate feasibility of proposed method and the impacts of both low-carbon transition and user side participation in energy production on urban energy systems optimal layout. Results show that main energy supply technology shifts and corresponding networks topology changes significantly under the requirement of decarbonization and energy supply mode revolution. Decarbonization and participation of user side in power generation reduce the average network capacity by 19% and 26% respectively, indicating a more interconnected energy network with low capacity to balance energy between areas is a preferred form for a low-carbon city.

**Keywords:** urban energy systems; systems modeling and optimization; network topology; low carbon transition.

## 1. Introduction

An urban energy system consists of a variety of energy generating units and interconnected pipeline networks of multiple energy categories, including electricity, heat, or cold, thus has great potential to integrate multiple types of energy. However, the high complexity of such a system also brings great challenges to its planning. Moreover, urban areas are the main places of various kinds of social activities, in which might lead to massive carbon emissions and various environmental problems. It is expected more than 70% of the population will live in cities in 2050 (C40 Cites, 2017), and a considerable part of emissions may come from energy production and utilization. Therefore, it is of great importance to carry out low-carbon oriented urban energy systems planning, especially under the new trend of decarbonization and renewable energy utilization (Stoeglehner et al, 2016).

Currently, a series of urban energy related researches exist. One mainstream of concern is urban emissions measurement and analysis based on emissions inventory (Kennedy et al, 2010) and index decomposition method such as LMDI (Gu et al, 2019), IPAT and improved STRIPAT (Wang et al, 2017), to quantify the impact of various social and economic indicators on carbon emissions. Another group of scholars apply commercial software, for example LEAP (Huang et al, 2019), MARKAL (Isi et al, 2021) and Energy PLAN (Thellufsen et al, 2020), to implement simulation and designing for a low-carbon energy system. However, most of these studies are similar to decarbonization researches at a national scale (Sun et al, 2019), which generally apply lumped parameter method and regard objective into a whole, mainly discuss the impacts of relevant indicators change on carbon emissions. Spatial dimension, the most unique and vital aspect at a city scale, is neglected and heterogeneities and correlations within a city are thus not considered enough. Conversely, existing studies on urban space mainly focus on land use planning (Penazzi et al, 2019) and various location problems (Bélanger et al, 2019), where concerns of low-carbon oriented revolution of urban energy systems are absent. As a result, the purpose of this study is to investigate the impacts of decarbonization as well as energy supply revolution represented by user side participation in energy supply on the optimal urban energy systems form and layout, aiming at facilitating spatial planning of low-carbon oriented urban energy systems.

## 2. Methodology

### 2.1. Overview of model structure

The aim of this study is to explore the impacts of decarbonization and low-carbon revolution on urban energy systems form and layout. Therefore, an urban energy systems spatial planning model is proposed, as illustrated in Figure 1.

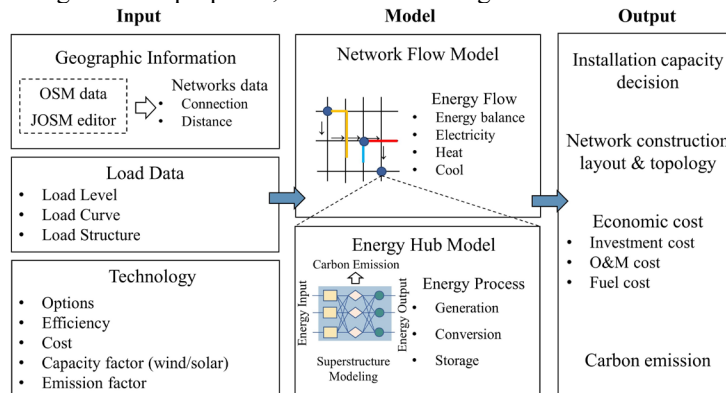

Figure 1 Model framework

Geographic information is derived from OpenStreetMap (OSM, 2022), a widely-used open-source map platform, and edited by Java OpenStreetMap (JOSM, 2022). Load data are used for depicting various energy demand and techno-economics parameters are applied for energy facilities modeling.

The core of the proposed model consists of two sub-models, namely the Network Flow Model and the Energy Hub Model. The purpose of the Network Flow Model is to characterize energy transmission in the energy network and energy balance at each node. The Energy Hub Model aims to establish a mathematical model for real energy facilities installed at energy hub nodes based on superstructure modeling method.

The planning goals are (a) which energy hub nodes should be selected, (b) which technologies and how much capacity to install in hubs, and (c) how to lay the energy pipe networks properly to satisfied all load nodes demand with minimum cost. By solving this problem, optimal installation decision, energy networks arrangement, detailed cost and carbon emissions can be obtained.

## 2.2. Mathematical formulation

### 2.2.1. Objective function

The optimization objective is to minimize the overall energy systems costs, including investment costs of technologies  $cost_{tech}$  and networks  $cost_{net}$ , operation and maintenance costs  $cost_{om}$  and fuel costs  $cost_{fuel}$ . The proportion coefficient of  $cost_{om}$  refers to literature (Xu et al., 2020).

$$cost_{total} = cost_{tech} + cost_{net} + cost_{om} + cost_{fuel} \quad (1)$$

$$cost_{tech} = \sum_{tech,node} CAPEX_{tech} \cdot ic_{node} \cdot \frac{r(1+r)^T}{(1+r)^{T-1}} \quad (2)$$

$$cost_{net} = \sum_{tdn,road_{id}} DISTANCE_{road_{id}} \cdot (C_0 + C_{1tdn}) \cdot icn_{tdn,road_{id}} \cdot \frac{r(1+r)^T}{(1+r)^{T-1}} \quad (3)$$

$$cost_{fuel} = \sum_{fuel,node_{hub}} FP_{fuel} \cdot \sum eimp_{node_{hub},s,dh,f} \quad (4)$$

$$cost_{om} = coefficient \cdot cost_{tech} \quad (5)$$

### 2.2.2. Network flow modeling

Expression (6) and (7) describe the upper limit of flow and energy balance of the energy flow in network.

$$-icn_{tdn,road_{id}} \leq flow_{road_{id},s,dh,e,tdn} \leq icn_{tdn,road_{id}} \quad (6)$$

$$\sum flow_{in,node} - \sum flow_{out,node} = \begin{cases} LOAD_{node}, & \text{if node} \in \text{load nodes} \\ 0 & \text{if node} \in \text{road nodes} \\ -output_{node_{hub},s,dh,e} & \text{if node} \in \text{hub nodes} \end{cases} \quad (7)$$

### 2.2.3. Energy hub modeling

Nine types of electricity generation technologies are considered, including Super-critical Pulverized Coal (SPC), Ultra-Supercritical Pulverized Coal (UPC), Combined-cycle Gas Turbine (CCGT), Biomass power plant (BE) and options of the above technologies with CCS. Solar Photovoltaic (PV) is selected as the option of renewable technologies. Besides, six types of heat and cool generation/conversion technologies, namely Biomass Power Plant Combined Heat and Power (BE\_CHP), Combined-cycle Gas Turbine Combined Heat and Power (CCGT\_CHP), Gas Boiler (GB) and Air-source Heat Pump (ASHP), Air-conditioner (AC), Absorption chiller (ABS\_CHILLER), and three kinds of energy storage technologies including Battery (BATTERY), Sensible Thermal Energy Storage (STES) and Ice Storage (ICES) are involved. Key expressions of energy generation, conversion and storage processes are presented in (8) to (11).

$$eimp_{node_{hub},s,dh,e} = \sum_{gnt} ei_{gnt,node_{hub},gnt,s,dh,e} \quad (8)$$

$$\sum_e ei_{gnt,node_{hub},gnt,s,dh,e} \times eff_{gnt,ee} = eo_{gnt,node_{hub},gnt,s,dh,e} \quad (9)$$

$$est_{node_{hub},stt,s,dh+1,e} = est_{node_{hub},stt,s,dh,e} \times (1 - LOSS_{STT}) - \frac{eo_{stt,node_{hub},stt,s,dh,e}}{eff_{stt,ee}} + ei_{stt,node_{hub},stt,s,dh,e} \quad (10)$$

$$\begin{aligned} output_{node_{hub},s,dh,e} = & \sum_{gnt} e_{gnt} e_{node_{hub},gnt,s,dh,e} + \\ & \sum_{cvt} e_{cvt} e_{node_{hub},cvt,s,dh,e} + \sum_{stt} e_{stt} e_{node_{hub},stt,s,dh,e} - \sum_{cvt} e_{cvt} e_{node_{hub},cvt,s,dh,e} - \sum_{stt} e_{stt} e_{node_{hub},stt,s,dh,e} \end{aligned} \quad (11)$$

### 2.2.4. Carbon emissions constrain

Emissions constrain is shown in (12), namely net emissions should be limited by quota. Specially, when quota is set as zero, it means carbon neutralization scenario.

$$\sum (e_{imp} e_{node_{hub},s,dh,f} - e_{ccs,node_{hub},gnt,s,dh,f} \cdot 0.9) \cdot CEI_f \cdot DAY_s \leq QUOTA \quad (12)$$

Eventually, the model proposed above is built in General Algebraic Modelling System (GAMS, 2022) platform and solved via applying built-in CPLEX solver.

## 3. Case study

### 3.1. Area information and scenarios setting

A case area commonly used in several literatures (Chen et al., 2018; Xu et al., 2020) is applied in this study. As shown in Figure 2, case area is consisted of 205 nodes, including 20 load nodes colored in orange triangle, representing points where energy demands exist, and 8 candidate energy hub nodes in red square meaning where energy facilities can be constructed, and 345 roads consist of existing roads in solid line and candidate in dotted line. All energy pipes are limited to build along roads. Basic load data and road distance are derived from literature (Xu et al., 2020). In this study the load data are further split into hourly scale via load profiles from a widely-used energy system planning software HOMER (NREL, 2022) to reflect the characteristics and changes of different categories of loads including residential, industry, and commerce, as shown in Figure 3.

Figure 2 Networks of case area

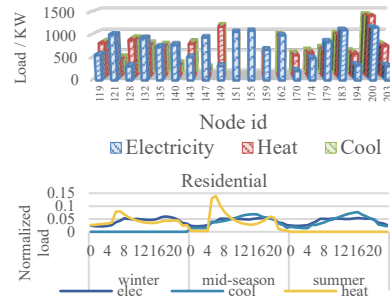

Figure 3 Load level and hourly-profile

To investigate the impacts of decarbonization on urban energy systems planning, three scenarios are set according to emissions constraint and energy supply mode, as shown in Table 1. **NC** is a reference scenario with no emissions constrain and follows the current mainstream idea of centralized energy supply, which means energy supply equipment except AC can only be installed in the energy hub. **DC-1** is a low-carbon scenario with the requirement of carbon neutralization but stays in traditional centralized energy supply mode, to illustrate the impacts of carbon neutralization. **DC-2** further indicates that distributed PVs are approved to be constructed at user side, namely load nodes and users play the role of both energy consumers and producers, which is an expected form of energy systems revolution in the process of decarbonization.

Table 1 Scenario setting and explanations

Scenario	Explanation
NC	No carbon emissions constrain; Centralized energy supply
DC-1	Decarbonization with carbon neutralization; Centralized energy supply
DC-2	Decarbonization with carbon neutralization; User side distributed PV available

3.2. Impacts of decarbonization on urban energy systems planning

3.2.1. Major energy technologies shifting

The choices of energy hubs in three scenarios are consistent, almost all candidate hub nodes are selected except node 205. However, the technology installing decisions are different as shown in figure 4 and figure 5. In DC-1, the capacity of PVs grows while UPC and ASHP descends markedly, and more types of technologies such as BE\_CHP and ABS\_CHILLER are used. The installed technologies at user side in these two scenarios are limited in AC only since scenarios setting. In DC-2 scenario, however, it can be found a considerable number of PVs are installed at the user side, and both batteries and thermal storage equipment are installed.

Figure 4 Installed capacity of energy hub

Figure 5 Installed capacity of user side

3.2.2. Energy networks topology

Figure 6 displays the electricity network and heat network topology between scenarios. Red, yellow, and blue nodes represent hub nodes, load nodes and road nodes respectively. Linkages between nodes mean where energy networks are constructed. It should be noticed that these topology diagrams only indicate the topological relationships, namely the connections between nodes, instead of real spatial direction and distance. Nodes unselected are not shown in diagrams.

Figure 6 Electricity network (6a-6c) and heat network (6d-6f) topology

In detail, electricity network in NC scenario consists of two independent subnets. By comparison, the network exists as a whole and is more complex with six rings in DC-1. This is because abundant PVs are constructed under the constraints of carbon neutralization, which implies the mismatch between load and energy supply will be more severe due to the inherent volatility of renewable energy. Therefore, a more interconnected supply network is needed to balance the energy between nodes. And in DC-2 scenario, with the participation of user side distributed PVs, the number of latent energy supply nodes and the requirement for load-supply matching increase, explaining further complications on the network topology. Table 2 summarizes specific results of networks. It can be found that the results of total capacity in NC and DC-1 are almost the same, while the number of pipe lines increase 23%. Comparing DC-1 and DC-2, the number of lines is almost identical while total capacity decreases by 24%. A similar trend can be observed in heat network. However, the structure of heat network is more concise and its average capacity is approximately twice that of the electricity network.

Table 2 Energy networks capacity

Unit: MW	EN capacity	Number of lines	Average capacity	HN capacity	Number of lines	Average capacity
NC	128.3139	90	1.42571	235.1022	75	3.134695
DC-1	128.4098	111	1.156845	235.6052	89	2.64725
DC-2	97.06535	113	0.858985	188.0379	95	1.979346

#### 4. Conclusions

Under the targets of decarbonization and energy systems revolution, the decision making and spatial layout of urban energy systems will change significantly. Results indicate that a dispatching and balancing oriented network with more complex topology and lower average line capacity is needed for the requirements of decarbonization and user side participation in energy supply, instead of a transmission-oriented net that carries energy from centralized plants to load nodes.

## Abstract

In a highly competitive retail market, many microbreweries have attempted to maximise profits and decrease energy consumption through retrofitting their operations with renewable energy. This paper develops an optimisation model to minimise investment and operation costs of a microbrewery meeting the dynamic energy demands, via an integrated photovoltaic (PV) system with energy storage and different boiler choices to lower carbon emissions. A microbrewery in UK has been used for the case study to demonstrate the approach on real data, with challenges in implementation and real-world constraints and considerations discussed. A set of rigorous multi-objective optimisation and sensitivity analyses are performed to analyse the resulting system. For the particular brewery, a modern electric boiler combined with photovoltaic system is an economic and sustainable choice, due to the cooling and other electric requirements in the brewery, leading to a 33 percent reduction in operational costs with a payback time of 2.6 years.

**Keywords:** microbrewery operation, optimisation model, PV system, sustainable.

## 1. Introduction

Beer is a popular alcoholic drink throughout the world. Global beer consumption reached approximately 177.50 million kiloliters in 2020, equivalent to 537.9 billion 33 cl bottles (Kirin Holdings, 2022). The UK is ranked 8<sup>th</sup> with 60.2 liters beer consumption per-capita. In the past two decades, environmental concerns and increasing energy cost have impacted companies and beer consumers. The new challenges for the brewing industry related to energy efficiency, water consumption, emission management and waste generation, have attracted great attention from breweries. Beer production is an energy intensive process, and the energy demand is approximately 262 MJ/hL (59% thermal, 41% electrical) (Fadare et al., 2010). Compared with large breweries, microbreweries consume up to 1.5-2.0 times more for thermal and electric energy (Kubule et al., 2016). In 2020, the number of active microbreweries in the UK was 1,852, with a steady increasing trend (Statista, 2022). Approximately 8% of the production cost is used in thermal processes like boiling, cooling, and fermentation (Kubule et al., 2016). Local microbreweries are trying to find a way to reduce energy consumption. Breweries have considered sustainability and lowering carbon footprints in their processes, seeking the strategies to minimise emissions and impact on the environment. Shifting load to a lower tariffs period is potential saving in other industries, but not suitable for microbrewery because the load demand is non-deferrable. Renewable energy sources and energy storage system can offer a solution for reducing the operation costs. Muster-Slawitsch et al.(2011) have analysed the use of different renewable sources, and identified solar energy as the best option to support the brewery industry.

The studies of solar sources for the brewery are focused on large size of breweries (Eiholzer *et al.*, 2017). Pino *et al.*(2019) used two case studies in Spain to model the integration of a hybrid PV system into thermal and electricity generation system. The simulation results showed that solar sources have potential benefits in microbreweries with payback period of 10.7 years. Another energy-related case study is based on a microbrewery in South Africa(Kusakana, 2020). A grid-connected tracking PV system and a battery were integrated into the microbrewery, and the payback period is 13.8 years based on simulation results. Very few published studies focused on the onsite small-scale PV panels electricity generation, and they have not looked at the application in the UK. Given the popularity of microbreweries and needs to reduce energy costs, this paper develops an optimisation model to minimise investment and operation costs of a microbrewery meeting the dynamic energy demands, via an integrated PV system with energy storage and different boiler choices to lower carbon emissions. A microbrewery in UK has been used for the case study to demonstrate the approach on real data, with challenges in implementation and real-world constraints and considerations discussed. The thermal and electricity load profile of the brewing process has been collected in summertime and, based on the collected data, the dynamic energy demand profiles for brewing days has been characterised. After an initial analysis, the number of PV panels, installation and type of the battery, and type of boiler are used as decision variables in model. A set of rigorous multi-objective optimisation and sensitivity analyses are performed to analyse the resulting system. The proposed optimisation model and hybrid system can be used in industrial, residential, or other demand sectors to reduce their operational energy costs through a detailed multi-objective analysis and sensitivity study.

## 2. Case study description

The case study for the model is a microbrewery called Langham Brewery located at 50°59'N,0°41'W, which regularly produces six types of craft beers. Langham is a typical, small-scale British microbrewery. Electricity is provided from Scottish Power for the cooling process, and thermal processes use a steam boiler fueled by Furnace Flame. The brewery has a capacity of producing one batch of 1,650 L of beer four times per week. Therefore, the yearly demand is assumed at an average of 208 brewing days. Additionally, the cold storage and the fermentation chamber run as the baseload throughout the year.

The load demand has been recorded in a summer day in July 2022. The first brewing day is the most energy intensive one, with the different processes shown in Figure 1 where the brewery's load demand is the highest. During the night, from 18h30 to 6h30 next day, the baseload is assumed at 4.4 kW including boiler (turned on, but not producing steam and on standby), cold storage and fermentation chamber. Starting at 6h30 to 7h15, the 2.9kW boiler and 0.65 kW pump begin to work and prepare for the mashing process. The temperature of hot water in the hot liquor tank (HLT) is 77°C and 700 L of hot water is discharged into an insulated mash tank (mixer). Malted barley and specialty grains are conveyed into the mash tank. The mashing stage starts from 7h15 to 8h30, boiler and pump are kept on during this stage reheating water in HLT for the next process. After mashing, the temperature of mixture is 66.3°C.

At 8h30, the sparging process begins. In this process, 1,950 L hot water from the HLT is added to the mash tank over a period of about 100 min. Simultaneously, using a 0.65 kW pump, the dissolved sugars in the water (wort) extracted from the grain husks is slowly drained from the bottom and pumped into a boiler where the hops are added to the mixture (wort). The mixture is heated for an hour. At the end of the sparging process, the temperature of the mixture is 90°C. From 11h00 to 12h00, the mixture is heated from

90°C to 100°C, preparing for boiling. The boiling process starts from 12h00 to 13h00. After 15 min rest, the mixture is cooled by cold water (5°C) via heat exchanger to reach 20°C, desirable for the required fermentation. The whole preparation process ends at 18h30 after pumping the mixture into fermentation tanks and finishing the cleaning process. The beer wort is moved to the fermentation which constitutes the 4.4 kW base load together with the cold storage.

Based on our data collection, the daily operation cost including electricity and fuel costs on a brewing day is approx. £158. This value excludes maintenance costs. The daily CO<sub>2</sub> emission is 0.35 tonnes per brewing day (ScottishPower, 2022).

### 3. Methodology

After analysing Figure 1, it can be noticed that most of the peak power demand is occurring during the day, matching the solar irradiance profile. The implementation of a PV system can be of great advantage in maximising the electrical energy that can be generated from the panels while minimising the cost and amount of energy acquired from the grid. A battery storage system can be added to the supply system to store some energy during excess generation times and can also be used in the event the PV system cannot supply the demand. This will also increase the availability of energy supply as well as provide an opportunity of applying demand response strategies through optimal power dispatch. This section will describe the proposed system's operation modeling; the selected size and the basis of the economic analysis to be performed.

#### 3.1. Optimal energy management model of the grid-connected PV system

The overall objective of this model is to minimize the total cost in the whole lifetime:

$$f = \min (C_{Operation} + C_{Investment}) = (\sum_{S=1,2,3,4} C_S^{grid} - I_S) * \text{Lifetime} + \sum_{Unit} AC_{Unit} \quad (1)$$

where  $AC_{Unit}$  is the capital cost of the equipment including PV panels, battery, and boilers;  $C_S^{grid}$  is the seasonal cost of buying electricity from the grid;  $I_S$  is the seasonal income from selling electricity to the grid. There are two choices of the boiler, one is a gas boiler, and the other is an electric boiler. The satisfaction of electricity demand  $P_{t,c}^{load}$  is described as below:

$$\sum_c P_{t,c}^{load} = P_t^{grid} + P_t^{PV} + P_t^{BAT} \quad (2)$$

where  $P_t^{grid}$  is the power got from the grid to satisfy the loads. If it is positive, electricity is bought from grid to satisfy the load; if it is negative, electricity is sold back to main distribution.  $P_t^{PV}$  is the amount of power generated by the PV that is used to satisfy the demand, and  $P_t^{BAT}$  is the amount of power used by the batteries. If it is positive, the battery is discharging; if it is negative, the battery charges. Note that indices  $t \in T$ ,  $c \in C$  refer to the timestep and boiler type. Similarly, the heat demand is satisfied by the heat generated (note that heat storage or heating networks are not included in the model).

The total power generated by the PVs, is described below:

$$P_t^{PV} \leq N^{Panel} * P_{PV} \quad (3)$$

where  $N^{Panel}$  is the number of panels installed (an integer variable) and needs to be decided,  $P_{PV}$  is the power generated each panel.

The model also ensures that electricity is not bought from or sold to the grid at the same time by the addition of the big-M constraints, which are similar to the constraints on the battery's charging or discharging status. The type of the boiler installed is limited by a binary variable  $K_c$ , constrained as follows:

$$\sum_c K_c = 1 \quad (4)$$

For proper operation, each power source must not be operated above its rated or maximum limit according to the manufacturer's specifications. The state variable also has boundaries where the minimum depends on the type of battery used.

#### 4. Optimisation results

All the constraints in the optimisation model are linear with integer variables. The optimisation problem are solved using cbc (Forrest & Lougee-Heimer, 2005) solver from Julia JuMP (Dunning et al., 2017) optimisation toolbox. Simulations are performed to assess the effectiveness of the developed grid-connected system optimal operation model to minimise the daily energy cost of power purchased from the grid. The simulations reported in the sections below explain the system's behavior for a brewing day in four seasons with different boundaries on investment, which means disposable investment is gradually decreasing. The maximum number of PV panels is 1000. The upper boundary of investment is £500,000.

##### 4.1. Different payback periods

We did not consider the maintenance costs for equipment, and there is no limit on the investment cost. In Figure 2, the relationships among daily operation cost, capacity of PV panels and payback period is shown. Under sufficient investment, the model chooses to install an electric boiler under all the payback periods. If the payback period is lower than 5 years, the brewery should only install an electric boiler, with no battery or PV panels. When the payback period is more than 5 years, with the installation of PV panels, operation costs decrease. To invest in an electric boiler, the operation cost will drop from approximately £158 per day to £102.6 per day, with an investment assumed to be £27,255, yielding a payback period of 2.6 years. This will also yield a CO<sub>2</sub> emissions reduction from the boiler system of 62 % and an overall business emissions reduction of 21 %.

Figure 1 Brewing day electricity demand profile.

Figure 2 The relationships among daily operation cost, payback period, and capacity of PV panels.

The installation of PV panels has a great Impact on the daily operation cost of brewing days, especially in spring and summer, because the solar irradiance value is relatively high in these two seasons. The daily costs will decrease with longer payback periods especially 8-13 years if we have enough investment budget to install more PV panels. When the payback period is higher than 17 years, the operation costs are negative.

#### 4.2. Different gas price and investment cost

To analyse whether gas boilers are ever considered, the payback period was set to 10 years gas prices from 4 to 40 p/kWh were simulated. When the price of natural gas is lower than 18 p/kWh, the model chooses to install a gas boiler not an electric one. Compared with the gas boiler, the CO<sub>2</sub> emissions can be reduced more than 50% through electrification. If the Smart Export Guarantee can increase the export price 20% (from 5p to 6p), carbon emissions can be reduced by 28%, though the overall cost is only reduced by 2%.

We also analyse the simulation results under different investment cost constraints, and the results are shown in Figure 3. Even under different investment conditions, the model always chooses an electric boiler due to high gas prices. Daily operation cost drops as number of solar panels increases, and a significant positive linear correlation between operation cost and installation of PV panels are shown in Figure 3. When the value of investment is lower than £42,000, the optimisation model chooses not to install a battery, the turning point is presented by a vertical dotted line with 18 kW PV capacity. On the right side of the line, the model chooses to install batteries. As the investment cost decreases, the operation cost gradually increases, with the increase in CO<sub>2</sub> emissions displayed by the orange line.

Figure 3 The relationships among daily operation cost, CO<sub>2</sub> emissions, and capacity of PV panels.

## 5. Conclusion

To be more competitive and sustainable, microbreweries need to reduce their energy cost without concession on the quality of final product. The aim of this work is to analyse the techno-economic benefits of using renewable sources by maximising profits and decreasing energy consumption through retrofitting their operations for a microbrewery. This paper develops an optimisation model to meet the dynamic energy demand based on data collection from a real microbrewery in UK, by minimising investment and operating costs and integrating PV systems (with energy storage and different boiler options to reduce carbon emissions). Along with the energy demand profiles, the solar resources, system components, and energy costs have been used as inputs to develop the model. Under the operational conditions and constraints, the model analyses the economic, technical, and sustainable performance of the system, together with company- and region-specific constraints related to budgets and incentives. The simulation results showed that the model can effectively optimise the capacity of PV system, installation of the battery, and type of boiler.

Compared to the scenario in which the grid is the only option for energy supply, the proposed system can significantly reduce energy costs. A potential energy cost saving of 33.3%, is possible when the optimal energy management model is applied to the proposed system, under the applicable operating condition. The length of the equipment life cycle has a great impact on the optimal investment strategy of the brewery, with a 7-year payback period important should the microbrewery wish to move towards electrification. Due to the installation of PV panels, there is a positive correlation between daily operation costs and carbon emissions. The carbon emissions of electric boilers are significantly lower than those of gas boilers, and the brewery prefers to install an electric boiler, unless the price of natural gas is lower than 18p/kWh. More PV panels installed brings lower daily operation cost and lower carbon emissions, but higher investment costs, and therefore the brewery needs to find a balance according to their own needs.

The satisfactory results obtained in this study demonstrate the potential techno-economic benefits of solar PV integration in the small-scale microbreweries. The proposed optimisation model and hybrid system can be used in industrial, residential, or other demand sectors to reduce their operational energy costs through a detailed multi-objective analysis and sensitivity study.

## Abstract

The flexibility of gasification, which incorporates both characteristics of the kind of biomass and options for producing heat or fuel, is what stimulates interest in biomass gasification research and application possibilities. One of the challenges with gasification is the accurate prediction of gasification products from the wide array of feedstocks and operational conditions, making the design and optimisation challenging. There are several studies on equilibrium models that have been published, but most of the models examined the impact of moisture and heating value. Examining the other parameter effects within the same model can enhance the accuracy of a gasification model. This work aims to create stoichiometric equilibrium models that enable the analysis of parameter effects on a specific feedstock's gasification products for use in optimisation and system modelling. A mathematical model for fixed bed gasifiers that use downdraft gasification for wood as a feedstock is presented. When the algebraic model equations are solved, the conversion behaviour of wood biomass throughout a gasification process is predicted in terms of the composition of the end products. The model has been verified with published experimental data from the literature demonstrating good agreement. The created model may be regarded as a helpful tool to simulate the impact of numerous different biomass feedstocks and operating conditions on gas characteristics and the simple algebraic formulation allows for the application of the model for optimisation purposes.

**Keywords:** Biomass gasification, modelling, equilibrium models

## 1. Introduction

Global warming is regarded as one of the top global challenges for contemporary civilisation, notwithstanding COVID-19 crisis global challenges. More waste is produced because of growing urbanisation and economic growth. The primary problem is reducing environmental pollution and worldwide warming brought on by the extensive use of fossil fuels including coal, petroleum, and natural gas. These fossil fuels serve as the main source of energy generation in many nations, which results in continuous greenhouse gas emissions. Because of its widespread availability and practical processing, biomass is predicted to grow significantly among the many renewable energy sources in the near future (Yamany et al. 2016). There is ongoing research on methods for enhancing the production of energy from biomass, and several organisations are working on its development (Janajreh et al., 2021). One of the most adaptable industrial processes is biomass gasification, which converts biomass fuels into consumable gaseous fuels that may be used for heating, power production, and hydrogen fuel cells in a range of residential and commercial applications (Sidek et al., 2020). Due to its versatility, gasification - a thermochemical reaction that transforms solid organic resources into gaseous fuels at temperatures ranging from 700 to 900 °C is highly popular (Okolie et al.,

2021). It yields valuable products like CO, trace amounts of CH<sub>4</sub>, H<sub>2</sub>, and undesirable gases like N<sub>2</sub>, CO<sub>2</sub>, and other hydrocarbons. Because experimental conditions can affect the behaviour of reactions like water gas, steam reforming reactions, Boudouard and water gas shift reactions, and these all have an effect on syngas formation, stability, and thermal efficiency, restricting its future uses, it is crucial to use caution when simulating experimental conditions (Baruah & Baruah, 2014b).

Multiple studies have revealed that modelling and theoretical predictions based on equilibrium modelling have a great deal of similarities (Kushwah et al, 2022; Chaurasia, 2018). For instance, Pradhan et al. (2019) used varied equilibrium reaction rates to test five different biomass gasification models. When compared to other models, they discovered that the model that contained basic methanation and the water gas shift reaction generated syngas with the most accurate composition. The correlation output predictions resembled those of the equilibrium model, with the exception of CH<sub>4</sub>. On the other hand, reliable correlations will require the integration of more empirical observations and the effect of other parameters.

Experiments generally consume significantly more time, money, and effort than modeling. Modeling has been shown to be a relatively quick and cost-effective option in situations when doing so is not always practicable or economically sensible (Galvanin et al., 2009). Thermodynamic equilibrium models forecast the highest possible yield of desired products without requiring any understanding of the conversion processes. Like this, downdraft gasifiers are widely employed in various energy platforms due to their straightforward construction, inexpensive maintenance requirements, and ability to produce gas with a low tar content for use in small-scale electrical generation. This paper proposes a thermodynamic stoichiometric equilibrium model for a downdraft gasifier is used for the gasification of wood at 800 °C with moisture content from 0-40 % in order to predict the composition of the fuel gas produced and its associated heating values. The gasifier system is modelled using an optimisation modelling package which includes mass conservation equations, energy conservation equations and the equilibrium equations. The developed model, based on thermodynamic calculations, has been validated with experimental published data of other authors and provides opportunity to evaluate downdraft gasification processes in a fixed bed reactor, as well as effects of variations in biomass properties and operating conditions.

## 2. Methodology

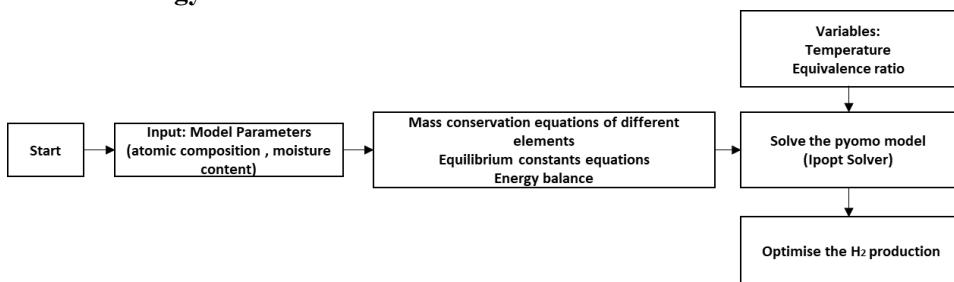

Figure 2.1: Structure of the simulation equilibrium model

In figure 2.1, the structure of the equilibrium model has been presented. In this, a mathematical model based on a single feedstock is created and developed in the algebraic modelling language, Pyomo (Hart et al. 2017) in order to determine the molar values of products. It includes the mass balance of carbon, hydrogen, oxygen, nitrogen in the woody

biomass, relative mass of the moisture and the molar water content. In next step, the composition of the producer gas is estimated, minimising the Gibbs free energy for calculation of the equilibrium constants. A Pyomo model has been implemented that relates equations between inlet biomass and equilibrium constants with temperature to solve the model. The equivalency ratio and temperature are used as optimization variables when the model is optimised using the IPOPT nonlinear programming solver to get the maximum hydrogen production rate.

### 2.1 Biomass composition

To develop the model, the chemical formula of feedstock is defined as  $CH_xO_yN_z$ . The following is an equation for the global gasification reaction:

Where x and y are the numbers of atoms of hydrogen and oxygen per atom of carbon in the feedstock, w is the amount of moisture per kmol of feedstock and m is the amount of oxygen per kmol of feedstock. On the right-hand side  $n_i$  are the numbers of moles of the species i that are unknown.

### 2.2 Chemical Equilibrium

Thermodynamic equilibrium is explained by minimisation of Gibbs free energy or by using an equilibrium constant. The two main equations (methane formation and water gas shift reaction) are considered in this case shown below:

Equation (5) is obtained by subtracting equation (2) from (3). In this model, thermodynamic equilibrium was assumed for all chemical reactions takes place in gasification zone. All the gases were assumed to be ideal and all reaction form at 1 atm. Therefore, the equilibrium constants which are functions of temperature for the water-gas shift reaction and methane formation reactions are:

$$K1 = \frac{(nCH_4)}{(nH_2^2)} \quad (\text{Equilibrium constant for methane reaction}) \quad (6)$$

$$K2 = \frac{(nCO_2)(nH_2)}{(nCO)(nH_2O)} \quad (\text{equilibrium constant for water gas shift reaction}) \quad (7)$$

The value of K1 and K2 are calculated from Gibbs free energy

$$K = \exp(-\Delta G^\circ_T / RT) \quad (8)$$

Where R is the universal constant, 8.314 KJ/ (kmol. K)

$-\Delta G^\circ_T$  represents the Gibbs function of formation at given temperature which can be expressed by empirical equation (Green, 1984):

$$\frac{d(\Delta G^\circ_T / RT)}{dT} = -\frac{\Delta H}{RT^2} \quad (9)$$

Where  $\Delta H$  is the heat of formation of biomass in KJ/kmol

$$\text{Therefore: } \frac{d \ln K}{dT} = -\frac{\Delta H}{RT^2} \quad (10)$$

Where, equation 9 shows the effect of temperature on the equilibrium constant;  $\Delta H$  represents the enthalpy difference between any given state and at reference state. It can be calculated by

$$\Delta H = \int_{298}^T Cp(T)dt \quad (11)$$

Where  $Cp(T)$  is specific heat at constant pressure in kJ/kmol K and is a function of temperature.

$$Cp(T) = a + bT + cT^2 + dT^3 \text{ where } a, b, c, d \text{ are specific gas coefficients} \quad (12)$$

Equations (8)-(12) is used to find the equilibrium constant for any reaction temperature T. Zainal et al. (2001), suggested the relationship for finding the equilibrium constant values for reaction temperature and calculating the lower heating value (LHV) of product gas that are:

$$K1 = \frac{7082.848}{T} - 6.567 * \ln(T) + 3.733 * 10^{-3} - 0.36066 * 10^{-6} + 0.3505 * \frac{10^{-5}}{T^2} + 32.54 \quad (13)$$

$$K2 = \frac{5870.53}{T} + 1.86 * \ln(T) + 2.7 * 10^{-4} - \frac{58200}{T^2} + 18.007 \quad (14)$$

$$LHV = n_1 LHV(H_2) + n_2 LHV(CO) + n_5 LHV(CH_4) \text{ MJ/Nm}^3 \quad (15)$$

However, the reference model is limited to moisture content and heating value but using an optimisation-based algebraic formulation can be used to study other parameter effects like equivalence ratio and gasification agent against temperature. For the desired product, this can also find the optimum parameters for gasification reaction. For different ranges of temperature, the values of equilibrium constant, numbers of moles and heating value have been calculated in a model, which is discussed in the next section.

### 3. Results and Discussion

The model developed in this study was used to optimise the production of hydrogen by varying temperature and equivalence ratio at 20% moisture content. Also, it was tested by comparing the calculation results of model with data from another researcher. To study the effect of moisture content of the wood biowaste, the amount of air was fixed at 0.3 of the stoichiometric requirement. Figure 3.1 shows the effect of moisture content in woody biomass on the product gas when the gasifier is operating at 800°C. It can be observed from the figure that the composition of methane produced is almost constant at a low percentage. The percentage of H<sub>2</sub> in the produced gas increases continuously with the moisture content from 0% to 40 %. A similar trend is also observed for the CO<sub>2</sub> however, the influence of the addition of more moisture will result in decrease in its concentration that might occur due to char, tar and soot formation, and water-gas shift reaction. Also, the concentration of CO reduces as moisture content increases. The results obtained from the model are in close agreement with experimental data from Zainal et al. (2001) which performed for wood biomass under similar operating conditions. Figure 3.2 shows the calorific value for wood biomass against moisture content. It is seen that the calorific values decrease with increases in moisture content. This is due to the greater reduction in carbon monoxide content compared to the increase in hydrogen content as moisture content increases.

Figure 3.3 explains the variation of calorific value against gasification temperature for the raw material wood with an initial moisture content of 20%. It can be observed that the predicted calorific values reduce with increase in temperature. Figure 3.4 shows the

comparison between model and experimental results for wood at 18.5 % moisture content and gasification temperature of 800°C. It can be observed from graph that the predicted value percentage of hydrogen and carbon monoxide content is predicted as 16.87% & 22.92% against an experimental value of 12.23% & 21.00%. The hydrogen percentage predicted is more than the experimental value, while the carbon monoxide percentage predicted is lower than the experimental result. Also, higher equivalence ratio (ER) result in higher operating temperatures, which in turn increases the degree of oxidation of available carbon.

Figure 3.1: Effect of moisture content in wood biomass on product gas at 800°C

Figure 3.2: Effect of calorific value against moisture content at 800°C

The model is optimised using nonlinear programming solver IPOPT to find the maximum hydrogen production rate with the equivalence ratio and temperature as optimisation variables. Higher ER results in more CO<sub>2</sub> production because of oxidation of carbon; hence, the optimum ER, calculated by model is 0.1957 at 853.23°C and 20 % moisture, which yields 21.214% H<sub>2</sub>. So, by combining the two above-mentioned gasification variables, temperature, and equivalence ratio, it is possible to optimise the operating conditions to magnify the H<sub>2</sub> production.

Figure 3.3: Calorific value against

Figure 3.4: Comparison between model and experimental results at 800°C

#### 4. Conclusion:

Stoichiometric thermodynamic equilibrium models for the biomass gasification process were developed in this work, with the entire conversion of carbon considered to estimate syngas composition.

For a wide range of temperatures, the equilibrium constants of the water gas shift process and the methanation reaction have been computed. The models are formulated in an algebraic modelling language for optimisation of the gasification process. This model can predict the composition of syngas from biomass sources and can also predict biomass gasification performance under a variety of operating parameters, such as temperature, moisture content and equivalence ratio. The optimum ER, calculated by model is 0.1957 at 853.23°C and 20 % moisture, which yields 21.214% H<sub>2</sub>. The study leads to the conclusions that the amount of hydrogen in the product gas nearly rises linearly with the amount of moisture for biomass. However, carbon monoxide content in the product gas decreases with moisture content almost in a linear variation. The proportion of methane in the product gas is relatively low and increases linearly with moisture content. The calorific value of the producer gas decreases as the moisture content increase. In short, with a known ultimate analysis of any biomass and its calorific value, the model can predict the composition and the calorific value of the producer gas under different operating conditions.

## Abstract

Aquaculture is a growing industry that provides high-quality protein, however, the growth of aquaculture production has a range of environmental concerns. Recirculating aquaculture systems (RAS) are a popular solution to accomplish intensifying fish production, and integrating renewable technologies is an attractive option that may provide low-carbon energy and promote sustainability. This paper presents an optimisation model for the control and operation of a grid-connected distributed energy system (DES) integrated with an RAS. A linear optimal power flow (OPF) combined with model predictive control (MPC) strategy is developed which simulates the thermal and electricity balances present throughout the renewable energy integrated electricity network and RAS, to make real-time optimal operation scheduling plans on different time horizons. The optimal results show that the MPC strategy improves the control performance of system operation and improves the process economics. With renewable energy sources (RES), operational costs can be reduced by up to 27%. Compared with a conventional scheduling plan, the rolling horizon approach can provide 3% energy cost saving, while maintaining fish well-being and system safety.

**Keywords:** recirculating aquaculture system, distributed energy systems, renewable energy, optimal power flow, model predictive control.

## 1. Introduction

Aquaculture is a main source of protein and income in many countries globally (FAO, 2020). Sustainable aquaculture is directly related to targets of the Sustainable Development Goals. In this context, the implementation of RAS are gaining more attention globally (Chen et al., 2021). RAS has the potential to provide a sustainable fish-rearing system since it is easily expandable, potentially environmentally friendly, and improves production by utilizing a small space. RAS is competitive since it is able to recycle 90-99% water for reuse. However, RAS has received little attention in terms of understanding the synergies between energy consumption and fish production. The application of RAS is difficult to commercialise. The reasons are that the high initial investments are hard to recover (Schneider et al., 2006) and the high energy consumption for operation (Ayer & Tyedmers, 2009). RAS integrating renewable technologies is an attractive option providing low-carbon energy and promoting sustainability.

The use of solar energy in RAS decreases the energy cost on fossil fuel, especially for fish farms with higher water temperatures. The PV system combined with a wind turbine (WT) can enhance the reliability of the system and smooth the power generation curve caused by the intermediate characteristics of RESs (Ruggles & Caldeira, 2022). Jamroen

(2022) developed design models to determine the appropriate size of PV and battery storage for fish farms. These models have common disadvantages. The first is that uncertainty of renewable energy is not considered, and another is the timescale considered. In real-time, the scheduling of the power system could be in minutes, and in these studies the scale of days is used, wherein it is possible that the system may not respond to changes quickly. Silvente et al. (2015) presented a linear operational model considering the prediction uncertainties from RESs, which is solved by an MPC rolling horizon strategy to correct the deviations from the initial conditions. MPC rolling horizon strategy is suitable for dealing with system control problems that are easy to model and have high stability. MPC includes four parts, a prediction model, rolling optimisation, feedback mechanism and reference trajectory. The feedback mechanism corrects the prediction model, and the error is compared with the reference trajectory. The final control decision applied to the system is calculated by the rolling optimisation.

This paper proposes a linear MPC approach for sustainable hybrid energy systems for RAS. The model simulates the thermal and electricity balances present throughout the renewable energy integrated electricity network and RAS, to make real-time optimal operation scheduling plans on different time horizons. First, a multi-time scale optimal scheduling problem is divided based on three scales: day-ahead long-term scale scheduling in 1 h, intra-day predictive control in 15 min and real-time adjustment in 5 min. Then, we establish an optimisation model based on the best economic operation of the system and the minimum penalty cost of start-up and shutdown. The inputs include the relevant climate parameters for renewable energy generation, the energy storage schedules, operation of facilities including climate and oxygen control equipment, as well as the fish biomass production quantity.

## 2. Model formulation

The components of the system are divided into load demand of RAS and power resources including generator, WT, PV and national grid as backup power in on-grid operation mode. The main load demand of the system is the thermal process to keep water temperature as required in RAS, and other demands such as lights, water pumps, water treatment system and aeration are treated as constant load demand in this model. The overall objective of this model is to minimise the daily operation cost:

$$OPERATION = COST_{gen} + COST_{grid} \quad (1)$$

$$COST_{grid} = \sum_t (P_t^{grid, buy} * C^{grid} - P_t^{grid, sold} * C^{tariff}) * \Delta t \quad (2)$$

$$COST_{gen} = \sum_t ((P_t^{gen} * F_1 + Y_{gen} * F_0) * C^{fuel} + S_{gen} * u^t) * \Delta t \quad (3)$$

The cost of buying electricity from the grid is  $COST_{grid}$ , with  $C^{grid}$  and  $C^{tariff}$  the tariffs of electricity grid.  $P_t^{grid, buy}$  and  $P_t^{grid, sold}$  are the power of buying or selling electricity to the grid respectively,  $\Delta t$  is the time interval. The cost of generator's operation is  $COST_{gen}$ ,  $P_t^{gen}$  is the output power of generator,  $Y_{gen}$  is the capacity of the generator,  $F_1$  is generator fuel curve slope,  $F_0$  is generator fuel curve intercept coefficient,  $C^{fuel}$  is the price of generator fuel,  $S_{gen}$  is the cost of start-up generator, and  $u^t$  is the start-up variable of generator.

$$\sum_t P_t^{gen} + W_t + P_{ess,t} + P_t^{grid} + PV_t - P_t^{HP} - P_t^{eb} = P_t^{load} \quad (4)$$

$W_t$ ,  $P_{ess,t}$ ,  $P_t^{grid}$ ,  $PV_t$ ,  $P_t^{HP}$ ,  $P_t^{eb}$ ,  $P_t^{load}$  are the output power of WT, battery, main distribution, PV, heat pump, electric boiler, and load demand of RAS respectively. The

output power of wind turbine and PV should be lower than the predicted output value according to the weather. Unit commitment:

$$\begin{aligned} x^{t-1} - x^t + u^t &\geq 0 \\ x^t - x^{t-1} + v^t &\geq 0 \end{aligned} \quad (5)$$

where  $x, u, v$  are binary variables.  $x$  is the unit commitment of generators (1 if the generator is committed at time  $t$ , and 0 otherwise).  $u^t$  is the start-up variable of generator (1 if generator starts at time  $t$ , and 0 otherwise).  $v^t$  is the start-up variable of generator (1 if the generator starts at time  $t$  and 0 otherwise).

The model also ensures that electricity is not bought from or sold to the grid at the same time through big-M constraints, which are similar to the constraints on the battery's charging or discharging status. For proper operation, each power source must not be operated above its rated or maximum limit according to the manufacturer's specifications. The state variable also has boundaries where the minimum depends on the type of battery used.

The water heat balance is used to calculate the energy flows of the water volume each hour. In other words, the water heating or cooling demand to maintain its temperature. The formulated simplified heat balance is:

$$Q_{conv}(t) + Q_{exchange}(t) = Q_{demand}(t) \quad (6)$$

The convective heat transfer,  $Q_{conv}$  represents the heat exchange on the surface of the tank between water and air, which is determined by (Holman, 2009):

$$Q_{conv} = h_{conv,w} \cdot A_{surface} \cdot (T_{air}(t) - T_w(t-1)) \quad (7)$$

where  $h_{conv,w}$  ( $kW/(m^2 \cdot ^\circ C)$ ) is the convective heat transfer coefficient decided by indoor air velocity,  $T_w$  is the water temperature,  $T_{air}$  is the air temperature, and  $A_{surface}$  ( $m^2$ ) is the surface area of the tanks. The water exchange that occurs in the system implies a heat gain or loss of  $\dot{Q}_{exchange}$ . The rate of water exchange in the system is assumed to be constant, with the same amount of water entering and leaving the system. The heat gain through water exchange can be calculated by:

$$\dot{Q}_{exchange}(t) = \dot{m}_{exchange} \cdot c_{p,w} \cdot (T_{w,in} - T_w(t-1)) \quad (8)$$

where  $\dot{m}_{exchange}$  is the mass flow of the water exchange,  $c_{p,w}$  is the specific heat of the water and  $T_{w,in}$  is the temperature of water entering the system.

The heating system will be active until a certain water temperature has been reached. When the temperature set point has been reached the heating system will be turned off, the water temperature will then drop to a lower limit where the heating system is activated again.

The core idea of MPC is rolling optimization and feedback correction, which solve the optimization problems with uncertainties, and can also conveniently include a variety of constraints. The rolling optimization process of MPC is shown in Figure 1. If the system operates at time  $t$ , based on the prediction information of the system disturbance variables in a future period, obtain the optimal outputs in the prediction domain with the objective of minimizing the operating cost. However, the optimization result is used only in one control domain, and the optimization process is repeated at time  $t + 1$ . The proposed scheduling is divided into three timescales: day-ahead, intraday, and real-time. The main decisions of the day-ahead dispatching are the unit start-up and shutdown plan in the next 24 hours, the charging and discharging state of energy storage, and the power purchase and sale to the main distribution network. The time interval in this model is 1 h. The intraday scheduling mainly corrects the output of the controllable units, the charging and discharging power of the energy storage and the purchasing and selling power of the main distribution grid in the intraday dispatching according to the latest renewable energy power output and thermal load forecast data. The time interval of this model is 15min and

the dispatching period is 2h. The time interval of real-time dispatching is 5min, and the dispatching period is 15min. It is mainly based on the real-time forecast data of wind power, PV output and thermal load to finetune the intraday scheduling plan. In the intraday and real-time dispatching time, the unit start-up and shutdown plan, energy storage charging and discharging status and power purchase and sale status of the main distribution grid in the day-ahead scheduling results are kept unchanged. The level-by-level coordination of the three-time scales can better deal with uncertainties and make scheduling results more consistent.

Figure 1 The rolling optimization process of MPC.

When optimising intraday and real-time scheduling, there is often a large error between the renewable energy output obtained by the short-term forecasting method and the daily forecast data, so the daily scheduling plan needs to be properly modified to ensure the effectiveness of the scheduling strategy. The objective function of intraday optimal scheduling model is:

$$\min \text{Operation}_{intra} = \min \sum_{t=1}^{N_T} [C_{G,t}^{intra} + C_{ESS,t}^{intra} + C_{M,t}^{intra}] \quad (9)$$

where  $N_T$  is intraday scheduling period,  $N_T = 2h$ ;  $C_{G,t}^{intra}$  is the generator operation cost at time  $t$ ;  $C_{ESS,t}^{intra}$  is the storage operation cost,  $C_{M,t}^{intra}$  is the operation cost of intraday purchasing or selling electricity from main distribution network.

During the intraday scheduling, the status of the generator is consistent with that of the day before, so the intraday scheduling cost of the controllable generator unit only includes the operation cost. The charging and discharging power of energy storage should follow the day-ahead scheduling results as much as possible. Therefore, intraday scheduling cost of energy storage is expressed as:

$$C_{ESS,t}^{intra} = \left\{ K_{ESS,i} \left[ \frac{1}{\eta_{E,dis}} P_{E,t}^{sum,dis} + \eta_{E,ch} P_{E,t}^{sum,ch} \right] + \lambda_{ESS}^{intra} |SOC_t - SOC_t^{ahead}| \right\} \Delta t \quad (10)$$

where  $\lambda_{ESS}^{intra}$  is the weight coefficient of energy storage adjustment during the intraday plan. Equation (10) has absolute value and auxiliary variables  $S_{E,t}^{au}$  are introduced and linearized:

$$\begin{aligned} C_{ESS,t}^{intra} &= \left\{ K_{ESS,i} \left[ \frac{1}{\eta_{E,dis}} P_{E,t}^{sum,dis} + \eta_{E,ch} P_{E,t}^{sum,ch} \right] + \lambda_{ESS}^{intra} S_{E,t}^{au} \right\} \Delta t \\ \text{s.t. } S_{E,t}^{au} &\geq SOC_t - SOC_t^{ahead} \\ S_{E,t}^{au} &\geq -[SOC_t - SOC_t^{ahead}] \end{aligned} \quad (11)$$

Similarly, the cost of intraday power purchase and sale of the main distribution network is the same as that of energy storage and also follows the day-ahead scheduling results as much as possible. During intraday scheduling, to track the day-ahead charging and discharging power of storage energy, the following constraint should be satisfied:

$$SOC_{4t}^{intra} = SOC_t^{ahead} \quad t = 1, 2, \dots, 24 \quad (12)$$

where  $E_{4t}^{Intra}$ ,  $E_t^{ahead}$  are the state of charge at the end of each hour for intraday and day-ahead scheduling respectively. Real-time optimal scheduling is similar to the intraday model, tracking the intraday dispatching plan as much as possible.

The process is summarized in Algorithm 1.

**Algorithm 1 Model predictive control**

1. Predict values for day ahead including renewable energy output, load demand. Input other parameters.
2. Solve the day-ahead model, with objective function (1), constraints are (2)-(8). Decide the binary variables of generator and battery.
3. Predict values for short-term scheduling, keep binary decision variables from day-ahead model, use rolling optimization, and objective function (9), solve intra-day model. Get the scheduling plan for intra-day.
4. Predict values for real-time, keep binary decision variables from day-ahead model, use rolling optimization, solve real-time model. Based on intra-day plan, adjust the output of each unit.

**3. Case study**

The test case considers a fictional RAS located in Lochinver, Scotland, where fish farming is a vital industry, as they are the largest producer of farmed salmon in the European Union. The system uses a heat pump (HP) and electric boiler to keep the water temperature in the feed tanks of RAS ranging 16°C to 17°C. The capacities of PVs, batteries, generator, and WT installed are decided by the solution of a design optimisation model, shown in Table 1. The results presented in Table 1 are used as inputs in this model, and a typical autumn day has been chosen specifically to test the model as renewable energy power generation is highest in this season.

Table 1 Model results summary.

PVs (kW)	Battery(kW)	Wind Turbines(kW)	Generator(kW)
13	7.7	19	35

Figure 2 The scheduling plan of each unit in the system for day-ahead.

First, the day-ahead scheduling plan is shown in Figure 2. Due to the influence of geographical environment and weather, the output of the WT is far greater than that of PV. When the output of renewable energy is insufficient, the demand is met by purchasing power from the main distribution instead of starting up the generator, and the SOC of the battery is basically unchanged. If the parameters are changed, the electricity price is increased and the fuel price is reduced, the generator power generation will make up for

the shortage of renewable energy, and the SOC of the battery will also change. The thermal demand is maintained at a relatively stable value, because of the high specific heat capacity. Compared with the original system without RESs, the daily operation cost can be reduced by about 27%, from £144.5 to £105.

Considering the disturbance of renewable energy output, rolling optimisation of MPC is introduced into the model. In intraday and real-time dispatching, to keep the energy balance of the network, the system prefers to purchase/sell the electricity from the main network rather than batteries, which is due to the lower electricity price compared with the use price of energy storage. Faced with renewable energy disturbance, the scheduling change of the MPC rolling algorithms is more stable and has less variation, which enhances the system's ability to cope with uncertainties. By using the rolling-horizon MPC model, the daily running expenses can be reduced by 3%.

#### 4. Conclusion

RAS as a popular fish production system requires high energy demand due to thermal processes, water circulation, and aeration. This paper presents an optimisation model for the control and operation of a grid-connected distributed energy system integrated with an RAS, that is developed to optimise the performance of the system in economic, sustainable, and technical aspects in real time. An MPC strategy for a sustainable hybrid energy system for the RAS is proposed in this work. To analyse the performance of the model, the optimal results of the proposed system were compared with the traditional system in economic and environmental aspects. The optimal results show that the MPC strategy improves the control performance of system operation and improves the economy of system operation. Compared with a conventional RAS, the integration of renewable energy can save up to 27% operation cost in a typical day. With the MPC rolling-horizon algorithm, the system's ability to cope with uncertainties has been improved.

## Abstract

This work presents a method based on Mixed Integer Linear Programming (MILP) to consider wholesale energy markets in the operational optimization of industrial energy systems. A two-stage optimization framework is presented to consider price differences between the day-ahead and the intraday spot markets to optimize the electricity procurement in both markets. A representative use case of an industrial process is used to optimize the energy supply from the power generators and storage units and minimize energy costs as well as to benefit from participating in the wholesale market. The results show potential to save energy costs and make additional profits on the intraday market.

**Keywords:** Flexibility, Optimization, MILP, Intraday Market

## 1. Introduction

A rising share of renewables and an increasing number of volatile power generators and consumers are causing imbalances and congestions in the power grid. With decarbonization and the demise of conventional power plants, our energy system needs new flexibility measures and market participants. In most countries, the industrial sector is one of the largest electricity consumers and can therefore play a significant role in supplying flexibility to balance the power grid and provide security of supply. Previous work (Schenzel, et al., 2022) presented a method to identify existing flexibilities based on a MILP approach (Halmschlager et al., 2020), which is integrated into this work to consider the participation in wholesale markets, specifically focusing on the day-ahead and intraday markets.

## 2. Leveraging Energy Markets

Conventional optimization methods focus on high efficiency and low operational costs, but neglect opportunities by not considering energy markets. Most industrial customers procure their energy through energy suppliers, with fixed or floating electricity tariffs that reduce both the actual effort needed to operate on the wholesale market and the exposure to price volatilities (Schnorr 2019). At the same time, there are opportunities for industrial customers to make profits by marketing their flexibility - either by directly acting on the wholesale market or partnering with aggregators to have access to the wholesale markets. The advancement in energy storage technologies and the staggering increase in price spreads of wholesale markets support the case for industrial plant operators to act as a Flexibility Service Provider (FSP).

### *2.1. Flexibility*

Villar, Bessa, and Matos (2018) define flexibility as the possibility of modifying generation and/or consumption patterns in reaction to an external signal (price or activation signals). Generally, industrial energy systems have three ways of providing flexibility. Firstly, they can adjust their production schedule. This is highly dependent on the processes involved and often needs more lead time and computational effort. Secondly, energy carriers can be substituted, meaning that in order to meet a certain electricity demand, it can either be consumed from the power grid or produced by generators such as gas turbines. Thirdly, energy storages can be used to shift energy demands in the process. While conventional power plants usually store electric energy by converting it to other forms of energy and backwards, with significant losses each conversion, industries can directly utilize the converted energy - like heat - to cover the demand of their production processes. Also, thermal heat storages are cheap in comparison to batteries and can be used to make industrial processes more efficient by reducing waste heat. Once identified, the electric industrial flexibility can be offered as bids on the intraday market at an electricity exchange like the European Power Exchange (EPEX) or as an ancillary service at the balancing markets of the Transmission System Operator (TSO).

### *2.2. Balancing Markets*

These markets are used for the operating reserve to restore the frequency of the electricity grid in case of imbalances of the system. There are three different products available, Frequency Containment Reserve (FCR), automatic Frequency Restoration Reserve (aFRR), or manual Frequency Restoration Reserve (mFRR). Each product has their own requirements, pricing, and activation times. The remuneration model for aFRR and mFRR consists of two parts: one part is for keeping the capacity available (capacity price), and one is for the actual activation (energy price). Depending on the product, the activation must follow very shortly after the activation signal. Since these activations are very hard to predict they can interfere with production planning and safety.

### *2.3. Intraday Markets*

To compensate for changes in energy production, often caused by insufficient weather forecasts on the day-ahead, energy companies can buy or sell energy to level their position. This can be done during the day and up to several minutes prior to delivery. With the growing number of volatile renewables, these markets have gained much importance in the last decade with more energy being traded at these markets each year. FSPs can provide their flexibility to the market, to increase liquidity, reduce the amount of balancing energy and to make additional profits.

## **3. Modelling Approach**

Mathematical optimization represents a powerful method to maximize profits for power plant operators, often referred to as Unit Commitment (UC) problem. UC problems - a subclass of optimization problems - have been widely used in the energy market for many years. Industrial energy systems often face similar problems, when deciding when and how to utilize their power, heat, or steam generators to cover their demand in the most efficient way, especially since decentralized energy systems tend to get more diverse. In contrast to conventional UC problems of power plant operators, industrial plant operators are also constrained by their own operational targets, e.g., minimum

production output, minimum up-times for batch processing, working hours, etc. For our purposes a fixed set of demand time series is sufficient, meaning that there is a predetermined production plan, the demand for different energy carriers such as steam on different pressure levels, gas and electricity can be derived. Scheduling is often impractical, since it means a bigger intervention in the operation and is therefore not considered. With the increase of digitization and the development of energy control systems, a focus on optimizing the energy management system is more applicable and reduces interference to operation to a minimum. In the following we present a method to include the intraday market in the optimization problem.

### *3.1. Optimization Method*

The problem is formulated as a UC problem on the basis of MILP formulations, which are implemented in Matlab<sup>®</sup> and solved with a state-of-the-art solver (e.g. GUROBI). The model uses a combination of linear, continuous, semi-continuous and binary decision variables. They represent all operation trajectories of the energy supply system of the industrial plant, such as the power generated by the gas turbine, the charging and discharging of storages etc. Constraints are used to define the optimization problem, to depict operational constraints such as the satisfaction of energy demands, operational limits, power outputs or ramp-up/down constraints. The objective is to minimize operational costs, by optimizing the trajectories of the individual generating units of the industrial plant. This is done by utilizing the storages to meet the demands in the most efficient way and considering price curves of power spot markets for a cost-efficient operation plan. To better represent the market mechanisms of spot markets, the method is split in two optimization runs or “stages”.

### *3.2. Two-stage Optimization*

Figure 1 shows the two-stage optimization method to consider price signals between the day-ahead and intraday spot markets. Based on historical data, we developed a regression model to predict day-ahead market prices, based on weather forecasts and the previous day’s market coupling results. In Stage 1 (D-1), the predictions for the day-ahead prices are used to calculate an optimal operation plan using MILP. Based on the results, we derive the electricity demand procured directly via placing price inelastic bids on the day-ahead market. The industrial plant acts as a price taker, meaning that the orders are executed independent the market price and all bids are accepted. In Stage 2 (D-0), the results from the day-ahead auction and the actual weighted average intraday market prices are used as input to solve a second optimization problem. We assume that price signals from the continuous intraday market are available at a single point in time and the weighted average result from each quarter hour can be used. Considering these price signals the plant operator can buy or sell additional electricity at a 15-minute resolution to make additional savings and reduce energy costs.

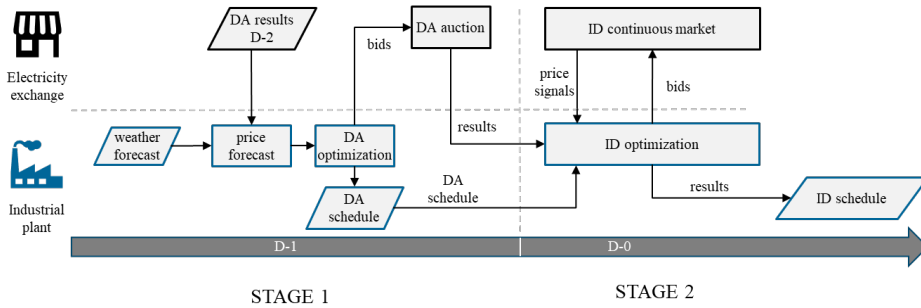

Figure 1: The two-stage optimization framework for day-ahead (DA) and intraday (ID) optimization.

## 4. Use Case

To demonstrate the proposed two-stage method, a simplified industrial energy system is modeled. The model consists of two demand curves, representing the power demand and steam demand, which result from a production plan. The power demand and the steam demand are fluctuating during the day but are set to a mean value of 1 MW. Both demands can be covered to a certain degree by a combined heat and power generator (CHP) with a maximal output of  $0.5 \text{ MW}_{\text{el}}$  and  $1 \text{ MW}_{\text{therm}}$ . A gas boiler can produce additional steam to cover the full steam demand. Additionally, a thermal and an electrical energy storage increase the efficiency and provide flexibility to the system.

### 4.1. Data

We used historical price data from the European Power Exchange (EPEX) spot market and the European Network of Transmission System Operators for Electricity (ENTSOE). We used hourly day-ahead market coupling results and weighted average results from the continuous intraday market for the Austrian bidding zone. Data from the year 2021 was used to train the linear regression model while data from the first half of 2022 was used to validate the regression model and to predict the daily day-ahead prices for the optimization framework.

### 4.2. Optimization Results

Figure 2 shows the optimization results of stage 2 for a single day in February 2022. The upper part of the plot shows the optimal trajectories to meet the electric power and steam demand of the production processes in the most cost-efficient way. Since the CHP has a limited electric power output, the industrial plant is dependent on power supplied by the public grid. The battery is charged and discharged to shift power demands to times of lower energy prices. Part B of Figure 2 shows the bids that were placed on the day-ahead and intraday markets to procure the power supply according to the optimal trajectories.

Figure 3 shows the potential energy cost savings for each day in correlation with the daily variance of the price spreads between the day-ahead and the intraday market. The savings are calculated by the difference of the cost function between stage 1 and stage 2. The mean value of the relative cost savings is 1.96 %. Generally, a higher price spread between these markets has shown a higher potential of saving energy costs.

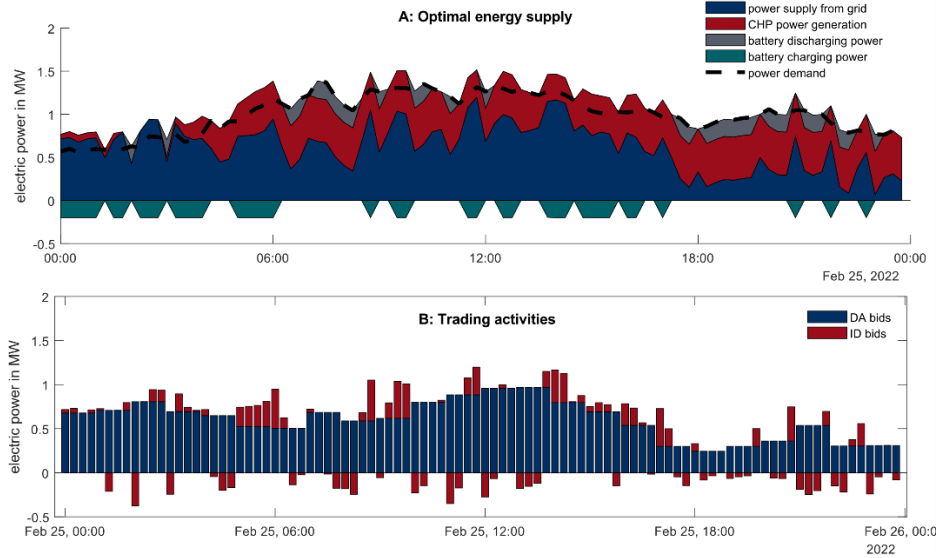

Figure 2: Optimization results for a single day. Part A shows the optimal operation trajectories of the energy supply system. Part B shows the corresponding bids on the day-ahead (DA) and intraday (ID) market.

Figure 3: Relative energy cost savings per price spread

### 4.3. Discussions

The intraday bids in Figure 2 B are the corresponding reaction to price differences between the day-ahead and intraday markets. These can be interpreted as price signals from the current market situation and as reactions to deviations of the predicted day-ahead price curves that are used for optimization in stage 1.

By using the average result of the intraday market, we assume perfect foresight of the intraday market prices in the second stage. These prices are hard to predict though and are not traded at a single point in time, but continuously during the day. Thus, it may be possible to additionally exploit the volatility in this market by using the flexibilities of industrial energy systems.

## 5. Conclusion

The proposed two-stage optimization method enables a deeper integration of industrial energy systems in the short-term energy market. Hereby, industrial energy systems can react to fluctuations in the system in the form of price signals in the intraday market. Using real price data from the first half of 2022, our method also shows significant potential for reducing energy costs. Assuming direct access to wholesale market, the intraday market offers a supplementary opportunity for marketing flexibility, as the entry barriers are lower than in other markets such as balancing or redispatch markets. Further research will show the possible exploitation of volatility in the intraday market. In the prospect of reduced entry barriers for balancing markets and new opportunities for industrial energy systems to act as FSPs, mathematical optimization methods based on MILP may play an important role when participating in flexibility markets.

## Abstract

A central problem in chemical engineering (and several related areas) is evaluating the correct sequence of unit operations, their design aspects, and the continuous optimization of their operations to efficiently convert input materials to final products. The numerous decisions to be made at each problem-solving stage renders this problem combinatorically complex. In this work, we propose a hybrid, artificial intelligence-based multi-level framework to perform fast, efficient, and reliable flowsheet design and optimization. We build upon the previously proposed SFILES-based text representation of flowsheets to incorporate additional contextual details in the extended SFILES framework using hypergraph representations. We discuss our eSFILES framework using the well-known hydridealkylation (HDA) process.

**Keywords:** process design; flowsheet prediction; artificial intelligence; computer-aided flowsheet synthesis

## 1. Introduction

Process flowsheet synthesis and design is a challenging task that involves identifying the correct set of unit operations and their optimal sequence that enables the conversion of input materials to desired output products, while considering energy consumption, environmental impact, safety, operability, and many more. The goal of synthesis is to identify the tasks, the operations that will perform these tasks, and their sequence to determine the flowsheet. The goal of design is to add operational and equipment details to the flowsheet so that the process can be verified, optimized, built, and operated. The size of the synthesis problem varies with the number of tasks and the number of alternative operations for each task. The complexity of the design problem is related to matching the tasks and their associated operations with design parameters so that the designed process matches the desired process specifications. The design parameters are further optimized to obtain a sustainable process design.

Model-based methods are usually used for the synthesis and design stages. Although, in principle, the synthesis, design and optimization steps could be performed simultaneously, the current practice is to solve them separately due to the size and complexity of the resulting mathematical problem. The challenge here is how does one incorporate issues, such as, economics, environmental impacts, operability, safety, and sustainability in the early stages of process synthesis and/or design (Tula et al., 2017).

Computer-aided approaches using AI-inspired methods combined with fundamental concepts offer several advantages over purely data-driven methods, which may lead to infeasible flowsheets, or purely model-based methods, which may run into difficulties in the numerical solution step due to the complexity of the models used.

To facilitate the development of such hybrid AI-based approaches combining process knowledge with computational algorithms, an appropriate flowsheet representation is needed that is concise, complete, and accurate. The SFILES representations developed by (D'Anterrosches, 2005), (Bommareddy *et al.*, 2011), and (Tula *et al.*, 2015) was the first step in this direction, and has been shown to have various applications, such as, flowsheet autocompletion (Vogel *et al.*, 2022), piping and instrumentation diagram generation (Hirtreiter *et al.*, 2022), and flowsheet pattern mining (Zhang *et al.*, 2019). The SFILES strings represent correctly and consistently a wide range of process flowsheets, involving typical operations found in chemical and biochemical processes. Note that, like the SMILES strings for a molecule, a parser is needed to convert SFILES strings to the actual process flowsheet diagrams. As originally developed, a process flowsheet is first represented by a set of process groups, which are similar to the functional groups that represent a molecule. The process group representation is then converted to a SFILES representation. Unlike the molecular representation with SMILES, several additional details need to be considered. For example, information about the number of chemicals and their effect on the system behavior; the direction of flow-paths for reactants, products, inerts, solvents, etc. need to be tracked; and, start and end of the process need to be clearly marked. These additional issues give opportunities for a symbolic AI-based intelligent system (Venkatasubramanian & Mann, 2022) need to be incorporated to the current process synthesis-design methods such that the application of SFILES to represent process flowsheets as well as its use in computer-aided process synthesis and design can be extended.

The objective of this paper is to present a hybrid multi-level AI framework for fast, efficient, and reliable flowsheet synthesis and design taking into account concepts and theory on chemical process development, together with the knowledge and data for hundreds of process flowsheets that are known already. We present an extended SFILES representation (eSFILES) based on SFILES of process flowsheets ((D'Anterrosches, 2005); (Bommareddy *et al.*, 2011); (Tula *et al.*, 2015)) and the annotated hypergraph representation, developed originally to study networks in organic chemistry (Mann & Venkatasubramanian, 2023). We highlight selected developments where we illustrate the hierarchical eSFILES representation framework for any chemical process flowsheet, also suitable for process synthesis, design, and innovation (Tula *et al.*, 2015). Namely, we propose a three-level, extended SFILES framework where the lowest level contains flowsheet connectivity information which could be used to generate text-based flowsheet representations like SFILES but with additional information; the middle level contains additional details on process groups and streams providing information necessary information for process synthesis (superstructure-based optimization or process group based enumeration and test); and the top level contains process operational data in terms of design parameters for process simulation and innovation through optimization and intensification. At the core of our approach lies a hypergraph representation of flowsheet (Mann & Venkatasubramanian, 2023) that represents process groups as hyperedges and streams as nodes with annotations indicating contextual information.

## 2. Current state of flowsheet representation: SFILES

A text-based representation for chemical flowsheets reported by (Tula et al., 2015) is called simplified flowsheet input line entry scheme (or SFILES) analogous to the SMILES representation for molecules. Such a representation offers a concise way of representing flowsheets and could also facilitate not only storage of flowsheets, but also, enumeration, analysis, and deployment for interactive text-based algorithms process synthesis, design, and simulation of a given flowsheet. (Tula et al., 2015) developed separate rule-based algorithms for process synthesis and design, whose solutions were not added to SFILES strings. The underlying idea behind SFILES is to identify analogous process components similar to a SMILES string as follows –

- represent processes as *process groups* akin to functional groups in molecules.
- represent process flow streams akin to chemical bonds in molecules.
- represent various connections, recycle streams, and branching of streams akin to branching in molecules.
- unlike SMILES, SFILES need special unidirectional input nodes and output nodes that indicate the start and end of a process flowsheet, through special characters ‘i’ and ‘o’, respectively.

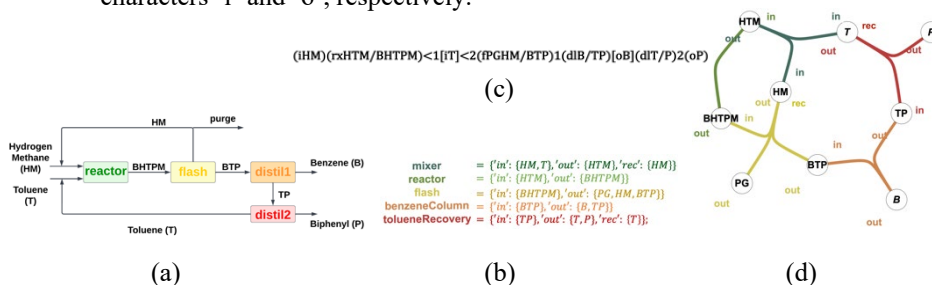

Figure 1: (a) HDA process flowsheet, (b) the various process groups, (c) the corresponding SFILES string, (d) HDA process represented by process groups. In the above subplots, the abbreviations refer to – mixture of hydrogen, methane (HM); mixture of benzene, hydrogen, toluene, biphenyl, methane (BHTPM); mixture of benzene, toluene, biphenyl (BTP); benzene (B); biphenyl (P); toluene (T); purge gas (purge). The hypergraph was generated using Wolfram Mathematica and algorithmic implementation would be done in Python.

We use the well-known hydrodealkylation (HDA) process to illustrate the basic concepts and the new developments. First the process flowsheet is represented by a set of process groups retrieved from the database (the process group representation is shown in Fig 1b) and the parser is used to generate the SFILES string (shown in Fig 1c). The reader is referred to (Tula et al., 2015) for detailed examples on SFILES generation.

## 3. Extended SFILES (eSFILES)

**Hypergraph:** The hypergraph representation of the HDA process is shown in Figure 1(d). While this new SFILES representation offer numerous benefits, there is scope for further improvement and incorporation of additional details that would aid in intelligent process flowsheet synthesis and design. The new information that, when incorporated, would generate additional, more complete information in the flowsheet representation such as:

- information on incoming/outgoing streams for each process group explicitly, especially when multiple streams enter or leave a process group.

- the minimum data needed to completely define a material and/or energy stream.
- information on driving force for the process groups indicating the ease/difficulty of conversion/separation.
- ability to systematically generate superstructure of flowsheet and enumerate valid alternatives aiding in the design problem.

Towards this end, we propose the extended SFILES (or eSFILES) representation that provides a framework for incorporation of this information in a hierarchical manner and further details on this are presented in the subsequent sections.

**Hierarchical framework:** A hierarchy is needed to efficiently organize process knowledge needed for different applications and to guide users to select, retrieve, and/or collect the data needed for a specific application. Namely, the eSFILES hierarchy has three levels of information -- first at the lower level, information needed to only represent the flowsheet (connectivity); next, at the middle-upper level, introduce additional details such as driving force and mixture composition that helps to establish the material and energy flows; and finally, the top level that contains information on composition and material/energy balance that would be needed to solve a flowsheet among other applications. The eSFILES hierarchy is shown in Figure 2.

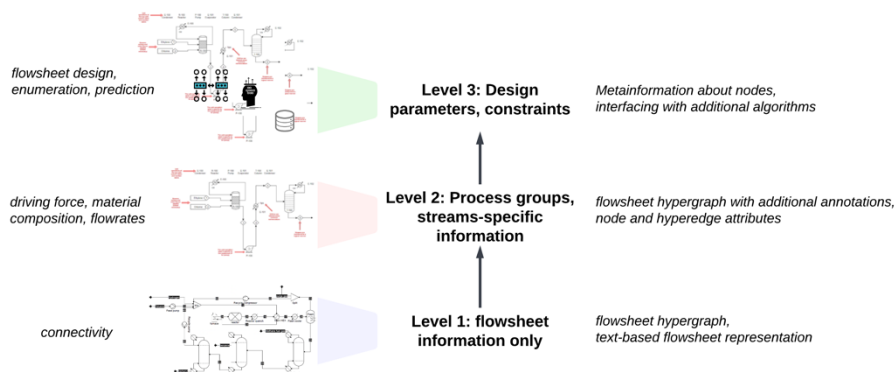

Figure 2: eSFILES framework with three levels of hierarchy

**Implementation of hierarchical framework:** The concept of hypergraphs is introduced to incorporate multi-level hierarchy of information with eSFILES. A hypergraph is a generalization of a graph where each edge is not limited to connecting only two vertices but could connect any number of vertices. Mathematically, a hypergraph consists of a set of hyperedges and vertices where each hyperedge consists of a non-empty subset of vertices. In addition, each vertex has a hyperedge-specific annotation indicating a predefined contextual information. The flexibility of hyperedges to connect more than one node and ability to have hyperedge-specific node annotations offers several advantages for flowsheet representation. Further details on the annotated hypergraph framework and its various applications in reaction engineering are presented in (Mann & Venkatasubramanian, 2023).

For instance, for the HDA process, the equivalent flowsheet hypergraph representation is shown in Figure 1(d) where each process group is represented as a colored hyperedge, process streams are represented as vertices, and the vertices have hyperedge-specific 'in'/'out' annotations indicating the incoming/outgoing nature of the process streams for

a corresponding process groups. Moreover, recycle streams are indicated with an additional annotation 'rec' wherever applicable for the process streams. Figure 1(b) shows each process group as a hyperedge which essentially is a set of named vertices where the names (or annotations) indicate the streams' nature.

The three levels of information in the eSFILES framework is shown for the 'toluene recovery' process group in Figure 3. In Figure 3(a), only the hyperedge representing the process group along with participating streams as vertices and role-specifying annotations are shown. In Figure 3(b), additional information for the entire process group (or hyperedge) such as driving force and stream (or vertex)-specific information such as mass fraction and composition is shown. Finally, information on design aspects and necessary information required for additional analyses such as mixture analysis, reaction analysis, and pure component properties are presented in Figure 3(c). Though the three levels in eSFILES are only shown for a process group brevity, the same could be done for an entire process using the same approach.

Figure 3: (a) Distillation column hyperedge with additional annotations. The corresponding text-based representation for this process groups is  $BTP(in) \rightarrow dl \rightarrow B(out, top, reflux) TP(out, bottom, reflux)$ , (b) the driving force, material compositions, reflux rate, and conversion indicated as hyperedge attributes (for process groups) and hyperedge-specific node attributes (for streams) (c) the design parameters, properties, and constraints are represented as additional meta information.

**Application of the eSFILES in sustainable process design:** (Tula et al., 2017) proposed a 3-stages sustainable process design method consisting of 12 hierarchical steps. Stage-1 consists of steps 1-4 where the process synthesis problem is solved. Stage-2 consists of steps 5-9 where the base case process design problem is solved. Stage-3 consists of steps 10-12 where the base case design is further improved to find innovative and more sustainable alternatives. The original multi-stage method of (Tula et al., 2017) now retrieves the necessary data from the stored hypergraph. Also, different alternatives for stage-3 can easily be generated through different alternatives of the hypergraph, allowing the user to generate and analyze multiple alternatives as well as store the information for future use without having to repeat any of the previously solved steps.

#### 4. Conclusions

The concept of hypergraph has been used to extend the original SFILES concept to multiple levels to store as well as retrieve information related to process synthesis, design, and innovation. In this way, an existing interactive multi-stage method has been made more intelligent and efficient through the adoption of an available AI method for

sustainable process design. Therefore, the eSFILES-based framework for process synthesis and design incorporates a combination of artificial intelligence-based methods and well-known chemical engineering knowledge incorporated through an intelligent system facilitating fast, correct, and consistent decision-making related to process synthesis and design.

Current and future work involves the development of an extended manuscript providing more details of the eSFILES, its adoption in the multi-stage sustainable process design method, and its application in several case studies. In particular, we plan to provide rigorous examples to demonstrate the usability of eSFILES for new process flowsheets and also use them to address real challenges such as provide flowsheet alternatives, perform process intensification, and flowsheet property prediction based on the text-based flowsheet representation using a natural language framework similar to molecular property prediction (Mann et al., 2022) and chemical product design (Mann et al., 2023).

## Abstract

Wastewater treatment units consist of biological treatment with activated sludge and are subject to many disturbances such as influent flowrate, pollutant load and weather conditions bringing about many challenges for the modeling of such plants. Data-driven models may respond to these challenges at the cost of issues such as overfitting or poor fitting due to the lack of high-quality data. To benefit from the available physics-based knowledge and to eliminate the drawbacks of suboptimal and poor training, physics informed neural networks might be quite promising. In this work, artificial, recurrent and physics-informed neural network models are utilized for the wastewater plant in Tüpraş İzmit Refinery. For recurrent models with selected features based on correlation technique, test mean squared error is up to 82% smaller compared to the standard artificial neural network models. Physics-informed trained neural network models with selected features improved the test performance by decreasing mean squared error up to 87% with acceptable decreases in training performance which addresses its strength compared to fully data-driven models.

**Keywords:** wastewater treatment; physics-informed neural networks; recurrent neural networks; process optimization; wastewater control

## 1. Introduction

Wastewater treatment is the removal of contaminants from the wastewater before being discharged into the sea to minimize the damage to the environment. Pre-treatment of

wastewater is a physical treatment that involves grid sieves, sand traps, equalization basins, and corrugated plate interceptor. Coagulants, flocculants, sodium carbonate, and hydrogen peroxide addition to the wastewater corresponds to the chemical treatment where disinfection, sanitization and purification is achieved. Then, the stream is further treated by dissolved air flotation (DAF) which reduces the amount of total suspended solids and oil and grease. Biological treatment involves the removal of biodegradable organic matter by making use of the bacteria which is called the activated sludge process occurring in aeration tanks. Here, bacteria use oxygen to break down the biodegradable organic matter. Activated sludge process is followed by a sedimentation tank also called clarifier. Suspended particles settle out of wastewater as it flows slowly through the tank therefore further purification is achieved. Part of the exiting flow from the clarifier with high mixed liquor suspended solids (MLSS) content is recycled to the aeration tanks (Benyahia et al., 2006.)

Raising concerns around the world about environment have started to shift the regulations for several process systems areas towards tighter windows. Wastewater treatment is among these areas where optimal operation will become inevitable. Since wastewater treatment is a complex, non-linear system including physical, chemical, and biological processes as expressed above and subject to many disturbances, mechanistic modeling of a wastewater treatment unit is challenging (Guo et al., 2015). Alternatively, data-driven models, in particular artificial neural networks (ANN), are widely used at the cost of outcomes of black-box models such as overfitting, underfitting and lack of high-quality data. Similarly, recurrent neural networks (RNN) are able to handle time-dependent responses. They are suited better than the ANNs for dynamic systems. On the other hand, RNNs are also subject to issues such as vanishing gradient problem. Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU) introduce more complex recurrent units with gates to retain long-term dependencies by controlling which information is passed through. The presence of dynamic data in wastewater treatment units makes it appropriate to construct RNN, LSTM and GRU models (Quaghebeur et al., 2022).

In this work, ANN, simple RNN, LSTM, GRU and physics informed ANN models are constructed to predict dissolved oxygen concentration (mg/L) at the aeration tanks, sludge volume index (mL/g) and waste activated sludge (m<sup>3</sup>/day) in Tüpraş İzmit Refinery. Prediction performance is further increased by removing some of the features based on a correlation technique. Section 2 involves the methodology. In Section 3, results are shown, and Section 4 concludes the results.

## 2. Methodology

### 2.1. Artificial and Recurrent Neural Networks

A feed forward, fully connected ANN can be expressed as follows:

$$\hat{y} = f_1(w_1 f_2(w_2 u + b_2) + b_1) \quad (1)$$

where  $f_1$  and  $f_2$  are activation functions,  $w_1$  and  $w_2$  are weights,  $b_1$  and  $b_2$  are bias terms at output and hidden layers, respectively. Moreover,  $u$  and  $\hat{y}$  represents input and output terms, respectively. RNNs extend the feed forward ANNs to handle the sequential data by repeatedly transferring information to the cell states throughout the time series. The prediction at the current time step depends on the input at the current time step and the memory of the cell state. LSTM and GRU architectures can track longer dependencies better than the traditional RNNs due to their complex gated mechanisms controlling the flow of information.

## 2.2. Physics-Informed Neural Networks

The training of the neural networks can be expressed as an optimization problem where the objective function is the loss function given in Eq. 2. Typically, the purpose of training the neural networks is to find the appropriate values of weights and biases that minimize the loss function which can be achieved using the backward propagation algorithm. In order to improve the performance via physics-informed knowledge, neural networks can be trained using a bi-objective loss function which includes user-defined physics term. A bi-objective loss function can be proposed as follows:

$$L = \frac{1}{N} \sum_i^N (y_i - \hat{y}_i)^2 + W_p P \quad (2)$$

where  $W_p$  is the scalar weight and  $P$  is the physics term.

## 3. Results

### 3.1. Comparison of Neural Networks for Prediction of Dissolved Oxygen Concentration at Aeration Tanks

Total suspended solids (TSS), chemical oxygen demand (COD), pH, oil and grease, ammonium ( $\text{NH}_4\text{-N}$ ), phenol, sulfide, TSS at return activated sludge which are measured after dissolved air flotation (DAF) are taken as inputs, and dissolved oxygen concentration in two parallel aeration tanks (Aeration tank A and B) is taken as output. The data is normalized between -1 and 1. The first 90% of the data is used as training data and the remaining is used as test data. An ANN, a simple RNN, an LSTM, and a GRU networks are developed using 3 hidden layers with 50 neurons with the rectified linear unit (ReLU) activation function. The mean squared error loss function with the Adam optimization algorithm in Python is used to train the models. Results based on mean squared error (MSE) and mean absolute percentage error (MAPE) given in Table 1 show that RNNs predicted the test data better than the feed-forward artificial neural network. Among the RNNs, LSTM can be selected as the network delivering the best prediction over test data since simple RNN and GRU converges to more oscillatory predictions as

shown in Figure 1, and it may be more useful to predict the direction. In addition, a correlation technique based on F-value for regression tasks in Sklearn library is used to select features for dissolved oxygen prediction in the aeration tanks based on the LSTM model. (Pedregosa et al., 2011). By this technique, COD, pH,  $\text{NH}_4\text{-N}$ , phenol, sulfide, and TSS at return activated sludge are chosen as inputs and TSS at DAF exit and oil are removed from features since the correlation between these features is low. The results are shown in Table 1 and Figure 1.

**Table 1.** Performance of the Data-driven Neural Network Models for Prediction of Dissolved Oxygen Concentration at Aeration Tanks.

	ANN	Simple RNN	GRU	LSTM	LSTM after feature selection
Train MSE	0.0194	0.0024	0.0028	0.0146	0.0089
Test MSE	0.1266	0.0374	0.0416	0.0327	0.0229
Train MAPE	1.7978	0.3580	0.3616	1.4553	1.224
Test MAPE	0.7006	0.3502	0.4316	0.4150	0.3293

Model

Training

Test

ANN

Figure 1.a.

Figure 1.b.

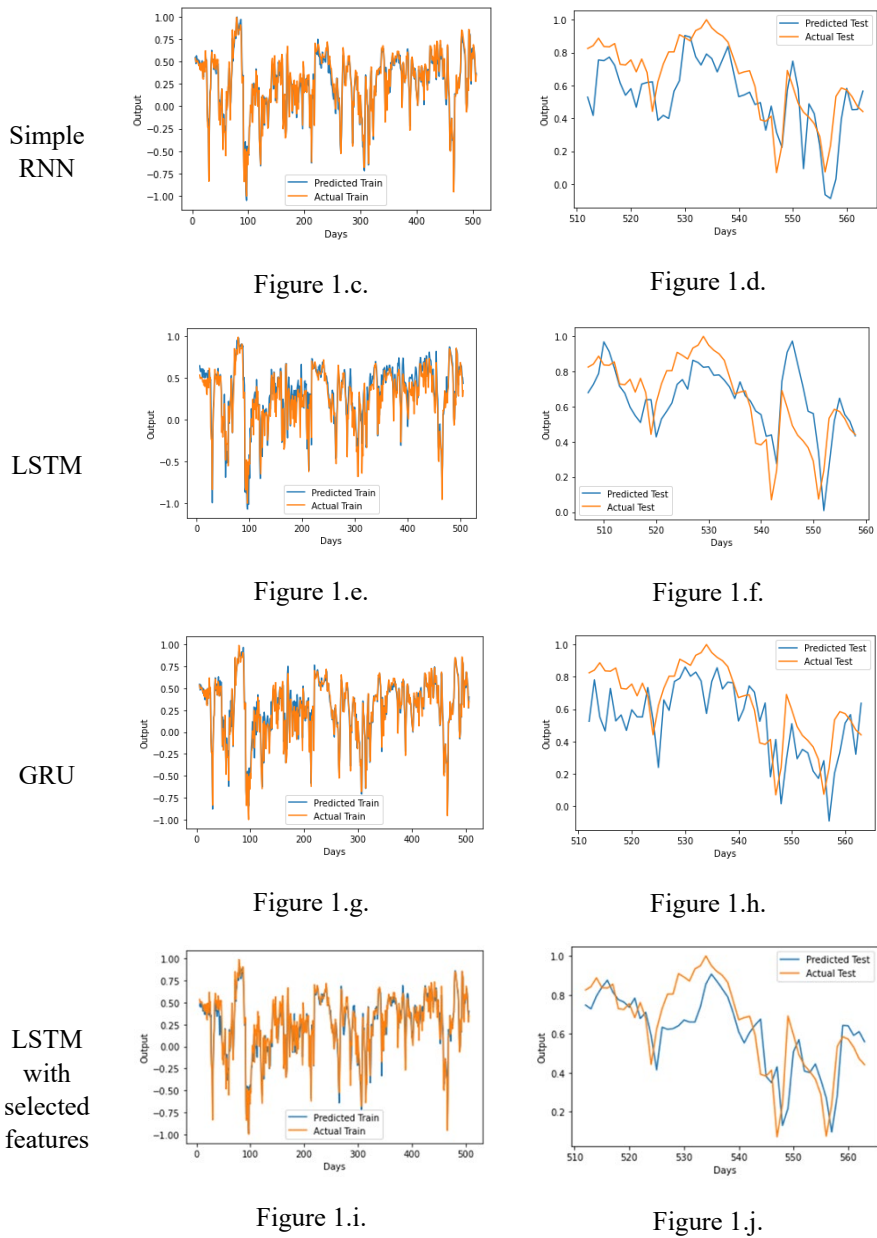

Figure 1. Training and test trends for the prediction of dissolved oxygen concentration at the aeration tanks.

### 3.2. The effect of Physics-Informed Loss Function

Feed-forward artificial neural networks trained with physics-informed (PI+) and physics-uninformed (PI-) loss functions are developed and the results are compared to observe the effect of bi-objective training.

#### 3.2.1. Sludge Volume Index (SVI) Prediction

Dissolved oxygen concentration, pH, temperature, TSS, results of imhoff cone experiments where settleable suspended solid is measured (mL/L), waste activated sludge, and food to microorganism ratio (F/M) in the aeration tank A are taken as inputs, and sludge volume index (SVI) in aeration tank A is taken as output. First 60% of the data is selected as training. A single hidden layer with 5 neurons with the ReLU activation function is used. Physics-term related to the SVI is constructed by a rule-of-thumb used in the operation in the refinery. In addition, based on the results of the feature selection, a physics-informed ANN is developed taking dissolved oxygen concentration, pH, TSS, and settleable suspended solids in the aeration tank A as inputs since the correlation is only observed between these parameters and SVI. Results are shown in Table 2.

**Table 2.** Performance of the ANN Models for SVI Prediction.

	PI-	PI+	PI+ with feature selection
Train MSE	0.0053	0.0067	0.0072
Test MSE	0.0650	0.0181	0.0088
Train MAPE	0.1187	0.1661	0.0969
Test MAPE	0.1520	0.1144	0.0623

Even though the bi-objective physics-informed model delivers slightly higher training errors, the test performance of the model is improved when the physics term is introduced to the loss function. Moreover, the performance of the physics-informed trained ANN is further increased with selected features. Overall, the MSE is reduced 86.5%.

*3.2.2. Prediction of Waste Activated Sludge*

Oily water sewer feed, DAF exit properties (pH, TSS, COD, oil and grease, NH<sub>4</sub>-N, phenol, sulfide), carbon-nitrogen ratio (C/N), COD load, aeration tanks' conditions (pH, dissolved oxygen concentration, temperature, TSS, F/M, settleable suspended solids, SVI), and TSS at return activated sludge are taken as inputs and waste activated sludge from both in aeration tank A and B are taken as outputs. First 80% of the data is selected as training data. There are 4 hidden layers with 50 neurons with the hyperbolic tangent (tanh) activation function. For the physics-term, as in the case for SVI, a rule of thumb related to the waste activated sludge is used. Furthermore, DAF exit properties are excluded from the inputs as a result of feature selection for physics-informed ANN model since they do not have a significant impact to predict the outputs. Training and test performances of the ANN models are evaluated and reported in Table 3. MSE values reduced 40.2% and 47.7% for tank A and B, respectively.

**Table 3.** Performance of the ANN Models for Prediction of Waste Activated Sludge.

	Waste Activated Sludge from tank A			Waste Activated Sludge from tank B		
	PI-	PI+	PI+ with selected features	PI-	PI+	PI+ with selected features
Train MSE	0.0005	0.0020	0.0004	0.0025	0.0022	0.0036
Test MSE	0.0169	0.0132	0.0101	0.0044	0.0029	0.0023
Train MAPE	0.0400	0.0882	0.0209	0.0338	0.0361	0.0171
Test MAPE	0.0307	0.0444	0.0308	0.0399	0.0259	0.0234

**4. Conclusion**

In this work, ANN, simple RNN, LSTM and GRU models are constructed to predict dissolved oxygen concentration at the aeration tanks in Tüpraş İzmit Refinery wastewater treatment unit. RNN-based models improved the prediction capability due to the dynamic nature of the data. LSTM is chosen as the model to be constructed since it predicts the direction better than the other models. Then, the prediction capability is further increased by selecting features based on correlation technique. As a result, the test MSE of LSTM with selected features is approximately 82 % better compared to standard ANN with a closer trend to the actual values. Accordingly, physics-informed knowledge is integrated into the training instances of the neural networks to improve test performance and reduce

the possibility of suboptimal training for the prediction of SVI and waste activated sludge. Test MSE of physics-informed feature selected ANN models for the prediction of SVI, waste activated sludge in aeration tanks A and B are 86.5%, 40.2% and 47.7% smaller, respectively compared to the standard ANN. Finally, this study shows that RNNs may result in more accurate models especially when the process nature is dynamic. In addition, physics-informed knowledge can also be included to the standard ANN models to increase the prediction accuracy.

## Abstract

Optimization is a crucial step to obtain an energy efficient and economically viable design in the chemical industry. The optimization of a chemical process is, however, often challenging due to the inherent complexity of chemical process designs. In this work, different combinations of speed up approaches – parallel computing (ParC), timeout function (TO), escape repeated simulations (ERS), dynamic bound (DB), and machine learning assisted optimization (ML) – are considered and their performances are compared. ParC is always activated as it has previously been found very effective to reduce optimization time. The results show that including DB as part of the speed up approach can ensure successful optimization for complex chemical processes. The TO and ML approaches can help reduce the optimization time significantly, but the ERS approach has no clear effect on the optimization performance. The approach with all speed up approaches activated together yields the best design in the shortest time.

**Keywords:** Stochastic optimization, genetic algorithm, parallel computing, machine learning, distillation

## 1. Introduction

Optimization is an important step in designing a chemical process, as an optimal design should not only have low capital and operating costs (CAPEX and OPEX) but also be energy efficient and sustainable. However, due to the complex nature of chemical process designs, their optimization is challenging, partly because of the difficulty in converging into a truly optimal design, but also due to the long optimization time. Different stochastic optimization methods (e.g., Genetic Algorithm (GA) and Particle Swarm Optimization (PSO)) and their corresponding settings (e.g., for GA, various types of parent selection, crossover, and mutation methods) are available that suit different designs and can help to improve convergence. However, the long optimization time is difficult to address as it is often caused by the high chance of failure of the initialization and re-initialization of the design (i.e., infeasible designs), which makes the solution time long. The optimization time can be significantly reduced if these infeasible designs could be avoided with the use of, for instance, dynamic bounds (Chia et al., 2021), removed by machine learning assisted optimization (Ibrahim et al., 2017), or timed-out using a timeout function. Moreover, escaping (i.e., skipping) repeated simulations is also a direct and efficient way to reduce optimization time. Finally, parallel computing (e.g., master-slave structure) is also widely used to speed up optimization.

## 2. Methodology

It has been reported that stochastic optimization, e.g., Genetic Algorithm (GA), is more robust but also more time-demanding compared with gradient-based deterministic optimization (Chia et al., 2021; Cavazzuti, 2013), and the stochastic optimization time of a chemical process may take up to a few hours. Therefore, in order to tackle long optimization times, different speed up approaches will be introduced in this work.

### 2.1. Parallel Computing (ParC)

The parallel computing approach (ParC) is one of the most successful and commonly applied methods. There are a few structures available to perform ParC, such as the master-slave model, island model, and cellular model, which are classified by different ways of communication within the model. Details of each type of parallel model can be found in Gong et al. (2015). In this work, the master-slave model is used. For this model, in each iteration, the individuals (e.g., chromosomes in GA) are assigned to available slaves (i.e., cores/processors) for evaluating the fitness and constraints. Once the results are obtained, the slaves return the results to the master to handle constraints and to generate the individuals for the next iteration (e.g., parent selection, crossover, and mutation in GA). Another important concept of ParC is the ways of assigning the tasks by either static or dynamic assignment (Mathew et al., 2014). In the case of static assignment, the tasks in a parallel job are assigned to a core/processor beforehand, while in the case of dynamic assignment, a task is assigned to whichever core/processor that is "free" at the moment. For the optimization of chemical processes, the dynamic assignment is preferred as the simulation time of each individual may vary considerably.

### 2.2. Timeout Function (TO)

From the authors' experience, some infeasible simulations (i.e., designs that fail to converge) may take a very long time before they fail to converge due to the multiple re-initialization performed to "confirm" that there is no numerical solution to that simulation. This is illustrated in Figure 1, which is one of the optimization results taken from the case study (10,000 simulations with 4,737 feasible simulations). Almost all the feasible simulations converged within 9 seconds but there is a proportion of infeasible simulations which take more than 9 s and may take up to about 38 s before they can be confirmed as "infeasible". A timeout function can therefore be used to rule out the simulations that take an unreasonably long time but have a high chance of being infeasible.

### 2.3. Escape Repeated Simulation (ERS)

Perhaps one of the most direct ways to reduce the optimization time is to escape any repeated simulations (i.e., skip the simulations that have the exact same input values). Repeated simulations can be present due to, for example, the elitism strategy adopted in GA. ERS can be achieved by saving and comparing the inputs to the simulation. In this work, a "short-term memory" strategy is adapted, where the inputs of the current iteration is saved and retained to the next iteration where the saved inputs and the "new" inputs generated are compared to identify any repeated simulations. The "old" inputs from the previous iteration are then discarded and replaced with the "new" inputs generated in this iteration. This strategy can reduce the need for memory allocation and avoid the slow down effect that will otherwise occur if a "long-term memory" strategy is used (i.e., saving and retaining all inputs that have occurred in all iterations so far).

### 2.4. Dynamic Bound (DB)

Dynamic bound (DB) is a function that changes (internally in the code) the upper and/or lower bound of a variable depending on the value of another variable. The benefit of DB may not be immediate in optimizing a purely mathematical problem, but the benefit is

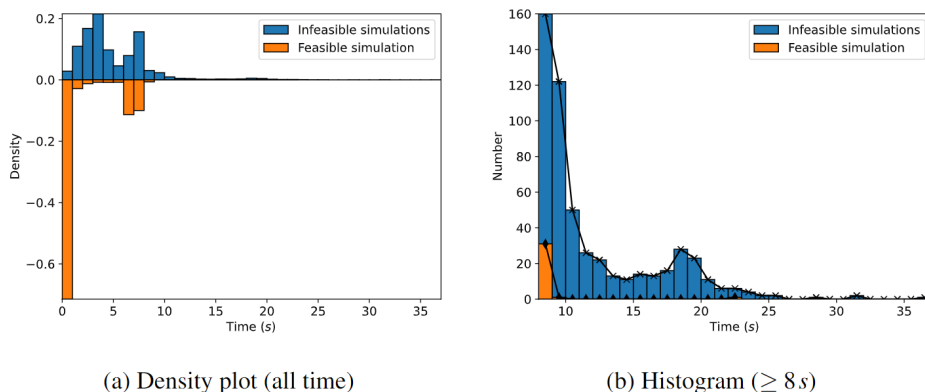

Figure 1. Distribution of infeasible and feasible simulations depicted as:  
 (a) density plot for the whole range of simulations times and  
 (b) histogram as a function of simulation time from 8 s onwards.

tremendous when it comes to optimizing a chemical process. For example, it is obvious that the feed stage ( $N_f$ ) of a distillation column should not be larger than the total number of stages ( $N_t$ ). However, if the bounds of  $N_t$  have a significant overlap with the bounds of  $N_f$  (e.g.,  $N_t$ : 10-40 and  $N_f$ : 5-35) due to lack of information about the process, there will be a very high chance that a design generated from the stochastic optimization has a higher value of  $N_f$  than  $N_t$ , which clearly leads to an infeasible simulation. The chance becomes even more significant if more feed locations and/or more distillation columns are involved in the optimization task. Therefore, if the rule (e.g.,  $N_f$  should not be larger than  $N_t$ ) is violated after generating new individuals (e.g., crossover in GA), then the DB function can be used to re-assign the feed location as a random integer within its lower bound and the total number of stages in the current design, thus reducing infeasibility.

### 2.5. Machine Learning Assisted Optimization (ML)

Due to the nature of the simulations of chemical processes, there are at least two sets of labels of a simulation, which are feasible/infeasible and on-/off-spec. The feasible/infeasible label describes if a simulation converges successfully or not, while the on-/off-spec label describes if a simulation stays within the constraint(s) or violates the constraint(s). Machine Learning (ML; e.g., Support Vector Machine (SVM)) is well suited for classification, which can be used to predict the status of a design before evaluating it. From the authors' experience, using ML to predict the on-/off-spec is more challenging as the training data requires a good balance between the number of on-spec and off-spec simulations, and for a complex chemical process, the proportion of on-spec simulation may be relatively low and even worse in the early iterations. Therefore, in this work, ML is applied to predict only the feasible/infeasible labels. ML will only collect the inputs and results of the simulations until the iteration reaches a user-defined iteration. After that, ML will use the information collected to train the model. Then, for the subsequent iterations, no training is required and only prediction with the trained model is carried out. For designs that are predicted to be infeasible, no evaluations will be carried out, thus the time required to process the "infeasible" designs can be saved.

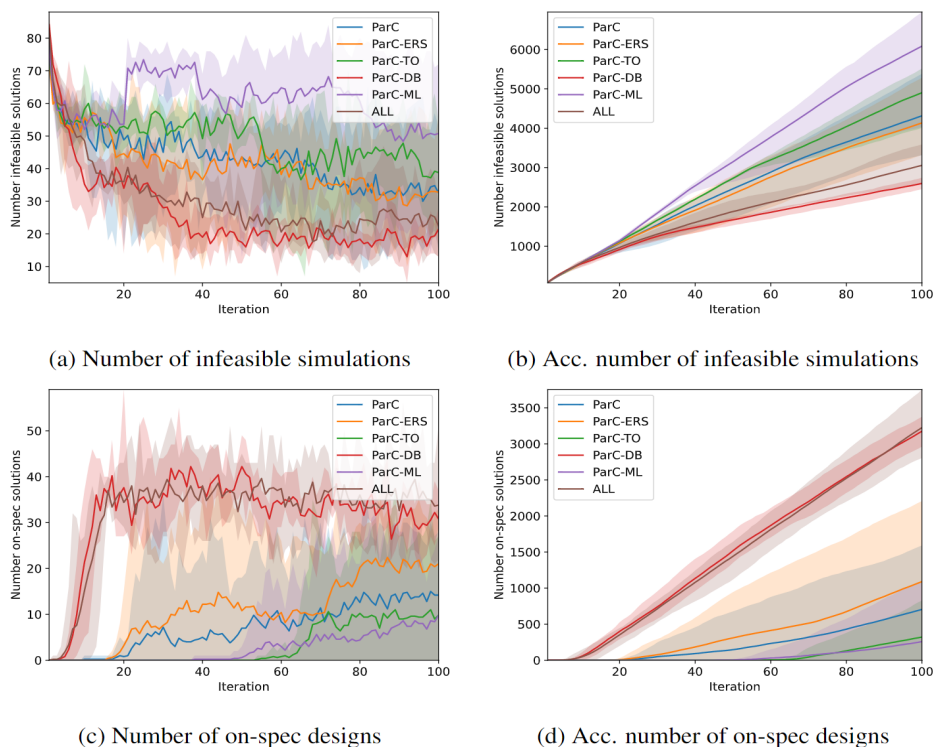

Figure 2. Performances of various combinations of speed up approaches on (a,b) reducing the number of infeasible simulations and (c,d) increasing the number of on-spec designs.

### 3. Case Studies

The case studies in this work were performed on a dual Intel Xeon Gold 6226R CPU with 16 Cores 2.90GHz (total 64 logic processors) for a highly integrated and complex hybrid dividing wall column (H-DWC) design to separate a mixture of ethyl acetate and ethanol, and the H-DWC details can be found in Chia et al. (2022). The simulation of a H-DWC involves two distillation columns (prefractionator and main column in the Petlyuk structure) and a membrane network, and the optimization variables are the design and operating variables of the distillation columns and membrane network. To compare the performance of different approaches, six optimization tasks are carried out: optimization with parallel computing (ParC); ParC with timeout function (ParC-TO); ParC with escaped repeated simulation (ParC-ERS); ParC with dynamic bound (ParC-DB); ParC with machine learning (ParC-ML); and all approaches activated together (ALL). ParC was always activated with 40 processors with the dynamic task assignment structure, as it had been found in previous work that ParC is very efficient in reducing optimization time (Chia et al., 2021). For TO, the timeout value was set as 10 s, decided through statistics shown in Figure 1. For ERS, the "short-term memory" strategy was adopted. For DB, a few rules related to column stages were defined, such as the feed locations should not be larger than its total number of stages (stage number is counted starting from the condenser), and the number of stages on both sides of the wall in the dividing wall column should be the same (although can of course be different). For ML, a support vector machine (SVM) library developed by Chang and Lin (2011) was used with a seventh-

degree polynomial,  $C = 5$ , and  $\epsilon = 0.1$ . The settings for SVM were decided through trial-and-error (not shown). The first 20 iterations were used for training the SVM. In this work, the H-DWC model was developed in gPROMS Process (Process Systems Enterprise, 2021). The Genetic Algorithm (GA) was used as external optimization (black-box optimization) and was coded in C# by the authors. GA was constructed with 100 iterations (generations) and 100 individuals (chromosomes), tournament with four players for the parent selection, flat crossover, and discrete random mutation.

Each optimization task was repeated five times and the results are plotted in Figure 2, where the solid lines are the average values. The bands bounded by the minimum and maximum values are plotted together. Figures 2a and 2b show the number of infeasible simulations and the number of accumulated infeasible simulations in each iteration, respectively. It can be seen that ParC-ML has the most infeasible simulations, and this is because the training of SVM is biased due to the fact that most of the simulations in the first 20 iterations are infeasible. ParC, ParC-ERS, and ParC-TO show similar trends, especially ParC and ParC-ERS. The finding is valid as for ERS, this function does not affect the operation of the GA, and for TO, a slightly larger deviation from ParC is also expected because there is still a chance that feasible simulations may be timed out and be considered as infeasible simulations, which may slightly reduce the performance of GA (considering the number of feasible and on-spec simulations). Considering ParC-DB and ALL, these have similar trends and the lowest number of infeasible simulations in each iteration. Compared with ParC, the total number of infeasible simulations (shown in Table 1) of ParC-DB and ALL drops from 4313 to 2596 (40 % reduction) and 3053 (29 % reduction), respectively, which indicates that DB is the key function to reduce the number of infeasible simulations. Considering the number of on-spec simulations shown in Figures 2c and 2d, it is not surprising that ParC-DB and ALL have higher number of on-spec simulations as many unreasonable (thus off-spec) designs are avoided by DB, so a higher chance of on-spec designs would be expected. Moreover, the use of DB balances the number of feasible and infeasible simulations in the first 20 iterations, thus the bias of ML in ALL is reduced compared to in ParC-ML.

To reflect the speed of the optimizations, three indicators are tabulated in Table 1, which are the convergence percentage (the number of successfully converged optimizations, i.e., the final optimal on-spec design divided by the total number of optimizations performed); quality of the fitness (e.g., the total annualized cost in the case studies); and optimization time. Starting with the convergence percentage, Table 1 shows that only ParC-DB and ALL could achieve 100 % convergence, which indicates that to obtain the same number of valid optimizations (i.e., converged optimizations), other approaches require more repeated optimizations leading to a longer total optimization time. Both ParC-DB and ALL yield designs with the lowest TACs ( $2.54 \text{ M } \$ \text{ y}^{-1}$ ), indicating better optimization efficiency. Note that all optimizations stop after 100 iterations, which is the stopping criterion. Moving to the most direct indicator, optimization time, starting with ParC, the averaged optimization time is 1886 s. The time for each individual is recorded and the summation of all individual times is considered as the total time taken without parallel. The optimization time without parallel computing is 30,963 s, which indicates the optimization with parallel computing only is about 15 times faster. The table shows that ERS does not save CPU time as the elitism percentage is low (10 %), and repeated designs rarely appeared due to the applied Flat crossover method. Moreover, ParC-DB has minor improvement due to the lower infeasible rate. For the other three approaches, ParC-TO,

Table 1. Key performance indicators of the different speed up approaches. The values reported are the mean values obtained from five optimizations unless stated otherwise.

	ParC	ParC-ERS	ParC-TO	ParC-DB	ParC-ML	ALL
No. infeasible solutions	4314	4134	4902	2596	6086	3053
No. on-spec solutions	704	1090	321	3075	259	3225
Optimization time (s)	1885	1939	1397	1756	1452	1033
Conv. percentage (%)	60	80	60	100	40	100
TAC* ( $M \$ y^{-1}$ )	2.65	2.63	2.80	2.54	2.67	2.54

\* Considering only converged optimizations

ParC-ML, and ALL, they all show good time savings with about 26 %, 23 %, and 45 % reduction, respectively.

#### 4. Conclusion

In conclusion, this work has compared five different approaches to speed up stochastic optimization. By considering the overall performance, the dynamic bound function is clearly the most effective function to ensure a successful optimization for a complex chemical process. Using a timeout function or machine learning has no clear improvement on the quality of the optimization results, but these functions show remarkable reduction in the optimization time. The escaping repeated simulation function shows no clear effect on the optimization speed. By applying all approaches together, the optimization achieves the best design, the same as for parallel computing with dynamic bound, but with the least time. In future work, a more comprehensive comparison will be performed with other stochastic optimization methods such as Particle Swarm Optimization and Simulated Annealing.

## Abstract

In this work, a new design for post-combustion capture (PCC) of CO<sub>2</sub> is introduced, using green deep eutectic solvent Choline chloride/Urea (1:2). A multi-objective optimization using meta-heuristic algorithm differential evolution and tabu list (MODE-TL) considering environmental and economic **objectives** is performed to obtain a sustainable process design. The proposed process was analyzed for treating flue gases from combustion of the most common fuels used in power plants. The process performs with a lower cost and environmental impact when treating flue gases from the combustion of coal. Through a simulation in Aspen Plus, it is shown that using ChCl/Urea (1:2) it's possible to obtain a process capable of recovering more than 95% of the CO<sub>2</sub> contained in the combustion gases with a purity of 95% molar. A sustainable capture processes according to the objectives of green chemical engineering and circular economy is developed.

**Keywords:** CO<sub>2</sub> capture, MEA, deep eutectic solvent

## 1. Introduction

The United Nation's 2030 Agenda for Sustainable Development has called for the taking urgent action to combat climate change and its impacts, mainly through Goals 7, 9, 12 and 13. Citing examples of the efforts companies can make to contribute by decarbonizing their operations and supply chains. Seeking to reduce the carbon footprint of their products, services and processes, and setting ambitious emissions reductions targets in line with climate science. As well as scaling up investment in the development of innovative low-carbon products and services. Post-combustion carbon capture (PCC) process is one of the most promising technologies due to its ability to treat high CO<sub>2</sub> concentration streams from emission points from fossil fuels or biomass in industrial facilities. Moreover it can be adapted as a complementary process in existing thermal power plants. Monoethanolamine (MEA) is conventionally used as solvent because of its high reactivity with CO<sub>2</sub> and relatively low cost. This technology has severe disadvantages including a high rate of corrosion of process equipment and degradation of amines due to the presence of SO<sub>2</sub>, NO<sub>2</sub> and O<sub>2</sub> in the combustion gases (Luis, 2015). In addition, MEA is considered toxic, so its implementation entails a high environmental impact.

In recent years, research has focus in a new category of green solvents called Deep Eutectic Solvents (DES) with selective absorption capacity towards CO<sub>2</sub>. DESs have the characteristics of low cost, low to no toxicity, and good biodegradation. In recent years

the properties of several DES have been reported in literature. Among them, the eutectic combination of choline chloride and urea in a 1:2 (ChCl/Urea (1:2)) molar proportion has shown the highest absorption rate for CO<sub>2</sub> (García et al., 2015). This property, along with its low vapor pressure and high thermal stability, has made it a candidate for replacing MEA in CO<sub>2</sub> removal processes.

DESs industrial applications have been developed in recent years. Ma et al. modeled, simulated and evaluated the upgrading of biogas by removing CO<sub>2</sub> with aqueous ChCl/Urea (1:2), demonstrating that this solvent was suitable for this process. Using choline chloride/urea (1:2) as the absorbing agent, Luo et al. (2021) designed and simulated an industrial-scale PCC process, to treat flue gases from coal combustion. Evaluation of life cycle environmental sustainability showed that the CO<sub>2</sub> capture with DES has significantly lower values compared to MEA, highlighting the advantage of lower environmental impact. However, the application of DES in an optimization framework considering sustainable targets, is not yet developed. In other words, no study has been conducted to analyze the impact of post-combustion absorption process design variables and their effect on the sustainability of the process, using ChCl/Urea (1:2) as solvent. Furthermore, the capacity of the DES to treat flue gasses with different CO<sub>2</sub> concentrations needs to be studied, as traditional power plants require a wide operational range in terms of the fuel used for energy generation, and the associated CO<sub>2</sub> concentration.

In this work, a novel PCC process using green solvent ChCl/Urea (1:2) is designed and optimized for the first time under a sustainability scheme, using Aspen Plus. The impact of the design variables on environmental and economic metrics is analyzed. Furthermore, the plant's capacity for treating flue gases with different CO<sub>2</sub> concentrations is studied through four case studies, considering the use of Natural Gas (NG), Associated Gas (AG), Biogas (BG) and Coal.

## 2. Study Case

The study case presented in this work evaluates the scenario of a power plant coupled to a carbon capture plant using DES as solvent (Fig. 1). The power plant consists in a traditional steam-generating boiler applied in a combined-cycle configuration. A fuel feed flow of 1000 kmol/h is considered, for natural gas, biogas, and associated gas. For coal, a flue gas flow of the same order of magnitude as those obtained for the combustion of the gasses is considered. The combustion process simulation is based in the simplified model proposed by Luyben (2013). The Peng-Robinson (PR) thermodynamic model was used to calculate physical properties, and an Aspen RGibbs chemical-equilibrium reactor model is used for the combustor. The PCC process consists of an absorber/desorber system with two intermediate flash tanks. The RADFRAC module is used for the absorber and desorber columns, considering an equilibrium-based physical absorption. ChCl/Urea was modeled in Aspen Plus using a group contribution method, and critical and temperature dependent properties, as well as Henry constants for the gaseous components in the solvent were taken from experimental data. The NRTL thermodynamic model was used to calculate the activity coefficient in the liquid phase, for ChCl/Urea + water. PR thermodynamic model was used to calculate fugacity coefficient for the gaseous components, with parameters taken from Aspen databank.

The multi-objective optimization of the process modeled in Aspen Plus represents a non-linear and multivariable problem, where the objective function used as optimization criterion is generally non-convex with several local optimums. Stochastic global optimization methods, such as Genetic Algorithms, have been proven to be robust

and can handle both MESH equations and phase equilibrium calculations with complete models. A multi-objective meta-heuristic optimization algorithm differential evolution and tabu-list (MODE-TL) is used to obtain an optimal design of the PCC process. This algorithm allows the comparison of multiple solutions in terms of the objective functions, described after the economic and environmental metrics considered. For the economic indices, total annual costs (TAC) were calculated with the module costing technique outlined by Turton *et al.* (2003). Return on Investment (ROI) was calculated according to Jiménez-Gutiérrez. Eco-Indicator 99, as a measure of environmental impact, was calculated according to the methodology developed by Goedkoop *et al.* (2001). Total Solvent Recovery Energy (TSRE) and Green House Gas Emissions (GHGE) environmental indices were also considered, according to the definitions proposed by Jiménez-González *et al.* (2012). A general mathematical expression for the objective function and its respective decision variables involved in the optimization procedure are shown in Equation (1).

$$\min[TAC, -ROI, EI99, TSRE, GHGE] = f(F_{air}, x_{H_2O}, F_{DES}, T_{DES}, N_{abs}, N_{PS1}, N_{PS2}, P_{abs}, P_{F1}, \Psi_{F1}, P_{F2}, \Psi_{F2}, RR, D, N_{des}, N_{feed}, P_{des}) \quad (1)$$

$$s.t. \ y_{i,f} \geq x_{i,f}, \text{ and } w_{i,f} \geq u_{i,f}$$

Where the solutions are restricted to satisfy the recovery of 95% of the CO<sub>2</sub> produced during the combustion and also to achieve a purity of 95% mol of CO<sub>2</sub>. Where  $y_{i,f}$  represents the CO<sub>2</sub> recovered in the desorber column and  $x_{i,f}$  represents the 95% of the CO<sub>2</sub> produced during the combustion. As well,  $w_{i,f}$  represents the purity achieved at the desorber column and  $u_{i,f}$  represents the purity expected of at least 95% mol of CO<sub>2</sub>.

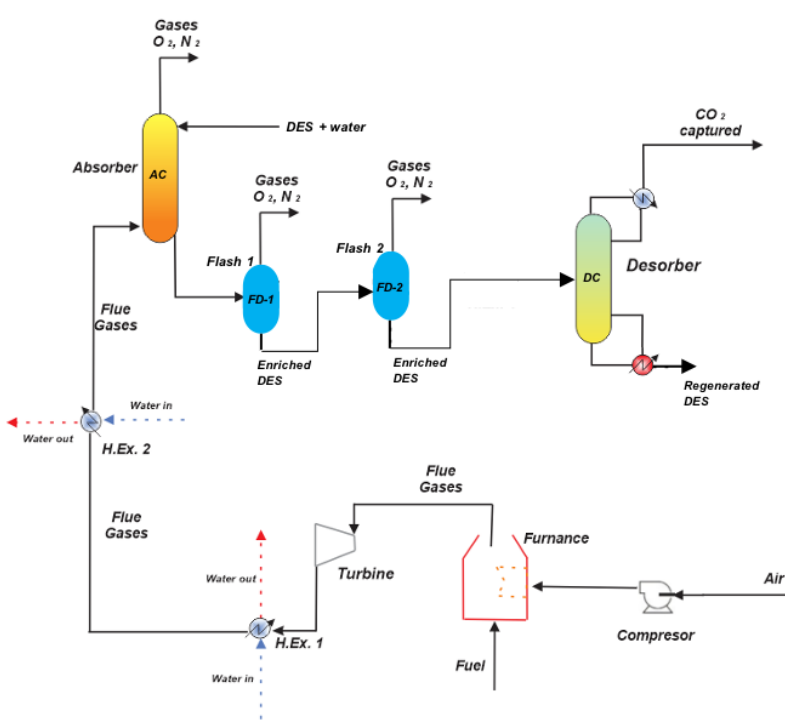

Figure 1. Process diagram of the combustion and PCC proposed scheme.

The decision variables and operation range considered for the optimization are described in Table 1. The optimization method was implemented using a hybrid platform that interconnects the Aspen Plus simulation with Excel through Visual Basic. The variable design vectors generated by the algorithm are fed to the process model, where the rigorous simulation is implemented. The outputs of the process model (flows, thermal loads, etc.) are fed back to Excel, where MODE-TL evaluates the objective functions and proposes new values of input vectors, according to the evolutionary nature of the algorithm, the process begins to iterate. The parameters used for the MODE-TL method were: 120 individuals, 800 maximum number of generations, taboo list of 50% of individuals, taboo radius of  $1 \times 10^{-4}$ , and 0.9 and 0.3 crossover probability and mutation factor, based on previously reported works in literature for optimization of multicomponent separation schemes using the RADFRAC module.

**Table 1.** Decision variables and search intervals

Variable Name	Variable Type	Symbol	Range or Value
Feed air molar flow rate, kmol h <sup>-1</sup>	Continuous	$F_{air}$	10025 – 35000
H <sub>2</sub> O:ChCl/Urea molar proportion	Continuous	$x_{H_2O}$	1.6 – 5.5
DES molar flow rate, kmol h <sup>-1</sup>	Continuous	$F_{DES}$	5000 – 120000
Absorber stages	Discrete	$N_{abs}$	20 – 100
1 <sup>st</sup> packing section ending stage	Discrete	$N_{PS1}$	2 - ( $N_{abs} - 1$ )
2 <sup>nd</sup> packing section starting stage	Discrete	$N_{PS2}$	( $N_{abs} + 1$ ) - $N_{abs}$
Temperature of solvent feed, °C	Continuous	$T_{DES}$	40 - 60

### 3. Results

This section provides the multi-objective optimization results for the PCC process. For all designs, CO<sub>2</sub> recovery constraint is set at 95%, and 95% mol purity for the CO<sub>2</sub> at the distillate of the DC.

#### 3.1. Pareto fronts

Two dimensional pareto diagrams obtained for the coal case study are presented in Fig. 2. The form of the pareto fronts for EI99 and TAC exhibits a trend of competing objective

functions. This behavior indicates that the selection of a design with the lowest EI99 causes the TAC to increase, hence the solutions that offer the best trade-offs between the two objectives are those located in the curve zone of the Pareto chart. The pareto front for TSRE and TAC indicates that a design selection with the lowest TSRE causes TAC to diminish, therefore, designs that minimize both objectives are found in the lower left corner. The solvent recovery energy has a direct impact in TAC, given that the high use of vapor in the PCC process represents 70-80% of all annual costs. The pareto front for EI99 and GHGE exhibits a competing objective function trend, similar to EI99 vs TAC, where the best trade-off between objectives can be found in the curve area of the chart.

In terms of the impact of some design variables on the indices considered, a trend between Water:ChCl/Urea proportion and TAC was found. A higher water to ChCl/Urea proportion diminishes CO<sub>2</sub> absorption capacity, increasing the need for solvent flow. This causes process equipment topology to increase, as well as increasing TSRE requirements. As a consequence, GHGE also increases, and from the pareto chart trends in Fig. 2 EI99 decreases. Higher ChCl/Urea concentration will increase environmental impact and pumping costs considerably due to a higher viscosity of a poorly diluted ChCl/Urea. As well, the reflux ratio is directly related to the energy requirements. A higher reflux ratio causes energy requirements for the capture to increase.

**Figure 2.** Pareto fronts for EI99 vs TAC, EI99 vs GHG, TSRE vs TAC and TSRE vs GHGE.

### 3.2. Optimal design performance indices

The optimal point (O.P.) was selected from the pareto fronts, considering a compromise between minimizing the objective functions. In the pareto front for EI99 and TAC, the highest and lowest ROI values found for the optimal designs were highlighted, along with the ROI value for the O.P. To showcase that a good performance in terms of this objective was also taken into consideration when searching for the optimal design.

The optimization results reveal that the Coal process provides the lowest energy usage per unit of CO<sub>2</sub> captured, with a TSRE and GHGE which is 12.3%, 27.7% and

31.7% lower than AG, NG and BG respectively. The energy savings are also reflected in the value of TAC for Coal (8.2%, 15.5% and 16.2% lower per tonne of CO<sub>2</sub> captured, compared with AG, NG and BG respectively). In terms of environmental impact, the Coal process presents a value that is 20.1%, 15.7% and 30.2% lower per tonne of CO<sub>2</sub> captured, as compared with AG, NG and BG respectively. The coal PCC process exhibits the best performance considering all environmental and economic indices simultaneously, although the highest ROI is obtained when AG is used as fuel.

The proposed scheme (Fig. 1) for solvent regeneration using two flash drums and a desorber column, allows the separation of CO<sub>2</sub> from the enriched solvent to occur at pressures between 1 and 5 bar, avoiding a costly vacuum pressure operation.

#### 4. Conclusions

The simulation of the PCC process shows that the CO<sub>2</sub> capture of different flue gases is possible by use of green solvent ChCl/Urea (1:2).

Multi-objective optimization considered simultaneously economic and environmental objectives and resulted in optimal solutions according to sustainable design for the PCC process. Through the MODETL optimization method, design and operating conditions were found as to avoid vacuum pressure operation at the solvent regeneration steps while using a considerably lower absorption pressure (13.9 bar) compared to the PCC process proposed by Luo et al (45 bar).

The optimization results reveal that the Coal process provides the lowest energy use compared, a lower TAC and diminished environmental impact per tonne of CO<sub>2</sub> captured, compared with other PCC processes. The highest ROI was obtained when using AG as fuel.

## Abstract

This paper focuses on a novel multistage retrofitting problem from conventional fossil-based refinery into biomass-based refinery with the aim of sustainable development of fuels. Given a typical refinery and potential biomass-based technologies, the problem has an objective to integrate the latter into the former by making use of existing units in the new process(es). A mixed-integer linear programming model that considers a ten-year long retrofit planning is formulated. Furthermore, the deterministic problem is extended to a multi-stage stochastic programming problem under both endogenous yield uncertainty and exogenous demand uncertainty and solved via a Lagrangean decomposition algorithm. The results provide flexible design alternatives by determining the units that should be added or modified for the selected biomass-based technologies. Regarding uncertainty, different schemes with strategic and operations decisions are determined. The results show advantages in considering retrofitting problem with detailed operation constraints for each year.

**Keywords:** Refinery; Biomass; Retrofit; Uncertainty; Lagrangean decomposition.

## 1. Introduction

Significant growth in renewable energy, such as solar and biomass, has taken place over the last 30 years. As the core part of energy supply, the petroleum refinery industry is increasingly gaining importance for producing more sustainable energy instead of fossil fuels. Among these novel energy forms, biomass-based energy is a promising alternative for the refinery industry since the biomass can be used to produce hydrocarbons that are drop-in replacements for the ones obtained from crude oils. This provides opportunities to repurpose existing crude oil refineries into biomass refineries. Such a plan has been under consideration in both industry and academia for a long time and has recently seen renewed interest (see for example Exxon Mobil (Sanicola, 2021), and in academia (Ericson et al., 2019)). The evaluation of such design is often executed with Life Cycle Assessment (LCA) (Garcia-Nunez et al., 2016) under predefined flowsheet and preselected biomass-based technologies. However, such framework usually ignores the flexibility to adopt flowsheets according to expected development in market and industry. This paper proposes a mixed linear programming (MILP) modeling framework to solve the long-term retrofit problem, while considering detailed production constraints in each year. Uncertainty is also addressed by extending the proposed model with stochastic programming.

## 2. Problem Statement

### 2.1. Crude-based Refinery Demonstration

The flowsheet of a prototypical crude-based refinery is shown in Fig. 1. The ranges of hydrocarbons are labelled to represent the corresponding components, typically considered in each stream/processed by each equipment. For example, the crude oil, is first distilled in crude distillation unit (CDU) into liquified petroleum gas (LPG, composed of hydrocarbons  $C_3$  to  $C_5$ ), naphtha (NAP composed of hydrocarbons  $C_5$  to  $C_{10}$ ), etc. These streams are then further hydrotreated, cracked and reformed in secondary processing units, such as continuous reformer unit (CRU), fluid catalytic cracking (FCC) and others. The final products, LPG, gasoline (GASO), jet fuel (JET), diesel (DIESEL) and fuel oil (OIL) are obtained by blending intermediates to satisfy quality specifications.

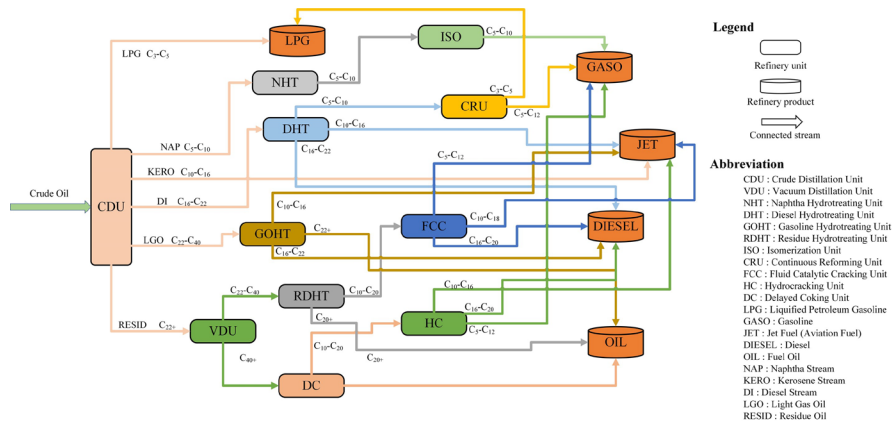

Fig. 1 Flowsheet of a given crude-based refinery. (Presented in Appendix)

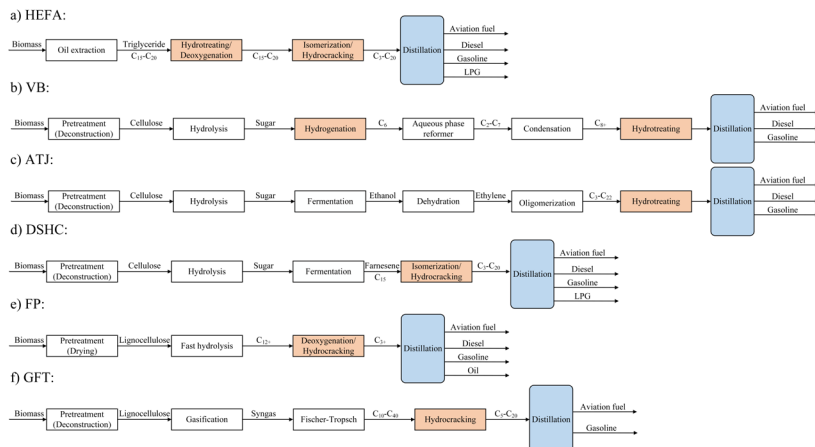

Fig. 2 Detailed process steps for potential biotechnologies. (Presented in Appendix)

### 2.2. Biomass-based Refinery Demonstration

To produce sustainable energy based on biomass, six biomass-based technologies are considered, namely, Hydroprocessed esters and fatty acids (HEFA), Virent's BioForming (VB), alcohol to jet (ATJ), direct sugar to hydrocarbon (DSHC), fast pyrolysis (FP), and gasification and Fischer-Tropsch (GFT) (Tanzil et al., 2021a, 2021b). Details of each technology path can be seen in Fig. 2 with illustration for every step and stream.

For example, the VB technology, which addresses the pine or stover as the feedstocks, first transforms the materials into cellulose. The cellulose is converted into sugar via hydrolysis. Then the sugar is hydrotreated into hydrocarbons and followed by aqueous phase reforming, condensation and hydrotreating. Finally, the biomass-based hydrocarbons are distilled to produce aviation fuel, gasoline and diesel. In the VB technology, the hydrotreating steps can be executed in a newly built unit or in an already existing refinery hydrotreating unit. We compare components of the streams entering each unit to find possible matches. In addition, the distillation step can also be done in the CDU instead of in new-installed units.

### 3. Mathematical Formulation

#### 3.1. Deterministic Model

The goal is to minimize the total cost over ten years by subtracting sales income from the summation of material operation reconnection and new unit installation costs. For each year, the operation constraints on selection of materials and production are also considered. The problem is formulated as a MILP as follows and details for the mathematical formulation can be seen in Appendix.

$$\begin{aligned} \min z &= a^T x + b^T y \\ Ax + By &\leq d \\ x \geq 0, y &\in \{0,1\}^m \end{aligned} \quad \text{MILP}$$

#### 3.2. Multistage Stochastic Programming Model

The problem is extended to a multistage stochastic programming (MSSP) under endogenous yield uncertainty and exogenous demand uncertainty (Apap and Grossmann, 2017). The scenario tree is formulated as Fig. 3, where each stage is formulated as an inner two-stage stochastic programming problem with endogenous  $\xi$  uncertainty and exogenous  $\theta$  uncertainty (Lara et al., 2019). The decisions are divided into strategic decisions and operational decisions. The strategic decisions, including the selection of biomass-based technology, capacity expansion and unit substitution, are assumed only related to endogenous uncertainty. The operational decisions, such as type of crude oil, amount of feedstock and sale strategy for products in each year, are assumed related to demand uncertainty and are independent in each year.

Fig. 3 Scenario tree illustration. (Presented in Appendix)

The mathematical formulation of the MSSP is given as follows. The set  $i \in I$  denotes the outer scenarios corresponding to endogenous yield uncertainty and set  $j \in J$  denotes the inner scenarios related to exogenous demand uncertainty appearing in each year. The problem is solved by reducing scenario pairs first, and then using a Lagrangean decomposition algorithm by dividing it into subproblems based on outer scenario pairs. Details on the modeling and algorithm can be found in Gupta and Grossmann (2014, 2011).

$$\begin{aligned}
 \min z = & \sum_{i \in I} p_i \left( \sum_{t \in T} c_{t,i} y_{t,i} + \sum_{j \in J} p_j d_{t,i,j} x_{t,i,j} \right) \\
 \text{s. t. } & \sum_{\tau \leq t} a_{\tau,i} y_{\tau,i} \leq b_{t,i} \quad \forall t \in T, i \in I \\
 & e_{t,i} y_{t,i} + f_{t,i,j} x_{t,i,j} \leq g_{t,i,j} \\
 & y_{t,i} = y_{t,i'} \quad \forall t \in \{T_1\}, i, i' \in I \\
 & Z_{t,i,i'} \Leftrightarrow F(y_{t1,i}, y_{t2,i} \dots y_{t-1,i}) \quad \forall t \in T \setminus \{T_1\}, i, i' \in I \\
 & \begin{bmatrix} Z_{t,i,i'} \\ y_{t,i} = y_{t,i'} \end{bmatrix} \vee [\neg Z_{t,i,i'}] \quad \forall t \in T \setminus \{T_1\}, i, i' \in I \\
 & y_{t,i} \in \{0,1\} \quad \forall t \in T, i \in I \\
 & x_{t,i,j} \in R \quad \forall t \in T, i \in I, j \in J
 \end{aligned}$$

MSSP

### 4. Results and Discussion

#### 4.1. Computational Performance

Both the deterministic problem and the MSSP problem are solved in Gurobi 9.5.2 via GAMS 41.1.0 on Windows 11 with Intel(R) Core(TM) i7-9700 CPU @ 3.00GHz and 16GB memory. The model statistics and computational results are shown in Tables. 1 - 2 and Fig. 4.

Fig. 4 Computational performance of Lagrangean decomposition algorithm. (Presented in Appendix)

Table.1 Model statistics.

Problem	# of continuous variable	# of binary variable	# of constraints
Deterministic model	14,197	7,146	13,954
MSSP	11,576,705	459,264	15,808,450

Table.2 Optimization results.

Problem	Solver	CPU time /s	Gap /%	Objective /M\$
Deterministic model	CPLEX	138.5	0.01	-1020.85
	Gurobi	16.6	0.01	-1020.85
MSSP	CPLEX	7200.0	/	/
	Gurobi	7200.0	/	/
	Lagrangean decomposition	4511.3	0.1	-24402.6

The deterministic model is solved to optimality quite fast. For the MSSP model, 64 outer scenarios are included related to the combinations of endogenous yield uncertainty and in each year, 27 scenarios related to exogenous demand uncertainty are considered, leading to 270 inner scenarios in total. The scale of the MSSP increases exponentially as shown in Table. 1 and commercial solvers fail to give a feasible solution within 2 h of

CPU time; the Lagrangean decomposition algorithm, solves the problem to an optimality gap of 0.1% in ~ 75 min.

4.2. Results of Deterministic Model

From the deterministic model, HEFA, VB, FP, GFT are selected to produce the desired bioproducts. The retrofitted flowsheets in year 1, year 2, year 5 and year 9 are displayed in Fig. 5. For a better illustration, high qualified figures are presented in Appendix.

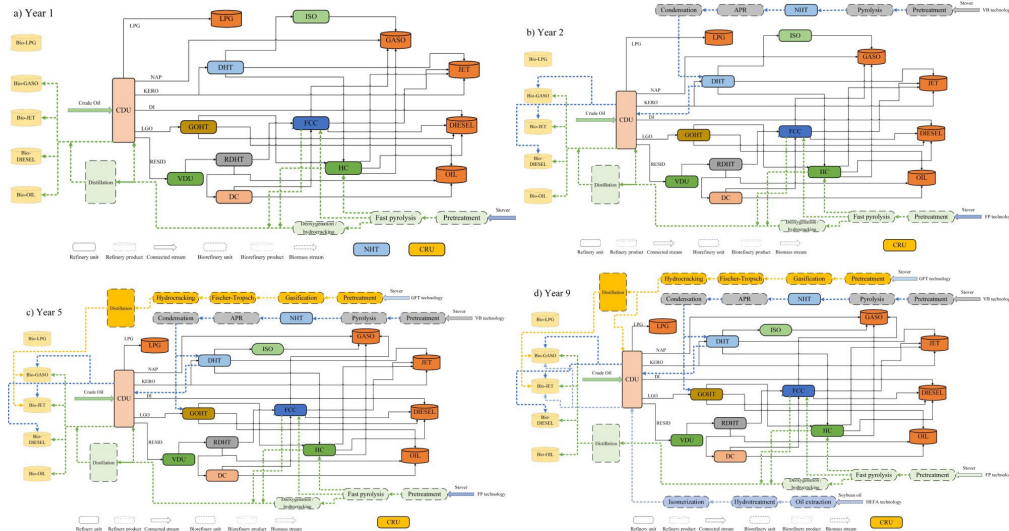

Fig. 5 Retrofitted flowsheet of the biorefinery over several years. (Presented in Appendix)

As can be seen VB is built in the first year to process corn stover. For each step in VB, a new operation unit is built. While in the hydrocracking step, the biomass-based hydrocarbon stream can be directly fed into the FCC and HC units for deep cracking. Although a distillation unit is built for VB, the CDU is still used to obtain bioproducts with the same time until year 7. The NHT and CRU units are removed from the refinery in the first year, and NHT is used in VB technology as the hydrotreating step as well as DHT unit in year 2. Later, the GOHT is also used to process the biomass-based hydrocarbons from VB as the final hydrotreating step in addition to oil-based stream. GFT is implemented in year 5 with all the units installed. In year 9, the HEFA technology is also installed and the products are obtained via the CDU. Note that the continuous reforming unit (CRU) is removed and never used during the time horizon.

Table.3 Statistics of result from MSSP

Bio-technology	Scenarios selecting bio-technology	Bio-technology	Scenarios selecting bio-technology
HEFA	28	DSHC	0
VB	64	FP	64
ATJ	0	GFT	36

4.3. Results of MSSP

With the MSSP model, the biomass-based technology selection statistics are presented in Table. 3. For a total of 64 scenarios, VB and FP are all selected as the main process to produce biomass-based hydrocarbons, while ATJ and DSHC are not. Comparing to VB and FP, the higher expense and lower yield of ATJ and DSHC prevent their applications. To compensate for the production demands, GFT and HEFA are the backup biomass-

based technologies to install in later years. The GFT is preferred since it is selected in 36 scenarios while HEFA is selected in 28 scenarios.

To evaluate the effect of MSSP, the value of stochastic solution ( $VSS$ ) is also calculated by solving the problem stage by stage iteratively (Zhang et al., 2018). The definition of  $VSS$  and  $\overline{VSS}$  are presented as follows.

$$VSS = z^{DP} - z^{MSSP} \quad (1)$$

$$\overline{VSS} = (z^{DP} - z^{MSSP}) / z^{DP} \quad (2)$$

$z^{DP}$  is the optimal solution from solving problem for each stage iteratively.  $z^{MSSP}$  is the solution from MSSP model. The  $VSS$  equals to 522 M\$ and the  $\overline{VSS}$  is 2.15% which reveal the benefit of implementing stochastic programming.

## 5. Conclusion

This paper addressed the retrofit problem from a conventional refinery to a biorefinery by incorporating new biomass-based technologies into an existing oil-based refinery. The problem is extended into a MSSP model under both endogenous and exogenous uncertainties. Each stage is divided into strategic and operational steps. The Lagrangean decomposition algorithm is used to solve such problem. The results show that the FP and VB technologies are preferred, and a cost saving of 522 M\$ can be obtained with stochastic programming with the evaluation of  $VSS$ .

# A Combined D-optimal and Estimability Model-Based Design of Experiments of a Batch Cooling Crystallization Process

Xuming Yuan<sup>a</sup>, Brahim Benyahia<sup>a,\*</sup>

<sup>a</sup> *Department of Chemical Engineering, Loughborough University, Epinal Way, Loughborough, LE11 3TU, United Kingdom*  
*B.Benyahia@lboro.ac.uk*

## Abstract

In this work, a systematic methodology is proposed to help develop model-based design of experiments to build robust and reliable mathematical model of a batch crystallization process. The cooling crystallization of paracetamol in water and propanol is used as the case study. The mathematical model consists in the mass balance and a set of population balance equations, involving primary and secondary nucleation, growth, agglomeration, breakage and dissolution kinetics. Firstly, a structural identifiability approach is used to investigate whether the model parameters can be determined uniquely with an idealized input-output behavior of the process. The approach is also critical to determine the minimum set of required observable outputs and help discriminate model candidates. A novel Model-Based Design of Experiments (MBDoE) is then proposed based on the combination of the D-optimality criterion and the estimability analysis. The objective is to reduce the uncertainties in the model parameters by enhancing the data information content and help maximize the estimability potential of all model parameters while reducing correlation amongst them. Moreover, a new operating strategy based on temperature cycling is used in a sequential design of experiment to maximize data information content from one single experiment while reducing the experimental burden and inherent wastes.

**Keywords:** Structural Identifiability, Estimability, Sensitivity Analysis, Model-Based Design of Experiment (MBDoE), Temperature Cycling, Batch Crystallization.

## 1. Introduction

Crystallization is an important separation and purification technique that is widely applied in the pharmaceutical industry. The successful development of crystallization technologies is a painstaking and costly process. The availability of a reliable mathematical models is critical at all development stages to help explore more effectively the design space and deliver robust and cost-effective designs, operation, and control procedures (Benyahia et al., 2021; Liu and Benyahia, 2022). Most importantly, mathematical models can help achieve built-in quality insurance (e.g., Quality-by-Design and Quality-by-Control). However, the prediction capabilities and inherent uncertainties of the models strongly depend on the experimental data obtained at early development stages, their information content, and the parameter estimation procedure.

To obtain the parameter values, parameter estimation is performed, where the difference between the experimental data and the prediction is minimized. However, an excellent matching between the collected data and the prediction does not necessarily indicate that all the model parameter estimates are accurate and precise. For example, it can be found

that wide ranges of parameter values may still result in similar model predictions (Balsa-Canto et al., 2010). Another common issue is the high uncertainty in the model parameter estimates. Such issues originate from the lack of structural identifiability or estimability (practical identifiability) of the model, and they may lead to the high uncertainty in model predictions which consequently affect the final designs and product quality.

To address these issues, extensive studies focusing on estimability have been carried out. In 2003, Yao et al. proposed the use of a sequential orthogonalization algorithm to rank the parameters according to their estimability potential and least correlation. The method became very popular over the last two decades and found many successful applications in various research areas (Benyahia et al. 2011 and 2013). Different estimability methods were also used to capture more effectively the minimum subset of the most estimable parameters using more effective cut-off procedures (Fysikopoulos et al., 2019). Another method based on the mean-squared-error (MSE) and transformed parameters was used by Kim and Lee (2019) to help identify the cut-off value more effectively. Nonetheless, structural identifiability, as a necessary condition of estimability, was usually neglected in previous studies. Hence, Balsa-Canto et al., 2010 performed structural identifiability analysis prior to the estimability analysis to confirm that all model parameters have unique estimates theoretically. Recently, model-based design of experiment (MBDoe) is gaining more attention and it has been implemented in optimal experimental design to obtain high-quality parameter estimates. For instance, Maheshwari et al., 2013 applied to a double feedback gene switching model a multi-objective optimal experimental design that maximized the D-optimality criterion and minimized the correlation between the parameters simultaneously.

In this work, a novel approach that combines the estimability and MBDoe is proposed as a systematic approach to build more predictive models and design more effective and information rich experiments. The aim of this study is to demonstrate the benefits of combining D-optimal design with the estimability to reduce the uncertainty in crystallization models. This work systematically performs structural identifiability analysis, estimability analysis and D-optimal design in a seeded batch cooling crystallization process of paracetamol (PCM), which includes primary and secondary nucleation, growth, agglomeration, breakage and dissolution. Several new experimental strategies are proposed in the MBDoe which includes temperature cycling with holds.

## 2. Methodology

### 2.1 Process Model

A seeded batch cooling crystallization of paracetamol (PCM) is conducted in a 4:1 water/propanol solvent system, and the model is based on the quadrature method of moments (QMOM). Due to the temperature cycling, two mathematical models are used (hybrid model) as described below to capture the dissolution of crystals. When the concentration of PCM is higher than the concentration at saturation, primary nucleation, secondary nucleation, growth, agglomeration and breakage are considered, while dissolution is suppressed. The population balance of the  $k$ th moment is given by

$$\frac{d\mu_k}{dt} = 0^k(k_{b1}S^{b1} + k_{b2}S^{b2}\mu_2^{j2}) + kk_gS^g \sum_{i=1}^{N_q} W_i L_i^{k-1} + \frac{1}{2}K_a \sum_{i=1}^{N_q} \sum_{j=1}^{N_q} W_i W_j (L_i^3 + L_j^3)^{1+\frac{k}{3}} - \frac{1}{2}K_a \sum_{i=1}^{N_q} \sum_{j=1}^{N_q} W_i W_j L_i^k (L_i^3 + L_j^3) + 2^{1-\frac{k}{3}}K_b \sum_{i=1}^{N_q} W_i L_i^{\gamma+k} - K_b \sum_{i=1}^{N_q} W_i L_i^{\gamma+k} \quad (1)$$

where  $N_q = 2$  is the order of quadrature approximation,  $W$  and  $L$  are the weights and abscissa obtained from quadrature approximation, and  $S$  is the absolute supersaturation:

$$S = C - C^* \quad (2)$$

$C^*$  is the concentration at saturation captured by a polynomial function of temperature  $T$ :

$$C^* = p_0 + p_1T + p_2T^2 \quad (3)$$

where  $p_0$ ,  $p_1$  and  $p_2$  are the known polynomial coefficients.

Let  $\bar{d}$ ,  $\rho$  and  $k_v$  be the mean crystal size, the density and the shape factor of PCM crystals. The evolution of the PCM concentration and mean crystal size along with time are mathematically expressed as

$$\frac{dC}{dt} = -3\rho k_v k_g S^g \sum_{i=1}^{N_q} W_i L_i^2 \quad (4)$$

$$\frac{d\bar{d}}{dt} = \frac{1}{\mu_0} \frac{d\mu_0}{dt} - \frac{\mu_1}{\mu_0^2} \frac{d\mu_0}{dt} \quad (5)$$

The cooling/heating rate  $\frac{dT}{dt} = R$  is the decision variables in the optimal experimental design problem. The evolution of concentration at saturation is given by

$$\frac{dC^*}{dt} = (p_1 + 2p_2T) \frac{dT}{dt} \quad (6)$$

In summary, the vectors of state  $\mathbf{x}(t)$ , observables  $\mathbf{y}(t)$ , control variables  $\mathbf{u}(t)$  and unknown model parameters  $\boldsymbol{\theta}$  are given by

$$\mathbf{x}(t) = [\mu_0(t), \mu_1(t), \mu_2(t), \mu_3(t), C(t), \bar{d}(t), C^*(t), T(t)]^T \quad (7)$$

$$\mathbf{y}(t) = [C(t), \bar{d}(t), \mu_0(t)]^T \quad (8)$$

$$\mathbf{u}(t) = \frac{dT(t)}{dt} = R(t) \quad (9)$$

$$\boldsymbol{\theta} = [k_{b1}, b_1, k_{b2}, b_2, j_2, k_g, g, K_a, K_b, \gamma, k_{ds}, ds]^T \quad (10)$$

When the PCM concentration is lower than its concentration at saturation, dissolution is activated; primary/secondary nucleation and growth are suppressed, while agglomeration and breakage still occur. The population balance of the  $k$ th moment becomes:

$$\begin{aligned} \frac{d\mu_k}{dt} = & k k_{ds} (-S)^{ds} \sum_{i=1}^{N_q} W_i L_i^{k-1} + \frac{1}{2} K_a \sum_{i=1}^{N_q} \sum_{j=1}^{N_q} W_i W_j (L_i^3 + L_j^3)^{1+\frac{k}{3}} - \\ & \frac{1}{2} K_a \sum_{i=1}^{N_q} \sum_{j=1}^{N_q} W_i W_j L_i^k (L_i^3 + L_j^3) + 2^{1-\frac{k}{3}} K_b \sum_{i=1}^{N_q} W_i L_i^{\gamma+k} - K_b \sum_{i=1}^{N_q} W_i L_i^{\gamma+k} \end{aligned} \quad (11)$$

In this scenario, the evolution of the PCM concentration becomes

$$\frac{dC}{dt} = -3\rho k_v k_{ds} (-S)^{ds} \sum_{i=1}^{N_q} W_i L_i^2 \quad (12)$$

while the evolution of mean crystal size and concentration at saturation can still be expressed using equations (5) and (6).

## 2.2 Formulation of the MBDoE Optimization Problem

Before performing MBDoE, a structural identifiability analysis was conducted, and it showed that the model is at least structurally locally identifiable. Afterwards, four operating strategies were proposed to achieve the intended systematic MBDoE namely: linear cooling, piecewise linear cooling with continuity, temperature cycling, and temperature cycling with holds (Figure 1 (A)). For the sake of brevity, only the formulation of the optimization problem using temperature cycling with holds is presented here.

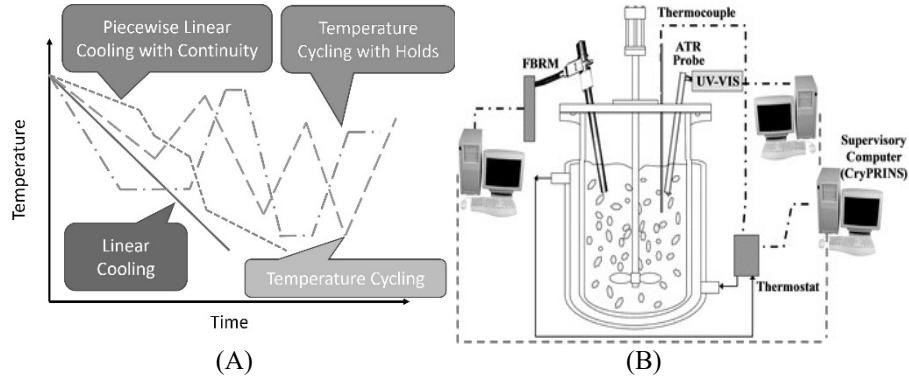

Figure 1. (A) Proposed operating strategies using different temperature trajectories. (B) Experimental set up.

The mathematical formulation of the multiobjective MBDOE is given by

$$\begin{aligned}
 & Obj1: \min_{R, \Delta t_R, t_s} \det(FIM^{-1}); \quad Obj2: \max_{R, \Delta t_R, t_s} \min ||Z_j|| \\
 & \text{s. t. } \dot{\mathbf{x}}(t) = f(t, \mathbf{x}(t; \boldsymbol{\theta}); \boldsymbol{\theta}), \quad \mathbf{x}(t_0) = \mathbf{x}_0(\boldsymbol{\theta}) \\
 & C1: -0.5 \leq R_i \leq 0 \quad (i = 1, 3, 5) \\
 & C2: 0 \leq R_i \leq 1 \quad (i = 2, 4, 6) \\
 & C3: 0 \leq \Delta t_{R,j} \quad (j = 1, \dots, 12) \\
 & C4: \sum_{j=1}^{12} \Delta t_{R,j} = 300 \\
 & C5: 21 \leq 42 + \sum_{i=1}^6 R_i \Delta t_{R,2i-1} \leq 42 \\
 & C6: 0 \leq t_{s,1} \\
 & C7: t_{s,10} \leq 300 \\
 & C8: t_{s,k} - t_{s,k+1} \leq 0 \quad (1 \leq k \leq 9)
 \end{aligned} \tag{11}$$

where  $R$  denotes the cooling/heating rate,  $\Delta t_R$  represents the durations of different cooling/heating stages, and  $t_s$  refers to the sampling times.

The first criterion is the minimization of the D-optimality criterion, which aims at the minimization of the joint confidence regions of the model parameters; the second criterion maximizes the estimability score of the least estimable parameter (Max Min), so that its effect on the observables is enhanced, which may ensure higher quality parameter estimates.

### 3. Results & Discussion

Figure 2 shows a sample of results obtained with the multi-objective optimal experimental design. The Pareto Front in Figure 2 (A) shows the best MBDoE compromises. The star represents one selected Pareto solution that can be experimentally implemented. Figure 2 (B) shows the temperature trajectory of the selected Pareto optimal solution. The estimability analysis revealed that  $k_{b2}$  was the least estimable parameter, while  $\gamma$  was found to be the most estimable.

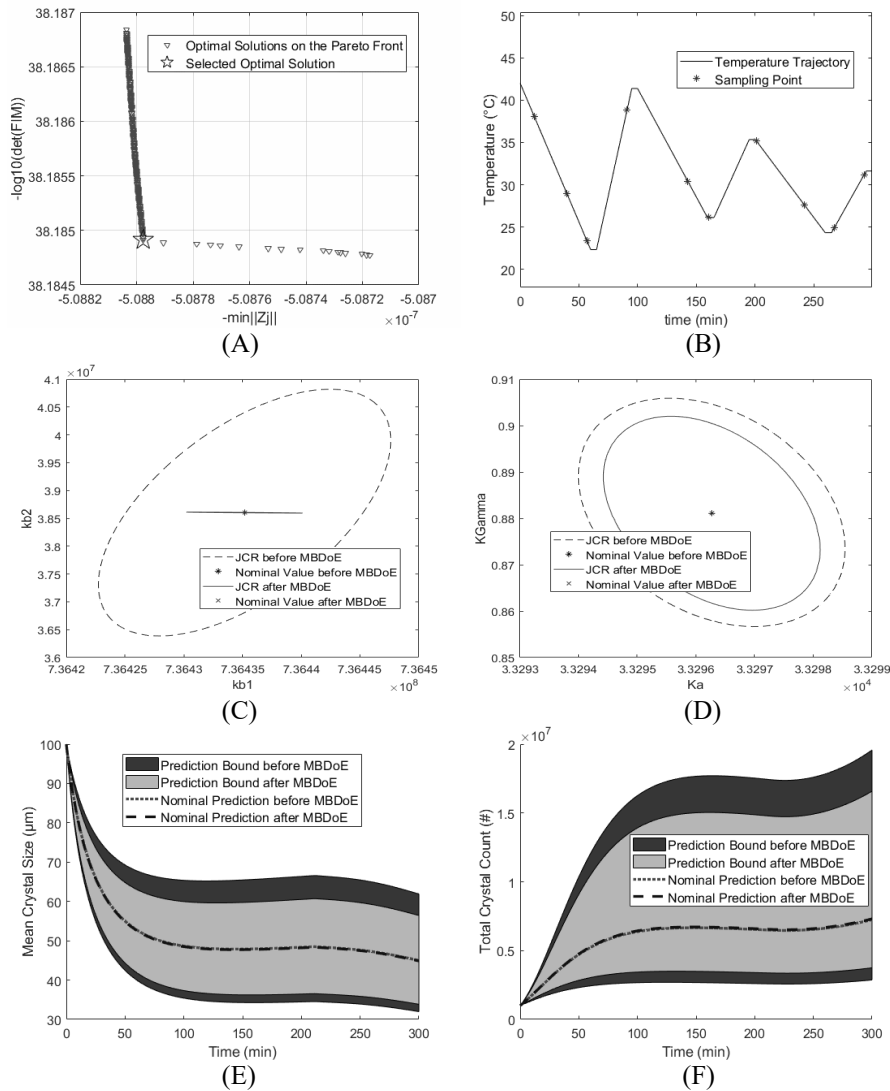

Figure 2. (A) Pareto Front of the optimal experimental design using temperature cycling and holds. (B) Optimal temperature operating trajectory. (C) 95% Joint confidence regions (JCR) of  $k_{b1}$  and  $k_{b2}$  before & after optimal experimental design. (D) 95% Joint confidence regions (JCR) OF  $K_a$  and  $\gamma$  before & after optimal experimental design. (E) Prediction bounds of mean crystal size before & after optimal experimental design. (F) Prediction bounds of total crystal count before & after optimal experimental design.

A basic single temperature cycle experiment was used as a reference case to show the benefits of the proposed MBDoe. Figure 2 (C) clearly shows that the joint confidence interval of  $k_{b2}$  and  $k_{b1}$  are significantly decreased and so is their correlation. The results shown in Figure 2 (D) demonstrate a decrease of the uncertainty in the most estimable model parameter  $\gamma$ . The decrease in parameter uncertainties resulted in more reliable predictions, as shown in Figure 2 (E) and (F), where the nominal predictions refer to the predictions using the nominal parameter estimates before and after applying the optimal

experimental design. Several additional operating strategies were also investigated in this study as outlined in Figure 1 (A) (the results are not shown here for the sake of brevity). However, temperature cycling with holds resulted in the best parameter quality and the lowest uncertainties in model prediction. Thus, this operating strategy has the potential to be implemented in the development of MBDoE for similar crystallization systems.

#### 4. Conclusions

A series of novel MBDoE strategies based on different operating trajectories were proposed and implemented to a batch crystallization process. Both D-optimal design of experiments and the estimability approaches were implemented to generate information-rich experiments and help reduce parameter uncertainties while increasing the estimability potential of the parameters. The combination of both strategies (multi-objective MBDoE) offered more optimal operating options and demonstrated the parameter estimates with reduced prediction uncertainties. The introduction of temperature cycling with holds was shown to be the best operating strategy in this study, which indicates that it has the potential to be a reliable alternative for the development and implementation of systematic MBDoE in crystallization.

## Abstract

In this work, a novel mixed-integer linear programming formulation is proposed based on the unit-specific event-based representation to address the short-term scheduling of multipurpose batch plants in network environment. Concepts of material transfers between processing units or storage tankers are introduced to conditionally sequence and align the related production and consumption tasks. In this case, material flows between the processing units can be explicitly tracked, resulting in decreases on appropriate number of event points and improvements on computational efficiency. Additionally, the processing units are allowed to temporarily store a batch after production over multiple event points. Computational studies shows that the developed continuous-time based formulation leads us to fewer numbers of event points in many cases and better objective results with a maximum improvement of 67%. More interestingly, all considered examples reach the optimality without any task spanning over multiple event points.

**Keywords:** Unit-specific event-based formulation, multipurpose batch process, material transfer, short-term scheduling

## 1. Introduction

Process scheduling is a key managerial tool for manufacturing, which seeks to allocate limited resources, determine task assignments and sequences to achieve production targets over time [Rakovitis et al. (2019)]. Multipurpose batch plants [Li et al. (2022)] widely exist in chemical industry for production of low-volume and high-value products. Unit-specific event-based formulation is an efficient continuous-time based approach to address the short-term scheduling of multipurpose batch plants. Numbers of event points have significant effects on the model size and computational performance. Attempts have been made to eliminate some unnecessary event points by relaxing some unconditional sequencing constraints enforced for the consumption and its related production tasks with the same state. Specifically, Seid and Majozi (2012) as well as Vooradi and Shaik (2013) relaxed the unconditional sequencing and alignments between the related production and consumption tasks if there is sufficient state inventory for consumption and storage space for production, respectively. However, the model of Seid and Majozi (2012) leads to real-time storage violation. Vooradi and Shaik (2013) introduced enormous variables, resulting in heavy computational burdens. More importantly, almost all existing models did not allow a batch of materials to be temporarily stored in processing units over multiple event points, leading to inefficient utilization of processing units.

In this work, a novel mixed-integer linear programming (MILP) model is proposed to address above mentioned limitations of the existing unit-specific event-based MILP formulations. Specifically, concepts on material transfer are introduced for the related production and consumption tasks at two adjacent event points. Material flows of states are monitored among units rather than specific tasks to decrease numbers of variables. And temporary holding of batches on units after production are modelled to yield better objective results for problems subject to finite intermediate storage (FIS).

## 2. Problem statement and material transfer

Multipurpose batch plants are formulated based on the state-task network [Kondili et al. (1993)]. Tasks  $i \in \mathbf{I}$  are processed on units  $j \in \mathbf{J}$ . Units  $j$  performing task  $i$  are included in the set  $\mathbf{J}_i$ . States  $s \in \mathbf{S}$  are consumed ( $\rho_{si} < 0$ ) or produced ( $\rho_{si} > 0$ ) by the consumption ( $i \in \mathbf{I}_s^C$ ) or production ( $i \in \mathbf{I}_s^P$ ) tasks with the proportion  $\rho_{si}$ . The formulation is proposed to minimize makespan to fulfill demands ( $D_s$ ) of products ( $s \in \mathbf{S}^P$ ) or maximize profit ( $z$ ) over a given horizon ( $H$ ). Material transfer between facilities is explicitly tracked to conditionally sequence the related production and consumption tasks of the same state. Four scenarios of material transfer (MT) are illustrated in Figure 1. In the first scenario (MT1), materials after production are transferred into its dedicated storage. In MT2, the batch of materials after production are first temporarily held on its processing unit and then flow into the storage. In MT3 and MT4, material after production at  $n$  are consumed by tasks at  $(n + 1)$ . MT3 illustrates the indirect material transfer in which materials available at  $n$  would be first transferred to the storage and then to the downstream unit at  $(n + 1)$  as there are sufficient storage space. In MT4, materials are directly transferred to the downstream units due to the storage limitation, which is termed as the direct material transfer. Two sets of binary variables are introduced to formulate the indirect ( $zI_{jj'n}$ ) and direct ( $zD_{jj'n}$ ) material transfer between units  $j \in \mathbf{J}_s^P$  and  $j' \in \mathbf{J}_s^C$  performing the production and consumption tasks, respectively, of a state  $s$ . Specifically,  $zI_{jj'n} = 1$ , if a state produced on  $j$  at  $(n - 1)$  is indirectly transferred to  $j'$  at  $n$ .  $zD_{jj'n} = 1$ , if a state produced on  $j$  at  $(n - 1)$  is directly transferred to  $j'$  at  $n$ .

Figure 1. Four scenarios of material transfer between units and storage tanks

## 3. Mathematical model

The binary variable  $w_{ijn'n'}$  is one if task  $i$  is processed on  $j$  from event point  $n$  to  $n'$  ( $n \leq n' \leq n + \Delta n$ ).  $\Delta n$  is the number of event points over which a task can span. Binary variables  $ys_{ijn}$  equal to one if one or partial batch of a task  $i$  is temporarily held on  $j$  at  $n$ . Allocation constraints demand at most one task to be processed or held on  $j$  at a time. Sets  $\mathbf{I}_j$  and  $\mathbf{I}^P$  include tasks that can be processed on  $j$  and held on units, respectively.

$$\sum_{i \in \mathbf{I}_j} \sum_{n - \Delta n \leq n' \leq n} \sum_{n \leq n'' \leq n' + \Delta n} w_{ijn'n''} + \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}^P)} ys_{ijn} \leq 1 \quad \forall j, n \quad (1)$$

Batch sizes  $b_{ijn'n'}$  are bounded by maximum ( $B_{ij}^{\max}$ ) and minimum ( $B_{ij}^{\min}$ ) unit capacity.

$$B_{ij}^{\min} \cdot w_{ijn'n'} \leq b_{ijn'n'} \leq B_{ij}^{\max} \cdot w_{ijn'n'} \quad \forall j, i \in \mathbf{I}_j, n \leq n' \leq n + \Delta n \quad (2)$$

Amounts of the batch of task  $i$  held on unit  $j$  at  $n$  are denoted by  $bs_{ijn}$ . Variables  $ST_{sn}$  express amounts of  $s$  stored at  $n$ , including units and its dedicated storage. Material balance of one state at  $n$  are formulated as Eqs. 3-4, where Eq. 3 is valid for the first event point. Variables  $ST0_s$  and  $bs0_{ij}$  express the initial inventory level of state  $s$  and initial amount for a batch of task  $i$  held in  $j$ , respectively. Amounts of states  $s$  stored at  $n$  should be always no less than its amounts temporarily held on the processing units (see Eq.5).

$$ST_{sn} = ST0_s + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \rho_{si} \cdot bs0_{ij} + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^c)} \sum_{n \leq n' \leq n + \Delta n} \rho_{si} \cdot b_{ijn'} \quad \forall s, n = 1 \quad (3)$$

$$ST_{sn} = ST_{s(n-1)} + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \sum_{n-1 - \Delta n \leq n' \leq n-1} \rho_{si} \cdot b_{ijn'(n-1)} + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^c)} \sum_{n \leq n' \leq n + \Delta n} \rho_{si} \cdot b_{ijn'} \quad \forall s, n > 1 \quad (4)$$

$$\sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \rho_{si} \cdot bs_{ijn} \leq ST_{sn} \quad \forall s \in \mathbf{S}^{FIS}, n \quad (5)$$

Start and finish time of a unit  $j$  at event point  $n$  are denoted by  $T_{jn}^s$  and  $T_{jn}^f$ , respectively. The unit  $j$  finishes the event point  $n$  after processing task  $i$  that is performed on  $j$  at  $n$ .

$$T_{jn}^f \geq T_{jn}^s + \sum_{i \in \mathbf{I}_j} \sum_{n \leq n' \leq n + \Delta n} (\alpha_{ij} \cdot w_{ijn'} + \beta_{ij} \cdot b_{ijn'}) \quad \forall j, n \quad (6)$$

Sequencing constraints require that on a unit  $j$ , an event point  $(n + 1)$  must start after the finish of its previous event point  $n$  (see Eq.7). Continuous variables  $T_{sjn}$  are the time for state  $s$  produced on unit  $j$  at  $n$  being available. Available time of the same state at the next event point  $(n + 1)$  should be larger than the available time at  $n$ , as Eq.8.

$$T_{j(n+1)}^s \geq T_{jn}^f \quad \forall j, n < N \quad (7)$$

$$T_{sjn} \leq T_{sj(n+1)} \quad \forall s \in \mathbf{S}^{in}, j \in \mathbf{J}_s^p, n < N - 1 \quad (8)$$

As formulated by Eqs. 9-10, the time when a state  $s$  is available at  $n$  should be after the finish of its production task on unit  $j$  and before the start of the next event point  $(n + 1)$ .

$$T_{sjn} \geq T_{jn}^f - M \cdot \left[ 1 - \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \sum_{n - \Delta n \leq n' \leq n} w_{ijn'n} \right] \quad \forall s \in \mathbf{S}^{in}, j \in \mathbf{J}_s^p, n < N \quad (9)$$

$$T_{sjn} \leq T_{j(n+1)}^s + M \cdot \left[ 1 - \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \left( \sum_{n - \Delta n \leq n' \leq n} w_{ijn'n} + y_{sijn} \right) \right] \quad \forall s \in \mathbf{S}^{in}, j \in \mathbf{J}_s^p, n < N \quad (10)$$

Indirect material transfer of a state takes place only with sufficient storage space for  $s$ . If it occurs from a unit  $j$  at  $n$  to  $j'$  at  $(n + 1)$ , the unit  $j'$  at  $(n + 1)$  must start not earlier than the finish of  $j$  at  $n$ . Set  $\mathbf{CJ}_j$  includes units  $j'$  consuming a state produced in unit  $j$ .

$$T_{jn}^f \leq T_{j'(n+1)}^s + M \cdot [1 - z_{I_j j'(n+1)}] \quad \forall j, j' \in \mathbf{CJ}_j, j \neq j', n < N \quad (11)$$

Continuous variables  $bT_{ijj'j'n}$  express amounts of a state through indirect material transfer from  $j$  to  $j'$ . For any consumption task, its consumed amounts of  $s$  cannot exceed the total amounts stored in the storage and transferred from the production tasks.

$$\sum_{j'} \sum_{i' \in (\mathbf{I}_{j'}^c \cap \mathbf{I}_j^p)} \left( -\rho_{si'} \cdot \sum_{n \leq n' \leq n + \Delta n} b_{i'j'nn'} \right) \leq ST_{s(n-1)} + \sum_j \sum_{j'} \sum_{i \in (\mathbf{I}_j^p \cap \mathbf{I}_{j'}^p)} \sum_{i' \in (\mathbf{I}_{j'}^c \cap \mathbf{I}_j^p)} bT_{ijj'j'n} \quad \forall s \in \mathbf{S}^{in}, n > 1 \quad (12)$$

$$\rho_{si} \cdot \sum_{n-1 - \Delta n \leq n' \leq n-1} b_{ijn'(n-1)} \geq \sum_{j'} \sum_{i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} bT_{ijj'j'n} \quad \forall s \in \mathbf{S}^{in}, j, i \in (\mathbf{I}_j \cap \mathbf{I}_s^p), n > 1 \quad (13)$$

$$-\rho_{si'} \cdot \sum_{n \leq n' \leq n + \Delta n} b_{i'j'nn'} \geq \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^c)} bT_{ijj'j'n} \quad \forall s \in \mathbf{S}^{in}, j', i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c), n > 1 \quad (14)$$

Amounts of  $s$  through indirect material transfer at  $n$  should not exceed the production amount finishing at  $(n - 1)$  and also the consumption amounts starting at  $n$  (see Eqs. 13-14). Without indirect material transfer, the corresponding variables on transfer amounts are zero, where  $B_j^{max} = \max_{s, i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} [\rho_{si} \cdot B_{ij}^{max}]$  and  $B_{j'}^{max} = \max_{s, i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} [-\rho_{si'} \cdot B_{i'j'}^{max}]$ .

$$\sum_{i \in \mathbf{I}_j} \sum_{i' \in \mathbf{I}_{j'}} bT_{ij'i'n} \leq \min[B_j^{\max}, B_{j'}^{\max}] \cdot zI_{jj'n} \quad \forall j, j' \in \mathbf{CJ}, j \neq j', n > 1 \quad (15)$$

Constraint (16) enforces that a unit  $j'$  consuming a state at  $(n + 2)$  or higher event points should always start after the state is available on unit  $j$  at  $n$  to avoid storage violation.

$$T_{sjn} \leq T_{j'(n+2)}^s + M \cdot \left[ 1 - \sum_{i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} \sum_{n+2 \leq n' \leq n+2+\Delta n} w_{i'j'(n+2)n'} \right] \quad \forall s \in \mathbf{S}^m, j \neq j', j \in \mathbf{J}_s^p, j' \in \mathbf{J}_s^c, n < N - 1 \quad (16)$$

When there is no sufficient storage space to store the production amount of a state  $s$ , this state must be transferred to the downstream unit directly or temporarily held on its processing unit, as indicated by Eq.17. Consequently, the unit  $j'$  should finish the processing at  $n$  before the end of unit  $j$  at  $n$  to avoid overlapping on  $j'$ , if direct material transfer of one state takes place from  $j$  at  $n$  to  $j'$  at  $(n + 1)$ , as constrained by Eq.18.

$$\begin{aligned} \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \left[ \rho_{si} \cdot \sum_{n-1-\Delta n \leq n' \leq n-1} b_{ijn'(n-1)} \right] + ST_{s(n-1)} \\ \leq ST_s^{\max} + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \rho_{si} \cdot bs_{ijn} \\ + \sum_j \sum_{j'} \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} \sum_{i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} bTd_{ij'i'n} \quad \forall s \in \mathbf{S}^{FIS}, n > 1 \end{aligned} \quad (17)$$

$$T_{j'n}^f \leq T_{jn}^f + M \cdot [1 - zD_{jj'(n+1)}] \quad \forall j, j' \in \mathbf{CJ}_j^f, j \neq j', n < N \quad (18)$$

Similar to the indirect material transfer, amounts of a state  $s$  transferred at  $(n + 1)$  through direct material transfer should be bounded by the amount available (i.e. produced or temporarily held) at  $n$  and the consumption amount by tasks at  $(n + 1)$ . And the amounts of state transferred should be zero without direct material transfer.

$$\rho_{si} \cdot \left[ \sum_{n-1-\Delta n \leq n' \leq n-1} b_{ijn'(n-1)} + bs_{ij(n-1)} \right] \geq \sum_{j'} \sum_{i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} bTd_{ij'i'n} + \rho_{si} \cdot bs_{ijn} \quad \forall s \in \mathbf{S}^{FIS}, j, i \in (\mathbf{I}_j \cap \mathbf{I}_s^p), n > 1 \quad (19)$$

$$-\rho_{si'} \cdot \sum_{n \leq n' \leq n+\Delta n} b_{i'j'nn'} \geq \sum_j \sum_{i \in (\mathbf{I}_j^p \cap \mathbf{I}_j)} bTd_{ij'i'n} \quad \forall s \in \mathbf{S}^{FIS}, j', i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c), n > 1 \quad (20)$$

$$\sum_{i \in \mathbf{I}_j} \sum_{i' \in \mathbf{I}_{j'}} bTd_{ij'i'n} \leq \min[B_j^{\max}, B_{j'}^{\max}] \cdot zD_{jj'n} \quad \forall j, j' \in \mathbf{CJ}_j^f, j \neq j', n > 1 \quad (21)$$

Equation 22 ensures sufficient storage space for state  $s$  produced on  $j$  at  $n$  when  $s \in \mathbf{S}^{FIS}$  is subject to FIS, by enforcing  $j'$  to finish at  $(n - 1)$  before the available time of  $s$  at  $n$ .

$$T_{sjn} \geq T_{j'(n-1)}^f - M \cdot \left[ 1 - \sum_{i' \in (\mathbf{I}_{j'} \cap \mathbf{I}_s^c)} \sum_{n \leq n' \leq n+\Delta n} w_{i'j'nn'} \right] \quad \forall s \in \mathbf{S}^{FIS}, j \neq j', j \in \mathbf{J}_s^p, j' \in \mathbf{J}_s^c, 1 < n < N \quad (22)$$

$$ST_{sn} \leq ST_s^{\max} + \sum_{j \in \mathbf{J}_s} \left[ \max_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^p)} (\rho_{si} \cdot B_{ij}^{\max}) \right] \quad \forall s \in \mathbf{S}^{FIS}, n \quad (23)$$

$$bs_{ijn} \leq B_{ij}^{\max} \cdot ys_{ijn} \quad \forall j, i \in (\mathbf{I}_j \cap \mathbf{I}^p), n \quad (24)$$

Amount of state  $s \in \mathbf{S}^{FIS}$  stored on units and storage at  $n$  should satisfy Eq. 23. Amount of the batch temporarily held on  $j$  should be no larger than the unit capacity. Tightening constraints (refer Eqs. 34, 35 and 37 of Li et al. 2022) are formulated to handle binary variables on allocation and material transfer. Indirect material transfer tasks place if there

is the direct material transfer between two units (Eq. 25). Bounds are added on variables as Eqs. 26-30. Both  $y_{sijn}$  and  $bs_{ijn}$  are zero if states produced by  $i$  are subject to UIS.

$$zI_{jj'n} \geq zD_{jj'n} \quad \forall j, j' \in \mathbf{CJ}_j^F, j \neq j', n > 1 \quad (25)$$

$$T_{jn}^s \leq H, T_{jn}^f \leq H \quad \forall j, n \quad (26,27)$$

$$w_{ijnn'} = 0, b_{ijnn'} = 0 \quad \forall i, j, n, (n' < n) \cup (i \notin \mathbf{I}_j) \quad (28,29)$$

$$bT_{ijj'j'n} = bT_{ijj'j'n} = zI_{jj'n} = zD_{jj'n} = y_{sijn} = bs_{ijn} = 0 \quad \forall i, i', j, j', n = 1, bs_{0ij} = 0 \quad (30)$$

$$y_{sijn} = 0, bs_{ijn} = 0 \quad \forall i \notin \mathbf{I}^P, j, n \quad (31,32)$$

The objective is to maximize profit (see Eq. 33) or minimize makespan (see Eq. 34-35). Equation (36) is the tightening constraint for minimization of makespan.

$$z = \sum_{s \in \mathbf{S}^P} \left[ p_s \cdot \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^F)} \sum_n \sum_{n - \Delta n \leq n' \leq n} (\rho_{si} \cdot b_{ijn'n}) \right] \quad (33)$$

$$T_{jn}^f \leq MS \quad \forall j, n = N \quad (34)$$

$$STO_s + \sum_j \sum_{i \in (\mathbf{I}_j \cap \mathbf{I}_s^F)} \sum_n \sum_{n \leq n' \leq n + \Delta n} (\rho_{si} \cdot b_{ijnn'}) \geq D_s \quad \forall s \in \mathbf{S}^P \quad (35)$$

$$\sum_{i \in \mathbf{I}_j} \sum_n \sum_{n \leq n' \leq n + \Delta n} (\alpha_{ij} \cdot w_{ijnn'} + \beta_{ij} \cdot b_{ijnn'}) \leq MS \quad \forall j \quad (36)$$

Development of the mathematical formulation is completed, which contains of equations (1-33) to maximize profit and (1-32) and (34-36) to minimize makespan.

Table 1. Computational results for examples 1-6 with FIS. (Exs1, 3 and 4 are addressed to minimize makespan. Exs2, 5 and 6 are addressed to maximize profit)

#### 4. Computational studies

Comparisons between the proposed model (M) and three existing continuous-time based models [V&S: Vooradi and Shaik (2013), L&F: Li and Floudas (2010), SLK2: Susarla et al. (2010)] are conducted. Considered examples 1 and 2 with FIS are the motivating example 2 and example 12 from Li et al. (2022). Examples 3-6 are examples 1a, 2b, 8 and 9 in their work. Models are solved using CPLEX 12.6.3/GAMS 24.6.1 on a desktop computer with AMD Ryzen 9 3900X 3.8 GHz, 48 GB RAM running Windows 10. Computational results of the examples 1-6 are listed in Table 1. Better objective results are obtained by M in examples 1 and 2 as the processing units can hold materials to share the storage burden under FIS. Computational time is reduced over 45% (1969 s vs. 3600 s) and 98% (82 s vs. 3600 s) by using M relative to model V&S for examples 3 and 4. That is attributed to the decreased number of binary variables. Concerning appropriate

numbers of event points to reach optimality for examples 4-6, it proves that model M does not require any task to span over multiple event points (i.e.  $\Delta n > 0$ ). Four instances (instances 9, 11, 14, and 15 in Vooradi and Shaik 2012) of the Kallrath example, are addressed using the developed model, as presented in Table 2. Results prove that the proposed model always generate lower makespan using less computational time. For instance, the model M obtains a 2.5% (39 h vs. 40 h) lower makespan using 45% (21890 s vs. 40000s) less computational time, compared with V&S.

Table 2. Computational results of the Kallrath examples with FIS to minimize makespan

In	Model	Events	RMILP	MILP	CPU (s)	Binary	Continuous	Constraints

	M	15	40	<b>54<sup>c</sup></b>	40000	906	1937	6534

Relative gap, <sup>a</sup>: 7.5%, <sup>b</sup>: 14.29%, <sup>c</sup>: 3.70%.

## 5. Conclusion

In this work, a novel unit-specific event-based MILP formulation is proposed to address the short-term scheduling of the multipurpose batch plants. Material transfer of states are explicated to conditionally sequence the related tasks on units. And batches of tasks after production are permitted to be held in the processing units. Computational results demonstrate that the proposed model leads us to better objective results and decreases the computational time up to 98%. More interestingly, the proposed model does not require any task to span over multiple event points to yield the global optima.

## Abstract

The cement sector needs to reduce its CO<sub>2</sub> emissions. An oxyfuel CO<sub>2</sub> capture technology allows to considerably reduce the emission. However, heat recovery and energy efficiency measures are essential to make the technology economically feasible. An approach to design heat exchanger networks applied to a 1<sup>st</sup> generation oxyfuel cement plant is described in this article. The approach consists of two steps: preliminary targeting and heat exchanger network design. For the studied cement plant, the steam Rankine cycle was identified to be superior to organic Rankine cycles. In the ideal case about 10.5 MW of power can be recovered. However, in a cost-efficient simple heat exchanger network recovery of only about 8.7 MW is economically reasonable.

**Keywords:** Heat integration, Heat exchanger network design, Oxyfuel cement plants.

## 1. Introduction

The cement sector is responsible for about 7% global anthropogenic CO<sub>2</sub> emissions (IEA, 2018). Two-third of the CO<sub>2</sub> emission originate from calcination of limestone while one-third come from the combustion of fuel. It is, therefore, impossible to reach CO<sub>2</sub> emission targets with fuel switching alone. CO<sub>2</sub> capture and storage is essential to become carbon neutral. An oxyfuel-based capture process is a promising candidate for capturing CO<sub>2</sub> from a cement plant (Voldsund et al., 2019). In the oxyfuel process the combustion is performed with oxygen mixed with recycled CO<sub>2</sub>. The CO<sub>2</sub> enriched flue gas allows a relatively cost-efficient purification and separation. Nevertheless, CO<sub>2</sub> purification consumes additional power and process heat must be transferred to air streams to dry the raw material energy-efficiently. The temperature levels in an oxyfuel plant are higher than in conventional plants because of the increased oxygen concentration in the combustion, and flue gas has to be cooled before it is recirculated. Waste heat recovery and heat integration are important for an economic implementation of oxyfuel technology in cement plants.

An existing cement plants was investigated for retrofit of the 1<sup>st</sup> generation oxyfuel process. The process simulations are performed with VDZs in-house cement process model. Afterwards, the heat integration is performed using a two-step methodology. This article focusses on a systematic approach to heat integration and applies it to an oxyfuel cement plant. In the following, a brief description of the model setup is given

followed by the introduction of the two-step methodology for heat integration and its application the oxyfuel cement plant is described.

## 2. Methodology

### 2.1. Modelling approach

The retrofit of the 1<sup>st</sup> generation oxyfuel process to cement plant was performed with several models. The clinker burning process was accessed by a kiln process model. The model described the process from the kiln meal feed to the outlet of the clinker from the cooler. It is made up by individual linked models of preheater, calciner, bypass, kiln and cooler, where material and energy balances are calculated (Koring, 2013). The process model outputs are performance data, thermal energy demand, clinker quality and available excess heat. Input data about the process design and some plant specific data to make the process model representative was provided by the cement producer and equipment supplier.

A second model, the heat integration model, access the waste heat recovery and the heat integration of the CO<sub>2</sub> Processing Unit (CPU). Data was iteratively exchanged between the two models.

### 2.2. Heat integration

Stream data from the process engineering model by VDZ was used to create the heat integration model in Aspen HYSYS. In addition, a CPU model was created in Aspen HYSYS. These models were used to access the energy streams of the 1<sup>st</sup> generation oxyfuel cement plant. In the following the two-step methodology consisting of a preliminary targeting step and a Heat Exchanger Network (HEN) design step, is presented.

#### 2.2.1. Preliminary targeting of the heat exchanger network design

The goal of the preliminary targeting is to identify the most promising heat to power cycles for the HEN design. A pinch analysis is performed which identifies the bottle neck of the plant regarding heat integration and allows to estimate an upper bound on the power production of the heat to power cycles. This step is also used to dimension the heat to power cycles. The stream data from this analysis is used in the HEN design phase.

#### 2.2.2. Heat Exchanger Network design

In the second step after the preliminary targeting the HEN is designed which allows cost-efficient design of the heat recovery in the cement plant. The best HEN involves optimizing the trade-off between capital costs determined by the number of heat exchanger units and their areas and the operating costs determined by the amount of hot and cold utilities required by the process. The software tool termed SeqHENS (Sequential Framework for HEN Synthesis) developed at the Norwegian University of Science and Technology and SINTEF Energy was used to design the optimal HEN (Anantharaman, 2011). An overview of the four-step methodology in the toolbox is given next:

- 1) Given stream data on the relevant hot and cold streams given by the preliminary targeting the minimum amount of hot and cold utility required is determined. The Linear Programming (LP) transshipment model is used to solve the optimization (Papoulias et al., 1983).
- 2) The absolute minimum number of heat exchanger units is determined where the heuristic is used that the optimal number is close to the minimum number of

units. This problem is solved with the Mixed-Integer Linear programming formulation (Papoulias et al., 1983).

- 3) Given the numbers of units and using engineering judgement the correct matches between hot and cold streams is determined. This “Steam Match Generator” problem is formulated using the vertical MILP transportation model (Anantharaman, 2011). The result is a Heat Load Distribution which gives the amount of heat exchanged between hot and cold stream.
- 4) Finally, the optimal topology of the HEN is determined. This problem is solved with a nonconvex Nonlinear Program (Floudas et al., 1986). The objective is to minimize the total cost of the HEN, where engineering judgment is used to get a simple HEN.

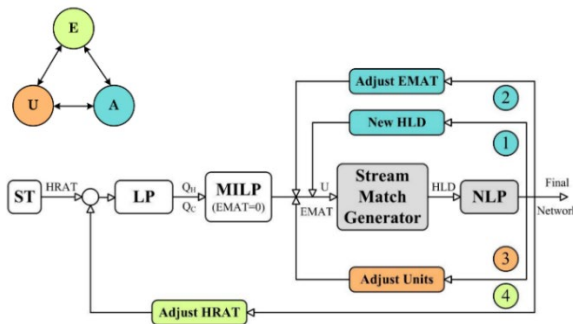

Figure 1. Overview of SeqHENS framework.

### 3. Case Study

The 1<sup>st</sup> generation oxyfuel cement plant consists of a preheater, pre-calciner, rotary kiln and cooler (Figure 2). The preheater exhaust is recirculated to the cooler, where a part of the recirculated stream is extracted and sent to the CPU. The Air Separation Unit (ASU) provides purified oxygen. An air stream is heated and used to dry the raw material.

The studied cement plant has an average annual clinker production of about 5600 t/d. The kiln line is a common dry process, and the raw material moisture is about 2-3%. The estimated drying demand for the raw material is about 300 kJ/kg<sub>clinker</sub>. This heat must be supplied by the excess heat of the process before additional excess heat can be used in a heat to power cycle.

The hot streams in the oxyfuel cement plant are the preheater exhaust stream at a temperature of about 450°C, cooler exhaust stream at a temperature of about 180°C, and the bypass stream, which is pinched with parts of the recycling stream, after which the combined stream has a temperature of 400°C. Additional heat streams are available from the CPU at a temperature of about 120°C. The cold streams are the heat required for drying the raw material, heat required in the CPU and heat for the heat to power cycle.

It is necessary that the recirculated stream is cooled down to about 50°C to remove chlorine, sulfur and water. Moreover, bag filters are used to remove dust. In addition, the air stream existing the raw mill should have required heat left for evaporate water. Therefore, a minimum temperature of 120°C was chosen for this stream.

#### 3.1. Preliminary targeting of 1<sup>st</sup> generation oxyfuel cement plant case study

The preliminary targeting phase was used to 1) find an optimal flue gas recirculation rate, 2) evaluate if heat from the Bypass should be used and 3) compare different heat to power cycles. The first and second step required iterations between the heat integration and

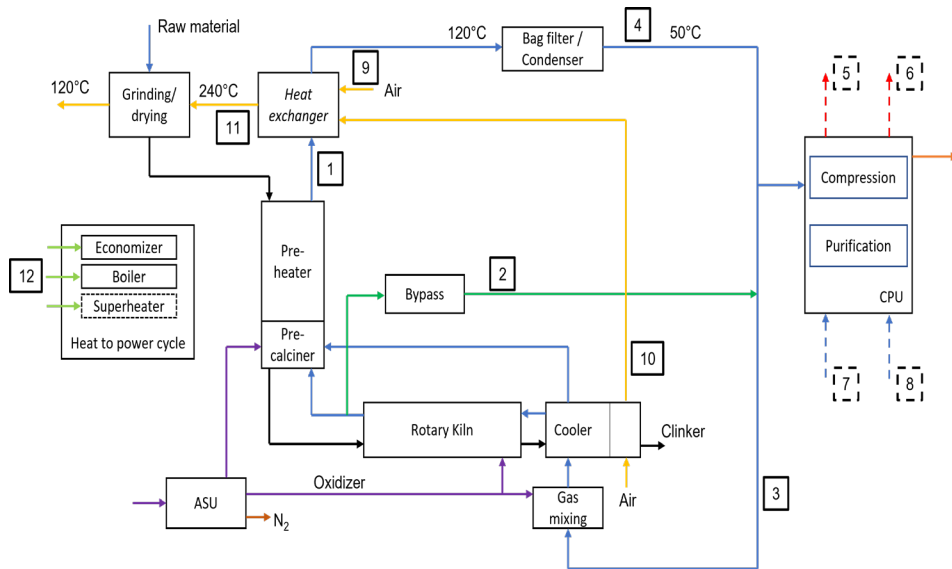

Figure 2. 1st generation oxyfuel cement plant. The numbers indicate hot and cold streams. Temperature constraints are displayed.

updating the process engineering model. It was concluded that no heat should be extracted from the Bypass since it increased the overall fuel use.

Organic Rankine cycles using Benzene or Butane and a steam Rankine cycle with different pressure levels were compared. The best performing Rankine cycle was the steam Rankine cycle at a pressure level of 15 bar, which was used for the HEN design (Table 1).

Table 1. Performance of different Rankine cycles.

Rankine cycle	Power production	Recirculation rate
Steam Rankine cycle (15 bar)	10.5 MW	0.49
ORC – Benzene	10.0 MW	0.49
ORC – Butane	8.4 MW	0.49

### 3.2. Heat exchanger network design of 1<sup>st</sup> generation oxyfuel cement plant case study

The preliminary targeting phase concluded that in the ideal case 10.4 MW power can be produced. However, this performance can only be reached with a complicated and expensive HEN. In the HEN design phase using SeqHENS stream splits and small heat exchangers which are not cost efficient were avoided. This resulted in a HEN which allows the required heat recovery and a power production in the steam Rankine cycle of about 8.7 MW (Figure 3). This is a 15% reduction compared to the ideal case.

In this study a retrofit is investigated, and the CPU will be located several hundred meters away from the kiln line. In the HEN obtained long pipelines are required between the CPU and the kiln line for only a small heat recovery. It was therefore decided to also investigate a case with the CPU excluded from the HEN design to create a simpler

network. The design of the simpler network (Figure 4) increases the overall heat exchanger area but reduces complexity and piping, which is not included in the objective function of SeqHENS. The same amount of power as before (8.7 MW) can be produced.

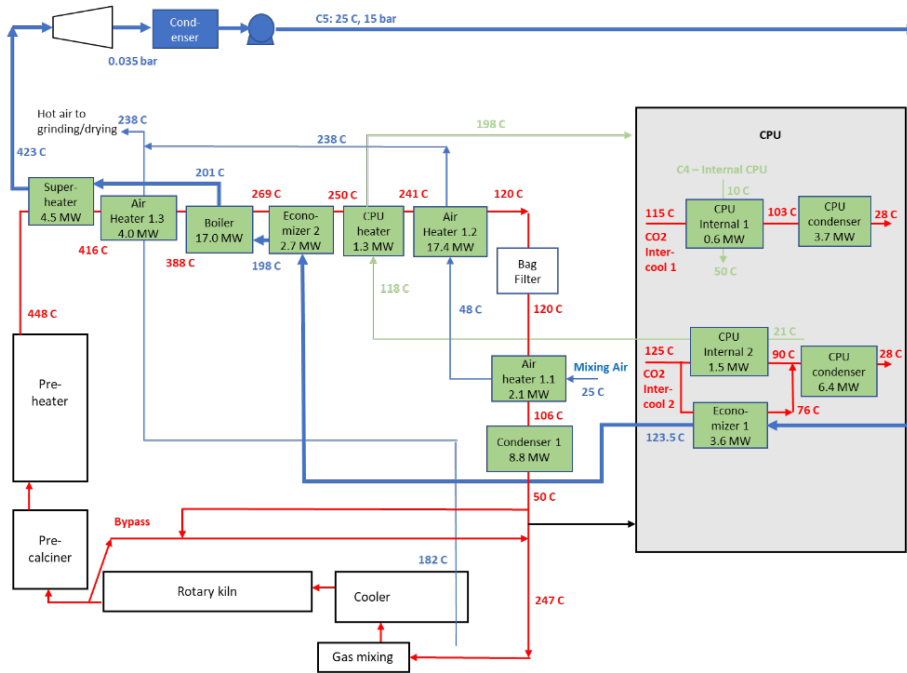

Figure 3. Heat exchanger network including heat integration of CPU.

In both HENs the Air Heater 1.2 is responsible for the majority of costs since it has a large duty, and it is a gas-gas heat exchanger with low heat transfer and large heat exchanger area.

#### 4. Conclusion

This article shows how to apply heat integration and heat exchanger network design to a 1<sup>st</sup> generation oxyfuel cement plant. Heat integration is essential for economically implementation of the oxyfuel technologies to existing cement plants. required heat exchanger is a gas-gas heat exchanger which also is the largest cost driver. This heat exchanger is essential since air must be heated for drying the raw material. The direct use of the preheater exhaust as in conventional cement plants is impossible since it would emit CO<sub>2</sub>. It is possible for this cement plant to recover about 8.7 MW of power which decreases the energy consumption of the plant. In future, a more detailed economic

assessment of the steam Rankine cycle and required heat exchangers must be performed to evaluate the profitability.

## Abstract

Food insecurity is one of the major issues that have loomed as a result of rapid population growth. In recent studies addressing modern-day resource issues, the energy, water and food (EWF) nexus approach was introduced as a holistic method to aid decision-makers in pre-empting unintended, and possibly damaging consequences resulting from an imbalance made in any part of the nexus system. Existing studies have focused on centralised approaches to study the interlinkages amongst EWF systems by focusing mostly on two elements of the EWF nexus. However, the current and future transitions should address the entire EWF system, holistically and sustainably. Besides, the existing indicator frameworks do not expressly capture the key interactions between the EWF resources to address the main challenges and risk factors associated with the EWF systems. Consequently, the aim of this study is to tackle this knowledge gap by integrating the analytical hierarchy process (AHP) tool along with EWF risk-associated optimisation as means to assess the changes in EWF resource availability, and therefore identify the tradeoffs of the large-scale implementation of decentralised energy and water technologies. The proposed framework utilises a nexus approach to optimise the energy and water technological portfolios in an efficient way; thus, supporting the decision-making for resource management in high-risk environments, such as the State of Qatar. The methodology consists of designing a composite risk indicator using the AHP method to determine the weight of different risk criteria for energy and water technologies. The obtained values are then used as an input for multi-objective optimisation that aims at minimising the tradeoffs between two objectives (i.e. risk and GWP). Results of the AHP indicate that wind energy is 11.8% riskier than solar energy, where the key issue is that the availability of these energy sources is far from constant but seasonal. In addition, treated wastewater was the most environmentally friendly, having the lowest impact on the ecosystem and resources, however, treated wastewater must be properly treated as it has the highest risk level (12.5%) and can lead to health issues. Finally, the multi-objective optimization model generates relatively 70 optimal solutions due to the mutual conflict between the two objectives.

**Keywords:** EWF nexus; food security; multi-objective optimisation; AHP.

## 1. Introduction

Energy, water and food systems, which are inherently interdependent, are essential for human health and survival, economic progress and resilience. These interrelated relationships were initially introduced at the Rio+20 Summit in 2012 as the “EWF” nexus. Developing a comprehensive decision-making framework necessitates the implementation of an effective EWF Nexus system that is adequate in tackling the multifaced issues within EWF systems to achieve resilient resource management. A

common approach to deal with risks and uncertainties is building a framework based on composite indicators (Becker, 2017). In the EWF nexus, the establishment of composite indicators is a common method for a quantitative assessment. Despite the availability of numerous indicators within the EWF nexus, developing a resilience indicator using the AHP technique is extremely beneficial; specifically, since they are a valuable tool that deals with interdisciplinary boundaries (Albrecht, 2018). In this context, Haji et al., (2020) used the AHP to design a risk assessment indicator for greenhouse planning in arid regions. While Zhang et al., (2021) developed an integrated approach to assess the composite risk of WEF nexus systems using a generalized copula-based chance-constrained programming model and generate risk-based plans. The proposed approach has been applied to an agricultural WEF nexus system in northern China, where the shortage of water, energy and land affected agricultural outputs. A recent study by Singh et al., (2022) established an assessment framework to rank individual countries whilst still allowing decision-makers with the possibility to allocate resources sufficiently and incorporate other appropriate indicators in countries that struggle in regard to food security, wherein the set of food security indicators was assessed based on the future climate change scenario. In this study, an assessment tool based on the EWF Nexus approach will be developed to support addressing dynamic decision-making, especially in hazardous non-resilience environments, in order to reduce the effect of overall risk, thus improving the national adaptability of EWF systems. This will be achieved through implementing an integrated approach based on the AHP method coupled with a multi-objective optimization model. A composite risk indicator was established using the AHP method to determine the weight of different risk criteria for energy and water technologies. The considered technologies consist of solar, wind and bioenergy for energy generation, while groundwater, treated wastewater and desalinated water as water supplies. The obtained values are then used as an input for multi-objective optimisation that aims at quantifying each EWF nexus system in terms of risk and environmental impact. The multi-objective linear program is formulated to minimise the tradeoffs between two objectives (i.e. risk and GWP).

## **2. Dynamic decision-making framework for EWF Nexus**

### *2.1. Development of Composite Risk Indicators using Analytic Hierarchy Process (AHP)*

The AHP method was used to design a composite risk indicator that will determine the weight of four risk criteria (cost, availability, readiness and applicability) for each energy and water technology that affect the overall goal, as illustrated in Figure 1. The technologies considered consist of solar, wind and bioenergy for energy generation, while groundwater, desalinated water and treated wastewater as water supplies. The assessment process begins with two-level pairwise comparisons between criteria and alternatives by identifying which of the two is riskier and by how much. In which the preference is expressed on a semantic scale of 1 to 9. The information which is related to the importance of each factor in comparison to one and another is obtained from previous literature. For the 2<sup>nd</sup> level, there are 21 pairwise comparisons between seven alternatives considering each risk factor. However, for the 1<sup>st</sup> level, there are 6 pairwise comparisons between four risk factors. Then, the normalized relative weight of each factor and alternative is obtained. Finally, the normalized principal eigenvector of risk factor and alternative was determined by averaging across each row, as demonstrated in Table 1.

Figure 1: Hierarchy structure for determining the risk level of the energy and water technologies.

Table 1: Eigenvalues of four criteria and seven alternatives generated from the AHP method.

Risk Criteria	Eigen Vector of Criteria	Solar Energy (i=1)	Wind Energy (i=2)	Biomass Energy (i=3)	Natural Gas (i=4)	Groundwater (i=5)	Desalinated water (i=6)	Treated wastewater (i=7)

### 2.2. Multi-Objective Optimisation Model Development

The multi-objective optimisation model aims at minimising the risk and global warming potential (GWP) of different energy and water technologies required for food production. A summary of the mathematical model formulation is presented in Table 2. Two constraints were introduced to ensure that the sum of all contribution percentages of energy or water technologies must be 100%. The third constraint is to restrict groundwater to participate in the water mix when exceeding the annual renewable rate since groundwater consider as the scarcest water resource in the country studied. Moreover, the optimisation model assumed that the EWF nexus adopted does not involve the food sector explicitly in the technology selection, however, its contribution is translated through the water and energy required to produce food. The risk level of each technology generated from the AHP method will be used to run the minimisation of the risk objective function. However, as of GWP, the required data have been adapted from a study by Namany et al., (2019) which will be used to run the minimisation of the second objective function. A Solver was used to run and solve the optimization problem.

Table 2: Mathematical formulation for the optimisation model.

Objective Function:	
$\text{Min Risk} = \sum_{i=1}^4 R_i^e x_i^e + \sum_{i=5}^7 R_i^w x_i^w$	Identifies the optimal energy and water technologies technology mix that minimises the total risk and global warming potential of the EWF system delivering 40% of Qatar's demand for food.
$\text{Min Global Warming Potential} = \sum_{i=1}^4 GWP_i^e x_i^e$	Identifies the optimal energy technologies mix that minimises GWP
Subject to:	
$\sum_{i=1}^4 x_i^e \leq 100\%$	The sum of all contribution percentages of energy technologies must be 100%.

$\sum_{i=5}^7 x_i^w \leq 100\%$	The sum of all contribution percentages of water technologies must be 100%.
$g x_6^w \leq A_{max}$	Restricts the participation of groundwater in the water mix, being the scarcest water resource in the country studied.
$R_i^e, R_i^w, GWP_i^e, GWP_i^w, x_i^e, x_i^w \geq 0$	It implies that all decision variables must be strictly positive.

*Decision variables:*

$x_i^w$ : the percentage of contribution of each water source.

$x_i^e$ : the percentage of contribution of each energy source

*Parameters:*

$R_i^e$ : the risk level of using energy technology (i) where i=1,2,3 and 4

$R_i^w$ : the risk level of using water technology (i) where i=5,6 and 7

$GWP_i^e$ : the global warming potential of energy source. where i=1,2,3 and 4

$GWP_i^w$ : the global warming potential of the water source. where i=5,6 and 7

$g$ : the amount of groundwater utilised for food production with a 40% self-sufficiency level.

$A_{max}$ : the annual renewable rate of groundwater in Qatar is assumed to be 58 million m<sup>3</sup> per year.

### 3. Result and Discussion

The result from the AHP method (shown in Table 3) indicates that wind energy (25.0%) is the most riskier technology to be used for energy supply, where the key challenge is that the availability of this energy source is far from constant but seasonal. On the other hand, treated wastewater (12.5%) is slightly riskier than groundwater (12.3%) mainly due to the fact that it should be properly treated to avoid any health issues. The risk values obtained from the AHP method and Namany et al., (2019) study which represent the GWP of each technology are summarised in Table 3 and were used as an input to run the multi-objective optimisation model that aims at minimising the tradeoffs between the two objectives (i.e., risk and GWP). The optimisation model has been conducted to determine the optimal energy and water supply share using different technologies within the existing EWF system. The result from the solver was practicing a tradeoff between the two mutually conflicting objectives and generated relatively 70 optimal solutions, as demonstrated in Figures 2 and 3. Thus, the decision maker can pick any of the optimal solutions based on additional criteria, such as which solution achieved the lowest risk/GWP. For instance, Table 4 illustrates that out of 70 solutions, Solution 1 achieved the lowest risk and solution 69 achieved the lowest GWP. However, by averaging all 70 solutions, then Solution 34 can achieve the balanced minimisation between risk and GWP.

Table 3: Risk and environmental data used for the optimisation model.

Technologies	Solar	Wind	Biomass	Natural Gas	Groundwater	desalinated water	Treated wastewater
Risk %	13.3%	25.0%	14.1%	10.9%	12.3%	11.9%	12.5%
GWP (kg of CO <sub>2</sub> eq)	98,328	1,588	-	994,305,184	43,575,206	390,796,923	114,201,322

Table 4: The risk and GWP value of the three optimal solutions.

Solution #	Solar Energy	Wind Energy	Biomass Energy	Natural Gas	Groundwater	Desalinated water	Treated wastewater	Risk	GWP
1	33.3%	33.3%	33.3%	0.0%	4.74%	5.32%	89.84%	0.299	125,500,268
69	0.0%	0.00%	0.00%	99.99%	25.90%	26.08%	47.92%	0.232	1,162,161,486

34	22.9%	1.14%	26.65%	49.29%	8.87%	9.43%	81.68%	0.249	624,080,242
----	-------	-------	--------	--------	-------	-------	--------	-------	-------------

Figure 2: The 70 optimal solutions for energy and water supply share representing (a) energy technologies and (b) water technologies.

Figure 3: The tradeoff between risk and GWP for the 70 optimal solutions.

Moreover, due to the existence of mutually conflicting objectives, the problem solutions will not be a unique optimal but a set of non-dominated solutions referred to as the Pareto front due to the Pareto dominance concept (Pareto et al., 1896). Moreover, the solution will be Pareto-optimal if there is no other feasible solution that enhances one objective without weakening one another. In this study, the two objectives (risk % and GWP) of the non-dominated solutions set are demonstrated as Pareto Front in Figure 4 using excel.

Figure 4: Schema of the Pareto front, for the minimization of two contradictory objectives risk and GWP.

#### 4. Conclusion

This study introduced an EWF Nexus assessment framework to define the technological share needed in optimally supplying energy and water that will minimise the risk and GWP of the overall EWF system using the AHP method and solver. The AHP method has considered financial and operational aspects (e.g., cost, availability, readiness and applicability) of energy and water technologies. The model aimed at providing optimal energy and water supply share from various technologies that minimised overall EWF system risk and GWP. The multi-objective optimization model generates relatively 70 optimal solutions due to the mutual confliction between the two objectives. However, the results from the AHP indicate that wind energy is 11.8% more riskier than solar energy, as the availability of these energy sources is seasonal. Furthermore, the treated wastewater was the most environmentally friendly, having the lowest impact on the ecosystem and resources, however, treated wastewater must be properly treated as it has the highest risk level (12.5%) and can lead to health issues. The assessment tool can support decision makers in understandings possible optimal ways of deploying various technologies to supply energy and water resources while minimizing overall risk and GWP of the EWF system.

## Abstract

The purpose of this work is to use Machine Learning algorithms to implement soft sensors to predict the material quality (MFR – Melt Flow Rate) at polymer production plants. The goal is to identify off-spec material in real-time without needing specialist online analyzer equipment. The Machine Learning algorithms use historical time series data of production plant measurements. These historical data comprise a wide variety of associated features, potentially driving the evolution of the material over time. The features are the time series values of specific physical parameters, such as temperature, pressure, etc., measured on or before the polymerization reactors. We investigated a variety of mathematical formulations for predicting MFR and Machine Learning Algorithms accordingly. We present the dataset, as well as machine learning models results along with performance metrics and future steps.

**Keywords:** machine learning, multivariate time series, autoregressive model, feature selection, polymer production.

## 1. Introduction

The aim of this work is to predict the material quality (ASTM-MFR) at polymer production plants, based on historical time series data. These historical data comprise a variety of associated features, potentially driving the evolution of the material over time. Accordingly, the given dataset is comprised of approximately three thousand signals measured in different timestamps among them, as well as with the target variable (MFR). The research started with an investigation of the statistical properties of the studied variables, followed by feature selection, and predictive modelling with Machine Learning Algorithms. In any predictive modelling computation, the predicted values always differ from the given ones in the raw dataset (Bakas, 2019). Hence, and despite the extended effort made to create a robust model, the predictions deviate from the actual values of MFR, especially in certain timestamps, due to the high amount of statistical noise existing within the variables. The input variables, exhibit distributions with no known patterns or even chaotic ones, and we present their computational handling, and numerical results.

We had to deal with specific challenges, such as the sparseness of MFR results (low frequency, measured every 4 hours on average), while the corresponding features utilized as an input in the Machine Learning Models are measured more frequently, e.g. per minute or even per second. Furthermore, we had to smooth the signals' outliers and deal with their dynamic nature, as the correlations of the features with the target variable, though strong, vary significantly with time and disorientate the predictive modelling. Furthermore, we present how we approached the cleaning of the data along with heuristic features' selection algorithms (Bakas, et al., 2022), so as to obtain a structured dataset to feed the Machine Learning Models. The amount of noise in the dataset was significant; hence we utilized a variety of autoregressive models and time lags (Bakas, 2019), in order to attain the best possible prediction accuracy. We found a combination of XGBoost (Chen & Guestrin, 2016; Xu & Chen, 2014), with the gradients of the features  $\nabla F_k$  at a time stamp  $k$ , to exhibit adequate accuracy. Furthermore, we investigate various ML models as new data are being obtained constantly. Particularly, we use Polynomial Regression (PR) (AlHamaydeh, et al., 2022), Random Forests (Breiman, 2001; Sadeghi, 2013), and Artificial Neural Networks (Bakas, et al., 2019).

To address the issue of noise and time-shift observations in the raw dataset, a hybrid approach was developed. This will use a simple model of the process equipment, which will precondition the data values by applying correct time offsets and filtering before sending it to the Machine Learning algorithms. This procedure removes the burden of processing noise and applying time offsets from the Machine Learning algorithms. As further development the model could identify different operating conditions, e.g., which catalyst is being used in the reactors, and/or change of raw material feeds to produce High/Low MFR product. This allows Machine Learning models to be trained for each condition with the expectation that each model will be more accurate within its defined range than a single combined model.

## 2. Specific Challenges

### 2.1. Sparseness of MFR results

We aim to predict MFR values which are measured every 4 hours on average (low frequency), while the corresponding features utilized as an input in the Machine Learning Models, are measured more frequently, e.g. per minute or even per second. We investigated a variety of models, initially we keep constant the previously known MFR value for the unknown regions, and ultimately, using only  $t$  timestamps with known values for all predictors and target.

### 2.2. Signal Outliers

The given dataset comprises a rich variety of potential features for the prediction of MFR. Twenty-one features exhibit high Pearson's Correlation with MFR ( $>0.9$ ). However, these correlations change with time strongly, along with the corresponding outliers in the features. Signal outliers disorientate the predictions made by any of the utilized models. To confront this, we used robust-to-noise machine learning models and also tailor-made algorithms for feature selection, to obtain a final set of features which predicts MFR with the best possible accuracy.

## 3. Computational Approach

Exploratory Data Analysis was performed for the fundamental statistical properties, as well as inter-item correlation and clustering among the time-series. Predictive modelling has started using various time-lags and linear models to identify prediction accuracy with the given data. The predictive modelling of the database was implemented by utilizing

four ML methods, and in particular: a. linear, b. higher-order regression, c. random forests, and d. gradient boosting. Machine learning methods exhibit diverse performance on the studied dataset, with respect to the error metrics each time utilized. The utilized error metrics were the Root Mean Squared Error, the Mean Absolute, the Mean Absolute Percentage Error, the Maximum Absolute Percentage Error, the slope of the Predicted vs Actual values, as well as the Pearson Correlation Coefficient. The studied data set contains a rich variety of input variables. However, many of them comprise extreme outliers. In order to identify an optimal subset of features, we use optimization algorithms (Bakas, et al., 2022; Plevris, et al., 2021).

### 3.1. Mathematical Formulation

Let  $Q$  be the sought Quality of MFR, which is intended to be predicted. We use symbol  $k$  as the index for the timestamps of  $Q$ .  $k$ , may iterate  $\in \{1, 2, \dots, m\}$  values of all time stamps where the features are being measured, or iterate  $\in \{1, 2, \dots, n\}$  known values of  $Q$ , with  $n \ll m$ . Hence at each time stamp  $k$  we have a particular value  $Q_k$ , while the entire vector of the target variable is

$$Q := Q_k \quad (1)$$

Accordingly, we define  $F_{k,j}$ , with  $j \in \{1, 2, \dots, p\}$ , for  $p$  features in total, the value of an input variable (feature) at time  $k$ , such that the vector of features at a time stamp  $k$  is

$$F_k := \{F_{k,1}, F_{k,2}, \dots, F_{k,p}\}, \quad (2)$$

and hence the entire matrix of features is

$$F := F_{k,j} \quad (3)$$

Let  $\mathcal{M}: R^p \rightarrow R$  be an continuous function of the features  $F_k$  returning the Quality values  $Q_k$ . We approximate  $\mathcal{M}$  with Machine Learning Algorithms, such that

$$Q_k = \mathcal{M}(F_k) + \epsilon_k, \quad (4)$$

and

$$\epsilon_k \sim \mathcal{U}(0, \sigma), \quad (5)$$

the regression errors, which should ideally follow a distribution  $\mathcal{U}$  exhibiting a Gaussian shape with zero mean.

This is the baseline approach. We may enhance this model, by utilizing the moving average of each feature  $j$ , select a subset  $o$  of the  $p$  features, add the time-lagged features as new features, and also add the differences of  $F_{k,j}$  along with the time passed until a difference occurs, as per the following formulation.

We define the differences of  $Q$ , at time  $k$  as

$$\Delta Q_k := Q_k - Q_{k-1}, \quad (6)$$

and the corresponding differences of  $F_{k,j}$ ,

$$\nabla F_k := \{\Delta F_{k,1}, \Delta F_{k,2}, \dots, \Delta F_{k,p}\}. \quad (7)$$

Let  $\mathcal{L}: R^{2p+1} \rightarrow R$  be an continuous function of the features  $F_k$ , such that

$$\Delta Q_k = \mathcal{L}(F_k, \nabla F_k, \Delta t_k) + \epsilon_k. \quad (8)$$

We now identify  $\mathcal{L}$  with Machine Learning, taking into consideration the distribution of the errors  $\epsilon_k$  as above-mentioned.

Afterwards, we may predict  $Q_k$ , by using

$$Q_k = Q_{k-1} + \Delta Q_k. \quad (9)$$

For the real-time, prediction stage, we iterate for each minute (or appropriate real-time interval), and sequentially add to the previous  $Q_{k-1}$ , the computed  $\Delta Q_k$ , as predicted, with  $\Delta t_k = 1$ , and  $k \in \{1, 2, \dots, m\}$ .

### 3.2. Latest data and Model

We retrain the models, after the data engineering as was automated by the HYPPOS program, enriched by new data, by using all raw features at MFR measurements timestamps as an input for the ML models, and target variable MFR. Particularly, this version is for ALL MFR values and both Catalysts. For Nonlinear Regression (NLR), XGBoost (XGB), and Random Forests (RF), we use exhaustive grid search with cross validation. The search parameters for tuning are presented in Table 1. For example, for XGBoost model, we run 36 combinations of Hyper-Parameters, times 100 intermediate rounds = 3600 different XGBoost models in total, and we select the best one. Furthermore, for each model, we run it 5 times in order to do cross-validation with a random permutation of the Train set. Hence the actual models are 18000.

*Table 1. Hyperparameter Tuning Search Space.*

<b>Nonlinear Regression</b>

## 4. Results

The best performing model for the new data after data engineering, was a combination of parameters of the Random Forests (Table 2). In Figure 1, we present the error analysis in the Test Set for Random Forests model. We may see that the errors are low on average, with some specific regions of high outliers (Figure 1).

Figure 1: Prediction Errors in the Test Set, using the Random Forests model.

In order to explain statistically the drives of outliers in Figure 1, we performed an error analysis by following the next steps: (a) we split the Train Set into 1000 bins, equally distributed from the minimum value of MFR, up to its maximum value, (b) we counted the number of MFR values found per each particular bin, (c) for each bin, we computed the Mean Absolute Error (MAE), among the given MFR values, and the predicted ones, in the Test Set, (d) we plotted the results in a scatter plot (Figure 2), along with the 95% & 99% Quantiles of the MAE.

Figure 2: Number of MFR values per bin in the Train Set vs MAE in the Test Set.

Interestingly, we observe an inverse association among the number of MFR values per bin in the Train Set, and the corresponding MAE in the Test Set. Hence, we empirically deduce that the density of MFR values per MFR range corresponds to low errors and vice versa. Hence, e.g. for high values of MFR (>25) the high errors occur as a result of low number of MFR values in the training dataset. We foresee in the future steps of this work to gather more data and train new models, to resolve the data adequacy issue.

Table 2: Performance Metrics for all Models Used

Model	Dataset	Pearson	M.A.P.E.	M.A.E.	R.M.S.E
Linear	Train	0.988	0.165	0.791	1.176
Linear	Test	0.946	0.310	1.246	2.120

ANNBN	Test	0.418	0.277	1.838	12.939
Random Forests	Train	1.000	0.005	0.032	0.080
Random Forests	Test	0.970	0.071	0.548	1.555

## 5. Conclusions

In this work, we developed machine learning models for the MFR time series prediction on real industrial conditions. The input for the models is a wide variety of industrial measurements, as obtained in the timestamps MFR was measured. We investigated various mathematical formulations, along with machine learning models. We found that hyperparameter tuning with exhaustive search, and tree-base models (XGBoost and Random Forests) yielded the best possible performance. The average errors are low for entirely out-of-sample data points. However, as outliers also exist in specific MFR timestamps, we foresee retraining the models with new data that will be obtained gradually in real-time industrial conditions. Despite the vast noise in data, irregular timestamps of MFR measurements and limited dataset, we developed a model exhibiting adequate accuracy on average.

## Acknowledgements

This work received financial support by the EuroHPC-JU project EuroCC (G.A. 951732) of the European Commission, and the Research and Innovation Foundation of Cyprus programs for research, technological development and innovation “RESTART 2016–2020” (RIF PROPOSAL NUMBER: ENTERPRISES/0521/0175). Parts of the runs were performed on the Cyclone machine hosted at the HPC National Competence Center of Cyprus at the Cyprus Institute (project pro21b103).

## Abstract

The HYPPOS software has been developed to encapsulate experience gained over 15 years of building bespoke solutions for the polymer industry. HYPPOS not only is configurable and easily maintainable, but it also uniquely provides the ability to combine data analytics and Artificial Intelligence to support decision making.

We developed a mathematical material tracking system that discretizes continuous manufacturing processes into identifiable slices of material (“Quanta”) and track them as they move through the manufacturing stages. To achieve this, HYPPOS is integrated with production and business management ICT systems. HYPPOS transforms data collected into information and applies different inferencing and Machine Learning algorithms, which calculate critical quality parameters, then tracking them in real-time. As the Quanta move past sensors, they collect KPI’s and quality parameters making the history of the material visible.

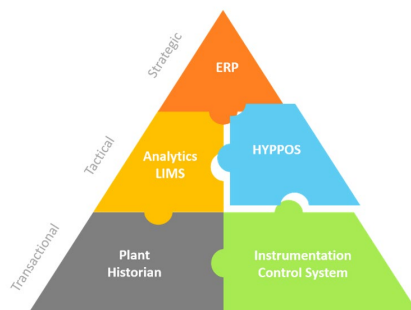

**Keywords:** petrochemicals, sustainability, real-time monitoring, waste reduction, decision support

## 1. Introduction

Today polymer production and forming processes account for more than 80% of the carbon footprint of plastic manufacturing (Hydrocarbon Processing, 2018). That presents detrimental environmental challenges that need immediate attention and intervention. The International Energy Agency ‘s (IEA) “Future of Petrochemicals” report (IEA, 2018) recommends building a more sustainable and efficient petrochemicals industry. Early identification of potential process issues and their correct handling is critical to reducing material waste and energy consumption. This can be achieved through specialized software technology that enables automatic and real-time analysis. However, current software platforms do not offer the required specialization, flexibility, and information without extensive customization.

Identifying the gap in the currently available solutions, we developed HYPPOS - Hyperion Predictive Production Online Software. HYPPOS as presented at the 11<sup>th</sup> International Conference on Chemistry and Chemical Engineering (ICCCE, 2020) and at the 9<sup>th</sup> International Conference on Chemical and Process Engineering Materials (ICCPE, 2020) is an all in-one Artificial Intelligence driven decision support tool that

addresses specific challenges of the polymers industry including quality traceability, real-time analysis, rapid and accurate reporting, process visualization and quality consistency. HYPPOS is positioned in Industry 4.0 Tactical Management Level, it collects data from systems at the Transactional Management Level, feeds and receives data from systems at the Strategical Management Level (e.g. Enterprise Resource Planning Systems such as SAP) and co-exists and interacts with other systems at the Tactical Management Level (e.g., Laboratory Information Management Systems).

*Figure 1: HYPPOS Positioning as per ISA 95 Industry Standard.*

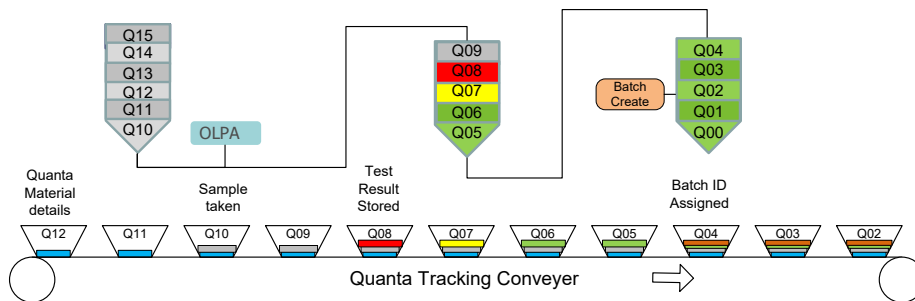

Polymer manufacturing requires quality monitoring at the different production stages from the polymerization reactors through to extrusion and batch assembly in blender silos. For this purpose, specialized On-Line Polymer Analysis equipment (OLPA) is available. Nevertheless, the majority of polymer plants are not equipped with such on-line analyzers primarily due to their high cost. Instead, process engineers and plant operators usually rely on off-line laboratory measurements of quality critical parameters. This does not allow real-time monitoring and early corrective actions, and as a result it leads to off-spec polymer product. Therefore, the aim of this work is to embed Machine Learning (ML) algorithms into HYPPOS software to create Soft Sensors to predict quality in real-time at early production stages eliminating the need for on-line physical sensors.

The Melt Flow Rate (MFR) is one of the most frequently used parameters in polymer manufacturing to control the material quality, and it is a measure of the viscosity of the polymer. Therefore, the MFR value range constitutes the most fundamental quality specification of the final polymer product since it determines the product grade.

## 2. Method

HYPPOS combines material flow models with AI/ML to create a digital twin of the production equipment and process. Its monitoring and inferential capabilities allow the online tracking of product quality as it moves through the production process and can forecast the final quality of polymer being produced enabling early corrective real-time actions. It uses a proprietary new method that allows the discretization of continuous processes and formulations of material into small ‘Quanta’ (depicted as  $Q_i$  in Figure 2), which act as a discreet container of trackable information enabling the traceability of material and its properties throughout the entire production process. The integrated tracking system is based on a unique, in-house developed process flow model which moves the Quanta through the equipment on a FIFO basis. Using an analogy, the ‘Quanta’

are located on a conveyor belt that helps them move through the process equipment advancing at the same speed as the production stream.

*Figure 2: Analogy for Quanta Tracking System.*

The model covers the main production stream from process feeds through to final product. The model is block based, with Equipment Blocks, Movements and Modifier blocks which merge/separate streams. The Movements transfer are driven by plant measurements, and transfer Quanta between Equipment using this information. The exact transfer rate calculation depends on the availability of plant measurements. Where instrumentation is missing, special proprietary algorithms calculate the movement rates based on measurements in surrounding equipment. The Equipment Block maintains details of the material holdup within the process equipment. Additionally analytical processes have been developed to process the information collected by the model and produce detailed reports for the final product.

When real time OLPA instrumentation is available, the Quanta can collect and carry this information and can be used to display the product quality properties as it advances through the production process.

Efforts to predict the polymer quality through Soft Sensors that use ML models based on plant measurements have been reported before (Shi, et al., 2006; Jumari & Mohd-Yusof, 2016; Liu, et al., 2018; Abeykoon, 2018; Yan, et al., 2023;). The innovation of this work lies in embedding the ML models in the HYPPOS Quanta algorithm that is implemented at industrial scale and it allows the real-time tracking of material together with its quality characteristics as it moves through the production equipment.

We have identified the following challenges when implementing ML algorithms to a continuous process such as polymer production. The process measurements used as input in the ML model are recorded continuously in real-time, whereas the target variable (MFR) is measured on average every 4 hours. Since MFR measurements come off-line from the lab, they become available with a delay of around 2 hours. Therefore, they need to be time shifted to various points in the process.

Furthermore, the plants are using relatively infrequent Lab test results for the quality parameter measurements, and this makes it difficult to obtain useful quantities of data to train the ML system to predict these parameters.

While initial tests using information from the plant were promising, they were not working well in all situations, especially during process transients. To simplify the ML algorithms task, we developed a pre-conditioning algorithm which is based on a simple model description of the process stages. The model defines the measurement signals, and the time duration of each stage. This allows the pre-conditioner to correctly time shift the measurements and apply noise reduction techniques to the values.

### 3. Case Study Results and Discussion

The objective was to predict the MFR on the polymerization reactor of an industrial scale polypropylene plant. To train the ML system, 5 months of raw process data from the plant including Lab measurements were used. Features selection algorithm was implemented, and 47 process variables were found to correlate the best with MFR measurements including among others the hydrogen feed rate to the polymerization reactors, doner concentration, teal concentration, the catalyst type, the reactor pressure and reactor temperature, and input material flow rates.

The raw data was run through a specially developed tool that converted the raw data into a training data set. The training data set contained the target variable values (MFR lab measurements) and all the pre-conditioned values that affected the production at that instant.

Using the trained ML algorithms, predictions were made using pre-conditioned process test data. This resulted in a marked improvement in prediction accuracy and better handling of process transients.

Figure 3 below shows XGBoost prediction of MFR parameter without using pre-conditioned data. It clearly shows that the predictions anticipate changes in MFR, therefore the Orange prediction line generally changes before the Blue measured line.

*Figure 3: MFR Predictions without Preconditioning.*

Figure 4 shows XGBoost prediction of MFR parameter with pre-conditioning. This shows great improvement in time shift and overall accuracy.

Figure 4: MFR Predictions with Preconditioning.

It is evident from the above graphs that there is a significant improvement in terms of tracking changes in operating conditions as now the Orange line is not time displaced from the Blue as in previous graph. There is also an improvement in prediction accuracy which is shown by the performance metrics calculated for each case as shown in the Table below.

Table 1. Performance Metrics for Methodologies Used.

	Pearson Correlation	Mean Absolute Percentage Error
No Preconditioning	0.92846	0.09523
With Preconditioning	0.98381	0.06697
Improvement	5.96%	-29.67%

The pre-conditioning technology has now been developed into a module within the HYPPOS software. This uses the process data values collected by HYPPOS in real-time, and at specified intervals it produces a table of pre-conditioned values. This table is passed to the ML prediction algorithm, which predicts the MFR, and the result is returned and passed to HYPPOS for use as part of the product quality management functionality.

It should be noted that these results were achieved with a relatively small quantity of training data, and that the installed system is expected to improve further on accuracy as it retrains itself based on continuous data collection.

#### 4. Conclusions

Based on this, HYPPOS is expected to have a significant positive impact on production efficiency, profitability, and competitiveness while also reducing waste, with a consequential contribution in lowering the carbon footprint.

The implementation of ML pre-conditioning has been a significant step forward in improving accuracy of the quality parameters. And it demonstrates that it can produce useful results with relatively little training data, allowing rapid deployment on new plants. This technology gives HYPPOS users a real-time view of the quality of the product being produced, enabling rapid intervention and reduction in waste and off-spec production.

## Abstract

Spray drying is widely used for dehydration of dairy products and among, the most energy-intensive unit operation in this field. An optimization problem for a production scale milk drying system was implemented and solved, considering plant capacity (maximization) and energy consumption (minimization) as the objective. Decision variables were inputs to the spray unit namely the inlet dry bulb air temperature, concentrate moisture, and dry solids flow rate. Product stickiness conditions and moisture content were the main constraints, which were modeled using mass and energy balances. A non-deterministic derivative free based optimization technique, namely Markov Chain Monte Carlo (MCMC) algorithm was chosen to solve the problem. The results showed that throughput maximization is achieved at the expense of a relative energy consumption penalization in the spray and revealed that the structure of the problem seems to be convex. This study shows a promising non-conventional use of MCMC algorithms in optimization studies.

**Keywords:** Milk drying process, process optimization, derivative free optimization, MCMC.

## 1. Introduction

The most widely used technique for dehydration of dairy products is spray drying after evaporation. These processes preserve food properties and allow storage of powders at an ambient temperature (Schuck et al., 2008). A drying plant normally presents three stages: 1) spray chamber; 2) internal fluid bed at the conical base of the spray chamber; and 3) external fluid bed to fine tune the outfeed product stream, as it is shown in Figure 1 (Schuck et al., 2005). As spray drying is the most energy-intensive unit operation in the dairy industry, process optimization becomes of critical importance to increase efficiency and reduce production costs (Petersen et al., 2015). As a continuation of previous works in a production scale system about modelling, uncertainty, identifiability, and sensitivity analysis from the point of view of identifying influential inputs/parameters and quantifying confidence intervals in model simulations (Ferrari et

al., 2015; Ferrari et al., 2016; Ferrari et al., 2017), an optimization problem for the entire milk drying process is here implemented and solved.

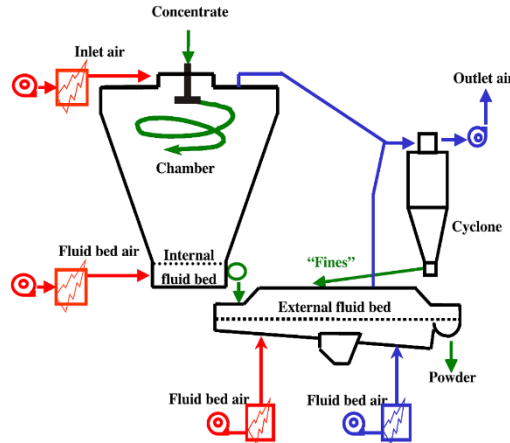

Figure 1. Physical system of three stage dryer scheme.

Maximization of plant capacity and minimization of energy consumption are considered in the objective function. Decision variables are all inputs at chamber inlet streams:

- $T_{A,1}$ : Chamber inlet dry bulb air temperature [K], which is feasible to be manipulated at the feed to the spray unit.
- $M_{P,1}$ : Concentrate moisture [ $\text{kg}_{\text{water}} \cdot \text{kg}_{\text{total}}^{-1}$ ], which is feasible to be manipulated by the output from the evaporation plant upstream of the drying processes.
- $S$ : Dry solids flow rate [ $\text{kg}_{\text{dry solids}} \cdot \text{h}^{-1}$ ], which is feasible to manipulate via the feed to the evaporation plant.

Product stickiness conditions at internal fluid bed and moisture content in final powder are assumed as the main constraints in the problem. A global sensitivity analysis of the optimization results is also performed respect to normal and not controlled variations in the chamber inlet air humidity ( $H_{A,1}$ ; range:  $0.003 - 0.020 \text{ kg}_{\text{water}} \cdot \text{kg}_{\text{dry air}}^{-1}$ ), finding the corresponding result for a different  $H_{A,1}$  value at a time. A non-deterministic/derivative free based technique (Markov Chain Monte Carlo algorithm) is chosen to solve the problem to overcome issues when using a deterministic gradient-based method. The MCMC use is also interesting for trying to visualize non-convexity patterns in the model finding the posterior density functions of decision variables, representing a non-conventional use of MCMC. Details and results about the deterministic approach are not covered in this paper because of length restrictions. The work is structured as follows: first the conceptual optimization problem is described, then the optimization technique is introduced, afterwards the obtained results are analyzed and discussed.

## 2. Materials and methods

### 2.1. Optimization problem

To consider plant capacity maximization and energy consumption minimization, the objective function (OF) is structured as follows:

$$OF = \alpha \cdot T_{A,1} - \beta \cdot P_{out} - \gamma \cdot W_{dried} \quad (1)$$

Being:

$$P_{out} = S \cdot \left[ 1 + \frac{M_{P,4}}{1 - M_{P,4}} \right] \quad (2)$$

$$W_{dried} = S \cdot \left[ \frac{M_{P,1}}{1 - M_{P,1}} - \frac{M_{P,4}}{1 - M_{P,4}} \right] \quad (3)$$

Where  $P_{out}$  is the total flow rate at system output [ $\text{kg}\cdot\text{h}^{-1}$ ];  $W_{dried}$ , the total water dried in the system [ $\text{kg}_{\text{water}}\cdot\text{h}^{-1}$ ];  $M_{P,4}$ , the final powder moisture [ $\text{kg}_{\text{water}}\cdot\text{kg}_{\text{total}}^{-1}$ ]; and  $\alpha/\beta/\gamma$ , dimensionless coefficients to have balanced terms in the objective function. It will be assumed  $\alpha = 20$ ,  $\beta = \gamma = 1$ , all constant during the complete study. The main inequality constraints to be considered are related to the product stickiness [using glass transition temperature as indicator (Silalai and Roos, 2010)] at the internal fluid bed, and also with the residual moisture content in final powder, in accordance to Eq. (4) and (5).

$$T_{P,3} \leq T_{g,3} \quad (4)$$

$$M_{P,4} \leq M_{P,max} \quad (5)$$

Where  $T_{P,3}/T_{g,3}$ , are the product one and its glass transition temperature at the internal fluid bed [ $^{\circ}\text{C}$ ]; and  $M_{P,max}$ , is the maximum allowed powder moisture at the end of the system [ $\text{kg}_{\text{water}}\cdot\text{kg}_{\text{total}}^{-1}$ ]. It is assumed in this work a value of  $0.030 \text{ kg}_{\text{water}}\cdot\text{kg}_{\text{total}}^{-1}$  for this parameter (commercial constraint for whole milk powder). The decision variables for the optimization are  $T_{A,1}$ ,  $M_{P,1}$ , and  $S$ , with the following bounds to screen an important range of operating conditions in the system.

$$453 \text{ K} \leq T_{A,1} \leq 503 \text{ K} \quad (6)$$

$$0.47 \text{ kg}_{\text{water}}\cdot\text{kg}_{\text{total}}^{-1} \leq M_{P,1} \leq 0.53 \text{ kg}_{\text{water}}\cdot\text{kg}_{\text{total}}^{-1} \quad (7)$$

$$5,000 \text{ kg}_{\text{dry solids}}\cdot\text{h}^{-1} \leq S \leq 6,600 \text{ kg}_{\text{dry solids}}\cdot\text{h}^{-1} \quad (8)$$

The optimization problem will minimize energy consumption and maximize throughput in the system, changing  $T_{A,1}$ ,  $M_{P,1}$ , and  $S$  as decision variables, subject to mass and energy balances with also powder stickiness and residual moisture constraints. The detailed process and product stickiness models are described in Ferrari et al. (2015), Ferrari et al. (2016), and Ferrari et al. (2017). The complete structure of the optimization problem is summarized as follows:

$$\begin{aligned} & \min_{T_{A,1}; M_{P,1}; S} OF \\ & \text{s. t:} \\ & T_{P,3} \leq T_{g,3} \\ & M_{P,4} \leq M_{P,max} \\ & T_{A,1}; M_{P,1}; S \in R \end{aligned}$$

## 2.2. Numerical methods

As a non-deterministic/derivative free technique, a Markov Chain based algorithm was used for solving the optimization problem and for detecting non-convex behaviours. This represents a non-conventional use of Markov Chain based algorithms, but it is interesting to analyze its capabilities and obtain first insights for finding posterior density functions of decision variables and trying to visualize non-convexity patterns. The Metropolis random walk algorithm (Gelman et al., 2004; Weinzierl, 2000) was also

used as the method to accept/reject new samples from transition distributions. The algorithm proceeds as follows:

Step 1: randomly select a feasible initial vector of decision variables,  $\theta^0$ . A uniform distribution is assumed for all of them.

Step 2: create a new trial vector,  $\theta^* = \theta^{k-1} + \Delta\theta$ , where  $\Delta\theta$  is randomly sampled from a jumping distribution  $q(\Delta\theta)$ . This is assumed as multivariate normal centered at current iteration and calculated as follows:

$$\Delta\theta = u \cdot \frac{2,4}{\sqrt{l(\theta)}} \quad (9)$$

Where  $u$  is a unit normal random number drawn for each decision variable; and  $l(\theta)$ , the length of  $\theta$  vector.

Step 3: calculate the adapted Metropolis ratio ( $r$ ):

$$r = \frac{OF_{Augmented}(\theta^k)}{OF_{Augmented}(\theta^{k-1})} \quad (10)$$

$$OF_{Augmented} = \left\{ \begin{array}{ll} OF & \text{if } \theta \in \text{Feasible Region} \\ OF_{Max} & \text{Otherwise} \end{array} \right\} \quad (11)$$

$$OF_{Max} = \alpha \cdot T_{A,1} \quad (12)$$

To compute the constraints of the optimization problem, an augmented objective function with a hard penalization term was defined in accordance to Eq. (11).

Step 4: accept the new vector by the following rule.

$$\theta^k = \left\{ \begin{array}{ll} \theta^* & \text{if a random probability} < r \\ \theta^{k-1} & \text{Otherwise} \end{array} \right\} \quad (13)$$

To report the optimal values for decision variables, the following criterion is applied: if chains show that a bound constraint is active, such bound value is assumed as the optimal; otherwise, the mean for all chains data is reported as the optimal value. All mathematical models and numerical methods were implemented in Matlab R2015a using an Intel(R) Core(TM) i7-3770 CPU@3.4 GHz with 8 GB RAM memory.

### 3. Results and discussion

The results are obtained using between 10 and 20 Markov Chains with 5,000 samples per chain. Optimal  $T_{A,1}$  and  $S$  values reach their upper bounds for all  $H_{A,1}$  range (default values in the plant are 468 K and 5,760  $\text{kg}_{\text{dry solids}} \cdot \text{h}^{-1}$  respectively), so throughput maximization is achieved at the expense of a relative energy consumption penalization in the spray. Respect to  $M_{P,1}$  results (between 0.525 – 0.529  $\text{kg}_{\text{water}} \cdot \text{kg}_{\text{total}}^{-1}$  covering the  $H_{A,1}$  range), the values are slightly higher than the default one (0.52  $\text{kg}_{\text{water}} \cdot \text{kg}_{\text{total}}^{-1}$ ) so this is aligned with water dried maximization in the system. Numerical issues were found during the deterministic approach, but the results here obtained confirmed main tendencies for decision variables. Figure 2 shows an example of the evolution for 20 chains, in which the convergence is achieved and requiring in most of the cases less than 5,000 samples. At the end of the chains upper bound is reached for  $T_{A,1}$  and  $S$ . The

computational burden was around 9 hours per optimization run and more representative results obtained from this example are presented in Table 1. Despite the acceptance ratio being low (0.021), most likely because of the constrained nature of the optimization problem, convergence was achieved for all decision variables (R-scale values close to 1), and the Monte Carlo estimation error presented low values for all cases (Gelman et al., 2004) as shown in Table 1.

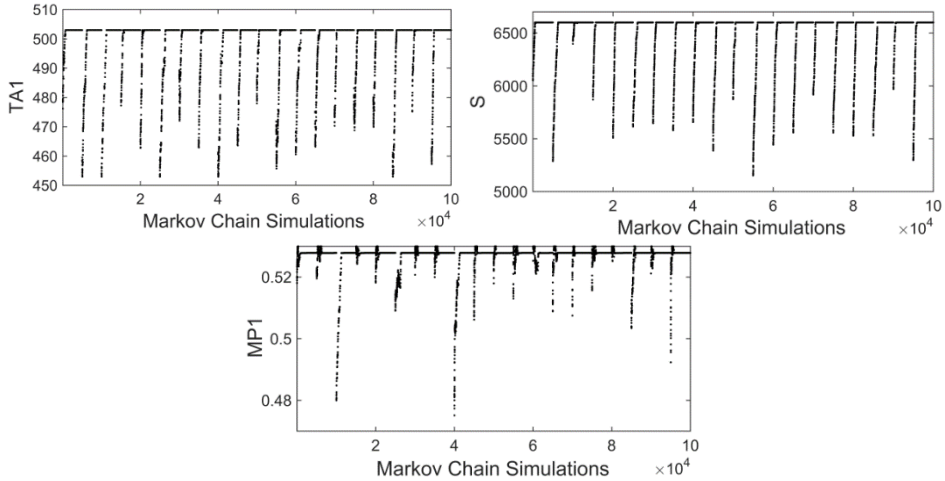

Figure 2. Simulation results for an example of 20 chains.  $[T_{A,1}] = K$ ;  $[M_{P,1}] = \text{kg}_{\text{water}} \cdot \text{kg}_{\text{total}}^{-1}$ ;  $[S] = \text{kg}_{\text{dry solids}} \cdot \text{h}^{-1}$

Table 1. Summary of performance for the example shown in Figure 2

	$T_{A,1}$	$M_{P,1}$	$S$
<b>R-scale</b>	1.0331	1.0348	1.0240
<b>Monte Carlo error</b>	0.0007 % of mean	0.0006 % of mean	0.0004 % of mean

Figure 3 shows the densities obtained for decision variables in accordance with the example shown in Figure 2.

Figure 3. Density functions for decision variables.  $[T_{A,1}] = K$ ;  $[M_{P,1}] = \text{kg}_{\text{water}} \cdot \text{kg}_{\text{total}}^{-1}$ ;  $[S] = \text{kg}_{\text{dry solids}} \cdot \text{h}^{-1}$

As can be interpreted, the nature of the problem seems to be convex since only one peak appeared in density functions. Hence, local optimum would also be global. In general MCMC explore the decision space using a random walk algorithm, which makes it robust against the initial conditions of decision variables. On the other hand, a prior

distribution is required for them and the slow convergence can be improved using different methods such as differential evolution, parallel computing, etc. (Vrugt, 2016).

#### 4. Conclusions

An optimization problem for a production scale milk spray and fluid bed drying was implemented and solved in Matlab. Results from a non-deterministic based technique (Markov Chain based random walk algorithm) revealed that dry bulb air temperature and dry solids flow rate could be controlled close to their upper bounds. These insights are aligned with the current situation in the production scale plant which this work is based on. It can also be observed that optimal concentrate moisture values are higher than the default one for the base problem, being this aligned with the maximization of total water dried in the system. The results involve an improvement in plant throughput but with a penalization in relative energy consumption in the spray dryer compared with the base operational point. The non-deterministic based results revealed that the structure of the problem seems to be convex. Despite it needs further theoretical analysis, the application case study shows promising results as a novel technique for non-deterministic/derivative free global optimization. This is especially suited for industrial applications, where the process models are not amenable for calculation of derivatives (Magnússon et al., 2020). Trying other non-deterministic tools such as Genetic Algorithms, Particle Swarm, etc., and doing a more comprehensive study on the multi-objective optimization problem, can be explored as future works. The developed model is expected to be a promising tool for decision-making at industrial scale.

## Abstract

In this work, a memory layer sequence-to-sequence digital twin (ML-StSDT) of a high-density polyethylene (HDPE) reactor simulated by ASPEN Dynamics<sup>TM</sup> was constructed using simulated grade transition and steady-state operating data. A reinforcement learning control (RLC) algorithm was developed by training with the ML-StSDT. The RLC was able to control both grade transition and steady-state operation of the simulated plant. The RLC performs better or equally well when compared with the direct application of ML-StSDT in nonlinear model predictive control (NLMPC) but substantially reduces the computation load. Our results demonstrate the feasibility of deep learning models serving as a digital twin for RLC training in nonlinear process control applications.

**Keywords:** Reinforcement learning; Sequence-to-Sequence with Memory Layer; Model Predictive Control, Grade transition.

## 1. Introduction

Model predictive control (MPC) has been used in the process industry to maximize the productivity of the process and reduce energy consumption. As the scope of the process being controlled increases, the following issues become more challenging. First, the number of state variables to be identified and decision variables to be optimized increases. Dynamic prediction horizons also become more and more complex and nonlinear. Hence a nonlinear model is required. Computation load becomes a challenging issue and control policies within the sampling period were increasingly difficult and suboptimal decisions may be made (Mayne et al. 2014) and The computation difficulty still limits control policy optimization over a less satisfactory horizon. The similarity between reinforcement learning (RL) and MPC has long been recognized, studied, and

reviewed by G6rges (2017). RL can drastically reduce online computing time. According to Nian et al. (2020), while RL methods such as deep deterministic policy gradient (DDPG) are suitable for online control, application of RL, application of RL to industrial control is mostly limited to a simulation environment. The Monte Carlo method is suitable for generating an infinite set of operations with a clear system terminal state, and the average return can be obtained after each trajectory calculation and does not require estimating values through previously estimated values to avoid the value function falling into local optima (Yoo et al., 2021).

## 2. Memory Layer Sequence-to-Sequence Model

In our previous work, Jiang et al. (2022), we developed a sequence-to-sequence with memory layer (ML-StS) model (Figure 1) for a high-density polyethylene slurry reactor simulator (Figure 2) using ASPEN Dynamics™, based on the kinetic model by Khare et al. (2002). The sensors, manipulation and controlled variables (SV, MV, and CV) are shown in Table 1. The operator employed catalyst flow and hydrogen flow as MV to control the hydrogen-to-ethylene ratio (HER) and pressure. The ML-StS model was able to predict dynamic behavior with high accuracy as well as consistent directionality of MV/CV pairs u shown in Table 2.

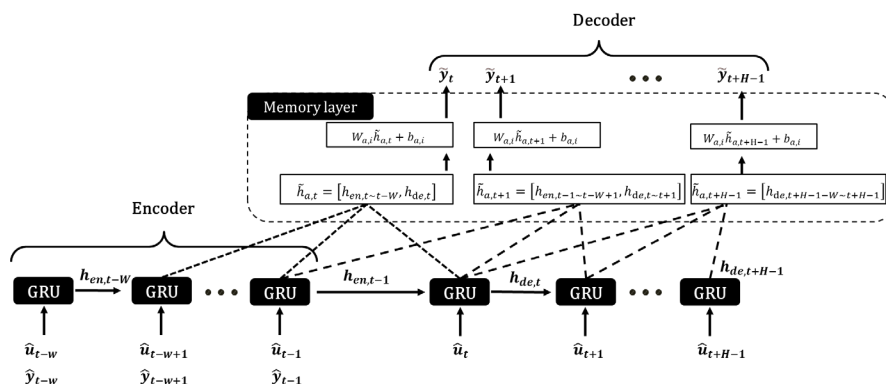

Figure 1. Structure of an StS model with the memory layer

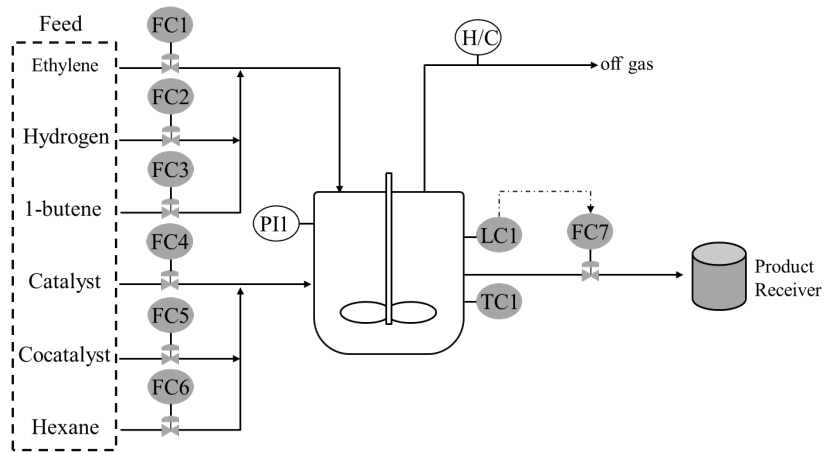

Figure 2. The schematic of the HDPE process.

Table 1: List of variables

Type	Tag
MV	The flow rate of ethylene
MV	The flow rate of hydrogen
MV	The flow rate of 1-butene
MV	The flow rate of catalyst
MV	The flow rate of cocatalyst
MV	The flow rate of hexane
MV	Temperature of reactor
CV	Pressure of reactor
CV	HER of purge gas

Table 2: Directionality of gain

	HER	Pressure
The flow rate of c	+	-
The flow rate of hydrogen	+	+

### 3. Nonlinear Model Predictive Control

The ML-StS model was then used in navigation as the predictive model used by nonlinear model predictive control (NLMPC) as shown in Figure 3. The differential evolution algorithm (DEA) was used to plan control actions in the future horizon and according to the future trajectory objective and operating constraints. While the NLMPC scheme is successful for both grade transition and steady-state operation, the computation load is too heavy to prevent frequent updating of manipulative variables.

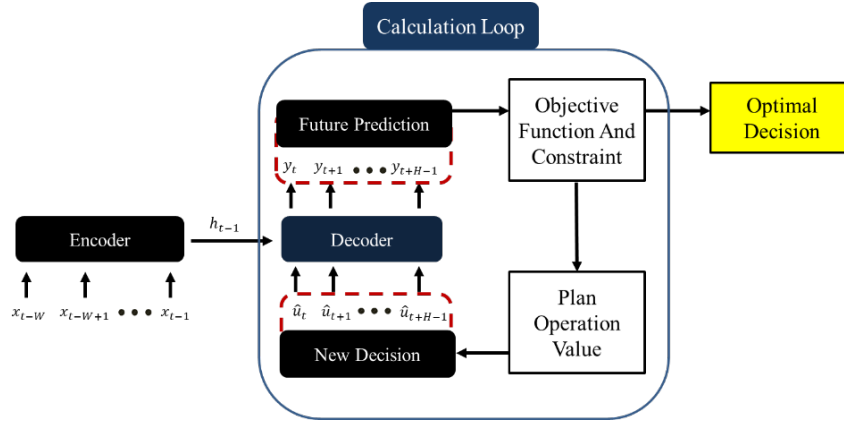

Figure 3. The schematic of the MPC calculation process.

#### 4. Reinforcement Learning Control

Instead of direct application in NLMPC, the ML-StS model can also serve as a digital twin (DT) environment for training a reinforcement learning control (RLC). In this study, the “state” in RL was defined as the input to ML-StS encoder and future CV target setpoints trajectory. The “actor” was defined as the control action of the immediate future. The Monte Carlo Deep Deterministic Policy Gradient (MC-DDPG) was used to train the state actor relation using the ML-StSDT as the “environment” (Figure 4). Eq. 1~8 are utilized to calculate the reward of action. Eq. 1 is the main target of the hydrogen-ethylene ratio. Eq. 2,3 make sure the current pressure (Pre.) is between the desired upper and lower limits (UL, LL). Eq. 4~7 limits the MV, catalyst flow (Cat.), and hydrogen flow (hyd.), within the allowable operating range. Eq. 8 allows RL models to achieve setpoint with minimal MV changes. After training using the ML-StSDT, RLC is then tested by the physical simulator.

$$R_1 = -|(\mathbf{HER}_{setpoint,state} - \tilde{\mathbf{y}}_{HER,t})| * 10^5 \quad (1)$$

$$R_2 = -|(\mathbf{Pre}_{UL} - \tilde{\mathbf{y}}_{Pre,t})| * 10^7, \text{ if } \tilde{\mathbf{y}}_t > \mathbf{Pre}_{UL} \quad (2)$$

$$R_3 = -|(\mathbf{Pre}_{LL} - \tilde{\mathbf{y}}_{Pre,t})| * 10^7, \text{ if } \tilde{\mathbf{y}}_{Pre,t} < \mathbf{Pre}_{LL} \quad (3)$$

$$R_4 = -|(\mathbf{Hyd}_{UL} - \mathbf{u}_{hyd,t})| * 10^6, \text{ if } \mathbf{u}_{hyd,t} > \mathbf{Hyd}_{UL} \quad (4)$$

$$R_5 = -|(\mathbf{Hyd}_{LL} - \mathbf{u}_{hyd,t})| * 10^6, \text{ if } \mathbf{u}_{hyd,t} < \mathbf{Hyd}_{UL} \quad (5)$$

$$R_6 = -|(\mathbf{Cat}_{UL} - \mathbf{u}_{cat,t})| * 10^6, \text{ if } \mathbf{u}_{cat,t} > \mathbf{Cat}_{UL} \quad (6)$$

$$R_7 = -|(\mathbf{Cat}_{LL} - \mathbf{u}_{cat,t})| * 10^6, \text{ if } \mathbf{u}_{cat,t} < \mathbf{Cat}_{UL} \quad (7)$$

$$R_8 = -|\Delta \mathbf{u}_t| * 10^1 \quad (8)$$

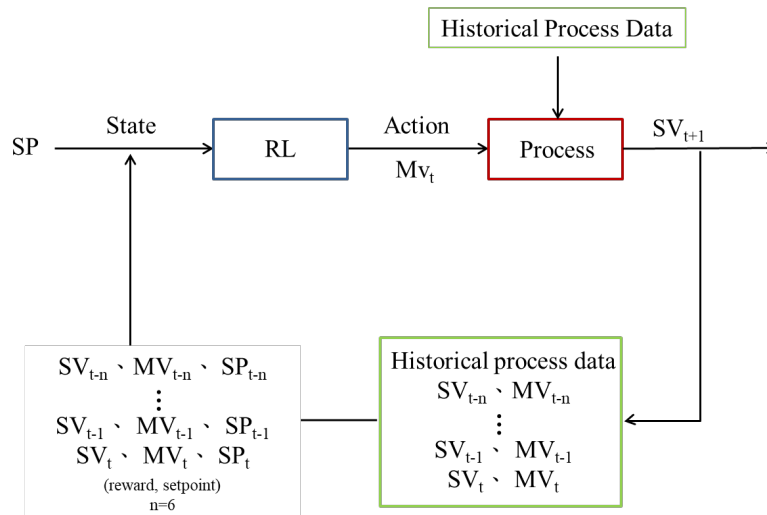

Figure 4. The schematic of the RL interacting with the HDPE process.

## 5. Results

Figure 5 and Figure 6 compared the results of two cases of grade transition directed by controlled LC and NLMPC. As shown in Figure 5 (a) the HER IAE of NLMPC is 34% lower in NLMPC but RLC produces a much smaller overshoot. In Figure 6 (a) the HER IAE of RLC and NLMPC are similar. However, NLNMC results in the oscillation of NLMPC being much more severe while RLC provides a smoother transition. Figure 5(b, d) and Figure 6 (b, d) showed that the action of NLMPC is much more aggressive while RLC provides a much smoother action due to higher frequency updating of control action. The changes in cumulative total and individual rewards of the RLC and NLMPC as shown in Figure 7. RLC also shows a much smoother trajectory. RLC computation time for each decision-making (18 milliseconds) is only about 1/1000 compared with the cost time of calculation of MPC (18 seconds). The 99.9% time reduction of RLC demonstrates the superior potential for the real complex process.

## 6. Conclusion

In this work, we demonstrated that a memory layer sequence-to-sequence digital twin (ML-StSDT) of a high-density polyethylene (HDPE) reactor can serve as a model for NLMPC as well as a surrogate environment for training an RLC. The RLC performs better or equally well when compared with direct application in NLMPC but the online computation load is much reduced.

## Abstract

The supply chain for ethylene production is becoming unstable, especially after Covid-19. This situation poses new challenges for ethylene plants to handle frequently changing feed supply conditions with more responsive scheduling strategies. This paper proposes a rolling horizon approach combined with moving average supply forecasting to assist in dynamic decision-making for ethylene production scheduling. When applied to an industrial case study, the proposed model shows superior calculation speed as well as the capability to find fairly good scheduling solutions under uncertain supply conditions.

**Keywords:** rolling horizon, scheduling, ethylene, inventory management

## 1. Introduction

Ethylene is one of the most important chemicals in the world and ethylene plants form one of the most profitable industrial chains (Li et al., 2022b). Owing to Covid-19, the global supply chain is experiencing ongoing turmoil, which increases the feedstock supply uncertainty in the ethylene industry. This brings pressing needs for ethylene plants to adopt a dynamic scheduling strategy to respond to unstable upstream supply conditions to guarantee optimal economic profits over time.

In recent years, ethylene production scheduling has been studied intensively. Ethylene cracking furnace systems process multiple feeds in multiple furnaces to produce ethylene and other olefin products. As the product yields vary with the furnace and the cracking duration as a result of coking inside the coil, the scheduling strategy, which determines the feedstock allocation between furnaces and the batch lengths in each furnace, has vital influences on the economic profits of the ethylene plants. And and Grossmann (And and Grossmann, 1998) first proposed a mixed-integer nonlinear programming (MINLP) model for the ethylene scheduling problem. After that, many modifications, for example, the non-simultaneous constraints (Liu et al., 2010) and integration with operation optimization (Li et al., 2022a) have been made to improve the model.

However, the dynamic response to the changing feedstock supply conditions has been overlooked in these previous scheduling studies. Facing this challenge, this paper developed a novel dynamic scheduling framework including (1) a Rolling horizon approach for the self-update of decision variables (2) Feed supply forecasting by moving average estimation (3) Mathematical formulation of the scheduling model with daily inventory constraints. This framework enables the model to receive new supply information from the environment and make quick responses by updating the scheduling

variables. To demonstrate the efficacy of the developed new dynamic scheduling framework, a reference industrial case study taken from the literature is presented.

## 2. Problem statement

Fig. 1 shows the mass flow in a typical ethylene cracking furnace system (Li et al., 2022a). Feed  $i$  ( $1, 2, \dots, NF$ ) is cracked in furnace  $j$  ( $1, 2, \dots, NF$ ) and finally produces product  $l$  ( $1, 2, \dots, NP$ ) after quenching and separating.

**Figure 1.** Mass flow of the ethylene cracking furnace system

However, because the feedstock supply conditions change frequently and decision-makers can't foresee the perfect information about the future feedstock supply conditions, updates of the following scheduling decision variables: (1) the inlet feed type in each furnace; (2) whether to perform decoking in a furnace given the visible future supply conditions, the inventory conditions, and the furnace conditions on the current day  $n$  are thus needed.

## 3. Methods

### 3.1. Rolling horizon approach

The rolling horizon approach is demonstrated in Fig. 2. The core idea is to optimize over a fixed horizon based on visible parameters and re-optimize the model repeatedly once the time step moves forward and new parameters are received. On the current day, the model will receive visible feed supply parameters from the market and optimize the schedule for the next  $H_1$  days (lookahead horizon, LH). Before the optimization, the variables for the first  $H_2$  days (fixed horizon, FH) will be fixed at variable solution levels from the previous schedule. In real cases, the time horizon of visible feed supply will be shorter than LH (referred to as imperfect information), which requires the model to estimate the future supply parameters based on the current information and generate the schedule. After the optimization, the schedule on the current day will be executed and the rest schedules in FH will be passed to the next optimization.

**Figure 2.** Illustration of rolling horizon approach

### 3.2. Supply forecasting by moving average estimation

Due to the existence of randomness, it's impossible to accurately foresee the long-term feed supply conditions needed for the scheduling optimization beforehand. We assume the feed supply conditions for the next  $H_2$  days will be known (perfect information). One possible solution to this is to estimate the future supply based on the current visible information. Here, we proposed the moving average estimation to achieve this. As shown in Eq. (1), on the current day, the supply parameters will be observed as the true value for the first  $H_2$  days. While for days between  $H_2$  and  $H_1$ , the supply amount will be estimated as the average supply amount of the first  $H_2$  days, as shown in Eq. (2).

$$supply_{i,k} = supply_{i,k}^{obs}, \quad \forall i, 1 \leq k \leq H_2 \quad (1)$$

$$supply_{i,k} = \frac{1}{H_2} \sum_{k=1}^{H_2} supply_{i,k}^{obs}, \quad \forall i, H_2 < k \leq H_1 \quad (2)$$

### 3.3. Rolling horizon scheduling optimization model

#### 3.3.1. Objective function

The objective of the rolling horizon scheduling model is to maximize the net profits over the next  $H_1$  days. As shown in Eq. (3), the net profits are the product revenue minus the raw material costs, operation costs, and the decoking costs. Binary variable  $y_{i,j,k}$  indicates whether feed  $i$  is processed in furnace  $j$  on day  $k$ . Binary variable  $x_{j,k}$  denotes whether to perform decoking for furnace  $j$  on day  $k$ .  $D_{i,j}$  is the flow rate of feed  $i$  in furnace  $j$ .  $P_l$  (the price of product  $l$ ),  $Cr_i$  (raw material cost of feed  $i$ ),  $Cv_{i,j}$  (operation cost for processing feed  $i$  in furnace  $j$ ),  $Cs_j$  (decoking costs for furnace  $j$ ) are price-related parameters.

$$Max \quad J = \sum_i \sum_j \sum_k \sum_l P_l y_{i,j,k,l} y_{i,j,k} D_{i,j} - (Cr_i + Cv_{i,j}) y_{i,j,k} D_{i,j} - Cs_j x_{j,k} \quad (3)$$

#### 3.3.2. Fixed horizon constraints

$invent_{i,k}$  denotes the inventory level of feed  $i$  on day  $k$ . The integer variable  $day_{i,j,k}$  is an indicator for the current batch lengths so far on day  $k$ . For each of the rolling horizon scheduling models, the decision variables in the fixed horizon will be fixed at the variable levels from the last scheduling model, as shown in Eq. (4). This guarantees decision consistency between adjacent days.

$$\begin{aligned} & invent_{i,k}, day_{j,k}, y_{i,j,k}, x_{j,k} \\ & = invent_{i,k}^{Fixed}, day_{j,k}^{Fixed}, y_{i,j,k}^{Fixed}, x_{j,k}^{Fixed}, \forall i, j, 1 \leq k \leq H_2 \end{aligned} \quad (4)$$

#### 3.3.3. Feedstock allocation and decoking constraints

When allocating the feeds in different furnaces, only one type of feed is allowed to be cracked in a furnace at one time. If the furnace undergoes decoking, no feed will be allowed, as shown in Eq. (5). Besides, simultaneous decoking is restricted (Eq. (6)). Additionally, furnaces are not supposed to execute decoking on two consecutive days (Eq. (7)). Eq. (8) assures that if a furnace will not change the inlet feed type without performing a decoking operation.

$$\sum_i y_{i,j,k} \leq 1 - x_{j,k}, \quad \forall j, k \quad (5)$$

$$\sum_j x_{j,k} \leq 1, \forall k \quad (6)$$

$$x_{j,k-1} + x_{j,k} \leq 1, \forall j, k \quad (7)$$

$$(1 - x_{j,k-1} - x_{j,k})(y_{i,j,k} - y_{i,j,k-1}) = 0, \forall i, j, k \quad (8)$$

### 3.3.4. Batch length and yields constraints

If decoking happens on day  $k$ , the indicator  $day_{i,j,k}$  will be 0. Otherwise, it will be  $day_{i,j,k-1}$  plus 1 day (Eq. (9)). Owing to the limits of coking thickness, the batch lengths are not allowed to exceed the upper limit  $tup_{i,j}$ , as shown in Eq. (10). Besides, to avoid overly short batches, decoking is not allowed before the current batch length reaches the lower limit  $tlo_{i,j}$  (Eq. (11)). The product yields  $yd_{i,j,k,l}$  are determined by the exponential yielding model in Eq. (12).  $a_{i,j,l}$ ,  $b_{i,j,l}$ ,  $c_{i,j,l}$  are yield-related parameters.

$$day_{i,j,k} = y_{i,j,k}(day_{i,j,k-1} + 1), \forall i, j, k \quad (9)$$

$$day_{i,j,k} \leq tup_{i,j}, \forall i, j, k \quad (10)$$

$$day_{i,j,k} x_{j,k} (day_{i,j,k-1} - tlo_{i,j}) \geq 0, \forall i, j, k \quad (11)$$

$$yd_{i,j,k,l} = c_{i,j,l} + a_{i,j,l} e^{b_{i,j,l} day_{i,j,k}}, \forall i, j, k, l \quad (12)$$

### 3.3.5. Daily inventory constraints

The inventory level for each type of feed is determined by the inventory level of the previous day  $invent_{i,k-1}$ , the arrival supply on the current day  $supply_{i,k}$  and the processed amount on the current day  $\sum_j y_{i,j,k} D_{i,j}$ , as shown in Eq. (13). Note that  $invent_{i,k-1}$  should be non-negative.

$$invent_{i,k} = invent_{i,k-1} + supply_{i,k} - \sum_j y_{i,j,k} D_{i,j}, \forall i, k \quad (13)$$

## 4. Case study

### 4.1. Feedstock supply conditions Parameters

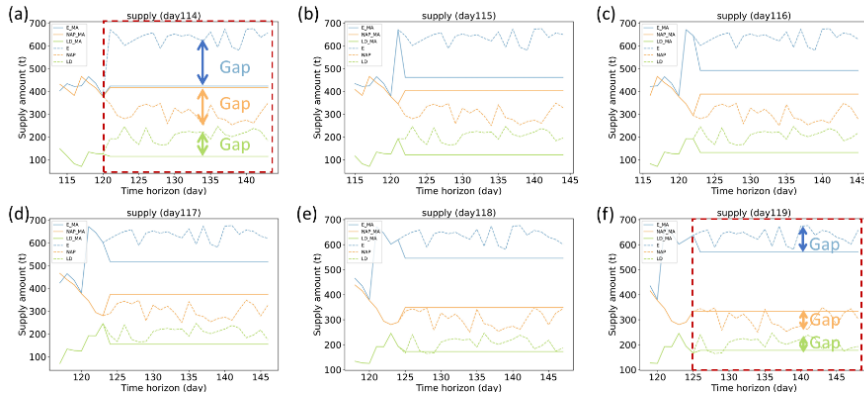

To evaluate the efficacy of the proposed model, a case study taken from the literature (Liu et al., 2010) with modification of feed supply conditions is used in this work. As shown in Fig. 3, the supply mode varies every 30 days. The other parameters remain the same as in the original literature.

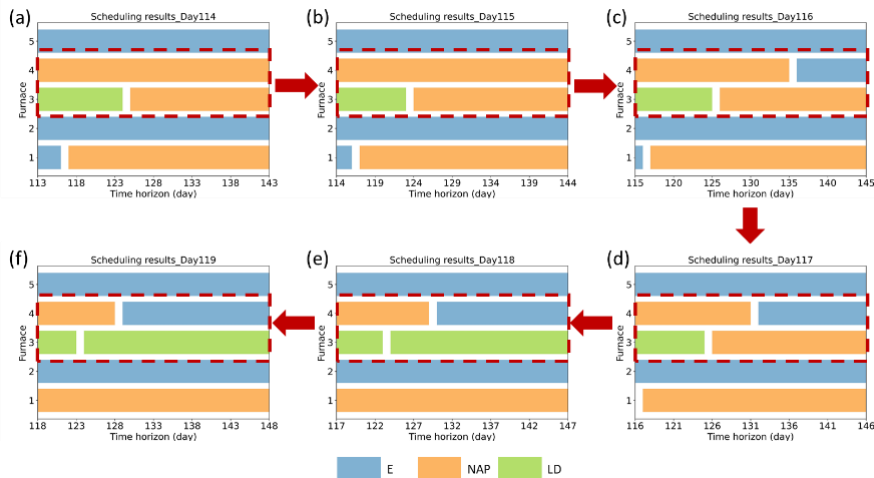

**Figure 3.** Feed supply conditions in 270 days.

### 4.2. Scheduling results

To demonstrate how our proposed rolling horizon model can respond to feed supply changes, Fig. 4 shows the supply parameters from day 114 to day 119. The solid line in each subplot represents the estimated parameters using moving average estimation, while the dotted line represents the future true supply parameters which are invisible on the current day.

**Figure 4.** Feed supply parameters from day 114 to day 119.

**Figure 5.** Scheduling results from day 114 to day 119.

As can be observed in Fig. 4, the feed supply mode experiences a shift around day 120 with the ethane and light diesel supply increasing and the naphtha supply decreasing. On day 114, the estimated supply isn't aware of the change. As time step moving forward, the supply estimation for ethane and light diesel gradually upshifts because more observations are available now. Accordingly, the optimal schedule adjusts itself. As shown in Fig. 5(a) and (c), Furnace 4 planned to process naphtha from day 113 to 143 originally, but the schedule changed on day 116 by executing decoking on day 136 and processing ethane from day 137. Similarly, Furnace 3 planned to process light diesel followed by naphtha on day 114 but changes to process light diesel followed by light diesel on day 118 (Fig. 5(e)). The schedule changes in the two furnaces show how our model can track the supply conditions change and update the schedule accordingly. The executed optimal schedule for a long horizon of 270 days is shown in Fig. 6.

**Figure 6.** The executed scheduling results over 270 days.

#### 4.3. Comparison of model size and solution with the original literature

The original model from the literature and our proposed model are developed in GAMS v38.2 on an Intel Core i7-9700CPU @ 3.00 GHz CPU with 16.0 GB RAM. Without daily inventory constraints, there's no guarantee that inventory constraints are satisfied at all times, as shown in Figure 7. Instead, the rolling model ensures feasible inventory levels.

**Figure 7.** Inventory comparison of the original solution and rolling-horizon solution. The model comparison results are listed in Table 1. The number of variables increases in the rolling model but the solution time is shortened. The objective value is quite close to the original solution, meaning good solution quality with supply uncertainties.

**Table 1.** Model size and solution comparison.

Variable	Original model	Rolling horizon model
Equations	8560	4442
Variables	1855	3392
Solution time	~ 32 min	~ 40 s
Objective value	151204 \$/day	148495 \$/day

## 5. Conclusion

This paper proposed a rolling horizon framework to deal with the ethylene production scheduling problem under feed supply uncertainty. When applied to a case study from the literature, our model shows superiority in reducing the model size as well as guaranteeing a good scheduling solution with consideration of daily inventory management.

## Abstract

In this work three different TSA process configurations were chosen, and these processes were optimized using genetic algorithm. One of the processes was a moving bed TSA process while the other two process were fixed bed processes using a packed bed containing pellets and hollow fiber modules. With Lewatit as the sorbent chosen, the cycle configurations were optimized to identify minimum energy and maximum productivity values for CO<sub>2</sub> capture from a natural gas combustion cycle (NGCC) flue gas. The hollow fiber TSA process had the highest productivity of 4.25 mol CO<sub>2</sub>/m<sup>3</sup> ads s, followed by the fixed bed and the moving bed TSA processes with values of 2.03 and 1.68 4.25 mol CO<sub>2</sub>/m<sup>3</sup> ads s, respectively

**Keywords:** TSA process, optimization, CO<sub>2</sub> capture

## 1. Introduction

Adsorption processes using solid sorbents rely on the differences in the affinities of the different gases towards the solid and has been implemented on a large scale for several gas separation applications. Adsorption processes are broadly classified into two types based on the mode of regeneration of the sorbent: Pressure/vacuum swing adsorption (PSA/VSA) where the sorbent is regenerated by lowering the pressure of the column and temperature swing adsorption (TSA) process where the sorbent is regenerated by the supply of heat directly or indirectly. TSA processes are better suited to low concentrations of CO<sub>2</sub> than PSA/VSA processes such as a natural gas combustion (NGCC) cycle, where it is possible to achieve purity values >95% from a feed containing 3-5% CO<sub>2</sub>. However, TSA processes applied to conventional fixed bed columns are usually slow due to the long heating and cooling times, and this is especially a drawback as it lowers the productivity of the process. Such a drawback could be mitigated through a combination of direct heating and the use of structured adsorbents like hollow fibres with better mass transfer and lower pressure drop, resulting in improved performance of the process in comparison with traditional packed bed systems [1,2]. At the core of an adsorption process is the adsorbent and the performance of an adsorbent depends on the specifics of the process. Therefore, each adsorbent must be mapped towards the best process configuration [3]. This information can only be obtained from detailed simulations and optimization of different adsorbent-process combination in a standardized manner to

accurately reflect competitiveness. The present work employs a homogenized model to study the following processes: 1. A fixed TSA process with pellets 2. A fixed bed TSA process with hollow fibers 3. A moving bed TSA process with pellets. The adsorbent chosen for this study is a commercially sold benzyl amine polymer, Lewatit for a representative NGCC cycle with 5% CO<sub>2</sub> and 85% N<sub>2</sub>. The three cycle configurations were optimized to identify minimum energy and maximum productivity values for purity-recovery targets of 95% and 90%, respectively.

## 2. Cycle design

For the fixed bed a 4-step TSA process was chosen. The four steps are as follows and the schematic of the process is shown in Figure 1.

1. Adsorption with feed: Feed enters the column at 313 K. Adsorption of the CO<sub>2</sub> takes place while nitrogen is collected at the product end. The outlet of the column is maintained at 1 atm. A part of the nitrogen is used to purge the column in the light reflux step.
2. Heavy reflux step with light reflux product (HRLRP): This step uses the product of the light reflux step. The duration of this step is the same as the light reflux (LR) step since the entire product of the latter is recycled back to the column. The CO<sub>2</sub> concentration in the column is enhanced during this step. The column is also heated up slightly with the gases coming from the LR step.
3. Desorption with steam purge: The desorption of the CO<sub>2</sub> is aided by counter-currently purging the column with steam/water at a high temperature.
4. Light reflux step (LR): The remaining CO<sub>2</sub> in the column is then purged with the nitrogen product of the adsorption step from the counter-current direction. The product is fully recycled back in to the HRLRP step.

A similar concept was also considered for the moving bed temperature swing adsorption (MBTSA) process shown in Figure 1. The moving bed process is a simplified process with the adsorption and desorption sections. In the adsorption step, the solid flows counter-current to the gas. Once the adsorption step is complete, the HRLRP step is carried out with the solid staying constant. Then the solid is circulated to the desorption section. Here steam is fed to the column in a counter current direction and CO<sub>2</sub> is collected as a product. The solid also flows in the same direction as the steam. Once this step is completed the solid flow is stopped and the LR step is carried out with adsorption product. The product of the LR step is sent to the HRLRP step and the solid is now moved back into the adsorption step.

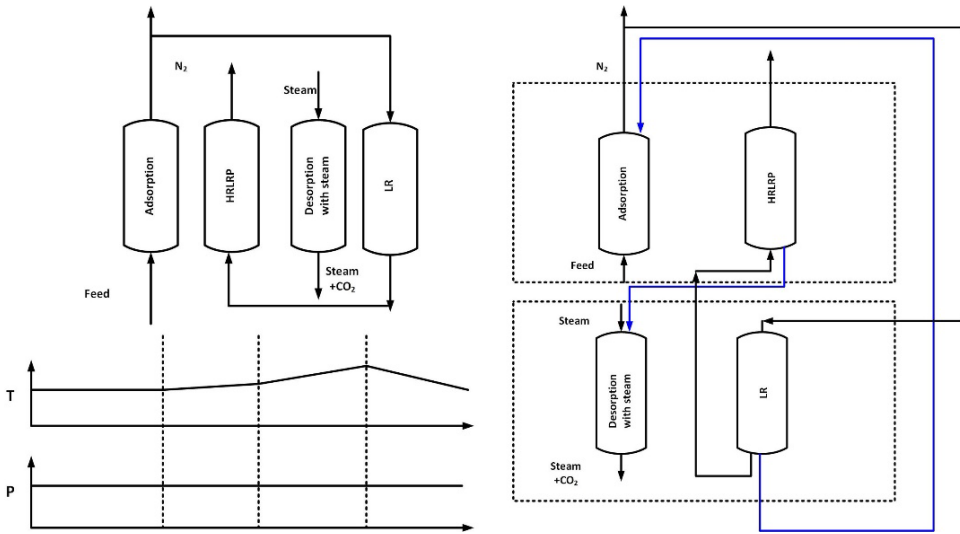

Figure 1: Schematic of the 4-step TSA process (left) and the 4-step MBTSA process (right). Solid blue lines represent the movement of solid, while black solid lines represent gas flow. The dotted lines in the figure on the right is for visual aid to separate the adsorption and desorption sections.

### 3. Model equations

The model equations used in this study are similar to the authors' earlier studies [4] on packed beds with the inclusion of additional terms to account for the solid movement. The equations are described below

$$\frac{\partial y_i}{\partial t} + \frac{y_i}{P} \frac{\partial P}{\partial t} - \frac{y_i}{T} \frac{\partial T}{\partial t} = \frac{T}{P} D_L \frac{\partial \left( \frac{P \partial y_i}{T \partial z} \right)}{\partial z} - \frac{T}{P} \frac{\partial \left( \frac{y_i P}{T} v \right)}{\partial z} - \frac{RT(1-\epsilon)}{P \epsilon} \frac{\partial \bar{q}_i}{\partial t} - \frac{T}{P} V_S \frac{\partial \left( \frac{y_i P}{T} v \right)}{\partial z} \quad (1)$$

$$\frac{1}{P} \frac{\partial P}{\partial t} - \frac{1}{T} \frac{\partial T}{\partial t} = -\frac{T}{P} \frac{\partial \left( \frac{P}{T} v \right)}{\partial z} - \frac{(1-\epsilon) RT}{\epsilon P} \sum_{i=1}^n \frac{\partial \bar{q}_i}{\partial t} - \frac{T}{P} V_S \frac{\partial \left( \frac{P}{T} v \right)}{\partial z} \quad (2)$$

$$\frac{\partial \bar{q}_i}{\partial t} = k_{LDF_i} (q_i^* - \bar{q}_i) - \frac{T}{P} V_S \frac{\partial \bar{q}_i}{\partial z} \quad (3)$$

$$\left[ \frac{(1-\epsilon)}{\epsilon} (\rho_s C_{ps} + C_{pa} \sum_{i=1}^n \bar{q}_i) \right] \left( \frac{\partial T}{\partial t} + V_S \frac{\partial T}{\partial z} \right) = \frac{K_z}{\epsilon} \frac{\partial^2 T}{\partial z^2} - \frac{c_{pg} v}{R} \frac{\partial T}{\partial z} - \frac{c_{pg}}{R} \frac{\partial P}{\partial t} + \frac{(1-\epsilon)}{\epsilon} \sum_{i=1}^n (-\Delta H_i - C_{pa} T) \frac{\partial \bar{q}_i}{\partial t} - \frac{2h_i}{\epsilon r_i} (T - T_w) \quad (4)$$

$$\rho_w C_{pw} \frac{\partial T_w}{\partial t} = k_w \frac{\partial^2 T_w}{\partial z^2} + \frac{2r_i h_i}{r_o^2 - r_i^2} (T - T_w) - \frac{2r_o h_o}{r_o^2 - r_i^2} (T_w - T_a) \quad (5)$$

$$\rho_f C_{p,f} \frac{\partial T_f}{\partial t} = -u_f \rho_f c_{p,eff} \frac{L_z}{L_x} \frac{\partial T_f}{\partial z} - \alpha_{f-HXW} h_f (T_f - T_s) \quad (6)$$

Equations 1-6 represent the component mass balance, total mass balance, adsorption rate, the energy balance, wall temperature and fluid temperature balances. The same set of equations were used for the fixed bed and the moving bed processes, with the solid velocity ( $V_S$ ) being zero in the fixed bed case. Between the hollow fiber and the packed bed, the differences are in the equations used for the pressure drop and axial dispersion terms as shown in Table 1. For the MBTSA process the velocity of the solid was obtained from the desorption/adsorption sections and the duration of the adsorption and steam purge steps. For simplicity in comparison, the length of the column was kept constant in all the simulations. This is also true for the MBTSA process where the length of the adsorption and desorption sections were fixed to be 1m. Appropriate boundary conditions

were used for the different steps along with the initial conditions for each step to simulate a cyclic process. The TSA and MBTSA cycles were simulated until cyclic steady state (CSS) condition was achieved.

The model equations were converted to a dimensionless form and discretized using the finite volume method. The resultant system of equations was solved using the ode 15s solver in MATLAB. The performance of the process was defined by 4 performance indicators, namely CO<sub>2</sub> purity, CO<sub>2</sub> recovery, energy consumption and productivity. Detailed optimization of the different cycle configurations was carried out using genetic algorithm. In total 3600 simulations were carried out for the different cases

Table 1: Correlations for axial dispersion and pressure drop in the simulations

Property	Hollow fiber	Packed bed/moving bed
Pressure drop	$\frac{-dP}{dZ} = 32 \frac{\varepsilon v \mu}{d_c^2}$	$\frac{-dP}{dZ} = 180 \left( \frac{(1-\varepsilon)^2}{\varepsilon} \right) \frac{v \mu}{d_p^2}$
Axial dispersion	$D_L = \frac{20D_{mol}}{\varepsilon} + 0.5v d_p$	$D_L = D_{mol} + \frac{(d_{channel} v_0)^2}{192D_{mol}}$

#### 4. Results and discussion

Figure 2 shows the pareto fronts for the fixed bed and the moving bed temperature swing adsorption processes. All the points on the pareto fronts satisfy 95% purity and 90% recovery constraints. The specific energy consumption is obtained from the energy consumed by the blower and compressor for the adsorption and HRLRP step and the sensible heat required to heat up the solid to the required temperature. It should be highlighted that the energy required to produce the steam is not accounted in the calculations. Based on the pareto plots, the hollow fiber TSA process was the best performing process in terms of productivity. Comparing the cycle times from Figure 3a reveal that the hollow fiber TSA process was able to operate at faster cycle times in comparison with the packed bed TSA process. This is due to the lower pressure drop of the hollow fiber process which helped to operate the cycle at higher flowrates. To minimize the CO<sub>2</sub> losses, the adsorption time is shorter and thereby the cycle time was reduced which improved the productivity. The energy consumption was higher for the hollow fibers due to the values of the regeneration temperatures chosen by the optimizer as seen from Figure 3b.

For the MBTSA process, the high energy and productivity values are a consequence of the high cycle time and higher steam temperature. In the MBTSA process, the feed velocity values were around 2.16-2.25 m/s. whereas for the packed bed it was between 1.8-2.3 m/s. The solid velocities for the MBTSA process were between 4-4.2 mm/s. The operating conditions corresponding to the minimum energy and maximum productivity values are shown in Table 2.

Figure 2: Specific energy vs Productivity plots for the different TSA processes

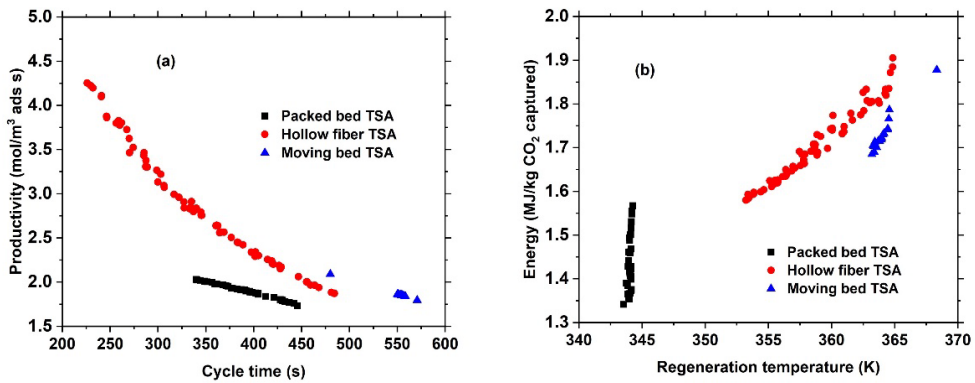

Figure 3: (a) cycle time vs productivity and (b) steam temperature vs Energy consumption

Process	$t_{ads}$ (s)	$t_{LR}$ (s)	$t_{steam-purge}$ (s)	$v_{feed}$ (m/s)	$v_{steam}$ (m/s)	$T_{steam}$ (K)
Minimum energy conditions						
Packed bed	242.10	4.93	193.55	1.79	0.99	343.53
Hollow Fiber	116.58	3.37	360.96	4.23	0.78	353.21
MBTSA	253.01	35.65	246.38	2.16	1.65	363.19
Maximum productivity conditions						
Packed bed	142.64	5.85	185.47	2.70	1.56	344.27
Hollow Fiber	111.60	1.51	111.47	4.66	2.13	364.85
MBTSA	240	20	200	2.25	1.56	368.32

## 5. Conclusions

Here we have used a homogenized model to simulate fixed bed and moving bed TSA processes. Detailed optimization of these processes revealed that the Lewatit sorbent was able to achieve 95% purity and 90% recovery values in all the three processes. The energy consumption was between 1.3-1.9 MJ/kg CO<sub>2</sub> captured for the different processes. It should be highlighted here that the MBTSA process is not the same cycle as that of Mondino et al., [5] and Morales Ospino et al., [6] where the solid moves between the adsorption, desorption and cooling sections. Further work is ongoing to improve the MBTSA process in order to simulate the existing cycles in literature. Additionally other optimization techniques like Bayesian optimization methods are also being explored by the authors

## Abstract

This work explores how artificial intelligence and machine learning (ML) together with rigorous optimization models can help in optimizing electronic bill of materials. We propose a mixed-integer linear programming (MILP) model that considers different real-life restrictions required to complete a customer BoM. Furthermore, we implement a data-driven approach to find a set of alternates for a given component based on data mining and machine learning techniques. With these techniques, the BoM is completed with the most similar alternates that have the same form, fit, and functionality as the given component. The results from a real-life use case illustrate that the proposed AI-enhanced optimization model leads to superior results in terms of solution quality (lower price and shorter lead times) in comparison to the standalone MILP model, with the highlight being a 4.4% improvement in the total cost and a 24% reduction in the lead time.

**Keywords:** EMS industry, Electronic BoM, Optimization, Machine learning, MILP.

## 1. Introduction

The number of electronics used in day-to-day devices has increased in recent years which in conjunction with the global pandemic has caused disruptions in the supply chain of electronic components. According to industry experts, only one-third of components are available for order and the lead times have increased from days to several months. Obviously, this is problematic for companies whose business is dependent on sales of goods that include any electrical components. Therefore, the electronics manufacturing services (EMS) industry is looking for new ways to ensure order completion while maintaining the low costs of electronics manufacturing.

A common method for lowering costs in manufacturing industries is to use mathematical optimization. The quality, quantity, lead time, and price of goods from suppliers provide a profound impact on the overall performance of the supply chain (Pan, 2015) and can all be optimized using MILP models. The information is usually listed in the Bill of Materials (BoM) which is considered one of the critical documents for production planning (Tao and Chang, 2006). An optimized BoM can help companies to plan the purchases of raw materials at minimal prices, avoid excess amounts, manage inventory, stay on schedule, and control the budget.

Machine learning (ML) and data mining techniques have become increasingly useful in finding insights and value from a massive amount of data. ML models can learn patterns and rules automatically from the data that would be impossible for a human. For this reason, ML models are utilized in such applications where rules are not known or are too complex to understand and formulate. Data mining methods refer to techniques that

utilize data to solve problems with algorithms (Leskovec et al., 2010). This definition covers methods ranging from clustering to different types of distance metrics.

Product matching is a well-known problem in e-commerce where vendors try to find duplicate items from their site and conduct price comparisons to other sites with different descriptions and part numbers of items. Proposed solutions incorporate both text-based (Shah et al., 2018) and image-based (Kiapour et al., 2015) models to find matching products. However, none of the proposed solutions address the problem of matching products in a domain where the same form, fit, and functionality of the matches are as crucial as in the electronics supply chain.

This paper proposes a MILP enhanced with an ML-based solution to optimize an electronic BoM. The optimization model strives to minimize the cost while fulfilling all restrictions, whereas the ML solution enables sufficient search space for components that are in stock or available with a short lead time. To experiment with the effect of this, we conduct a case study with real data from the EMS industry and compare our proposed AI-enhanced optimization to a standalone optimization model.

## 2. Problem Statement

A bill of materials (BoM) is a list of the raw materials, assemblies, components, parts, and quantities that are needed to manufacture a product. BoMs can also be enriched by some other information e.g., prices, lead times, minimum quantity that can be ordered, etc. In this work, we consider an enriched electronic BoM, as shown in Table 1. The BoM features 20 line items, with some having a few alternates. For example, line item I1 indicated in the light grey is an alternate (already determined by the customer) for  $I_{EMK107BJ105KA-T}$  (with the subscript indicating the manufacturing part number (MPN)), whereas the one in the dark grey is the one we are trying to find from a massive amount of data using ML techniques, which we will discuss later in Section 3.

Table 1: Example electronic BoM considered in this work.

LI <sup>a</sup>	QTY <sup>b</sup>	Supplier	MPN	MFr <sup>c</sup>	In-stock	Min	Mult	Price (\$)	M-LT <sup>d</sup>
I1	9000	Digikey	EMK107BJ105KA-T	Taiyo Yuden	2400	500	1	0.018	250
I1	9000	Digikey	EMK107BJ105KA-T	Taiyo Yuden	2400	2000	200	0.015	250
I1	9000	Digikey	EMK107BJ105KA-T	Taiyo Yuden	2400	4000	4000	0.011	250
I1	9000	Digikey	GRM188R61C105KA12D	Murata	20000	4000	4000	0.008	300
I1	9000	Myarrow	GRT188R61C105KE13D	Murata	3000	4000	100	0.010	100
⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
I20	5200	Avent	0603YC104KAT2A	Kyocera AVX	12000	2000	500	0.320	120

<sup>a</sup>Line item, <sup>b</sup>quantity required, <sup>c</sup>manufacturer, <sup>d</sup>manufacturing lead time. Note: Numbers are dummy and just for indications.

For the line item  $I_{EMK107BJ105KA-T}$ , we have  $Min = (500, 2000, 4000)$ ,  $Mult = (1, 100, 4000)$ , and  $price = (0.018, 0.015, 0.011)$ , meaning that any order for  $I_{EMK107BJ105KA-T}$  from Digikey should be a function of the Min and Mult of form  $Min + n \times Mult$  where  $n$  is a positive integer number ( $n \geq 0$ ). For example, if we want to order 2050 from  $I_{EMK107BJ105KA-T}$ , we need to order 2000 with a unit price of \$0.015 and the remaining 50 with a unit price of \$0.018. Note that all 2050 cannot be ordered with the price of \$0.015, because there is no integer number  $n$  for which  $2050 = 2000 + 100n$ . The requested quantity for I1 is 9000 and if we order all of them: i) from  $I_{GRT188R61C105KE13D}$  supplied by Digikey, then we need to order 12000 ( $4000+4000 \times 2$ ), i.e., 3000 units more than the requested quantity, which is called *excess quantity*, ii) from  $I_{GRT188R61C105KE13D}$  supplied by Myarrow, we need to wait at least 100 days (manufacturing lead time = 100) as the current in-stock (3000) is not sufficient. In this work, we will develop a MILP to consider all combinations for order quantities while minimizing BoM cost.

### 3. Models and Architecture

The following section describes the models and architecture of our proposed system. First, we define the MILP model that is used to minimize the BoM while considering the restrictions. After that, we describe our alternative search solution that can find alternative components with the same form, fit, and functionality for the reference component.

#### 3.1. MILP model

Here we develop a mixed integer linear programming (MILP) model to optimize a given BoM in terms of costs subject to some restrictions.

The binary variable  $X_{i,m,s}$  is one if component  $i$  with MPN  $m$  is ordered from supplier  $s$  (hereafter as line item  $(i, m, s)$ ). If line item  $(i, m, s)$  is not ordered, then its order quantity ( $Q_{i,m,s}$ ) should be equal to zero, as imposed by Eq. (1).

$$Q_{i,m,s} \leq M \cdot X_{i,m,s} \quad \forall (i, m, s) \in IMS \quad (1)$$

Note that the tuple  $(i, m, s)$  is based on BoM's columns (LI, MPN\_i+MFr, Supplier), in which  $m$  is built by first indexing MPN column and then combining it with MFr column. For example, for the BoM in Table 1, we have  $IMS = \{(I1, EMK107BJ105KA-T_1+Taiyo Yudan, Digikey), (I1, EMK107BJ105KA-T_2+Taiyo Yudan, Digikey), (I1, EMK107BJ105KAT_3+Taiyo Yudan, Digikey), (I1, GRM188R61C105KA12D_4+Murata, Digikey), \dots\}$ .

If line-item  $(i, m, s)$  is ordered, the order quantity should be a function of minimum ( $q_{i,m,s}^{\min}$ ) and mult ( $q_{i,m,s}^{\text{mult}}$ ) quantities. In Eq. (2)  $Z_{i,m,s}$  is a continuous integer variable.

$$Q_{i,m,s} = q_{i,m,s}^{\min} \cdot X_{i,m,s} + q_{i,m,s}^{\text{mult}} \cdot Z_{i,m,s} \quad \forall (i, m, s) \in IMS \quad (2)$$

As expressed in Eq. (3), the amount of line-item  $i$  ordered from all suppliers should be at least as large as the demanded quantity ( $dem_i$ ) by the customer, otherwise, the backordered demand (or shortage) could take a positive value and result in delays in production. Note that Eq. (3) also considers the excess amount.

$$\sum_{(m,s) \in MS | (i,m,s) \in IMS} Q_{i,m,s} + ST_i \geq dem_i \quad \forall i \quad (3)$$

Eq. (4) controls the inventory, meaning that the total amount of component  $i_m$  that can be ordered must not exceed the in-stock at supplier  $s$ .

$$\sum_{i \in I} Q_{i,m,s} \leq in_{m,s} \quad \forall (m, s) \in MS \quad (4)$$

The objective function will minimize the component cost and backorder cost. Notice the shortages coefficient  $bc = N \times \max_{m,s} \{cc_{m,s}\}$ , where  $cc_{m,s}$  is the unit cost of a component, and  $N$  is an integer number ( $N > \max_{i,m,s} |dem_i - q_{i,m,s}^{\min}|$ ).

$$\min z = \sum_{(i,m,s) \in IMS} cc_{m,s} \times Q_{i,m,s} + \sum_{i \in I} bc \times ST_i \quad (5)$$

#### 3.2. Alternatives search

Components that can be considered alternatives have the same form, fit, and functionality as the reference component. Such components are often called *Exact* or *Direct crosses*. The exact crosses are components that differ only in the manufacturer or packaging of the component, whereas direct crosses can contain alternate components that have higher specifications or compliances. Alternative components may have same or different MPN, description, and manufacturer compared to the known component.

Our alternatives search solution (Figure 1) utilizes rule-based search logic, machine learning and fundamental data mining techniques to find alternative components for reference component. Our system contains several machine learning models (e.g., random forest) and data processing steps which aim to improve the quality of the results. First, the incoming MPN is cleaned from characters that are known to be irrelevant for MPNs (Kolhase 2019) and the MPN is normalized to same form as rest of the data. This means that only lower-case characters are allowed, and extra spaces are removed. Next, the system infers component *Description* from the database of known descriptions for the MPN. If the MPN is not found in the database, it matched is approximately to the closest MPN based on character level string distance metric (Gonzalo 2001). In our experiments, Levenshtein distance worked the best.

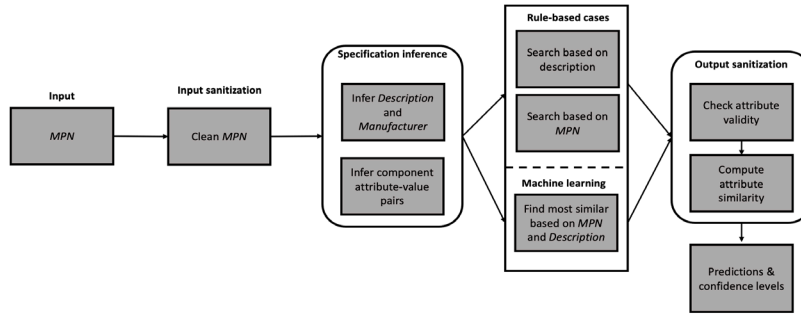

Fig. 1: Flowchart of our proposed alternatives search solution

After the component is inferred and both description and manufacturer for the MPN are found, the system extracts attribute-value pairs from the database, such as {resistance: 100-ohm, tolerance: 5%}. The inferred information is then utilized to find matching components based on *Rule-based cases* and two *Machine learning models*. The rule-based cases include: i) components that have same description but different MPN or manufacturer than the original component, and ii) components that have same MPN but different manufacturer.

Two machine learning models, one trained for description similarity and the other for MPN similarity, are utilized to find most similar components from the database of known MPNs and descriptions. The confidence of both models is averaged to obtain overall ML confidence for a candidate component.

$$Conf_{ML} = 0.5 \times (Conf_{Description} + Conf_{MPN}) \quad (5)$$

Rule-based and machine learning based matching components are then combined and output sanitization is carried out. First, components with conflicting attribute-value pairs (e.g., 1-kohm vs. 10-kohm) are removed from the set of matching components and attribute similarity is computed for each matching component. The attribute similarity is utilized in the computation of the final confidence for a matching component:

$$Conf_{Final} = 0.5 \times (Conf_{ML} + Similarity_{Attributes}) \quad (6)$$

The output is then ordered according to the  $Conf_{Final}$  which is used in the subsequent processing steps.

### 3.3. Solution procedure

Figure 2 depicts the solution procedure that consists of three steps: *preprocessing*, *alternatives addition*, and *optimization*. In the first step, the BoM is cleaned from items that are not viable in terms of client-specific restrictions, such as components from

blacklisted suppliers or with incorrect packaging type. In addition, preprocessing step removes any items that have higher lead time than the client specified maximum lead time. This decreases the size of optimization space while maintaining the quality of the results.

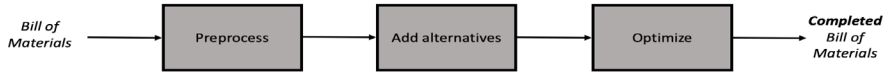

Fig 2: Illustration of three steps of our proposed solution procedure

Next, the BoM is complemented with new alternatives based on our alternatives search solution. Alternatives are queried for any component that have lower total inventory than total demand or no alternatives at all. Highest confidence alternative is picked from alternative search results that satisfies the requirements specified in preprocessing step. Finally, the MILP solver is used to complete the BoM while minimizing the cost and considering specified restrictions, such as inventory and lead time. The output of the solution is a completed BoM that may contain backorders.

#### 4. Case Study

The optimization model was implemented with a Python-based software package *Pyomo* 6.4.2 and solved using *Cbc* 2.10.8 (Coin-or branch and cut) and *GLPK* 4.32 (GNU Linear Programming Kit) open-source MILP solvers. We consider a real customer BoM with 181 components, some having a few alternates already determined by the customer. In total, the BoM consists of 5752 line items. We assume the client-specified maximum lead time is 1 year. Being solved to optimality using *Cbc* in 10s, the standalone optimization (with 0 lead time) involves 1702 constraints, and 10877 (7668) total variables (integers) and corresponds to an optimal cost of \$183695.50 and a total backorder of 16671. Note that *GLPK* could not provide any solutions in 1 hour. After adding the alternate components using the techniques discussed in section 3, the BoM ended up with 7940 line items and the optimal solution (with 0 lead time) decreased by 44.4%. However, the solution CPU time was increased from 10s to 189s, due to enlarging the solution space of the MILP model. Figure 3 and Table 2 show the computational results for the case study (with different lead times) for the standalone MILP and its AI-enhanced counterpart. Summarizing the results, one can observe from Table 2 that the completed BoM with the standalone MILP would feature a lead time of at least 300 days, whereas the AI-enhanced MILP completes the BoM with a lead time of 240 days while still providing slight improvement in the BoM cost.

Table 2: Results obtained using standalone MILP optimization and its AI-enhanced version

Lead time	Optimization		AI + Optimization		The relative improvement in cost (%)
	Backorder	Cost (\$)	Backorder	Cost (\$)	
0	16671	183695	8384	102080	44.4
30	16671	183695	8384	102080	44.4
60	16671	183695	8384	102080	44.4
90	16671	183695	8384	101817	44.5
120	13082	148201	4932	67078	54.7
150	13082	148201	4932	67078	54.7

360	0	38493	0	36818	4.4

Fig 3: Comparison between standalone MILP and its AI-enhanced version

## 5. Conclusions

In this paper, we developed an AI-enhanced optimization model to complete an electronic bill of material with minimum cost and shorter lead time. The mathematical optimization is based on a mixed-integer linear programming (MILP) model that could consider different real-life restrictions required to complete a customer BoM. Furthermore, we implemented a data-driven approach to find a set of alternates for a given component with ML-powered alternative search solution. With this solution, the BoM is completed with the most similar alternates that have the same form, fit, and functionality as the given component. We considered a customer BoM and implemented the resulting optimization model in Pyomo. Compared to the stand-alone MILP model, the AI-enhanced MILP model provides better solutions in terms of solution quality and lead times but might deteriorate the computational time due to enlarging the solution space.

## Abstract

To clean highly viscous fluids from pipework, flushing processes are used. The cleaning time for a pair of fluids, one being flushed and one used for flushing the other out, is typically estimated by using expensive experiments or costly fully resolved numerical simulations. In this work the authors propose a new approach to determine an accurate approximation of the cleaning time for a flushing process at substantially lower cost. This is done through a simplification of the cleaning process. The process is composed of two phases: core removal and layer removal. Sub-models for each phase are developed and then combined yielding the cleaning model. Subsequently, this model is validated using highly resolved CFD data of a cleaning process. The cleaning model is able to predict the cleaned radius over time with an error of less than 8% during core removal and less than 2% during layer removal compared to the CFD data. The computing time is negligible which makes the model highly suitable for practical application.

**Keywords:** Simulation, Cleaning, Highly Viscous Fluid, Flushing, Modelica.

## 1. Introduction

Cleaning is a vital process step during production to ensure that manufactured goods are safe for consumers and that they contain no contaminations from any other goods produced on the same line. During manufacturing of highly viscous products, such as oil, food and cosmetics, flushing processes are often employed to clean pipes of the product and at the same time replace it with a different product, thus ensuring quick product changeover, resulting in lower downtimes. The majority of such products are non-Newtonian fluids, i.e., they exhibit a viscosity dependent on the shear rate. A possible approach to classifying non-Newtonian fluids is to divide them into fluids with and without yield stress  $\tau_0$  and by shear-thinning and shear-thickening behavior. They can be modelled accordingly by using appropriate rheological models, e.g. Bingham, Herschel-Bulkley (Macosko, 1994) and Windhab model (Eischen and Windhab, 2002). For the majority of these models, analytical solutions of laminar single-phase flow exist in the literature, e.g. Bird et al. (1983) for Bingham, Kim and Lapushina (1968) and Grinchik and Kim (1972) for Herschel-Bulkley and Pitsillou et al. (2020) for Windhab.

Each flushing process is characterized by two fluids. The first is the flushed fluid, that is supposed to be displaced and the second the flushing fluid, which is used to displace the first. In the literature, flushing processes have been studied for various combinations of fluids. Hasnain et al. (2017) studied buoyant displacement of two Newtonian fluids with different densities and identical viscosity, Oladosu et al. (2020) and Swain et al. (2015)

studied the displacement of a non-Newtonian fluid by Newtonian fluid with different densities. Typically, highly complex experiments or simulations of flushing processes and their results are only transferable to systems, where the process parameters and fluids involved are similar. Since both experiments and simulations are time consuming, it is not practical to conduct and develop them for each individual flushing process. To obtain fast and yet accurate results, the current work proposes a new method, using only the fluids parameters, the geometry of the pipe and a mass flow rate as input to determine the flushing time necessary to obtain a cleaned radius  $r_c$  or a remaining mass of previous product.

The flushing process of two chocolates is selected as an example to showcase the applicability of the method. Before developing the method in more detail in section 3, the problem and its limitations are detailed in section 2. The obtained results are discussed in section 4 and finally, a conclusion is provided in section 5.

## 2. Problem description

In the present work flushed and flushing fluid are assumed to be incompressible, non-Newtonian and of similar density. The algorithm is developed and applied for the fully developed axisymmetric flow of two chocolates at  $\vartheta = 40$  °C. They exhibit non-Newtonian behavior as described by the Windhab model (Eischen and Windhab, 2002), which relates shear stress  $\tau$  and shear rate  $\dot{\gamma}$  using a specific function  $\tau(\dot{\gamma})$ .

The pipe to be cleaned has a radius of  $R = 13$  mm and a length of  $L = 0.5$  m. White chocolate initially fills the entire pipe and is then flushed out by dark chocolate. Based on experience with detailed simulations, the cleaning process is divided into two phases. First, the core material is removed (Figure 1 a). This phase is characterized by a strong dependency of the cleaned radius  $r_c$  on the position  $x$  inside the pipe. The second phase occurs, when the cleaned radius  $r_c$  is nearly independent of  $x$  and the remaining layer of the previous fluid is slowly thinned out.

Figure 1 Schematic of the considered flushing process. a) first phase of cleaning – core removal; b) second phase of cleaning – layer removal

Following the distinction of the two phases, the authors first develop a model for core removal and then for layer removal, which is done in sections 3.1 and 3.2, respectively. A condition for the transition between the two phases is described in section 3.2.3.

## 3. Reduced Model

### 3.1. Core removal

The velocity profile  $u(r)$  for an axisymmetric flow of a single fluid with Windhab viscosity can be derived analytically from the Navier-Stokes equations using the approach by Pitsillou et al. (2020). The Windhab model contains a parameter  $\tau_0$  to describe the yield stress of the fluid. For  $\tau_0 > 0$  a plug flow region forms in the center of the pipe, i.e., for  $r \leq r_0$ , where  $r_0 = 2\tau_0/f$  is called the plug flow radius, with  $f = \Delta p/L$  being the pressure loss over pipe length. Starting from the wall, where a no-slip boundary condition is applied,  $u(r = R) = 0$ , the velocity  $u(r)$  increases reaching a maximum velocity  $u_{max}$  at  $r = r_0$ , which remains constant until the center of the pipe at  $r = 0$ . Starting from  $r =$

$R$ , the velocity gradient  $u'(r)$  decreases, from the maximum at the wall to zero within the plug flow radius  $r \leq r_0$ .

For  $f \leq 2\tau_0/R$  no flow develops in the pipe, because the yield stress of the fluid is not overcome. With  $f$  increasing above that threshold the mass flow rate  $\dot{m}$  and the maximum velocity  $u_{\max}$  continuously increase, while the plug flow radius  $r_0$  decreases.

The convective transport of a scalar  $\alpha$  in one dimension can be described by

$$\partial_t \alpha + u_{\text{tr}} \partial_x \alpha = 0, \quad (1)$$

with the transport velocity  $u_{\text{tr}}$ . The method of characteristics may be used to solve this partial differential equation. For this paper only a characteristic of eq. (1), along which  $\alpha = \text{const.}$  is used and given by

$$x = u_{\text{tr}} t. \quad (2)$$

Eq. (1) can be used to describe the core removal in a flushing process, by using  $\alpha$  as a phase indicator. Then  $\alpha(x, t) = 1$  indicates the presence of the first fluid at time  $t$  and location  $x$ , while  $\alpha = 0$  indicates the absence of the first fluid and presence of the second fluid. Assuming both fluids have identical physical properties, the pipe flow is axisymmetric, laminar and no diffusion between the two fluids occurs, the transport velocity  $u_{\text{tr}}$  in eq. (2) can be replaced by the analytical solution  $u(r)$  of the flushing fluid described above. The interface between the two fluids is identified here with  $\alpha = 0.5$ . The cleaned radius  $r_c$  for a given location  $x_0$  along the flow axis  $x$ , can then be determined using with  $x_0 = u(r_c) t$  (see eq. (2)). Defining a non-dimensional time using  $\hat{t} = u_{\max} t / x_0$  with the maximum velocity  $u_{\max}$  and the spatial coordinate  $x_0$  yields a universal curve for  $r_c(\hat{t})/R$  as shown in Figure 2.

Figure 2 Cleaned radius  $r_c/R$  over dimensionless time  $\hat{t} = u_{\max} t / x_0$ .

Cleaning starts after an offset time  $\hat{t} = 1$ . This is the time needed for the plug flow region of the flushing fluid traveling at  $u_{\max}$  to reach the cross section at  $x_0$ . When the plug flow region passes, the cleaned radius instantly increases from  $r_c = 0$  to  $r_c = r_0$ . From then on, the cleaned radius increases further. The rate of change, however, decreases since  $u(r)$  decreases towards the wall.

### 3.2. Layer removal

#### 3.2.1. Basic algorithm

Once the core has been removed, the remaining layer is transported away. A linear velocity profile is assumed in the remaining layer, i. e. for  $r_c < r < R$

$$u_L(r) = u_c \left( 1 - \frac{r_c - r}{r_c - R} \right), \quad (3)$$

where  $u_c$  is the velocity on the interface located at  $r_c$ . Integrating eq. (3) over the cross section yields the mass flow rate in the layer  $\dot{m}_L$  as shown in eq. (4)

$$\dot{m}_L = 2\pi\rho \int_{r_c}^R u_L(r) r dr = \frac{\pi}{3} \rho u_c (R - r_c) (R + 2r_c) \quad (4)$$

The mass of the fluid in the remaining layer  $m_L$  is calculated using eq. (5).

$$m_L = \pi\rho(R^2 - r_c^2)L \quad (5)$$

Given these three equations, a simple algorithm to determine the cleaned radius  $r_c$  over time is derived. The problem is initialized with radius  $r_c^0 = r_c(t = t_0)$ . The determination of the starting value is discussed in section 3.2.3. Then, four steps are performed for each time step  $t^n$ . First, the velocity  $u_c^n$  is determined from the given cleaned radius at that time  $r_c^n$ , as detailed in section 3.2.2. Second, the mass flow rate  $\dot{m}_L^n$  is determined using eq. (4). Third, the mass of the remaining layer at the next time step is calculated from  $m_L^{n+1} = m_L^n - \dot{m}_L^n(t^{n+1} - t^n)$ . Finally, the height of the remaining layer at the next time step,  $r_c^{n+1}$ , is determined by rewriting eq. (5). These steps are repeated until a desired radius is cleaned or a maximum time is reached.

### 3.2.2. Determining $u_c$

Figure 1 shows that, during layer removal the radius  $r_c$  is nearly independent of  $x$ , so that the flushing fluid is assumed to create a cylinder with radius  $r_c$  concentric to the pipe with radius  $R$ . Assuming a smooth interface between the two fluids, the flow of the flushing fluid can be treated like the flow inside a second pipe with a pipe radius equal to  $r_c$  and a velocity at the wall  $u(r_c) = u_c$ . The analytical solution by Pitsillou et al. (2020) is modified accordingly to yield the velocity profile  $u_{fl}(r)$  inside the flushing fluid. Finally, the value of  $u_c$  is determined from the condition that the shear stress at the interface is the same for the remaining layer of flushed and flushing fluid, i.e.,  $\tau_L(r_c) = \tau_{fl}(r_c)$ . This implies a smooth interface between the phases. The shear stress at the interface is determined via the Windhab law  $\tau(\dot{\gamma})$ . For the flushing fluid the shear rate  $\dot{\gamma}_{fl}$  obtained by differentiating the velocity  $u_{fl}$  in the core region is used. A second expression for the shear stress at the interface is obtained from using the shear rate obtained from the linear velocity profile in the remaining layer (eq. (3)) to  $\dot{\gamma}_L$ . Combining both expressions yields the unknown  $u_c$ .

### 3.2.3. Defining a starting value for $r_c$

The initial value of  $r_c$  to start the algorithm in section 3.2.1 must be sufficiently close to  $R$  and sufficiently far away from the plug flow radius  $r_0$  to justify the approximation of a linear velocity profile inside the remaining layer. To find the starting value  $r_c^0$  the analytical solution for the mass flow  $\dot{m}_{L,an}$  and the solution found by the linear approximation  $\dot{m}_L$  from (4) are compared. The former is found by integrating the analytical solution for the velocity profile  $u(r)$  from Pitsillou et al. (2020) to

$$\dot{m}_{L,an} = 2\pi\rho \int_{r_c}^R u(r) r dr. \quad (6)$$

Figure 3 shows the relative error  $\varepsilon = \dot{m}_L/\dot{m}_{L,an}$  for different total mass flow rates. Each mass flow rate corresponds to a different plug flow radius  $r_0$ , which is related to the cleaned radius  $r_c$ . The latter is varied as the choice affects the error  $\varepsilon$ . If  $r_c/r_0 \approx 1$ , the

Figure 3 Influence of the choice of  $r_c$  on the error  $\varepsilon$  of the mass flow rate in the remaining layer that arises due the linear approximation of the velocity there. Parameters from Liebmann et al. (2022).

plug flow radius and the cleaned radius are approximately equal. In that case the error  $\varepsilon$  is high for all values of  $r_c$ . This is due to the fact, that at the plug flow radius  $r_0$  the velocity  $u(r)$  transitions from the high gradient at the wall to zero gradient within the plug flow region, which is not well approximated by a linear function. For values of  $r_c/r_0 \gg 1$ , the error is smaller, since the cleaned radius is further away from the plug flow radius, where the velocity gradient transitions to zero. The higher the ratio  $r_c/r_0$  and the lower the value for  $r_c$  the more pronounced this effect becomes. For the second phase, the authors propose an initial cleaned radius of  $r_c^0 = 0.97 R$  which provides errors  $\varepsilon < 2\%$  in this configuration. For more accurate results a higher value of  $r_c$  may be chosen.

### 3.3. Implementation in Modelica

The two-stage model described above was implemented in OpenModelica v1.19.2. The input parameters are the radius  $R$ , the length  $L$  of the pipe and the mass flow rate of the flushing fluid. For the first phase, the physical properties of the flushing fluid are used. For the second phase the flushed and flushing fluids properties are used. The values for the two chocolates are taken from Liebmann et al. (2022). The mass flow rate is used to determine the analytical solution of the Windhab velocity profile  $u(r)$ . The cleaned radius  $r_c(t)$  during the core removal phase is determined according to section 3.1. Once the cleaned radius  $r_c^0 = 0.97 R$  described in section 3.2.3 is obtained during core removal, the algorithm in section 3.2.1 is used for layer removal.

## 4. Results

Figure 4 depicts the results obtained from a fully resolved OpenFOAM simulation, which took 20 hours to complete on 16 CPUs (see Liebmann et al., 2022) and the results obtained from the reduced model in OpenModelica. The latter required only 0.05 seconds on a single CPU to complete the calculation. Core removal starts when the plug flow region reaches the cross section at the considered position  $x$ . The time needed for that is shorter for smaller distances  $x$ . After that,  $r_c$  increases instantly by the plug flow radius and then continually grows. The cleaned radius in the OpenFOAM simulation is up to 8% higher during core removal. This may be due to additional effects at the interface not considered within the reduced model or because the physical properties of the two fluids are similar but not equal. At  $r_c = 0.97 R$  layer removal begins. During this phase, the reduced model shows very good agreement with the OpenFOAM simulations both in quality and quantity. The reduced model predicts  $r_c$  up to 2% smaller than the results from OpenFOAM. The model in OpenModelica runs about seven orders of magnitudes faster, offering a considerable speedup compared to the fully resolved simulation, with little error arising from the use of the reduced model, especially during layer removal.

Figure 4 Comparison of results for the cleaned radius  $r_c(t)$  obtained from a fully resolved simulation using OpenFOAM and the reduced model in OpenModelica introduced in this paper. The blue triangles with the right axis indicate the relative error between both results.

## 5. Conclusion and Outlook

The paper proposes an approach for a reduced model of a flushing process of two non-Newtonian fluids with yield stress in a straight pipe. The flushing process is divided into two phases. During the first phase (core removal) the presented results for the cleaned radius  $r_c(t)$  are within 8% of the results obtained using a fully resolved numerical simulation. During the second phase (layer removal) this error is further reduced. The reduced model implemented in OpenModelica offers accurate results after less than a second. Compared to the current state of the art, i.e. conducting fully resolved simulations or experiments, which are time consuming, expensive and complex, the model can be applied in the rapid design of industrial flushing processes. It offers a method of designing new or adapting old processes to new process parameters while reducing the time and cost compared to current methods. Processes not adapted so far due to excessive cost of classical methods can now be optimized, thus saving resources, costs and time.

The approach presented for layer removal is only applicable if the velocity profile in the remaining layer is approximately linear. For cases where the layer is thicker, the authors were able to successfully employ an alternative approach to determine  $u_c$  from the analytical solution of the velocity within the remaining layer. However, this approach is specific to a particular combination of rheological models for the flushed and flushing fluid and, hence, not generally applicable. For these cases and for  $r_c < r_0$  further development of the presented method is necessary. The approach can be extended for other combinations of fluids using the literature provided in section 1. This requires two adaptations of the present model: one for the velocity profile of the flushing fluid and one for the rheological behavior  $\tau(\dot{\gamma})$  of the two fluids. The method has already been employed for a set of different fluid combinations. Further tests will be conducted to determine the limitations in the ratio of the two fluids physical properties.

## Abstract

Retrofitting existing plant equipment to a more energy efficient setup is a promising and sustainable way to cut down on the energy demand and consequently the operating costs of a chemical processing plant. While this opportunity is attractive in terms of low capital expenditure and construction time, it is also highly challenging for the design engineers. Degrees of freedom in grassroot design transform into constraints in the retrofit project and finding an optimal design within the constraints of the existing equipment, requires a sophisticated model-based approach. In this work, such an approach is presented for the retrofit of distillation column sequences to thermally coupled side-stream configurations. Based on this approach, an easy evaluation of retrofit opportunities in terms of investment and operating costs is facilitated. The potential of this retrofit is illustrated in the current contribution by means of a case study, which compares the retrofit option to a fully thermally coupled dividing wall column grassroot design. While the dividing wall column generally allows for higher energy savings, the investment in the retrofit is significantly smaller, which yields a considerably quicker amortization.

**Keywords:** Distillation, Thermal Coupling, Retrofit, Optimization

## 1. Introduction

In light of rapidly increasing energy and resource prices as well as sociopolitical pressure due to the quickly progressing climate crisis, the arguably biggest goal of the chemical industry is to become more energy-efficient and sustainable. A focus in this effort lies on distillation, the most frequently applied fluid separation technique in the chemical industry, which is accountable for a major share of the energy consumption in chemical plants (Sholl and Lively 2016). A well-established approach to reduce the energy demand of distillation sequences is the thermal coupling of distillation columns in the form of side rectifiers (SR), side strippers (SS) and fully thermally coupled dividing wall columns (DWC). Out of these three configurations, the DWC is unmatched in terms of operating costs and investment, which sets the DWC as one of the frontrunners of distillation innovation with more than 300 industrial applications (Lukač et al. 2019). However, constructing an energy and cost-efficient grassroot design is not the only promising option in the effort to re-engineer the chemical industry. Retrofitting existing plant equipment can facilitate a considerable decrease in energy consumption and related operating costs, combined with the opportunity to increase process capacity, with comparably little capital expenditure, effort and construction time. This becomes possible due to commonly applied design margins on plant equipment (Rangaiah 2016). Retrofitting and revamping projects account for the major share of design projects

conducted in the chemical industry, offering potential for innovative retrofit options and optimal design methods (Rangaiah 2016).

One particularly interesting concept in that context is the so-called Liquid-Only-Transfer (LOT) configuration proposed by Agrawal (2000), which transforms the bidirectional vapor and liquid transfer in thermal couplings to an unidirectional liquid transfer. This can be achieved for SR and SS configurations by extending the side-columns with an additional column section and heat exchanger, which facilitates the elimination of the intercolumn vapor transfer. The resulting LOT configuration provides an excellent retrofitting option of an existing column sequence through integration of an additional side stream.

Although we are not aware of a dedicated industrial implementation of the LOT concept, it offers several advantages over the classical thermal coupling. Here, it is important to note that the LOT-configurations are thermodynamically equivalent to their thermally coupled counterparts (Madenoor Ramapriya et al. 2014) and as such hold the same potential energy savings, which can amount up to 30 % (Amminudin et al. 2001) for a ternary separation. In addition to these energy savings, the elimination of the vapor connection between the column allows for the hydrodynamic decoupling of both columns, enabling the application of thermal coupling to columns operated at different pressures. This presents the option for further heat integration in the thermally coupled columns through targeted pressure variation, providing potentially significant energy savings (Skiborowski 2020). Furthermore, replacing the generally uncontrolled vapor stream or vapor split with a controllable manipulated variable like the heat duty or reflux ratio, allows for a more precise control of the internal vapor streams and as such supports the control at the energy optimal operating point (Madenoor Ramapriya et al. 2014). Lastly, the structural similarity of LOT-sequences to uncoupled (in)direct sequences consisting of two regular distillation columns connected via a liquid stream, makes them perfect candidates for retrofitting simple distillation sequences with minimal effort.

In this contribution, a framework for the optimal retrofit of an uncoupled distillation sequence to thermally coupled LOT-side stripper and side rectifier configurations is presented. While these do generally not allow for the same energy savings as a fully thermally coupled DWC, they are oftentimes thermodynamically more efficient than the DWC (Agrawal and Fidkowski 1998). However, exploiting these benefits in an optimal retrofit design is a complex task, since structural constraints for the given equipment, including column height, vapor capacity, pressure drop and available heat exchanger area, have to be adhered in the design process. The current contribution proposes a superstructure based design approach, which builds on a modified mixed integer nonlinear programming (MINLP) problem originating from the grassroot design of column sequences as presented by Waltermann and Skiborowski (2019). In an exemplary case study, the performance of this developed methodology is showcased, addressing the question if a retrofit design can compete with an optimally designed fully thermally coupled grassroot DWC.

## 2. Methods

In this chapter, the concept of thermally coupled Liquid-Only-Transfer distillation sequences is explained based on the example of the side rectifier configuration. Subsequently, the optimization procedure for the grassroot design and the retrofit is described.

### 2.1. Liquid-Only-Transfer (LOT) Sequences

As introduced by Agrawal (2000) and theoretically proven by Madenoor Ramapriya et al. (2014), a thermodynamically equivalent LOT configuration can be developed through elimination of the vapor transfer in thermal couplings in three steps: First, the stripping section of the second column ( $S2$ ) including the reboiler is duplicated ( $S2^*$ ) and placed at the bottom of the first column, where the recycle vapor stream ( $V$ ) enters the first column. As the second step, the intercolumn vapor stream  $V$  is redirected to originate from the duplicated stripping section ( $V^*$ ). Lastly, the duplicated section  $S2^*$  is connected to the stripping section of the first column ( $S1$ ). This procedure is visualized in Figure 1. The development of the LOT-side stripper and the LOT-DWC is done in a similar manner.

Figure 1: Development of thermodynamically equivalent LOT-side rectifier

### 2.2. Optimization-based design

Both the optimal grassroot design as well as the optimal retrofit design are obtained based on an equation-oriented superstructure-based optimization approach implemented in GAMS 31.2.0. The superstructure builds on an equilibrium-stage model of the distillation columns on the basis of the MESH-equations (**M**ass balance, **E**quilibrium conditions, **S**ummation constraint, **E**nthalpy balance). The thermodynamic properties are calculated by means of an external function programmed in C which communicates with GAMS via a dynamic link library, while the optimization problems are solved as a series of successively relaxed MINLP problems (Skiborowski et al. 2015). The grassroot design procedure is described in detail by Waltermann and Skiborowski (2019). For retrofit design this approach is extended to account for pressure drop and separation efficiency and is subsequently adapted to calculate optimal retrofit designs for a predefined column sequence with given height and diameter.

#### 2.2.1. Modelling of pressure drop and separation efficiency

In the original MESH-based grassroot design model described by Waltermann and Skiborowski (2019), the pressure drop is assumed to be negligible and the height equivalent to one theoretical plate (HETP) is considered to be constant. The column height and diameter are determined in accordance with the required number of equilibrium stages and the vapor flowrates. While this is a reasonable simplification for conceptual grassroot designs, the pressure and separation efficiency need to be modelled more precisely for retrofit calculations, considering the utilization of existing equipment and the resulting changes in gas and liquid loads.

The pressure drop per height ( $\Delta p/h$ ) as well as the separation efficiency, which is represented by the HETP, are calculated based on the vapor load. The vapor load is described by the F-factor  $FF = \dot{V}/A_{column} \cdot \sqrt{\rho_V}$  which is calculated as the product of the superficial gas velocity, given as the ratio of vapor  $\dot{V}$  per column section  $A_{column}$  and the square root of the vapor density  $\rho_V$ .

In this work, the properties of the Montz B1-500 packing are utilized. The correlation for the pressure drop is approximated with a third-degree polynomial  $\Delta p/h = 0.83F^3 - 1.3F^2 + 1.6F - 0.3$  ( $R=0.999$ ) and the *HETP* is approximated with a second-degree polynomial  $HETP = 0.01F^2 + 0.01F + 0.24$  ( $R=0.999$ ). Both correlations are fitted to the vendor given and packing specific pressure drop and separation efficiency diagrams (Julius Montz GmbH 2022).

### 2.2.2. Optimal Retrofit

Feed properties, purity constraints and a maximum stage number of the superstructure are input information for both the grassroot design procedure as well as the retrofit design. Furthermore for the retrofit, structural constraints for the available column heights, column diameters and heat exchanger areas are considered. The model initialization and heat duty minimization is performed based on initial flash calculations and successive model refinement as described by Waltermann and Skiborowski (2019).

The grassroot design and the retrofit design optimization differ as described in the following. For the grassroot design, the total annualized costs (*TAC*)

$$TAC = C_{op} \cdot t_{op} + C_{inv} \cdot \alpha \quad (1)$$

are minimized, considering an optimization of the equipment sizing and operating conditions, based on variable column heights, feed and side stream locations and heat duties. The *TAC* include the operating costs ( $C_{op}$ ) considering heat duties and utility prices with an annual operation time ( $t_{op}$ ) of 8000 h, and the investment costs ( $C_{inv}$ ) which are based on a correlation from Biegler et al. (1997) with a depreciation factor  $\alpha = f(z, t_a) = 0.37$ , based on an interest rate ( $z$ ) of 6 % and depreciation time ( $t_a$ ) of 3 years. In the retrofit procedure only the operating costs  $C_{op}$  are minimized, if the existing equipment suffices. Therefore, the column structure is optimized on the basis of the superstructure model such that structural constraints on the available column height and diameter are obeyed and variable side stream and feed location result in maximum energy savings. In order to allow for more flexibility, a rearrangement of the columns for the LOT sequence is considered in the design process. If based on the resulting design the heat exchanger area of the available heat exchangers is insufficient, an additional, parallel heat exchanger is considered and depreciation costs are added to the objective. The heat exchanger costs are calculated based on the same correlation as in the grassroot case. The main steps of the grassroot design and the retrofit procedure are summarized in Figure 2.

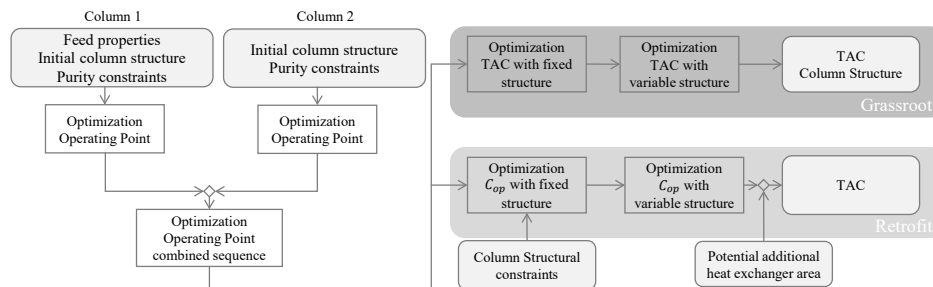

Figure 2: Modeling and solution approach for grassroot design and retrofit; “Optimization Operating Point” for individual columns and combined sequence according to Waltermann and Skiborowski (2019)

## 3. Case Study

As previous shortcut screening calculations highlighted the importance of feed compositions for the potential energy savings (Skiborowski, 2020), two exemplary feed compositions are evaluated for the separation of benzene, toluene and xylene, an

equimolar feed  $F_1$  and a second feed with low amount of mid boiling component  $F_2=(0.45/0.10/0.45)$  mol/mol. For both cases, a saturated liquid feed of 1 kmol/s at 1 atm shall be separated with product purities of at least 0.99 mol/mol. The liquid phase activities are modelled with the NRTL (Non-Random-Two-Liquid) model, while the vapor phase is assumed to behave ideal.

As a basis for the retrofit, an optimal grassroot design of a column sequence for the separation task is calculated. Since the direct sequence results in lower TAC than the indirect sequence, it is used as the reference case for both case studies. Design safety factors are applied to the height (+10 % stages), the cross-sectional area (80% of flooding velocity) and the heat exchanger area (+10 %) (Rangaiah 2016). The operating costs of this uncoupled sequence are the benchmark that will be compared to the grassroot DWC design and the retrofit design of the LOT-side rectifier. The costs for the direct sequence, as well as the retrofit and DWC for both study cases are summarized in Table 1.

Table 1: Summary of operating costs, investment, total annualized costs and possible amortization period for the initial direct sequence, the grassroot DWC and the retrofit LOT-SR.

		Operating Cost $C_{op} \cdot t_{op}$ [k€]	Investment $C_{inv}$ [k€]	TAC [k€]	Amortization [a]
Case 1 $F_1$	DS	133	466	307	-
	Retrofit	124	18	131	2.2
	DWC	93	394	240	9.9
Case 2 $F_2$	DS	112	420	269	-
	Retrofit	90	30	101	1.3
	DWC	74	361	209	9.5

For the grassroot design DWC, both operating and investment cost and consequently the TAC are below that of the direct sequence for both cases. To guarantee comparability, the DWC design also contains safety factors of the same magnitude. The grassroot DWC is excellently suited for both cases with 30 % ( $F_1$ ) and 34 % ( $F_2$ ) of operating cost savings, which equals a saving potential  $S$  of 40 k€/year ( $F_1$ ) and 38 k€/year ( $F_2$ ). Based on the necessary investment, this yields an amortization period

$$A = C_{inv}/S \tag{2}$$

of 9.9 years and 9.5 years, respectively. Thus, it takes almost 10 years until the 30 %-34 % savings in operating costs amount to the necessary investment for the DWC.

For the retrofit LOT-side rectifier designs, investments of 18 k€ and 30 k€ are determined based on additional heat exchanger area that needs to be added for the retrofit. The retrofit reduces the operating costs by 6 % ( $F_1$ ) and 20 % ( $F_2$ ).

As to be expected, the energy saving potential of the retrofit remains lower than that of the fully thermally coupled DWC. However, since the necessary investment is much lower, the amortization period is noticeably shorter for the retrofit in both cases with only 2.2 years and 1.3 years, respectively. As a consequence, the TAC of the retrofit are considerably below the TAC of the DWC for both cases. The setup of the direct sequence, the retrofitted LOT-sequence and the DWC for the equimolar case  $F_1$  is visualized in Figure 3.

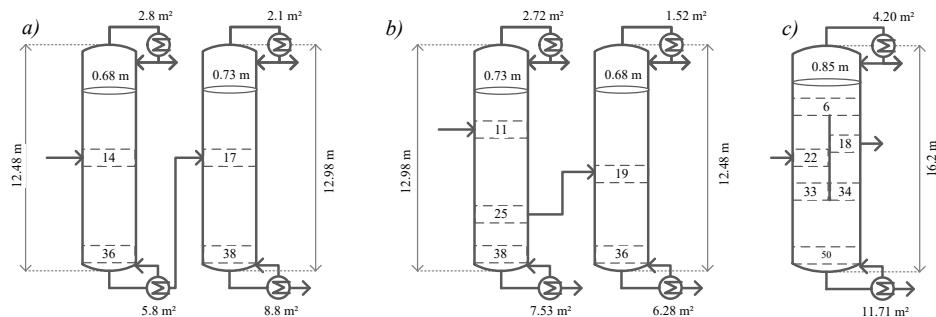

Figure 3: Results of (a) the grassroot design of the direct sequence, (b) the resulting retrofitted LOT-sequence and (c) the grassroot design of the DWC.

#### 4. Conclusion

The current work presents an optimization-based methodology for the retrofit of distillation sequences to thermally coupled side stream configurations and illustrates the benefits of these configurations for the separation of two exemplary feed compositions of a benzene-, toluene- and xylene mixture. While the implementation of a new dividing wall column offers larger energy savings than the simple retrofit, the drastically lower investment of the side stream retrofit results in much lower pay out times. Considering the frontrunner status of the dividing wall column, this showcases the potential of such Liquid-Only-Transfer configurations when used for retrofit. For a final implementation of such a retrofit option further cost factors for reassembly and lost earnings for plant shutdown, which depend on the given plant, should be considered. However, the resulting retrofit configuration also enables further potential for process intensification by means of heat integration, which can even exceed the energy savings that are enabled by dividing wall columns, as has been illustrated by Skiborowski (2020).

## Abstract

The search of new alternatives of processing for the production of sustainable products, designed under energy efficiency tools, has gained the interest of scientific community. In this work is proposed the conversion of a microalgae (*Chlorella vulgaris*) through a biorefinery scheme to produce biojet fuel, other biofuels and value-added products. Process intensification and energy integration tools were applied as energy efficiency strategies to improve the system. The biorefinery is modelled in Aspen Plus. The application of both strategies increases the equipment cost up 7 %, but reduces in 70 % the thermal energy consumption and 45% the CO<sub>2</sub> emissions released.

**Keywords:** microalgae biorefinery, biojet fuel, process intensification, energy integration.

## 1. Introduction

Microalgae are micro-organisms able that covert sunlight and CO<sub>2</sub> to biomass, from which biofuels and value-added products can be produced; they do not require fertile soil, and can grow in wastewater (Romero-Izquierdo et al., 2022). In particular, the use of microalgae for the sustainable aviation fuel production has gained attention; this biofuel is the most resilient strategy to achieve the sustainable recovery of the sector (IEA, 2021). Various reports present the use of microalgae oil to produce biojet fuel (Gutiérrez-Antonio et al., 2017; O'Neil et al., 2019; Martínez-Villarreal et al., 2022), while a few ones present the conversion of whole-microalgae strains into a biorefinery scheme (de Carvalho et al., 2022; Siddiki et al., 2022; Elkelawy et al., 2022); however, the biojet fuel generated in these processes is not competitive with its fossil counterpart (NESTE, 2022). The microalgae strain cost and the high energy requirements for the processing are the main issues to reach its profitability (Romero-Izquierdo, 2020). Thus, the efforts must be oriented to the application of strategies to make more efficient the use of energy, such as process intensification and energy integration. Therefore, in this work the computer-aided design of intensified and integrated routes for the conversion of whole-microalgae (*Chlorella vulgaris*) to biojet fuel, other biofuels and high-value products in a biorefinery scheme is presented; the implementation of such strategies over the energetic, economic and environmental indicators of the production route is analyzed.

## 2. Modelling and simulation of microalgae biorefinery

*Chlorella vulgaris* is cultivated by 14 days in wastewater, estimating a microalgal biomass after the harvesting of 442,795.64 kg by production lot (Romero-Izquierdo, 2020). This biomass is composed by proteins (46 wt %), carbohydrates (18 wt %) and lipids (27 wt %) (Becker, 2007). The biorefinery (Figure 1) is divided in three zones: oil extraction (Z1), press cake treatment (Z2) and microalgal oil treatment (Z3); modelling each one using NRTL for Z1 and Z2, and Peng-Robinson and BK10 for Z3. Z1 considers the modelling of oil extraction by ultrasonication; Natarajan et al. (2014) reported a maximum cell disruption of 75 % is reached with 0.8 kWh/L. This process is modelled with *CFuge* module, from which oil and press cake streams are obtained. The press cake is processed in Z2: 10 wt % enters to pyrolysis process, 10 wt % to anaerobic digestion and 80 wt % to ethanol production. The pyrolysis is realized at 500 °C and air, obtaining bio-oil (mainly composed by levoglucosan, toluene and hexadecenoic acid) and biochar modelled by the empirical formula  $C_{1.7}H_{8.2}N$  (Brown et al., 2012). This process was modelled by *RStoic* module. The anaerobic digestion is carried out at 55 °C with a water-biomass ratio of 1:1 (Li et al., 2014), and represented by the Buswell equation (Symons and Buswell, 1933). The biogas obtained is fed to isentropic turbine (module *Compr*) to produce power. In the case of ethanol production, the available biomass enters to a separate saccharification and fermentation process (SHF). The first step is the acid hydrolysis at 121 °C with 1 % of sulfuric acid; its outlet stream enters to the fermentation reactor (*RStoic* module) at 30 °C adding *Z. mobilis*. The non-converted biomass is removed (by *Sep* module) of the outlet stream from fermentation reactor to be fed to a distillation train with three columns. From the first column, 35 stages without condenser, the CO<sub>2</sub> is obtained by the top, extracting side stream rich in ethanol, which enters to second column, 13 stages and partial-vapor condenser, concentrating the ethanol at the top. The ethanol-rich stream enters to the third column, 15 stages and total condenser, breaking the ethanol-water azeotrope with glycerol. All columns are modelled with *RadFrac* module, reaching 99 % recovery for key components. The produced ethanol is inserted to the ATJ process on Z3, where are three consecutive reactors (modelled by *RStoic* modules): ethanol dehydration, oligomerization, and hydrogenation. The first one at 450 °C operates with a superheated steam stream with a 1:1 ethanol-steam ratio, reaching 99.4 % yield of ethylene; the second one at 120 °C and 35 bar reached 99 % yield to alkenes, and the last one operates at 110 °C with 99 % conversion to paraffins. The ethylene purification before the second reactive stage is realized using a heat exchanger (Heat-X module) and two flash tanks (Flash2 modules), reaching 99 % of ethylene purity. The outlet stream is conditioned until 30 °C and 1 bar before the separation, along with the hydrocarbons from hydroprocessing. The hydrotreating process uses 20 wt % of microalgae oil from Z1, and operates at 410 °C and 50 bar adding 1500 mL of hydrogen per oil mL (Verma et al., 2011), using a *RStoic* module. The outlet stream is conditioned until 27 °C and 1 bar using an isentropic turbine (*Compr* module); then, it is mixed with the ATJ hydrocarbons stream, to separate the hydrocarbons in a unique distillation train with two columns (conventional scheme). The first column, 52 stages, separates the naphtha fuel (C4-C7) by the top, whilst the bottom enters to second column, 106 stages, separating the biojet fuel (C8-C16) by the top and the green diesel (C17-C20) at the bottom. Both columns were designed with *DSTW* module, and later rigorously simulated with *RadFrac* module. The thermodynamic model used in both cases was BK10. The 80 wt % of the oil from Z1 is transesterified with methanol, at 62 °C, 1 atm and sodium methoxide as catalyst (Farooq et al., 2016), using *REquil* module and UNIFAC model. The biodiesel refining takes place on three stages; in the first one a

Decanter module is used to separate the FAME from glycerol, water and methanol. In the second stage, the FAME stream enters to a washing column (*RadFrac* module and UNIF-DMD model) with 2 stages, to remove the alcohol and glycerol traces. The washed stream enters to an evaporator (*Flash* module and UNIFAC model) to remove the water traces. Two energy efficiency tools are implemented on the biorefinery scheme: process intensification (PI) on separation zone, and energy integration (EI) for the whole biorefinery. In this work, the PI through the Rong and Errico (2012) methodology is applied on the separation zone of hydrocarbons from ATJ and hydrotreatment processes. On the other hand, EI application is realized by the pinch point methodology (Kemp, 2006) on whole biorefinery, considering the scheme with the intensified distillation train.

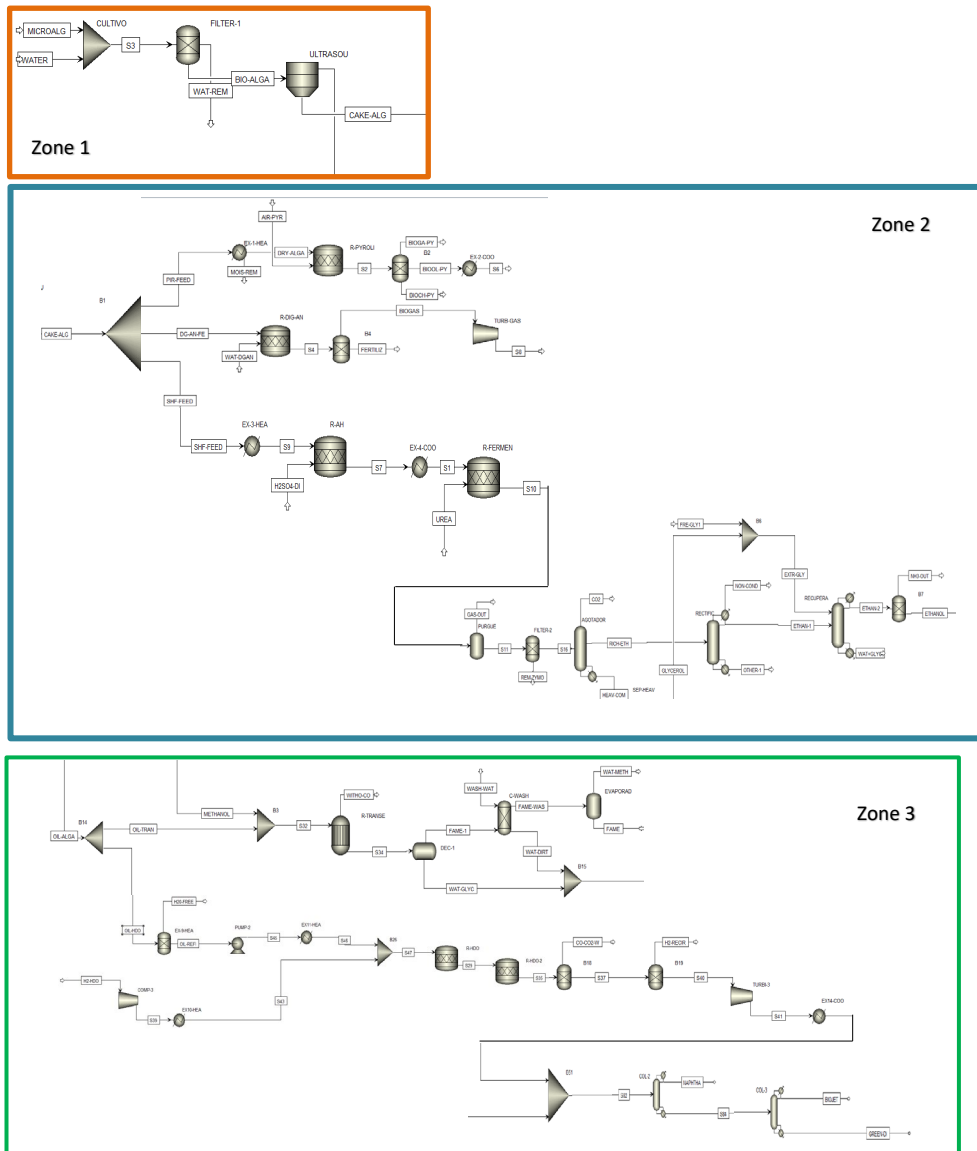

Figure 1. Biorefinery of microalgae by processing zones, non-intensified scheme.

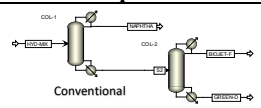

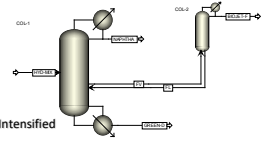

### 3. Assessment of the biorefinery scheme

The assessment of the biorefinery is carried out with the total annual cost (TAC) and CO<sub>2</sub> emissions by processing. The TAC involves capital cost, calculated by Aspen Economics, adding 18% (A1) and 61% (A2) due to contingencies, installation fees and equipment maintenance (Turton et al., 2012). The operating cost involving utilities cost (heating and cooling), raw material cost (microalgae, hydrogen, methanol) and additional reagents cost (glycerol, urea, H<sub>2</sub>SO<sub>4</sub>, etc), excluding catalyst and filters. The CO<sub>2</sub> emissions considers the steam and electricity requirements, according to Gutiérrez-Antonio et al. (2016).

### 4. Analysis of results

In this section the main results obtained for the microalgae biorefinery are described. This biorefinery allows to obtain biojet fuel (16,538.18 kg/h), naphtha (10,055.994 kg/h), green diesel (277.025 kg/h) and biodiesel as fuels; also, glycerol (5,130.888 kg/h), acetic (113,329.49 kg/h), succinic (734.855 kg/h) and lactic (910.893 kg/h) acids, along with bio-oil (8,130.41 kg/h), bio-char (8,463.90 kg/h) of pyrolysis, power and water with nutrients. As can be seen the total biojet fuel produced is 22,844.07 kg/h (58 % from hydrotreatment and 42 % from ATJ); also, acetic acid, succinic and lactic acids, respectively, are produced as value-added products. Regarding to PI applied on the separation zone from ATJ and hydrotreating, the results of the conventional and intensified schemes are presented in Table 1.

Table 1. Results of conventional and intensified sequence.

Sequence	Q tot con (kW)	Q tot reb (kW)	No. Stages
 <p>Conventional</p>	5,052.76	5,797.92	158
 <p>Intensified</p>	5,007.29	5,722.55	157

The energy savings for the condenser and reboiler are 1.3 % and 0.9 %, regarding the conventional scheme. Also, the intensified scheme has two less stages than the conventional, thus the equipment cost could be reduced. With respect to energy integration, the biorefinery scheme was analyzed through two routes: the first one (R1) including the Z1 and Z2 processes, and the route 2 (R2) for Z3 processes. R1 has 5 and 4 cold and hot streams, respectively; whilst R2 6 and 5 cold and hot streams respectively. According to the pinch point methodology, and considering  $\Delta T_{min}$  of 10°C, it is possible to reach 23 % and 8.89 % of savings for heating and cooling, respectively, for R1. In the case of R2, the savings for heating and cooling are 75.43 % and 74.76 %, respectively. The exchanges between the process streams for R1 and R2 are presented in Figure 2. Both designs were constructed taking into account the minimum number of heat exchangers. The TAC estimation of the scheme with energy efficiency tools is 61,487.335 million USD/y. In the case of equipment cost, it is 7 % higher (30.479 million USD/y), regarding to original scheme due to the additional heat exchangers and the size increase of intensified column. Nevertheless, economic savings of 72.31 % (0.375 million USD/y) and 55 % (0.036 million USD/y) are obtained for heating and cooling costs. Additional

factors involved in the estimation of TAC are the same for both schemes. Moreover, the original scheme releases 1,284.54 MTon CO<sub>2</sub>/y, due to its steam requirements; whilst the scheme with energy efficiency tools releases 706.497 MTon CO<sub>2</sub>/y, representing savings of 45 %.

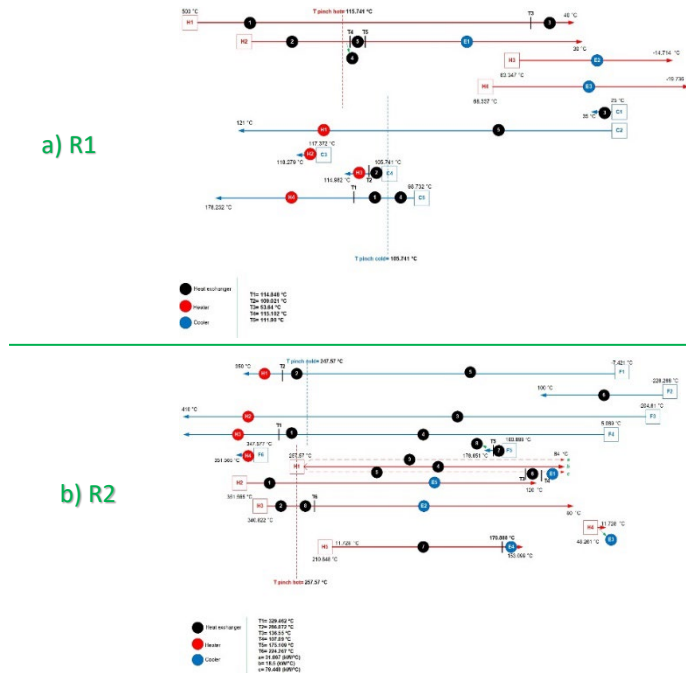

Figure 2. Heat exchanger networks: a) R1, b) R2.

## 5. Conclusions

The modeling and simulation of a microalgae biorefinery proposal with energy efficiency tools has been presented. The biorefinery produces biojet fuel, other biofuels and high value products. Based on results, the application of PI on the separation zone reduced 1.3 % of energy requirements at the reboilers. Likewise, the EI allowing reaching savings until 23 % and 75.43 % of heating utilities for R1 and R2, respectively. These energy savings enhanced the operational cost until 72.31 %, regarding to original scheme. However, microalgae cost has the higher contribution, which is the main opportunity area.

## Abstract

In this paper, we investigate a surrogate-based optimization of Simulated Moving Bed (SMB) Chromatography with Langmuir adsorption isotherm using an iterative approach. Artificial neural networks are fitted in each iteration based on randomly distributed sampling points around the optimal solution of the previous iteration. Crucial (Hyper)parameters of this surrogate-based optimization are related to the sampling region, e.g. the size, the position, and the number of samples within. It is shown that for highly efficient chromatographic columns with a large number of theoretical stages, the surrogate-based optimization is much faster than the numerical optimization of the full-blown model.

**Keywords:** SMB, Surrogate model, Optimization, Neural network, Chromatography

## 1. Introduction

SMB is an advanced technology that realizes continuous chromatographic separations (Schmidt-Traub et al., 2020). In the last decade, biotechnology, fine chemistry, and pharmaceutical industries have benefited greatly from SMB applications. The main advantages of this process over conventional batch processes are increased productivity and reduced solvent consumption. Generally, chromatographic processes contribute significantly to the overall cost of the corresponding process chains. It is therefore essential to optimize their design and control through efficient process optimization.

Figure 1 illustrates a standard binary separation configuration. The process consists of four zones, each of which consist of at least one chromatographic column. They are interconnected and form a ring shape. The component with the higher affinity to the solid phase is obtained in the extract, whereas the component with the lower affinity to the solid phase is found in the raffinate. In order to achieve continuous separation, cyclic switching of the inlet- and outlet-ports in the direction of the fluid flow is used to simulate counter-current flow of the solid phase. SMBs are complex processes that involve periodic nonlinear dynamics governed by partial differential equations (PDEs). It is crucial to design and operate SMBs optimally, as this allows to maximize the economic potential of the process and helps with the successful implementation on an industrial scale.

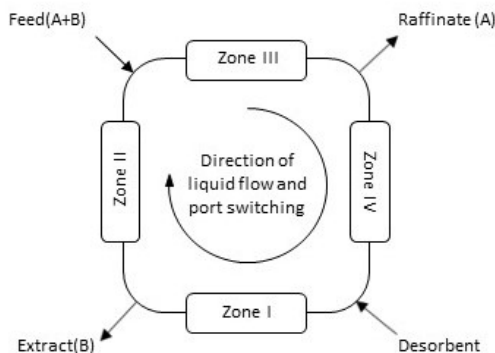

Figure 1. Schematic illustration of 4-zone SMB

The economic potential is maximized by finding optimal operating conditions regarding productivity and solvent consumption. Additionally, the process needs to fulfill certain purity requirements. For total separation, the well-known triangle theory developed by Storti et al. (1993) can be used in a first approximation to identify the optimal operating conditions. It is based on the assumptions of a true moving bed process, neglects axial dispersion and assumes thermodynamic equilibrium between the solid and the liquid phase. Productivity can be increased substantially if purity requirements can be relaxed, which depends on the specific type of application. For reduced purity requirements, Kaspereit et al. (2007) presented an extension of the triangle theory. However, the extension is involved, has limitations and is based on the same simplifying assumptions as mentioned above. By using genetic algorithms, Zhang et al. (2003) have optimized the productivity and purity of the SMB process based on a dynamic model, and compared it to the Varicol process, however computational time is rather high. In Li et al. (2014), a surrogate model was used to optimize SMB processes. They used two different types of surrogate models. The proper orthogonal decomposition (POD) method is employed to derive cost-efficient reduced-order models (ROMs) for the SMB process and the other one is a coarse model. To create a low-fidelity DAE model, they applied the Finite Element Method to the SMB model with coarser spatial discretization. In the present paper, a numerical optimization of a more detailed model is proposed instead. Due to the complexity of the used SMB model, rigorous numerical optimization is highly time-consuming. This paper adapts the methodology from Kessler et al. (2019) to develop a surrogate-based iterative approach by using a simple feed forward artificial neural network, requiring only minimal data, thereby increasing its numerical efficiency.

## 2. Description of the Optimization Problem

There are linear and nonlinear solvers in the optimizer toolbox in MATLAB (MathWorks, 2023) of which the 2021 version was used here. In this work the following types of optimization problems are considered:

$$\min J(\mathbf{x}), \quad (1)$$

$$\begin{aligned} \mathbf{h}(\mathbf{x}) &= 0, \\ \mathbf{g}(\mathbf{x}) &\leq 0, \quad x_i \in R, \\ lb_i &\leq x_i \leq ub_i, \quad \text{for } i=1,2, \end{aligned}$$

Where  $J(\mathbf{x})$ , is the objective function,  $\mathbf{h}(\mathbf{x})$  are the equality constraints, e.g. material balances,  $\mathbf{g}(\mathbf{x})$  are the inequality constraints, such as purity requirements, and  $\mathbf{x}$  are the decision variables, which are the ratios between the liquid and solid phase flow rate. The well-known equilibrium dispersion model can be used to describe chromatographic columns.

$$\left\{ \begin{aligned} \varepsilon \frac{\partial c_i}{\partial t} + (1 - \varepsilon) \frac{\partial q_i}{\partial t} + \varepsilon v \frac{\partial c_i}{\partial z} &= D_{ax} \varepsilon \frac{\partial^2 c_i}{\partial z^2} \\ q_i &= \frac{H_i c_i}{1 + \sum_{i=1}^{n_c} b_i c_i} \end{aligned} \right. \quad (2)$$

In the first equation, which is the equilibrium model,  $v$  represents the interstitial velocity, while  $D_{ax}$  represents the apparent dispersion coefficient, which lumps together all effects that contribute to band broadening. Furthermore,  $c_i$  is the fluid phase concentration of component  $i$ , while  $q_i$  is the solid phase concentration and  $\varepsilon$  is the volume fraction of the fluid phase. In the second equation, which is the Langmuir isotherm,  $H$  and  $b$  are the adsorption constants of each component and  $n_c$  is the number of components. According to the adsorption isotherm,  $q_i$  depends on the fluid phase composition since the model assumes thermodynamic equilibrium between the two phases. There are linear and nonlinear solvers in the optimizer toolbox in MATLAB. In this case, we are using `fmincon`. The objective function to be maximized is the productivity for a given minimum product purity. Our decision variables,  $\mathbf{x}$ , are the  $m$ -values, which are the dimensionless ratios between the liquid and the solid phase flowrates in each column. Maximum productivity is obtained by maximizing the difference between  $m_3$  and  $m_2$ , which is equivalent to find a feasible operating point farthest from the diagonal  $m_2 = m_3$ . At the beginning, the Henry constants are used as the starting point, i.e. the first  $m_3$  and  $m_2$ . Since they are the optimal point of the linear adsorption isotherm for total regeneration, they can be used as initial guess for Langmuir adsorption isotherm. The domain for the optimization area is given by  $m_2 \in [3, 7]$  and  $m_3 \in [5.5, 9.5]$ . In order to maintain total regeneration,  $m_1$  and  $m_4$  have a safety margin of 10% from Henry constants. A nonlinear inequality constraint of a minimum purity of 0.85 for both products is used for this maximization. In a cyclic steady state system, the purity of the raffinate and extract streams is defined as follows:

$$\left\{ \begin{aligned} pu_{raf} &= \frac{\int_t^{t+tsw} c_2^{raf} dt}{\int_t^{t+tsw} c_1^{raf} dt + \int_t^{t+tsw} c_2^{raf} dt} \\ pu_{ex} &= \frac{\int_t^{t+tsw} c_1^{ex} dt}{\int_t^{t+tsw} c_1^{ex} dt + \int_t^{t+tsw} c_2^{ex} dt} \end{aligned} \right. \quad (3)$$

Therein,  $tsw$  is the switching time. Variables  $pu_{raf}$  and  $pu_{ex}$  indicate the purity of raffinate and purity of extract, respectively, while  $c$  refers to the concentration of the components. The numerator indicates the quantity of target component collected during the switching period, and the denominator indicates the sum of two components collected during the switching period. Table 1 shows the parameters and operating conditions for SMB simulation.  $n_{col}$  is the number of columns,  $\epsilon$  is the porosity and c-feed is the concentration of the feed. Optimizing is performed using Matlabs multi-start algorithm with 100 starting points and the sqp algorithm. The step tolerance option is set to  $1e^{-8}$ . An extension of the optimization is possible for all m-values.

Table 1. Model Parameters of the reference model

SMB Parameters					
$n_c$	2	c-feed <sub>1</sub>	0.5[gr. L <sup>-1</sup> ]	$b_2$	0.3
$n_{col}$	4	c-feed <sub>2</sub>	0.4[gr. L <sup>-1</sup> ]	$m_1$	8.25
$n_z$	1000	$H_1$	5	$m_2$	$x_1$
$tsw$	99.5 s	$H_2$	7.5	$m_3$	$x_2$
$\epsilon$	0.74	$b_1$	0.15	$m_4$	4.5

### 3. Surrogate Model

A surrogate model is developed to replace the detailed but expensive full-order SMB model for optimization purposes. In this work an artificial neural network is used as a surrogate model. Using the methodology introduced in Kessler et al. (2019), this paper proposes a surrogate-based iterative approach, requiring minimal data, which increases the numerical efficiency. The initial guess defined by the Henry constants and an area around it is defined. Some sample points are generated inside the area based on the Halton set algorithm from Kocis et al. (1997). Halton set creates points based on the Halton sequence in a quasi-random manner. To fill the space uniformly, the Halton sequence uses different prime bases in each dimension. The location of these points inside the sampling area is used as m-values ( $m_2, m_3$ ). A simulation is performed for each point inside the area and the output data, such as purity and productivity, are saved for every point (pair of m-values). Here 150 points are generated. The reference model is used to calculate the purity of the products, as well as the productivity for each point. The purity must be greater than 0.85 to be considered for the further calculation. Only the points that meet the purity criteria are used for the surrogate model optimization. During each iteration, the sample points are saved and reused if they are in the sampling area of the next iteration as well. Each iteration may have more or fewer samples than 150. The data obtained from this calculation are used to train the neural net. The neural net is feed forward and has one layer with 15 neurons. The surrogate model uses the same optimization algorithm as the full model, multi-start with 100 random starting points and step tolerance option set to  $1e^{-8}$  to find an optimal point in each iteration. If the deviation of an optimal point at each iteration to the previously calculated optimum is bigger than the termination condition which is 0.019, the next calculation starts, otherwise the final optimal point is found. Using the current optimal point as an initial guess, the following formula defines the new sampling region (Kessler et al. (2019)):

$$lb/ub = x_{opt,k-1} \pm \frac{1}{2k} \quad (4)$$

The integer variable  $k$  corresponds to the iteration counter. The optimal point found by the previous iteration is the center of the current calculation area. The area is shrinking according to equation 4 and the density of samples inside it is increasing. In the present calculation procedure, the algorithm terminated after 4 iterations. The progress is shown in Figure 2. The first figure shows the optimal point as red star for the first iteration, while the red circle is illustrating the first initial guess. The black dots are the whole sample data generated by the Halton set, and the blue ones are the samples that are matching the purity requirement. A convex hull is created that includes all blue dots, and the optimizer searches for the solution inside this new area. It is clear that the shrinking effect is significant only in the first iteration indicating the importance of the first sampling region. The big difference from first to second iteration is due to the usage of equation 4. It can be seen from the second figure that the area decreases at a constant rate. Due to the reduced purity requirement that defines the convex hull, the optimal point lies on its boundary with maximal distance to the diagonal  $m_2 = m_3$ . In the last figure, the final optimal point found by surrogate-model (red star) almost coincides with the optimal point found by full-model optimization (yellow star). Further, the deviation from the previous optimum is less than the termination condition. The same initial guess point is used as the full-model optimization in the surrogate model.

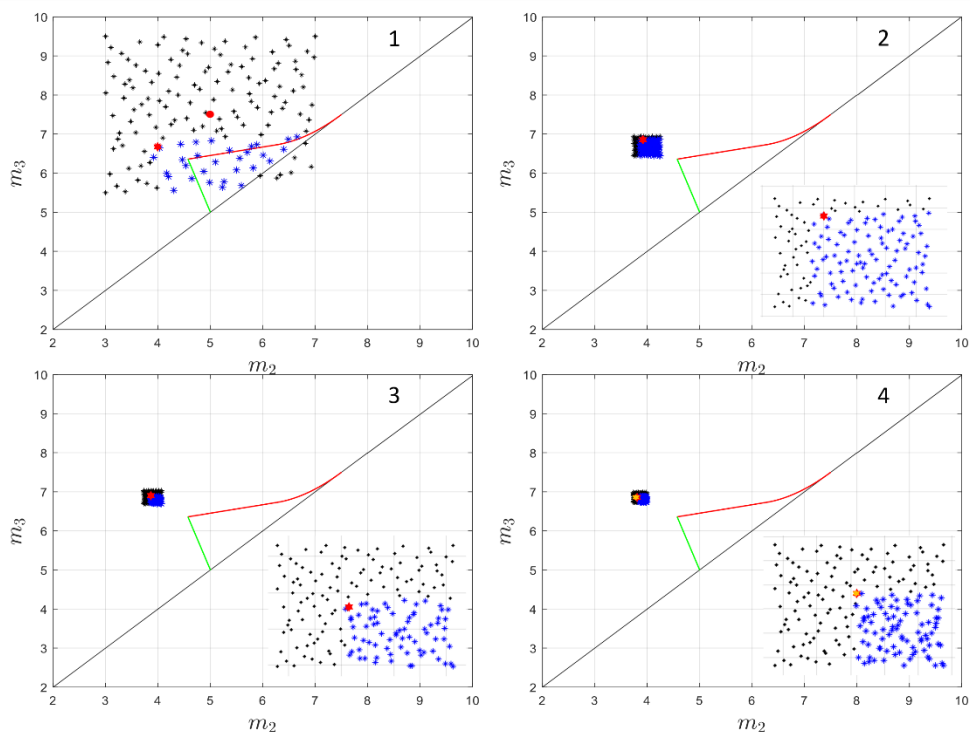

Figure 2. Optimal point of every iteration and how it converges to the final optimum.

#### 4. Results and Conclusion

A surrogate based optimization approach for the SMB process is proposed in this work. In place of the time-consuming rigorous model, a surrogate model is used for optimization. Table 2 compares the final optimal points obtained by both models to show the effectiveness of this approach. Using the surrogate model, SMB productivity was optimized resulting in a reasonable computational effort. It was expected that the optimal point would be outside the triangle because of reduced purity. The concentration of the extract as well as the raffinate and the productivity are calculated by the reference model for the optimal points found by both models. It is shown that the purity requirements are met. Though the full-model's optimal point produces higher productivity than the surrogate-model, the difference is marginal. Despite almost identical results, the surrogate model's computational time is much faster than the full model for the presented optimization set-up, making it a better choice.

Table 2. CPU time comparison

	$x_{opt}$	cpu-time	$pu_{ex}$	$pu_{raf}$	productivity
Sur-model	3.8582, 6.8806	5423.75 s	0.8501	0.8504	3.0224
Full-model	3.8578, 6.8826	152453 s	0.8500	0.8500	3.0249

The proposed methodology could be particularly useful if deterministic global optimization is applied as in Kessler et al. (2019), which relies on a very large number of model evaluations but was beyond the scope of this paper. Future work will be concerned with minimizing the solvent consumption, which is achievable by minimizing  $m_1 - m_4$ . Furthermore, optimization of the SMB with Bi-Langmuir isotherm is also of interest.

## Abstract

The development of high-fidelity and predictive models is one of the cornerstones of process engineering. Often mathematical models involve several unknown parameters to be identified from experiments. Designing the minimum set of information rich experiments for precise estimate is a critical to reduce the examination costs and help improve model prediction capabilities. In this work, we present a novel Multi-Objective Model-Based Design of Experiments (MOMBDoE). The proposed approach is based on the simultaneous maximizing the D-optimal design of experiments criterion and the estimability potential of the model parameters (Estimability). Global sensitivity analysis is used to build the Fisher Information Matrix (FIM), which allows the maximization or minimization of MOMBDoE criteria. The Pareto optimal solutions which represent the best experimental compromises were ranked using a multicriteria decision aiding method to help identify the best alternatives for experimental validation. To validate the proposed MOMBDoE framework, a tablet lubrication process is used as a case study. Kushner and Moore's model is used to predict the tensile strength and hardness of the tablets as one of the main critical quality attributes in tablet manufacturing.

**Keywords:** Multi-objective Optimization, Estimability Analysis, Model-Based Design of Experiments, Tablet Lubrication Process.

## 1. Introduction

Pharmaceutical tablets are the most important dosage forms which commonly contain one or more active pharmaceutical ingredients and several excipients. The optimization of the process performance and product quality is painstaking as the aim is to produce tablets that meet a set of optimal critical quality attributes such as tensile strength, hardness, friability, dissolution, etc. The development of robust digital technologies in pharma requires systematic methodologies to build reliable and predictable mathematical models, soft sensors, and digital twins to help optimize the process/plant design and operation while delivering quality assurance. One of the most effective approaches to address these challenges is to implement a Model-Based Design of Experiments (MBDDoE) to generate the minimum set of information-rich experiments.

Model-based design of experiments have been widely investigated for such purposes. Most of these methods are based on the Fisher Information Matrix which can be obtained from the sensitivity analysis. While the current model-based design of experiments aims at designing experiments with rich information, the estimability analysis is mainly used to assess whether the available experimental measurements contain sufficient information

to reliably estimate all model parameters or only a subset of them. Combining these two approaches (i.e., MBDoe and estimability analysis), can consequently consolidate the advantages of each method and allow the design of a minimum set of experiments for precise estimates.

This work presents a novel multi-objective model-based design of experiments which combines a D-optimal design of experiments and global estimability analysis. The approach is formulated as a constrained multi-objective optimization problem that accounts for two objectives, the first is based on the D-optimal MBDoe criterion and the second is based on the estimability. The optimization problem is also subject to a set of operating constraints and bounds. The set of Pareto optimal solutions obtained from multi-objective optimization provide the best experimental compromises or tradeoffs. Here, the solutions are ranked using a multicriteria decision aiding method to help identify the best candidates for experimental implementation. To validate the proposed approach, a pharmaceutical tablet lubrication model is considered.

## 2. Model and methods

### 2.1. Lubrication model

In tablet press, tensile strength and hardness are very important Critical Quality Attributes (CQAs) which need to be tightly monitored and controlled. These CQA can be related the solid fraction of tablets to the powder lubrication extent through several expressions among which, are the ones developed by Kushner and Moore (2010) and Pitt et al. (1988):

$$\frac{ts}{ts_{sf=0.85,0}} = (1 - \beta) + \beta \exp(-\gamma k) \quad (1)$$

$$H = \frac{t\pi D^2}{10} \left( 2.84 \frac{\sigma}{D} - 0.126 \frac{\sigma}{\sigma - 2\sigma_c} + 3.15 \frac{\sigma - 2\sigma_c}{D} + 0.01 \right) \quad (2)$$

Where  $ts_{sf=0.85,0}$  is the initial tensile strength at 0.85 solid fraction,  $\gamma$  is the lubrication rate constant of the blend, and  $\beta$  is the total fraction of tensile strength that can be lost due to lubrication.  $D$  is the diameter of the tablet,  $\sigma$  is the total thickness of the tablet, and  $\sigma_c$  is the thickness of the convex cups.

To avoid dependence on the initial solid fraction, the following empirical equations were introduced (Cenci et al., 2022):

$$ts_{sf=0.85,0} = a_1 \exp(b_1(1 - sf)) \quad (3)$$

$$\beta = a_2(1 - sf) + b_2 \quad (4)$$

The resulting model captures the impact of two main factors or inputs namely the solid fraction  $sf$  and lubricant extent  $k$ , and involves a vector of five unknown parameters to be identified from experiments ( $\theta = [a_1(MPa); b_1(-); a_2(-); b_2(-), \gamma(dm^{-1})]$ ).

### 2.2. Multi-objective MBDoe

The proposed multi-objective model-based design of experiments relies on the Fisher Information Matrix (FIM), which is computed from the global sensitivity indices of the model unknown parameters for a given set of experimental recipes or operating conditions:

$$Z = \begin{pmatrix} S_{1,1}|_{m_1} & \cdots & S_{1,n_\theta}|_{m_1} \\ \vdots & \ddots & \vdots \\ S_{n_y,1}|_{m_x} & \cdots & S_{n_y,n_\theta}|_{m_x} \end{pmatrix}, \quad (5)$$

where  $m_i$  is the  $i^{th}$  sampling point or experiment.  $n_\theta$  is the number of model parameters and  $n_y$  is the number of observed/measured outputs.  $S_{i,j}$  is the individual sensitivity coefficient of the  $i^{th}$  output with respect to the  $j^{th}$  parameter.

The FIM matrix is given by:

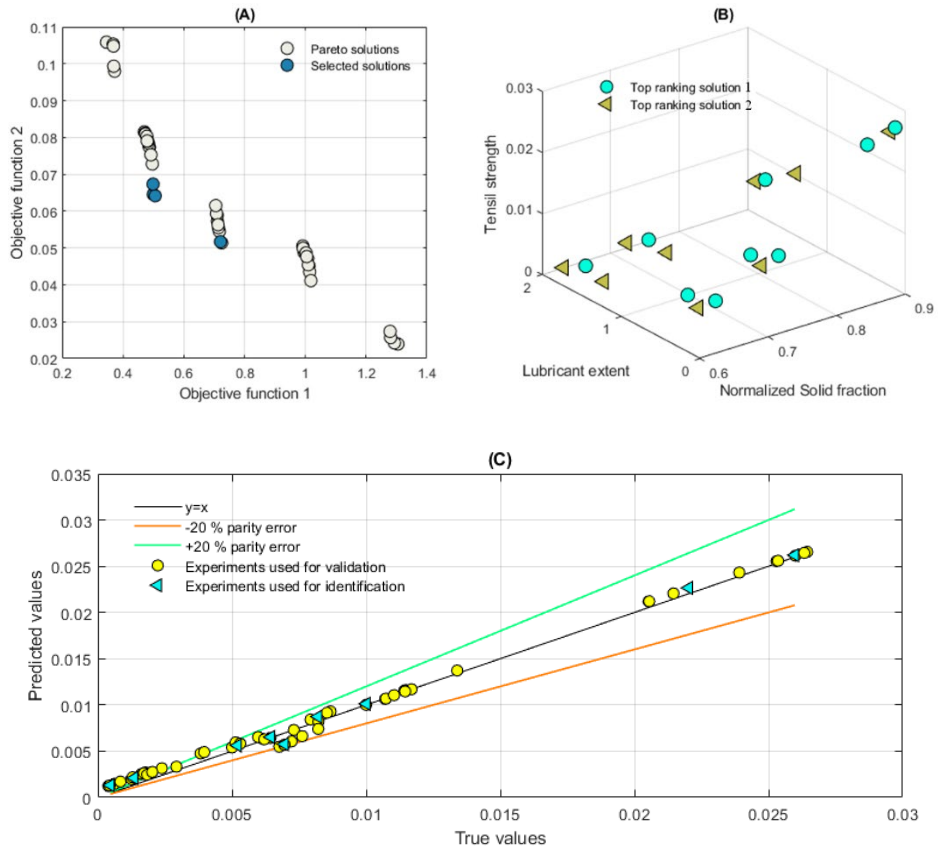

$$\mathbf{FIM} = Z \cdot Z^T \quad (6)$$

$S_{i,j}$  is the individual sensitivity coefficient of the  $i^{th}$  output with respect to the  $j^{th}$  parameter which can be calculated using the algorithm developed by Saltelli (2012). The sensitivity matrix is then used to generate the FIM to optimize the D-optimal MBDoe criterion and to calculate the estimability magnitude of the least estimable parameter (Benyahia et al. 2011a; Fysikopoulos et al., 2019; Bouchkira et al., 2023). A regularization test is firstly performed to determine whether the FIM is invertible. If this condition is satisfied a multi-objective optimization is performed to determine the Pareto optimal solutions which can be ranked using a multicriteria decision-aiding method.

The mathematical formulation of the proposed MOMBDoe problem is given by:

$$\begin{aligned} \max_{\mathbf{u}} \mathbf{F} &= [f_1, f_2]^T \\ f_1 &= \det(\mathbf{FIM}) \\ f_2 &= \min \sum_i \|r_{i,j}\| \\ \text{St. } 0 &< Sf_{j-1} \leq Sf_j, \quad j \in [1; n] \\ 0 &< k_{r-1} \leq k_r, \quad r \in [1; m] \\ Sf_{j-1} - Sf_j &\leq \omega_{sf} \\ k_{r-1} - k_r &\leq \omega_k \\ \text{Cond}(\mathbf{FIM}) &\leq \delta \\ \mathbf{u} &= [Sf_1, \dots, Sf_n, k_1, \dots, k_m] \end{aligned} \quad (\text{S.1})$$

where  $\det$  and  $\text{Cond}$  refer respectively to square diagonal of FIM and conditioning number of FIM.  $r_{i,j}$  are orthogonalization residuals calculated as in Benyahia et al. 2013,  $\omega_{sf}$  and  $\omega_k$  represent the difference between two solid fractions and lubricant extents, used to avoid duplicated experiments, and  $\delta$  is a cut-off criterion to guarantee that FIM is invertible, in this work  $\delta = 10$  is considered as in Cenci et al., 2022.

**Figure 1:** MOMBDoE results. (A) Pareto front and top-ranking solutions. (B) Experimental strategies / recipes for the 2 top ranking solutions from Pareto front. (C) Model validation showing normalized tensile strength and hardness data.

**Table 1:** Sample of four top ranking Pareto optimal solutions (ranked using MAUT).

$k_1$	$k_2$	$k_3$	$Sf_1$	$Sf_2$	$Sf_3$	Objective 1	Objective 2
0.132	0.368	1.863	0.615	0.704	0.848	0.499	0.064
0.179	1.376	1.883	0.618	0.710	0.868	0.724	0.051
0.287	1.058	1.753	0.726	0.807	0.886	1.304	0.023
0.249	1.373	1.818	0.640	0.737	0.897	1.011	0.045

### 3. Results and discussions

The global sensitivity analysis based on Sobol approach was first performed. A Quasi-Monte Carlo sampling of size 8000 is used to achieve convergence of the global sensitivity indices. Sensitivity indices are then used to build the Z sensitivity matrix and FIM. The latter is used in the proposed MOMBDoE. The resulting multi-objective optimization problem was solved using a Genetic Algorithms solver under MATLAB to generate a large set of Pareto optimal solutions which represent the best experimental compromises.

The optimal profiles i.e.,  $X^{opt}$  from the multi-objective optimization approach are used to generate information rich data, to be used for the identification of the unknown model parameters and model validation. The approach used in this work consists of identifying model unknown parameters from two sets of experiments: (i) from true measurements generated using  $X^{opt}$ . (ii) and from noisy measurements, then to compare model performances in both scenarios to see if it keeps very good prediction capabilities, even from noisy measurements. It is worth noting that that noisy data used in this work is created by adding gaussian noise to true data from Cenci et al., 2022.

The optimal solutions (i.e.,  $X^{opt}$ ) are given in the Pareto front as shown in Figure 1A. Indeed, in the Pareto front, each point corresponds to an optimal profile. For demonstration purposes, four points labeled “1-4” in the Pareto front are given in Table 1. The Pareto solutions represent the best tradeoffs which are commonly considered as equally good. However, the experimental validation requires a small set of solutions to be implemented. Consequently, it is important to implement a decision-aiding method to select the best profile.

The Multi-Attribute-Utility-Theory (MAUT), which has been successfully used as a robust decision aiding method in many engineering problems (Benyahia et al. 2011b; Bouchkira et al., 2022) was used to rank the Pareto optimal solutions based on the utility functions that capture the distance from the best single objective and its criticality. The Pareto solutions were ranked accordingly from the best to the worst which allows the identification of the best experimental strategies /recipes to demonstrate the benefits of the proposed MOMBDoE approach.

The Pareto solutions are shown in Figure 1A with a sample of the top-ranking solutions highlighted in a different color. The experimental conditions/recipes associated with 2 selected top-ranking solutions (Table 1) are shown in Figure 1B. Each of the 2 identified optimal experimental campaigns require 9 experiments at various lubricant extents and solid fractions. The top-ranking experimental campaign, identified as the best experimental candidate using the proposed approach above, was implemented to generate true and noisy data, based on which model performances are compared in Figures 1C. It is shown that the predicted values from the novel MOMBDoE are in good agreement with the true values from the literature (Cenci et al., 2022). The data in blue triangles are used in the parameter identification, while the data in yellow circles represents measurements that were not used in the identification process. The parity errors between the two compared sets of outputs lie between -20% and 20% which reflects good model performances and highlight the reliability of the proposed approach.

#### 4. Conclusion

In this work, a novel multi-objective model-based design of experiments is presented and implemented to a case study relevant to a pharmaceutical tableting process. The proposed MOMBDoE relies on global sensitivity analysis to combine traditional MBDoE with global estimability analysis. This new approach consequently allows the design of experiments which guarantee that all model unknown parameters are estimable and exhibit higher estimate precision (lower uncertainties). As the approach proposes several optimal solutions, decision-aiding is used to select a set of experimental candidates to be implemented. The results from the case study showed that the model developed based on the proposed MOMBDoE approach shows enhanced prediction capabilities and accuracy.

## Abstract

In this work, we propose an integrated water quality model of an artificial reservoir that is the drinking water source for two cities and undergoes recurrent algal blooms. The integrated model is formulated within a dynamic optimization framework as an optimal control problem to address its restoration through the combination of different restoration techniques. The model includes a global mass balance that takes into account inflows from tributaries and rain, and outflows for drinking water and evaporation. Composition gradients are considered along the water column, rendering a Partial Differential Algebraic Equations (PDAE) system. Dynamic mass balances are formulated for the main biogeochemical variables in both reservoir and wetland, as well as artificial floating islands (AFIs) platform. The PDAE is then transformed into a DAE. Numerical results allow analyzing the performance of the different restoration strategies and their joint application on a eutrophic reservoir, showing the efficiency of AFIs as complement of artificial wetlands.

**Keywords:** eutrophication control, optimal control problem, AFI, dynamic optimization

## 1. Introduction

Eutrophication is a severe environmental problem caused by anthropogenic nutrient enrichment (mainly nitrogen and phosphorus) that causes Cyanobacteria Harmful Algal Blooms (CyanoHABs), and biodiversity and economic losses (WHO, 2020). In 2007 a severe algal bloom in Taihu Lake (China) caused economic losses of US\$ 6.5 billions (Tao and Xin, 2014). CyanoHABs affect public health, commercial and sports fishing, tourism and recreational activities around the world. The potential production of toxins by cyanobacteria (cyanotoxins) is nowadays one of the main environmental and public health concerns (Figueiredo *et al.* 2004). Many water quality restoration strategies have been applied to attempt to mitigate eutrophication and control cyanobacteria growth (Hamilton *et al.* 2016). Since the 90s, there has been a lot of debate about the relative importance of control phytoplankton blooms by nutrients decrease (bottom-up control) (Siniscalchi *et al.* 2020) or by zooplankton grazing (top-down control) (Beklioglu, 1999; Estrada *et al.* 2011). Constructed Wetlands (CW) and Artificial Floating Islands (AFIs) has been both proposed as bottom-up strategies. CW are portions of land covered with

macrophytes (plants that can live in flooded lands), built next to the banks of the tributaries to reduce nitrogen and phosphorus loading by runoff. On the other hand, in AFIs, the macrophytes are sown in buoyancy structures on the surface of the water body and the N and P (and micronutrients) are up-taken by roots directly from the water column.

In this work, we propose an integrated water quality mechanistic model of an artificial reservoir (Siniscalchi *et al.*, 2020) that is the drinking water source for more than 450,000 people and undergoes recurrent algal blooms. The integrated model includes the water quality model for Paso de las Piedras Reservoir (PPR), CWs model for the two reservoir's tributaries, and the AFIs model. It is formulated within a dynamic optimization framework as an optimal control problem to address its restoration through the combination of CW and AFIs strategies. The optimization integrated model includes CWs and AFIs areas as design variables and the fractions of tributaries that are diverted through the wetlands as control variables.

## 2. Case Study

Paso de las Piedras Reservoir, is an eutrophic freshwater reservoir, that supplies drinking water to more than 450,000 inhabitants of two cities and for industrial purposes at a petrochemical complex nearby. It has two tributaries that run through an important agricultural area in the country, with a drainage basin area of 1620 km<sup>2</sup>. The lake has a surface area of 36 km<sup>2</sup>, while its mean depth is 8.2 m and its retention time is 4 years. The eutrophic characteristic of the reservoir is mainly caused by the external discharge of nutrients (mainly P and N). This fact causes recurrent algal blooms, which produce several problems in the potabilization process.

## 3. Mathematical Model description

A first principle-based ecological water quality model for Paso de las Piedras Reservoir (PPR model) was previously formulated, calibrated and validated (Estrada *et al.*, 2009 a,b, 2011; Di Maggio *et al.*, 2016). This model includes dynamic mass balances for main biogeochemical components in the water body: three taxonomical groups of phytoplankton (cyanobacteria, chlorophytes and diatoms), two groups of zooplankton (copepoda and cladocera), three nitrogen species (organic nitrogen, nitrate and ammonia), two phosphorus species (organic phosphorus and orthophosphate), dissolved and particulate organic carbon and dissolved oxygen. and calibrate the model with experimental data (Estrada *et al.*, 2009a), respectively. The model was formulated within an optimization framework to evaluate the application of top-down restoration strategies (Estrada *et al.*, 2011). Also, the model includes a global mass balance that takes into account inflows from tributaries and rain, and outflows for drinking water, and evaporation. Composition gradients are considered along the water column, rendering Partial Differential Algebraic Equations (PDAE) system. The PDAE is then transformed into an ordinary Differential Algebraic Equation system (DAE) by spatial discretization in horizontal layers. Siniscalchi *et al.* (2020) integrated the PPR model with a constructed wetland model (CWs model) which includes the possibility of installing CW in both tributaries of the lake. The model includes mass balances for: macrophyte biomass, three nitrogen species (organic nitrogen, nitrate and ammonia), two phosphorus species (organic phosphorus and orthophosphate), dissolved and particulate organic carbon and dissolved oxygen. For a detailed description of this model see Siniscalchi *et al.* (2020). In this work we formulated the AFIs model integrated with PPR model and CWs model in order to evaluate different restoration strategies. AFIs model includes a mass balance

for macrophytes (Eq. 1). The experimental data to set the parameters used for plant growth and harvest both in AFIs and in CWs correspond to the species *Senecio bonariensis*, a native plant with known remedial potential (Sinscalchi, 2013). The *S. bonariensis* biomass balance ( $C_{Biomass}$  in  $\text{mgC L}^{-1}$ ) includes a growth term ( $R_{Biomass, growth}$ ) ( $\text{d}^{-1}$ ) (Eq. 2) that considers the maximum growth of the planted species multiplied by the main factors that affect photoautotrophic organisms: temperature ( $f(T)$ ) (Eq. 3), solar radiation ( $f(I)$ ) (Eq. 4), P and N concentrations ( $f(N)$ ) (Eq. 5) from the upper layer of the reservoir; a mortality term ( $R_{Biomass, death}$ ) ( $\text{d}^{-1}$ ) (Eq. 6) dependent on temperature, and a harvest term ( $R_{Biomass, harvest}$ ) ( $\text{d}^{-1}$ ) (Eq. 7) that is performed only when the plant reaches its maximum growth.

$$\frac{dC_{Biomass}}{dt} = r_{Biomass} = R_{Biomass, growth} - R_{Biomass, death} - R_{Biomass, harvest} \quad \text{Eq. 1}$$

$$R_{Biomass, growth} = k_{Biomass, growth} f(T)f(I)f(N)C_{Biomass} \quad \text{Eq. 2}$$

$$f(T) = \left(\frac{T_{emp}}{T_{opt}}\right) \exp\left(1 - \left(\frac{T_{emp}}{T_{opt}}\right)\right) \quad \text{Eq. 3}$$

$$f(I) = \left(\frac{I_o}{I_{opt}}\right) \exp\left(1 - \left(\frac{I_o}{I_{opt}}\right)\right) \quad \text{Eq. 4}$$

$$f(N) = \left(\frac{C_{upper layer, PO_4}}{K_P + C_{i, PO_4}}\right) \left(\frac{C_{upper layer, NO_3}}{K_N + C_{i, NO_3}}\right) \quad \text{Eq. 5}$$

$$R_{Biomass, death} = k_{Biomass, death} \theta_{Biomass, death}^{(T-20)} C_{Biomass} \quad \text{Eq. 6}$$

$$R_{Biomass, harvest} = \begin{cases} 0, & \text{if } R_{Biomass, growth} < k_{Biomass, growth max} \\ \beta * C_{Biomass}, & \text{if } R_{Biomass, growth} = k_{Biomass, growth max} \end{cases} \quad \text{Eq. 7}$$

Were  $Temp$  and  $T_{opt}$  are the water temperature and the optimal growth temperature ( $^{\circ}\text{C}$ ), respectively;  $I_o$  and  $I_{opt}$  are irradiance and optimal irradiance for growth ( $\text{wm}^{-2}$ ), respectively;  $K_P$  and  $K_N$  are the half saturation constants ( $\text{mgL}^{-1}$ ) for P and N uptake;  $k_{Biomass, growth}$  and  $k_{Biomass, death}$  are the maximum growth rate and the mortality rate ( $\text{d}^{-1}$ );  $\theta_{Biomass, death}$  is the temperature for mortality rate; and  $\beta$  is the proportion of harvested biomass. As the Paso de las Piedras Reservoir model is spatially discretized in two horizontal layers, and the AFIs implementation leads to a vertical difference in components concentrations (i.e., Areas covered and non-covered by AFIs), the model was again discretized including two vertical compartments in the upper layer.

#### 4. Optimization Problem

The objective function (Eq 8, Table 1) follows the dual criteria (P and N) recommended by Environmental Protection Agency of U.S. (EPA, 2015) and is the minimization of the sum of integrals of the square differences between inorganic phosphorus (P- $\text{PO}_4$ ) and inorganic nitrogen (N- $\text{NO}_3$ ) concentrations and a desired value below eutrophication (0.02 for P and 0.3  $\text{mg L}^{-1}$  for N) (Wetzel, 1983). As degrees of freedom of the control problems are the area of the constructed wetlands for El Divisorio Stream ( $CW_{ED}$ ) and Sauce Grande River ( $CW_{SG}$ ) (design variables) (Eqs. 11 and 12, Table 1), the area covered by AFIs ( $A_{AFI}$ ) (design variable) (Eq. 18, Table 1) (Saviolo Osti *et al.*, 2020), and the fraction of the tributaries diverted to the wetlands ( $F_{CW_{SG}}$  and  $F_{CW_{ED}}$ ) (control variables) (Eqs. 14 and 15 Table 1). Also, a path constraint is included (Eq- 13, Table 1) to satisfy that the sum of the areas ( $A_{CW, Total}$ ) of both wetlands ( $A_{CW_{SG}}$  and  $A_{CW_{ED}}$ ) does not exceed a quarter of the total area of the reservoir (9  $\text{km}^2$ ). To solve the formulated optimal control

and design problems, a control vector parameterization approach is applied within an equation-oriented framework (gPROMS, PSEnterprise Ltd., 2019).

## 5. Numerical Results

The resulting integrated (PPR+AFIs+CWs) model has 64 differential equations and more than 200 algebraic ones. The model is implemented in a personal computer with an Intel® Core™ i7-4700 K processor, operating at a CPU frequency of 3.6 GHz, and with 8 Gb RAM. The total CPU time is 4.469s. Numerical results provide optimal areas of AFIs and CWs, as well as nutrients, phytoplankton, zooplankton, fish, dissolved oxygen, *S. bonariensis* biomass in both CWs and AFIs profiles along a five-year time horizon. Numerical results (Figures 1 and 2, Table 2) allow assesses the performance of the different bottom-up strategies and their combination to restore the water quality in a eutrophic reservoir, showing the synergy between both combined strategies (CWs and AFIs). With the application of this approach the theoretical reduction of inorganic P and N is 61 % and 92 %, respectively. It is important to note that when only CWs strategy is applied, the reduction of 10 % in P (Table 2) is achieved with 3 and 6 km<sup>2</sup> of CW<sub>SG</sub> and CW<sub>ED</sub>, respectively, which seems inapplicable in practice. However, with an area covered by AFIs of 1.8 km<sup>2</sup> (5% of the total area of the reservoir, Saviolo Osti *et al.*, 2020) the necessity for CWs area is halved and it is only necessary to construct a wetland on El Divisorio Stream. With this combination P reduction is 56 % (Table 2). Figures 1 and 2 shows that the best strategy is the combination of restoration techniques (AFIs + CWs) approach for the substantial reduction in nutrients and, also, for phytoplankton and cyanobacteria concentration.

**Table 2.** Nutrient removal and decrease in phytoplankton and cyanobacteria biomass concentrations for each restoration strategy in percentage, as compared to no restoration

	Phosphorous	Nitrogen	Phytoplankton	Cyanobacteria
AFIs (%)	56	14	5	1
CW <sub>SG</sub> and CW <sub>ED</sub> (%)	10	48	3	1
AFIs + CW <sub>ED</sub> (%)	61	92	50	20

**Figure 1:** Concentration time profiles for **a)** inorganic phosphorus and **b)** inorganic nitrogen concentrations. NR: without restoration; A: AFIs; CW: Constructed wetlands.

**Figure 2:** Concentration time profiles for **a)** total phytoplankton biomass and **b)** cyanobacteria biomass concentrations. NR: without restoration; A: AFIs; CW: Constructed wetlands.

## 6. Conclusions

In this work we study the water quality improvement after combined restoration strategies application formulated as optimal control problems. The integrated optimization model includes a water quality model of Paso de las Piedras Reservoir, and models for two bottom-up restoration strategies, constructed wetlands and floating artificial islands. Numerical results indicate that implementation of AFIs would be an effective green technology to restore contaminated ecosystems by reducing excess of nutrients and controlling cyanobacteria and total phytoplankton growth in combination with constructed wetlands. Finally, integrated models used with dynamic optimization approaches are powerful management tools for rational evaluation and planning of bottom-up strategies for water quality restoration.

### Abstract

With the increased availability of process data, data-driven methods are becoming more appealing to use in process modelling. Data-driven methods are especially interesting in systems where the existing first-principles models are not adequate in describing the full system dynamics. This work compares a serial semi-parametric hybrid-modelling approach, integrating Machine Learning and first-principles modelling, to a stochastic greybox modelling approach proposed by (Kristensen et al. 2004). Through a CSTR case study both modelling approaches shows accurate predicting performance and robustness towards noisy data. The stochastic greybox modelling is found to be more robust towards measurement frequency as the true model structure is provided when fitting the parameters. Through this work, it is found that good modelling performance can be achieved without providing an explicit model structure by utilizing process data.

**Keywords:** Process Simulation, Machine Learning, Hybrid-Modelling, Kalman Filter

### 1. Introduction

With Industry 4.0 the accessibility and quality of data from the production lines in the chemical and biochemical industries is improving due to digital advances such as better data infrastructure and more advanced sensors for on-line/at-line measurements. The increased availability of process data along with improved computational power and algorithmic developments is improving the possibility for introducing data-driven modelling methods in chemical engineering applications (Udugama et al. 2020). The use of data-driven methods enables the modelling of systems where the existing physical and chemical knowledge is limited and, as a result, the existing first-principles models are inaccurate. A problem arising when using data-driven methods is the process data not being truly “big-data” (Venkatasubramanian 2019), a usual requirement for the development of accurate Machine Learning (ML) models. Problems often also arise in predicting the states, interpreting the models, and extrapolating the models when using data-driven modelling. The introduction of semi-parametric hybrid-models, in which process knowledge is combined with data-driven methods, has shown promising performance in mitigating the issues in “purely” data-driven modelling. Semi-parametric hybrid-models shows improvements in state prediction, interpretability, and extrapolability compared to “purely” data-driven modelling when using the same data (von Stosch et al. 2014). Semi-parametric hybrid-models have previously been used in chemical reactor modelling (Bellos et al. 2005) and for modelling flocculation processes (Nazemzadeh et al. 2021). Experimental knowledge can also be included in modelling through stochastic greybox modelling in which maximum likelihood or maximum a

posteriori parameter estimates are used for modelling using a system of stochastic differential equations (Kristensen et al. 2004). Stochastic greybox modelling has proven accurate in modelling several different processes including fed-batch cultivation (Rasmussen et al. 2006) and alternating activated sludge process (Halvgaard et al. 2015).

## 2. Serial semi-parametric hybrid-modelling

Lack of process knowledge is mitigated in semi-parametric hybrid-models by modelling unknown or uncertain phenomena in the system using ML. In this work, a serial semi-parametric hybrid-model is introduced using the workflow given in figure 1.

Figure 1 Workflow for serial semi-parametric hybrid-modelling using ML model trained on unknown phenomena,  $\varphi_t$ , estimated for training and validation data using a Continuous-Discrete Extended Kalman Filter.

Considering a process, which is described by a set of ODEs as given in equation (1).

$$dx_t = f(x_t, u_t, \varphi_t)dt \quad (1)$$

In which  $t \in \mathbb{R}$  is the time,  $x_t \in \mathbb{R}^n$  is the state variables,  $u_t \in \mathbb{R}^m$  is the input variables,  $f(\cdot) \in \mathbb{R}^n$  is a non-linear function based on first-principles, and  $\varphi_t \in \mathbb{R}^p$  is some unknown phenomena in the system. The unknown phenomena,  $\varphi_t$ , is modelled by introducing a ML model,  $f_{ML}(\cdot) \in \mathbb{R}^p$ , such that  $f_{ML}(x_t, u_t) = \varphi_t$  resulting in the system equations (2).

$$dx_t = f(x_t, u_t, f_{ML}(x_t, u_t))dt \quad (2)$$

A problem arise in training the ML model using supervised learning as the unknown phenomena,  $\varphi_t$ , often cannot be measured. This problem is mitigated by estimating  $\varphi_t$  for the training and validation data before training the ML model.  $\varphi_t$  can be estimated using a Continuous-Discrete Extended Kalman Filter (CDEKF) in which  $\varphi_t$  is included as an additional state (Cox 1964) with system equation (3) and measurement equation (4).

$$d \begin{pmatrix} x_t \\ \varphi_t \end{pmatrix} = \begin{pmatrix} f(x_t, u_t, \varphi_t) \\ 0 \end{pmatrix} dt + \sigma(u_t, \varphi_t) d\omega_t \quad (3)$$

$$y_k = h(x_k, u_k, \varphi_k) + e_k \quad (4)$$

In which  $k = 0, \dots, N$  is the discrete time index,  $y_k \in \mathbb{R}^l$  is the measured output variables,  $\sigma(\cdot) \in \mathbb{R}^{n \times n}$  and  $h(\cdot) \in \mathbb{R}^l$  are functions,  $\omega_t$  is a  $n$ -dimensional standard Wiener process, and  $e_k \in N(0, S)$  is an  $l$ -dimensional white noise process. A ML model can now be trained using the CDEKF estimates of  $\varphi_t$  before introducing the ML model to the system equations (2).

### 3. Case Study: Synthetic CSTR

To investigate the performance of different data-driven modelling methods, a CSTR case study (Figure 2) is considered using simulated data. A first-order exothermic conversion of  $A$  to  $B$  is taking place in the CSTR system with the material- and energy balance (5) being the governing equations.

$$d \begin{pmatrix} C_A \\ C_B \\ T \end{pmatrix} = \begin{pmatrix} \frac{F}{V} (C_{A,f}(t) - C_A(t)) - r(t) \\ -\frac{F}{V} C_B(t) + r(t) \\ \frac{F}{V} (T_f(t) - T(t)) - \frac{\Delta H}{\rho c_p} r(t) \end{pmatrix} dt \quad (5)$$

Figure 2 Systematic diagram of CSTR

In which  $C_A$  and  $C_B$  are the concentrations of  $A$  and  $B$  respectively,  $T$  is the temperature in the CSTR,  $F$  is the feed flowrate,  $V$  is the volume of the CSTR.  $C_{A,f}$  is the concentration of  $A$  in the feed,  $T_f$  is the temperature in the feed.  $\Delta H$  is the heat of reaction,  $\rho$  is the density of the mixture, and  $c_p$  is the heat capacity coefficient of the mixture. For the CSTR case, both stochastic greybox modelling and serial semi-parametric hybrid-modelling is applied, introducing data-driven methods for modelling  $r(t)$ .

#### 3.1 Stochastic Greybox Modelling

Three different model structures are introduced for the reaction rate in the stochastic greybox modelling: 1) assuming 0<sup>th</sup> order reaction rate,  $r(t) = r$ , 2) assuming 1<sup>st</sup> order reaction,  $r(t) = k \cdot C_A(t)$ , and 3) using an Arrhenius expression,  $r(t) = k_0 \exp\left(-\frac{E_a}{RT(t)}\right) C_A(t)$ .

Table 1 Maximum likelihood estimates of parameters for stochastic greybox models.

Model	Parameter
0 <sup>th</sup> Order	$r = 1.78 \cdot 10^{-1}$
1 <sup>st</sup> Order	$k = 1.81 \cdot 10^{-1}$
Arrhenius	$k_0 = 3.50 \cdot 10^7$
	$E_a = 1.18 \cdot 10^4$

Plotting the model predictions along with the measurements (Figure 3) it is evident that the models using 0<sup>th</sup>- and 1<sup>st</sup> order reaction rates are performing significantly worse than the model using an Arrhenius expression.

#### 3.2 Serial semi-parametric Hybrid-modelling

A semi-parametric hybrid-modelling structure is constructed by introducing a feedforward artificial neural network ( $f_{NN}$ ) for modelling the reaction rate resulting in the system equations (6).

Figure 3 Stochastic greybox model predictions of output variables.

$$d \begin{pmatrix} C_A \\ C_B \\ T \end{pmatrix} = \begin{pmatrix} \frac{F}{V} (C_{A,f}(t) - C_A(t)) - f_{NN}(C_A(t), T(t)) \\ -\frac{F}{V} C_B(t) + f_{NN}(C_A(t), T(t)) \\ \frac{F}{V} (T_f(t) - T(t)) - \frac{\Delta H}{\rho c_p} f_{NN}(C_A(t), T(t)) \end{pmatrix} dt \quad (6)$$

The reaction rate is first estimated using a CDEKF in which the reaction rate is included as an additional state resulting in the system- and measurement equations (7).

$$d \begin{pmatrix} C_A \\ C_B \\ T \\ r \end{pmatrix} = \begin{pmatrix} \frac{F}{V} (C_{A,f}(t) - C_A(t)) - r(t) \\ -\frac{F}{V} C_B(t) + r(t) \\ \frac{F}{V} (T_f(t) - T(t)) - \frac{\Delta H}{\rho c_p} r(t) \\ 0 \end{pmatrix} dt, \quad \begin{pmatrix} y_1 \\ y_2 \\ y_3 \end{pmatrix}_k = \begin{pmatrix} C_A \\ C_B \\ T \end{pmatrix}_k + e_k \quad (7)$$

The CDEKF is applied to the training data, for training a neural network (NN) with one hidden layer, and to the validation data, for selecting hyper-parameters using a grid search. The possible number of neurons,  $n$ , are specified in the grid search to be  $n \in [2, 4, 8, 16, 32, 64, 128]$ . The best prediction performance on the validation data set was achieved in a NN with 2 neurons in the hidden layer (Figure 4).

Predictions of the three output variables are obtained after introducing the trained NN model to the system equations (6). Plots of the output predictions (Figure 5) shows that the serial semi-parametric hybrid-model provides accurate predictions for all three output variables.

#### 4. Robustness

When modelling real production processes the available data may be noisy and the measurement frequency may be low, especially when using off-line measurements. In the following an assessment of the robustness of the two different modelling approaches towards noise and measurement is provided.

##### 4.1. Noise

White noise is added in the generated data sets as both output measurement noise and input noise on the three input parameters,  $C_{A,f}$ ,  $T_f$ , and  $F$ , with the same standard deviation

Figure 4 Predictions, estimates, and true reaction rate.

Figure 5 Serial semi-parametric hybrid-model predictions of output variables.

for all noise terms in the individual datasets. Three different levels of noise is investigated using standard deviation of 0.01, 0.02, and 0.05. Both stochastic greybox models using an Arrhenius expression as the reaction rate, and serial semi-parametric hybrid-models using a NN as reaction rate are trained using each of the noisy data sets.

Table 2 fitness of prediction with different noise levels for the three output variables using both stochastic greybox model with Arrhenius expression as reaction rate and serial semi-parametric hybrid-model.

Noise std.	Arrhenius			Serial semi-parametric hybrid-model		
	$C_A$ fitness	$C_B$ fitness	$T$ fitness	$C_A$ fitness	$C_B$ fitness	$T$ fitness
	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )
0.01	0.008 (0.99)	0.008 (0.87)	0.014 (0.99)	0.009 (0.99)	0.009 (0.85)	0.053 (0.99)
0.02	0.017 (0.97)	0.016 (0.69)	0.016 (0.99)	0.018 (0.97)	0.018 (0.66)	0.095 (0.99)
0.05	0.041 (0.88)	0.039 (0.38)	0.041 (0.99)	0.041 (0.88)	0.040 (0.36)	0.093 (0.99)

The MAE is approximately the same as the noise standard deviation for all output predictions at each of the noise levels with the exception of the  $T$  predictions when using a serial semi-parametric hybrid-model (Table 2). This indicates that the two different approaches are able to predict the trend in the data, while the increase in error is a result of the increase in the noise.

#### 4.2. Measurement Frequency

The robustness towards measurement frequency of the two modelling approaches is investigated using data sets generated using different sampling time. The NN in the serial semi-parametric hybrid-model is sensitive to sparse data, posing a problem when training the model. This problem is mitigated in the data sets with low measurement frequency by interpolating between the measurements using cubic smoothing splines when preprocessing the training data, generating more data for training.

Table 3 fitness of prediction with different measurement frequency for the three output variables using both stochastic greybox model with Arrhenius expression as reaction rate and serial semi-parametric hybrid-model.

Freq. ( $hr^{-1}$ )	Arrhenius			Serial semi-parametric hybrid-model		
	$C_A$ fitness	$C_B$ fitness	$T$ fitness	$C_A$ fitness	$C_B$ fitness	$T$ fitness
	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )	MAE ( $R^2$ )
30	0.008 (0.99)	0.008 (0.87)	0.014 (0.99)	0.009 (0.99)	0.009 (0.85)	0.053 (0.99)
15	0.008 (0.99)	0.008 (0.87)	0.008 (0.99)	0.010 (0.99)	0.009 (0.84)	0.066 (0.99)
3	0.007 (0.99)	0.008 (0.89)	0.008 (0.99)	0.008 (0.99)	0.009 (0.86)	0.041 (0.99)
1	0.006 (0.99)	0.007 (0.92)	0.012 (0.99)	0.018 (0.99)	0.016 (0.86)	0.190 (0.99)

The stochastic greybox model is found to be robust towards measurement frequency, as the fitness does not decrease when lowering the measurement frequency (Table 3). The serial semi-parametric hybrid-model is found to be less robust towards measurement frequency, as the MAE is increasing when the measurement frequency is low. The higher robustness of the stochastic greybox model towards measurement frequency may be a result of the higher utilization of process knowledge through the introduction of the “true” structure for the reaction rate in the model. Effectively data is only used to fit two parameters in the stochastic greybox model, whereas the full structure of the reaction rate has to be learned by the NN in the serial semi-parametric hybrid-model.

## 5. Conclusion

Two different approaches for applying hybrid-models, stochastic greybox modelling and serial semi-parametric hybrid-modelling, were used in this paper. The two approaches were applied to a CSTR case study using simulated data. Both approaches were successful in developing models with accurate output predictions and robustness towards noisy data, with the stochastic greybox model being slightly more accurate. The stochastic greybox model was found to be more robust towards measurement frequency due to the “true” structure of the reaction rate being provided for the model. While the stochastic greybox modelling provides a better model, it has higher requirements for process knowledge, as an appropriate model structure has to be provided for good performance to be achieved. It is found that good prediction performance can be achieved without providing an explicit model structure by introducing a ML part for modelling unknown or uncertain phenomena to the first-principles model.

## Abstract

The present work focuses on a new application of the Generalized Polynomial Chaos (gPC) approach: the stochastic response of a three-dimensional simulation of slurry pipe flows in pipelines subject to parametric uncertainties. Initial and boundary conditions (e.g., the slurry flowrate used at the pipe entrance, initial solid concentration), material properties (e.g., particles size), model parameters (e.g., specular coefficient when the kinetic theory of granular flow (KTGF) is coupled with the Eulerian-Eulerian model), and geometry-related factor (e.g., pipe inclination) are considered as random parameters. gPC surrogate model is built through a least angle regression (LAR) methodology in order to perform uncertainty quantification and global sensitivity analysis following a variance-based approach. The use of gPC is motivated based on its ability to estimate Sobol' indices efficiently. These variance-based sensitivity indices are effective to perform sensitivity analysis without any assumptions about the model's linearity or monotony. Retaining the gPC technique has the advantage of giving the global sensitivity Sobol' indices in a straightforward manner at a lower computing cost than the usual Monte Carlo (MC) method. The first order and total Sobol' indices of the pressure drop along the pipe are calculated and their inspection show that the variability of the pressure gradient is mainly due to the principal effects of the inlet velocity, followed by the inclination of the pipe and then the size of particles. Within the framework of uncertainty quantification, the gPC expansions will also be applied as a surrogate model, as its objective is to recreate the global behavior of the CFD model in a manner that is consistent with a polynomial decomposition.

**Keywords:** Phosphate slurry flow, Generalized polynomial chaos, CFD, Global sensitivity analysis

## 1. Introduction

With the advancement of computational methods, numerical simulation has become a popular method for predicting the behavior of physical systems. Upon its simulation with a numerical model, uncertainties are ubiquitous and arise from a variety of sources that may contain substantial randomness in their description. Hence, the results in model outcomes are necessarily subject to uncertainty. To improve prediction reliability, it is consequently necessary to quantify the related uncertainties. This is generally achieved through the non-linear propagation of the initial parameter's uncertainties in CFD simulations (Walters and Huyse, 2002). Global Sensitivity Analysis (GSA) can be carried out to attribute to each input its contribution to the resulting output uncertainty. In the

previous two decades, several methodologies have been developed to assess the uncertainty propagation in CFD simulation. The reader is referred to Saltelli et al. (2006) who provides a thorough state-of-the-art of the methods. As sensitivity metrics, the Sobol' indices are extensively used in this context. Several approaches can be employed for calculating the Sobol indices (Sobol, 2001; Kucherenko et al., 2005). Nevertheless, the cornerstone of this method is the highly expensive cost of computations needed to estimate these indices (Sudret, 2008). To overcome the computational requirement associated with the stochastic simulations, new methodologies based on the use of surrogate models have been introduced. gPC expansions have been demonstrated to be effective for Uncertainty Quantification (UQ) and GSA (Blatman and Sudret, 2011), among other options.

To this purpose, the issue of slurry flows in pipes is tackled using GSA together with the gPC expansion approach, to rank the input parameters based on their influence on quantity of interest. As model inputs, five variables are investigated and sampled within a physical range. Initially, we address the physical parameters defining the transport of the intended slurry, including the solids particle size distribution, solid concentration in the flow, and the entrance velocity of the flow mixture. In slurry transport, the inclination of the pipe, a geometry-related factor, is also taken into consideration as a crucial component. Furthermore, the specular coefficient, which is a wall boundary coefficient related to the kinetic theory for granular flows (Zhong et al., 2015), is considered as a modeling parameter. After identifying the model's uncertain inputs and modeling them within a probabilistic framework, the second stage involves propagating the uncertainty across the model. Finally, a sensitivity analysis is performed, in which the input parameters are ranked according to their effect on the prediction uncertainty.

## 2. Polynomial Chaos Expansion for Sensitivity Analysis

The gPC expansion aims at recreating the global behavior of a simulation in a manner that is consistent with a polynomial decomposition. The latter are multivariate orthogonal polynomials and serve as the basis functions that are selected in accordance with the joint probability distributions of the stochastic input variables following the so-called Askey scheme of polynomial (Xiu and Karniadakis, 2002). In the present study, if our variables (shown in Tab. 1) are stored in the vector  $\mathbf{X} \in R^d$ , and  $\mathcal{Y}$  represents the model responses discussed earlier, then one may write, according to the gPC expansion:

$$\mathcal{Y} = \mathcal{M}(\mathbf{X}) = \sum_{\alpha \in \mathbb{N}^d} \pi_{\alpha} \Psi_{\alpha}(\mathbf{X}), \quad (1)$$

Where  $\mathbb{N}^d$  denotes a multi-index  $\alpha = \{\alpha_1, \dots, \alpha_d\}$ ,  $\{\pi_{\alpha}, \alpha \in \mathbb{N}^d\}$  are the expansion coefficients that has to be computed.  $\{\Psi_{\alpha}(\mathbf{X}), \alpha \in \mathbb{N}^d\}$  are multivariate polynomials that are orthonormal with regards to the joint (pdf)  $f_{\mathbf{X}}$  of  $\mathbf{X}$ , i.e.,  $E[\Psi_{\alpha}(\mathbf{X})\Psi_{\beta}(\mathbf{X})] = 1$  if  $(\alpha = \beta)$  and 0 otherwise. The multivariate polynomials  $\Psi_{\alpha}$  are constructed by taking the tensor product of their corresponding univariate polynomials, i.e.,

$$\Psi_{\alpha}(\mathbf{X}) = \prod_{i=1}^d \phi_{\alpha_i}^{(i)}(X_i), \quad (2)$$

where  $\phi_{\alpha_i}^{(i)}$  is a polynomial in the  $i$ -th variable of degree  $\alpha_i$ . gPC expansion in Eq.1 must be truncated after  $p$  terms for computational purposes. Typically, the polynomials  $\Psi_{\alpha}$  with

total degree up to  $p$  are maintained as  $\Psi_\alpha(\mathbf{X}) = \sum_{\alpha \in \mathcal{A}^{d,p} \subset \mathbb{N}^d} \pi_\alpha \Psi_\alpha(\mathbf{X})$ . The set  $\mathcal{A}^{d,p}$  is defined here based on a total polynomial degree.

The next step is the computation of the polynomial chaos coefficients. The regression technique can be used to estimate the spectral coefficients  $\pi_\alpha$ . This could be achieved by solving a least-square (LS) minimization problem in  $\ell_2$ -norm (Berveiller et al., 2006). We first define the metric error  $\epsilon_{PC}$  as the difference between the (exact) model's evaluation ( $\mathcal{Y}$ ) and the gPC surrogate estimates for a finite training set of randomly sampled input variables  $\mathbf{X}$ . A set of  $N_{ts}$  realization of the input vector,  $\mathbf{X} = X(1), \dots, X(N_{ts})$ , is then needed, called experimental design (ED). The input ED is achieved in the present work using the well-known method Latin Hypercube sampling (LHS) approach. The regression problem is solved using a Least-angle-regression (LAR) approach, which offers a sparse gPC representation. This allows us to overcome the curse of dimensionality. Here, we follow the procedure as suggested in Blatman and Sudret (2011). Evaluating its quality is of crucial interest, therefore, Leave-One-Out (LOO) error is employed as it gives an excellent measure of accuracy by enabling error estimates at a reasonable processing. The definition of the relative LOO error is as follows:

$$\epsilon_{LOO} = \frac{\sum_{i=1}^N \left( \frac{\mathcal{M}(x^{(i)}) - \mathcal{M}^{PC}(x^{(i)})}{1 - h_i} \right)^2}{\sum_{i=1}^N (\mathcal{M}(x^{(i)}) - \widehat{\mu_Y})^2} \quad (3)$$

where  $h_i$  is the  $i^{th}$  diagonal term of matrix  $\Psi(\Psi^T\Psi)^{-1}\Psi^T$ , where  $\Psi = \{\Psi_{ij} = \Psi_j(X^i)\}$  and  $(\widehat{\mu_Y}) = \frac{1}{N} \sum_{i=1}^N \mathcal{M}(x^{(i)})$ . Once the PCE is built, the mean  $\mu$  and the total variance  $D$  can be obtained using properties of the orthogonal polynomials, such that  $\mu = y_0$  and  $D = \sum_{\alpha \in \mathcal{A} \setminus 0} y_\alpha^2$ . As mentioned above, the Sobol' indices of any order can be computed in a straightforward manner. The first order and total Sobol' indices are then given by  $S_i = \sum_{\alpha \in \mathcal{A}_i} y_\alpha^2 / D$  and  $\mathcal{A}_i = \{\alpha \in \mathcal{A}: \alpha_i > 0, \alpha_{j \neq i} = 0\}$ , and  $S_i^T = \sum_{\alpha \in \mathcal{A}_i^T} y_\alpha^2 / D$  with  $\mathcal{A}_i^T = \{\alpha \in \mathcal{A}: \alpha_i > 0\}$ , respectively.

### 3. CFD modeling procedure

The system under consideration is a three-dimensional pipeline of diameter  $D = 0.103m$  and of length  $L = 140D$ , thus ensuring a fully developed flow. The transported slurry consists of a mixture of phosphate and water with densities of  $\rho_s = 2600$  and  $\rho_w = 1000$   $kg/m^3$ , respectively. The current CFD modeling approach is based on the Euler-Euler two-fluid formulation, which treats both solid and fluid phases as interpenetrating continua (Gidaspow, 1994). We explore this two-phase slurry flow in pipes numerically using the open-source continuum mechanics suite OpenVFOAM®, which is a C++ toolkit for developing numerical solutions. The CFD simulations are run using the solver TwoPhaseEulerFoam, which has been adapted to accommodate mixtures of solids and liquids (Elkarii et al., 2020). The reader is directed to (Elkarii et al., 2022) for further information on the current CFD modeling technique as well as to review the numerical validation. In the present work, the head loss parameter will be estimated using the CFD simulations. This will serve as the quantity of interest for the GSA, since it constitutes a good proxy for the energy requirements of the pipe flow.

#### 4. UQ methodology

To perform UQ and GSA for the problem of slurry flows in pipelines, one should identify the various sources of uncertainty, which will be considered as model inputs. As stated in the introduction, the slurry pipe flows behavior is often defined through the properties of the materials (El Moçayd and Seaid (2021)). This motivates the choice of  $\mathbf{X} = \{\phi_s, u_m, d_p, \theta, SC\}$  as random parameters. These random variables are presented according to their respective pdf's (cf. table1). In order to assess the quality of the gPC expansion, four design of experiments of sizes  $N = \{200, 500, 900, 1000\}$  are considered. They are generated using the LHS method. Once the design of experiments are defined it remains to run the computational model for each sampling node in those sets to obtain the vector  $\mathbf{Y}$  of observations of the quantity of interest (QOI).

Table 1: Phosphate slurry flow: parameters of the model

Parameters	Type of PDF	Orthogonal polynomials	Range of variability
Inlet velocity $u_m$ [m/s]	Uniform	Legendre	[1.75, 5]
Solid concentration $\phi_s$ [-]	Uniform	Legendre	[20%, 40%]
Particles size $d_p$ [ $\mu\text{m}$ ]	Uniform	Legendre	[44, 250]
Pipe inclination $\theta^\circ$	Gaussian	Hermite	[0, 4]
Specularity coefficient SC[-]	Uniform	Legendre	[0, 1]

#### 5. Results and discussion

To ensure results convergence, the LOO error (Eq. 3) is calculated for each design of experiment and portrayed in figure 1. The LOO error convergence rate indicates that 1000 samples are sufficient to build a high quality gPC expansion.

A further investigation of gPC accuracy is performed. First, the sensitivity of the gPC with respect to the polynomial degree is evaluated as depicted in Fig. 2a. A polynomial degree  $p = 6$  is sufficient to carry on UQ and GSA using the surrogate model. Then, the ability of the surrogate model to mimic the physical behavior of the CFD model is presented in Fig. 2b. This constitutes a good validation for the gPC ability to serve as a low-cost meta-model.

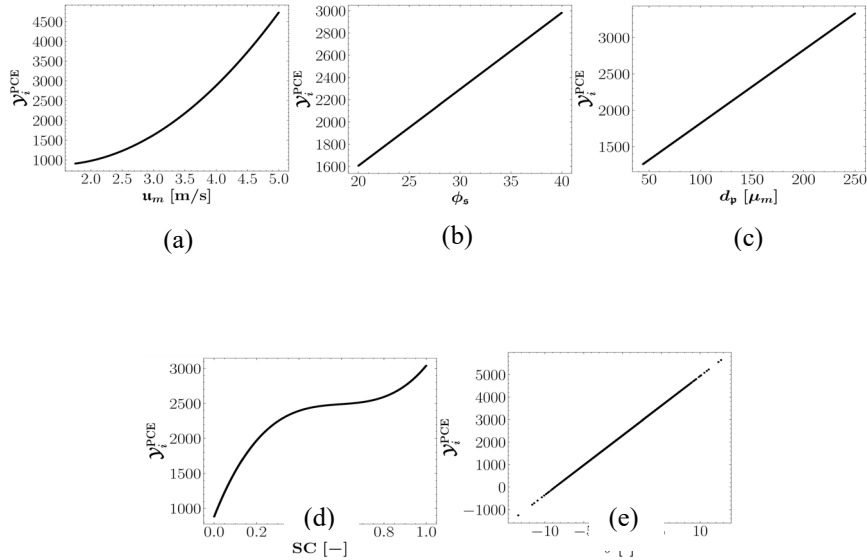

Figure 2: (a) Optimal gPC degree with respect to gPC degree and (b) Comparison between gPC and the exact model using 1000 samples.

Next, we examine the marginal effect of the uncertain parameters on the model response. It is observed that there is a good fit, which is highlighted by a minor LOO error (less than 0.001) (Fajraoui et al., 2017), and which corresponds to an optimal PCE of degree  $P = 6$ . We carry out this analysis on the total head loss, in order to better understand how energy loss in pipelines is impacted, since the total head loss is a measure of the energy reduction produced by the sum of elevation head, velocity head and frictions head of the fluid as it passes through a fluid system. The sensitivity of the head loss to the variability of the random parameters  $\{\phi_s, u_m, d_p, \theta, \mathcal{SC}\}$ , can be assessed by means of the Sobol’ indices. Figure 3 shows bar plots of the computed first and total Sobol’ indices.

around  $u_m \leq 1.75$ . This occurs as a result of approaching the limit deposition velocity, at which point a stationary regime emerges, culminating in total particle sedimentation. As for  $\theta$  (cf Fig. 3e),  $\Delta H_{Total}$  increases with positive slopes and decreases on the other hand with the negative ones. At positive slope, the longitudinal resultant force acts as an extra

resistivity force for the wall contact layer and tends to reduce its velocity compared to horizontal flow. However, as a suspension goes down a pipe, flow is increased due to elevation effects, and pressure levels rise downstream. This extra kinetic energy is utilized to compensate for frictional consequences. With respect to the solids concentration and the particle sizes,  $\Delta H_{Total}$  grows as both of these variables rise, as noticed in Figs. 3b and 3c. Finally, when it comes to the specular coefficient  $SC$ , it is remarked that the pressure drop increases with the latter (cf Fig. 3d). We recall here that  $SC$  quantifies the momentum and energy transfer caused by colliding particles with the pipe wall. As a result, a larger specular coefficient implies that it is fair to expect a considerable loss of kinetic energy once particles collide with the pipe wall, resulting in an increase in pressure drop. Finally, we evaluate the sensitivity of the head loss uncertainty to the variability of the random parameters  $\{\phi_s, u_m, d_p, \theta, SC\}$ . This will be assessed using the Sobol' indices resulting from the gPC expansion. Figure 4 shows bar plots of the computed first and total Sobol' indices. Inspection of the sensitivity indices showed that the variability of the total head loss  $\Delta H_{Total}$  is mainly due to the principal effects of  $u_m$  followed by  $\theta$  and then  $d_p$ . A small but not negligible influence of  $\phi_s$  and  $SC$ , is also observed. There is a notable difference between first and total order sobol' indices, indicating interactions among the random parameters.

## 6. Conclusion

In this study, a sensitivity analysis of turbulent phosphate slurry flow in the pipeline has been performed. The effects of our input parameter on the pressure drop along the pipe have been investigated. The choice of the parameters is performed with the aim to improve the physical understanding of the considered flow configuration. Results showed that the variability of the pressure drop is largely influenced by the effect of  $u_m$ ,  $\theta$ , and  $d_p$ . It can be also deduced, that a good calibration of  $SC$  in the numerical validation step is crucial, to ensure reliable predictions of the pressure drop along the pipe.

# Hybrid dynamic model of monoclonal antibody production using CHO cells

Mariana Monteiro,<sup>a</sup> Cleo Kontoravdi<sup>a</sup>

*<sup>a</sup>Sargent Centre for Process Systems Engineering, Department of Chemical Engineering, Imperial College London, Exhibition Road, London SW7 2AZ, United Kingdom*

## Abstract

Mammalian cells are used to produce up to 80% of the commercially available therapeutic proteins, with Chinese Hamster Ovary (CHO) cells being the main production host. Antibody production occurs in a train of bioreactors typically operated in fed-batch, i.e., semi-continuous, mode. Real-time monitoring of antibody concentration is costly and involves sampling and offline analytics. Current reactor models lack extrapolation power while being highly reliant on extensive amounts of data for parameterization. This work aims to leverage knowledge of the cell's metabolism and incorporate it in the production reactor model, thus creating a hybrid formulation with increased predictive capability and generality. This novel formulation can make predictions without requiring kinetic parameter estimations. The applicability of the proposed formulation is demonstrated with a soft sensor for antibody production.

**Keywords:** Biomanufacturing, Hybrid Modeling, Fed-Batch, CHO cells, monoclonal antibodies

## 1. Introduction

The global market of biologics reached an annual value of US\$265 billion in 2020, with an expected increase to US\$856 billion by 2030 (Precendence Research, 2021). Mammalian cells are used to produce up to 80% of the commercially available therapeutic proteins, with Chinese Hamster Ovary (CHO) cells representing the major fraction of that (Fan, *et al.*, 2015), because they produce safe and efficacious protein products. As a result of high demand, there is pressure to optimize the manufacturing process even further. Current upstream optimization techniques focus on medium composition, feeding strategies and process conditions (e.g., temperature and pH) (Bassem, *et al.*, 2021). Given the number of possible operating parameters to manipulate, it is both time-consuming and costly to perform experiments covering the entire design space. However, this burden can be lessened using a combination of predictive process models and targeted experimentation.

Current mathematical models describing the production reactor assume saturation kinetics and typically treat the cell as a black box. Although this formulation tends to fit cell culture data well, it offers little extrapolating power given that most parameters heavily rely on the process conditions for which the model was parameterized, such as temperature and pH. In this work, we propose a hybrid modeling approach comprising a stoichiometric model of cell metabolism and a dynamic reactor model, in which the rate

of change of each metabolite concentration is calculated using the metabolic model instead of treating the cell as a black box.

Metabolic models depict the network of chemical reactions occurring inside the cell and describe the consumption and production of metabolites. CHO cell metabolic network models can range from a few tens of reactions (Nolan and Lee, 2011) to over 6000 reactions and 4000 metabolites (Hefzi, *et al.*, 2016). Even when using a relatively small-scale network, it is not possible to experimentally obtain reaction rates of all reactions. As such, given that the system is underdetermined, it is necessary to solve the system of equations as an optimization problem and constrain the solutions to feasible and biological relevant spaces. The typical way to solve these problems is to define a feasible objective function that describes the cell's objective; examples include the maximization of growth rate or ATP production, minimization of ATP consumption, or minimization of NADH production (Carvalho *et al.*, 2019; Höffner *et al.*, 2019).

In this work we take advantage of our knowledge of cell metabolism to define a metabolic network model and we incorporate it in a dynamic model of the fed-batch production reactor. Since the core reactions in a cell's metabolic network always hold true, our novel formulation offers increased generality. We apply this approach to describe an antibody-producing CHO cell culture and demonstrate its applicability as a soft-sensor of antibody concentration (one of the costliest sensors).

## 2. Methodology

### 2.1. Hybrid Model

Figure 1 Proposed hybrid model

Figure 1 depicts the proposed hybrid modeling algorithm. The dynamic simulation loops over the following steps:

*Step 1.* We calculate the measured fluxes by subtracting the current (time  $t$ ) and past (time  $t-1$ ) concentrations of each metabolite. As shown in figure 1, we have available a subset of the total number of fluxes required (12 out of the 34 fluxes), none of which are intracellular.

*Step 2.* We perform the metabolic network optimization using the measured fluxes (graphically represented as the pink boxes in the metabolic model). As a result, we calculate the fluxes of the entire network for the current time  $t$ .

*Step 3.* We perform an integration of future time steps, in the reactor model, to calculate the predicted metabolite concentrations for time  $t+1$ , using the 34 calculated fluxes.

*Step 4.* We repeat each step iteratively, for each daily measurement available. Python library Scipy (Virtanen, *et al.*, 2020) was used for both optimization and simulation of the proposed hybrid model.

### 2.2. Metabolic model

The implemented optimization routine is shown below (equation 1), and it is formulated as a Metabolic Flux Analysis (MFA) problem, i.e., a minimization of the squared difference between measured and calculated fluxes:

$$\min_{v_k^{calc}} \sum \left( \frac{v_k^{calc} - v_k^{meas}}{v_k^{meas}} \right)^2 \quad \forall k \in \text{measured fluxes} \quad (1)$$

$$S \cdot v = 0$$

$$0 < v_{irrev}$$

where  $v_k^{calc}$  are the calculated fluxes,  $v_k^{meas}$  are the measured fluxes,  $S$  is the stoichiometric matrix,  $v$  are the fluxes of the entire networks,  $v_{irrev}$  are the irreversible fluxes and  $k$  represents the number of the flux. The measured fluxes,  $v_k^{meas}$  are the inputs for the optimization and the calculated fluxes,  $v_k^{calc}$ , are the optimization decision variables. The stoichiometric matrix is a  $m \times n$  matrix, where  $m$  is the total number of metabolites and  $n$  is the total number of reactions of the network. As such, there is a row per metabolite and a column per reaction. The stoichiometric matrix used contains 24 metabolites and 34 reactions. The network and reactions were taken from previous published work (Nolan and Lee, 2011).

This optimization routine is subject to two constraints. The first one enforces a *quasi-steady* state for each metabolite, meaning that it is assumed that the total rate of production equals the total rate of consumption for each metabolite, during each short time iteration. The second constraint provides information of which fluxes are irreversible and bounds them to biologically meaningful values.

### 2.3. Fed-batch model

The fed-batch model is implemented as a system of differential and algebraic equations, describing the mass balances for each metabolite, of the following form:

$$\frac{d\text{Metabolite}}{dt} = ([\text{Metabolite}]_{t=0} - [\text{Metabolite}]_{t=t}) * \frac{F(t)}{V} - \text{flux}_{\text{Metabolite}}(t) \quad (2)$$

$$* X_v(t)$$

where  $X_v$  is the cell volumetric density,  $F(t)$  is the inlet flow to the fed-batch and  $V$  is the working volume. Given that there is no outlet flow of the reactor, the working volume is solely a function of the inlet:

$$\frac{dV}{dt} = F_{in}(t) \quad (3)$$

### 2.4. Soft Sensor Validation

The applicability of the hybrid model formulation to soft sensing is demonstrated using published data from a fed-batch experiment (Kyriakopoulos and Kontoravdi, 2014). The cell line used is CHO GS46 and the expressed protein is a chimeric IgG4 monoclonal antibody. The cells were grown in a working volume of 250 mL for 14 days and fed on alternate days. Available daily measurements include viable cell density, viability and

extracellular glucose, lactate, ammonia, and amino acid concentrations. The soft sensor capability is demonstrated by rerunning the implemented algorithm with no measurement data of antibody concentration except for the initial time point.

### 3. Results

In this paper, we describe the formulation of a hybrid model comprising a metabolic network and a reactor model, which can use early measurement data to predict key metabolite concentrations throughout the culture. The model is then used as a soft sensor for antibody concentration. Figure 2 compares the hybrid model's predictions for key extracellular metabolite concentrations to experimental data. In addition, the graphs show the soft sensor results, for which no antibody measurements were used to solve the metabolic model except for the initial time point.

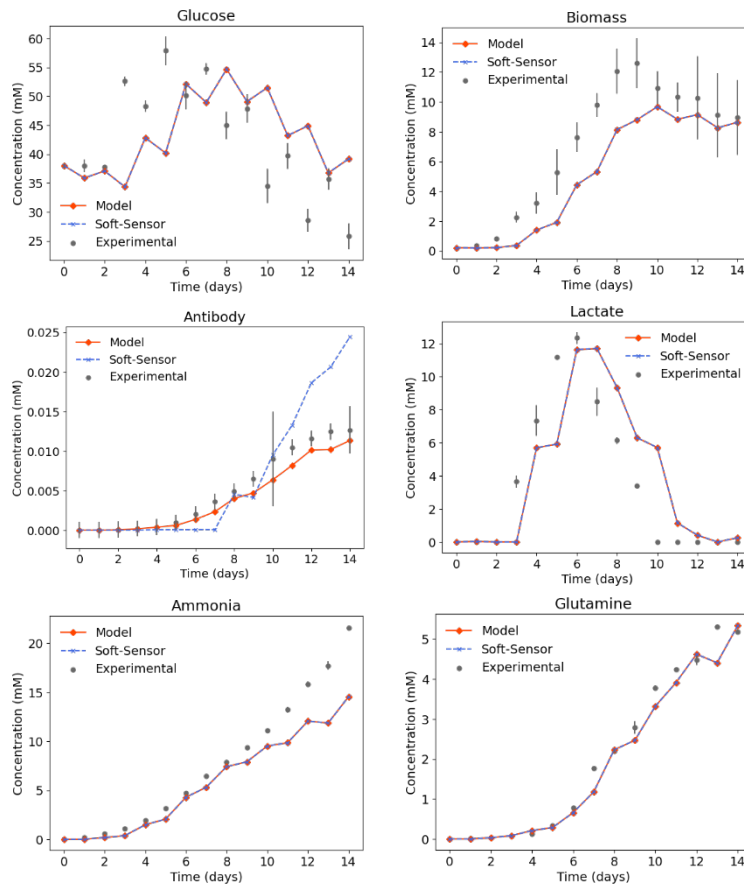

Figure 2 Model Validation Results: Measured vs Predicted Concentrations (in mM) of glucose biomass, antibody, lactate, ammonia, and glutamine, with (Hybrid) and without (Soft-Sensor) antibody, as a function of fed-batch time (in days)

Overall, the proposed hybrid model shows good agreement for the exponential growth phase (initial stages of the batch). Furthermore, the model can capture the lactate shift from consumption to production. The model shows deviations in glucose consumption in the later stages of the culture, which have a cascading effect on the other metabolites. Given that the model is predicting a lower glucose consumption, the cells do not produce as much energy, so they cannot grow as much or produce as much antibody product. The main reason for this underprediction of glucose lies in the *quasi*-steady state assumption, which is one of the constraints of metabolic network optimization. This assumption is valid for the early stages of the culture, when there is a high-nutrient uptake, resulting in fast cell growth. However, it proves insufficient to explain cellular behavior in the later stages, when cells stop growing at a high rate and significant metabolic changes occur, which are dependent on process conditions. As such, the assumption of *quasi*-steady state for the duration of one day (in the metabolic model) leads to higher deviations in the model predictions (Coulet, *et al.*, 2022). Additionally, metabolic network models are known to underpredict glucose consumption as there are energy requirements not captured in the stoichiometry of the reactions of the model, resulting in an underprediction of energy demands. As an improvement, we hope to remove the glucose steady-state constraint in the later stages of the batch and replace it with a minimum glucose uptake rate, backed by experimental data of multiple batches.

The soft sensor is able to estimate monoclonal antibody concentration in the first half of the batch, overpredicting it in the later stages of the batch. The overprediction is linked to an underestimation of the energy requirements of the cell. Given the simplicity of the metabolic model, the entirety of glucose consumed is directed mostly to cell growth and antibody production. There are, however, other metabolic functions that also take up energy, that are not accounted for in the model used herein. This shortcoming could be overcome by using a more comprehensive metabolic network.

The soft-sensor formulation shows the highest deviation from experimental values. When we compare the deviation of the soft sensor from the data and that from the hybrid model, the difference is not as pronounced, reflecting how much closer the hybrid model predictions are to the data. The soft sensor does not show any significant changes when compared to the original hybrid model formulation, for the remaining amino acids. This seems to indicate that removing the measured flux of antibody does not increase the deviation error of the predictions for the remaining amino acids. A possible reason for the low impact of antibody is its low flux value when compared to the remaining amino acids in the network optimization.

The novelty of the proposed model is the estimation of antibody from metabolite concentrations readily available online without the requirement of kinetic parameters estimation. We envisage this formulation as a technological tool towards Industry 4.0, as it paves the way for advanced process control without the need for online monitoring of hard-to-measure data. Our formulation can be integrated into a real-time optimization framework and act as feedback for a control system. Defining control objectives such as maximizing yield or minimizing the batch duration can be possible with the proposed framework, as the soft-sensor would provide the current state of the product.

#### 4. Concluding Remarks

In this paper, we propose a hybrid formulation which integrates a metabolic network in the reactor model that avoids parametrization by using knowledge of cell metabolism to predict key metabolite concentrations. Initial results show that our hybrid formulation offers good predictions for the early stages of the batch, where cells are showing a high nutrient consumption and growing at a fast pace. We demonstrate the applicability of the proposed formulation as a soft sensor for antibody concentration.

## Abstract

We propose an efficient framework that employs Bayesian optimization and global sensitivity analysis for the optimization of detailed pharmaceutical flowsheets. Global sensitivity analysis based on quasi-random sampling is utilized to reduce the dimensionality of the problem by identifying critical process and economic parameters that contribute significantly to the variability of Key Performance Indicators (KPIs) such as batch size and OpEx. Then, Bayesian optimization is performed in the previously identified critical input space based on gaussian process surrogate models and a number of different acquisition functions to find the optimal critical operating conditions that minimize the aforementioned KPIs. We apply this framework to the manufacture of plasmid DNA (pDNA), which is a critical raw material for advanced therapeutics, leading to a surge in demand for pDNA for clinical or commercial use. Optimized manufacturing recipes identified with the proposed framework are projected to achieve an up to 170% increase in the batch size and a 34.7% decrease in the OpEx per batch.

**Keywords:** flowsheet optimization, Bayesian optimization, global sensitivity analysis

## 1. Introduction

Plasmid DNA (pDNA) is a carrier of genetic information, which makes it a critical raw material in the manufacturing and delivery of Advanced Therapy Medicinal Products (ATMPs). Some of the main pharmaceuticals that use pDNA include DNA and mRNA vaccines and cell and gene therapies (Gosse *et al.*, 2022). The fast-growing interest in ATMPs has led to a growing demand for the production of pDNA for clinical and commercial use. Scaling up the pDNA manufacturing process to meet current and future demands is one of the major challenges in the cell and gene therapy market (Ohlson, 2020). Simultaneously, pDNA production costs and manufacturing timeframes need to be minimized in an attempt to decrease the cost of goods (COGs) and maximize the production of these innovative products. The pDNA manufacturing process is described by long batch times, high capital, operating and labour expenditures. Nevertheless, pDNA manufacturing is considered a well-known process and limited process development and optimization are observed compared to other similar products such as viral vectors and monoclonal antibodies.

Manufacturers need to develop strategies for the establishment of scalable and cost-effective manufacturing processes that will accelerate the wider adoption of ATMPs. Process systems engineering tools can be employed for the development of (bio)pharmaceutical processes, which mostly rely on batch processes that may not be

operated at optimal conditions (Boukouvala & Ierapetritou, 2013). Techno-economic analysis using flowsheet modelling is an efficient way to verify the feasibility of a process and compare different technologies. In addition, flowsheet optimization can significantly improve process efficiency by identifying the optimal operation conditions that minimise/maximise key performance indicators (Wang *et al.*, 2017), while data-driven techniques can be employed for simulation-based flowsheet optimization (van de Berg *et al.*, 2022).

In this study, we present a framework for (bio)pharmaceutical process flowsheet optimization that utilizes Bayesian Optimization (BO) and variance-based Global Sensitivity Analysis (GSA). GSA is used as means for uncertainty quantification in the flowsheet. This information is utilized to rank variables and decrease the dimensionality of the black-box model that is then optimized with BO. BO is a sample-efficient optimization method that utilizes a probabilistic model to represent the uncertainty in the objective function. The proposed framework is used for the identification of optimal operating conditions in the production of pDNA.

## 2. Materials & Methods

The proposed framework combines techno-economic assessment (TEA), global sensitivity analysis and Bayesian optimization. The underlying algorithm is displayed below:

---

### Algorithm 1 Combined TEA, GSA, and BO.

---

**Start:** Design process and gather process and economic data.

**Input:** Converged flowsheet, an initial set of  $N$  uncertain parameters  $\mathbf{P} = \{p_1, p_2, \dots, p_N\}$  and their acceptable ranges  $[\mathbf{P}_{min}, \mathbf{P}_{max}]$ .

**while**  $threshold \leq S_{T,min}$  **do**

1. *Screening:* Select subset  $n \subseteq N$  of uncertain parameters  $\mathbf{P} = \{p_1, p_2, \dots, p_n\}$ .
2. *Sampling:* Draw 4,096 input samples  $P$  based on Sobol sequence and run the converged flowsheet to obtain the target outputs  $\mathbf{y} = \{y_1, y_2, \dots, y_n\}$ .
3. *GSA:* Compute the total sensitivity indices  $S_T$  based on the RS-HDMR metamodel.

**end while**

**BO initialization:** train  $\mathcal{GP}^0$  with an initial data set  $D_0 = (\mathbf{P}_0, y_0)$

**for**  $i = \text{NumberOfIterations}$  **do**

1. Find  $\mathbf{P}_i$  by optimizing the acquisition function over the  $\mathcal{GP}^i$ , where  $\mathbf{P}_i = \text{argmin}_p u(\mathbf{P}|D_{1:i-1})$ .
2. Run the flowsheet to sample the objective function  $y_i = f(\mathbf{P}_i) + \varepsilon_i$ .
3. Augment the data set  $D_{1:i} = \{D_{1:i-1}, (\mathbf{P}_i, y_i)\}$  and update the  $\mathcal{GP}^i$ .

**end for**

---

### 2.1. Techno-economic Modeling & Global Sensitivity Analysis

A fed-batch production process for pDNA is modelled using SuperPro Designer (Intelligen, Inc) (Ferreira & Petrides, 2021). SuperPro Designer uses built-in process and economic models based on sets of algebraic and differential equations to compute equipment sizes, operation scheduling, CapEx and OpEx. The pharmaceutical pDNA production flowsheet includes cell cultivation, pDNA recovery, purification, formulation and fill & finish as shown in Fig. 1. Information on process and economic parameters and

their proposed accepted ranges are based on literature, cGMP manufacturers, suppliers and expert feedback for the design of the specific process at hand.

Global sensitivity analysis is then performed to quantify manufacturing uncertainty based on the contribution of uncertain input parameters to the output variance of specific KPIs, namely batch size, formulation concentration, throughput, batch time, cycle time, CapEx, OpEx, and production cost. GSA was performed using a SobolGSA (Kucherenko, 2013)-Matlab-Component Object Model (COM)-SuperPro interface with 4,096 quasi-randomly generated samples of the uncertain input variables based on Sobol quasi-random sequence within the pre-defined ranges shown in Table 1. Critical parameters have, for at least one of the KPIs, total sensitivity indices exceeding a user-specified threshold ( $S_{T,min} = 1\%$ ). A higher  $S_{T,min}$  would lead to a lower-dimensional design space but for the purpose of this work, the capabilities of the algorithm are tested for a high-dimensional space. Non-influential parameters are fixed after each global sensitivity run until the algorithm converges and all the critical parameters are identified. The use of GSA enables the ranking of uncertain parameters and therefore dimensionality reduction of the design space by only considering a subset of the most influential inputs.

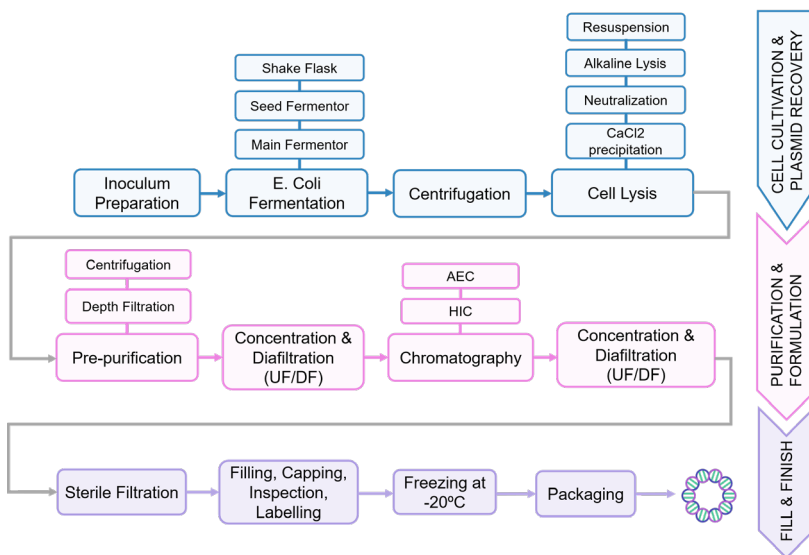

Figure 1. Process flowsheet for the production of plasmid DNA.

## 2.2. Bayesian Optimization (BO)

Once the critical design space has been identified, BO is used to derive the optimal manufacturing recipes. The pDNA flowsheet is treated as a black-box function ( $f(\mathbf{P})$ ) that can be sampled at the critical inputs ( $\mathbf{P} \in \mathbb{R}^n$ ) to obtain the optimal solution ( $\mathbf{P}^*$ ). Gaussian processes (GPs) with zero mean and the Matérn kernel function are used as the surrogate model. GPs are chosen because they can reliably quantify uncertainty and point to unexplored regions of the search space and due to their ability to incorporate prior knowledge into the model (Rasmussen & Williams, 2006). Initially, the GP surrogate is trained with 5 samples based on Sobol sequence and then BO iteratively updates the GP based on adaptive sampling. Adaptive sampling is achieved through the optimization of an acquisition function that can balance exploration versus exploitation. In this work, we test four of the most well-known acquisition functions—probability of improvement (PI),

expected improvement (EI), upper (or lower) confidence bound (UCB or LCB), and max-value entropy search (MES). UCB and LCB are tested for two different confidence values that control the level of exploration. Before the GP is trained, data features are normalized, and data outputs are standardized. The BO part of the algorithm is built using the Python packages PyTorch and BoTorch (Balandat *et al.*, 2020).

### 3. Results & Discussion

The screening for critical parameters considers an initial set of more than 25 parameters including task lengths, conversions, buffer volumes, working volumes, rejection and concentration coefficients, failure rates, etc. The parameters that had an insignificant effect on the output metrics were fixed to their nominal values without adding extra uncertainty to the model. The GSA part of the algorithm was repeated until all remaining parameters were critical. The final subset of critical parameters that are responsible for at least 1% of the output variability for at least one output and their corresponding acceptable ranges are displayed in Table 1.

Table 1. Critical parameters in pharmaceutical pDNA production, their acceptable ranges, nominal values, and optimal values for the maximization of the batch size and the minimization of OpEx.

Input	Process step	Range	Nominal	Optimal <sub>batch-size</sub>	Optimal <sub>OpEx</sub>	Unit
Fermentation duration (seed)	Seed Fermentor	12–30	30	23.25	12	<i>h</i>
Fermentation duration (main)	Main Fermentor	18–40	40	20.75	18	<i>h</i>
Fed-batch medium volume		1.5–4.5	3	2.63	1.5	<i>L</i>
Starting working volume		8.1–24.2	16.1	14.1	8.1	<i>L</i>
Resuspension buffer volume	Resuspension	22.78–68.36	45.57	28.48	22.79	<i>L</i>
Lysis buffer volume	Lysis	22.78–68.36	45.57	28.48	22.79	<i>L</i>
Neutralization buffer volume	Neutralization	22.78–68.36	45.57	28.48	22.79	<i>L</i>
Diafiltration volumes 1	1 <sup>st</sup> UF/DF	10–50	50	42	10	–
Flush volume per filter area 1		1.5–4.5	3	4.12	1.5	<i>L/m<sup>2</sup></i>
Diafiltration volumes 2	2 <sup>nd</sup> UF/DF	10–50	40	43	10	–
Flush volume per filter area 2		0.67–2	1.33	1.17	0.67	<i>L/m<sup>2</sup></i>

The BO algorithm is performed for all critical parameters in a 9-dimensional space. However, the critical parameters are ranked and contribute differently to each output metric. Fig. 2 illustrates the variance as defined by the GSA algorithm by summarizing the first ( $S_i$ ) and second ( $S_{ij}$ ) order sensitivity indices for two of the output metrics. Fig. 3 illustrates the total variance of the two output metrics when all critical inputs are simultaneously varied within their acceptable ranges.

The BO algorithm leads to (a) an increase of 170% in the batch size and (b) a decrease of 34.7% in the OpEx per batch from the nominal points while operating within the acceptable ranges for all critical inputs (Fig. 3). Optimal manufacturing recipes are shown

in Table 1. The nominal point of the OpEx lies far up from the median because the base case flowsheet operates on the upper bounds of the seed and main fermentor task durations.

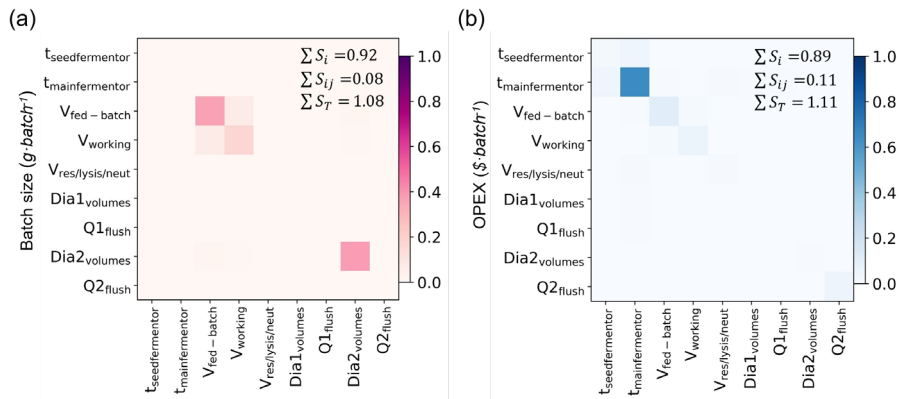

Figure 2. GSA of the nine critical input parameters on the batch size and OpEx for the production of pharmaceutical pDNA. First-order effects ( $S_i$ ) are displayed in the diagonal and second-order effects ( $S_{ij}$ ) are presented in the upper and lower triangular.

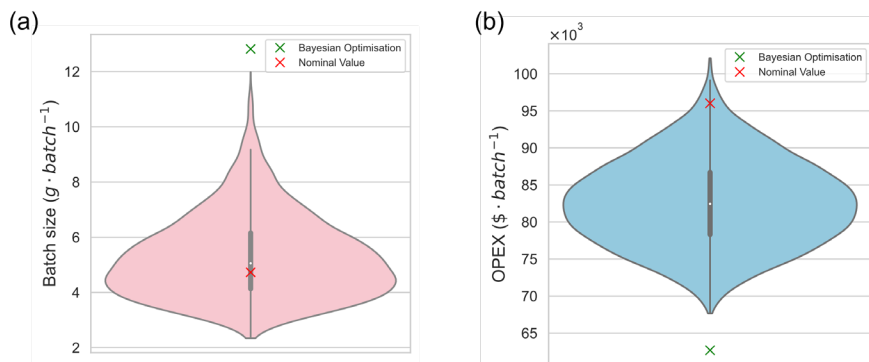

Figure 3. Violin plots for two of the key output metrics. The black bar in the center is the interquartile range, the white dot inside the black bar is the median value, and the black lines stretched from the bar are the lower/upper adjacent values. Bayesian optimization is used to (a) maximize the batch size and (b) minimize the OpEx.

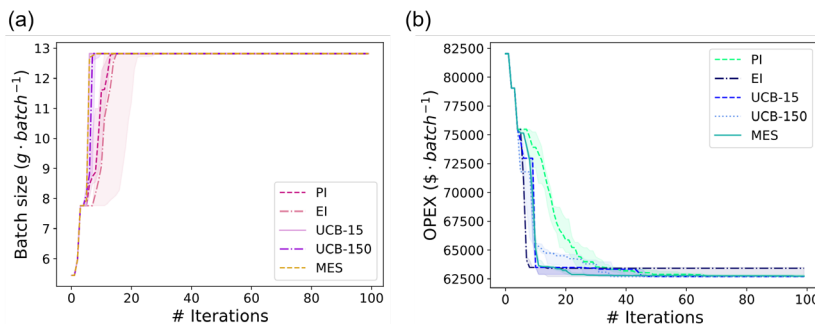

Figure 4. Bayesian optimization progress for different acquisition functions for (a) batch size maximization and (b) OpEx minimization. Plot presents the median and confidence intervals ( $1^{st}$  and  $3^{rd}$  quartiles) from 10 random seeds.

Fig. 4 shows the progress of the BO algorithm for the different acquisition functions for 100 iterations. Most acquisition functions converge to the optimum after a few iterations. In the batch size maximization problem, the best-performing acquisition function is UCB, for both confidence values, resulting in convergence to the optimum in less than 10 iterations. On the contrary, EI performs worse compared to the others, converging after 17 iterations. In the OpEx minimization, MES performs the best, reaching the optimum after 25 iterations, with UCB-150 following at 20 iterations. It can be observed that the algorithm requires more iterations to find the optimum for OpEx because this metric has a wider range of critical variables contributing to the overall variability (Fig. 2).

#### 4. Conclusions

In this work, we present a framework for black-box optimization of simulation-based pharmaceutical processes that relies on the principles of global sensitivity analysis and Bayesian optimization. The case study shows that the proposed algorithm performs reliably well and leads to optimum solutions after a few iterations. We use four different acquisition functions that use different strategies for exploration and exploitation and the algorithm converges in all cases. The right acquisition function for each output metric is key for optimum algorithm performance, with cases of acquisition functions performing differently for different objective functions being observed.

## Abstract

Mathematical modeling is an important tool in chemical engineering. Not only to understand processes, it is also used in many fields such as design and scale-up, process control, optimization, experimental design, trouble shooting, etc. One application in adsorption process is to represent adsorption isotherm. In contrast to the real processes, most of researches studied single-component isotherm. Wastewater from electroplating industry always comprises of several heavy metal ions which are harmful to human and ecosystem. In this work, EDTA modified SBA-15 was used to treat copper, nickel, and chromium ions in multicomponent system. It was found that adsorption of heavy metals preferred higher pH. Moreover, adsorption of nickel ions was very low. The multicomponent isotherm models were applied. The RMSEs (Residual root mean square errors) of Freundlich, Langmuir, extended Langmuir, and modified competitive Langmuir models were 2.02, 3.37, 9.12, and 10.72, respectively.

**Keywords:** adsorption, heavy metals, multicomponent isotherm, EDTA, SBA-15.

## 1. Introduction

The COVID-19 pandemic extremely affected this world. Million people died. Many cities were locked down. Human activities dropped dramatically. This pandemic still had positive impacts such as bluer skies, fewer crimes, lower accidents, better hygiene, stronger relationships, etc. Considering environmental remediation, it was evident that pollution was mainly caused by human. Many pollutants were contaminated in air, water, and soil.

Heavy metals are hazardous pollutants. They are always contaminated in wastewater from electroplating processes. One effective way treating heavy metal ions is adsorption. Adsorbents are the key of adsorption processes. Novel adsorbents are developed and investigated.

Surface modification is used to improve adsorption performance. Silica is favored in adsorbent production because it is easy to adjust its surface and has large surface area. Silica materials can have different pore structures. However, our previous study found that adsorption capacities of modified silica do not depend on pore structure (Pornchuti et al., 2021). As a consequence, SBA-15 was selected in this work since it is convenient

to synthesize. In addition, EDTA was grafted onto SBA-15 surface to catch copper, nickel, and chromium ions in multicomponent system.

Generally, real wastewater contains various heavy metal ions. There are interactions among these ions (Girish, 2017). Consequently, the study of multi-ion adsorption is essential. In case of single ion adsorption, Freundlich and Langmuir models are always chosen for the representation of adsorption isotherm. These two models are simple but in case of multi-ions system they do not include the effect of other ions. For multicomponent system, extended Langmuir and modified competitive Langmuir models were developed to cover their interaction. As a consequence, Freundlich, Langmuir, extended Langmuir, and modified competitive Langmuir models were selected in this study. In summary, this work was set up to study the modeling of competitive adsorption of copper, nickel, and chromium ions onto EDTA modified SBA-15.

## 2. Materials and Methods

### 2.1. Materials

TEOS (Tetraethyl orthosilicate), Pluronic P123, APTES (Aminopropyltriethoxysilane), EDTA disodium salt, ethanol, toluene, HCl, acetic acid, and ammonium hydroxide were purchased from Sigma Aldrich or Merck.

### 2.2. Synthesis of SBA-15

SBA-15 was synthesized by following the method of Naik et al. (2011). In brief, 6.64 g of Pluronic P123 and 13.5 mL of HCl solution were agitated with 202 mL of deionized water. Then 13.86 g of TEOS was dropped into the solution. The mixture was kept for 24 h at 90°C. After vacuum filtration, the solid was washed and dried. SBA-15 was obtained by calcination at 550°C for 3 h.

### 2.3. Integration of amino functional groups

Amino functional group was grafted onto SBA-15 surface by applying the method of Parida and Rath (2009). At first, 2 g of SBA-15 was suspended in 60 mL of toluene. Next, 1.2 mL of APTES was added dropwise. The mixture was refluxed at 110°C for 8 h. The solid was dried after washing with ethanol and deionized water.

### 2.4. Incorporation of EDTA

The method of Repo et al. (2009) was adapted to the incorporation of EDTA. Briefly, 2 g of amine functionalized SBA-15, 5.4 g of EDTA disodium salt, and 42.0 mL of ethanol-acetic acid solution were mixed together. The solid was filtered and washed with ammonium hydroxide solution, ethanol-acetic acid solution, deionized water, and ethanol, respectively. The EDTA modified SBA-15 was received after dried at 105°C.

### 2.5. Multicomponent Adsorption

Normally, multi-ion adsorption experiments were conducted as follows. 100 mg of EDTA modified SBA-15 was shaken in 50 mL of multi-ion solution at 105 rpm for 48 h. The solid was separated by vacuum filtration. The filtrate was analyzed by atomic absorption spectroscopy (AAS). Eq. (1) was applied to calculate adsorption capacity.

$$q_e = \frac{(C_i - C_e)V}{m} \quad (1)$$

$q_e$  is equilibrium adsorption capacity;  $C_i$  is metal concentration at start;  $C_e$  is equilibrium metal concentration;  $V$  is the volume of metal solution;  $m$  is the adsorbent mass. To compare the suitability between models, the RMSE was determined from Eq. (2).

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (q_{i,exp} - q_{i,model})^2} \quad (2)$$

$q_{i,exp}$  is the experimental adsorption capacity of component  $i$  and  $q_{i,model}$  is the adsorption capacity of component  $i$  calculated from the model.

### 3. Results and Discussion

#### 3.1. Effect of pH

The amount of metal ions adsorbed on EDTA modified SBA-15 at various pH was shown in Figure 1. Effect of pH on competitive adsorption was similar to those of single metal adsorption. Metal adsorption was hindered by hydrogen ion at low pH. As a result, the amount of adsorbed metals increased with an increase of pH.

Figure 1. pH Effect.

#### 3.2. Mathematical Modeling

Adsorption isotherm was illustrated as Figure 2. It can be seen that adsorption of nickel ion was very low comparing to copper and chromium ions. It was suppressed by other ions. Other adsorbents were also found this antagonistic effect such as adsorption by amine functionalized SBA-15 (Pornchuti et al., 2022), olive stones, date stones, peat, sphagnum moss, laterite, and bentonite (Girish 2018). Since the amount of nickel adsorbed was low, the mathematical models were applied only with copper and chromium ions.

Although Freundlich and Langmuir models are designed for single component adsorption, their utilization in multicomponent adsorption can be found such as the investigation of Qi and Pichler (2017). Freundlich model can be represented as Eq. (3).

$$q_{e,i} = K_{F,i} C_{e,i}^{1/n_i} \quad (3)$$

$K_F$  and  $n$  are the Freundlich constants, while  $i$  indicates the component. Langmuir model is expressed as Eq. (4).

Figure 2. Adsorption isotherm.

$$q_{e,i} = \frac{q_{m,i} b_{L,i} C_{e,i}}{1 + b_{L,i} C_{e,i}} \quad (4)$$

$q_m$  is the maximum loading and  $b_L$  is the Langmuir constant. The linearized form of both models were applied to compute their parameters and listed in Table 1.

Table 1. Parameters of isotherm models.

Parameters of isotherm models	Cu	Cr
Freundlich isotherm		
$K_{F,i}$	4.1505	23.7739
$n_i$	2.8531	6.8213
Langmuir isotherm		
$q_{m,i}$	26.5252	45.2489
$b_{L,i}$	0.0382	0.6500
Extended Langmuir isotherm		
$q_{m,i}$	23.6173	206.3216
$b_{L,i}$	13.1572	5.9948
Modified competitive Langmuir isotherm		
$q_{m,i}$	97.0874	163.9344
$b_{L,i}$	0.0258	0.0667
$\eta_{L,i}$	5.8333	8.9594

Extended Langmuir model is shown as Eq. (5).

$$q_{e,i} = \frac{q_{m,i} b_{L,i} C_{e,i}}{1 + \sum_{j=1}^N (b_{L,j} C_{e,j})} \quad (5)$$

Total number of ions is represented as  $N$ , while  $j$  indicates the component. The parameters of this model were computed by minimization of the error in non-linear regression analysis and shown in Table 1. Modified competitive Langmuir model can be written as Eq. (6).

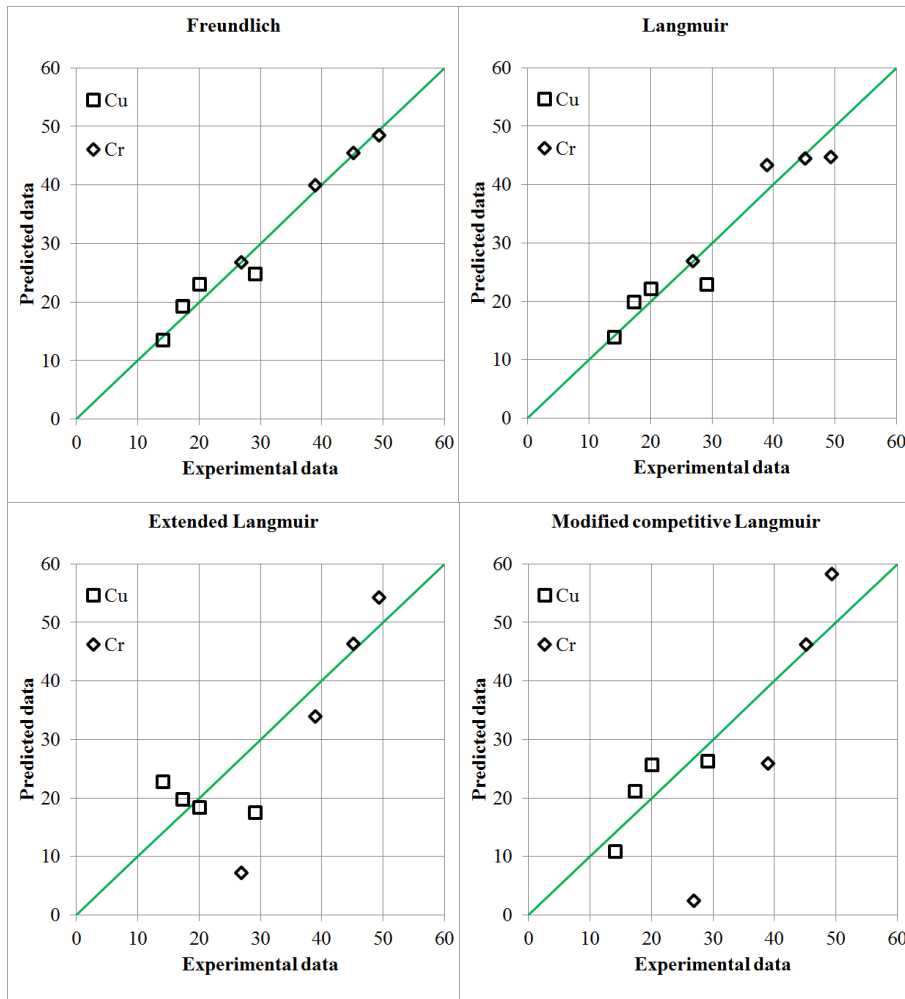

Figure 3. Comparison between predicted adsorption capacities and experimental data.

$$q_{e,i} = \frac{q_{m,i} b_{L,i} (C_{e,i} / \eta_{L,i})}{1 + \sum_{j=1}^N (b_{L,j} (C_{e,j} / \eta_{L,j}))} \quad (6)$$

$q_m$  and  $b_L$  in this model is Langmuir parameters of single-ion adsorption. They were obtained from our previous study (Pornchuti et al., 2021).  $\eta_L$  is interaction factor. They were computed from experimental data of multi-ion adsorption by minimization of the

error in non-linear regression analysis. All parameters of this model were listed in Table 1.

Each isotherm models were utilized to predict adsorption capacities and compare with the experimental data as demonstrated in Figure 3. The RMSEs of Freundlich, Langmuir, extended Langmuir, modified competitive Langmuir models were 2.02, 3.37, 9.12, and 10.72, respectively. It obviously indicated that Freundlich and Langmuir were more appropriate in the representation of experimental data in this case. Many researches illustrated isotherm in 2D like Figure 2 which lead to erroneous interpretation. The concentration of each ion was related to the others. It should be realized that both models cannot explain the effect of other ions. For extended Langmuir and modified competitive Langmuir models, they took the concentration of other ion in the model but gave high RMSEs. This might be caused by the complexity of the models and more observational data were required to improve their RMSEs.

#### 4. Conclusions

Simultaneous adsorption of copper, nickel, and chromium ions onto EDTA modified SBA-15 was conducted. It was figured out that adsorption of these ions favored high pH. Moreover, nickel ion was hindered by other ions. Finally, fitting of Freundlich model was better than those of Langmuir, extended Langmuir, and modified competitive Langmuir models.

## Abstract

This work proposes a systematic methodology based on graphic methods for the conceptual design of simultaneous reactive distillation-extractive distillation processes in one single apparatus (named extractive-reactive distillation). The configuration is useful to overcome azeotropes that reactive distillation alone cannot. A key assumption of the methodology is the use of an entrainer that is part of the components consumed in the reaction (i.e. an auto-entrainer). In the methodology, the analysis of the statics is used to generate a reactive distillation configuration, while an iso-volatility and bifurcation analysis is used to generate an extractive distillation configuration. For the combined system, we propose to extend the analysis of the statics to include the auto-entrainer effect in reactive distillation. The methodology is applied to the production of isopropyl myristate from acid oleochemical streams. A new column configuration that has the potential to reduce additional azeotropic separation units is proposed.

**Keywords:** Reactive distillation; extractive distillation; isopropyl myristate

## 1. Introduction

Reactive distillation (RD) is a well-known method for process intensification. In RD, reactants are fed to a reactive section and the products are separated via distillation in the same apparatus at the same time. In some special cases, however, an RD process may also show an auto-extractive behavior (Coker, 2010), i.e., one of the reactants behaves like an internal mass separation agent (entrainer), so that at least one of the azeotropes in the system is overcome. In such cases, the entrainer is the component with the highest boiling point in the system and does not form azeotropes with the other components. The double functionality reactant-entrainer generates a synergetic effect, which is not always obvious. This effect can be exploited in the synthesis of intensified process configurations that have so far not been reported in the literature. In spite of this potential benefit, available methodologies only consider the reactive phenomena (Almeida-Rivera et al., 2004). This contribution presents a methodology that explicitly takes the auto-extractive behavior into account. The methodology was applied exemplarily on the esterification of fatty acids, e.g., myristic acid (MA), with isopropanol (IPA) to produce isopropyl myristate (I-MA). Besides its auto-extractive behavior, the system is of interest because it can be used for the valorization of acid oleochemical streams, which are an industrial

waste rich in free fatty acids. In these systems, the alcohol (i.e., IPA) forms a minimum-boiling azeotrope with water (W) produced by the reaction (Bock et al, 1997). In addition, the system contains a liquid phase split that is considered during the analysis.

**Table 1.** Methodology outline.

Step	Purpose	Input	Output
<b>Topology</b> (quaternary system)	Determination of the thermodynamic characteristics of the system.	Component boiling points. Thermodynamic model.	Graphical representation of phase equilibria. Residue curves. Characteristic distillation maps.
<b>Analysis of the statics</b> (quaternary system)	Determination of the initial single-feed structure of the RD..	Stoichiometric coefficients. Chemical equilibrium. Residue curves.	Limiting steady states. Trial trajectory. Localization of the reactive zone.
<b>Isovolatility</b> (ternary subsystem)	Determination of the extractive distillation configuration (direct or indirect).	Thermodynamic model.	Locus of the constant relative volatility in the composition space.
<b>Bifurcation analysis</b> (ternary subsystem)	Determination of feasible entrainer flows in extractive distillation	Pinch equations. Initial guess entrainer/feed ratio.	Pinch branches. Pitchfork bifurcation.
<b>Coupled synthesis</b> (quaternary-ternary system)	Determination of the single-feed reactive distillation- extractive distillation configuration	Feasible reactive distillation trial trajectories. Feasible extractive distillation mass balance lines.	Reactive distillation feed composition that matches bottoms composition of extractive distillation in the same composition space. Feasible entrainer to feed ratio

## 2. Methodology

An outline of the proposed methodology is presented in **Table 1**, in which the motivation, the input, and the output of each step is given. The individual steps are described in more detail in the following sections.

### 2.1. Thermodynamic Topological analysis

Most of the graphic methods in distillation begin with a thermodynamic characterization of the systems based on its fixed points and boundaries. The case study in this contribution is a reactive quaternary system: IPA (21,15°C), W (100,00°C), I-MA (314,85°C) and MA (326,20°C). There are four ternary subsystems, from which the subsystem IPA-W-MA presents a residue curve map type 1-0-0 according to the nomenclature reported by Matsuyama et al. (1977). This is the characteristic map of extractive distillation with heavy entrainer and without additional azeotrope formation (Foucher et al., 1991). There are six binary subsystems, one of them with a homogeneous binary azeotrope (IPA-W). The map does not include first-order separatrices (distillation boundaries), but it has a second-order separatrix (geometric) that subdivides the composition space in two subregions with a different saddle node each one. There is a liquid-liquid equilibrium in three of the four ternary subsystems and in the quaternary region near the water node.

### 2.2. Analysis of the statics (AS)

The method is based on the geometric theory of distillation and was recently reviewed by Cardona et al (2020). The AS determines the limiting steady states (LSS) of a reactive distillation system, which are defined as the steady states that maximize the yield of a target product. The AS uses a reactive distillation process model that assumes a) kinetically reversible chemical reaction in the liquid phase, b) an infinitely high separation efficiency ( $\infty/\infty$ ), c) a sufficiently high volume of the reaction zones in the column, and d) catalyst placed anywhere in the column. The AS requires little initial information, such

as the reaction stoichiometry and parameters for the physical and chemical equilibria. The procedure that is followed in the analysis of the statics consists of the following steps. For more details, the reader is please referred to (Cardona et al, 2020) or the original paper by Pisarenko et al. (2001) in which the terms are explained more extensively.

1. *Complete set of steady states* These steady states are lines representing mass balances of distillation columns where for a defined top or bottoms, the conjugated product falls in the boundary of the composition space. Each steady state is determined for a given feed composition and conversion. For a direct arrangement in the production of isopropyl myristate, a representative sample of the steady states is shown in **Figure 1a**.
2. *Limiting steady states based on complete set of steady states.* From the lever rule it is known that the steady states have a corresponding relation of product flows P/W (top flow/bottom flow). This relation depends on conversion and feed composition. By computing P/W as function of the conversion, it is possible to find the LSS. In the case study, the LSS were grouped in the a, b, c, d types shown in **Figure 1b**.
3. *Segregation of LLS based on feasibility criterion of distillation to ensure the occurrence of all chemical species for the separation.* For the case study, only the LSS type “b” were found to be feasible because only this line contains all four components. The other three lie on the ternary sub-planes.
4. *Determination of the reactive distillation process design able to develop the feasible LSS.* For the case study, this is exemplified in **Figure 1c** for the feasible LSS corresponding to a stoichiometric feed composition  $X_F$ . This feed follows a reaction along a stoichiometric line until the feasible steady state is achieved, which is characterized by the conversion,  $\xi$ . For this steady state,  $X^*$  represents the overall composition of the column products in mixture that are joined by a mass balance between the top product  $X_p$  and the bottom product  $X_w$  of the column. A “trial distillation trajectory” (Pisarenko et al., 2001) joins the top and bottoms product of the mass balance. This trial trajectory is a simplified representation of a residue curve starting at the top composition, and therefore it is similar to the trajectory followed by a column with infinite reflux and number of separation stages  $\infty/\infty$ .
5. *Flowsheet synthesis.* The synthesis of the RD flowsheet begins with the definition of the reactive and non-reactive sections of the column. The location of the trial trajectory with respect to the equilibrium defines those profile sections, in which the reaction should be promoted with a catalyst addition. In the case study, the entire trial trajectory lays in a region of the composition space where the presence of catalyst promotes the forward reaction. Consequently, the whole column is a catalytic section, see **Figure 2**.

**Figure 1:** Analysis of the statics for the esterification of myristic acid with isopropanol, a) set of steady states, b) set of limiting steady states, c) trial trajectory for the limiting steady state type b that corresponds to an equimolar feed.

**Figure 2:** Smoothing of the trial trajectory to a residue curve, configuration.

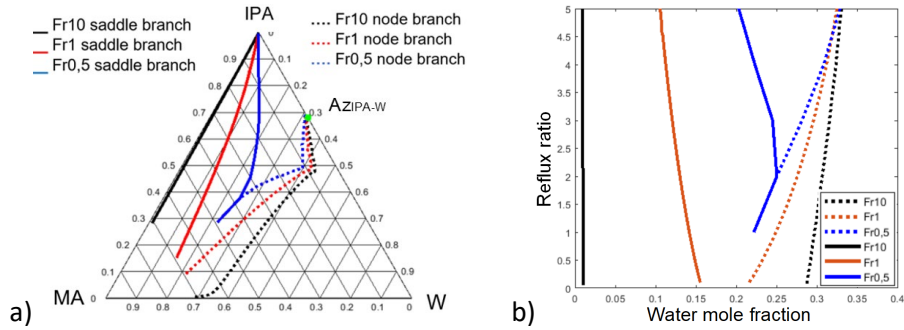

**Figure 3:** Residue curve map (blue lines) for the ternary system IPA-W-MA. Univolatility line (red).

### 2.3. Iso-volatility curve

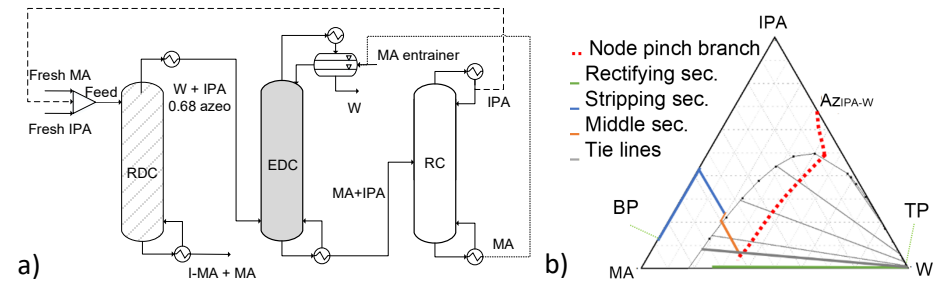

An iso-volatility curve is the locus of the ternary composition space in which the relative volatility of two defined components is constant. The iso-volatility curve of constant value one is a uni-volatility line that starts in the azeotrope composition and ends in one of the opposite edges of the ternary composition space. In the ternary system IPA-W-MA, the univolatility line falls into the edge W-MA, see **Figure 3**. This indicates that the distillate of the extractive distillation column is almost pure water (indirect configuration). Consequently, the bottoms product is a mixture IPA-MA that requires an additional fractionation column for separation. The two-column arrangement is shown in the upper left side of the **Figure 3**. For a given MA/azeotrope feed ratio, it is possible to define a global mass balance and specify all the streams. However, the MA/azeotrope feed ratio is sometimes difficult to obtain and requires the more detailed analysis introduced in the next section.

### 2.4. Bifurcation analysis

A method for the definition of the minimum entrainer flow (minimum MA/azeotrope feed ratio) that is required for separation via extractive distillation was previously proposed by Knapp et al. (1994). The method is based on the bifurcation analysis of the pinch branches of the middle section in an extractive distillation column. The bifurcation analysis observes the behavior of the middle section pinch branches with respect to small additions of entrainer. Thus, the minimum amount of entrainer is determined with the help of the phenomenon called “pitchfork”, which precedes a strong change in the topology of the pinch branches (please refer to Figure 14 presented by Knapp et al. (1994) for a visualization of this behavior). For the ternary system IPA-W-MA, different additions of entrainer generated the pinch branches changes shown in **Figure 4**. For an entrainer-to-feed ratio  $Fr=0.5$ , **Figure 4** shows that the end points of the pinch branches have achieved a reflux ratio of zero, and even with more additions of entrainer it is not possible to find the pitchfork phenomena. This indicates that for the case study, extractive distillation alone is not feasible because it is not possible to find a continuous profile joining the stripping-middle section to the rectifying section of the column in absence of the pitchfork phenomena (see **Figure 5,b**). However, if the rectifying section is replaced by a top decanter as is shown in **Figure 5a**, the LLE helps to join the top product water in a heterogeneous extractive distillation column profile (**Figure 5,b**). As the bottom product is mainly a mixture of IPA-MA, it is possible to separate this mixture and send the IPA back to the RDC and the MA to EDC (**Figure 5a**).

**Figure 4:** a) Pinch branches at entrainer to feed ratios of 0.5, 1 and 10; b) reflux ratio along the pinch branches

**Figure 5:** a) Heterogeneous extractive distillation column (EDC) with recovery column (RC) to overcome the azeotrope formed in the reactive distillation column (RDC) in **Figure 2**. b) Composition profiles of the EDC (BP=Bottom product; TP=top product).

2.5. Coupled system

Both the reactive distillation and the extractive distillation can be represented in the same quaternary composition space. Assuming the top product of the extractive column is almost pure water, it is possible to plot a mass balance line that starts at the water vertex and ends in the binary edge IPA-MA, see **Figure 6a**. As the bottom composition of the EDC is similar to the feed composition of the RDC, they can be recirculated, and with this, the recovery column is not necessary anymore, see **Figure 6b**. The bottoms binary composition depends on the amount of entrainer that has been added in the extractive distillation column, but this amount can be varied to achieve different stoichiometric lines in the reactive column.

**Figure 6:** a) Representation of the overall extractive distillation mass balance and a feasible reactive distillation steady state, b) corresponding flowsheet.

### 3. Results and discussion

Based on the proposed methodology, the coupled arrangement showed in **Figure 6** reduces one of the columns in the **Figure 5** (the RC). On the other hand (see **Figure 6**), as the bottoms product of the EDC is similar to the RDC feed, and the top product of the RDC is similar to the EDC feed, the two totally integrated configurations shown in **Figure 7a** and **b**, are proposed. The main difference between both configurations is the IPA feed location in the reactive section (RS). When the feed stage is located above the reactive section (**Figure 7a**), the section is a single-feed reactive section and follows the behavior of a reactive residue curve. Such a behavior limits the quality of the products because the I-MA falls in a saddle node, and therefore it cannot be obtained as pure component. This drawback is avoided by feeding the alcohol at the bottom of the reactive section (**Figure 7b**). In this case a double-feed reactive section is generated (the section is defined by the location of the catalyst) and, in analogy to extractive distillation, the area of possible products is expanded.

**Figure 7:** a) Extractive distillation with reactive stripping, b) reactive distillation with extractive rectification.

### 4. Conclusions

A method for designing an auto-extractive reactive distillation column has been presented. This method contributes to synthesis of configurations able to overcome azeotropes that reactive distillation alone cannot. The method was applied for the esterification of myristic acid with isopropanol. It was demonstrated that this system presents an auto-extractive phenomenon. Given the heterogeneous nature of such phenomenon, a decanter was considered by the methodology. An extension of the analysis of the statics was presented to include the auto-extractive phenomenon. The analysis was used to generate a process flowsheet that avoids the use of a secondary column in the recovery of the auto-entrainer. The extended analysis of the statics was also used to propose a configuration with a two-feed, heterogeneous, auto-extractive reactive distillation that ensures pure product streams. To our understanding, this configuration has not been proposed in previous studies for the production of IMA. A reduction in capital and energy cost is expected with the new configuration.

## Abstract

This work presents a stochastic capacity and production planning model for network environments with multiple stages and shared manufacturing lines. Network-wide capacity decisions are modelled under uncertainties in demand and objective function coefficients with uncorrelated capacity expansions. A framework is presented for evaluating the model under uncertainty and it is applied to a case study from pharmaceutical manufacturing. First, the relevant uncertainties are defined through a sensitivity analysis and their effects on the optimal capacity decisions are explored. A sensitivity analysis of the input distributions is used to systematically study the required locations and total expansion amounts subject to different means, standard deviations, trends, and distribution types for the relevant uncertain demands. It is shown that capacity requirements are underestimated when the uncertainties are not considered, and that uncertainty sets with larger demand volatilities lead to larger capacity expansions.

**Keywords:** Capacity expansion, production planning, stochastic programming, sensitivity analysis

## 1. Introduction

Capacity planning (CP) is essential to ensure the long-term ability to deliver medicines and increase revenues from exclusive sales. Most pharmaceuticals are made in multi-stage processes where intermediates are produced for storage and each manufacturing line can produce multiple products. As such, production planning (PP) details should be considered in the CP problem to describe the allocation of time on shared manufacturing lines and the inventories of all materials (Marques et al. (2020)). Capacity decisions are resource intensive and irreversible, so the decisions should be made while considering relevant parameter uncertainties. An early work used 2-stage stochastic programming to define which new facilities to construct in a single-stage environment under clinical trial uncertainty (Levis & Papageorgiou (2004)). C. M. Marques et al. (2018) used Monte Carlo Simulations to find candidate process designs for a simplified flowsheet which were passed on to a second model that decided the optimal design per period for each product. Uncertainties in clinical trials and product demands were considered. Vieira et al (2020) applied a 2-stage stochastic programming model for design and scheduling of multiproduct plants under demand uncertainty to achieve a trade-off between profits and financial risk. Chou et al. (2014) used a dynamic programming model to determine capacity requirements subject to uncertain demands with constant trends and different

volatilities. They conclude that higher demand volatilities increase the capacity requirements for problems with demand satisfaction. Sensitivity and uncertainty analysis can be used to identify how individual parameter uncertainties affect the model output, which is the sensitivity analysis problem, or what uncertainty in the model outputs can be expected subject to an uncertain input space, which is the uncertainty analysis problem (Saltelli et al. (2019)). Different methods have been developed to consider uncertainties directly in optimization models (Gabrel et al. (2014)) but even if a representation of uncertainty is considered that representation might itself be uncertain. This work therefore studies the effects of different uncertainty sets on the here-and-now capacity decisions to provide a recommendation on where and how much to expand capacity.

### 1.1. Problem Statement

The engineering context for the problem is defined as follows: a company wants to determine the required capacity expansions in its manufacturing network to provide a tradeoff between inventory risk and expansion cost. The studied system is a general network with multiple stages and multiple lines on each stage. Each line can produce a set of materials with given initial capacities. The goal is to determine the location and amount of capacity expansion as well as material inventory profiles subject to uncertain demands and capacity expansion costs. The company policy requires that the inventories be maintained above the safety level and as close to the strategic level as possible. Capacity expansions for different materials are assumed independent with costs defined through economies of scale.

## 2. Methodology

### 2.1. Model

The developed model follows the state-task-network (STN) structure (Kondili et. al (1993)) that has been expanded to include variable capacities and uncertainty through its formulation as a stochastic program. The main variables are inventory for material  $m$  at time  $t$  in scenario  $s$ ,  $I_{mts} \in \mathbb{R}^{\geq 0}$ , safety inventory violation,  $B_{mts} \in \mathbb{R}^{\geq 0}$ , inventory distance above/below the strategic inventory,  $I_{mts}^+/I_{mts}^- \in \mathbb{R}^{\geq 0}$ , manufacturing amount of task  $i$  on line  $j$ ,  $P_{ijts} \in \mathbb{R}^{\geq 0}$ , fractional time allocation  $W_{ijts} \in \mathbb{R}^{\geq 0}$  and the choice of capacity level  $n$ ,  $Y_{ijn} \in \{0,1\}$ . The allocation variable from the original STN has been relaxed and a variable capacity has been added to choose the required capacity level  $\kappa_{ijn}$  through the binary variable  $Y_{ijn}$  for all task-line combinations under demand and cost coefficient uncertainties. Capacity decisions are modelled as here-and-now variables that are chosen once for each task-line combination across all scenarios and time periods. This approach assumes independent capacity upgrades or in other words no synergies between capacity expansions. The PP details are wait-and-see variables under the assumption that the production scheduling on each line can be modified based on realized demand.

$$\text{minimize } C^I + C^r \quad (1)$$

$$I_{mts} = I_{m,t-1,s} + \sum_{i \in I_m^+} \sum_{j \in J_i} \rho_{im}^+ P_{i,j,t-\tau_i,s} - \sum_{i \in I_m^-} \sum_{j \in J_i} \rho_{is}^- P_{i,j,t-\tau_i,s} + B_{mts} - B_{m,t-1,s} - \delta_{mts}, \forall mts \quad (2)$$

$$\sigma_{mt}^{sfty} \leq I_{mts}, \quad \forall mts \quad (3)$$

$$1 - \frac{I_{mts}}{\sigma_{mt}^{strat}} \leq I_{mts}^-, \quad \forall m \in \mathbf{M}_p, ts \quad (4)$$

$$\frac{I_{mts}}{\sigma_{mt}^{strat}} - 1 \leq I_{mts}^+, \quad \forall m \in \mathbf{M}_p, ts \tag{5}$$

$$\sum_{i \in \mathbf{I}_j} \sum_{n \in \mathbf{P}_{ij}} \sum_{t'=t}^{t-\tau_i+1} W_{ijt'ns} \leq 1, \quad \forall jts \tag{6}$$

$$P_{ijts} \leq \sum_{n \in \mathbf{P}_{ij}} \kappa_{ijn} W_{ijtns}, \quad \forall j, i \in \mathbf{I}_j, ts \tag{7}$$

$$\sum_{n \in \mathbf{P}_{ij}} Y_{ijn} \leq 1, \quad \forall j, i \in \mathbf{I}_j \tag{8}$$

$$\sum_{t \in \mathbf{T}} W_{ijtns} \leq Y_{ijn} |\mathbf{T}|, \quad \forall j, i \in \mathbf{I}_j, n \in \mathbf{P}_{ij}, s \tag{9}$$

$$\sum_{m \in \mathbf{M}_p} \sum_{t \in \mathbf{T}} B_{mts} = 0, \forall s \tag{10}$$

$$C^I = \sum_{s \in \mathbf{S}} \alpha_s \sum_{m \in \mathbf{M}_p} \sum_{t \in \mathbf{T}} I_{sts}^+ v_m^{I+} + I_{sts}^- v_m^{I-} + B_{mts} v_m^{I,bl} \tag{11}$$

$$C^R = \sum_{j \in \mathbf{J}} \sum_{i \in \mathbf{I}_j} \sum_{n \in \mathbf{P}_{ij}} Y_{ijn} v_{ij}^{cb} \kappa_{ijn} v_{ij}^{ce} \tag{12}$$

The objective function is defined in Eq. (1) as the minimization of costs for inventory and capacity expansion. Eq. (2) sets the inventory balance with slack variables to allow inventories to go below the safety level in Eq. (3). Eqs. (4-5) define the distance below/above the strategic safety level. Eq. (6) limits the maximum allocation to each line, Eq. (7) constraints the maximum production based on the chosen capacity level, Eq. (8) ensures that only one capacity level is chosen, and Eq. (9) forces all capacity allocations for capacity levels not chosen to 0. Eq. (10) ensures that safety violations are only possible for products. Eq. (11) defines the inventory cost for not being at setpoint with three terms for being either above/below the strategic inventory or below the safety inventory. Individual parameters are used to define their relative importance where it generally applies that  $v_m^{bl} > v_m^{I-} > v_m^{I+}$ . Finally, Eq. (12) defines the capacity expansion cost through a sum of individual capacity expansions in which an economy of scale exponent  $v_{ij}^{ce}$  is used to ensure that few larger expansions are preferred over many small expansions.

### 2.2. Uncertainty Treatment

The model uses an uncertainty set composed of discrete scenarios for demands, base capacity costs and economy of scale exponents as input. Its solution provides here-and-now CP decisions which are shared across all scenarios and wait-and-see PP decisions for each individual scenario. The demands are time series, and the cost factors depend on the required changes to achieve a given capacity expansion. The available information on the cost factors depends on the amount of work that has been carried out to investigate expansion possibilities while for demands, both the levels, trends and volatilities are uncertain. In this work a 4-step solution framework is used: (1) baseline deterministic model solution with an uncertainty set of one scenario with expected values for all parameters, (2) sensitivity analysis of the deterministic model with different single-scenario uncertainty sets to determine parameters for further analysis, (3) baseline stochastic programming solution for an uncertainty set with scenarios sampled from expected parameter distributions, (4) sensitivity analysis of the stochastic program with different uncertainty sets sampled from different parameter distributions to provide recommendations in the presence of incomplete distribution information. Scenarios are created by combining samples from each parameter distribution. For demands, a sample is drawn for each time point and Figure 1 shows 100 example paths created by

independent and identically distributed samples from a normal distribution with mean 1 and standard deviation 0.2. The paths with highest, lowest, and median mean demands are highlighted and the right plot shows the distribution of mean demands, which approaches normal distribution as sampling number increases.

Figure 1: Demand paths (left) and mean demand distribution (right)

### 3. Case Study

The proposed model is applied to a case study abstracted from a real pharmaceutical manufacturing network consisting of three stages with three lines on the first stage, five lines on the second stage and two lines on the third stage. Six products are produced, and the total number of materials is 14. The time horizon is 10 years divided in a discrete yearly time grid. Capacity expansions of 0%, 10% or 20% were allowed.

#### 3.1. Baseline Deterministic Solution

The baseline deterministic model solution was created by solving the stochastic program with the nominal scenario. In this case, no capacity expansions are required.

#### 3.2. Sensitivity Analysis of Deterministic Model

The sensitivities to product demands were tested by sequentially solving the deterministic model with demands increased by a factor 10% or 20% at all time points for one product at a time. No demand decreases were tested as no capacity expansions were seen in the baseline solution and lower demands require less capacity. The sensitivities to the capacity base cost  $v_{ij}^{cb}$  and the capacity exponent  $v_{ij}^{ce}$  were tested by varying them around their nominal point for each demand increase of each product. Table 1 shows the total capacity expansion for each combination of increased demand and cost parameters. The results show relevant demand uncertainties for products B, C and F. Both capacity cost uncertainties are relevant for demand increases of 20%.

Table 1: Total capacity expansion requirement for increased demand of each product and different cost parameters (change from nominal value given in parenthesis)

Demand Factor	Capacity Base cost	Capacity Exponent	Product demand varied					
			A	B	C	D	F	G
	$v_{ij}^{cb}$	$v_{ij}^{ce}$	<b>Total capacity expansion, %</b>					
+10%	150	0.8	0	10	10	0	0	0
+10%	125 (-25)	0.8	0	10	10	0	0	0
+10%	175 (+25)	0.8	0	10	10	0	0	0
+10%	150	0.7 (-0.1)	0	10	10	0	0	0
+10%	150	0.9 (+0.1)	0	10	10	0	0	0
+20%	150	0.8	0	10	20	0	0	0
+20%	125 (-25)	0.8	0	10	20	0	10	0
+20%	175 (+25)	0.8	0	10	20	0	0	0

+20%	150	0.7 (-0.1)	0	40	20	0	10	0
+20%	175 (+25)	0.9 (+0.1)	0	10	20	0	0	0

3.3. Baseline Stochastic Programming Solution

Without specific distribution information, the costs were assumed uniformly distributed with the bounds from Table 1 and the demands for products B, C and F at each time point were created by multiplying the nominal demand  $\delta_{mt}^{nom}$  with a sample from a uniform distribution with a lower/upper bound of 0.8/1.2. An uncertainty set with 100 equiprobable scenarios was created by random sampling, and the stochastic program was solved which resulted in no capacity expansions. Also, the deterministic model was solved for each scenario, giving in an average total expansion of only 2.4% distributed over two different product-line combinations which indicates that capacity expansions might be achieved through optimizations of the existing process and equipment.

3.4. Sensitivity Analysis of Uncertain Parameter Distributions

A sensitivity analysis was carried out on the demand distributions to identify locations in scope for capacity expansions and to test the robustness of the recommendations. A computational study with 54 uncertainty sets was defined with variations along the demand dimensions of distribution type  $D$  (uniform, normal), base level  $\mu$  (1.0, 1.1, 1.2), standard deviation  $\sigma$  (baseline, +25%, +50%) and trend  $\psi$  (1.0, 1.01, 1.02). The demand in each period was created as  $\delta_{mts} = \delta_{mt}^{nom} \cdot \psi^t \cdot D(\mu, \sigma)$  and the stochastic program was solved for each uncertainty set while the deterministic model was solved for each scenario in each set. Figure 2 shows the total capacity expansion for each uncertainty set based on the overall mean and standard deviation of all the uncertain demands combined. Higher mean demands require larger expansions and the middle region for mean demands is affected by larger demand volatilities. The uniform and normal distributions produce similar results although larger expansions are needed in three cases for uniformly distributed demands. The deterministic model results are comparable to those of the stochastic model, but for some of the uncertainty sets it underestimates the capacity expansion due to its larger flexibility which contrasts with its higher capacity increase in section 3.3. Now, larger capacity expansions are preferred by the stochastic program to benefit the high demand scenarios while lower demand scenarios will experience overcapacity. The effect of demand trends at a given base demand can be seen by comparing the three points on the upward diagonal starting from any point with mean demand in the set (1.0, 1.1, 1.2). As such, demand trends become important if the base demand level is also increased.

Figure 2: Total capacity expansion for uniform (o) and normal (x) demands at different means and standard deviations. Stochastic model (left) and deterministic model (right).

The model determines the locations that should be expanded, and we suggest to use this information to guide investigations into optimization or retrofit projects. Table 2 shows

the frequency of expansion choices based on the 54 uncertainty set solutions of the stochastic program. Table 2 shows that five lines may require capacity expansions if demand increases are realized, and it provides the product on that line that is relevant to expand. Naturally, an expansion for one product on a line might affect the other products as well but this interaction can be included in subsequent solutions of the provided model.

Table 2: Frequency of expansion size choice across parameter combinations

Line	A1	A2	B4	C1	C2
Product	B	C	F	B	C
0%	0.57	0.44	0.67	0.19	0.13
10%	0.0	0.26	0.17	0.37	0.37
20%	0.43	0.3	0.17	0.44	0.50

#### 4. Conclusion and Perspectives

A stochastic programming model was presented to determine the location and size of capacity expansions under uncertainty. A framework was used to find and explore the input uncertainties that influence the capacity decisions. The relevant parameters were determined through sensitivity analysis of a deterministic model. Then, a sensitivity analysis of the stochastic program with uncertainty sets from different distributions was used to study the decisions subject to incomplete distribution information. The framework was applied to a case study which shows that the capacity expansion is underestimated by the deterministic model and that higher demand volatilities increase the expansion need at moderate demand increases. Generally, the same expansion was needed regardless of the distribution type but in some cases, the requirements were larger for uniformly versus normally distributed demands. The proposed framework can be used to identify where to expand capacity to meet long-term demand given limited information on the input uncertainties. As such, the results can be used to identify the need for retrofit and optimization projects as well as determine which product demands that should be monitored more closely since their increase will require capacity expansions.

## Abstract

A comprehensive trickle bed reactor model for simulation purposes was developed in this work. As an industrially relevant case study, the model was applied on selective sugar oxidation to sugar acid on gold catalyst extrudates. The obtained results revealed that the maximum conversion for extrudates is only 25% for a reactor length of 0.5 m and diameter of 1 cm, which is due to slow mass transfer inside the catalyst layer and external mass transfer limitations. Variation of the residence time and the reactor length revealed that a reactor length of 2m minimum is required to achieve complete conversion of the sugar (arabinose) to the corresponding sugar acid (arabinonic acid).

**Keywords:** Trickle Bed Reactor, Oxidation, Extrudates, gProms, Dynamic model.

## 1. Introduction

Trickle bed reactors (TBR) are continuous packed beds where liquid moves in downwards through a catalyst packing whereas gas can move either in a downward or upward direction (Lange et al., 2004). These reactors are solid-gas-liquid contacting devices in which the gas-liquid stream is in continuous contact with the catalyst particles (Hamdan and Abdullah, 2022). Trickle beds are the classical workhorses of chemical industry: in fact these reactors have been used extensively in a wide range of chemical industries from petro-chemical and refinery processes such as hydrodesulfurization and hydrogenation, to the oxidation of biomass and organics in wastewaters, volatile organic compound abatement in air pollution control, enzymatic reactions and bio-methanation (Aleksandrov et al., 2022; Dudukovic et al., 1999; Jønson et al., 2022), in addition to the oxidation of sugar (glucose) (Diallo et al., 2017; Tsukamoto et al., 1982). Trickle beds offer several advantages: simplicity in operation, flexibility for a variety of materials, high catalyst loading per unit volume, and low capital and operating costs as well as lower energy consumption and higher gas conversion rate and higher productivities compared to tank and bubble column reactors (Klasson et al., 1992; Li et al., 2013; Ranade et al., 2011). In contrast to slurry reactors, trickle beds enable safe continuous operation, whereas slurry reactors are in practise limited to batch and semibatch operation.

In this work, the goal was to develop a general and comprehensive trickle bed reactor model, and use it to study the catalytic oxidation of arabinose on gold based catalyst extrudates. The model can be used as framework for the simulation of various reaction

systems as well as a tool to assist process design, scale-up and life cycle assessment for arbitrary reaction systems carried out in trickle beds.

## 2. Materials and methods

The trickle bed reactor model was developed to be as general as possible. The concentration profiles inside the reactor tube and within the catalyst particles were computed by solving simultaneously the mass and energy balances of the components including rate equations (kinetic laws) as well as semi-empirical correlations for pressure drop and fluid dynamics. It was assumed that all the reactions take place inside the catalyst particles only, therefore the rate term is present only in the mass balance of the solid phase, and the active metal of the catalyst is assumed to be distributed evenly inside the catalyst particles. The kinetics of sugar oxidation from batch experiments (Herrero Manzano et al., 2021) was used as an input for the model and realistic values of physical properties were selected. The most essential parameters are summarized in Table 1.

Table 1. List of parameters that characterize the simulation

Parameters	Value	Unit	Parameters	Value	Unit	Parameters	Value	Unit
$\rho_{cat}$ : Catalyst density	400	Kg/m <sup>3</sup>	Reactor radius	5	cm	Reactor length	0.5	m
$\rho_L$ : Density of liquid phase	950	Kg/m <sup>3</sup>	CO <sub>2</sub> S :saturation concentration of O <sub>2</sub>	0.103	mol/m <sup>3</sup>	Effective diffusivity ( $D_{eff}$ ) of O <sub>2</sub>	2.403 10 <sup>-9</sup>	m <sup>2</sup> /s
m(O <sub>2</sub> ): Molar mass	32	g/mol	$Pe_G$ : Péclet number of gas phase	100		$k$ : rate constant	53.99	m <sup>6</sup> /(s mol.kgcat)
$\sigma_{H_2O}$ : Water surface tension	72.8 10 <sup>-3</sup>	N/m	$Pe_L$ : Péclet number of liquid phase	10		Effective diffusivity ( $D_{eff}$ ) of Arabinose	2.474 10 <sup>-9</sup>	m <sup>2</sup> /s
$\eta_{H_2O}$ : Water viscosity	0.2 10 <sup>-3</sup>	Pa s	Effective diffusivity ( $D_{eff}$ ) of arabinic acid	9.851 10 <sup>-9</sup>	m <sup>2</sup> /s	Arabinose diffusivity in water ( $D_L$ )	4 10 <sup>-8</sup>	m <sup>2</sup> /s
$a^*$ :limiting activity factor	0.47282							

## 2.1. Mass balances

The mass balance of the gas-phase components displayed in equation (1) affirm that the accumulation term is the sum of gas-liquid mass transfer with a negative sign, axial and radial dispersion alongside the convection terms (Russo et al., 2015).

$$\frac{\partial C_{i,g}(t,z,r)}{\partial t} = \frac{-k_{i,L}a}{\varepsilon_G} (C_{i,L}^* - C_{i,L}) - \frac{\partial(u_G(z,r)C_{i,g}(t,z,r))}{\varepsilon_G \partial z} + D_{z,g}(z,r) \frac{\partial^2 C_{i,g}(t,z,r)}{\partial z^2} + D_{r,g}(z,r) \left( \frac{\partial^2 C_{i,g}(t,z,r)}{\partial r^2} + \frac{1}{r} \frac{\partial C_{i,g}(t,z,r)}{\partial r} \right) \quad (1)$$

The liquid-phase mass balance equation is shown in equation (2): the accumulation is the sum of gas-liquid mass transfer term with a positive sign in opposition to the gas phase, in addition to the convection and axial and radial dispersion terms, and finally the mass transfer flux from/to the solid catalyst phase as represented in the last term.

$$\frac{\partial C_{i,L}(t,z,r)}{\partial t} = \frac{k_{i,L}a}{\varepsilon_L} (C_{i,L}^* - C_{i,L}) - \frac{uL}{\varepsilon_L} \frac{\partial(C_{i,L}(t,z,r))}{\partial z} + D_{z,L} \frac{\partial^2 C_{i,L}(t,z,r)}{\partial z^2} + D_{r,L} \left( \frac{\partial^2 C_{i,L}(t,z,r)}{\partial r^2} + \frac{1}{r} \frac{\partial C_{i,L}(t,z,r)}{\partial r} \right) - \frac{s D_{eff,i}}{\varepsilon_L R_p} \frac{\partial C_{i,s}(t,z,r,r_p)}{\partial r_p} \Big|_{r_p} = R_p \quad (2)$$

For the solid catalyst phase, the concentration field depends on the effective diffusivity, catalyst shape factor and the holdups of the liquid and solid phases. Moreover, the reaction term is included comprising the catalyst density, ratio of holdups, stoichiometric coefficients and reaction rate, as shown in equation (3) below.

$$\frac{\partial C_{i,s}(t,z,r,r_p)}{\partial t} = \frac{D_{eff,i}}{\varepsilon_p} \left( \frac{\partial^2 C_{i,s}(t,z,r,r_p)}{\partial r_p^2} + \frac{s}{r_p} \frac{\partial C_{i,s}(t,z,r,r_p)}{\partial r_p} \right) + \rho_{cat} \sum (\vartheta_{i,j} r_j(t,z,r,r_p) \frac{\varepsilon_L}{\varepsilon_p}) \quad (3)$$

## 2.2. Physical properties and reactor parameters

The liquid viscosity, which is required to calculate the Reynolds number, was included in the model, the correlation adopted in equation (4) was based on arabinose hydrogenation experiments (Sifontes Herrera et al., 2016) and taken into account the dependence of the viscosity on both temperature and arabinose concentration ( $x_a$ ).

$$\eta_{fluid} = 10^{-3} \exp \left( \frac{1.54x_a}{T_{in,L}-273} + 3.81 \cdot 10^{-4} x_a^2 - 1.10 \cdot 10^{-2} x_a - 2.85 + \frac{194}{T_{in,L}-273} - \frac{3890}{(T_{in,L}-273)^2} \right) \quad (4)$$

The gas-liquid mass transfer coefficient is taken into account in the mass balance as shown previously in equations (1) and (2). The equation 6 adopted from Ranade et al. (2011) was used in this study.

$$k_L a(z,r) = \gamma 0.45 \left( \frac{DL}{dK^2} \right) (X_G(z,r))^{0.65} ReL^{1.04} WeL^{0.26} ScL^{0.65} \left( \frac{\alpha sp dK}{1-\varepsilon_p} \right)^{0.325} \quad (5)$$

The axial dispersion coefficient was calculated by using the Péclet number as shown in equations (7) and (8), while the radial dispersion coefficient was taken equal to one third of the axial one as shown in the equations (9) and (10) as has been reported previously

(Russo et al., 2015). According to our previous work by (Durante et al., 2014; Kilpiö, 2013) the order of magnitude of the liquid phase Péclet number was 2-10, while for the gas phase the Péclet number can go up to 100. For numerical simulations, the Péclet number for liquid-phase was taken 10 and for the gas phase 100.

$$Dz = uL \cdot \frac{L}{Pe} \quad (6) \qquad DzG(z, r) = uG(z, r) \cdot \frac{L}{PeG} \quad (7)$$

$$Dr = \frac{Dz}{3} \quad (8) \qquad DrG = \frac{DzG(z, r)}{3} \quad (9)$$

The shape factor is evaluated by equation (10) proposed by Salmi et al., (2019), where  $V_p$  and  $A_p$  are respectively the volume and surface area of the catalyst particle.

$$s = 1 + R_p \frac{A_p}{V_p} \quad (10)$$

### 2.3. Kinetics of the case study

The case study is the selective oxidation of arabinose to arabinic acid on gold catalyst (Herrero Manzano et al., 2021; Kusema et al., 2012, 2010). The kinetics has been described by classical Langmuir-Hinshelwood rate expression as shown in the equations (12) and (13). The kinetic expression and parameters values were adapted from the work of Herrero Manzano et al. (2021).

$$r(t, z, r, r_p) = a^2 \frac{K(t, z, r, r_p)C_{O_2, s}(t, z, r, r_p)C_{Ar, s}(t, z, r, r_p)}{1 + K_{Ar, s}C_{Ar, s}(t, z, r, r_p) + K_{O_2, s}C_{O_2, s}(t, z, r, r_p)} \quad (13)$$

The model equations were implemented in the software gPROMS, which was chosen due to its high convergence speed and its user-friendliness: In fact, in this case study the convergence time was in order of 5-10 minutes. The partial differential equations (PDEs) describing the mass balances (1)-(3) were converted to ordinary differential equations (ODEs) by discretization of the radial and axial coordinates with finite differences. A stiff differential equation algorithm was used for solving the ODEs, the initial value problem.

## 3. Results and discussion

The obtained results are summarized in Figure 1. The simulations reveal that the maximum conversion for the catalyst extrudates at the reactor output is only 25% for a reactor length of 0.5 m and diameter of 1 cm, which can be due to slow mass transfer inside the catalyst particles but also the existence of external mass transfer limitations, which can be surmounted by using smaller particle sizes, slurry reactor technology or structured catalysts, such as monoliths or solid foams. The results show that the radial position is not affecting the sugar conversion as illustrated by Figure 1, where the conversion is practically the same for various radial positions across the reactor tube, in contrast to the axial position, where the sugar conversion increases as the length of the reactor increases.

Figure 1: Conversion rate at various axial (left) and radial (right) positions

In order to increase the conversion, the residence time and the reactor length were varied and the conversion at the reactor outlet was computed as displayed in Figure 2, which confirms that a reactor length of 2m minimum is required to achieve complete conversion of the sugar (arabinose) to the corresponding sugar acid (arabinonic acid).

Figure 2: Effect of Simultaneous increase of reaction time and length of the reactor on the Conversion Rate (left). Conversion rate at the outlet of the scaled-up reactor (2m) (right)

The obtained results demonstrate quite interesting modelling stability that might pave the way to the investigation of the scale-up of various reaction systems, although more accurate simulations would require further kinetic and flow experiments using trickle bed reactors.

## Abstract

This work presents the implementation of the Ergun force term on the DualSPHysics code, to simulate flow in porous media using a representative element volume (REV). In the study of microscopic seepage and fluid-solid interactions, a typical approach is a pore-scale simulation due to its precision; however, it involves a high computation cost, making it more suitable to adopt the REV scale. Here are presented nine simulations comparing the velocity, at the outlet of the system, obtained by a pore-scale geometry and the Ergun force term and REV simulations using SPH. The results have a good fit between the pore-scale simulations and the Ergun force term simulations, where the lowest and highest errors are  $2.92 \times 10^{-3}$  and  $1.43 \times 10^{-2}$ , respectively. These results present novel and alternative simulations in the study of the flow in porous media using the SPH method where the pore-scale geometry is usually used.

**Keywords:** Porous media, SPH, Ergun force, CFD.

## 1. Introduction

Smoothed particle hydrodynamics (SPH) is a fully Lagrangian particle method introduced by Lucy (1977). Since then, due to its ease of implementation and flexibility, the method has spread into numerous branches of computational physics and engineering. SPH has a Lagrangian nature making enabling simulations of complex systems that would be very difficult to carry out with the use of more conventional grid-based schemes. In SPH, the discretization is carried out by computing an interpolating kernel function that uses the properties of the surrounding particles over the studied one to compute its physical properties. Due to the characteristics of discretization in SPH, the dynamic of the fluid volume element is controlled by the local variations of pressure and density, making it possible to simulate the direct inclusion of boundaries, treatment of the free surface, and recently the treatment of multiphase flows. SPH can be used in several branches of science, including the flow in porous media (Tartakovsky et al., 2007; Kunz et al., 2015; Klapp et al., 2022), which presents a great interest to the industry due to its connection with crude oil extraction, the dynamics of flow in aquifers, agricultural irrigation

processes, and into materials that can be used as filters. In general, the dynamic of fluid is controlled by the principles of conservation of momentum, energy, and mass. These differential equations do not allow analytical solutions for this kind of problem, which opens the way for the introduction of numerical simulations as a tool for prediction. In the case of flow in porous media, Darcy's Law has been widely used, when the Reynolds number is small. This equation, obtained through experimental measurements, approximates the behavior of the fluid in the porous media, using empirical relationships that associate the permeability of the medium and geometric variables. The purpose of this work is to extend the empirical relation of Darcy and provide a more accurate representation of flow in porous media. To do this, the Ergun term was added to the movement equation, which includes a friction expression and allows for the quantification of the pressure drop and energy required for pumping the flow, (Ergun, 1952). A novel SPH model was developed to simulate flow in porous media, making use of the Ergun force term in the momentum equation. The model avoids the need to depict the internal shapes of the porous media in the simulation and instead uses parameters that describe the media's specifications. This enables the simulation of large length scales and provides a better understanding of the internal flow in porous media. The work is structured as follows: Section 2 presents the complete SPH numerical model. Section 3 validates the velocity profile in a Poiseuille flow. Section 4 compares numerical cases to demonstrate the effectiveness of using the Ergun force term in the momentum equation. Finally, the conclusions of the work are presented in Section 5.

## 2. The SPH Numerical Model

Smoothed Particle Hydrodynamics (SPH) is a meshless Lagrangian method that recently has been applied to simulate a wide range of applications within the field of Computational Fluid Dynamics.

For viscous incompressible flows, the governing equation is the Navier–Stokes expressed in SPH form as

$$\frac{d\mathbf{v}_a}{dt} = - \sum_b m_b \left( \frac{p_a + p_b}{\rho_a \rho_b} + \Gamma \right) \nabla_a W_{ab} + \mathbf{g} \quad (1)$$

where  $\rho$  is the density,  $p$  pressure,  $\mathbf{v}$  is the velocity vector,  $W$  is the kernel function,  $\mathbf{g}$  is the gravity acceleration and  $\Gamma$  is the viscosity dissipative term. In a standard SPH formulation, where the pressure is given as a function of the density, local variations of the pressure gradient may induce local density fluctuations in the flow. Therefore, flow is modelled by an artificial fluid that is slightly compressible. The particle mass remains constant and only is associated with density fluctuations. Such density fluctuations are calculated by solving the continuity equation expressed in Eq. (2). The dynamical pressure  $p$ , is calculated using the relation expressed in Eq. (3).

$$\frac{d\rho_a}{dt} = \sum_{b=1}^N m_b (\mathbf{v}_a - \mathbf{v}_b) \cdot \nabla_a W_{ab}, \quad (2)$$

$$p = p_0 \left[ \left( \frac{\rho}{\rho_0} \right)^\gamma - 1 \right] \quad (3)$$

where  $\gamma=7$ ,  $p_0 = c_0^2 \rho_0 / \gamma$ ,  $\rho_0$  is a reference density, and  $c_0$  is the sound speed at the reference density.

The viscous stress tensor  $\Gamma$  is described using the laminar viscosity model and the Sub Particle Scale (SPS) model, proposed by Darlympe & Rogers, (2006) and reported in the DualSPHysics code as

$$\Gamma_{ab} = \sum_b m_b \left( \frac{4v_0 \mathbf{r}_{ab} \cdot \nabla_a W_{ab}}{(\rho_a + \rho_b)(r_{ab}^2 + \eta^2)} \right) \mathbf{v}_{ab} + \sum_b m_b \left( \frac{\tilde{\tau}_{ab}^j}{\rho_b^2} + \frac{\tilde{\tau}_{ab}^i}{\rho_a^2} \right) \nabla_a W_{ab}, \quad (4)$$

where  $v_0$  is la kinematic viscosity and  $\tilde{\tau}_{ab}^j$  is the shear stress.

In the field of fluid dynamics in porous media, numerical simulations are a crucial tool for predicting fluid flow behavior. When conducting these simulations, two scales are typically considered: the pore scale and the Representative Elementary Volume (REV) scale. Pore-scale simulations provide more accurate results and have an advantage in the study of microscopic seepage and fluid-solid interactions. However, they are computationally expensive and not feasible for large systems, such as those of an oil reservoir. In these cases, REV-scale simulations are the more practical option, despite their limitations in terms of accuracy.

Since the geometry of the porous media is not used in the REV-scale simulations, the porous media are modeled by adding the resistance term in the momentum equation (Eq. 5), and the interaction of the solid matrix with the fluid is out of consideration, which reduces the computation time.

$$\frac{d\mathbf{v}_a}{dt} = -\sum_b m_b \left( \frac{p_a + p_b}{\rho_a \rho_b} + \Gamma \right) \nabla_a W_{ab} + \mathbf{g} + \frac{\mathbf{F}_a}{m_a}. \quad (5)$$

The Ergun formula is widely used to calculate the additional resistance term due to its simple form, which is

$$\mathbf{F} = -\frac{\epsilon v}{K} \mathbf{v} - \frac{\epsilon F_e}{\sqrt{K}} |\mathbf{v}| \mathbf{v}, \quad (6)$$

where  $\mathbf{v}$  is the velocity vector,  $v$  is the viscosity of the fluid;  $K$  is the permeability of the porous medium,  $\epsilon$  is the porosity and  $F_e$  is a structure-function, the parameters shown in Eq.(6) are reported in detail by Lai et al., (2020).

In this work, Eq. (6) is applied in the last term of Eq. (5) by particle, for the cases of a REV scale. The implementation was performed using version 5 of the DualSPHysics code (Dominguez et al., 2022).

### 3. Validation test.

The SPH model presented in section 2 is validated with the simulation of the Poiseuille flow which has an analytical solution. The SPH numerical results are compared with the analytical solution of the system. For this case was considered the geometry shown in Figure 1, where the distance between plates is 1 mm and the length is 5 mm. The properties of the fluid are according to the liquid water,  $\rho = 100\text{kg/m}^3$ ,  $\nu = 1 \times 10^{-6} \text{ Pa*s}$ , and the particles have an acceleration of  $1 \times 10^{-4} \text{ m/s}^2$  in the right direction. This case was simulated with different resolutions changing the initial distance between particles  $dp = 0.1, 0.05, 0.025, \text{ and } 0.01 \text{ mm}$ . The velocity profiles obtained from the numerical results using the model reported in section 2 and their comparison with the analytical solution are shown in Figure 1. The errors (RMSE) for each simulation are reported in Table 1 where is clear that the error decrease when the resolution is increased.

Figure 1. The left figure represents the dimensions and boundary conditions for the Poiseuille flow simulation, and the right one the velocity profiles for the different initial distances between particles ( $dp$ ).

Table 1. Root mean square error between the numerical results and the analytical solution in the validation test cases.

$Dp$ (mm)	0.1	0.05	0.025	0.01
RMSE	$1.01403 \times 10^{-6}$	$4.04818 \times 10^{-7}$	$1.10592 \times 10^{-7}$	$5.28235 \times 10^{-8}$

### 4. Comparative cases.

The pore-scale simulations were conducted in 2D with porosities of 0.55, 0.44, and 0.3, represented by three different arrays of circles named square, diagonal, and random (as shown in Figure 2). A total of 9 study cases were carried out. The porous media were inserted in the center of a rectangular channel with dimensions of 10 cm x 5 cm. The inlet boundary was located at the left side of the channel and was set to a constant velocity profile (as shown in Figure 2). The outlet boundary was located at the right side of the channel, where the velocity value of the particles was computed (as shown in Figure 2). The top and bottom boundaries were no-slip boundary conditions, using the dynamics particle method described in (Crespo et al., 2007). The fluid was characterized with the same parameters used in the validation case, with an initial particle distance of  $dp = 0.001$  mm for all cases reported in this section. In the simulations using the Ergun Force, the geometry of the porous media was changed to a rectangular section (as shown in Figure 2) and the Ergun force (Eq. 6) was imposed in the momentum equation (Eq. 4), while maintaining the same parameters and channel dimensions as the pore-scale simulations.

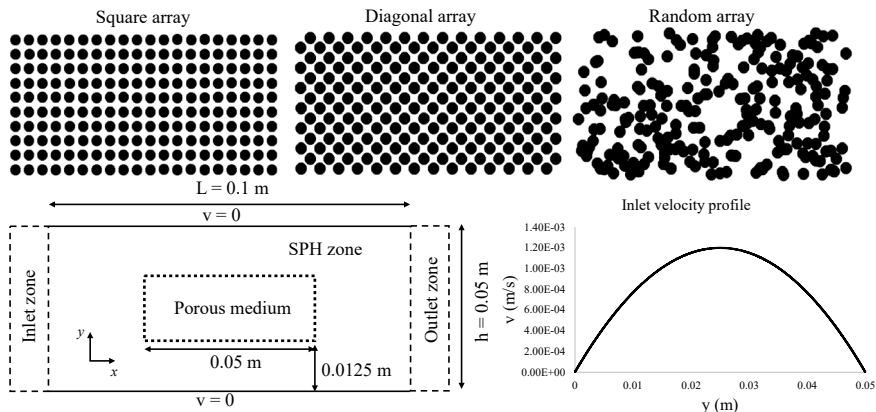

Figure 2. The three different left arrays, shown an example of the PM used for each porosity value. Right frame: at top is shown the geometry used for all cases, and the bottom is the inlet velocity profile.

The velocity profiles at the outlet obtained in the pore-scale and REV scale were compared to prove the accuracy of the Ergun force to represent the flow in different porous media. The velocity fields obtained from both scale simulations are shown in Figure 3, only for the case with  $\epsilon = 0.55$  and the random array, both results are very similar in qualitative analysis. The quantitative fit was obtained using the velocity profiles at the outlet shown in Figure 4 for all cases. Here, the root-mean-square error (RMSE) is used as the error of the models. RMSE is a measure of accuracy, typically used to compare forecasting errors of different models for a particular dataset and not between datasets, as it is scale dependent. The results presented in Figure 4 have very similar profiles, between the simulations carried using the Ergun force term and those using the porous geometry for different porosities and geometries. The error between the profiles shown in Figure 4 are reported in Table 3. The errors reported in Table 3 are two order of magnitude less than the maximum velocity shown in Figure 4 for all cases.

Figure 3. Comparison of the velocity field between the pore-scale and REV simulations: left frame pore-scale, right frame Ergun force.

Figure 4. Velocity profiles comparison for all cases reported in the section 4.

Table 2. Root mean square error between the numerical results and the Ergun force term simulations.

	$\epsilon = 0.33$	$\epsilon = 0.44$	$\epsilon = 0.55$
RMSE (Squared)	$2.84 \times 10^{-5}$	$3.82 \times 10^{-5}$	$4.36 \times 10^{-5}$
RMSE (Diagonal)	$3.20 \times 10^{-5}$	$5.23 \times 10^{-5}$	$5.77 \times 10^{-5}$
RMSE(Random)	$3.19 \times 10^{-5}$	$5.12 \times 10^{-5}$	$5.91 \times 10^{-5}$

## 5. Conclusions.

In this work was implemented the Ergun force term in the momentum equation using the Smoothed Particle Hydrodynamics (SPH) method. The implementation was validated through a Poiseuille flow simulation and a comparison of the numerical results with the

analytical solution. Additionally, a convergence test was conducted and the error between the numerical and analytical data decreased as the resolution increased, reaching a minimum error of  $5.28235 \times 10^{-8}$  in the simulation with a particle distance of 0.01 mm and 501501 total particles. The results demonstrate the successful implementation of the Ergun force using the DualSPHysics code. Comparing the pore-scale and REV simulations, the velocity profiles at the outlet were similar, with a maximum error of  $5.91 \times 10^{-5}$  in the case of a porosity of 0.55 and the random array and a minimum error of  $2.84 \times 10^{-5}$  in the case of a porosity of 0.3 and the square array. The square geometry resulted in better emulation of the Representative Elementary Volume (REV) area, with a lower error in all cases, due to the similarity of the squared area to the area where the Ergun force is applied. The error increased with the porosity, but further simulations with a wider range of porosities are necessary to confirm the proper application of the Ergun force in porous media simulations.

## Abstract

Driven by global targets to reduce greenhouse gas emissions, energy systems are expected to undergo fundamental changes, and the proportion of electricity and hydrogen may greatly increase. Scenarios analysis based on optimal planning is beneficial to exploring how this growth affects the structure of an energy system, whilst at the same time reducing costs, better fulfilling the carbon emission target and ensuring energy security. This study sets two groups of different scenarios based on share of electricity and hydrogen in end use respectively, and uses China Regional Energy Supply System Optimization Model (CRESOM) as an analysis tool. China is chosen as a case study due to the large scale, complex structure, fast growth rate, strict yet changing emissions constraints of its energy system. Results show that with an increase in electrification rate, cumulative carbon dioxide emissions over a certain planning horizon could reduce, at a priced of increased unit reduction cost. By increasing the share of electricity and hydrogen in the end use from 71% to 80% in 2060, the unit carbon reduction cost rises by 17%. Increasing share of hydrogen could move the carbon emissions peak time by approximately five years.

**Keywords:** Scenarios analysis; Low-carbon transition; China; Electricity; Hydrogen

## 1. Introduction

Low carbon development has become a worldwide consensus, but the task is arduous. Fossil energy is still the main part of the global energy consumption. According to BP's scenario forecast (BP, 2020), the proportion of fossil energy will drop from 84% (2018) to 21.7% (2050) to achieve near zero emissions. The global energy system is expected to undergo a profound low-carbon transition inevitably. In the next 30 years, with the promotion of decarbonization of the energy system, the end use of electricity and hydrogen could grow significantly (BP, 2020). Therefore, it is necessary to conduct research to get guidance such as determining the transition objectives and reducing the total cost in the transition process.

At present, there are many studies on transition of the energy system. Dai et al. (2016) built two scenarios from the perspective of renewable development, and assessed the impact of large-scale renewable development on economy and environment by 2050. Guo et al. (2017) established the LoMLoG model, gave the most likely scenario in the future, proved the importance of the goal of clean energy for reducing carbon emissions in the power sector and promoting the use of renewable energy. Guo et al. (2021) conducted scenario analysis on building energy consumption, taking China as a case, and pointed out that the carbon peak time is expected to be 2020-2035. Duan et al. (2021) compared

the results of various models, pointed out that China will reduce carbon emissions by 90% with the target of 1.5 °C under the scenario of policies, explained the importance of negative emission technology in the future. Zhang et al. (2022) set different scenarios, analyzed the contribution of emission reduction measures in different periods, and analyzed the uncertainty of key parameters.

However, previous studies paid little attention to the impact of the increase in the end-using electricity proportion and end-using hydrogen proportion in the energy system. Ignoring these two factors may well leads to unclear description of energy substitution process, so it is necessary to consider in the setting of scenarios.

Based on the existing optimization model, this study analyzes the impact of the increase in the end use of electricity and hydrogen in the transition of energy structure by setting different scenarios.

The structure of this paper is as follows. The methodology will be introduced in Section 2. The case study and the results will be introduced in Section 3, and Section 4 is the conclusions.

## 2. Methodology

Scenario analysis based on optimization model is chosen as a method. Through scenario analysis, we can get some valuable transition guidance for countries with fossil energy as the main energy.

### 2.1. The introduction of CRESOM

The model used in this study is China Regional Energy Supply System Optimization Model (CRESOM) developed by Tsinghua-BP Clean Energy Research and Education Center, which is mainly used for the optimal planning of energy supply system under the given low-carbon transformation strategy.

The main inputs of the model include the historical data used to describe the current energy supply and demand and infrastructure construction, prospective data used to describe future economic growth, energy intensity and energy technology cost, scenario data used to describe the emission reduction policies and carbon policies.

The model first calculates the energy demand by category of each terminal energy department in each region from 2016 to 2060 through the terminal energy demand forecasting model, then the final planning scheme is obtained by minimizing the total cost through the power-thermal system optimization model.

The output data includes the forecast of the future and the planning scheme at different stages. The structure of the model is shown in Figure 1.

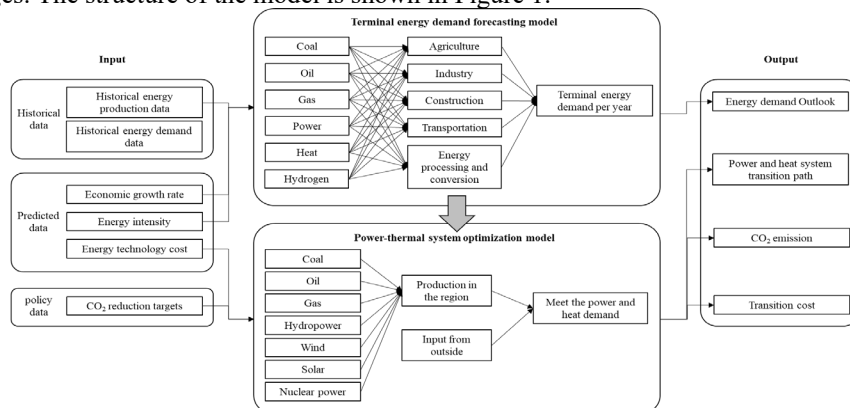

Figure 1. The structure of CRESOM

2.2. Scenario setting

This study focuses on the impact of electricity and hydrogen in the process of energy transition, and constructs two groups of scenarios. One is the high proportion electricity scenario, the other one is high proportion hydrogen scenario. The relevant settings of the scenarios are shown in the tables below.

Table 1. The setting of high proportion electricity scenario

Scenario	EH65	EH68	EH71	EH74	EH77	EH80
End-using electricity proportion in 2060 (%)	55	57.5	60.1	62.6	65.2	67.7
End-using hydrogen proportion in 2060 (%)	10	10.5	10.9	11.4	11.8	12.3
Total proportion (%)	65	68	71	74	77	80

Table 2. The setting of high proportion hydrogen scenario

Scenario	H12	H15	H18	H21	H24	H27	H30
End-using electricity proportion in 2060 (%)	65	62	59	56	53	50	47
End-using hydrogen proportion in 2060 (%)	12	15	18	21	24	27	30
Total proportion (%)							77

3. Case Study

As the largest developing country in the world, China’s energy structure needs to be transformed pressingly, thus its energy transition research is essential. This study takes China as a case to study the impact of the increase of end-using electricity and hydrogen proportion on the energy system through multi scenario calculations, aiming to provide guidance for its transition and provide experience for other countries with fossil energy as the main energy source.

3.1. High proportion electricity scenario results

3.1.1. Total emissions and system costs

As shown in Figure 2A, the carbon emissions show a decline after reaching the peak in 2025, and the promotion of electrification makes the carbon emissions decline faster.

The *costyear* is the sum of the costs of all subsystems each year, as shown in Eq. (1). The *costyear* increases by 26.4% in 2060 (EH65 to EH80), mainly due to the large-scale energy substitution in 2040-2060 (Figure 2B).

$$costyear = costyear_c + costyear_o + costyear_g + costyear_h + costyear_e \tag{1}$$

The *cost<sub>CUTCRC</sub>* (Cumulative Unit Transition Carbon Reduction Cost) is shown in Eq. (2). The molecular part is the total cost of all scenarios compared with the scenario without energy substitution policy. The denominator part is the carbon dioxide reduction of all scenarios compared to the scenario without energy substitution policy. It reflects the cost performance of the system's carbon reduction.

$$cost_{CUTCRC} = \frac{\sum_{2020}^{2060} costyear_{EH} - \sum_{2020}^{2060} costyear_{BAU}}{\sum_{2020}^{2060} CO_{2BAU} - \sum_{2020}^{2060} CO_{2EH}} \tag{2}$$

As the end-using electricity proportion increases, the  $cost_{CUTCRC}$  continues to rise, especially when the total proportion is greater than 74%, where the proportion of end-using electricity in EH80 is 6% higher than that in EH74, but the  $cost_{CUTCRC}$  is 17% higher. Therefore, excessive promotion of electrification leads to a decline in the emission reduction cost performance.

Figure 2 Changes in carbon emissions and system costs under the high proportion electricity scenario. (A) Total carbon emission. The darker the color, the higher the end-using electricity proportion. The following figures are the same. (B)  $cost_{year}$ . (C)  $cost_{CUTCRC}$ .

### 3.1.2. Power supply structure

Non fossil power shows a significant increase, as shown in Figure 3A. The EH80 (2060) and the EH65 (2060) have increased by 9.3 times and 8.5 times respectively compared with 2020. For fossil power, the capacity of fossil power remains stable from 2020 to 2040, and declines after 2040 (Figure 3B). However, with the increase of end-using electricity proportion, the installed capacity of fossil power declines slowly. In 2060, fossil power installations are dominated by coal power with CCS and gas power with CCS, which mainly play a peak shaving role. This phenomenon indicates that the rising non fossil power installations lead to the growth of power fluctuations. From the perspective of cost, the fossil power installation with CCS brings more construction costs and operating costs than the non fossil power installation, thus it brings an increase in the system cost of unit power generation (Figure 3C), and this cost of EH80 is 20.3% higher than that of EH65.

Figure 3: Changes in power supply structure under the high proportion electricity scenario. (A) Non fossil power installations capacity (B) Fossil power installations capacity (C) System cost of unit power generation

3.1.3. High proportion hydrogen scenario results

3.1.4. Total emissions and system costs

Under the setting of high proportion hydrogen scenario, the sum of end-using electricity and hydrogen proportion among different scenarios is the same, so there is little difference in carbon emission trajectory and annual system cost close to 2060. The difference in results is mainly reflected in the advance of peak year due to the increase of hydrogen (Figure 4A) and the change of total accumulated cost ( $cost_{TAC}$ ). The expression of  $cost_{TAC}$  is as follows:

$$cost_{TAC} = \sum_{2020}^{2060} (cost_{year_c} + cost_{year_o} + cost_{year_g} + cost_{year_h} + cost_{year_e}) \quad (3)$$

The  $cost_{TAC}$  of H15 decreased by 0.5% compared with H12, while the  $cost_{TAC}$  of H30 increased by 2.7% compared with H12 (Figure 4B). From the perspective of cost performance of emission reduction. The  $cost_{CUTCRC}$  increases first and then decreases with the increase of hydrogen, it shows that both lower and higher end-using hydrogen proportions have good emission reduction cost performance.

Figure 4: Changes in carbon emissions and system costs under the high proportion hydrogen scenario. (A) Carbon emissions. (B)  $cost_{TAC}$  (C)  $cost_{CUTCRC}$

3.1.5. Power supply structure

The installed fossil capacity shows a decline after a steady change in time (Figure 5A). With the increase of hydrogen, the decline time of the fossil capacity is advanced. The decline time of H12 is 2046, while the decline time of H30 is 2025. At the same time, the decline speed of the scenario with a higher hydrogen proportion is relatively slow. A higher hydrogen proportion means a higher demand for wind power and photovoltaic installation (Figure 5B). The installed capacity in H12 (2060) and H30 (2060) has increased by 15.76 times and 20.15 times respectively compared with that in 2020.

Figure 5: Changes in power supply structure under the high proportion hydrogen scenario. (A) Fossil capacity. (B) Non fossil capacity. (C) Operating hours of coal power. (D) Energy storage capacity

The operating hours of coal power decrease in advance with the increase of hydrogen (Figure 5C), which means that hydrogen promotes the transition of coal power from the main power generation energy to the energy with peak shaving function. This advance also shows that the development of hydrogen in 2030-2050 brings a large number of wind power and photovoltaic installation that need a large amount of energy storage for peak shaving (Figure 5D). From 2050 to 2060, it can be seen that electric energy storage decreases with the increase of hydrogen in the last ten years. Therefore, the increase of hydrogen causes the increase of energy storage pressure from 2030 to 2050, but the decrease of electricity reduces the energy storage pressure from 2050 to 2060.

#### 4. Conclusions

Based on CRESOM, this study reveals the impact of electricity and hydrogen on the low-carbon transition of energy supply system through multi scenario calculations.

Under the high proportion electricity scenario, the promotion of electrification can promote the reduction of carbon emissions, whilst excessive promotion of the end-using electricity proportion brings about an increase in the  $cost_{CUTCRC}$ , this also means the reduction of the cost performance of emission reduction the system. The higher non fossil power installations capacity, the higher the demand for peak shaving. Therefore, more fossil power with CCS is retained, but system cost of unit power generation rises.

Under the high proportion hydrogen scenario, the increase of hydrogen brings forward the peak year of carbon. For  $cost_{CUTCRC}$ , both lower and higher end-using hydrogen proportions have good emission reduction performance. The increase of wind power and photovoltaic installation brought about by the increase of hydrogen demand has led to more peak shaving demand. Fossil energy has changed to peak shaving energy in advance, and the demand for energy storage has increased in advance.

## Abstract

The low-carbon transition pathway of the power sector, especially thermal power plants is significant for reducing greenhouse gas emissions worldwide. Carbon capture and storage (CCS) technology is identified as a critical decarbonization technology, especially in a thermal power-dominated power system. Previous studies have focused on the potential of CCS in low-carbon transformation of large-scale coal-fired power plants, but rarely considered the fact that many thermal power plants locate far from suitable CO<sub>2</sub> storage places, which may lead to deviations in the CCS potential. To quantify the application potential of CCS technology in power sector at a regional level, a long-term power generation expansion planning model is proposed in this paper, featuring detailed technical and economic characteristics of various source–sink matching options, retrofitting options and carbon emission constraints, which can get the optimal planning for thermal power plants with CCS. The power supply system of China is selected as a case study, due to its large capacity and relatively young average life of thermal power plants. Results show that with consideration of source–sink matching, technically and economically viable capacity of power plants that can be retrofitted with CCS can be reduced by 50 percent with a more concentrated distribution in North China.

**Keywords:** Carbon capture and storage; Coal-fired power plants; Source–sink matching; China

## 1. Introduction

The decarbonization of power sector is decisive to tackle climate change challenge. Carbon emissions from electricity and heat generation sector account for 40 % of global energy-related carbon emissions, and the share of electricity in energy consumption will keep rising in the future (IEA, 2019). Besides, the power sector is projected to attain carbon neutral or even negative carbon emissions earliest among all sectors, due to its higher concentration of carbon emissions and more advanced carbon emission reduction technologies (Zhang et al.,2013).

Carbon capture and storage (CCS) technology is identified as a critical decarbonization technology, especially in a thermal power-dominated power system, for the reason that CCS is the only technology choice to achieve net-zero emission of fossil energy. If the large fleet of existing thermal power plants, especially coal-fired power plants are not retrofitted with carbon capture and storage (CCS) technologies, they will

retire earlier than designed lifetime, which will bring about high stranding cost (Zhang et al., 2021). Besides, when penetration of renewable energy becomes high, more flexibility is needed to ensure the reliability of the power supply (Chen et al., 2021). CCS technology is an important technical choice for coal-fired and gas power stations to participate in balancing the fluctuation of renewable energy in the carbon-neutral power system (Xiao et al., 2022).

Many researchers have studied the potential of CCS from the perspective of power sector development and carbon emission constraints. In the Intergovernmental Panel on Climate Change (IPCC) Special Report on Global Warming of 1.5°C, it is proposed that CCS technology plays an important role in the three scenarios with a 1.5°C target (IPCC, 2018). For the power industry, CCS can contribute 14% of the emission reduction by 2050 (IEA, 2017). However, these studies pay little attention to the fact that many thermal power plants locate far from suitable CO<sub>2</sub> storage places, which may lead to rather high costs for transportation and storage of CO<sub>2</sub> (Wei et al. 2021). The lack of CCUS source-sink matching constraints will lead to deviations in the CCS potential.

Relevant studies rarely focus on CCUS source-sink matching compared with other topics, such as cost and investment evaluation (Fan et al., 2020). Wang et al. (2020) proposed a source-sink matching model for optimal CCUS deployment in China's existing coal power plants to achieve the 2 °C target, and found 175 GW coal-fired power plants need to be retrofitted with CCS under the 2 °C constraint. Fan et al. (2020) evaluated the deployment potential of CCUS in existing coal-fired power plants by a high precision CCUS source-sink matching model. However, these studies on CCUS source-sink matching lack consideration of the whole power system development, such as the power supply mix and the scale of power transmission.

To address the research gap, a long-term power generation expansion planning model with source-sink matching options is proposed, which can give the optimal planning of thermal power plants with CCS with the overall consideration of power sector development and source-sink matching constraints. Seven scenarios are set to quantitatively analyze the impact of source-sink matching constraints on coal power development.

The structure of this paper is as follows. Section 2 introduces the methodology, section 3 introduces the case study and its results, and section 4 is the conclusion.

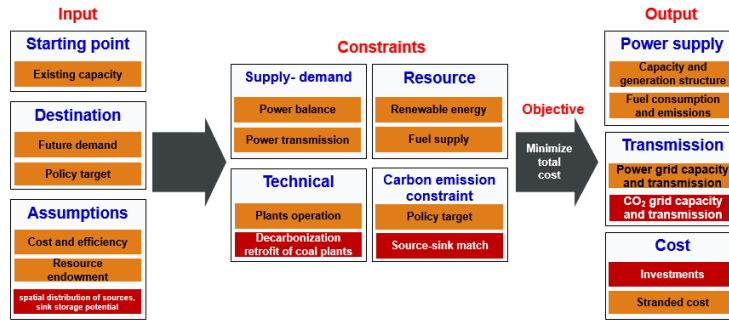

## 2. Methodology

### 2.1. Model structure and assumptions

The long-term power generation expansion planning model with source-sink matching options proposed here aims to optimize long-term planning both for power systems and CCS. The model structure is shown in Fig.1. The input part includes the existing installed capacity, costs, and efficiency of different power generation technologies, predicted future power demand, policy target, and resource endowment of renewable energy and fossil fuels. The constraints can be divided into four parts: (1)the balance of power supply and demand; (2)the potential of each energy source; (3)the technical factors of power plants; (4)the carbon target. The model objective is to minimize the total system cost in the planning horizon. The output can provide the power supply mix, power, and CO<sub>2</sub> transmission, the annual investment. Among them, the spatial distribution of sources, sink storage potential and the cost of CO<sub>2</sub> transport cost constitute the regional source-sink matching options, which will get the distribution of CCS technology and the transmission of CO<sub>2</sub>.

The model includes sixteen different power generation technologies: Sub and super-

critical coal power plants (SPC), Ultra-supercritical coal power plants (UPC), Sub and super-critical coal power plants with CCS(SPCC), Ultra-supercritical coal power plants with CCS(UPCC), Sub and super-critical coal-biomass co-firing power plants with CCS(SPCCOCCS), Ultra-supercritical coal-biomass co-firing power plants with CCS(UPCCOCCS), Natural gas combined cycle(NGCC), Nuclear(NU), Hydropower(HD), Wind onshore(WD), Wind offshore(WDOFF), Centralized solar photovoltaic(PV), Distributed solar photovoltaic(PVDIS), Biomass(BE), Biomass with CCS(BECCS). Among them, coal-fired power plants and natural gas combined cycle power plants can be retrofitted with CCS or decommissioned earlier than the anticipated lifetime, and all power plants with CCS will be constrained by source-sink matching. The model is a multi-regional model that includes 17 regions based on resources and grid structure. It also takes into account short-term planned cross-region transmission lines. Each year in the planning horizon is split into 24 time slices in the temporal module, with

four typical days for each season.

Fig.1 Model structure

## 2.2. Mathematical formulation

The six subscripts (t, r, b, g, f, s) are set respectively to cover different dimensions (year, region, basin, technology, fuel type, and time slice) for the parameters and variables.

### 2.2.1. Objective function

The model objective is minimizing the accumulated total system cost (*atoc*) in the planning horizon (from 2020 to 2060), including capital cost  $tocac_{r,t}$ , capital cost for retrofit  $torfac_{r,t}$ , operation, and maintenance cost  $toomc_{r,t}$ , fuel cost  $tofc_{r,t}$ , power transmission cost  $totrc_{r,t}$ , and CO<sub>2</sub> transmission cost  $toctrc_{r,t}$ , as shown in Eq. (1) – (7).

$$atoc = \sum_r \sum_{t=2020}^{2060} \left( \frac{tocac_{r,t} + torfac_{r,t} + toomc_{r,t} + tofc_{r,t} + totrc_{r,t} + toctrc_{r,t}}{(1+I)^{t-2020}} \right) \quad (1)$$

$$tocac_{r,t} = \sum_g \sum_{t'=t-ELT_g+1}^t \left( CAC_{r,t',g} \cdot nbca_{r,t',g} \cdot \frac{I \cdot (1+I)^{-1}}{1 - (1+I)^{-ELT_g}} \right) \quad (2)$$

$$torfac_{r,t} = \sum_g \sum_{t'=t-ELT_g+1}^t \sum_{t''=t'+1}^t \left( RFCAC_{r,t',g} \cdot rf_{r,t',g} \cdot \frac{I \cdot (1+I)^{-1}}{1 - (1+I)^{-(t'+ELT_g-t'')}} \right) \quad (3)$$

$$toomc_{r,t} = \sum_g OMC_{t,g} \cdot inca_{r,t,g} \quad (4)$$

$$tofc_{r,t} = \sum_f FEULP_{f,r,t} \cdot \sum_{g,s} feuld_{f,r,t,g,s} \quad (5)$$

$$totrc_{r,t} = \sum_s \sum_{r' \neq r} idpt_{r,r',t,s} \cdot PTRC_{r,r'} \quad (6)$$

$$toctrc_{r,t} = \sum_s \sum_b cot_{r,b,t,s} \cdot CTRDIS_{r,b} \cdot CTRC_{r,b} \quad (7)$$

### 2.2.2. Operational constraints

Regional power demand is needed to satisfy by regional power supply, which equal regional power generation  $pge_{r,t,g,s}$  (installed capacity  $inca_{r,t,g}$  multiply hours of operation  $H_{r,t,s,g}$ ) coupled with net power import  $npi_{r,t,s}$  (power import  $pit_{t,r',r}$  minus power export  $pit_{t,r'',r}$ ) and the net electricity provided by energy storage (electricity discharged  $dchar_{r,t,s}$  minus electricity charged  $char_{r,t,s}$ ), as expressed in Eq. (8)–(10). Ideal power transmission from  $r$  to  $r'$  equals the negative value of that from  $r'$  to  $r$  and is limited by transmission capacity.

$$PD_{r,t,s} \leq \sum_g egs_{r,t,g,s} + npi_{r,t,s} + dchar_{r,t,s} - char_{r,t,s} \quad (8)$$

$$egs_{r,t,g,s} \leq inca_{r,t,g} * H_{r,t,s,g} \quad (9)$$

$$npi_{r,t,s} = \sum_{r'',r' \neq r} [pit_{t,r',r} - (1 - TRLOSS_{r,r'}) * pit_{t,r'',r}] \quad (10)$$

### 2.2.3. Construction constraints

The installed capacity of technologies equals the sum of newly built capacity ( $nbca_{r,t,g}$ ) each year during the past years (i.e. lifetime of each power plants) minus the early retired capacity ( $rfca_{r,t,g}^{t'}$ ) and retrofitted capacity ( $erca_{r,t,g}^{t'}$ ) plus the capacity retrofitted by other power plants ( $erfca_{r,t,g}^{t''}$ ), as shown in Eq. (13).

$$inca_{r,t,g} = \sum_{t'=t-ELT_g+1}^t nbca_{r,t',g} - \sum_{t'=t-ELT_g+1}^t \sum_{t''=t'+1}^t (rfca_{r,t',g}^{t''} + erca_{r,t',g}^{t''}) + \sum_{t'=t-ELT_g+1}^t \sum_{t''=t'+1}^t (erfca_{r,t',g}^{t''}) \quad (11)$$

Other inequality constraints such as the upper bound of regional total installed capacity of renewable energy, annual newly-built capacity are also considered.

### 2.2.4. Carbon emission and source-sink matching constraints

The annual net CO<sub>2</sub> emission ( $tocoe_t$ ) equals CO<sub>2</sub> emission from fuel energy combustion minus the amount of CO<sub>2</sub> capture, which equals the sum of CO<sub>2</sub> stored in each basin. The total emission in the planning horizon cannot exceed the 1.5°C carbon target ( $COET$ ). Each basin's injection capacity is limited, including storage potential ( $CSP_b$ ) and annual injection rate ( $ACSP_b$ ).

$$tocoe_t = \sum_f tofueled_{f,t} \cdot COEF_f - \sum_r \sum_s \sum_b cot_{r,b,t,s} \quad (12)$$

$$\sum_{t=2020}^{2060} tocoe_t \leq COET \quad (13)$$

$$\sum_t \sum_r \sum_s cot_{r,b,t,s} \leq CSP_b \quad (14)$$

$$\sum_r \sum_s cot_{r,b,t,s} \leq ACSP_b \quad (15)$$

## 3. Case Study

The power supply system of China is selected as a case study, due to its large capacity and relatively young average life of thermal power plants. At the same time, the source-sink matching of China's CCS technology is not ideal, which makes it difficult to reduce fossil energy emissions and achieve carbon neutrality target. This study will apply the above method to explore the impact of consideration and non-consideration of CCS source-sink matching and the number of storage sites and transportation costs on the trajectory of thermal power unit development during the planning period of 2020–2060.

The economic and technical parameters of each power plant are incorporated from previous work (Chen et al., 2021). The transmission cost of carbon dioxide is set based on the report about China's CCUS development (Zhang et al., 2021). And the injection

capacity of each basin and the distance from emission source to sink refer to the research of current China CCUS source–sink matching situation (Chen et al.,2021).

7 scenarios (S1–S7) are set in this study. S1 don't take the CCS source-sink matching restrictions and relative cost into account. S2 consider the CCS source-sink matching constraints with only 9 basins (Tarim, Junggar, Ordos, Songliao, Erlian, Tuopan-Hami, Sanjiang, Qaidam, Hailaer), which are far from populated areas for security reasons. S3-S7 consider the CCS source-sink matching with 16 basins, which also includes 7 basins in Central and South China (Sichuan, Qinshui, Bohai Bay, Suibei, Hehuai, Jiangnan, Nanxiang ). In S2-S7, the cost of transporting CO2 will decrease by 50%, 90%, 70%, 50%, 30%, and 10% in 2060 compared to 2020. For modelling and optimization, the General Algebraic Modelling System (GAMS, GAMS Development Corporation, Washington, DC, USA) Linear Programming Solver was employed.

3.1. Installed capacity of thermal power plants with CCS in 2060

As shown in Figure 1 the constraint of source-sink matching will have a great impact on the total installed capacity of thermal power plants with CCS. When there are only 9 optional basins and the cost of CO2 transportation drops by 50 %, the total installed capacity falls from 592 GW to 145 GW, with a decrease of 76.1 %, and the overall installed capacity was 236GW when there were 16 chosen basins, with a decrease of 60.1%. Among these thermal power plants, the most affected is the UPCC, with a decreased by 86.3 % and 77.8 % in S2, S5 relative to S1. Analysis of S3-S7 shows that for every 20 % reduction in carbon dioxide reduction rate, the installed capacity of thermal power CCS units also decreases by 29-36 GW.

Figure 1 Installed capacity of thermal power plants with CCS in 2060

3.2. Spatial distribution of thermal power plants with CCS in 2060

With the consideration of CO2 transmission cost, the installed capacity of coal plants with CCS in Inner Mongolia and East and BECCS in Chuan-Yu, Central and Henan will decline significantly. There will be more thermal power plants with CCS in places near to storage basins, such as Xinjiang, Northeast and Shandong.

Figure 2 Spatial distribution of coal plants with CCS (UPCC and UPCCOCCS) in 2060  
 Figure 3 Spatial distribution of BECCS in 2060

### 3.3. CO<sub>2</sub> storage amount in each basin

As shown in Figure 4, CO<sub>2</sub> will be buried in Ordos, Junggar, Songliao, Erlian, and Turpan basins in the S2 scenario. The two basins with the most CO<sub>2</sub> storage are Ordos Basin and Junggar Basin, with 4.3 Gt and 2.9 Gt, respectively. CO<sub>2</sub> will also be stored in

Sichuan, Qinshui, Bohai Bay, Subei, and Nanxiang basins in the S5 scenario. Among them, the Ordos Basin, Sichuan Basin, and Bohai Bay Basin have the largest sequestration amount, with 4.3Gt, 3.7Gt, and 3.5Gt respectively.

Figure 4 CO<sub>2</sub> storage amount in each basin

## 4. Conclusions

This study proposes a low-carbon transition model of power system with source-sink matching module, which can be used to quantitatively analyze the development path of thermal power plants with CCS with minimum transition costs based on both the power system development and CCS source-sink matching constraints. The results of scenario analysis show that the total installed capacity of thermal power plants with CCS will drop significantly when source-sink matching is taken into account. The spatial distribution of CCS will change greatly, and the distance to the storage sinks will also become a key factor in the layout of CCS. The Ordos, Junggar and Bohai Bay Basin will become important CO<sub>2</sub> storage locations in the future.

## Abstract

In this paper, we present strategies for reformulating discrete time-based mixed-integer programming models for chemical production scheduling. We introduce several new integer variables, which we refer to as record keeping variables, that mixed-integer linear programming solvers are able to exploit in order to reduce total solution time. We consider these record keeping variables in the context of both batch process networks and continuous process networks. Results of several computational tests are provided that demonstrate the utility of incorporating record keeping variables in chemical production scheduling models.

**Keywords:** batch process, continuous process, scheduling, discrete time, reformulation.

## 1. Introduction

We consider a chemical processing facility that converts raw materials into higher value products. In this context, production scheduling involves assigning tasks to processing units and determining the times at which the processing of these tasks should begin, possibly subject to a set of restrictions. As these task assignments and timing decisions ultimately govern a significant portion of a facility's operations, scheduling is a crucial decision-making step with applications in a broad range of systems, from batch production of low-volume products such as pharmaceuticals (Papavasileiou et al., 2007) to crude oil blending (Castro and Grossmann, 2014). Determining an appropriate schedule requires knowledge of the processing duration of each task, any limitations on the units to which a given task can be assigned, material conversion coefficients, and many other complex, application-specific details. As such, much research in the field of chemical production scheduling has been devoted to developing strategies for modeling various process characteristics such as limits on utility and/or resource availability (Méndez et al., 2001), changeovers (Wolsey, 1997), and material transfer restrictions (Giménez et al., 2009). In considering this wide array of process characteristics, researchers aim to develop highly general models that can be readily employed in a wide range of industrial applications. However, discrete-time models grow at least linearly with the number of time periods (Velez et al., 2017). As such, a major research direction in production scheduling has been the development of computationally efficient procedures for solving existing scheduling models. Research efforts to reduce the computational costs of solving chemical production scheduling models have included the development of reformulations (Velez and Maravelias, 2013a), decomposition-based algorithms (Harjunkoski and Grossmann, 2002), parallel computing tools

(Subrahmanyam et al., 1996), and tightening methods using valid inequalities (Velez, 2013b). In this work we present a reformulation strategy for discrete time-based mixed-integer linear programming (MILP) models for production scheduling. We divide our discussion into two categories: (i) reformulations for MILP models related to batch processes, and (ii) reformulations for MILP models related to developments for continuous processes.

## 2. Preliminaries

### 2.1. Batch and Continuous Process Modeling Differences

There are significant modeling differences between batch and continuous processes, primarily due to the fact that continuous processes produce (output) and consume (input) materials continuously and simultaneously, whereas batch processes are assumed to consume all required materials at the start of a task and produce all outputs at the end. The amount of material produced/consumed in continuous production depends on both the rate and duration of task execution, where the duration is not strictly fixed. This implies a different number of degrees of freedom (DOF). Batch processes have one DOF: the batch size. Continuous processes, however, have two DOF: the processing rate and duration of a task. Because of this, MILP models for continuous processes are often carefully constructed extensions of MILP models for batch processes. Hence, we first discuss model reformulations for batch process and later discuss them for continuous processes.

### 2.2. Notation

We employ the following convention for notation: (i) sets are indicated using bold, upper-case, Roman letters, (ii) indices are indicated using lower-case Roman letters, (iii) parameters are indicated using lower-case Greek letters, and (iv) variables are indicated using non-bold, upper-case, Roman letters. Throughout the work we utilize  $i \in \mathbf{I}$  to represent tasks,  $j \in \mathbf{J}$  to represent processing units,  $k \in \mathbf{K}$  to represent materials, and  $n \in \mathbf{N}$  to represent discrete time points. We note that, while the typical use of  $n \in \mathbf{N}$  is to represent a discrete time *point* that is  $n\delta$  time units beyond the start of the scheduling horizon, it can also be used to represent the time *period*  $[(n-1)\delta, n\delta)$ . For a given  $i \in \mathbf{I}$ , we use  $\mathbf{J}_i \subseteq \mathbf{J}$  to represent the set of units capable of processing task  $j$ . Additionally, for a given  $k \in \mathbf{K}$ , we use  $\mathbf{I}_k^+$ ,  $\mathbf{I}_k^- \subseteq \mathbf{I}$  to represent the sets of tasks producing and consuming material  $k$ , respectively. The MILP models we employ also rely on the parameters:  $\eta$  - the scheduling horizon;  $\delta = \frac{\eta}{|\mathbf{N}|}$  - the discretization time step;  $\tau_{i,j}$  - the time required to process task  $i \in \mathbf{I}$  in unit  $j \in \mathbf{J}_i$ ;  $\beta_j^{\text{MAX}}/\beta_j^{\text{MIN}}$  - the maximum/minimum capacity of unit  $j \in \mathbf{J}$ ;  $\chi_k^{\text{MAX}}$  - the maximum amount of material  $k \in \mathbf{K}$  that can be stored;  $\rho_{i,k}$  - the conversion coefficient of material  $k \in \mathbf{K}$  produced or consumed by task  $i \in \mathbf{I}$ ; and  $\xi_{k,n}$  - the net shipment of material  $k \in \mathbf{K}$  at time  $n \in \mathbf{N}$ . We also use the variables:  $X_{i,j,n} \in \{0,1\}$ , which equals 1 if task  $i \in \mathbf{I}$  begins in unit  $j \in \mathbf{J}_i$  at time point  $n \in \mathbf{N}$ ;  $B_{i,j,n} \in \mathbb{R}_+$ , the batch size of task  $i \in \mathbf{I}$  processed in unit  $j \in \mathbf{J}_i$  at time point  $n \in \mathbf{N}$ ; and  $S_{k,n} \in \mathbb{R}_+$ , the inventory level of material  $k$  during time period  $t$ . The MILP models we employ can utilize various objectives, but all include at least the following sets of constraints:

$$\sum_{i \in \mathbf{I}_j} \sum_{t=0}^{\lceil \tau_{i,j}/\delta \rceil - 1} X_{i,j,n-t} \leq 1 \quad \forall j \in \mathbf{J}, n \in \mathbf{N}$$

$$\beta_{i,j}^{\text{MIN}} X_{i,j,n} \leq B_{i,j,n} \leq \beta_{i,j}^{\text{MAX}} X_{i,j,n} \quad \forall i \in \mathbf{I}, j \in \mathbf{J}_i, n \in \mathbf{N}$$

$$S_{k,n+1} = S_{k,n} + \sum_{i \in \mathbf{I}_k^+} \sum_{j \in \mathbf{J}_i} \rho_{i,k} B_{i,j,n} + \sum_{i \in \mathbf{I}_k^-} \sum_{j \in \mathbf{J}_i} \rho_{i,k} B_{i,j,n} + \xi_{k,n} \leq \chi_k \quad \forall k \in \mathbf{K}, n \in \mathbf{N}$$

### 3. Batch Processes

Beginning with the MILP model employing the three sets of constraints given above, Velez and Maravelias (2013a) propose a reformulation that involves adding an integer variable  $N_{i,j}$  that represents the number of times task  $i$  is carried out in unit  $j$ . Specifically, for each  $i \in \mathbf{I}$  and  $j \in \mathbf{J}_i$  the authors add the constraint  $\sum_{n \in \mathbf{N}} X_{i,j,n} = N_{i,j}$  and bound  $N_{i,j}$  as  $0 \leq N_{i,j} \leq \left\lfloor \frac{\eta}{\tau_{i,j}} \right\rfloor$ .

We propose the use of several additional integer variables and associated constraints. Consider the variables  $N_i \in \mathbb{Z}$  - the number of times task  $i$  is performed;  $N_j \in \mathbb{Z}$  - the number of times unit  $j$  performs a task;  $N_n \in \mathbb{Z}$  - the number of tasks performed at time  $n$ ; and  $N \in \mathbb{Z}$  - the total number of tasks performed. These can be incorporated into the MILP model using the following constraints and bounds:

$$N_i = \sum_{j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} X_{i,j,n}; \quad 0 \leq N_i \leq \sum_{j \in \mathbf{J}_i} \left\lfloor \frac{\eta}{\tau_{i,j}} \right\rfloor \quad \forall i \in \mathbf{I},$$

$$N_j = \sum_{i: j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} X_{i,j,n}; \quad 0 \leq N_j \leq \left\lfloor \frac{\eta}{\min_{i: j \in \mathbf{J}_i} \{\tau_{i,j}\}} \right\rfloor \quad \forall j \in \mathbf{J},$$

$$N_n = \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} X_{i,j,n}; \quad 0 \leq N_n \leq |\mathbf{J}| \quad \forall n \in \mathbf{N},$$

$$N = \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} X_{i,j,n}; \quad 0 \leq N \leq \min \left\{ \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} \left\lfloor \frac{\eta}{\tau_{i,j}} \right\rfloor, \sum_{j \in \mathbf{J}} \left\lfloor \frac{\eta}{\min_{i: j \in \mathbf{J}_i} \{\tau_{i,j}\}} \right\rfloor \right\}.$$

As each of the variables  $N_{i,j}$ ,  $N_i$ ,  $N_j$ ,  $N_n$ , and  $N$  serves to *keep record* of a quantity of interest, we refer to each as a *record keeping variable* (RKV). We now summarize the results of a study in which we compare the performance of branch-and-bound (BB) when a carefully chosen subset of these RKVs are included within our model. We note that this, as well as the remainder of the tests described in this work, were conducted using GAMS v36.1 for modeling and CPLEX 20.1 as the MILP solver. The tests described here are performed using a combination of randomly generated instances and instances obtained from minlp.org and from Velez and Maravelias (2013a). In total, we utilize 115 instances and consider cost minimization and profit maximization objectives. For brevity, and because the results for both objective types displayed relatively similar patterns, we only present results for cost minimization here. We report results for all instances that at least one of the considered formulations was able to solve in under 5 hours. The results are summarized in the performance profile displayed in Figure 1.

In Figure 1, we use the following notation: O - no RKVs are added; B -  $N_{i,j}$  is added; I -  $N_i$  is added; BIA -  $N_{i,j}$ ,  $N_i$ , and  $N$  are added; BIJA -  $N_{i,j}$ ,  $N_i$ ,  $N_j$ , and  $N$  are added; and BIJNA -  $N_{i,j}$ ,  $N_i$ ,  $N_j$ ,  $N_n$ , and  $N$  are added. Here O is selected as it represents the original formulation with no RKVs, B is selected as it represents the most promising reformulation considered in (Velez and Maravelias, 2013a), and the rest of the considered reformulations are selected for their relatively strong performance. Of the 115 instances

considered, there were 11 that no considered formulation was able to solve in 5 hours, 8 that were solved in under 5 hours by B and BIJA but not by O (B - 4667.8s avg; BIJA - 170.4s avg), and 22 that were solved in under 5 hours by BIJA but not be either O or B (BIJA - 399.4s avg). Moreover, of the remaining 74 instances, there were 44 that at least one of the formulations O, B, or BIJA took more than 5 seconds to solve, and on average BIJA solved these in 1.16% of the time used by O and 2.63% of the time used by B.

Figure 1: Performance Profile for Batch Process Formulations

#### 4. Continuous Processes

In the field of chemical production scheduling, less focus has been given to continuous processes relative to batch processes. The simultaneous production and consumption of materials in conjunction with the flexibility to choose the duration of task execution adds a layer of processing complexity to continuous process models. Strategies to more efficiently model continuous processes, such as introducing RKVs, would prove to be valuable, especially when considering transient operations such as startups, shutdowns, and direct transition tasks that notably escalate model complexity; transient operations can result in the addition of up to four more binary variables per task as well as the ancillary constraints needed for their modeling. A general optimization framework that accurately represents system dynamics, specifically transient operations, is utilized; however, the reader is directed to the literature for the extensive list of modeling constraints (Wu and Maravelias, 2021).

From a modeling perspective, a continuous task is represented as a series of identical subtasks, each having a processing time of one discrete time step. Any set of consecutive executions of a single subtask are then referred to as a *run* of the associated continuous task. The minimum/maximum processing rates of a task  $i \in \mathbf{I}$  executed in a unit  $j \in \mathbf{J}_i$  during each time period are comparable to batch sizes in the batch process model, so they are represented similarly ( $\beta_{i,j}^{\text{MIN}}/\beta_{i,j}^{\text{MAX}}$ ). In terms of run duration, parameters to enforce run length restrictions ( $\tau_{i,j}^{\text{MIN}}/\tau_{i,j}^{\text{MAX}}$ ) are also applied. In addition to  $X_{i,j,n}$ , two new binary variables containing information about the start and end times of a run are employed;  $Y_{i,j,n}^{\text{S}}$  and  $Y_{i,j,n}^{\text{E}}$  indicate that a run of task  $i$  in unit  $j$  starts, or ends, at time  $n$ , respectively. The values of these variables are enforced as:

$$Y_{i,j,n}^{\text{S}} = X_{i,j,n} - X_{i,j,n-1} + Y_{i,j,n}^{\text{E}} \quad \forall i \in \mathbf{I}^{\text{P}}, j \in \mathbf{J}_i, n \in \mathbf{N}$$

The above equation ensures that  $Y_{i,j,n}^S = 1$  whenever a run of a production task  $i \in \mathbf{I}^P \subseteq \mathbf{I}$  begins. We note that production tasks are simply tasks that are not transition tasks, i.e., their role is to produce material, as opposed to transitioning to/from other tasks.

The same RKVs introduced in Section 3, i.e., those defined in terms of the  $X_{i,j,n}$  binary variables, can be written for continuous process models. However, with the availability of the  $Y_{i,j,n}^S$  binary variable, an additional class of RKVs can be as follows:

$$\begin{aligned}
 N_{i,j}^Y &= \sum_{n \in \mathbf{N}} Y_{i,j,n}^S; & 0 \leq N_{i,j}^Y &\leq \left\lfloor \frac{\eta}{\tau_{i,j}^{\text{MIN}} + \alpha_{i,j}^{\text{MIN}}} \right\rfloor & \forall i \in \mathbf{I}^P, j \in \mathbf{J}_i, \\
 N_i^Y &= \sum_{j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} Y_{i,j,n}^S; & 0 \leq N_i^Y &\leq \sum_{j \in \mathbf{J}_i} \left\lfloor \frac{\eta}{\tau_{i,j}^{\text{MIN}} + \alpha_{i,j}^{\text{MIN}}} \right\rfloor & \forall i \in \mathbf{I}^P, \\
 N_j^Y &= \sum_{i: j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} Y_{i,j,n}^S; & 0 \leq N_j^Y &\leq \left\lfloor \frac{\eta}{\min_{i: j \in \mathbf{J}_i} \{\tau_{i,j}^{\text{MIN}}\}} \right\rfloor & \forall j \in \mathbf{J}, \\
 N_n^Y &= \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} Y_{i,j,n}^S; & 0 \leq N_n^Y &\leq |\mathbf{J}| & \forall n \in \mathbf{N}, \\
 N^Y &= \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} \sum_{n \in \mathbf{N}} Y_{i,j,n}^S; & 0 \leq N^Y &\leq \min \left\{ \sum_{i \in \mathbf{I}} \sum_{j \in \mathbf{J}_i} \left\lfloor \frac{\eta}{\tau_{i,j}^{\text{MIN}} + \alpha_{i,j}^{\text{MIN}}} \right\rfloor, \sum_{j \in \mathbf{J}} \left\lfloor \frac{\eta}{\min_{i: j \in \mathbf{J}_i} \{\tau_{i,j}^{\text{MIN}}\}} \right\rfloor \right\}.
 \end{aligned}$$

In the above,  $\alpha_{i,j}^{\text{MIN}}$  represents the minimum transition time needed to transition to and from a production task  $i$ . If a production task has no transitions associated with it,  $\alpha_{i,j}^{\text{MIN}} = 0$ . To test the utility of continuous models that incorporate RKVs, we include various combinations of the above RKVs that track the number of runs of a task ( $Y_{i,j,n}^S$ ) and the RKVs that track the task execution ( $X_{i,j,n}$ ) within our cost-minimization MILP model. A total of 96 instances were solved to optimality by all formulations within a 24-hour time limit, and a performance chart of the results is given in Figure 2.

Figure 2: Performance Profile for Continuous Process Formulations

In Figure 2 we use similar notation to that of Figure 1, but we prefix the run-related variables with “Y.” and the task execution-related variables with “X.” We note that we considered several combinations of RKVs beyond those for which results are

displayed. However, for brevity, only formulations that showed strong performance relative to the original formulation with no RKVs are illustrated in the figure. From our results, it appears that the run-related RKVs perform better than the task execution-related RKVs. Additionally, we observe from the curves labeled “X.I;Y.I” and “Y.I” in Figure 2 that  $N_i^Y$  was the most impactful of our considered RKVs. We also point out that formulation Y.I solved about 40% of the instances the fastest. One possible explanation for these results is that by branching on  $N_i^Y$ , the solver is able to bound the number of runs of each task  $i$ , thus efficiently eliminating suboptimal or infeasible schedules and closing the optimality gap more quickly.

## 5. Conclusion

We have presented results that demonstrate the large computational improvements that can be achieved by simply incorporating RKVs into chemical production scheduling MILP models. Moreover, we have provided evidence that such improvements can be obtained in the context of both batch processes and continuous processes. However, this reformulation technique is not limited to only chemical production scheduling models but can also be extended to various other types of MILP models that utilize a large quantity of integer variables.

### Abstract

Recently in process engineering field, there is an increasing demand for high fidelity, large and multi-scale mathematical models. In most cases, these models involve several unknown parameters whose identifiability from experimental measurements is often not guaranteed. It is therefore necessary to carry out an estimability analysis to determine which parameters can be reliably estimated. This task is however laborious and is still neglected in most studies. Most importantly, its wide adoption is hampered by the lack of standardized tools or methodologies. To address these issues, a new estimability toolbox, ESTAN, was developed to make the estimability analysis accessible to a broader community of specialist and non-specialist users. ESTAN can handle different types of mathematical models including dynamic and non-dynamic models. It uses a Quasi-Monte Carlo method to sample the unknown model parameters within their range of variation. Then, depending on whether the studied model is computationally cheap or expensive, global sensitivity indices are calculated using either the Sobol method or the Fourier Amplitude Sensitivity Test. The sensitivities are exploited within an orthogonalization algorithm to rank the parameters from the most to the least estimable followed by the identification of the subset of the most estimable parameters based on a preset estimability threshold. Finally, more reliable parameter estimates are obtained for the subset of the most estimable parameters. To validate the toolbox and demonstrate its capabilities, ability analysis of three models is performed using the developed toolbox. They are given by a non-dynamic, a dynamic, and a computationally expensive model. The results for the case studies are found to be very promising, showing how the presented toolbox simplifies the investigation of the estimability analysis, and significantly improves the model's precision.

**Keywords:** Sensitivity analysis, Estimability analysis, Orthogonalization, Toolbox.

### 1. Introduction

For many years, mathematical models have been employed extensively in various branches of science and engineering. They are frequently utilized in the design of processes and plants, risk analysis, process optimization, and control. These models typically consist of thermodynamic, kinetic, and hydrodynamic equations as well as momentum, mass, and energy balances. Recently, with the advent of industry 4.0 and inherent digital transformation, there is an increasing need for more precise, high fidelity, large, and multi-scale models. However, these models always involve several parameters

to be identified from available experimental measurements. The presence of a large number of model parameters to be identified combined with poor data information content and data redundancy, model structure, correlation between parameters, non-linearity with respect to model states and parameters etc., result in poor prediction capabilities, and poor model interpolation and extrapolation. To address some of these critical issues, it is necessary to implement an estimability analysis approach to assess whether the model parameters can be identified from the available or planned experimental data. The current local/global estimability approaches involve complex and laborious calculations, among which, Monte/Quasi-Monte Carlo sampling, estimation of local and/or global sensitivity indices, assessing sensitivity indices convergence, orthogonalization etc. These techniques are difficult to develop, implement, or verify, and quite often, do not necessarily belong to the modeler's skills. Consequently, the estimability part is commonly neglected by simply assuming that the available data contain the necessary information to identify all the unknown model parameters, which is very often not true.

Several estimability approaches have been investigated in the literature (Bouchkira et al., 2021, Fysikopoulos et al., 2017). These techniques are not unified, and currently, no single toolbox is available. ESTAN toolbox addresses these gaps and suggests a user-friendly interface to help address estimability in the cases of dynamic and non-dynamic models (i.e., ODEs, DAEs, Algebraic expressions). The objective is also to propose a versatile and standard tool for all engineering and scientific subjects and make the estimability analysis accessible to non-specialist users (i.e., modelers with only basic background in sensitivity and estimability analysis and/or MATLAB). The toolbox is proposed as an open-source package to allow experienced modelers to easily use it, customize and even integrate it to other digital tools.

## 2. ESTAN structure

Figure 1 shows the framework of the parameters estimability analysis toolbox ESTAN. It is based on computing the global sensitivity indices of the model inputs (with respect to the outputs) and then process the sensitivity matrix  $Z$  using an orthogonalization algorithm to determine which parameters can be reliably estimated, and in which order. The estimability matrix  $Z$  below represents the global sensitivity indices of the model inputs with respect to the outputs at a given set of operating conditions, for steady models, and sensitivity indices at given sampling points for the dynamic models.

$$Z = \begin{pmatrix} S_{1,1}|_{m_{1,k}} & \cdots & S_{1,d}|_{m_{1,k}} \\ \vdots & \ddots & \vdots \\ S_{n,1}|_{m_{n,k}} & \cdots & S_{n,d}|_{m_{n,k}} \end{pmatrix}, k \in [1; M] \quad (1)$$

where  $m_{i,k}$  is the  $i^{th}$  sampling point of the  $k^{th}$  experiment (dynamic models) or the set of operating conditions (steady state models) and  $M$  is number of observed/measured outputs,  $n$  is the number of model parameters and  $d$  is either the number of sampling points (dynamic) or number of repeated experiments (steady state or algebraic models).  $S_{i,j}$  is the individual sensitivity coefficient of the  $i^{th}$  output with respect to the  $j^{th}$  parameter.

Among several sensitivity analysis approaches available in the literature, Saltelli's approach (Saltelli, 2008) and Fast approach (Cukier et al., 1973) have been adopted in the proposed toolbox, as they are very reliable, precise, and widely accepted. In both

approaches, the variance-based sensitivity indices are given by partial and total output variances:

$$S_{i,k} = \frac{V_i}{Var(Y)} |_{k}, \quad k \in [1; M] \tag{2}$$

ESTAN toolbox requires several user inputs for sensitivity analysis performance, among which, the number of parameters and measured outputs, the variability bounds of the unknown parameters, the initial conditions etc. Before performing sensitivity analysis, well informed variability bounds are required which can be obtained from the literature for existing models. Moreover, depending on whether the model to be evaluated is computationally cheap or expensive, the toolbox computes the  $S_{i,k}$  either based on the approach developed by Saltelli (2008), using Quasi-Monte Carlo sampling and statistical estimates to approximate the average and the variance of the model outputs, or the Fast method developed by (Cukier et al., 1973), which is based on Fourier series to evaluate the partial and total variances in  $S_{i,k}$  (Test 1). Once the sensitivity indices  $S_{i,k}$  are computed, they are used to build the Z estimability matrix, to be processed by the orthogonalization algorithm as in (Fysikopoulos et al., 2019). The later allows to determine the most estimable parameters as well as their ranking according to their estimability from the available experimental measurements (Test 2).

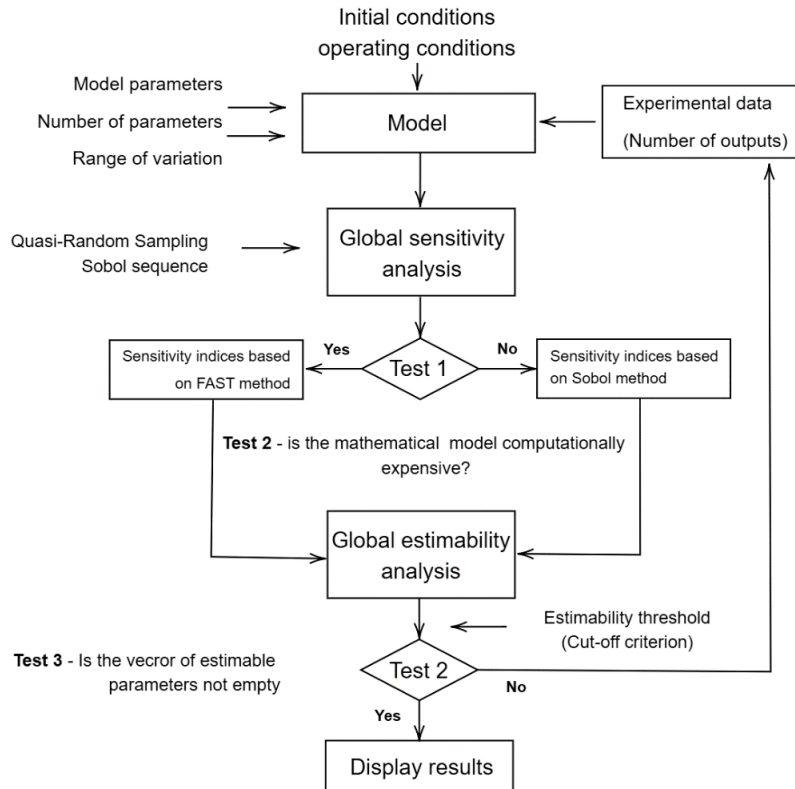

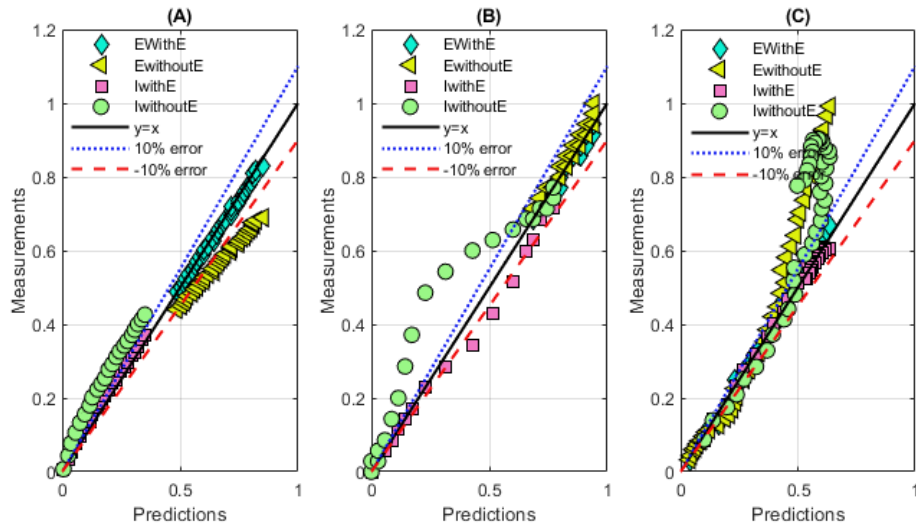

Figure 1: Simplified Framework of the parameters estimability analysis using the toolbox.

**Figure 2:** Results for model extrapolation and Interpolation. (A): Case of the non-dynamic model. (B): Case of the dynamic model. (C): Case of an expensive model. E/Iwith/withoutE: Extrapolation/Interpolation with/without estimability

**Table 1:** Summary of the outcomes of the GSA and estimability analysis.

	Interpolation	Extrapolation
Non-dynamic model		
Estimable parameters	3 out of 6	
Fixed values (3)	(Bedel et al., 2017)	
CPU time (Sobol)	173.02 seconds	
MPE with estimability (%)	4.114	4.541
MPE without estimability (%)	33.10	13.45
Dynamic model		
Estimable parameters	3 out of 4	
Fixed values (1)	(Benyahia et al., 2017)	
CPU time (Sobol)	187.21 seconds	
MPE with estimability	0.226	0.441
MPE without estimability	0.238	39.51
Expensive model		
Estimable parameters	4 out of 10	
Fixed values (6)	(Bouchkira et al., 2022;2023)	
CPU time (FAST)	359 seconds	
MPE with estimability	2.331	2.121
MPE without estimability	17.91	31.74

### 3. Case studies

#### 3.1. Models

To validate the developed toolbox, three case studies are considered. They include (1) an adsorption isothermal model from (Bedel et al., 2017) involving 6 unknown parameters. (2) A dynamic cooling batch crystallization model from (Benyahia et al., 2021) involving 4 unknown parameters. (3) A thermodynamic model from (Bouchkira et al., 2023) involving 10 unknown parameters.

#### 3.2. Experimental measurements

A database of experimental measurements was developed mainly from our previous works. For the estimability of the parameters of the adsorption isothermal model, measurements of carbon dioxide adsorption on a commercial adsorbent are taken from (Bedel et al., 2017). For the estimability of the batch cooling crystallization model, experimental measurements concerning particle size distribution of crystallized paracetamol are taken from (Anandan et al., 2021). Finally, for the thermodynamic model, equilibrium measurements are taken from (Bouchkira et al., 2022;2023).

#### 3.3. Computational method

The present toolbox was developed based on App Designer MathWorks and involves several MATLAB built-in functions which are available only in MATLAB v.2020 onwards. A reasonable computational power is required to cope with GSA and inherent simulation (e.g., Intel or AMD x86-64 processor and > 4 GB RAM). All calculations in this work were performed using an ASUS workstation with 12th Gen Intel(R) Core (TM) i9-12900K 3.20 GHz 128GB Ram processor.

### 4. Results and discussion

The estimability analysis results for the three case studies based on ESTAN toolbox are summarized in Table 1 and Figure 2. The sensitivity analysis for the first two cases was performed based on Saltelli (2008) in view of their non-expensive computing nature. To this end, a Quasi-Monte Carlo sampling of size 5000 was used. Whilst, for the last case, where the model is moderately expensive, FAST method based on Cukier et al. (1973) was investigated. The CPU times to achieve convergence of global sensitivity indices were estimated to 173 seconds for the non-dynamic model, 187 seconds for the dynamic model, and 359 for the algebraic expression-based model. The computed global sensitivity indices were then used to fill the Z estimability matrices for all tree cases, and these matrices were used to determine the number of estimable parameters in each case study, as well as their estimability-based ranking. Based on the collected data, it has been found that 3 parameters out of 6 are estimable in the first case, 3 parameters out of 4 are estimable in the second case and 4 parameters out of 10 are estimable in the last case. For each case, two scenarios are carried out for comparison purposes. In the scenarios “with estimability”, only estimable parameters are identified from the available measurements and non-estimable parameters are fixed from previous works. While in the scenario “without estimability”, all model parameters are identified neglecting the estimability analysis results. Moreover, for both scenarios, in each case study, the resulting models are used for model interpolation and extrapolation.

As expected, the results show how carrying out estimability analysis can significantly improve the model precision. This can be shown quantitatively from the computed Mean Percentage Errors (MPE) between models’ predictions and experiments. It has been found

that taking into account estimability analysis results reduced the MPE from 33.10% to 4.11% and from 13.45% to 4.54% respectively for interpolation and extrapolation in the case of the non-dynamic model, from 0.24% to 0.22% and from 39.51% to 0.44% respectively for interpolation and extrapolation in the case of the dynamic model, from 17.91 to 2.33% and from 31.74% to 2.12% respectively for interpolation and extrapolation in the case of the algebraic expression based model. These results can finally be presented in a normalized parity diagrams as in figure 2, where it can be seen that the models keep good prediction capabilities when taking estimability analysis results into account, while they fail to keep good interpolation and extrapolation performances when neglecting estimability.

## 5. Conclusion

ESTAN toolbox was developed to standardize the estimability analysis, and to help improve model prediction capabilities and precision. As demonstrated in the three case studies, ESTAN can be used for both cheap and expensive computationally models, through its ability to switch between Sobol and FAST methods for the calculation of sensitivity indices, to help enhance model prediction capabilities. Moreover, it is developed to avoid all laborious tasks involved in estimability analysis. It is worth mentioning that the current ESTAN version uses an arbitrary estimability criterion to determine the set of estimable parameters, and it is possible to implement a systematic approach to determine the optimal value of this cutoff estimability criterion as in (Bouchkira et al. 2021). This is a very interesting perspective that we will address in our future works. The estimability open-source toolbox will be freely available from the authors for non-commercial research and educational purposes.

## Abstract

Considering multiple technologies when synthesizing separation networks can lead to a more efficient separation. We present a superstructure-based approach to synthesize separation networks while considering multiple technologies. The approach uses key separation properties to generate potential separation sequences for each technology and employs richly connected superstructure to represent numerous potential configurations. Using a generalized problem statement, the proposed model can handle variable inlet and outlet streams thereby allowing the coupling with reactor network synthesis models.

**Keywords:** process synthesis, separation, global optimization, superstructure.

## 1. Introduction

In many chemical processes, a sequence of separation tasks is typically performed to recover unconverted raw materials and to purify final products. Synthesizing an appropriate separation network can result in significant savings for the overall process. Most of the available studies on separation network synthesis revolve around distillation with other technologies being an afterthought. Consequently, the benefits of having multiple technologies in the separation network are not fully exploited. Nevertheless, attention toward non-thermal separations has recently gained traction due to their potential for energy-efficient processes and positive environmental impact (Sholl and Lively, 2016). The incorporation of different technologies in separation network synthesis expands the search space, and thus allows potentially better networks to be found.

The separation network synthesis problem has been addressed using various approaches. Heuristic approaches rely on rules based on engineering knowledge and judgment, whereas evolutionary approaches generate a network by sequentially improving several initial flowsheets based on heuristics. Alternatively, most potentially useful units and their relevant interconnections can be embedded in a superstructure (Sargent and Gaminibandara, 1976). Superstructure-based approaches consider multitudes of promising network configurations in an optimization problem. Agrawal (2003) introduced a systematic method to generate all possible basic distillation configurations, and Heckl et al. (2006) considered different technologies explicitly. However, the former approach used a problem statement where complete information on the feed stream is required. Ryu et al. (2020) discussed a generalized problem statement which allows the seamless integration of the separation network and reactor network synthesis.

Accordingly, we propose a superstructure-based approach for separation network synthesis with multiple technologies where the feed streams may be variable, enabling coupling with reactor network synthesis. The approach employs a superstructure that

encompasses numerous promising configurations comprising multiple separation technologies. For each technology, we construct a separation matrix (Shah and Agrawal, 2010) based on the key properties that enable separation. We identify all possible separations and connections using these matrices and generate the corresponding superstructure. The synthesis problem is formulated as a mixed-integer nonlinear programming (MINLP) model. We demonstrate the applicability of the proposed approach through a multicomponent mixture separation case study.

## 2. Framework

### 2.1. Problem statement

For all technologies, we consider simple sharp split separators with no distributed components. This separation is performed by exploiting the difference in the magnitude of some key properties (e.g., volatility for distillation). Consequently, a component ranking system based on a specific key property is used to generate possible separation splits. In zeotropic distillation network synthesis, for example, all possible sequences of the separations can be enumerated if the ranking of components' relative volatilities is given. Analogously, we can generate sequences of separations for other technologies. The difference in the rankings between technologies provides an opportunity for more efficient separation. If two components are adjacent in technology A's ranking but not in technology B's ranking, separating them using technology B may be easier. It is worth noting that the actual separation may favor the former technology depending on the magnitudes of the key properties. If components have the same ranking, then it would be impractical to separate these components using that technology.

Traditionally, reactor and separation systems are synthesized sequentially; therefore, the conventional separation network synthesis problem requires full information on the inlet stream. When these two systems are considered simultaneously, the flowrates of the separation network's inlet stream vary depending on the decisions made in the reactor system. In this case, the inlet stream is termed variable inlet stream. The generalized separation network synthesis problem can be stated as follows. We are given variable inlet and outlet streams (with some specifications), the ranking of postulated components for all technologies, and cost functions for the separation tasks. The objective is to find the least cost separation network.

### 2.2. Superstructure generation

We use the concepts of nodes and arcs to represent the superstructure (Kong and Maravelias, 2020). We introduce set  $\mathbf{N}$  to denote all nodes and set  $\mathbf{I} = \{A, B, C, \dots\}$  to denote the components in the superstructure. Set  $\mathbf{N}$  can be split into three subsets: (1) source nodes  $\mathbf{N}^{SO}$  (inlets to the network); (2) sink nodes  $\mathbf{N}^{SI}$  (outlets of the network); and mixture nodes  $\mathbf{N}^M$  (nodes where separation or direct transfer to the sink nodes can take place). Each mixture node  $n$  is uniquely associated with a set of present components  $i \in \mathbf{I}_n^M$ . Throughout the manuscript, mixture nodes are labeled by the present components in alphabetical order (e.g.,  $\mathbf{I}_{ABC}^M = \{A, B, C\}$ ).

To enumerate potential sequences from an initial mixture, we utilize the matrix method of Shah and Agrawal (2010), originally developed to find a distillation sequence to separate a  $|\mathbf{I}|$ -component mixture into  $|\mathbf{I}|$  pure product streams. The construction of the matrix for technology  $t \in \mathbf{T}$  requires the ranking of the components,  $\rho_{t,i}$  and an initial mixture. For an element (or equivalently mixture) located in row  $j$  and column  $k$ , the candidate top products are in the same row (i.e.,  $j' = j, k' > k$ ) while the candidate

bottom products are in the same diagonal (i.e.,  $j' = j + k' - k, k > k$ ). To illustrate, in Fig 1 (left panel), we construct matrices for initial mixture ABCD for three technologies with different rankings. The solid/dotted arrows represent top/bottom arcs connecting a mixture to a candidate top/bottom product, and the dashed arrows connect equivalent mixtures in different matrices. One possible separation sequence for mixture ABCD is split AC/BD in technology T2 followed by split A/C in technology T1 and split B/D in technology T3. Note that since component B (or A) is missing from the top (or bottom) product of split AC/BD, mixture AC (or BD) is equivalent to mixture ABC (or ABD) in the matrix for technology T1 (or T2). The equivalent sequence in the aggregated matrix is shown in Fig 1 (right panel). Here, both mixtures AC and BD are assigned unique labels.

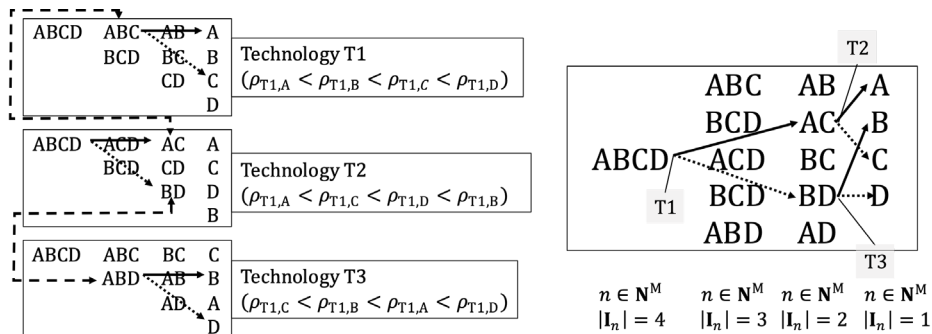

Figure 1: Different technology separation matrices (left) and aggregated matrix (right). Similar to the aggregated matrix, in the final superstructure, mixtures from different technology matrices are combined into unique nodes,  $n \in \mathbf{N}^M$ , (see Fig 2); and the top and bottom arcs are included in set  $\mathbf{A}_t^{\text{TECH},T}/\mathbf{A}_t^{\text{TECH},B}$ . The overall top/bottom arcs are contained in set  $\mathbf{A}^T/\mathbf{A}^B$ , the union of  $\mathbf{A}_t^{\text{TECH},T}/\mathbf{A}_t^{\text{TECH},B}$  over  $t \in \mathbf{T}$ .

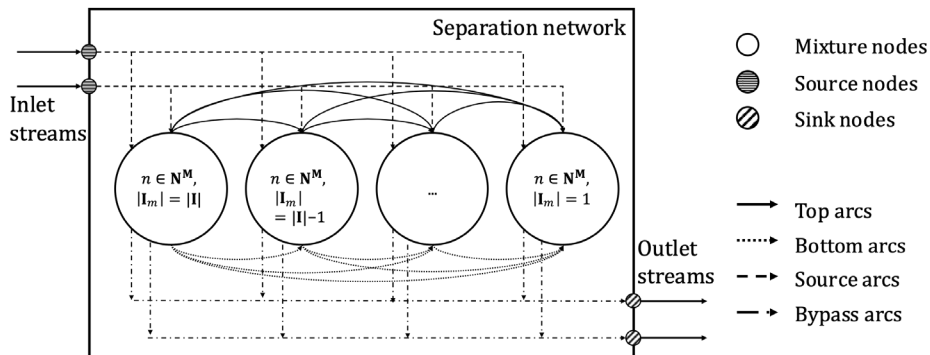

Figure 2: Superstructure representation of the separation network.

### 2.2.1. Mixture nodes

In each mixture node, streams from (1) sources, (2) top products, and (3) bottom products are mixed (see Fig. 3, left panel). A fraction of this mixed stream can be sent to the outlets directly, thereby bypassing unnecessary separations, while the remaining stream is sent to a separation block where technology  $t$  is performed leading to the outgoing top and bottom products. A separation block in this approach represents a set of operations that enables a sharp split separation. In solvent extraction, for instance, a separation block consists of an extraction column and the solvent recovery system (see Fig. 3, right panel). Similarly, in reverse osmosis, we utilize multi-stage membrane units to achieve a sharp

split separation. We also introduce subset  $\mathbf{N}^{M,P} \subset \mathbf{N}^M$  to denote mixture nodes containing only pure component (i.e.,  $|\mathbf{I}_n^M| = 1$ ). In these nodes, no separation will be performed; hence, the mixed stream is directly sent to the outlets.

Figure 3: Mixture node (left) and separation block for  $t = \text{extraction}$  (right). Separation block and its streams are relevant only for  $n \in \mathbf{N}^M \setminus \mathbf{N}^{M,P}$ .

### 2.2.2. Connectivity

Using the previously defined sets, we employ  $X_n^M \in \{0,1\}$  to indicate if mixture node  $n$  is active and  $Y_{\hat{n},n}^0 \in \{0,1\}$  to denote the activation of the source arc connecting source node  $\hat{n} \in \mathbf{N}^{SO}$  to mixture node  $n$ . From each source node, there can only be one active arc entering an active mixture node. We employ  $Z_i \in \{0,1\}$  to denote the existence of component  $i$  in the separation network, and using this variable, we deactivate several mixture nodes when a component is not present.

To represent connections between mixture nodes, we employ  $Y_{n,\hat{n}}^{T/B} \in \{0,1\}$  to denote the active top/bottom arc connecting mixture node  $n$  to its top/bottom product mixture node  $\hat{n}$ . The active pairs of top and bottom arcs represent the performed separation splits in the network. We employ  $Y_{n,\tilde{n}}^{BP} \in \{0,1\}$  to denote active arcs from the splitter which bypasses separation and directly goes to sink node  $\tilde{n} \in \mathbf{N}^{SI}$ . For node  $n \in \mathbf{N}^M \setminus \mathbf{N}^{M,P}$ , the remaining mixed stream can undergo separation which produces top and bottom products. The selection of separation technology in this node is done via variable  $Y_{n,t}^C \in \{0,1\}$ . On the other hand, all outgoing arcs from mixture node  $n$  will go to only sink nodes  $\tilde{n} \in \mathbf{N}^{SI}$ .

### 2.2.3. Active streams

Arcs in the superstructure essentially represent streams in the network; hence, we associate each arc (binary variable) with component molar flowrates (continuous variables). The component molar flowrate of the inlet stream from source node  $\hat{n}$ ,  $F_{i,\hat{n}}^0 \in \mathbb{R}^+$ , is disaggregated into  $F_{i,\hat{n},n}^{0,D} \in \mathbb{R}^+$  for each mixture node  $n$ . The value of  $F_{i,\hat{n},n}^{0,D}$  is positive only when its corresponding arc is active (i.e.,  $Y_{\hat{n},n}^0 = 1$ ). We use the inlet streams' flowrates to detect the existence of a component in the network. Moreover, we disaggregate the top and bottom product streams,  $F_{i,n}^T \in \mathbb{R}^+$  and  $F_{i,n}^B \in \mathbb{R}^+$ , into  $F_{i,n,\hat{n}}^{T,D} \in \mathbb{R}^+$  and  $F_{i,n,\hat{n}}^{B,D} \in \mathbb{R}^+$ , respectively, to represent the material transfer from one mixture node to another. Similarly, only flow variables associated with active  $Y_{n,\hat{n}}^{T/B}$  have positive values. Finally, we use split fraction  $K_{n,\tilde{n}}^{BP} \in [0,1]$  to calculate the amount of the mixed stream which bypasses separation and goes directly to the sink node  $\tilde{n}$ ,  $F_{i,n,\tilde{n}}^{BP} \in \mathbb{R}^+$ . Both  $F_{i,n,\tilde{n}}^{BP}$  and  $K_{n,\tilde{n}}^{BP}$  can be deactivated by variable  $Y_{n,\tilde{n}}^{BP}$  via big-M constraints.

### 2.3. Separation block model

Since only sharp separations are considered, we characterize a separation by the selection of a pair of key components in a mixture. The candidate pairs can vary depending on the chosen separation technology. We adopt the terms “light” and “heavy” keys and

generalize them by defining the light/heavy key as the component in the separation block feed stream with the highest/lowest ranking  $\rho_{t,i}$  that is not present in the bottom/top product stream. In each mixture node, we find candidate light and heavy keys according to a specific technology. We introduce  $Y_{i,n}^{\text{LK/HK}} \in \{0,1\}$  to indicate if component  $i$  is the light/heavy key in the separation performed in mixture node  $n$ . Using these binary variables, we write constraints to describe the relationship between the light and heavy keys and the top and bottom arcs. Since we consider only adjacent sharp splits, components with a ranking lower/higher than or equal to the ranking of the light/heavy key will not be present in the bottom/top products.

### 3. Examples

Our approach can be applied to separations where alternative technologies are considered. One such example is xylene isomers separation for which distillation is energy-intensive and thus non-thermal technologies (e.g., reverse osmosis and extraction) are investigated. All MINLP models are solved using BARON 38.3.0 to global optimality (optcr =  $10^{-6}$ ).

#### 3.1. Conventional separation network synthesis

A mixture of 1 kmol/s containing four components (15% A, 30% B, 35% C, 20% D) is to be separated into pure components (Fig 3, left panel). We consider three technologies: distillation, reverse osmosis, and solvent extraction. Components A and C have similar polarities and molecular sizes, which makes separation split between these two components impractical. The objective is to minimize the annualized separation cost:

$$\Phi_1 = \sum_{n,t} \gamma_{n,t}^{\text{FC}} \gamma_{n,t}^{\text{VC}} + \sum_{i,t,n} \gamma_{i,t,n}^{\text{VC}} F_{i,n,t}^{\text{F,LK}} \quad (1)$$

where  $F_{i,n,t}^{\text{F,LK}}$  is the molar flowrate of the stream undergoing separation using technology  $t$  with  $\hat{i}$  as the light key, and  $\gamma_{n,t}^{\text{FC}}/\gamma_{i,t,n}^{\text{VC}}$  is the parameter for fixed/variable cost. The cost parameters can be obtained by doing offline calculations.

The resulting model has 2,567 equations and 1,115 variables (236 binaries) and is solved in 4 s. In the optimal solution (Fig 3, right panel), all three technologies are used. The reverse osmosis block separates B and sends the bottom product (ACD) to the distillation block. The distillation then separates A taking advantage that component B is missing, resulting in an easier separation. Finally, mixture CD is separated using solvent extraction.

Figure 4: Conventional separation network synthesis problem (left) and its optimal solution (right). DIS: distillation, RO: reverse osmosis, EXT: solvent extraction.

#### 3.2. Integrated reactor-separation network synthesis

Raw materials  $B$  and  $C$  are purchased and fed into the reactor network to undergo one of three reactions:  $2C + B \rightarrow 3A$  (80% conversion);  $C + 2B \rightarrow 3D$  (90% conversion);  $C + B \rightarrow A + D$  (80% conversion) (Fig 4, left panel). The reactor effluent is then fed into the separation network to recover valuable product  $A$  or  $D$ . For each product, the reactor can only produce up to 10 kmol/s. Depending on the chosen reaction, the reactor effluent may contain different combinations of components at different concentrations. Due to the

partial conversions, there will be unconverted reactants that can be recycled. The technologies along with the associated rankings are the same as in the previous example. Our goal is to identify the raw material purchases, reactor selection, and separation network which result in the maximum profit:

$$\Phi_2 = \sum_{i,\tilde{n}} \gamma_{\tilde{n}}^{\text{SELL}} F_{i,\tilde{n}}^{\text{P}} - \left( \sum_i \gamma_i^{\text{RM}} R_i^{\text{RM}} + \sum_{rx} \gamma_{rx}^{\text{RX}} R_{rx}^{\text{FEED}} + \Phi_1 \right) \quad (2)$$

where  $R_i^{\text{RM}}$  denotes the purchased raw material,  $R_{rx}^{\text{FEED}}$  denotes the flowrate of the feed undergoing reaction  $rx$ , and  $\gamma_{\tilde{n}}^{\text{SELL}}/\gamma_i^{\text{RM}}/\gamma_{rx}^{\text{RX}}$  are the product price/raw material price/reaction cost. The influence of feed compositions on the separation cost is considered via the use of cost parameter  $\gamma_{i,t,n,i}^{\text{VC}}$  which depends on the component molar flowrate in the separation block feed stream.

Figure 5: Integrated reactor-separation network synthesis problem (left) and optimal solution (right).

The resulting MINLP model has 2,623 equations and 1,134 variables (239 binaries) and is solved within 6 s. In the solution (Fig 5, right panel), reaction 1 is chosen, and the effluent (mixture ABC) is first separated by reverse osmosis followed by distillation. Unconverted reactants are recovered, mixed, and recycled. Finally, raw materials purchases are such that, given the recycle stream, the reactor feed stream is sufficient to produce 10 kmol/s of A.

#### 4. Conclusion

We proposed a superstructure-based approach to synthesize separation networks with multiple technologies. We utilize rankings based on key properties to generate possible separations using each technology. To account for interactions between different separation technologies, rich interconnections between mixture nodes are considered (e.g., bypass streams). The adopted generalized problem statement allows variable feed to the network, enabling the simultaneous synthesis of separation and reactor networks.

## Abstract

The two-dimensional cutting stock problem (CSP) is critical in several industries. Reinforcement learning (RL) is a novel method to obtain a quality solution of two-dimensional CSP in a short computation time. In this research, we applied a model-free off-policy RL algorithm to an industrial example of exact guillotine two-dimensional CSP, and compared the results with mixed-integer programming (MIP), which is a common traditional mathematical method for optimization. The results showed that RL had a much lower computation time than MIP with a solution closed to optima, and the ability to make a trade-off between waste, inventory level, and back order.

**Keywords:** Reinforcement learning, machine learning, cutting stock problem

## 1. Introduction

The CSP is a problem of minimizing stock material waste while cutting stock material into pieces of required sizes. The two-dimensional CSP has been applied to a variety of industrial applications, such as paper, metal, and glass manufacturing. It is critical for industries to minimize costs, including waste costs, inventory costs, and back-order costs. The two-dimensional CSP is divided into guillotine cutting and non-guillotine cutting. Guillotine cutting can be classified into an exact guillotine and a non-exact guillotine (Andrade et al. (2016)), which increases the complication and difficulty of the two-dimensional CSP.

The computation time of traditional mathematical optimization methods such as MIP grows rapidly as the amount of data increases and the problem becomes more complex. The exact guillotine that caused some items cannot be scheduled, leading to back-order increases when there are no matching items due to the inflexible limitations of traditional MIPs. For addressing the scheduling problem, RL is a promising method that is expected to provide solutions close to optimal within a very short period after training. (Hubbs. et al. (2020)) However, only one previous research is committed to solving CSP by RL, but for one-dimensional. (Pitombeira-Neto et al. (2022))

The purpose of this study is to provide a RL model named Monte Carlo-Deep Deterministic Policy Gradient (MC-DDPG) to solve a two-dimensional exact guillotine CSP in the paper-cutting factory, with the flexibility to switch to the non-exact

guillotine mode for no matching items to reduce back-order and accelerate the scheduling. In the industrial case, there are several bins with different length, width, and weight per area (called base weight) to cut into various items which corresponding to the orders for daily scheduling. Each order may contain one or more items with varying specifications, and total weight of the items finally produced must meet the order's demand. Furthermore, the width requirement of the items is fixed, but the length may be a range, thus the length is also a variable that must be determined. There are several constraints that must be satisfied due to physical and procedural limitations.

This paper is divided into four sections. Section 2 describes the details of our proposed approach. Section 3 and 4 discuss the results and conclusions.

## 2. Method

### 2.1. Reinforcement learning (RL)

RL involves an agent to interact with the environment. The agent determines an *action* according to a given *state*, and the environment returns next state and *reward* (Fig 1). Sets of state, action, reward, and next state at time step  $t$  can be denoted as the following form:  $(s_t, a_t, r_t, s_{t+1})$ . The  $(s_t, a_t, r_t, s_{t+1})$  sequence of an episode with several time steps is called a *trajectory*. The goal of the agent is to maximize the reward, thus RL develops a *policy* for choosing action depending on the state.

RL can be divided into on-policy and off-policy. The main difference between on-policy and off-policy is that whether the policy which is improved (target policy) is same as the policy that is used to select actions (behavior policy). Same for on-policy and not for off-policy. Thus, current data and historical data can both be used for off-policy training.

Fig 1. Reinforcement learning system diagram.

### 2.2. Monte Carlo- Deep Deterministic Policy Gradient (MC-DDPG)

DDPG is an off-policy method in RL, composed of two neural networks: actor and critic. Actor determines the actions, and the critic estimates the expected return value which indicates how good are the actions of corresponding states. Actor is trained by maximizing the value output by critic, and the critic is trained by minimizing the difference with the expected return value. (Casas (2017))

Monte Carlo (MC) is a common method for critic updating that estimate the expected return value as:

$$G_t = \sum_{k=t}^{\infty} \gamma^k r_k \quad (1)$$

However, we assume that the current action has a negligible effect on the reward of future actions in our problem, thus we proposed an expected return value function which is explained in the later chapter instead. We store the transition  $(s_t, a_t, r_t, s_{t+1})$  after the end of an episode instead of step by step due to the calculation of  $G_t$ .

### 2.3. Purposed method

The proposed framework of MC-DDPG is composed of two parallel parts: replay buffer management (solid line in Fig 2) and critic and actor training (dashed line in Fig 2). After an episode of interaction between the actor and the environment, the expected return values  $G_t$  were calculated, and the trajectory was stored into the replay buffer. It should be noted that whether an episode ends or not is according to the parameter  $D_{target}$ , which was adjusted when replay buffer stored more than a set amount of data for the training to start, ensuring that there was enough data with action that met the

constraints to improve the policy. Once the training began, a batch size of data was sampled from replay memory at each time step and used to update both actor and critic.

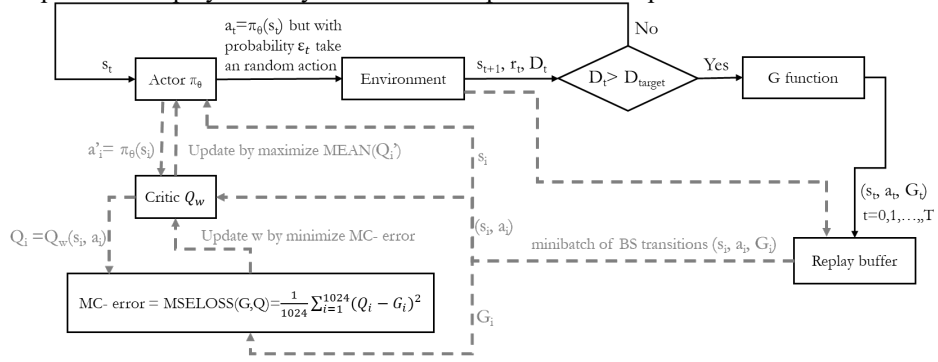

Fig 2. Proposed process diagram.

2.3.1. Environment (Sur et al. (2022))

At the beginning of each episode, we sample M bins and N orders from the database which is provided by a real-world factory, where  $M = \text{DiscUnif}(1,100)$  and  $N = \text{DiscUnif}(1,50)$ .

Fig 3 and Table 2 showed detailed information in state and action provided by actor. Noted that the size of state is fixed to 190 and the size of action is fixed to  $6 \times 18 = 108$ . There have 4 types of action:

I. Slit: Select one of the 15 items to schedule on the current bin in the width direction (called as slit), and also determine the length  $l$  of the item. To determine the length, we define a variable called ratio, then the length of item would be:

$$l = \text{ratio} \times (h_{\max} - h_{\min}) + h_{\min} \tag{2}$$

We may select a ratio of 0, 0.25, 0.5, 0.75, or 1. In addition, we have another option of setting  $l$  equal to the length of the previous slit item without using the ratio.

II. Cut: Finish the scheduling in width direction, and cut the length at the longest length of the slit items after previous cut.

III. Finish: Finish the scheduling of the current bin.

IV. Abandon: Abandon the current bin without scheduling.

The constraints of the system were categorized as physical constraints, process constraints, and environmental constraints. Physical constraints contained the total width of slit items should be no larger than the width of the bin, the total length of cuts should be no larger than the length of the bin, and the item length should be between maximum and minimum length of the item. Process constraints contained the number of slit items should be no larger than 6 and the total produced weight of the order should be no larger than the demand weight. Environmental constraints contained there should be no action if the current bin is to be abandoned, there should be a cut action just before finish action, there should be some slit items before cut action, there should be a

Table 1. Design parameters and variables in process diagram.

parameter/variable	value/statement
$D_{\text{target}}$	$\begin{cases} 2, \text{ while replay buffer size} < 50000 \\ 1, \text{ otherwise} \end{cases}$
$\epsilon_t$	$\begin{cases} 1, \text{ while replay buffer size} < 50000 \\ 0.1, \text{ while } \epsilon_{t-1} \times 0.999 \leq 0.1 \\ \epsilon_{t-1} \times 0.999, \text{ otherwise} \end{cases}$
BS	batch size = 1024
$\pi_\theta$	actor network following parameter matrix $\theta$
$Q_w$	critic network following parameter matrix $w$
T	total time step of the episode

previous slit item if 1 is assigned the length of the previous slit item, the item should exist if it is selected to slit.

Fig 3. State and action of our proposed method.  
Table 2. Definitions of variables in state.

variable	statement
$n/m$	number of items/bins in state
$I$	number of the slit items after previous cut
$L_{max}$	the maximum length in the slit items after previous cut
$C$	number of cuts in the current bin
$W/L$	residual width/ length of the current bin after $I$ slits/ $C$ cuts
$B/BT$	base/ total weight of the current bin
$BR$	residual weight of the current bin after $C$ cuts
$\sigma_i/de_i$	number/ allowable demand error of corresponding order of $i$ -th item
$ds/d_i$	total produced/ demand weight of corresponding order of $i$ -th item
$h_{max}/h_{min,i}$	maximum/minimum length of $i$ -th item
$w_i$	width of $i$ -th item
$wr_i$	total produced weight of $i$ -th item / $d_i$
$c_k$	number of cuts at $k$ -th action (slit or cut)
$h_k/w_k$	length/width of items chose by $k$ -th action, if $k$ -th action=slit -1, if $k$ -th action=cut

A cut reward would be observed if a cut action is executed, cut reward can be formulated as:

$$r_{cut} = \frac{\text{utilization area of current cut}}{\text{total area of current cut}} \quad (3)$$

A bin reward would be observed when taking a finish action, bin reward can be formulated as:

$$r_{bin} = \frac{\text{utilization area of current bin}}{\text{total area of current bin}} \quad (4)$$

Fig 4. Schematic diagram of the scheduled bin.

A reward of -1 would be observed if the action violates the constraints, and 0 otherwise.

There is a variable  $D_t$  to determine whether the episode ends. The value of  $D_t$  is 2 if all of the bins or items are done, 1 if the action violates the constraints, and 0 otherwise.

The expected return value of the environment is estimated as:

$$G_{j,k} = \bar{r}_{cut,j} \times r_{bin,j}, \bar{r}_{cut,j} = \frac{\sum_z^{Z_{T,j}} L_{z,j} \times r_{cut,z,j}}{\sum_z^{Z_{T,j}} L_{z,j}} \quad (5)$$

where  $G_{j,k}$  is the expected return value for  $k$ -th action in bin  $j$ ;  $\bar{r}_{cut,j}$  is the mean utilization rate of all of the cuts in bin  $j$  based on length;  $Z_{T,j}$  is the total number of cuts in bin  $j$ ;  $L_{z,j}$  is the length of  $z$ -th cut in bin  $j$ ;  $r_{cut,z,j}$  is utilization rate of  $z$ -th cut in bin  $j$ .

### 3. Results and discussion

#### 3.1. Training curve.

The higher the mean bin used ratio the better ability for agent to continuously provide actions that satisfied the constraints. After training, the mean bin used ratio achieved about 0.4 (Fig 5-(a)), and the mean utilization rate achieved about 0.7 which is the mean value in the factory (Fig 5-(b)).

#### 3.2. Testing

4 weeks data was used to evaluate the performance of our proposed RL agent. To efficiently reduce the inventory level and the back-order, we force the agent to select the action with the largest probability and satisfying the constraint, so that the agent would never terminate by taking an action that violates the constraints. We compare the result of inventory level, back-order, and utilization rate with MIP. There is an addition constraint in MIP that the utilization rate of each bin should be larger than 0.7, to ensure the mean utilization rate achieve 0.7. To compare our proposed method with MIP fairly, we also add the constraint to our agent and called as “RL\_0.7”.

Although we forced the agent to take an action, avoiding violate the constraints, there are still some reasons lead to a bin used ratio less than 1, such as all of the orders are satisfied and some bins are abandoned (type IV action). Surprisingly, our RL agent solved most bins with a mean utility rate closed to 0.7 (Fig 6).

Fig 5. Training curve of (a) mean bin used ratio and (b) mean utilization rate (average of the last 20 episodes) for each training episode.

Fig 6. RL testing result of (a) Mean bin used ratio and (b) mean utilization rate for each day.

According to Fig 7-(a) and Table 3, MIP had the highest mean utilization rate, but also the highest computation time. RL\_0.7 showed no utilization rate lower than 0.8 with quite lower computation time than MIP which is important in real-world factory for rescheduling. Although RL had the lowest mean utilization rate, the value was also close to 0.7 which is the mean value in the factory and with the lowest computation time. The inventory level of MIP gradually increased every day. RL and RL\_0.7 both showed a lower inventory level compared to

Table 3. Computation time of testing.

Model	Computation time
MIP	23min 50s
RL	2min 36.4s
RL_0.7	9min 11s

MIP and ability to decrease inventory from a high level. (Fig 7-(b)). Fig 7-(c) showed that RL produced the most orders result in the least back-order. RL\_0.7 had less back-order compared to MIP.

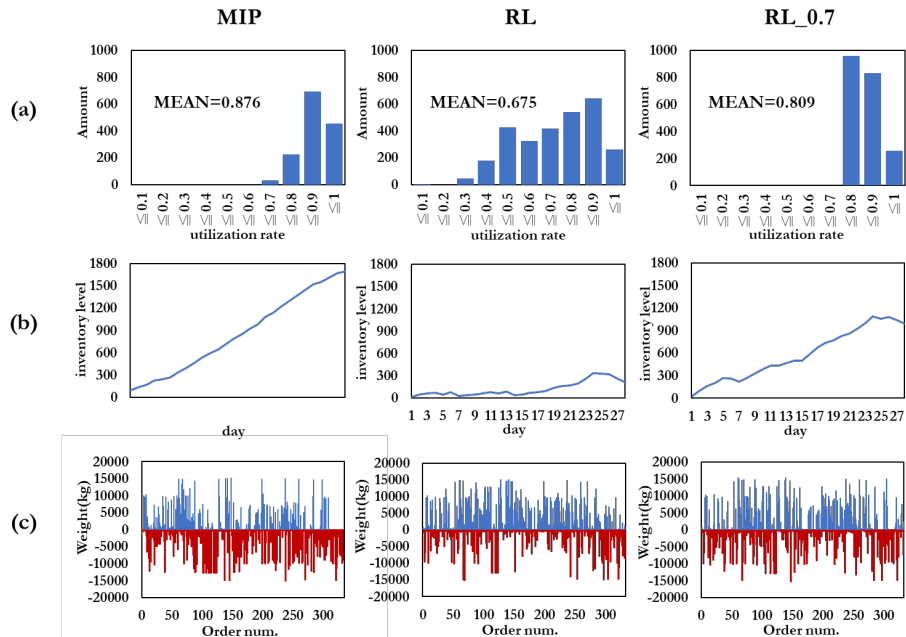

Fig 7. (a) Utilization rate statistics histogram (b) Inventory level for each day (c) Satisfied demand weight (blue) and back-order weight (red) for each order of MIP, RL and RL\_0.7.

#### 4. Conclusion

The proposed RL showed a much better result of inventory level and back-order compared to MIP. Although the mean utilization rate of MIP is the best, the computation time of MIP is also the longest. Furthermore, RL may easily and flexibly make a trade-off between waste, inventory level, and back order, but MIP must add more constraints to take these issues into account, which may make the problem more difficult to solve. The surprising result indicated that RL ability to deal with complex practical industrial problems.

## Abstract

Reinforcement learning (RL) has many new applications in recent years, and its results often exceed human performance, especially in environments where the action space is discrete. However, it is challenging to use RL in the chemical industry, where variables are often continuous and various constraints are complex. This study applies RL with continuous actions to maximize the productivity of a continuous process. The RL agent provides optimal setpoints of flow rates and temperatures while the concentrations of raw materials are changing. Two environments with one and six actions were established after the sensitivity analysis. In the one-action environment, the agents SAC, PPO and A2C showed similar performances, but A2C needed fewer timesteps for training. SAC outperforms PPO and A2C in the environment with six actions. This paper shows the successful RL applications in a continuous process and the high applicability of SAC in both low-dimension and high-dimension environments.

**Keywords:** reinforcement learning, real-time optimization, continuous flow reactors, continuous action space

## 1. Introduction

Reinforcement learning (RL) is a machine learning technique that learns an optimal decision policy based on defined rewards and observations of an environment. Because of its flexibility, it gained popularity in many applications in recent years. The RL results often exceed human performance, especially in the environments (e.g. game) where the action spaces are discrete and the reward is straightforward. However, chemical processes are more difficult to use RL as the common settings should be approached in a continuous way (e.g. flow rates, temperatures). Usually, more trials are done and more time is required compared to discrete spaces at the training stage. Nevertheless, the calculation of the RL agent at the application stage is much faster than classic methods (e.g. linear or nonlinear programming), as no models are used. In the open literature, a RL agent needs 87.7% less calculation time than the nonlinear programming when optimizing a

continuous stirred tank reactor (CSTR) (Powell et al., 2020). Moreover, various constraints in chemical plants are challenging to define in the reward function. Because the RL agent encourages the actions which can lead to higher reward values, the reward function should be designed wisely to meet different constraints. Pèrè et al. (2022) have studied the impact of rewards for the microgrid control. However, the open literature lacks the studies about real-time optimization of continuous flow reactors (CFR) via reinforcement learning and the corresponding designs of reward functions.

This study used RL to optimize the productivity of a chemical plant with six continuous action spaces. The applicability of three RL algorithms, namely Soft actor-critic (SAC) (Haarnoja et al., 2018), proximal policy optimization (PPO) (Schulman et al., 2017), and advantage actor-critic (A2C) (Mnih et al., 2016), in the low- and high-dimension environments was investigated. The following section explains the details of the chemical plant and how RL works.

## 2. Methodology

The plant consists of four identical CFRs in series (see Figure 1). The first three are equipped with jackets, and the last one is air-cooled. The real-time optimization provides six setpoints, which are raw materials A and B flow rates ( $F_{A,SP}$ ,  $F_{B,SP}$ ), feed temperature ( $T_{f,SP}$ ) and three jacket temperatures ( $T_{J1,SP}$ ,  $T_{J2,SP}$ ,  $T_{J3,SP}$ ). The optimization aims to maximize the throughput of product C. A simulation model of this plant for steady states was developed via swarm intelligence (Wu et al., 2022), which was used as the environment in the RL training phase.

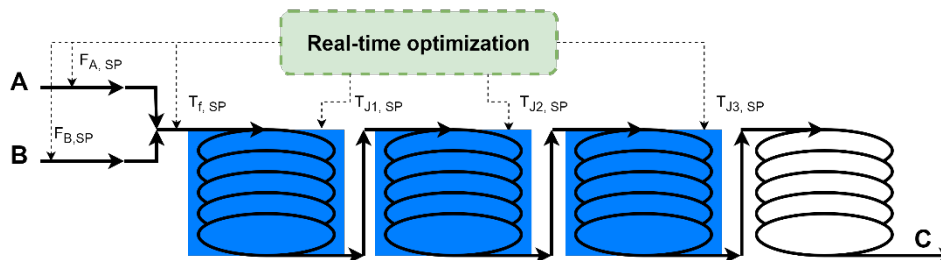

Figure 1: A schematic drawing of the chemical plant. This plant consists of four identical flow reactors. In this system, the feeding raw materials are A and B, and the product is C. The real-time optimization provides six setpoints: A and B flowrates ( $F_{A,SP}$ ,  $F_{B,SP}$ ), feed temperature ( $T_{f,SP}$ ) and three jacket temperatures ( $T_{J1,SP}$ ,  $T_{J2,SP}$ ,  $T_{J3,SP}$ ).

RL consists of two main parts: Agent and Environment. The agent can be structured via different RL algorithms. In this paper, SAC, PPO and A2C are utilized and compared. The simulation environment is only required during the training phase. When the deployment of the trained RL agent is done, the simulation model is not needed any longer (i.e. model-free algorithms). Also, the agent calculation time is usually much less than classic model-based methods because of the high computational complexity of accurate models involved in model-based approaches (Alizadeh et al., 2020). The interaction loop between the agent and the environment in RL is shown in Figure 2.

At each timestep, the agent provides actions after getting observations from the environment. After actions are executed, the environment gives a reward and transits to a new state with new observations. The observations in this paper are set to the changing concentrations of raw materials A and B. The reward value is the normalized outlet

throughput of product C, which is the multiplication of the C concentration and the total flow rate.

Figure 2: Interactions between the environment and the agent in reinforcement learning. At each time step ( $t$ ), after getting observations from the environment, the agent provides actions. After the actions are executed, the environment gives a reward and transits to a new state.

Because of the environment complexity, the RL training can require more than 100,000 environment evaluation steps. Therefore, to reduce the system complexity, a sensitivity study is conducted to check the importance of six actions to the productivity (Li et al., 2010). The RL agent is first trained for the most important action. Then with similar structures, the agent for six actions is developed. The calculation time and the agent performance are also analyzed to obtain the suitable methodology to develop the RL agent. The environments are encoded in “OpenAI Gym v0.21.0” (Brockman et al., 2016) and the python library “Stable-Baseline3 v1.6.2” is utilized (Raffin et al., 2021).

### 3. Results

A steady-state model for the studied was used to establish the training environment. The agent learning is based on the environment, and the utilized model accuracy is crucial. The model in the paper has high accuracy and fast calculation as demonstrated in the previous work. To reduce the model system complexity, a sensitivity study is conducted to check the importance of six actions.

Figure 3: Sensitivity indices of actions to the productivity in the environment. The black vertical lines at the top of the bars show the confidence intervals, and the small ranges of the confidence interval confirm the robustness of the utilized simulation model.

#### 3.1. Sensitivity analysis of available actions

The aim of the global sensitivity analysis is to rank the importance of six available actions with respect to the productivity. The actions with higher sensitivity indices are more important than the others, which means these actions should be considered first if the computation power or the time is limited. Latin Hypercube Sampling generated 1,000 analysis samples within 30% deviations from the baseline setpoints. The baseline setpoints were provided by plant operators and they are 97 kg/h ( $F_{A,SP}$ ), 80 kg/h ( $F_{B,SP}$ ),

20 °C ( $T_{f,SP}$ ), 32.5 °C ( $T_{J1,SP}$ ), 32.5 °C ( $T_{J2,SP}$ ), and 32.5 °C ( $T_{J3,SP}$ ). Moreover, the feeding raw material concentrations ( $C_{f,A}$ ,  $C_{f,B}$ ) are kept constant at 91 wt% and 40 wt%.

The calculated global sensitivity indices of actions are shown in Figure 3. The analysis returned  $F_{B,SP}$  to be the most important action. Physically, this is because B is the raw material in both main and side reactions.  $T_{J1,SP}$  gives a relatively high sensitivity index resulting from that the fact that most reactions are fast and can complete in the first reactor. Therefore,  $F_{B,SP}$  is selected as the most important action in this paper to test three algorithms – SAC, PPO, A2C firstly. After the initial development for the one-action environment, the RL agent for six actions in the high-dimension environment is developed as well.

### 3.2. Performance analysis of agents

The training progresses of SAC, PPO, A2C with one and six actions are illustrated in Figure 4a. The reward value is the normalized productivity, and in all cases the RL training stops when the total timesteps reach 100,000. For the one-action system, all three algorithms reached the maximum reward at the end of the training, and A2C already approached it with less than 20,000 steps. However, A2C got the lowest ending reward in the six-action environment where SAC outperforms the other two algorithms.

Figure 4b gives the required training time to reach the maximum reward value in different approaches. It can be seen that the agents trained in the one-action environment reached the maximum reward faster than the ones trained in the high-dimension environment with six actions, which meets the initial hypotheses. For A2C, the six-action agent requires 25.1% more time than the one-action agent, and that number is 154.5% in SAC. PPO did not even reach the maximum reward value at the end of the training. It shows the high applicability of SAC in both low- and high-dimension environments. A2C is more suitable for the low-dimension environments compared to SAC and PPO, which requires a low amount of training time.

Figure 4: a) The training progress of SAC, PPO, A2C with one and six actions. The reward value is the normalized C productivity. The maximum number of training steps is the same, which is 100,000. b) The required training time of SAC, PPO, A2C with one and six actions to reach the maximum reward values. The used processor is Intel® Xeon® Gold 5220 CPU @2.20GHz.

After completing the training, the developed agent was applied, where the concentrations of the raw materials A and B ( $C_{f,A}$ ,  $C_{f,B}$ ) changed randomly over 50 hours, as shown in Figure 5a. The agents proposed one or six actions to reach a high reward value, and the corresponding reward values are given in Figure 5b and Figure 5c. In the one-action system, SAC, PPO and A2C offered similar performances, which follows the findings in their training progress. Only SAC gave a slightly low reward at the beginning. In the six-action system, SAC outperformed PPO and A2C. In other words, SAC returned a better optimization than PPO and A2C in the high-dimension environment. Figure 6 shows the

behaviors of the six actions from SAC agent. As the concentrations of raw materials changed, the SAC agent gave six setpoints in order to obtain the highest productivity at the new conditions.

Figure 5: The reward values of RL agents for one and six actions over 50 hours. The upper plot shows how the concentrations (in weight mass percentage wt%) of the raw materials A and B ( $C_{f,A}$ ,  $C_{f,B}$ ) change with time. The RL agents were developed via three algorithms (SAC, PPO, A2C) for one and six actions, respectively.

Figure 6: The provided six actions ( $F_{A,SP}$ ,  $F_{B,SP}$ ,  $T_{f,SP}$ ,  $T_{J1,SP}$ ,  $T_{J2,SP}$ ,  $T_{J3,SP}$ ) from SAC agent, which obtains higher reward values than PPO and A2C.

#### 4. Conclusions

This study successfully applied reinforcement learning (RL) in a chemical plant with continuous flow reactors for the real-time optimization. In the plant, the concentrations of the raw materials changed over time. In order to obtain the maximum productivity, six setpoints of flow rates and temperatures were available to be optimized. The developed RL agents provided optimal setpoints based on their learned strategies. The agent learning or training process relies on the interactions between the environment and the agent. Two environments with one and six actions and three RL agent algorithms (soft actor-critic (SAC), proximal policy optimization (PPO), and advantage actor-critic (A2C)) were investigated. The one-action environment was established after the sensitivity analysis. In the one-action environment, SAC, PPO and A2C showed similar performances, but A2C needed less training time. This indicates that A2C is more suitable in the low-dimension environment due to its high efficiency. SAC outperformed PPO and A2C in the environment with six actions, which illustrates the high applicability of SAC in both low-dimension and high-dimension environments. This paper showed the performance of RL agents in the chemical industry. The future work will compare the employed RL algorithms with classic model-based methods. Also, the applied reward functions in both environments for steady states are simply the normalized productivity in this paper. The future work will design new reward functions considering complex constraints, and will study the transit behaviors of the plant from dynamic models.

## Abstract

Although distillation is considered the most mature and computationally easiest to analyze and optimize fluid separation process, support for flowsheet synthesis for the separation of multicomponent azeotropic mixtures is still limited. Commercial simulation software like Aspen Plus mainly offers a graphical analysis of residue curve maps for ternary (sub)systems or an iterative evaluation based on tedious simulation studies. The current work presents an integrative algorithmic approach that pursues an automatic synthesis of distillation processes for azeotropic mixtures, building on a topological analysis of the distillation regions and evaluation of residue curves, pinch lines, and rectification bodies. The derived flowsheet structures and the estimated minimum reflux ratios are the basis for optimization-based initialization of rigorous column models and full-scale simulations of the integrated flowsheets in the industrial in-house simulation tool Chemasim. Thus, the method provides an algorithmic fast-track from a thermodynamic mixture model to a rigorous simulation of automatically derived flowsheets.

**Keywords:** process synthesis, simulation, distillation, conceptual design, azeotropic mixtures.

## 1. Introduction

The conceptual design of separation processes has been subject to continuous research for more than 40 years, with various developments, especially for the design of distillation-based processes. While the separation of zeotropic mixtures is well understood and all basic and complex column sequences can be generated (Madenoor Ramapriya et al., 2018) and evaluated efficiently by systematic and optimization-based methods (Jiang et al., 2019), the synthesis of distillation processes for the separation of azeotropic mixtures appears to present a more challenging problem, which has not been satisfactorily solved yet. The most established tools for the generation of process concepts rely on graphical analysis by means of residue curves or distillation line maps, which represent the vapor-liquid equilibrium characteristics, including the location of azeotropes and the illustration of distillation boundaries. While available in many

flowsheet simulators, such as Aspen Plus, such tools are limited in applicability to ternary and quaternary mixtures. Few algorithmic methods have been proposed to automate this process since the early 2000s. Superstructure optimization methods either consider linear approximations of distillation boundaries and the treatment of azeotropes as pseudo-components (Yang et al., 2011) or, e.g., a limitation to binary azeotropes, which can be separated by extractive distillation (Tsai and Ward, 2020). A more general concept builds on an analysis of split feasibility considering topological distillation regions, as proposed by Rooks et al. (1998), which was the basis for the synthesis methods proposed by Tao et al. (2003) and the work of Thong et al. (2004), who illustrated the potential application to multicomponent mixtures with several azeotropes and distillation regions. Yet, only the method of Waslykiewicz and Castillo (2001), which was developed as part of DISTIL, was shortly available in Aspen Plus after the acquisition of Hyprotech by Aspen Tech. Yet, to our knowledge, there is no documented case of an industrial application of these methods. One potential reason for the lack of adoption is the lack of a consistent connection between the process synthesis methods and a rigorous process simulation, which is the main tool used for process development in industrial practice and which, given sufficiently accurate thermodynamic models, can be seen as a validation of the feasibility of the derived process concept.

In order to bridge this gap, the current study presents an integrated workflow for the automated synthesis of distillation processes for the separation of homogeneous azeotropic mixtures that allows for a direct transfer and validation of the results by means of a converged rigorous steady-state simulation of the derived flowsheets. Flowsheet alternatives are generated using a recently developed automatic process synthesis (APS) tool (Sasi and Skiborowski, 2020), building on a topological analysis, residue curve and pinch line computations, and the rectification body method (Bausa et al., 1998), providing an estimate of the minimum energy demand of the individual separations. The resulting flowsheet configurations, mass balance information, and energy estimates are further processed in a FlowsheetExplorer, which determines initial composition profiles and actual reflux ratios for individual columns with finite stage numbers that are finally transferred to the BASF in-house flowsheet simulator Chemasim, where the full process flowsheet is generated and optimized providing a converged rigorous flowsheet simulation, which satisfies the product specifications. The method is demonstrated for the separation of a well-known quaternary mixture of acetone-chloroform-benzene and toluene, which exhibits a strongly curved distillation boundary. The results illustrate the potential benefits of an algorithmic flowsheet synthesis and the possible speed-up of the conceptual design process.

## 2. Method

The proposed integrated workflow that allows for a direct application in an industrial context is schematically illustrated in Figure 1. It consists of two main steps for an automated process flowsheet synthesis (APS Tool, Fig. 1 left) and an optimization-based column and flowsheet initialization (FlowsheetExplorer, Fig. 1 right), which are pursued in a sequence of steps further outlined in the following subsections. The combination allows for the derivation of converged flowsheet simulations on the basis of rigorous equilibrium tray models of the individual distillation columns, which satisfy the desired product specifications, starting from a definition of the separation problem and the thermodynamic property models.

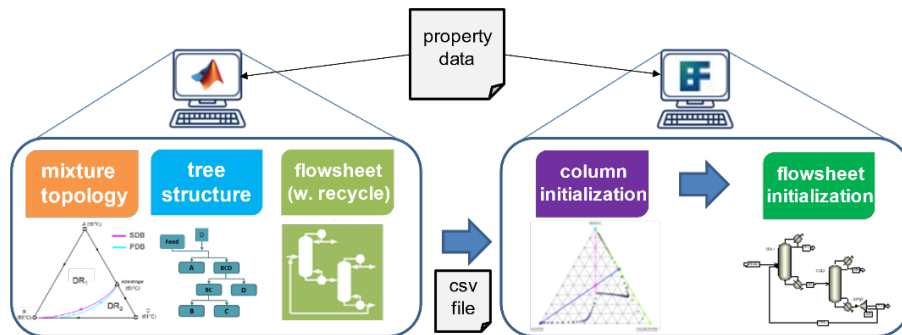

Figure 1: Illustration of the individual steps of the topology-based process synthesis (APS Tool) and optimization-based initialization and flowsheet simulation (FlowsheetExplorer).

### 2.1. Automated process synthesis

The APS tool aims at the generation of feasible process configurations based on the specification of a thermodynamic model for the phase equilibria of the considered mixture and the specification of the feed and desired products. In the first step, the topology of the mixture is analyzed, i.e., the computation of azeotropes and the characterization of all singular points regarding their stability, as well as the identification of the topological distillation regions (DR), based on the concept of the adjacency and reachability matrices (Rooks et al., 1998). The knowledge of the topological distillation regions is the foundation on which process variants are derived in the subsequent step, building on an algorithmic split feasibility check, which combines repeated computations of residue curves (total reflux distillation) and pinch lines (reversible distillation) to check if the products are located in the same DR for at least one mode of limiting operation. Further application of the rectification body method (RBM) (Bausa et al., 1998) evaluates the minimum reflux ratio of individual splits, given an intersection of the linear approximation of the potential manifolds of the individual column section profiles. Based on the derived tree structure, potential recycle streams and locations are identified following the ideas of Tao et al. (2003), closing the respective recycle loops in an iterative approach with additional RBM evaluations. The final flowsheets are thereby characterized by the respective mass balances for the individual columns and the estimates of the required heat duties, which not only allow for an initial ranking of alternative flowsheet configurations, but also provide essential information for the initialization of more rigorous flowsheet simulations based on consistent equilibrium tray models. This information is further transferred to the FlowsheetExplorer for the subsequent initialization and flowsheet optimization in a specific CSV file format. Refer to the article of Sasi and Skiborowski (2020) for further details on the process synthesis method, including potential pressure modifications. The MATLAB tool can be evaluated via the open GitLab project (APS tool), including respective examples.

### 2.2. Optimization-based column and flowsheet initialization

The second part of the integrated workflow aims at the initialization and subsequent optimization of rigorous flowsheet models in BASF's in-house flowsheet simulation software Chemasim. The results of the variant generation provide the necessary connectivity and mass balance information to build the individual flowsheet models for the derived candidates in the FlowsheetExplorer.

Since the minimum heat requirements derived from the RBM build on the computation of pinch points alone, they do not provide continuous composition and temperature profiles for the individual columns. To derive appropriate stage numbers for each column

section and to provide reasonable estimates for the composition and temperature profiles, individual optimization problems are first solved for all columns. These optimizations aim to find a composition profile such that the compositions of the bottom and top streams of the column are close to the compositions found by the APS tool. The optimizations are constructed as described by Seidel et al. (2020). The profiles are partially calculated using tray-to-tray calculations starting from the top and bottom streams and calculated towards the feed stage. The equations of the feed stage are included as constraints in the optimization problem. This means that after the optimization has converged, all equations for the rigorous simulation of the column are satisfied. For the optimization of each column, a constant molar overflow is assumed, and the optimizer can vary the number of stages and the reflux ratio for each individual column.

The goal of the individual column optimizations is to find good initial profiles quickly and robustly. However, in the transfer, the compositions calculated by the APS tool and this initialization procedure will not match perfectly, such that the feed streams of columns in the flowsheet will potentially change, and the profiles calculated by a rigorous flowsheet simulation may deviate due to the connection of the different columns. In order to further improve the flowsheet initialization, a second optimization can be started in the FlowsheetExplorer to find an initial profile that matches the concentrations, but this time with respect to the connected closed-loop flowsheet. Since the first optimization already found good initial profiles, this second optimization can be done within Chemasim. The FlowsheetExplorer automatically sets up and executes this second optimization, which not only verifies the feasibility of the derived process configurations, but also allows for further derivation of more informative cost estimates for the different process variants.

### 3. Case Study

As a representative case study, the separation of the four-component mixture of acetone, chloroform, benzene, and toluene (ACBT) with an equimolar composition and a flow rate of 10 mol/s, as investigated in the article of Liu et al. (2004), is considered. While the algorithmic approach of Liu et al. (2004) was able to derive a variety of flowsheets with at least four distillation columns, Kraemer et al. (2009) proposed three additional process configurations with only three distillation columns by means of graphical analysis of the pitchfork distillation boundary (PDB), which were shown to be favorable in terms of the minimum energy demand estimates of the RBM. The APS tool automatically derives 12 process configurations as feasible flowsheets, including the three configurations with only three distillation columns proposed by Kraemer et al. (2009). This becomes feasible due to the consideration of both limiting operation modes by computation of residue curves and pinch lines. The computations take less than five minutes of computational time on a standard desktop computer. Figure 2 summarizes the respective minimum heat duties estimated by means of the RBM in the APS tool (right) and illustrates the four most promising process variants (left), which include all three of the previously mentioned three-column configurations. All remaining process variants consist of either four or five column flowsheets, with an increase in the accumulated heat requirement of up to 135%.

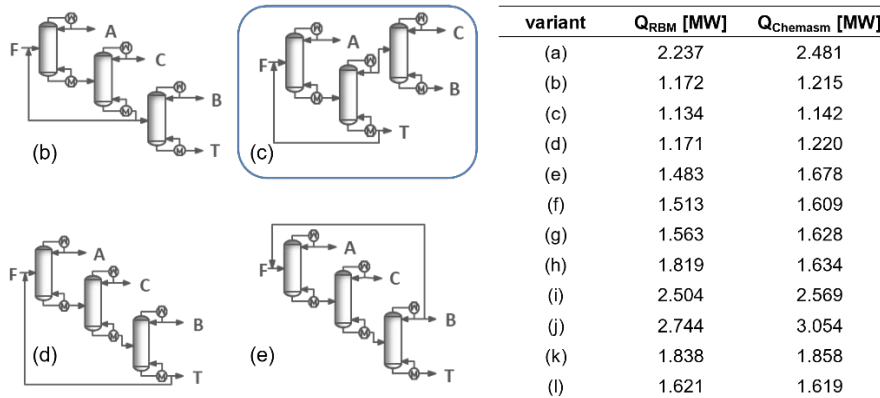

Figure 2: Illustration of the four most promising process flowsheets for the ACBT separation (left) and overview of the cumulative heat requirement of all 12 derived process variants (right).

Based on the results of the APS tool, adequate tray numbers and column profiles are first determined for each individual column and then for the entire flowsheets by means of the FlowsheetExplorer, which takes around 16 minutes of computational time. Converged closed-loop flowsheet simulations were obtained for all 12 process variants. Figure 3 exemplarily illustrates the composition profiles of the individual components in the respective columns 1-3 for process configuration (c), which provides the lowest energy requirements. The resulting flowsheets and the obtained starting profiles were passed over to Chemasim to pursue a heat minimization with rigorous equilibrium tray models and product purities of 99 mol% set as constraints. The optimization of all 12 flowsheets takes around 52 minutes. The excellent agreement of the resulting accumulated heat duties of the rigorous flowsheet optimization and the initial shortcut evaluation are illustrated by the side-by-side comparison in Figure 2 (right).

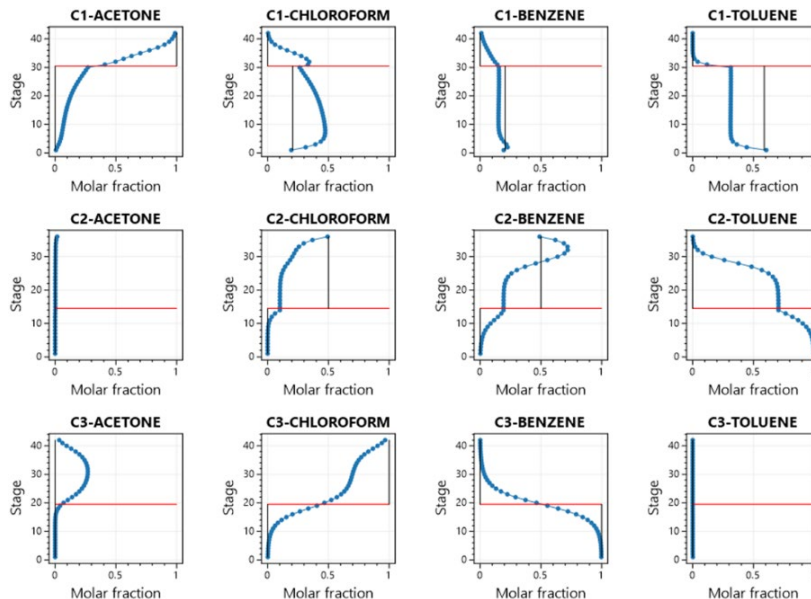

Figure 3: Illustration of the resulting composition profiles of the three columns in the flowsheet variant (c) after initialization and optimization in Chemasim.

Especially for the three best variants, a mean deviation of only 3% is reached. Overall, even larger deviations, which can be explained by the linear approximations of the RBM and variations in the recycle compositions, are limited (< 15%) and do not significantly affect the ranking of the variants. Furthermore, it can be noted that the results of the rigorous flowsheet evaluation of the best flowsheet variant fit very well with the optimization results reported by Kraemer et al. (2009).

#### 4. Conclusion and outlook

The current article illustrates how a set of multi-purpose tools for the conceptual design of distillation-based separation processes can be integrated for a fully automated synthesis and rigorous simulation of distillation processes to separate homogeneous azeotropic mixtures. The basis for the integrative approach is a specification of the separation problem and a consistently applied thermodynamic model, which is the fundamental requirement for any meaningful flowsheet simulation. Since the applied topological synthesis tool of Sasi and Skiborowski (2020), which also allows for the consideration of pressure variations, does not build on constant relative volatilities, a graphical interpretation or a geometric approximation of the distillation boundaries, it is practically not limited with respect to the number of components or complexity of the mixture. The derived flowsheet structures and the estimated minimum reflux ratios build the basis for the subsequent optimization-based initialization of rigorous equilibrium tray models and the final simulation of the integrated closed-loop flowsheet in Chemasim.

Future investigation will not only evaluate the application to much larger multicomponent mixtures, but also extend the design space to consider liquid-liquid separations, as in heteroazeotropic distillation (Sasi and Skiborowski, 2020) and liquid-liquid extraction (Sasi and Skiborowski, 2022), as well as extractive distillation. Furthermore, the possibility for process intensification and energy integration may also be explored in an automated form by further extending the synthesis method with adapted shortcut-screening methods (Skiborowski, 2018). Also, to speed up the closure of multiple recycle streams simultaneously, we are currently exploring the option to adaptively determine points on the distillation boundary and formulate a linear optimization problem.

# A Hybrid Modelling Framework for Dynamic Modelling of Bioprocesses

Haiting Wang<sup>a</sup>, Cleo Kontoravdi<sup>a</sup>, Ehecatl Antonio del Rio Chanona<sup>a</sup>

<sup>a</sup> *Sargent Centre for Process Systems Engineering, Department of Chemical Engineering, Imperial College London, London, United Kingdom SW72AZ*

## Abstract

One of the main hurdles in the computer-aided design and optimization of industrial bioprocesses is the limited capability of models to accurately represent biosystems. On one hand, mechanistic models have drawbacks in terms of expressing all potential biomechanisms. On the other hand, data-driven models have limited extrapolation ability. Thus, hybrid models may represent the best of both worlds. However, it is challenging to build a hybrid model that can accurately balance its data-driven and first principles components, hence allowing for extrapolation ability and accuracy.

In this work, we propose a framework for the development of hybrid models that includes a mechanistic backbone for its construction and judiciously adds the data-driven components. Statistical methods e.g., Bayesian Information Criterion (BIC), Akaike Information Criterion (AIC) and Hannan Quinn Criterion (HQC), are employed to choose the statistically best hybrid model structure. The proposed framework is tested on a simplified microalgae cultivation case study and shows good prediction capabilities under different noise levels, especially by applying BIC for hybrid model selection.

**Keywords:** Model selection, Hybrid modelling, Bioprocess modelling, Information criteria.

## 1. Introduction

Industrial bioprocesses have experienced fast development in many fields. However, most bioprocesses suffer from low production yields, and experimental optimization of these systems is both resource-intensive and time-consuming. Therefore, building mathematical models which can accurately describe the dynamic behavior of biosystems is crucial for process design, scale-up and optimization. Constructing a mechanistic (first principles) model based on physical and biological knowledge has been widely investigated with very good success, but also room for improvement (Tsopanoglou and Jiménez del Val, 2021). Because investigating and quantifying cellular mechanisms is very challenging, especially considering the intracellular metabolic reaction networks of living cells and how they are influenced by variations in operating conditions. To address these challenges, data-driven models have attracted a lot of attention given that they do not require physical knowledge. However, the biggest drawback of data-driven modelling is the requirement for high quantity and quality of measured data for model training, and their inability to extrapolate, which is critical for optimization and control.

To take advantage of both mechanistic and data-driven models while avoiding their drawbacks, hybrid models are considered good potential solutions. They have mechanistic backbones to promote extrapolation performance. At the same time, complicated biomechanisms are modelled with properly selected data-driven components

that avoid heavy mechanistic expressions. Therefore, when training a hybrid model with the same dataset, it has better extrapolation and interpretation ability compared to the data-driven model, and it is easier to construct than a mechanistic model.

However, to build a good performing hybrid model, it is important to balance the weight of the data-driven sub-model and the mechanistic backbone. To achieve this, empirical model selection methods such as the L1 and L2 regularizations have been widely applied (Tibshirani, 1996). However, these methods are non-statistical, and the model selection results are not consistent. Alternatively, in this work, statistically-derived information criteria are applied for model selection, specifically, the Akaike Information Criterion (AIC) (Stoica and Selen, 2004), Bayesian Information Criterion (BIC) (Stoica and Selen, 2004), and Hannan Quinn Criterion (HQC) (Hannan and Quinn, 1979).

AIC is derived from information theory, which defines the best model as the one that can minimize the information divergence between the observed data and simulation results. The equation of AIC can be represented as below:

$$J = 2n_{\theta} + 2NLL(\theta) \quad (1)$$

Where  $NLL(\theta)$  is the negative log-likelihood (NLL) function based on parameter  $\theta \in \mathbb{R}^{n_{\theta}}$ , which represents the goodness of fit between the model prediction and the measured data, and the total number of parameters in the model candidate,  $n_{\theta}$ , is penalized.

On the other hand, BIC is derived from the Bayes' rule, which assumes that a 'true' model exists among all candidate models, and the best model is the one which has the maximum posterior probability value to be the best model (Stoica and Selen, 2004):

$$J = 2n_{\theta} \ln(n_d) + 2NLL(\theta) \quad (2)$$

It can be seen from Eq.2 that BIC penalises model complexity by considering not only  $n_{\theta}$ , but also  $n_d$  which is the number of data points in the training set. Like the BIC, the HQC is derived to select the 'true' model instead of the one that minimizes the information loss from data, and the expression can be shown below:

$$J = 2n_{\theta} \ln(\ln(n_d)) + 2NLL(\theta) \quad (3)$$

In terms of penalty terms, the HQC also considers the impact of the training dataset size, while it penalises the model complexity less strongly than BIC. By using these information criteria for model selection, the best model is chosen by minimizing the value of these information criteria.

Because these information criteria are derived from different statistical perspectives, they show different model selection behaviors. It can be found from the literature that BIC tends to consistently choose the 'true' model and penalizes model candidates with higher model complexity more than the 'true' model, while AIC prefers to select the model with better fitting performance even if it is more complex than the 'true' model (Vrieze, 2012). In this work, we propose a hybrid modelling framework with the application of statistical information criteria to efficiently construct hybrid models with good extrapolation ability for the dynamic modelling of bioprocesses.

## 2. Hybrid modelling framework

The proposed hybrid modelling framework comprises 4 steps: mechanistic backbone construction, data-driven sub-modelling, hybrid model integration and model validation as shown in Figure 1. To find the best hybrid model that balances the fitting and extrapolation performance, AIC, BIC and HQC are used for statistical model selection and embedded into the framework. During this step, model structure selection and parameter estimation are conducted. In the end, the parameter uncertainty analysis and robustness test are carried out on the constructed hybrid model.

Figure 1 Illustration of the hybrid modelling construction framework.

### 3. Case study –Microalgae Cultivation

#### 3.1. Microalgae cultivation system

A simplified microalgae cultivation process under fed-batch operating conditions was used as a case study. This model is a simplification from the model which describes the biomass growth and nitrate consumption in a bioreactor (del Rio-Chanona et al., 2015). A mechanistic model is introduced to describe the dynamic change of biomass concentration  $C_X$  and nitrate concentration  $C_N$  with a constant feeding rate  $F_{in}N_{feed}$ :

$$\frac{dC_X}{dt} = \mu_M C_X \frac{C_N}{C_N + K_N} - \mu_d C_X^2 \quad (4)$$

$$\frac{dC_N}{dt} = -Y_{N/X} \mu_M C_X \frac{C_N}{C_N + K_N} + F_{in}N_{feed} \quad (5)$$

Where  $\mu_M$  is the specific biomass growth rate,  $\mu_d$  is the biomass death rate,  $Y_{N/X}$  is the specific nitrate uptake ratio, and  $K_N$  is the half-velocity coefficient.

#### 3.2. In-silico data generation

The mechanistic model above is used for in-silico data generation for model training. In this work, three computational experiments are generated with different initial concentrations for  $C_X$  and  $C_N$ . These computational experiments simulate the dynamic change of  $C_X$  and  $C_N$  in 384 hours of operational time, and the generated data for  $C_X$  and  $C_N$  is collected in 10-hour intervals. Different levels of Gaussian noise are applied to the training datasets to mimic real-life measurements. Noise levels of  $C_X$  and  $C_N$  are certain percentages of their mean values respectively. At the same time, three validation datasets are generated with different initial concentrations, but the same data collection intervals compared to training datasets.

#### 3.3. Hybrid model construction

Following the first step in the framework, the mechanistic backbone is designed first. By applying simple mass balance on  $C_X$  and  $C_N$ , the mechanistic backbone is shown below:

$$\frac{dC_X}{dt} = \mu_m C_X - \mu_d C_X^2 \quad (6)$$

$$\frac{dC_N}{dt} = -Y_{N/X} \mu_m C_X + F_{in}N_{feed} \quad (7)$$

Among all variables in the mechanistic backbone, it is challenging to accurately describe the biomass growth rate  $\mu_m$  dependence on metabolite concentrations and bioreactor operating conditions. Thus, to avoid the complex mechanistic expression, we choose a data-driven method to represent it in terms of the variable it depends on.

In this work, the data-driven sub-model aims to determine the relationship between  $\mu_m$ ,  $C_X$  and  $C_N$ . Third-order polynomial regression is chosen for this purpose as shown below:

$$\mu_m = p_0 + y_0 p_1 C_{X\_norm} + y_1 p_2 C_{N\_norm} + y_3 p_4 C_{X\_norm}^2 + \dots + y_8 p_9 C_{N\_norm}^3 \quad (8)$$

$$C_{X\_norm} = \frac{C_X}{C_{Xmax}} \quad (9)$$

$$C_{N_{norm}} = \frac{C_N}{C_{N_{max}}} \quad (10)$$

Where  $p_i$  are coefficients of each polynomial term and  $y_i$  are binary variables. Binary variables are used to describe whether their corresponding polynomial term is selected or not when carrying out statistic model selection. Moreover,  $C_{X_{max}}$  and  $C_{N_{max}}$  are the maximum measured value of  $C_X$  and  $C_N$  respectively and they are introduced to normalize the dependencies. Other data-driven methods can also be applied instead of polynomial regression, especially for highly nonlinear systems, such as Artificial Neural Network (ANN), Partial Least Square regression (PLS) and Gaussian Process (GP).

By integrating the mechanistic backbone with the polynomial expression of  $\mu_m$  we can get the basic structure of the hybrid model. Then, to find the best structure of the hybrid model, statistical model selections are applied, which is the core of the model integration step. During this step, parameter estimation and model selection can be carried out by solving a MINLP problem to obtain the best hybrid model. Finally, the best hybrid model is validated using 3 sets of validation data as described in section 3.2.

#### 4. Results and Discussion

First, a simple task is carried out to demonstrate the concept of statistical selection of the best-performing hybrid model. In this case, we assume the ideal behavior of each state variable is described by the mechanistic model that we used for data generation, thus the best hybrid model is the one that gives the best agreement with the mechanistic model even if it is trained by noisy data. The agreement is judged based on the mean square error from validation datasets. Then, to further test the proposed hybrid model construction framework, we assess its performance when it is trained with datasets with different noise levels, from 5% of the mean of  $C_X$  and  $C_N$  to 20%.

##### 4.1. Proof of concept

To empirically study whether the information criteria can effectively select the best hybrid model structure that can avoid overfitting and achieve the best extrapolation capability, we generate 9 hybrid model structures by adding polynomial terms in the sequence in Eq.8. The existence of polynomial terms is represented by setting their corresponding  $y_i$  to 1. Then, each hybrid model is trained with a dataset with 5% noise. All three information criteria and NLL values are estimated for each structure. Moreover, each model is validated using validation datasets and the results are shown in Figure 2:

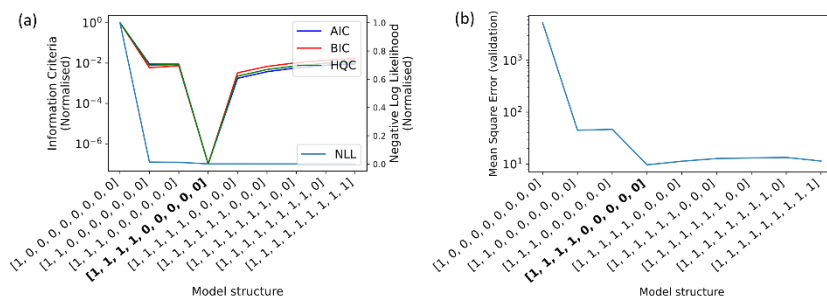

Figure 2. Training and validation results of 9 hybrid model structures. (a) Estimation of AIC, BIC, HQC and NLL for each hybrid model structure. (b) Validation results of each hybrid model structure.

As shown in Figure 2, the increase of polynomial terms in sequence of the hybrid model decreases the corresponding NLL values, which indicates an improvement in the fitting. However, the improvement becomes much less significant after a certain stage, indicating the occurrence of overfitting. By calculating the value for AIC, BIC and HQC, we can see from Figure 2(a) that all three information criteria start to penalize the over-complexed structure when the model has more than the first 4 polynomial terms. The validation results show a strong agreement on the best hybrid model structure selected by information criteria among these 9 candidates, highlighting the effectiveness of statistical model selection methods.

4.2. Robustness test under different noise levels

As mentioned in Section 1, AIC, BIC and HQC have different statistical properties. Thus, we need to evaluate their robustness, especially under different noise levels since low-quality data is one of the most common problems for bioprocess modelling. Therefore, 4 training datasets are generated with the noise level of 5%, 10%, 15% and 20% respectively. Also, under each noise level, 10 datasets are generated and used for hybrid model construction to quantify result uncertainties.

The total number of polynomial terms ( $n_p$ ) in Eq.8 can vary from 1 to 8. Therefore, we can first find 7 potential best hybrid models with certain  $n_p$  value (models with  $n_p = 8$  are significantly overfitted and not presented here). Then the corresponding information criteria's values and the validation results can be estimated for each model with a certain standard deviation as shown in Figure 3.

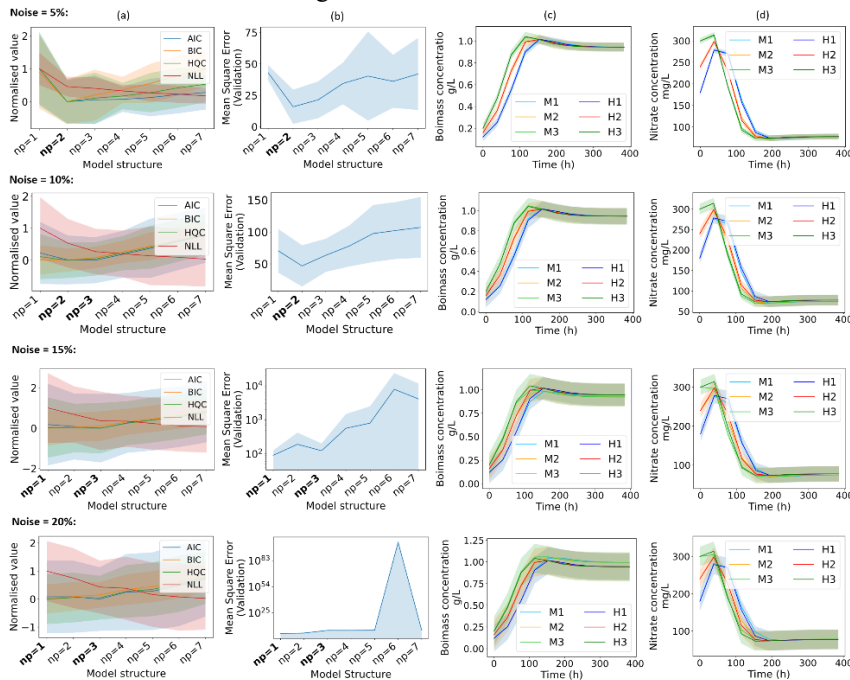

Figure 3. Training and validation results of all potential hybrid model structures under different noise levels. (a) Estimation of AIC, BIC, HQC and NLL for each hybrid model structure. (b) Validation of each hybrid model structure. (c) and (d) Validation results of biomass and nitrate concentration prediction given by the best hybrid model respectively. (M1, 2 & 3 represent validation datasets from the mechanistic model, while H1, 2 & 3 represents validation results given by the hybrid model)

It can be seen from the validation results in Figure 3(b) that the best hybrid model structure varies with the increase of noise level because the model is easier to overfit when data is highly noisy. The best hybrid model is the one with  $n_p = 2$  under 5% and 10% noise while it becomes the one with  $n_p = 1$  when noise increases to 15% and 20%.

Statistical model selection results are shown in Figure 3(a) at each noise level. It can be seen that all information criteria choose the same model structure under 5% noise. However, they show different model selection results under different noise levels. When noise increases to 10%, BIC and HQC still successfully select the best hybrid model structure, while AIC chooses a model structure with worse performance ( $n_p = 3$ ). Under a 15% noise level, both HQC and AIC select the wrong model structure ( $n_p = 3$ ) while BIC still selects the correct one. By increasing the noise level to 20% only BIC and HQC can find the best model structure.

In summary, our results suggest that BIC is the most robust information criterion which shows stable performance on choosing the best model structure, while HQC and AIC are not as reliable since they put more weight on getting the better fitting performance and penalise model structure complexity weaker. Additionally, it can be seen from Figure 3 (c) and (d) that by using information criteria for model selection, even if the hybrid model is trained under strong noise, the model can maintain good extrapolation ability and shows good agreement with the purely mechanistic model.

## 5. Conclusion

In this work, a hybrid model construction framework was proposed and tested on a biomass cultivation case study. The results show that by applying this framework, and especially by using statistical information criteria, the best hybrid model structure can be efficiently selected. Among all three information criteria, BIC shows the most consistent performance against the increase of noise level from the training dataset. In the future, we will apply this framework to more complex case studies such as the photo-production process, and the polynomial regression will be replaced with a more complex data-driven model such as ANN. Finally, an uncertainty analysis of the constructed hybrid model will be carried out.

## Abstract

Synthesis of separation networks has been researched for many years because of their potential in improving profit and reducing carbon emissions. However, most of the presented work concentrated on identifying novel solutions for the downstream section such as improving thermal efficiency by using complex heat exchanger networks, applying advanced separation techniques, and optimizing the design/operating parameters, etc., without considering the effect of upstream reaction pathways. This work aims to develop a mixed integer non-linear programming (MINLP) optimization model, which integrates reaction pathway selection and downstream separation optimization. To ensure both process profit and sustainability, the objective is to maximize the process profit per carbon emission. Decision variables such as binary variables, which represent the selection of reaction pathway and separation task, and continuous variables, which influence the separation mass/energy balance, are considered. By giving parameters like reaction conversion rate, component relative volatility, component enthalpy, raw material/product price, etc., this optimization model can simultaneously identify the optimal reaction pathways and their separation network. The optimization model was applied to isobutylene and methanol utilization case studies. The results indicate that the model could identify the best product and the associated best performing process.

**Keywords:** Reaction pathway identification, separation synthesis, optimization.

## 1. Introduction

The downstream separation network is defined as a process that comprises different unit operations, such as separators, heat exchangers and mixers, etc., to handle multicomponent separation and produce the desired products. In general, several configurations based on different separation techniques and separation sequences can be generated, and the selected options significantly influence the overall process cost and sustainability. Therefore, the optimal configuration has to be identified to ensure overall process profitability and sustainability. One established approach is the superstructure-based model, where all feasible separation configurations are generated, and the optimal choice is identified through mathematical optimization. Despite significant research on this approach, most work has been limited to downstream separation optimization, such as adding intensified equipment into the separation configurations (Caballero and Grossmann 2001, 2013), systematically identifying novel intensified unit operations (Demirel et al., 2017), simultaneous optimization of distillation networks and heat exchanger networks (Yeomans and Grossmann, 2000), but the effect of upstream conditions/decisions was not considered explicitly. Ryu et al. (2020) pointed out that the

separation network synthesis efforts should also consider the upstream reaction because the choice of the reaction influences the decisions on the downstream separation.

Integrating different reaction pathways and separation process configurations to determine the optimal products/feedstocks and process configuration has been widely researched in the biochemistry area. Kong and Shah (2016) proposed a mixed integer linear programming (MILP) model to determine the optimal reaction and separation process for utilizing bio-based materials. Zondervan et al. (2011) reported a superstructure-based optimization model to determine the optimal reaction and separation steps for biorefinery systems under different optimization objectives. Kelloway and Daoutidis (2014) developed an optimization model to identify the optimal feedstocks, products, and process configurations by maximizing the net present value and carbon efficiency for the biorefinery systems. However, with the progress of sustainable design, it is also necessary to construct a generalized optimization model for the conventional process industry to simultaneously select/optimize reaction pathways and downstream separation networks.

## 2. Methodology

The main goal is to construct an optimization model to identify the best process for producing a specific product or utilizing raw materials, which includes two parts: 1) selection of reaction pathways that convert raw materials into products. 2) identification of separation configurations that separate the reaction outlet into the final product. An example superstructure representation of this problem is illustrated in Figure 1. Given a low-value raw material, various reaction pathways can be applied to convert the raw material into different high-value products, and the outlet mixture can be separated by passing through the separation networks. The objective is to identify the most valuable product and the optimal separation configuration that ensure both process profit and sustainability.

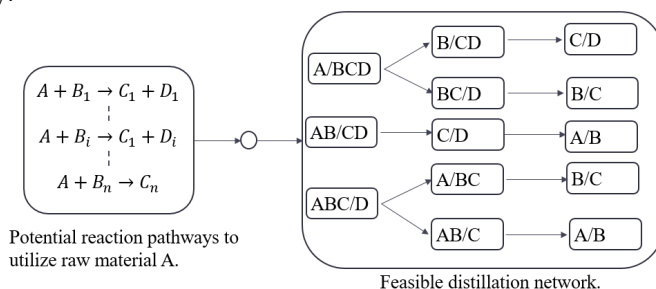

Figure 1. Superstructure representation of the optimization model.

### 2.1. Optimization model formulation

The objective is to identify the optimal reaction pathway and separation network that has the maximum process profit per carbon emission (Eq. 1). The whole process profit involves product sales and process operating costs. Also, to ensure the process sustainability, carbon emissions is considered. Reaction pathways selection and distillation mass balance constraints are given in Eqs. (2) and (3). To calculate the distillation operating cost, a short-cut distillation model (Ryu et al., 2020) that is based on distillation column vapor flowrate and enthalpy balance is given in Eqs. (4) – (7). Note here, because the number of inlet components varies according to the selection of different reaction pathways, a pseudo-component that has zero inlet flowrate is defined

in this model. To find feasible solutions of the short-cut model when the inlet component has zero flowrate, a disjunctive constraint is formulated in Eq. (4). The carbon emission constraint is given in Eq. (8). Here, natural gas is set as the primary fuel for generating the utility. By converting the heat duty into the amount of standard natural gas, the carbon emissions can be calculated based on the standard natural gas conversion factor (50.15 Kg CO<sub>2</sub>/GJ) (Shi et al., 2022). In this model, the purity of the product is specified at 99.5%, which is given in Eq. (9).

$$\max: \frac{\sum_k P_k F_k - \sum_j Q_j}{\sum_j C_j} \quad (1)$$

$$s. t. \quad \sum_i y_i = 1, \quad y_i \in \{0,1\} \quad (2)$$

$$y d_j F_{j,k} = F_{j,k,0} + F_{j,k,1}, \quad y d_j \in \{0,1\} \quad \forall j \in J, k \in K \quad (3)$$

$$\left[ \begin{array}{l} F_{j,k} F_{j,k+1} = 0 \\ \phi_l = 0, l = k \end{array} \right] \vee \left[ \begin{array}{l} F_{j,k} F_{j,k+1} \neq 0 \\ \sum_k \frac{\alpha_k F_{j,k}}{\alpha_k - \phi_l} = 0 \\ \alpha_k < \phi_l < \alpha_{k-1} \end{array} \right], \quad \forall k \in K, j \in J, l \in L \quad (4)$$

$$V_{j,0} \geq \sum_k \frac{\alpha_k F_{j,k,0}}{\alpha_k - \phi_l}, \quad \forall j \in J, l \in L \quad (5)$$

$$V_{j,1} \geq \sum_k \frac{-\alpha_k F_{j,k,1}}{\alpha_k - \phi_l}, \quad \forall j \in J, l \in L \quad (6)$$

$$Q_j = U_{j,0} V_{j,0} H_{j,0} + U_{j,1} V_{j,1} H_{j,1}, \quad \forall j \in J \quad (7)$$

$$C_j = \eta V_{j,1} H_{j,1}, \quad \forall j \in J \quad (8)$$

$$g(F_k) \geq 0.995, \quad \forall k \in K \quad (9)$$

Here, the sets  $k \in K, j \in J, i \in I$ , and  $l \in L$  represent components, separation tasks, reaction pathways, and active roots.  $P$  is the product price.  $F$  is flowrate.  $Q$  is distillation heat duty.  $U$  is the utility price (Kalakul et al., 2014).  $C$  is the amount of carbon emission.  $y$  is a binary decision variable for reaction pathway selection.  $y d$  is a binary decision variable for separation task selection.  $\alpha$  is relative volatility.  $\phi$  is active root.  $V$  is the vapor flowrate inside the stripping (1) and rectifying (0) section.  $H$  is latent heat.  $\eta$  is carbon emission coefficient.

### 3. Case study

The developed optimization model was applied to two case studies, which aim to find the best product and process configurations for utilizing isobutylene and methanol. In these two case studies, two different optimization objectives (process profit and process profit per carbon emission) are considered. All the optimization problems are solved by using BARON. Note here, for all the case studies, the separation pressure is adjusted to guarantee that cooling water is used for condensation. For temperature-sensitive products such as pivalic acid, the separation pressure is close to vacuum.

#### 3.1. Isobutylene utilization

Isobutylene was widely applied for methyl t-butyl ether (MTBE) production, which is an important gasoline additive. However, with the development of the electric car, the market demand for isobutylene may drop in the future, so three alternative isobutylene utilization reaction pathways that produce pivalic acid (PA), prenol, and tert-butylamine,

are considered in this case study. The parameters like reaction conversion rate, component relative volatility, price data ([www.echemi.com](http://www.echemi.com), [www.sunsirs.com/uk](http://www.sunsirs.com/uk)), and latent heat, which are the input for the optimization model, are listed in Table 1. In this case study, the isobutylene inlet flowrate is 150 kmol/h and the co-reactant inlet flowrate is calculated based on reaction stoichiometry.

Table 1. Parameters for the isobutylene utilization case study.

	Components	Conversion	Rel. Vol.	Price, \$/kmol	Latent heat, kJ/mol
R1	A: isobutylene	0.8	5548.36	51.79	25.31
	B: water	-	25.5	0	44.02
	C: PA	-	1	510.65	58.91
	D: <i>pseudo</i>	-	1	0	0
R2	A: formaldehyde	-	16.86	5.76	18.63
	B: isobutylene	0.8	7.82	51.79	16.99
	C: prenol	-	1	301.46	36.11
	D: <i>pseudo</i>	-	1	0	0
R3	A: ammonia	-	5.94	13.42	19.86
	B: isobutylene	0.52	2.61	51.79	16.99
	C: tert-butylamine	-	1	234.048	20.97
	D: <i>pseudo</i>	-	1	0	0

The optimal solution, including the reaction pathway, process configuration, detailed stream flowrate, carbon emissions, etc., are shown in Figure 2 and Table 2. The results indicate that using isobutylene for PA production has both the highest overall process profit and the highest process profit per amount of carbon emission (291.6 \$/(h, kg CO<sub>2</sub>)). The corresponding optimal separation configuration is based on the sequence of component boiling point.

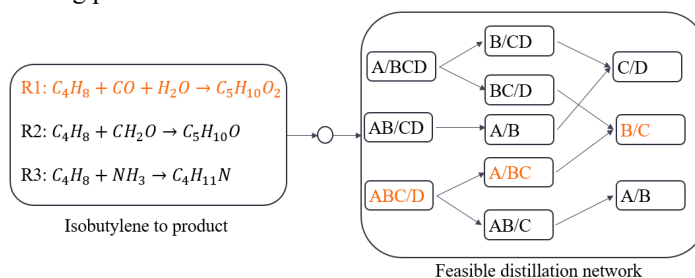

Figure 2. Optimal reaction pathway and configuration for isobutylene utilization.

Table 2. Optimization results of using isobutylene for PA production.

		Separation task					
		ABC/D		A/BC		B/C	
		Distillate	Bottom	Distillate	Bottom	Distillate	Bottom
Component flowrate, kmol/h	A	30	0	29.85	0.15	0.15	0
	B	30	0	0.15	29.85	29.25	0.6
	C	120	0	0	120	0	120
	D	0	0	0	0	0	0
Carbon emissions, kg CO <sub>2</sub> /h		0		84.23		104.35	
Operating cost, \$/h		0		31.44		33.62	

3.2. Methanol utilization

In this case study, four reaction pathways are considered. R1 uses methanol for dimethyl ether (DME) production. R2 converts methanol into gasoline with liquefied petroleum (LPG) gas as a by-product. R3 directly converts methanol into acetic acid (AA). And R4 utilizes methanol and propylene carbonate (PC) to produce dimethyl carbonate (DMC) with by-product propylene glycol (PG). The model input parameters are listed in Table 3. In this case study, the methanol inlet flowrate is 150 kmol/h and the co-reactant inlet flowrate is calculated based on reaction stoichiometry.

Table 3. Parameters for the methanol utilization case study.

	Components	Conversion rate	Relative volatility	Component price, \$/kmol	Latent heat, kJ/mol
R1	A: DME	-	81.28	25.7	17.91
	B: methanol	0.82	3.38	11.7	30.24
	C: water	-	1	0	36.9
	D: <i>pseudo</i>	-	1	0	0
R2	A: LPG	-	10	39.1	16.58
	B: methanol	0.98	3.27	11.7	29.56
	C: gasoline	-	1	139	35.45
	D: <i>pseudo</i>	-	1	0	0
R3	A: methanol	0.95	5.91	11.7	35.27
	B: AA	-	1	26.4	23.38
	C: <i>pseudo</i>	-	1	0	0
	D: <i>pseudo</i>	-	1	0	0
R4	A: methanol	0.78	175.95	11.7	35.27
	B: DMC	-	37.94	81.5	33.67
	C: PG	-	7.1	103.9	52.14
	D: PC	-	1	15.8	49.14

The solution for this case study is shown in Figure 3 and Table 4. The results show that using methanol for gasoline production has the highest process profit per amount of carbon emission (78.2 \$/(h, kg CO<sub>2</sub>)). The process configuration, which separates gasoline first, has the best performance. However, without considering the process carbon emission, using methanol for DMC production has the highest overall process profit.

Table 4. Optimization results of using methanol for gasoline production.

	Component	Separation task					
		AB/CD		A/B		C/D	
		Distillate	Bottom	Distillate	Bottom	Distillate	Bottom
flowrate, kmol/h	A	13.08	0	13.07	0.01	0	0
	B	2.7	0.3	0.07	2.64	0.3	0
	C	0	58.8	0	0	58.8	0
	D	0	0	0	0	0	0
Carbon emissions, kg CO <sub>2</sub> /h		58.83		29.96		0	
Operating cost, \$/h		11.75		5.99		0	

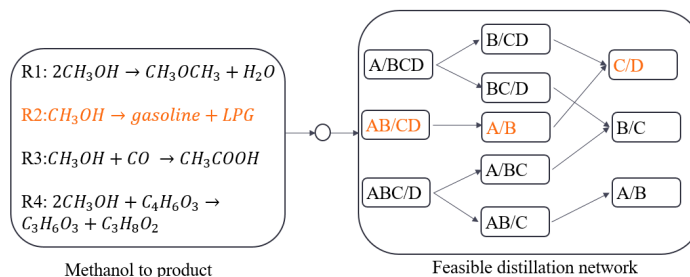

Figure 3. Optimal reaction pathway and configuration for methanol utilization.

## Conclusions

This paper developed a generalized MINLP model for simultaneous reaction pathway selection and separation network optimization. Given a product/raw material and the potential reaction pathways, this model can find the most valuable product or promising raw materials and the optimal separation configuration that ensures both process profit and the sustainability.

The model was applied to isobutylene and methanol utilization case studies. The results show that the best process for isobutylene utilization, which guarantees both process profit and process sustainability, is to convert isobutylene into PA and separate the mixture based on the sequence of boiling point. For the methanol utilization case study, the best product is gasoline, and the configuration, which separates gasoline first, gives us the most promising process performance. Future work will focus on solving multistep reaction pathway selection and separation network optimization problems.

## Abstract

Mechanistic models are an important tool as they allow storage of process knowledge and enable model-based techniques to plan, monitor, and control biological processes. Fundamental to these operations are models that can accurately describe their in vivo counterpart. Therefore, good modelling practices have been described including different analysis steps to ensure and maintain identifiability of model parameters during model calibration and the model life cycle (Daume et al., 2020).

Here, a workflow to analyze, adapt and apply a mechanistic model for experimental planning is suggested and its application demonstrated with a set of fed-batch refolding experiments conducted in the controlled environment of a stirred tank reactor. The model is based on the folding kinetics of a recombinant protein solubilized from aggregated proteins accumulated inside bacterial inclusion bodies. Along the adaptation cycle the model is analyzed for unique identifiability of model parameters both from simulations and noisy measurements.

**Keywords:** Mechanistic Model, Identifiability, Fisher Information, Protein Refolding, MBDOE

## 1. Introduction

In light of the current quality by design (QbD) paradigm and the process analytical technology (PAT) framework, introduced by the FDA, the use of process models for process monitoring and control are drawn into focus (FDA, 2004). Such models can either be black box data-driven models based on large data sets. Alternatively, they can be more deterministic models such as mechanistic models based on first principles or mass-, energy and momentum balances, or hybrid combinations thereof.

The focus of this work are purely mechanistic models, as they offer some important advantages: i) They require significantly smaller data sets compared to data-driven models. This is relevant, as measurements of biological processes are often expensive, involve long evaluation times such as chromatographic methods and sometimes, as is the case with cell specific reaction rates, there are no direct measurements available. ii) They serve as a good storage medium for process knowledge since they contain easily interpretable information due to correlation of data and physical parameters and physical equations. iii) Furthermore, this knowledge can be used for process monitoring (Kager et al., 2018; Sinner et al., 2019), process control (Kager et al., 2020; Ulonska et al., 2018) and optimal experimental design.

Model-based design of experiments (MBDOE) aims to generate optimal and valid models from as few experiments as possible. Thus, techniques exist to either discriminate different model variants statistically against each other to find the model that best suits the process (Brik Ternbach et al., 2005; Franceschini and Macchietto, 2008) or to design an experiment with maximal information content - usually done by maximizing D- or E-optimality of the fisher-information-matrix - to uniquely identify model parameters and achieve a valid model with good fit (Daume et al., 2019; Franceschini and Macchietto, 2008).

MBDOE generally starts with the use of a basic model structure to define different possible model variants, however, despite the advantages mentioned above, mechanistic models often require expert knowledge for the setup of the model. This contribution focuses on the generation of different model or kinetic substructures for mechanistic models. Therefore, a workflow is developed on how to adapt and improve a mechanistic model in accordance with defined good modelling practices including analysis of model sensitivity and model parameter identifiability. This workflow is applicable during the whole life cycle of the model, including the initial process development, adaptation to new products or process modes, integration of new measurement systems leading to improved parametrization potential and reoccurring model validations in the production of biopharmaceuticals. As an example, a fed-batch protein refolding process was used, optimization potential of the model was analyzed, and an experiment was designed to specifically analyze dependencies on the reaction kinetics. Furthermore, the superiority of this optimized process compared to the classical fed-batch process was shown.

This publication is organized as follows: First, the experimental and computational methods are explained. Then the model adaptation workflow is introduced, and its application discussed using the protein refolding example. Finally, some thoughts about the further application potential are given.

## 2. Methods

### 2.1. Protein Refolding Model

The basic non-linear process model of the protein refolding process consists of four protein states: solubilized protein S, folding intermediates I, native protein N and aggregated protein A. It is assumed, that solubilized protein instantly starts the folding process upon entering the refolding buffer and thus state S is removed from the model. Furthermore, extension of the model by the changing denaturant concentration D and reaction volume V due to the feeding during the fed-batch dilution is necessary. The reaction kinetics are described by the following rates depending on the concentration of the denaturant:

$$k_n = a_n \cdot (1 + D)^{b_n} \quad a_n: [0, \infty), \quad b_n: (-\infty, 0] \quad (1)$$

$$k_a = a_a \cdot (1 + D)^{b_a} \quad a_a: [0, \infty), \quad b_a: (-\infty, 0] \quad (2)$$

Here,  $k_n$  denotes the reaction rate of native protein formation and  $k_a$  the reaction rate of aggregate formation. For a more thorough review of the model see (Pauk et al., 2021).

### 2.2. Model Analysis & Optimization

*Model Fitting:* Fitting of the basic model on experimental data is performed using the genetic algorithm from the global optimization toolbox in MATLAB (2020a, MathWorks, Natick, USA) by minimizing the residual sum of squares between simulation and measured data, weighted by the measurement variances:

$$WRSS(\theta) = \sum_{p=1}^m \sum_{k=1}^d \frac{(y_{p,k} - \hat{y}_{p,k})^2}{\sigma_{p,k}^2} \quad (3)$$

Here,  $y_{p,k}$  denotes the measured concentration,  $\hat{y}_{p,k}$  denotes the simulated concentration,  $\sigma_{p,k}^2$  denotes the variance of state  $p$  at time point  $k$ .  $m$  is the number of states and  $d$  is the number of sampling times.

*Structural & practical identifiability:* Structural and practical identifiability are important attributes of a model describing if fitting of model parameters yields a unique solution from the model structure itself or the noisy measurements, respectively. Local structural identifiability analysis is performed by calculating the discrete-time scaled sensitivity matrix  $S$  with entries,

$$s_{ij} = \theta_j \cdot \frac{\partial y_i}{\partial \theta_j} \quad (4)$$

and checking for full matrix rank (Daume et al., 2020). Here,  $s_{ij}$  denotes the local sensitivity of model parameter  $j$  on the model output  $y$  at measurement  $i$ . Practical identifiability focuses on the assessment of measurement noise on the unique identifiability of all model parameters. Furthermore, correlations between model parameters resulting in multiple possible solutions where parameter value changes counteract each other need to be analyzed. One possibility to calculate parameter co-linearity is to calculate the fisher information matrix (FIM) from the sensitivity matrix and measurement variance. From the Cramer-Rao theorem follows, that the minimum parameter covariance matrix is the inverse of the FIM and following normalization yields the parameter correlation matrix (Daume et al., 2020). Here, values close to one or negative one on the off-diagonal entries imply high correlation between these parameters and therefore problems with the practical identifiability. (Brun et al., 2001) suggested two parameters which can help finding suitable parameter subsets to facilitate practical parameter identifiability. The parameter importance index can be used to rank model parameters based on their influence on model outputs due to changes in the parameter. The co-linearity index quantifies the linear dependency of model parameters of a given subset of the model parameters in regard of their practical identifiability.

*Experimental optimization & model fitting:* Optimization of the experiment was done using the genetic algorithm NSGA2. It is embedded in the pyOptSparse framework, can handle non-convex and non-smooth global optimization problems using a tournament selection-based strategy (Wu et al., 2020).

### 2.3. Protein Refolding

Protein refolding was conducted via dilution in fed-batch mode. Solubilized lactate dehydrogenase (7 g L<sup>-1</sup> protein, 4 M guanidine hydrochloride (GuHCl), 150 mM phosphate buffer, pH 6.0) originating from bacterial fermentation with recombinant Escherichia coli BL21 (DE3) was fed with constant feed-rate of 6.48 mL h<sup>-1</sup> for 9 hours into a Labfors 5 stirred tank reactor (Infors AG, Bottmingen, Switzerland) containing 0.8 L refolding buffer (150 mM phosphate buffer, 1 mM EDTA, 20  $\mu$ M NADH, pH 6.0). Refolding was carried out under controlled conditions at a temperature of 10 °C, constant stirring with a Rushton impeller at 200 rpm, headspace aeration with pressurized air at a flow-rate of 1 vvm. The pH was controlled to 6.0 by addition of 0.2 M HCl and 0.5 M NaOH.

Offline samples for the analysis of folding intermediates and native protein in the soluble fraction were measured via SEC-HPLC (Dionex UltiMate 3000, Thermo Fisher, Waltham, USA) with a BEH 200A SEC 1.7  $\mu$ m, 4.6 x 300 mm, 3.5  $\mu$ m column (Waters Corporation, Milford, USA). 2  $\mu$ L of sample were injected and eluted at a flow-rate of

0.5 mL min<sup>-1</sup> via isocratic elution (80 mM phosphate buffer, 250 mM KCl, pH 6.8) at a runtime of 18 minutes. The column oven was controlled at 25 °C and absorbance was monitored at a wavelength of 214 nm and 280 nm. The samples were further analyzed for the concentration of soluble proteins via RP-HPLC on a Polyphenyl BioResolve-RP-mAb 2.7 µm 3.0 x 100 mm column (Waters Corporation, Milford, USA) according to Kopp et al. (2020). The concentration of aggregated proteins was determined by BCA-assay as the difference of unprocessed and centrifugated sample.

### 3. Results & Discussion

#### 3.1. Workflow

The workflow illustrated in Figure 1 shows a cyclic model-based optimization approach to find suitable model structures during the model development process. An initial model either from literature or preliminary experiments (1) is used to analyze for optimization potential of the process model (2). The model-based optimization is performed (3) and the experiment conducted (4). During the evaluation process the model is analyzed regarding sensitivity, identifiability and suitable parameter subsets before the new model structure is fitted on the data set (5). The fit can now be compared to the original model using the WRSS, NRMSE of single states or a specifically targeted behavior (6). Improved fits result in adapted process models, otherwise the process can be analyzed for new optimization potential.

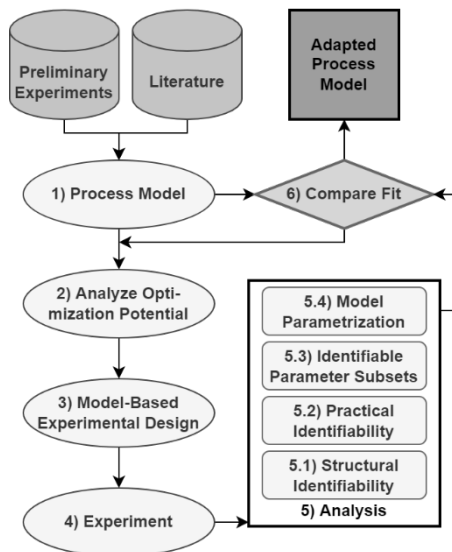

Figure 1: Experimental design cycle.

#### 3.2. Adaptation of a Protein Refolding Model

From a preliminary refolding experiment (data not shown), it was observed that the refolding rate started to stagnate after a total protein concentration of 0.6 g L<sup>-1</sup> and a denaturant concentration of 0.2 mol L<sup>-1</sup> was reached while aggregation started to increase. From equation 1 follows, that indeed the rate decreases with increasing denaturant concentration. However, a clear dependency with the total protein concentration is not described. Therefore, the rates are extended by a term penalizing increasing total protein concentration,

$$k_n = a_n \cdot (1 + D)^{b_n} \cdot (1 + P)^{c_n} \quad c_n: (-\infty, 0] \quad (5)$$

$$k_a = a_a \cdot (1 + D)^{b_a} \cdot (1 + P)^{c_a} \quad c_a: (-\infty, 0] \quad (6)$$

with  $P$  the total protein concentration in the refolding vessel. Furthermore, an experiment is designed to analyze the dependency of rate and protein concentration by changing one of the parameters while keeping the other constant. The process consists of three phases: (I) an initial fed-batch phase, (II) a phase of constant protein and denaturant concentration, and (III) a phase with constant denaturant but decreasing protein concentration (see Figure 2, left). These phases are realized by using three different reservoirs and feed pumps with reservoir one containing the solubilized protein (7 g L<sup>-1</sup>, 4 M GuHCl), reservoir two containing pure refolding buffer, and reservoir three containing refolding

Figure 2: Feeding strategy (left) and data of the experiment optimized through model-based optimization (right). Three phases (vertical dashed lines): initial fed-batch phase, phase with constant protein and denaturant concentrations, phase with constant denaturant and declining protein concentration.

buffer spiked with 0.031 M GuHCl. The first feed rate and the concentrations in reservoir one was set according to section 2.3, the other two feed rates and the concentration of the denaturant (GuHCl) in reservoir three were optimized by the NSGA2 algorithm ( $F_{R2} = 0.2667 \text{ L h}^{-1}$ ;  $F_{R3} = 0.3962 \text{ L h}^{-1}$ ).

Figure 2 (right) shows measurements of the protein states and the total soluble protein concentration as symbols and the theoretical total protein concentration as solid line. Although the total soluble protein concentration decreases during the later stages of the process due to aggregation, the protein concentration follows the optimized trajectory well and the process results in a final yield of 64 % compared to 28 % in the preliminary experiment.

Analysis of the model by calculating the rank of the sensitivity matrix and the FIM suggested that all model parameters are structurally and practically identifiable. However, the correlation matrix and calculation of the co-linearity index showed moderate correlation of the model parameters  $a_n$  to  $b_n$  and  $a_a$  to  $b_a$  in case of the initial rates as well as high correlation of  $b_n$  to  $c_n$  and  $b_a$  to  $c_a$  for the adapted rates. Thus, a subset analysis or an optimization of the information density by optimizing sampling times would be necessary to accurately estimate the model parameters (Daume et al., 2019).

Table 1: NRMSEs comparing the fit of the model with initial (I) and adapted rates (II).

States	I	N	A	D	V
NRMSE (I)	0.1437	0.0878	0.1410	0.0027	0.0167
NRMSE (II)	0.1414	0.0775	0.1443	0.0027	0.0165
Improvement	1.61 %	11.73 %	-2.33 %	0.73 %	1.09 %

Nonetheless, the fit of the model with old and adapted rates is compared using the NRMSE of each state (see Table 1). A slight overall improvement is visible and a large improvement specifically in state N, the native protein. N is the most important state regarding a protein refolding process, therefore, the conducted optimized experiment results in a sufficiently different adapted process model structure for further analysis in the model discrimination process. The designed experiment was able to identify the potential of the adapted rates by decoupling protein and denaturant concentrations during the different phases of the experiment.

#### 4. Conclusion

This paper suggested a workflow to generate new model or kinetic structures as prerequisite for a model discrimination step. The potential of model-based experimental design was shown. An experiment specifically targeted to identify dependencies of the reaction kinetics on protein and denaturant concentration was designed, resulting in a new set of reaction kinetics to better describe the refolding process, specifically the concentration of native protein. The example also showed difficulties with co-linear model parameters. Furthermore, due to the low protein concentration resulting from the high dilutions in phase II and III, the yield of native protein was increased by almost two-fold compared to a fed-batch experiment with only one feed.

## Abstract

In this work a nonlinear mechanistic model was developed predicting the product formation of recombinant lactate dehydrogenase (LDH) using fed-batch cultivations of *Escherichia coli*. The derived product formation kinetics consider the inclusion body (IB) fraction as well as the soluble protein fraction. After the structural identifiability of the model parameters was analyzed, five fed-batch cultivations were conducted in total in order to identify the model parameters and to validate the model subsequently. The accuracy of the final model was overall good with NRMSE values of around 0.1 to 0.2 for both product fractions. The derived model can be seen as an enabler for advanced monitoring and control strategies like model predictive control and other advances technologies defined in the process analytical technology (PAT) initiative.

**Keywords:** *Escherichia coli*, bioprocess control, product formation, mechanistic model, process analytical technology

## 1. Introduction

In contrast to the chemical process industry, industrial bioprocess control strategies are still mainly based on linear closed-loop control schemes like PID control or simple predefined open-loop trajectories (Narayanan et al. 2020). So far in bioprocess development, feed rate optimization is often realized by design of experiments (DoE) approaches. Instead of optimizing the feed rate directly, modern approaches aim to optimize the biomass specific substrate uptake rate ( $q_s$ ) as a physiological parameter resulting in a more generic approach independent of the bioreactor scale (Wechselberger et al. 2012). However, these solutions are assuming a direct linear relationship between  $q_s$  and the specific product formation rate ( $q_p$ ), which might not be valid throughout the course of the process. Furthermore, batch-to-batch variability is an inherent nature of bioprocesses and therefore open-loop control strategies come to their limits as they cannot react on process disturbances. Advantages of using more advanced model-based control algorithms were discussed previously (Ulonska et al. 2018; Wechselberger, Sagmeister, and Herwig 2013; Kager et al. 2022). Especially due to the complex multivariate and nonlinear relationships in bioprocesses, model predictive control (MPC), which is taking the interrelations between process variables into account, offers higher flexibility than decoupling the control task into several single setpoint tracking control loops (Mears et

al. 2017). Kager et al. (2022) developed a two-degree of freedom control strategy using nonlinear feedback linearization in order to directly control the specific product formation rate  $q_p$  in cultivations of recombinant *Escherichia coli* and stated increased biomass specific titers with this model-based controller compared to optimal constant feed-rate setpoints. The prerequisite of such advanced control strategies is a process model representing the dynamics of the system with sufficient accuracy. In this work we developed a simple mechanistic model for the product formation of a recombinant *Escherichia coli* strain producing LDH. In five fed-batch strain characterization experiments we analyzed the soluble product content as well as the aggregated inclusion body (IB) fraction of the product and included both as separated states in our model, which to our knowledge has not been done before.

## 2. Methods

### 2.1. Cultivation of *Escherichia coli*

Five cultivations were conducted in total. Four out of five experiments (1, 2, 4, 5) were used as a training dataset for parameter estimation and one experiment (3) was used as validation dataset. Recombinant *Escherichia coli* BL21(DE3) was cultivated in fed-batch mode on DeLisa (DeLisa et al. 1999) minimal medium. The target product was the enzyme L-lactate dehydrogenase (LDH). The bioreactor system Labfors 5 (Infors, Bottmingen, Switzerland) with a total volume of 3.3 L was used for cultivation. 1 L medium was supplemented with 100 mM Ampicillin and 15 gL<sup>-1</sup> glucose and inoculated with 100 mL of preculture (1 L shake flask, 37 °C, 230 rpm, 12 h) The controlled value for pH was 6.75 (by addition of NH<sub>4</sub><sup>+</sup> and H<sub>3</sub>PO<sub>4</sub>), for temperature 37 °C before induction and 31.5 °C after induction, and for pO<sub>2</sub> 30% via stirrer speed (400 rpm to 1200 rpm). After the batch phase was finished a fed-batch phase was initiated by controlling the specific substrate uptake rate  $q_s$  to 0.25 gg<sup>-1</sup>h<sup>-1</sup>. After 24 h of process time the product formation was induced with 1 mM isopropyl  $\beta$ -d-1-thiogalactopyranoside (IPTG). Then, different values for  $q_s$  were applied. Table 1 shows the mean values of  $q_s$  after induction of the product formation.

Table 1: Conducted experiments

Name	$q_{s,mean}$
Process 1	0.25 gg <sup>-1</sup> h <sup>-1</sup>
Process 2	0.14 gg <sup>-1</sup> h <sup>-1</sup>
Process 3	0.35 gg <sup>-1</sup> h <sup>-1</sup>
Process 4	0.23 gg <sup>-1</sup> h <sup>-1</sup>
Process 5	0.14 gg <sup>-1</sup> h <sup>-1</sup>

### 2.2. Analytical methods

Online measurements of pH, dissolved oxygen tension (pO<sub>2</sub>), liquid temperature ( $\theta_L$ ), substrate feed rate ( $F_R$ ), airflow rate ( $F_{AIR}$ ), oxygen flow rate ( $F_{O_2}$ ) and offgas analysis (BlueInOne, BlueSens, Herten, Germany) were recorded and used for real-time calculations. For offline reference analytics samples of the culture broth were taken every 2 h during the bioprocess. For biomass quantification the dry cell weight (DCW) was analyzed. After centrifugation of 1 mL sample (20000 g, 10 min), the pellet was dried at 105 °C and gravimetrically quantified in 1.5 mL tubes. The optical density (OD) was determined at 600 nm and the substrate content was obtained through an automated photometric assay using a hexokinase kit (BioHT, Roche, Germany). The live-dead analysis was carried out via a Flow Cytometry (CyFlow® Cube 6, Sysmex Partec GmbH, Germany) with the staining protocol described in (Langemann et al. 2016). The recorded forward-scatter and fluorescence signals were correlated with the amount of dead cells. In order to measure the intracellularly produced LDH the cell pellets were resuspended and disrupted by a combination of chemical lysis and a sonication rod. After centrifugation the supernatant was analyzed for its soluble content of the target enzyme

and the pellet containing the IBs was further processed. The latter was washed and then solubilized using a solution of Guanidinium chloride, denaturing and dissolving the aggregated protein chains. By diluting the resulting protein solution the enzyme refolded into its active form. The enzymatic activity of the soluble and the refolded LDH was determined using an adaptation of the enzyme assay procedure described in (Ponsoda et al. 1991), utilizing the catalytic nature of LDH for the reduction of pyruvate to lactate. The change in adsorption was measured at 340 nm with the automatic Spark® multimode microplate reader (Tecan Trading AG, Switzerland). Additionally, several samples were analyzed with a RP-HPLC (Thermo Fisher Scientific Inc., USA) using the method of (Kopp et al. 2020) together with a BSA-standard curve. The activities of the same samples were correlated to their protein content and a conversion factor of 51400U g<sup>-1</sup> was determined. This was further used to translate all activity measurements to protein concentrations.

### 2.3. Bioprocess model

The model structure which was used is an unstructured model of six states, namely liquid volume (V), living biomass (X<sub>v</sub>), dead biomass (X<sub>d</sub>), substrate (S), total product (P) and inclusion body product (P<sub>IB</sub>).

$$\begin{aligned} \frac{dV}{dt} &= F_{in} - F_{out} & \frac{dX_v}{dt} &= Y_{X/S} \cdot q_S \cdot X_v - k_d \cdot X_v - F_{out} \cdot \frac{X_v}{V} \\ \frac{dX_d}{dt} &= k_d \cdot X_v - F_{out} \cdot \frac{X_d}{V} & \frac{dS}{dt} &= F_R \cdot c_{SR} - q_S \cdot X_v - F_{out} \cdot \frac{S}{V} \\ \frac{dP}{dt} &= q_P \cdot X_v - k_d \cdot P - F_{out} \cdot \frac{P}{V} & \frac{dP_{IB}}{dt} &= q_{P_{IB}} \cdot X_v - k_d \cdot P_{IB} - F_{out} \cdot \frac{P_{IB}}{V} \end{aligned} \quad (1)$$

Three kinetic equations were used to describe the cell specific rates. Monod kinetics were used to describe specific substrate uptake  $q_S$ , a combination of Monod and Haldane kinetics were used to describe total product formation  $q_P$  and Moser kinetics were used to describe IB formation  $q_{P_{IB}}$ .  $q_P$  is modeled dependent on  $q_S$  and on the cumulated metabolized substrate  $S_{met}$ , which is obtained as the integral of  $q_S \cdot X_v$  since the induction.

$$q_S = q_{Smax} \cdot \frac{c_S}{k_S + c_S} \quad q_{P_{IB}} = q_{P_{IB},max} \cdot \frac{q_P^N}{q_P^N + K_{P,q_{P_{IB}}^N}} \quad (2)$$

$$q_P = q_{P,max} \cdot \frac{q_S}{q_S + K_{S,q_S}} \cdot \frac{S_{met}/X}{\frac{(S_{met}/X)^k}{K_{I,q_P}} + S_{met}/X + K_{S,q_P}}$$

### 2.4. Model analysis and parameterization

Before parameter estimation a structural identifiability analysis was performed. Therefore, the sensitivity matrix

$$S = \frac{\partial(x_1, \dots, x_m)}{\partial(\theta_1, \dots, \theta_n)}, \quad S_{i,p} = \frac{\partial x_i}{\partial \theta_p} \quad (3)$$

of the model was derived and the rank was calculated. If S has full rank, the model is structurally identifiable, which means that all model parameters  $\theta$  can be uniquely identified from the measured states  $x$ .

### 2.5. Real-time implementation

Data analysis and model development was executed with MATLAB® and Simulink® (Version R2022a, MathWorks, Natick, Massachusetts, USA). Real-time process control and communication to the equipment was realized through the Lucullus Process

Information Management System PIMS (Securecell, Urdorf, Switzerland). Lucullus was connected via OPC to a computer running MATLAB<sup>®</sup>, where the data preprocessing, the feed control and the state estimation model were executed for the different experiments. The numerical derivative of the feed weight signal was computed and smoothed with a Savitzky-Golay-Filter approach (Savitzky and Golay 1964) to obtain the feed rate  $F_R$  used as model input.

### 3. Results & Discussion

The exploration of the collected data yielded a correlation between the productivity  $q_P$ , the specific substrate uptake  $q_S$  and the metabolized substrate  $S_{met}$  as an inhibitor, which acts as an indicator for cell age. This hypothesis is supported by the data as seen in fig. 1 for the biomass specific product titer  $P_{specific}$ .

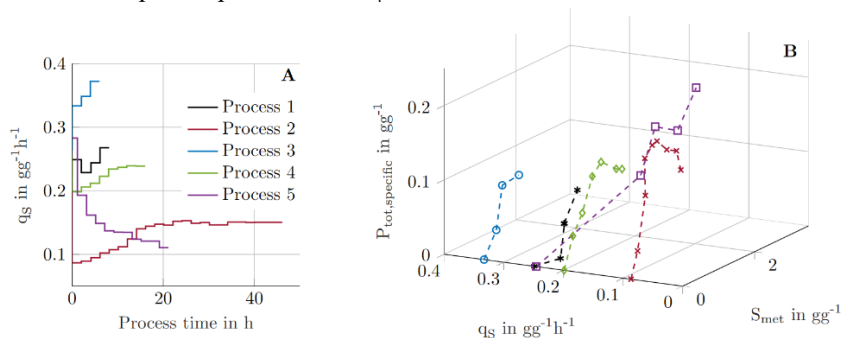

Figure 1: Cell-specific total product titer in  $gg^{-1}$  dependent on substrate uptake rate  $q_S$  and metabolized substrate  $S_{met}$  for all six processes.

These states were further used to find a kinetic equation modeling the cell productivity after induction. Several kinetic formulations, combining Monod and other substrate uptake equations with inhibition terms were tested for their suitability and performance. Additionally, the structural identifiability of the resulting models were analyzed to proof that the selected structure can be uniquely parameterized when no measurement error is assumed. The same was done for the subsequent inclusion body formation, expressed through  $q_{PIB}$ . Here, a linear connection to the overall productivity  $q_P$  was observed in the data and was therefore chosen as the variable for the kinetic equations. The structural analysis and parameterization with the data sets yielded two optimal kinetic equations by comparing their scores for the  $R^2_{adjusted}$  and the NRMSE values. The specific productivity  $q_P$  of choice was a combination of a Monod term with a Haldane inhibition term triggered by  $S_{met}$ . For the product localization the best specific inclusion body formation  $q_{PIB}$  among the tested kinetics was one of Moser type (eq. 3). The performance of the final model against the given data sets together with the respective scores can be seen in fig. 2. The identifiability analysis yielded that the chosen kinetics with 5 parameters for the total productivity and 3 parameters for the IB formation yield a structural identifiable model. A practical analysis of the identifiability also revealed a sensitivity towards the process noise, which can create problems for the parameterization and lead to unstable solutions for the parameter vector or leave some positions as unidentifiable.

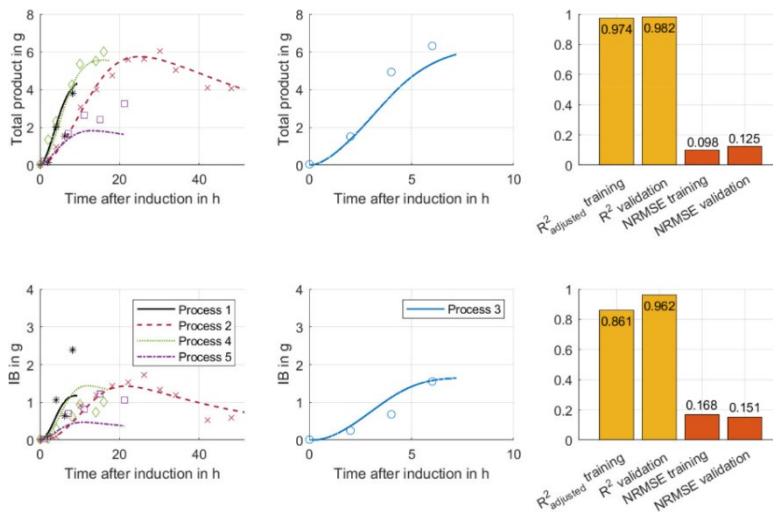

Figure 2: Results of the parameterization with the final model kinetics for the total product and the IBs. Model parameters:  $q_{p,max} = 0.0396 \text{ gg}^{-1}\text{h}^{-1}$ ,  $K_{s,q_s} = 0.0727 \text{ gg}^{-1}\text{h}^{-1}$ ,  $k = 5.56$ ,  $K_{s,q_p} = 0.4669 \text{ gg}^{-1}$ ,  $K_{L,q_p} = 3.6960$ ,  $q_{PIB,max} = 0.0195 \text{ gg}^{-1}\text{h}^{-1}$ ,  $K_{p,qPIB} = 0.0282 \text{ gg}^{-1}\text{h}^{-1}$ ,  $N = 1.9627$

The simulation shows that the final model structure and choice of variables allows a good tracking of the productivity, both in the strong surge right after the induction, as well as the decline over the progress of the process. The NRMSE values for the parameterization datasets as well as for the validation datasets range between 0.1 and 0.2 indicating an overall satisfactory model calibration. The model validity spans in a high range of feed rate inputs ( $q_s$  from  $0.14 \text{ gg}^{-1}\text{h}^{-1}$  to  $0.35 \text{ gg}^{-1}\text{h}^{-1}$ ) and the model can probably be easily transferred to other feeding strategies. Overall, the impact of the chosen  $q_s$ -setpoints on the product and IB formation is well represented enabling the usage of this model in future prediction and control algorithms.

#### 4. Conclusion

We developed a mechanistic model for the product formation of *Escherichia coli*. The model is based on macro-kinetic principles describing product formation dependent on the specific rate of substrate uptake  $q_s$  and the cumulative metabolized substrate  $S_{met}$ , which were considered as indicators for the metabolic load of the cell. In contrast to some other unstructured models described in literature (Neubauer, Lin, and Mathiszik 2003; Kim et al. 2022; Kager et al. 2022) here we describe the formation of soluble product as well as the aggregation into inclusion bodies which opens up the possibility to separately control the two states of the product and possibly steer the production in a specific direction. Model predictive control (MPC) can serve as a framework to implement this strategy and control directly on the product formation and its status. Further, transferability of the identified mechanism to other products and organism needs to be proven to see the developed model as a platform.

## Abstract

Computational fluid dynamics (CFD) is utilized for chemical reactor design/analysis and enables accurate predictions by solving numerical methods. However, real-time prediction is currently infeasible due to its high computational cost. As a result, physics-informed neural networks (PINNs), which integrate data-based machine learning and physical principles, have recently emerged as a surrogate model of CFD (Raissi, M., et al. (2019)). But previous PINNs can only predict properties in terms of location or time. Here, we offer novel PINNs that can also handle operating conditions as input variables to evaluate the impact of various design variables for reactor design optimization (Raissi, M., et al. (2020)). The proposed model is applied to an autoclave reactor for free radical polymerization of ethylene and demonstrated to be capable of interpolating/extrapolating solutions accurately under various settings.

**Keywords:** Computational fluid dynamics; deep learning; optimization; reactor design; artificial intelligence

## 1. Introduction

Computational fluid dynamics (CFD) solves fundamental nonlinear differential equations using numerical methods to analyze flow characteristics. Especially in chemical process engineering, CFD optimizes operating conditions and considerably reduces costs. However, for the physics residual of the governing equations to converge, a huge computational cost is required. As a result, a data-based model called physics-informed neural networks (PINNs) emerged as a surrogate model of CFD.

To integrate the data-driven model and physics-based model, PINNs solve partial differential equations (PDEs) by transforming the issue of finding the solution into a loss function optimization problem. The physical residual terms are added to the loss function and act like a penalty that limits the space of the solution (Cuomo, S., et al. (2022)). Therefore, PINNs can consider governing principles, rather than inferring solutions based only on training data. In addition, PINNs are based on a mesh-free approach and can be applied to complex geometries satisfying physical details with enhanced generalization,

training speed, and accuracy (Karniadakis, G.E., et al. (2021)). Initial PINNs models have been developed to solve mathematical models or inverse problems, solving nonlinear PDEs such as Schrödinger, Burgers, and Allen-Kahn equations (Raissi, M., et al. (2017)). Moreover, PINNs have also been applied to fluid dynamics to solve high-dimensional problems dominated by the Navier-Stokes equation. However, since previous PINNs models could only predict properties in terms of space and time, we intend to develop a novel PINNs model that can even handle operating conditions as input variables.

This study uses PINNs to analyze the flow and reaction in an autoclave reactor where ethylene is polymerized. Unlike previous models, the proposed model was constructed by adding two operating conditions to search for optimal conditions. The potential of PINNs as a surrogate model of CFD was demonstrated by comparing the accuracy of prediction according to location and two driving conditions (inlet temperature and concentration of initiator).

## 2. Methodology

### 2.1. Polymerization reactor modeling via CFD

Figure 1 depicts the geometry of the 3D autoclave reactor, with a pitched blade impeller rotating at a speed of 100 rpm. In this reactor, the monomer flows in from the inlet at the top, the initiator flows in from the side, and generated polymer flows out through the outlet at the bottom. The reactor model is divided into two domains: the inner domain and the outer domain. The governing equations depend on the domain. In the case of the inner domain, the governing equation is determined by the moving reference frame (MRF), since it is a region directly affected by the impeller. In comparison, the outer domain is the part excluding the inner domain, so the governing equation is determined by the stationary frame. The governing equations used in the reactor model are shown in Table 1. Details of variables used in partial differential equations are listed in the appendix.

To generate data, polymerization reactor modeling was performed using ANSYS-Fluent v21.2. Each component's velocity, pressure, temperature, and concentration were extracted according to location and operating conditions. A total of 357 combinations of operating conditions were used as training data, 17 for inlet temperature and 21 for inlet concentration.

## 2.2. Physics-informed neural networks for reaction systems

### 2.2.1. Model Description

The architecture of the PINNs model is shown in Figure 2. Input variables are coordinates ( $x$ ,  $y$ ,  $z$ ) and inlet temperature, inlet concentration of the initiator. Output variables are velocity, temperature, pressure, and concentration of initiator and monomer. The loss function of PINNs is summed up of empirical loss and physics loss. Empirical loss refers to the mean square error (MSE) between prediction and target data. On the other hand, the physics loss is the residual of the governing equations obtained by automatic differentiation. This loss term forces PINNs to obey the laws of physics. To consider the scale between the governing equations (continuity, momentum, and species transport), physics loss is calculated by assigning a weight corresponding to each loss. PINNs are trained by updating the neural network parameters to minimize total loss.

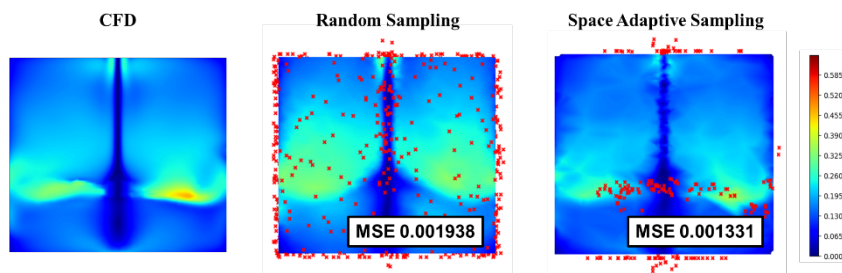

**Figure 2.** Schematic of PINNs: The architecture of PINNs consists of 13 layers including 100 neurons for each layer. Empirical loss measures how well the neural network reflects the training data. Physics loss ensures that the solution is consistent with the known physics.

### 2.2.2. Learning Strategy

For training data, a total of 200000 data with 4000 collocation points were used. We split the CFD simulation data into 3 sets: a train set used to train the model, a validation set used to limit overfitting, and a test set used to test the performance of our model. Learning rate reduction and early stopping by monitoring validation loss were also applied to our model to prevent overfitting. Additionally, we normalized our dataset to consider the scale between input and output variables and improve model stability. To reduce learning time, the proposed model is trained using distributed data-parallel (DDP) utilizing Pytorch v1.7.1 and GPU of NVIDIA GeForce RTX 3090.

In the process of obtaining the derivative for PDE calculation, the computational cost of PINNs increases exponentially. Therefore, we implemented space adaptive sampling to increase the efficiency of training. For every 1000 epochs, we added the top 200 data with the greatest error to the training dataset. Space adaptive sampling was compared with random sampling, which continuously adds 200 random data. The experiment in figure 3 verified that space adaptive sampling had a 30% accuracy improvement compared to random sampling.

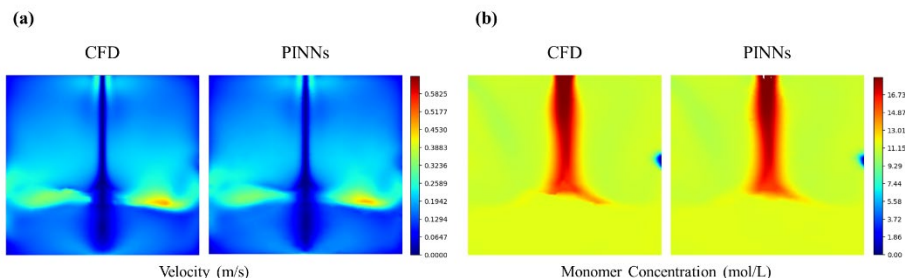

**Figure 3.** Comparison of CFD, random sampling, and space adaptive sampling model for velocity: Red points are the top 200 points with the largest empirical loss and are added to the training data.

### 3. Results

#### 3.1. Performance of physics-informed neural networks

To check the validity of the proposed model, the target data and prediction of PINNs were compared by contour plot of velocity and monomer concentration. Figure 4 shows that PINNs prediction has high accuracy for both velocity and monomer concentration, and MSE between the target and predicted value was within 0.01%. In addition, to demonstrate that PINNs can reflect changes in driving conditions, we compared the conversion value between PINNs and CFD simulation data (Figure 5). The predicted conversion and target value were comparable, and the conversion graph form based on operating conditions was equivalent to CFD. The higher the inlet concentration of the initiator and the lower the inlet temperature of the initiator, the higher the conversion. To summarize, PINNs can accurately predict fluid flow and reaction.

**Figure 4.** Comparison of CFD and PINNs for (a) velocity and (b) monomer concentration

**Figure 5.** Comparison of CFD and PINNs for conversion: (a) Parity plot of the predictions for conversion with the proposed PINNs over the corresponding CFD results, (b) Conversion corresponding to input concentration of the initiator, (c) Conversion corresponding to input temperature of the initiator.

### 3.2. Operating condition interpolation & extrapolation

As the results show above, the suggested model is possible to search for optimal operating conditions, when applied to chemical reactors. However, there was no substantial difference between PINNs and neural networks (NNs). Therefore, to obtain the distinction of PINNs through additional experiments, the physical residual, interpolation, and extrapolation performance of PINNs were compared with NNs.

Figure 6 (a) compares the physical residuals of PINNs and NNs. The fact that PINNs have smaller physical residuals in governing equations indicates that it is trained to obey physical rules more than NNs. The bar plot in figure 6 (b) compares the interpolation and extrapolation performances of PINNs and NNs. Interpolation was performed inside the training data range, and extrapolation was derived using 264 simulated data outside of the training data range.

The accuracy of conversion prediction was tested, and PINNs outperformed NNs in both interpolation and extrapolation. The performance difference was greater in extrapolation than in interpolation. In the case of interpolation, the area to be predicted existed inside the training data range, hence the training data had a significant influence on interpolation results. Extrapolation, on the other hand, amplified the effect of the physics law, resulting in a considerable difference between PINNs and NNs.

**Figure 6.** Comparison of PINNs and NNs: (a) Physics loss of continuity, momentum, species transport equation, (b) Conversion MSE based on interpolation results, (c) Conversion MSE based on extrapolation results

## Conclusion

In this study, we proposed a novel PINNs model that can predict changes based on driving conditions. According to experimental results, the suggested method can explore optimal operating conditions by resolving nonlinear problems and interpolating solutions under various settings. Overall, we emphasize the significance of PINNs when it comes to data-driven system optimization and control. Our future work will be focused on geometric optimization to complete the PINNs-based reactor design framework. Following that, the PINNs-based framework is expected to be a key component of digital twin or multi-scale simulations.

## Abstract

Scheduling often involves making decisions in presence of uncertainty, which governs the pricing of raw materials, energy, resource availability, demands, etc. A common approach to incorporate uncertainty in the decision-making process is using two-stage stochastic formulations. Unfortunately, the mathematical complexity of the resulting problems grows exponentially with the number of uncertainty scenarios, which is further complicated by the presence of binary variables. The authors have recently proposed a method using the so-called Similarity Index for discrete-time two-stage scheduling problems that enable scenario-based decomposition. This paper extends this method for scheduling problems formulated on a continuous-time basis. The fundamental idea is to use the Similarity Index to meet non-anticipation in the binary variables and Progressive Hedging on the continuous ones. The proposal is tested on a literature case study that consists of a multiproduct plant with a single processing unit. The combined SI-PH decomposition managed to solve the problem much faster than its monolithic counterpart.

**Keywords:** Similarity Index, Progressive Hedging, Optimization under uncertainty.

## 1. Introduction

The authors recently presented a decomposition method based on the idea of the Similarity Index (SI) to efficiently solve two-stage stochastic scheduling problems (TSSP) formulated using a discrete-time basis (Montes et al., 2022a, 2022b). TSSP handles uncertainty by discretizing the underlying probability distribution of uncertain parameters in a set of scenarios with associated probabilities. Then, the decision variables of the problem are grouped into two sets: first-stage and second-stage ones. In the first stage, the actual value that uncertain parameters will have is still unknown, but some decisions must be made regardless. Hence, the schedule within this first stage cannot be tailored to each scenario, as the uncertainty is not revealed yet. This is known as non-anticipation, i.e., decisions in the first stage must be unique. In the second stage, the values of the uncertain parameters are realized and assumed known, so the decisions can be adjusted to each realization accordingly.

Two-stage formulations are challenging to solve, as the problem size grows exponentially with the number of scenarios considered. This fact is further complicated by the presence of many binary variables, usual in scheduling formulations. One approach to tackle this

issue is to solve each scenario as an independent subproblem of reduced size, but the non-anticipation criterion for the first stage must be satisfied. The Progressive Hedging Algorithm (PHA) was originally proposed for convex problems involving only continuous variables and has convergence and optimality guarantees (Rockafellar & Wets, 1991). However, although the assumptions and guarantees vanish in presence of discrete variables, this method has been used successfully as a heuristics for mixed-integer problems (Bashiri et al., 2021; Peng et al., 2019). In the PHA, the non-anticipation constraints are relaxed, which enables scenario decomposition. Non-anticipation is then progressively enforced by penalizing the deviation from the average schedule in the first stage, i.e., the decision-variables average values computed from the subproblems solutions in a previous iteration.

Likewise, the Similarity-Index decomposition also enables scenario decomposition by approximating, or estimating, the degree of non-anticipation in the discrete decisions of the first stage. The scenario subproblems are solved independently and the similarity among their solutions is then measured using the SI. A weighing parameter is used to progressively increase the importance of maximizing the similarity. Eventually, all scenario solutions are equal in the first stage so non-anticipation is met. However, the SI decomposition was originally devised for discrete-time scheduling formulations. In this work, the authors aim to combine the SI decomposition with Progressive Hedging to decompose TSSP based on continuous-time formulations. The SI handles the binary variables of the problem, while Progressive Hedging handles the continuous ones. The proposal is tested successfully on a literature case study.

The paper is organized as follows: Section 2 presents a summary of the SI concept and its extension to continuous-time scheduling formulations. Section 3 describes the proposed SI-PH decomposition algorithm. The case study is presented in Section 4. A comparison between the proposed approach and the standard monolithic approach is summarized in Section 5. Conclusions and open issues are outlined in Section 6.

## 2. Similarity Index in Continuous-Time Formulations

In discrete-time basis, the Similarity Index relies on the idea of fuzzifying the binary decision variables along the surrounding time periods. The generated areas from the fuzzification for each scenario are compared and their overlap is used as a measure of similarity. Consequently, even if the decisions are not made in the same period among scenarios, one could quantify their similarity by temporal proximity. As the non-anticipation constraints (NAC) require the scenario schedules to be equal in the first stage, the SI can be used to remove the NACs from the formulation, enabling scenario decomposition. The SI can be pushed up through adding it to the objective function.

Two main difficulties arise for extending the Similarity-Index Decomposition to continuous-time TSSP: Time synchronization of decisions among scenarios; and weighing the slot duration as part of the SI computation. To get around these limitations, we propose: 1) not to consider the slot duration in the fuzzification process, and 2) to fuzzify in a slots basis instead of time periods. Then, the SI formula becomes:

$$SI: = \sum_{l \in \mathcal{L}_1} \frac{\min_{e \in \mathcal{E}} \|y_{le} + 0.5y_{(l+1)e} + 0.5y_{(l-1)e}\|_1}{2|\mathcal{L}| - 1} \quad (1)$$

Where the time slots  $l$  belong to an ordered set  $\mathcal{L}$ . The subset  $\mathcal{L}_1 \subset \mathcal{L}$  implies that the Similarity Index is only computed for the decisions made in the first stage of the problem.  $y_{le}$  are the decision variables indexed by the slots and the scenarios  $e \in \mathcal{E}$ . In essence, the Similarity Index is computed as the intersection of the generated areas from fuzzifying the decisions divided by the maximum intersection possible. Formula (1) implies that the similarity is only weighed in the two surrounding slots. As in the time-basis case (Montes et al., 2022b), this formula can be generalized for different fuzzification lengths.

Note that (1) does not cover the slot duration and other continuous variables that might be present in the problem (such as inventory levels, production levels, etc.). We propose to use Progressive Hedging (PH) to handle these variables, which results in a hybrid SI-PH method. Incorporating both the SI and the PH in a general TSSP, each subproblem formulation is given by:

$$\begin{aligned} \min_{x,y} J_e - \lambda SI_e + \sum_{l \in \mathcal{L}_1} \left( \omega_{le} x_{le} + \frac{\rho}{2} \left( \frac{x_{le} - \bar{x}_l}{\bar{x}_l} \right)^2 \right) \\ \text{s. t. :} \\ \text{Specific process constraints} \\ SI_e = \frac{\sum_{l \in \mathcal{L}_1} |s_{le}|_1}{2|\mathcal{L}| - 1} \\ s_{le} \leq y_{le} + 0.5y_{(l+1)e} + 0.5y_{(l-1)e} \quad \forall l \in \mathcal{L}_1 \\ s_{le} \leq \bar{y}_l + 0.5\bar{y}_{l+1} + 0.5\bar{y}_{l-1} \quad \forall l \in \mathcal{L}_1 \\ x \in \mathbb{R}, y \in \{0,1\} \end{aligned} \tag{2}$$

Note that the exact/global SI cannot be computed inside the subproblems to be solved independently, and that the element-wise operator  $\mathbf{min}\{\cdot\}$  in (1) is non-linear, so it cannot be used in the usual MILP scheduling formulations. Thus, the SI is estimated locally in each subproblem (2) by replacing the intersection of the fuzzified variables with a set of slack variables that are upper-bounded. The slack variables  $s_{le}$  are maximized in the objective function so this bound is tight. The  $SI_e$  is then an approximatin of the local SI by scenario, computed as the similarity of the scenario schedule with a reference schedule defined by fixed values  $\bar{y}_l$ . For details about this estimation refer to (Montes et al., 2022b).  $\lambda$  and  $\omega_{le}$  are the weighing parameters for the SI and the PH. They are updated in each iteration  $k$  from the scenario solutions, as follows, where  $\bar{x}_l$  is the expected value of  $x$ , using probabilities  $p_e$ , in the first stage:

$$\begin{aligned} \lambda^{(k+1)} = \lambda^{(k)} - \alpha(SI - 1); \quad \omega_{le}^{(k+1)} = \omega_{le}^{(k)} + \rho \left( \frac{x_{le} - \bar{x}_l}{\bar{x}_l} \right) \quad \forall l \in \mathcal{L}_1, e \in \mathcal{E} \\ \bar{x}_l = \sum_{e \in \mathcal{E}} p_e x_{le} \quad \forall l \in \mathcal{L}_1 \end{aligned} \tag{3}$$

The parameters  $\alpha$  and  $\rho$  are the step-size for  $\lambda$  and  $\omega$ . They greatly influence the algorithm behavior, both in terms of optimality and convergence, as discussed later.

### 3. SI-PH Decomposition

Non-anticipation can be enforced progressively using the SI and PH ideas. Hence, the original problem can be decomposed into scenario subproblems (2) by dropping the non-anticipation constraints. Each subproblem is solved independently and in parallel. The subproblems solutions are later used to update the required parameters for the SI and PH

with (3). The procedure is repeated until either the convergence criteria are met, or the maximum number of iterations is reached. Algorithm 1 below shows the pseudo-code for the SI-PH decomposition.

---

**Algorithm 1**

---

**Require**  $\alpha, \rho, k_{\max}, \Delta, \text{tol}$

1:  $k \leftarrow 0, \lambda^{(0)} \leftarrow 0, \omega_{le}^{(0)} \leftarrow 0, \bar{y}_l \leftarrow 0, \bar{x}_l \leftarrow 0$

2: **repeat**

3:   **for**  $e \in \mathcal{E}$  **do**

4:      $y_{le}^*, x_{le}^* \leftarrow \arg \min_{y_{le}, x_{le}, s_{le}} J_e - \lambda^{(k)} SI_e + \sum_{l \in \mathcal{L}_1} \left( \omega_{le}^{(k)} x_{le} + \frac{\rho}{2} \|x_{le} - \bar{x}_l^{(k)}\|_2^2 \right)$

5:      $SI_e^* \leftarrow SI_e(s_{le}^*)$

6:   **end for**

7:    $SI \leftarrow SI(y_{le}^*)$  using (1)

8:    $\bar{y}_l \leftarrow \arg \min_{y_{le}^*} SI_e^*$

9:    $\lambda^{(k+1)} \leftarrow \lambda^{(k)} - \alpha(SI^{(k)} - 1)$

10:    $\bar{x}_l^{(k+1)} \leftarrow \sum_{e \in \mathcal{E}} p_e x_{le}^{(k)} \quad \forall l \in \mathcal{L}_1$

11:    $\omega_{le}^{(k+1)} \leftarrow \omega_{le}^{(k)} + \rho \left( x_{le}^{(k)} - \bar{x}_l^{(k+1)} \right) \quad \forall l \in \mathcal{L}_1, e \in \mathcal{E}$

12:    $k \leftarrow k + 1$

13: **until**  $(SI = 1 \wedge \|x_{le}^{(k)} - \bar{x}_l^{(k+1)}\|_2 \leq \text{tol}) \vee k = k_{\max}$

14: **return**  $y_{le}^*, x_{le}^*$

---

The convergence criteria need to check that non-anticipation is met. For binary variables, that is easy to verify, as the SI needs to reach the value of 1. For continuous variables, non-anticipation can be confirmed if the 2-norm of the difference between the scenario solutions and the reference value is beyond a small enough tolerance.

#### 4. Case Study

The SI-PH decomposition was tested on a case study originally presented by Dogan & Grossmann (2006). The model uses a continuous-time representation for simultaneously integrating both the scheduling and planning of a continuous multiproduct plant with a single processing unit. The planning horizon is divided into fixed-duration time periods  $t \in \mathcal{T}$  (weeks), which are further subdivided into variable-duration time slots  $l \in \mathcal{L}$ . Products  $i \in \mathcal{I}$  are committed to each slot using binary variables  $W_{ilt}$ . Only the modifications to the original formulations are listed in this work for brevity and not the original equations.

The original formulation of Dogan & Grossmann (2006) is here extended to consider the production rates  $r_i$  as uncertain. Consequently, an additional index  $e \in \mathcal{E}$ , corresponding to the set of uncertainty realization scenarios, is added to all variables and equations of their model. As the time horizon is divided into both weeks and slots, additional variables  $W_{ije}^{\text{aux}}$ , with an additional auxiliary slot index  $j$ , are introduced to compute the Similarity Index as in (1). This variable is equal to the product assignment  $W_{ilt}$  but indexed by  $j$ . The index  $j$  enumerates the slots from 1 to  $N \cdot |\mathcal{T}_1|$ . Where  $N$  is the number of slots per time period and  $\mathcal{T}_1$  is the subset of time periods belonging to the first stage. For instance,

given time periods made up of three slots, the first slot of the second time period corresponds  $j = 4$ .

$$W_{ije}^{\text{aux}} = W_{ilte} \quad \forall j = l + |\mathcal{L}| \cdot (t - 1), l, t, e \quad (4)$$

The original formulation of the problem did not explicitly consider the slot duration  $\phi_{lte}$ . As the non-anticipation criterion of the two-stage formulation requires the slot duration variables to be equal among the scenarios in the first stage, some additional constraints are added to compute them from the starting time of the slots  $TS_{lte}$ :

$$\phi_{lte} = TS_{l+1,te} - TS_{lte} \quad \forall l \neq l_N, t \in \mathcal{T}_1, e \quad (5)$$

$$\phi_{l_N te} = HT_t - TS_{l_N te} \quad \forall t \in \mathcal{T}_1, e \quad (6)$$

Where  $HT_t$  is the elapsed time (in hours) from the beginning of the time horizon, at the end of each time period.

In addition to the economic function of the problem  $z^P$ , the objective function shall include the terms corresponding to the SI and the PH. The SI is computed for the product assignment variables  $W_{ije}^{\text{aux}}$  while the PH is applied to the slot duration  $\phi_{lte}$ , and the inventory levels  $INV_{ite}$ . The objective function to minimize in each subproblem is:

$$J_e := z_e^P - \lambda SI_e + \sum_{i,t \in \mathcal{T}_1, e} \omega_{ite} \frac{INV_{ite}}{\overline{INV}_{it}} + \sum_{l,t \in \mathcal{T}_1, e} \mu_{lte} \frac{\phi_{lte}}{\overline{\phi}_{lt}} + \frac{\rho_1}{2} \sum_{i,t \in \mathcal{T}_1, e} \left( \frac{INV_{ite} - \overline{INV}_{it}}{\overline{INV}_{it}} \right)^2 + \frac{\rho_2}{2} \sum_{l,t \in \mathcal{T}_1, e} \left( \frac{\phi_{lte} - \overline{\phi}_{lt}}{\overline{\phi}_{lt}} \right)^2 \bar{x}_l \quad (7)$$

After solving each subproblem, the multipliers  $\lambda$ ,  $\omega_{ite}$  and  $\mu_{lte}$ , and the expected values  $\overline{INV}_{it}$  and  $\overline{\phi}_{lt}$  need to be updated, as follows:

$$\begin{aligned} \lambda^{(k+1)} &= \lambda^{(k)} - \alpha(SI - 1); & \overline{INV}_{it} &= \sum_{e \in \mathcal{E}} p_e INV_{ite} \quad \forall i, t \in \mathcal{T}_1; \\ \omega_{ite}^{(k+1)} &= \omega_{ite}^{(k)} + \rho_1 \frac{INV_{ite} - \overline{INV}_{it}}{\overline{INV}_{it}} \quad \forall i, t \in \mathcal{T}_1, e; & \overline{\phi}_{lt} &= \sum_{e \in \mathcal{E}} \pi_e \phi_{lte} \quad \forall l, t \in \mathcal{T}_1; \\ \mu_{lte}^{(k+1)} &= \mu_{lte}^{(k)} + \rho_2 \frac{\phi_{lte} - \overline{\phi}_{lt}}{\overline{\phi}_{lt}} \quad \forall l, t \in \mathcal{T}_1, e \end{aligned} \quad (8)$$

Values  $\alpha$ ,  $\rho_1$ , and  $\rho_2$  are the tuning parameters of the algorithm.

## 5. Preliminary results

The combined SI-PH decomposition algorithm was tested on a case study instance of five products (A, B, C, D, E), eight weeks, and five slots. A total of eight uncertainty realization scenarios were considered. Problem 2a parameters from (Dogan & Grossmann, 2006) were used as a basis for the instance. The resulting problem had 17601 variables, 2240 of which were binary, and 17827 equations. GAMS 40.2.0 was used to code the model, and Gurobi 10.0 to solve it. All calculations were performed on a 2-CPU Xeon Gold 6130 computer. The optimality gap for Gurobi was set to 0.5% in all cases.

The monolithic instance was assigned 32 threads. The solver failed to provide an optimal solution after 10 hours of computation. The reported objective value of the best feasible solution found till that moment was  $z^P = 57643$ , reporting a 6.06% optimality gap.

Each of the subproblems in the decomposed instance was assigned 8 threads. Note that although the machine only has 32 cores, some scenarios are solved much faster than others, which frees cores for other threads. Note that, if too few threads are assigned per subproblem, the overall CPU capacity may be underutilized.

The tuning parameters greatly affected the quality of the solution. The values  $\rho_1 = 95$ ,  $\rho_2 = 120$ , and  $\alpha = 190$  provided the highest quality solution. The decomposition approach arrived at an objective value of  $z^P = 54682$  in 1552 seconds. Compared to the objective value of the monolithic approach, this solution is around 5% worse. However, just setting  $\rho_2 = 115$  reaches a much suboptimal  $z^P = 48717$ , and with  $\rho_2 = 125$  the algorithm did not converge after 2000 iterations.

## 6. Summary

This paper presented a hybrid decomposition method for TSSPs formulated on a continuous-time basis. The non-anticipation constraints are replaced by a combination of the Similarity Index and Progressive Hedging. This allows decomposing the original problem into smaller subproblems that are easier to solve. Their solutions are combined to iteratively build a high-quality feasible solution to the original problem.

Unfortunately, tuning the algorithm is not smooth due to the PH part, and small parameter variations lead to very different objective values. Some reported solutions are even far from optimality. Future work will focus on rethinking the PH decomposition strategy.

## Abstract

A dynamic multiscale model was developed to simulate the adsorption and desorption process in a fixed bed for air drying. This model is described by equations of mass balance, thermodynamics, and adsorption/desorption kinetics. The temperature-dependent Toth-Aranovich-Donohue equation was applied to predict the water vapor amount adsorbed on hopcalite. Experimental adsorption and desorption breakthrough curves at different water vapor concentrations and gas flow rates are measured and used to identify the different kinetic resistances, particularly the axial dispersion, external film mass transfer, pore diffusion, and internal mass transport. The model was implemented and solved within COMSOL Multiphysics<sup>®</sup>. The identified model is validated using different water vapor adsorption and desorption breakthrough curves from those used for parameter identification. The model predictions and the measurements showed a good agreement, quantified using performance indices and confirmed by a Kolmogorov-Smirnov statistic test.

**Keywords:** Water vapor adsorption, Hopcalite, Breakthrough curves, Modeling and simulation, Multiscale model.

## 1. Introduction

The air treatment system is an essential part of medical air installations: it ensures the drying and purification of the compressed air produced, to provide healthcare facilities with medical air that complies with the European Pharmacopeia n°1238-medical air in NF EN ISO 7396-1. A medical compressed air dryer is produced by pressure swing adsorption (PSA) using water-selective adsorbents. The dew point of the air treatment system reaches a minimum of -45°C which allows for high air quality. The production of dry medical air is ensured by air compressors and a column operating in PSA mode with a counter-current regeneration mode. The common industrial column is a fixed bed with various moisture adsorbents such as alumina, hopcalite and activated carbon in series in the form of granules. The state of the art is based on the choice of the nature of the adsorbents, their arrangement in the column and their respective volume (Cardenas et al, 2022). Qualitatively, the adsorbents placed at the bottom of the column are the least hydrophilic and adsorb the most moisture, while the adsorbents placed at the top of the column are the most hydrophilic and allow moisture adsorption at low concentrations. In the literature some models to describe the dynamic adsorption of water vapor on alumina are found, contrary to hopcalite where there is limited. Therefore, this study proposes to develop a fickian multiscale model to predict the adsorption and desorption breakthrough

fronts on hopcalite as a function of gas flow rate, concentration, and temperature. This model is described by mass balance, thermodynamic, and adsorption/desorption kinetics equations. Several parameters are needed to implement the model, thus the hopcalite is characterized, and water vapor adsorption isotherm measurements are carried out. Experimental adsorption and desorption breakthrough curves at different water vapor concentrations and gas flow rates are measured and used to estimate the axial dispersion, external film mass transfer, mixture diffusion and internal mass transport coefficients involved in the model equations, which are implemented, and solved within COMSOL Multiphysics®. The identified model is validated using different water vapor adsorption and desorption breakthrough curves from those used for parameter identification. The model predictions and the measurements showed a good agreement, quantified using performance indices and confirmed by a Kolmogorov-Smirnov statistic test. The validated model can be used as a predictive tool for the design and optimization of an industrial air dryer.

## 2. Adsorption isotherms

In the model development of the water vapor adsorption/desorption process on hopcalite, one of the main issues is to select the adsorption equilibrium isotherm that best describes the process. Experimental adsorption isotherms of water vapor on hopcalite in a temperature range of 288-313 K and pressures up to the saturated concentration were measured using a manometric BelsorpMax 2 instrument.

### *Toth-Aranovich-Donohue (Toth-AD) equation*

The temperature-dependent Toth-Aranovich-Donohue equation was applied to approximate the equilibrium relationship of water vapor on hopcalite. The model equation is as follows:

$$q_e = \frac{q_m \cdot b \cdot c}{\left[1 + (b \cdot c)^{t_0}\right]^{\frac{1}{t_0}} \left[1 - b_2 \cdot c\right]^{n_2}} \quad (1)$$

where  $q_e$  (mol.kg<sup>-1</sup>) is the equilibrium amount adsorbed,  $c$  (mol.m<sup>-3</sup>) is the water vapor concentration,  $q_m$  (mol.kg<sup>-1</sup>) is the maximum amount adsorbed,  $b$  and  $b_2$  (m<sup>3</sup>.mol<sup>-1</sup>) are the equilibrium constants at low and high concentrations, respectively,  $t_0$  is the Toth's heterogeneity factor and  $n_2$  is an adjustable dimensionless factor. The temperature-dependent parameters  $q_m$ ,  $b$ ,  $b_0$  and  $t_0$  are detailed in the study by Cardenas et al. (2022a).

## 3. Dynamic adsorption/desorption modeling

A comprehensive one-dimensional fickian multiscale model is developed to simulate the dynamic process of adsorption and desorption of water vapor. The model is based on mass balance, thermodynamic, and kinetic equations.

### *3.1. Model assumptions*

The assumptions of the model are as follows: (i) the gas mixture obeys the ideal gas law, (ii) water vapor is the only adsorbed molecule, (iii) the pressure drop along the bed is negligible, (iv) the resistance to mass transfer through the boundary layer surrounding the solid particles is characterized by an external film mass transfer coefficient, (v) the mass transfer within the particles is due to Fick's diffusion and characterized by an effective diffusion coefficient in the macropores, (vi) the mass transport of water vapor in the mesopores is due to mesopore diffusion, (vii) the Toth-Aranovich-Donohue equation describes the equilibrium isotherm of the gas phase with the adsorbent, (viii) the adsorbent particles are assumed to be spherical and homogeneous in size and density, (ix)

the temperature and physical properties of the adsorbent are assumed to be constant, (x) only the axial dimension is considered (one-dimensional model), and (xi) the adsorption and desorption process is reversible.

### 3.2. Fickian multiscale model

The multiscale model considers the bed scale and the particle scale. The particle is divided into two phases: a gas and a solid phase.

(i) In the bed column, the equation of the water vapor mass balance in the gas phase is expressed as follows:

$$\frac{\partial c}{\partial t} - D_{ax} \frac{\partial^2 c}{\partial z^2} + \frac{\partial(vc)}{\partial z} = -\frac{1-\varepsilon_b}{\varepsilon_b} \frac{3}{r_{pe}} k_f \left( c - c_{pe}|_{r_p=r_{pe}} \right) \left( \frac{1}{1+B_i} \right) \quad (2)$$

(ii) In the particle, assuming the absence of lateral and azimuthal variations of the concentration, the mass balance in the radial direction can be written as:

$$\varepsilon_{pe} \frac{\partial c_{pe}}{\partial t} + (1-\varepsilon_{pe}) \frac{\partial q}{\partial t} = \frac{D_e}{r_p^2} \frac{\partial}{\partial r_p} \left( r_p^2 \frac{\partial c_{pe}}{\partial r_p} \right) \quad (3)$$

(iii) In the particle, the water vapor adsorbed on the solid surface is approximated by the linear driving force LDF model and is written as:

$$\frac{\partial q}{\partial t} \approx \frac{\partial \bar{q}}{\partial t} = k_l (q_e^* - \bar{q}) \quad (4)$$

where  $c$  (mol.m<sup>-3</sup>) is the water vapor concentration in the gas phase,  $v = u/\varepsilon_b$  (m.s<sup>-1</sup>) is the interstitial gas velocity,  $D_{ax}$  (m<sup>2</sup>.s<sup>-1</sup>) is the axial dispersion coefficient,  $\varepsilon_b$  (m<sub>gas</sub><sup>3</sup>.m<sub>col</sub><sup>-3</sup>) is the bed porosity,  $r_{pe}$  (m) is the mean radius of the adsorbent particle,  $k_f$  (m.s<sup>-1</sup>) is the external film mass transfer coefficient,  $c_{p}|_{r_p=r_{pe}}$  (mol.m<sup>-3</sup>) is the water vapor concentration at the surface of the particle,  $B_i = r_{pe}k_f/(5D_e)$  is the material Biot number,  $D_e = \varepsilon_{pe}^{4/3}D_M$  (m<sup>2</sup>.s<sup>-1</sup>) is the effective diffusion coefficient, which depends on the porosity, and the mixture diffusion  $D_M$  (m<sup>2</sup>.s<sup>-1</sup>) in the particle,  $\bar{q}$  (mol.m<sup>-3</sup>) is the average water vapor amount adsorbed on the solid surface,  $q_e^* = q_e \rho_s$  (mol.m<sup>-3</sup>) is the equilibrium water vapor amount adsorbed,  $\rho_s$  (kg.m<sup>-3</sup>) is the solid density, and  $k_l$  (s<sup>-1</sup>) is the internal linear driving force factor. This equation is completed by the following initial and boundary conditions:

- For  $0 \leq z \leq L$ , at  $t = 0$ :  $c = 0$ ,  $c_{pe} = 0$ ,  $\bar{q} = 0$

- For  $t$  and  $r_p > 0$ , at  $z = 0$ :  $-D_{ax} \frac{\partial c}{\partial z} = v(c_0 - c)$ ,  $\bar{q} = 0$ , and at  $z = L$ :  $\frac{\partial c}{\partial z} = 0$

- For  $t$  and  $z > 0$ , at  $r_p = 0$ :  $\frac{\partial c_{pe}}{\partial r_p} = 0$ , and  $r_p = r_{pe}$ :  $-D_e \left( \frac{\partial c_{pe}}{\partial r_p} \right)_{r_p} = k_f \left( c - c_{pe}|_{r_p=r_{pe}} \right)$

Because of this reversibility, we can propose to treat the desorption breakthrough curve as if it were an adsorption breakthrough curve. Only the initial conditions and the boundary conditions are different. Therefore, the same model as described above is used along with the following modified initial and boundary conditions:

- For  $0 \leq z \leq L$ , at  $t = 0$ :  $c = c_0$ ,  $c_{pe} = c_{pe}|_{r_p=r_{pe}}$ ,  $\bar{q} = q_e$

- For  $t$  and  $r_p > 0$ , at  $z = 0$ :  $\frac{\partial c}{\partial z} = 0$

### 3.3. Implementation and simulation of the model

The external mass transfer coefficient is estimated using the Wakao and Funazkri (1978) correlation:

$$k_f = \frac{D_{AB}Sh}{2r_{pe}} \text{ with } Sh = c_{m1} + c_{m2}Re_p^{0.6}Sc^{1/3} \text{ and } c_{m1} = 2 \quad (5)$$

For the axial dispersion coefficient, the correlation of Rastegar and Gu (2017) was used:

$$D_{ax} = \frac{2r_{pe}v}{Pe'} \text{ with } \frac{1}{Pe'} = \frac{0.7D_{AB}}{2r_{pe}v} + \frac{\varepsilon_b}{c_{m3} + c_{m4}(Re_p)^{0.59}} \quad (6)$$

where  $Sh$ ,  $Re_p$ ,  $Sc$ , and  $Pe'$  are the dimensionless Sherwood, Reynolds, Schmidt and Peclet numbers respectively,  $D_{AB}$  ( $\text{m}^2 \cdot \text{s}^{-1}$ ) is the molecular diffusion coefficient. It is important to point out that  $D_{ax}$  and  $k_f$  increase with increasing gas flow rate. To keep this property,  $c_{m2}$ ,  $c_{m3}$  and  $c_{m4}$  are also considered as unknown parameters to be identified from the measurements (Esposito et al, 2022). A total number of five estimable parameters is therefore identified, i.e.,  $k_f$ ,  $D_M$ ,  $c_{m2}$ ,  $c_{m3}$  and  $c_{m4}$ . Comsol Multiphysics<sup>®</sup> version 6 is used to implement and solve the set of partial differential equations of the model. The estimability analysis algorithm using the orthogonalization algorithm described by Yao et al. (2003) is applied to the multiscale model and the value of the estimability threshold was set equal to 0.04 as suggested by Bouchkira et al., (2021). The following estimability order:  $k_f > D_M > c_{m2} > c_{m3} > c_{m4}$ . It should be noted that all parameters are estimable based on available measurements.

### 3.4. Model prediction performance

The prediction performance of the model is quantitatively assessed by means of criteria which compares model predictions with the experimental measurements. In this study, it is evaluated according to two different criteria: The root mean-square error function (*RMSE*) and the Pearson correlation coefficient (*r*).

## 4. Results and discussion

### 4.1. Parameters identification

The experimental data used consist of breakthrough curve measurements carried out at a room temperature of 20 °C, at gas flow rates of 90, 120, and 150  $\text{mL} \cdot \text{min}^{-1}$  with a water vapor concentration of 0.67  $\text{mol} \cdot \text{m}^{-3}$ , and at a gas flow rate of 135  $\text{mL} \cdot \text{min}^{-1}$  with four water vapor concentrations of 0.19, 0.38, 0.48, 0.72, and 0.77  $\text{mol} \cdot \text{m}^{-3}$  i.e., eighth adsorption and desorption experimental measurements to identified parameters. The optimal parameters identified and estimated during adsorption are used in the desorption simulation, except for the parameter  $k_f$ , which is estimated simultaneously from available desorption experimental measurements. Figures 1 compare the experimental measurements to the model predictions obtained using the optimized parameters in the adsorption and desorption process. The water vapor/hopcalite isotherm model used is the Toth-Aranovich-Donohue.

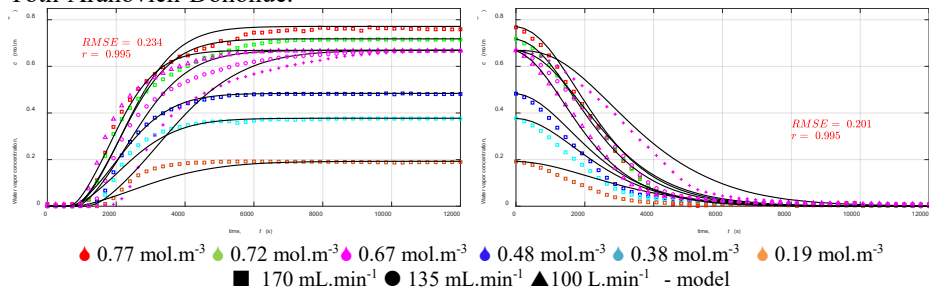

Figure 1: Comparison of water vapor adsorption (left) and desorption (right) breakthrough curves predicted with the measurements using the multiscale model.

The figure show that the predictions of the multiscale model are consistent with the experimental measurements because the Pearson correlation coefficient is close to 1

( $r=0.99$ ) and the root mean square error ( $RMSE<0.23$ ) is low. The optimized parameter values as well as their 95% confidence intervals ( $CI$ ), and the dimensionless material Biot number ( $Bi$ ) of is reported in the Table 1.

Table 1. Optimized parameter values for water vapor adsorption on hopcalite

Parameters	$B_i=4.63$					
	Adsorption			Desorption		
$c_{m2}$	$c_{m3}$	$c_{m4} \times 10^{-5}$	$D_M, (m^2 \cdot s^{-1})$	$k_{l,ads} (s^{-1})$	$k_{l,des} (s^{-1})$	
Value	5.93	0.005	1.01	$4.3 \times 10^{-5}$	0.065	0.0018
CI (95%)	$\pm 1.26$	$\pm 0.002$	$\pm 0.09$	$\pm 8.5 \times 10^{-6}$	$\pm 0.005$	$\pm 0.0006$

The fast saturation of the adsorbent bed at higher flow rates is since as the flow rate increases, the thickness of the film surrounding the particles decreases, reducing the resistivity value of the film for mass transfer. The value of the material Biot number (see Table 1) is greater than 3. Therefore, the adsorption mechanism is controlled by internal pore diffusion. Moreover, the breakthrough time, defined as the time required to reach 10% of the water vapor concentration in the bed column, decreases with increasing water vapor concentration at the inlet. It can also be observed that an increase in water vapor concentration at the inlet results in bed saturation being reached earlier due to relatively faster transport. Since the confidence interval values are lower than the parameter values reported in Table 1, the parameter identification can be considered accurate given the excellent fit indices. The coefficients for external film mass transfer and axial dispersion could be estimated with a different correlation than the one used, for example, by Delgado (2006) and Valdés-Solis et al., (2004) to improve the agreement between measurements and predictions. Despite this discrepancy, the values of the estimated coefficients at different gas flow rates reported in Table 1 are consistent with the magnitudes reported in the literature (Cardenas et al. 2021).

#### 4.2. Model validation

The identified model is then validated with additional measurements of water vapor adsorption and desorption breakthrough curves obtained on hopcalite at different temperatures, i.e., 15, 30, 40, and 50 °C, corresponding to the water vapor concentrations of 0.48, 0.47, 0.46, 0.45 mol.m<sup>-3</sup> and a gas flow rate of 150 mL.min<sup>-1</sup>. The results are shown in Figure 2. It is important to note that these operating conditions (concentration, gas flow rate, and temperature) are different from those used in parameter identification. The Kolmogorov-Smirnov statistical test is used and is based on the calculation of the divergence ( $D_n$ ) between two distributions. For more details, see the study by Cardenas et al. (2022b).

Figure 2: Comparison between predicted and measured breakthrough curves on hopcalite at four temperatures of 15, 30, 40, and 50 °C corresponding to water vapor concentrations of 0.48, 0.47, 0.46, 0.45, mol.m<sup>-3</sup> and a gas flow rate of 150 mL.min<sup>-1</sup>.

The calculated divergence values that are below the critical value ( $D_n^*=0.2$ ) allow us to accept the null hypothesis ( $H_0$ ), i.e., we can claim with 95% probability that the predicted and measured breakthrough curves have the same distribution. As shown in Figure 2, the predictions of the water vapor adsorption model guarantee this null hypothesis in almost all cases, so we can fully validate the multiscale model prediction of water vapor adsorption on hopcalite. On the other hand, the predictions of the water vapor desorption model, despite being very close to the critical value, cannot be guaranteed to be predicted.

## 5. Conclusions

The accuracy of the one-dimensional dynamic adsorption and desorption model using the temperature-dependent Toth-Aranovich-Donohue equation developed, identified, and validated for the simulation of a packed bed column in which water vapor is physically adsorbed on hopcalite was demonstrated. The fickian multiscale model allowed the finding that the adsorption process is controlled by the diffusion of water vapor in the macropores by a value of the material Biot number higher than 3. The statistical validation and the performance of the model performance indices ensure the quality of the model predictions, which is not always the case in modeling studies. This model coupled with an energy balance to improve the design and optimization of commercial adsorption columns using multilayer beds.

# Multi-fidelity Bayesian Optimisation of Reactor Simulations using Deep Gaussian Processes

Tom Savage,<sup>a</sup> Nausheen Basha,<sup>a</sup> Omar K. Matar,<sup>a</sup> Antonio del Rio Chanona,<sup>a</sup>

<sup>a</sup>*Imperial College London, London SW7 2BX, United Kingdom.*

## Abstract

Coiled tube reactors under pulsed-flow conditions have been shown to provide promising mixing characteristics. In order to validate performance in an industrial setting, and investigate the underlying physics of successful mixing, coiled tube reactors must be optimised. In this work, we apply a novel framework to locate optimal solutions to this nonlinear, computationally expensive, and derivative-free problem. Our optimisation framework takes advantage of deep Gaussian processes to learn a multi-fidelity surrogate model. We apply this model within a novel Bayesian optimisation algorithm, using faster, less accurate, and potentially biased lower-fidelity simulations to enable faster reactor optimisation. We subsequently investigate the physical insights into the swirling flows of these optimal configurations, directly informing the design of future coiled-tube reactors under pulsed-flow conditions. We demonstrate our design framework to be extensible to a broad variety of expensive simulation-based optimisation problems, supporting the design of the next-generation of highly parameterised chemical reactors.

**Keywords:** Optimisation, Computational Fluid Dynamics, Multi-fidelity Modelling

## 1. Introduction

### 1.1. Background

Achieving plug flow performance in chemical reactors is critical for processes involving the manufacture of chemicals, pharmaceuticals, biodiesel production, and waste treatment to minimise energy consumption and costs, and maximise product quality. Plug-flow conditions are dependent upon the reactor geometry, with product distributions of low variance being desired. Here, we study coiled-tube reactors, which have been shown to demonstrate promising plug flow performance in previous computational and experimental studies (Mansour, Liu et al. 2017, McDonough, Ahmed et al. 2019, McDonough, Murta et al. 2019, de Brito Lira, Riella et al. 2022).

Chemical reactors including coiled-tube reactors have been extensively explored through computational fluid dynamics (CFD) simulations, where numerical solutions are solved iteratively for a system of partial differential equations (PDEs) with large degrees of freedom resulting in large computational cost. In addition to being expensive, gradient information is practically unavailable. Derivative-free optimisation has found significant application in domains where mathematical expressions or gradients are unavailable. Examples include the optimisation of proprietary chemical process software (Caballero and Grossmann 2008, Savage, Basha et al. 2022), chemical reaction optimisation (Felton, Rittig et al. 2021), and topology optimisation of two-dimensional chemical reactor

channels (Cai, Guo et al. 2021). With the advent of new technologies in reactor design, reactor geometries are becoming more highly parameterised, resulting in higher-dimensional, more complex derivative-free optimisation problems.

In certain situations, computational expense can be traded off with accuracy via one or multiple fidelity parameters. Examples include training epochs in the context of hyper-parameter optimisation (Wu, Toscano-Palmerin et al. 2019, Schmucker, Donini et al. 2020), mesh fidelities in the context of finite element analysis (Huang, Allen et al. 2006), or combining real-time measurements and predictions in industrial processes (Petsagkourakis, Chachuat et al. 2021). Including fidelity control within a Bayesian optimisation framework enables optimisation with fewer computational resources whilst gaining a ‘high fidelity’ solution (Lindauer, Eggenesperger et al. 2019). Equation 1 describes this multi-fidelity problem

$$x^* = \arg \max_{x \in X} f(x, z^*). \quad (1)$$

where potentially M different fidelities,  $z \in \mathbb{R}^M$  become controllable parameters, and  $z^*$  indicates the highest-fidelity evaluation that is the one of interest.

**Contribution:** In this work, we present the real-world problem of optimising the geometry of a coiled-tube reactor to maximise its plug-flow performance. We apply a state-of-the-art deep GP (DGP)-based, multi-fidelity Bayesian optimisation algorithm to identify novel reactor configurations using an amalgam of different fidelity simulations, modelled using a DGP. Figure 1 demonstrates how our approach takes advantage of lower-fidelity simulations. Our approach contains no additional hyper-parameters when compared to standard Bayesian optimisation. Having identified an optimal geometry, we investigate the physical insights to inform future design of pulsed flow coiled tube reactors.

Figure 1: Left: The progression of multi-fidelity Bayesian optimisation using DGPs as a multi-fidelity model. Multiple different fidelity levels are selected for evaluation throughout optimisation, reducing optimisation time. Right: the best coil geometry which has a relatively large coil radius and low pitch.

## 2. Method

By applying DGPs within a Bayesian optimisation framework, we enable an end-to-end model of all fidelities. A more accurate model of higher fidelities should enable the optimisation procedure to make more evaluations at lower, less expensive fidelities.

### 2.1. Parameterisation

A coiled tube reactor is parameterised by a coil radius, and a coil pitch. Inversions within coiled tube reactors have been shown to provide effective mixing properties (Singh and

Nigam 2016, Rossi, Gargiulo et al. 2017, McDonough, Murta et al. 2019). Therefore, in addition to coil radius and coil pitch, we include an additional inversion parameter  $\delta$  to

investigate geometries which involve a change of coil direction.  $\delta$  takes values between 0 and 1, and specifies where along the coil the inversion takes place. Figure 2 demonstrates the effect of  $\delta$  on helical tube geometry.

(a): The effect of  $\delta$  for a helical tube with fixed length, viewed from above.

(b): The effect of  $\delta$  for a helical tube with fixed length, viewed from side. Figure 2: From left to right:  $\delta$  is evaluated at 0, 0.15, 0.3, 0.6, and 0.75 with coil radius and pitch remaining constant.

Two fidelity aspects, axial and radial, can be varied when meshing is performed given a tube geometry. (Savage, Basha et al. 2022) demonstrates how these two fidelities affect the final mesh. Five discrete fidelities were simulated and compared with experimental data, in order to test assumptions regarding the accuracy of a simulation. Figure 3 validates the tracer concentration profile of simulations at five fidelities against two sets of experimental data. The objective of the optimisation is to maximise the number of equivalent tanks-in-series (McDonough, Murta et al. 2019), where high values of  $N$  are an indicator for good radial mixing and poor axial mixing. Figure 3 also demonstrates how increasing fidelity (and therefore cell count) results in a closer approximation to the experimental value of  $N$ , derived from each concentration profile. The accuracy of prediction when increasing cell-count in experiment 2 drops slightly.

*Left:* The concentration profile of a tracer injection at five fidelity levels between 0 and 1 against experimentally obtained data.  $E(\theta)$  represents dimensionless concentration as a function of dimensionless time  $\theta$

*Right:* The value of  $N$  corresponding to the concentration profile from each fidelity, which has been converted to cell count.  $N$  represents plug-flow characteristic which is the quantity optimised for.

Figure 3: Validation of five discrete mesh fidelities corresponding to different cell counts, across two sets of experimental data under different conditions.

## 2.2. Model Specification

To model each fidelity level we apply Deep Gaussian processes as demonstrated by (Cutajar, Pullin et al. 2019). DGPs provide a natural extension to sequentially trained multi-fidelity models, where a generating function  $f$  at a given discrete fidelity  $z$  is modeled as a linear or nonlinear function of lower fidelities plus a mismatch term. For example, in the nonlinear case,  $f_z(x)$  is given by

$$f_z(x) = \rho_{z-1}(f_{z-1}(x), x) + \phi_{z-1}. \quad (2.1)$$

Multi-fidelity DGPs combine  $\rho_{z-1}$  and  $\phi_{z-1}$  into a single term  $g_{z-1}$  which is modelled using a GP and trained end-to-end, resulting in a composition of GPs. For example, for  $Z$  different fidelity levels, and observations  $x$  at each fidelity, the highest fidelity is modeled as

$$f_z(x_z, \dots, x_1) = g_z(\dots g_{z-1}(g_1(x_1), x_{z-1}), x_z). \quad (2.2)$$

In this work, we assume five discrete fidelity levels. Thus the resulting DGP has five layers ( $Z = 5$ ), corresponding to simulations at fidelities equal to 0, 0.25, 0.5, 0.75, and 1. MF-DGPs are implemented in Python using Emukit (Paley, Pullin et al. 2019).

## 2.3. Discrete Multi-fidelity Bayesian Optimisation using Deep Gaussian Processes

Whilst continuous approximations have been applied for multi-fidelity Bayesian optimisation (Kandasamy, Dasarathy et al. 2017), we present an algorithm that takes advantage of the discrete fidelity predictions of a deep Gaussian process. Our approach is similar in spirit to that of (He, Tuo et al. 2017) and the experimental design work of (Thodoroff, Kaiser et al.). We perform a standard Bayesian optimisation step on the layer corresponding to the highest fidelity. Highlighting our interest only in the high-fidelity model. We then subsequently evaluated the variance of this solution with respect to the variance of other fidelities, providing insight into potential information gain. These variances are weighted by simulation cost enabling us to trade off information-gain with computational expense. Algorithm 1 highlights this approach.

---

### Algorithm 1 Deep GP-based Multi-fidelity Bayesian Optimisation

---

**Require:**  $f_1(x) \dots f_{z^*}(x)$ ,  $\mathcal{X}$ ,  $n$   
**for**  $z$  in  $1, \dots, z^*$  **do**  
    Generate  $n$  samples,  $\mathbf{x}_z$ , and evaluate  $f_t(\mathbf{x})$  resulting in  $\mathbf{y}_z$ .  
     $\tau_z \leftarrow$  average simulation time  
**end for**  
**while** Budget not exhausted **do**  
    Train DGP using  $\mathbf{x}_1, \dots, \mathbf{x}_{z^*}$  and  $\mathbf{y}_1, \dots, \mathbf{y}_{z^*}$   
    Solve UCB for highest-fidelity:  $x^* \leftarrow \arg \max_x \{ \mu_{z^*}(x) + \beta^{1/2} \sigma_{z^*}(x) | x \in \mathcal{X} \}$   
    Choose fidelity based on variance of DGP and simulation cost:  $z^* \leftarrow \arg \max_z \{ \gamma_z \beta^{1/2} \sigma_z(x^*) \}$  where  $\gamma_z = \max(\tau) / \tau_z$   
    Evaluate  $f_{z^*}(x^*)$ , add  $x^*$  to  $\mathbf{x}_{z^*}$  and  $f_{z^*}(x^*)$  to  $\mathbf{y}_{z^*}$   
**end while**

---

We note that in choosing  $\gamma_z$  based on the points sampled to construct the initial DGP, the algorithm contains no additional hyper-parameters than standard UCB Bayesian optimisation. In addition,  $\gamma_z$  may be updated after a simulation has been performed, more accurately reflecting the simulation time at that fidelity.

## **Experimental Results**

Figure 1 demonstrates the MF-DGP based optimisation, which shows the selection of multiple simulation fidelities throughout optimisation. We note that initialising the DGPs for multi-fidelity modelling requires simulations at each fidelity. This presents a disadvantage in discrete over both single-fidelity and continuous fidelity settings, as the number of fidelities grows so does the initial data required. The number of initial data points and at what respective fidelities is the subject of future work.

### *2.4. Recommendations*

Overall, we find that it may not be beneficial in situations where a large number of discrete fidelities are available, to apply all fidelities within an optimisation framework. A large number of fidelities results in a large number of hyper-parameters, more difficult to train multi-fidelity models such as DGPs with more layers resulting in longer inference times, and potentially slower exploration. If a discrete multi-fidelity Bayesian optimisation method is to be used, we make the recommendation to apply 2 or 3 discrete fidelities in systems with no prior knowledge, despite more being available. Alternatively, if more fidelities are required, modelling multi-fidelity data in a continuous space and applying an appropriate algorithm such as the one presented in (Kandasamy, Dasarathy et al. 2017) may be necessary. Future work will apply multi-fidelity Bayesian optimisation approaches in continuous domains, as well as apply similar methods on more industrial case studies for engineering discovery. Further experiments will be performed to correlate dimensionality of the problem with the number of discrete fidelities.

## **4. Conclusions**

The optimisation of coiled tube reactor geometry is critical to maximise plug-flow behaviour and investigate industrial viability. The optimisation problem is formulated as an expensive black-box problem. In this paper, we propose multi-fidelity Bayesian optimisation using Deep Gaussian processes to find good reactor configurations, taking advantage of less accurate but faster simulations. We demonstrate experimental validation of five discrete fidelities and present a modified multi-fidelity Bayesian optimisation algorithm which relies on fewer hyper-parameters than existing approaches. A multi-fidelity DGP provides correct quantification and propagation of uncertainty, which we use to select not only the next experimental design, but also the fidelity of the evaluation within the algorithm. Our approach can be extended to other problems involving parameterised CFD simulations. This work demonstrates an industrially relevant use case of multi-fidelity deep Gaussian processes for the optimisation of expensive black-box functions. We hope it provides insight and inspiration for people in the chemical engineering community to apply multi-fidelity methods across a variety of potential problems.

## Abstract

A multi-objective optimization is proposed for determining the optimal operating conditions for biodiesel production. The objective functions considered were the production cost, the carbon footprint, and the yield of palm oil transesterification. The kinetic model proposed by Narváez et al. (2015) was validated with state-of-the-art experimental data. The optimization was conducted using Python 3.8.8 and openLCA 1.11.0 to determine environmental parameters. Four-decision variables were optimized by using 3 methodologies: Pareto Set, R-Method, and a Techno-economic analysis. The optimal solution resulted in a maximum yield of 80.29% with a minimum production cost of 0.44\$/kg, and a minimum carbon footprint of 0.144 kg CO<sub>2</sub>-eq/kg.

**Keywords:** Multi-objective Optimization, Kinetic model, Carbon footprint, Biodiesel

## 1. Introduction

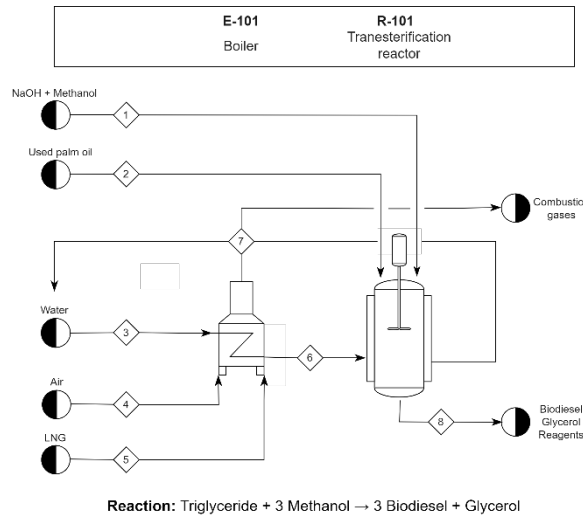

Nowadays, the predominant energy source is fossil fuels. However, research on alternative fuels has begun due to increased energy demand and limited fossil resources. One major alternative is biodiesel production which is now implemented in many countries. Nevertheless, the drawback of the industrialization of this process is the high volume of reactants used such as methanol and conventional catalysts, which leads to a high production cost and a high carbon footprint. For instance, an Ecuadorian company produces 144 thousand tons per year (Roca Meza, 2014), and the production costs exceed \$1000/ton. This causes the price of biodiesel to be 5.56 \$/gal (Clickgasoil, 2021) higher than diesel 4.33 \$/gal (EP PETROECUADOR, 2022). Several experimental studies have focused on finding the optimal conditions to maximize performance. Castillo González et al. (2020) shows that, for the formation of alkyl esters, a molar ratio of alcohol:oil 6:1 result in a high yield of biodiesel. Narváez et al. (2007) performed experimental tryouts on the kinetics of palm oil transesterification, obtaining high-yield results with elevated temperatures and molar ratios. Suzihaque et al. (2022) state that the catalyst's concentration is an important variable to consider since low concentrations imply a

smaller catalytic surface area to conduct the transesterification reaction, while high concentrations could lead to saponification. Either way, yield is affected negatively. Research on biodiesel optimization (Pugazhendhi et al., 2020) is often focused on maximizing yield. However, an optimization also including production cost and carbon footprint would be a suitable approach toward sustainable production. Therefore, the scope of this study is to perform a multi-objective optimization that minimizes the production cost and the carbon footprint and maximizes the yield of the transesterification reaction of palm oil.

## 2. Methodology

### 2.1. System description

Figure 1 shows the process flow for the biodiesel batch production proposed. A NaOH-methanol mixture (Stream 1) and palm oil (Stream 2) enter the batch-type reactor (R-101) for the transesterification reaction. R-101 uses steam supplied (Stream 6) by the boiler (E-101). E-101 works with liquefied natural gas (Stream 5) as fuel and air intake (Stream 4) at ambient conditions for combustion.

**Figure 1.** Process flow diagram to produce biodiesel from waste oil

### 2.2. Kinetic model and Validation

The kinetic model for the palm oil's transesterification reaction was implemented in Python 3.8.8. The model was based on a previous study from Narváez et al. (2015) which assumes that palm oil's transesterification reaction involves three reversible chain reactions that follow an elementary rate law. Equations 1 to 6 present the kinetic model,

$$\frac{d[TG]}{dt} = -k_1 e^{\frac{E_1}{RT}} \left( \frac{C_{cat}}{k_{1cat} + C_{cat}} \right) [TG][M] + k_{-1} e^{\frac{E_{-1}}{RT}} \left( \frac{C_{cat}}{k_{-1cat} + C_{cat}} \right) [DG][EM] \quad (1)$$

$$\frac{d[DG]}{dt} = k_1 e^{\frac{E_1}{RT}} \left( \frac{C_{cat}}{k_{1cat} + C_{cat}} \right) [TG][M] - k_{-1} e^{\frac{E_{-1}}{RT}} \left( \frac{C_{cat}}{k_{-1cat} + C_{cat}} \right) [DG][EM] - k_2 e^{\frac{E_2}{RT}} \left( \frac{C_{cat}}{k_{2cat} + C_{cat}} \right) [DG][M] + k_{-2} e^{\frac{E_{-2}}{RT}} \left( \frac{C_{cat}}{k_{-2cat} + C_{cat}} \right) [MG][EM] \quad (2)$$

$$\frac{d[MG]}{dt} = k_2 e^{\frac{E_2}{RT}} \left( \frac{C_{cat}}{k_{2cat} + C_{cat}} \right) [DG][M] - k_{-2} e^{\frac{E_{-2}}{RT}} \left( \frac{C_{cat}}{k_{-2cat} + C_{cat}} \right) [MG][EM] - k_3 e^{\frac{E_3}{RT}} \left( \frac{C_{cat}}{k_{3cat} + C_{cat}} \right) [MG][M] + k_{-3} e^{\frac{E_{-3}}{RT}} \left( \frac{C_{cat}}{k_{-3cat} + C_{cat}} \right) [G][EM] \quad (3)$$

$$\frac{d[EM]}{dt} = k_1 e^{\frac{E_1}{RT}} \left( \frac{C_{cat}}{k_{1cat} + C_{cat}} \right) [TG][M] - k_{-1} e^{\frac{E_{-1}}{RT}} \left( \frac{C_{cat}}{k_{-1cat} + C_{cat}} \right) [DG][EM] + k_2 e^{\frac{E_2}{RT}} \left( \frac{C_{cat}}{k_{2cat} + C_{cat}} \right) [DG][M] - k_{-2} e^{\frac{E_{-2}}{RT}} \left( \frac{C_{cat}}{k_{-2cat} + C_{cat}} \right) [MG][EM] + k_3 e^{\frac{E_3}{RT}} \left( \frac{C_{cat}}{k_{3cat} + C_{cat}} \right) [MG][M] - k_{-3} e^{\frac{E_{-3}}{RT}} \left( \frac{C_{cat}}{k_{-3cat} + C_{cat}} \right) [G][EM] \quad (4)$$

$$\frac{d[G]}{dt} = k_3 e^{\frac{E_3}{RT}} \left( \frac{C_{cat}}{k_{3cat} + C_{cat}} \right) [MG][M] - k_{-3} e^{\frac{E_{-3}}{RT}} \left( \frac{C_{cat}}{k_{-3cat} + C_{cat}} \right) [G][EM] \quad (5)$$

$$\frac{d[M]}{dt} = -\frac{d[EM]}{dt} \quad (6)$$

where *TG* represents triglycerides, *DG* diglycerides, *MG* monoglycerides, *G* glycerol, *EM* methyl esters, and *M* methanol. This model considers the influence of the reaction temperature and catalyst concentration on the kinetics of the reaction.

To validate the kinetic model, the degree of fit of the experimental kinetic data of Narváez et al. (2007) and Leevijit et al. (2004) were compared with the curve predicted by the model. Then, experimental data from Narváez et al. (2007), Cheng et al. (2004), Silva et al. (2021) and Wongjaikham et al. (2021) were used to compare their reported yield (*Y*%) or conversion (*C*%) results with those predicted by the kinetic model according to Equations 7 and 8 respectively. The relative errors between the experimental and model-predicted results were determined.

$$C \% = \frac{[TG]_0 - [TG]_f}{[TG]_0} \times 100\% \quad (7) \quad Y \% = \frac{[EM]_f}{3 [TG]_0} \times 100\% \quad (8)$$

### 2.3. Multi-objective optimization

For the multi-objective optimization, an algorithm was developed and implemented in Python 3.8.8. The independent variables considered were *reaction temperature* (*T*), *reaction time* (*t*), *NaOH catalyst concentration* (*C<sub>cat</sub>*), and *methanol: oil molar ratio* (*RM*). Therefore, the vector with *e* decision variables is presented in Equation 9:

$$x = (T, t, C_{cat}, RM) \quad (9)$$

The optimization algorithm started by evaluating each of the independent variables within the objective functions included in *Table 1*. The openLCA 1.11.0 program along with the *ef\_secondarydata\_202202* database was used to propose the carbon footprint objective function.

Three different strategies were used to discriminate the results of the solution set. First, the Pareto set was determined using the Python package *pareto* 1.2.0. This package is based on the skyline operator methodology that identifies the non-dominated solutions of the set, i.e., those that are the best in all or at least one of the objectives. Then, the R-Method proposed by Rao & Lakshmi (2021) was used. This is a ranking algorithm to select the *best* solution based on the level of importance of each of the objectives. In this case, yield and production costs were set as objectives with the same degree of interest. Finally, the ten solutions with the highest score from the R-Method analysis were selected to perform a techno-economic analysis. The methodology proposed by Turton et al.

(2018) was used to determine the cash flow, Internal Rate of Return (IRR), Net Present Value (NPV), and Payback Period for each solution. The solution with the highest IRR, NPV, and shortest payback period was selected as the optimal solution. This solution would not only maximize yield, minimize production costs, and carbon footprint but also would have the best economic potential.

**Table 1.** Objective functions

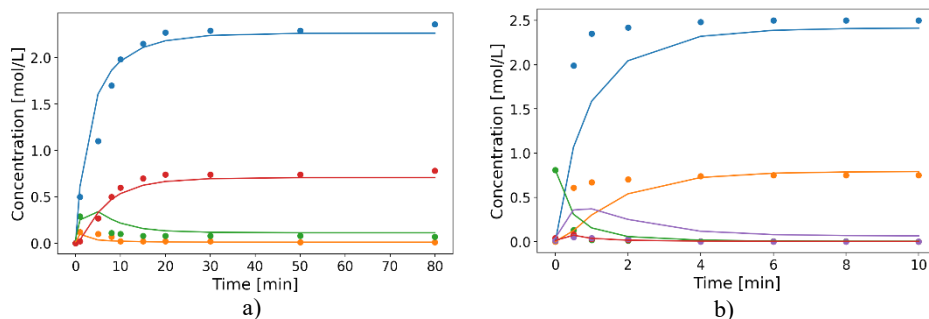

Yield* (%)	Production Cost** (\$/kg)	Carbon footprint** (kg CO <sub>2</sub> -eq/kg)
$\max_x \frac{[EM]_f}{3 * [TG]_0} \times 100\%$	$\min_x \frac{C_M + C_{Cat} + C_E + C_C}{M_{bio}}$	$\min_x \frac{CF_M + CF_{Cat} + CF_E + CF_F}{M_{bio}}$
Restrictions		
$45 \leq T (^{\circ}C) \leq 60$	$30 \leq t (min) \leq 120$	$3:1 \leq RM \leq 10:1$
		$0.5 \leq C_{cat} \left(\frac{\%w}{w}\right) \leq 1.5$

\* $[EM]_f$  the final concentration of methyl ester,  $[TG]_0$  the initial concentration of triglycerides.

\*\* $C$  and  $CF$  represent the cost and carbon footprint of methanol ( $M$ ), catalyst ( $Cat$ ), electricity ( $E$ ), and fuel ( $F$ ).  $M_{bio}$  is the mass of biodiesel produced.

### 3. Results

The kinetic model for the palm oil's transesterification reaction was validated. As shown in *Figure 2*, the theoretical kinetic model in comparison with the data from Narváez et al. (2007) (a) and Leevijit et al. (2004) (b) have a suitable approximation with  $R^2$  values of 0.983 and 0.924 respectively.

**Figure 2.** Comparison between experimental data (●) and the kinetic model (—) for palm oil transesterification at RM 6:1 and a)  $T = 50^{\circ}C$  and  $C_{cat} = 0.2\%$  and b)  $T = 60^{\circ}C$  and  $C_{cat} = 1.0\%$

*Table 2* presents the experimental and model-predicted results for conversion or yield. The relative errors are below 5%. Based on this, it can be concluded that the model proposed by Narváez et al. (2015) is highly reliable to describe the kinetics of palm oil transesterification. Also, that is possible to extrapolate the model for the selected operating ranges and obtain acceptable results.

The solution set consisted in 12544 results for *Yield (%)*, *Production Cost (\$/kg)* and *Carbon Footprint (kg CO<sub>2</sub>-eq/kg)*. As yield increases, production costs and carbon footprint also increase as shown in *Figure 3*. The Pareto set contained 286 solutions that are on the lower boundary of the solution set showing that these are the non-dominated solutions according to the criteria of this optimization.

**Table 2.** Kinetic model validation results

Reference	T (°C)	t (min)	C <sub>cat</sub> (% w/w)	RM	Parameter	Experimental	Model	% Error

Narváez et al. (2007)	60.0	80	1.0	6:1	Y %	97.60	96.94	0.68
Silva et al. (2021)	45.0	60	1.0	4:1	Y %	88.50	90.08	1.75
Wongjaikham et al. (2021)	62.5	40	1.5	3:1	Y %	77.00	80.41	4.39

**Figure 3.** Yield, production cost and carbon footprint results of the solution set

The operating conditions that maximize yield while minimizing production costs and carbon footprint are  $T = 45^{\circ}\text{C}$ ,  $t = 30$  min,  $\text{RM} = 3:1$  and  $C_{\text{cat}} = 1.5\%$ . Under these conditions, a biodiesel production yield of 80.29%, a production cost of 0.26 \$/kg, and a carbon footprint of 0.144 kg CO<sub>2</sub>-eq/kg is achieved. This production cost only includes raw materials and reactor utilities as proposed in its objective function. However, in the techno-economic analysis, a final cost of 0.44 \$/kg was estimated considering other costs such as operating labor and maintenance.

Similar proposals for biodiesel production via vegetable oil transesterification obtained a biodiesel cost between 0.58 \$/kg (El-Gharbawy, 2017) and 1.35 \$/kg (Mohammadshirazi et al., 2014). The product cost can be reduced up to 67.37% when the process operates at the obtained optimal conditions. Therefore, this solution turns out to be the most favorable not only in the studied range but also against other proposals. In addition, the optimal solution makes the proposal attractive and viable, with an IRR of 128.94% and a NPV of \$1.42 million. The invested capital would be recovered in 8 months and 12 days.

#### 4. Conclusions

The multi-objective optimization algorithm determined the optimal temperature, molar ratio, catalyst concentration and reaction time. This solution not only maximizes yield while minimizing production costs and carbon footprint but also has the best economic potential. In addition, this solution reduces production costs by up to 67.37% compared to other similar proposals. The proposed framework could be a potential tool for developing countries to target the biofuel market with sustainable production. In future work, a different optimization algorithm could be used in order to compare and further evaluate the obtained results.

## Abstract

Delayed Coker Unit (DCU) converts the vacuum residual feedstock to lighter and more valuable products such as motor fuels and eliminates the low-order and environment-damaging streams. Thus, optimal operation of this unit provides great economic return. In this direction, we have modeled an industrial DCU which exists in the TUPRAS Refinery. The steady-state model consists of the furnace and coke drums and implemented using MATLAB. Physical properties are determined by Aspen HYSYS. The obtained model was used for predicting the coke level in the coke drums where the reaction takes place and the distribution of the products. Both furnace and coke drum models were verified by comparing obtained results with actual plant data.

**Keywords:** Delayed coking, furnace and coke drum models.

## 1. Introduction

Delayed Coker Unit (DCU) is a critical refinery unit that enables the conversion of heavy materials such as vacuum residue into valuable products. This conversion occurs in coke drums where thermal cracking reactions take place. In the literature, there are a limited number of studies about modeling of the unit. Among these studies, Lima et al. (2016) and Borges et al. (2015) have modeled coke drums as plug flow reactor (PFR) by preparing in-house codes or by using simulation programs such as Aspen HYSYS/PLUS. On the other hand, Bozzano and Dente (2005) and Zhou et al. (2007) focused on the estimation of product yields with kinetic models as well. With this study, separate models of the coke drums and the furnace were created and the content of the coke drum outlet stream was estimated close to the reality.

## 2. Process Description

The main purpose of Delayed Coker Unit is thermal cracking the Vacuum Residue (VR) feed into valuable products such as Coker Fuel Gas, LPG, Stabilized Naphtha, Light Coker Gas Oil (LCGO), Heavy Coker Gas Oil (HCGO), and Coke. A simplified diagram of the delayed coking section is shown in Fig. 1. It consists of a fractionator tower, four

coke drums, and coke heaters. Fresh vacuum residue is preheated and enters the bottom of the main fractionator where it is combined with HCGO recycle. The combined fresh feed and recycle is pumped through the heaters in order to increase the temperature to a point at which coke formation occurs in the coke drums. As can be seen in Fig. 1, coking occurs only at one of the coke drum pairs, while the other drum is being cleaned and prepared for the next coking cycle. The mixture leaving the heaters passes through the coke drums where cracking reactions take place and solid coke accumulates. Product vapors obtained by cracking are returned to the bottom of the main fractionator above the fresh feed entry tray.

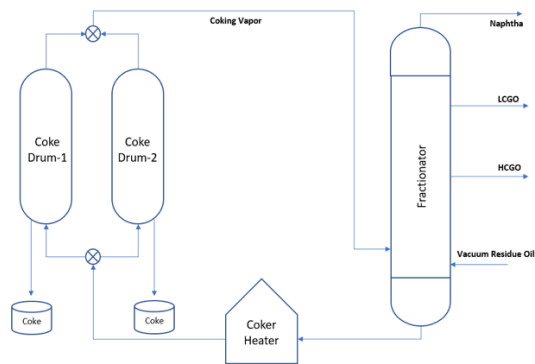

Figure 1. General representation of the Delayed Coker Unit (DCU)

### 3. Delayed Coker Furnace Model

The main role of the furnace is to increase the temperature of the VR feed before sending it to coke drums. VR enters into the furnace as a subcooled liquid and is transformed into a vapor-liquid mixture containing fresh vacuum residue and some products by some cracking reactions in the furnace tubes. While the two-phase stream flows through the furnace tubes, significant pressure drop can develop. In this study, the rigorous furnace model is generated based on the assumptions that there is two-phase flow with endothermic reaction under pressure drop effect, and there is no coke formation. For modeling of the coker furnace, the model structure proposed by Skogestad et al. (1986) has been used with Vapor-Liquid Equilibrium (VLE) for phase split calculations. It is basically based on the mass, energy and momentum conservation equations.

The mass balance is obtained for plug flow reactor (PFR) based on the kinetic model of 5 discrete lumps proposed by Singh et al. (2005). For each discrete lump, kinetic parameters are estimated based on feed and product properties by using the correlations proposed by Castellanos et al. (1991). The reactions only take place in liquid phase. Therefore, the reaction rate expressions have been derived by assuming first-order power-law approach for the PFR as following.

$$\frac{dF_i}{dz} = -r_i A_{liq} \quad (1)$$

where  $i = \text{VR, HCGO, LCGO, Naphtha, Gas lumps}$ ;  $A_{liq}$ , liquid fraction in the tube ( $m^2$ );  $r_i$ , reaction rate of  $i^{\text{th}}$  lump ( $\text{kmol}/\text{sm}^3$ );  $F_i$ , molar flowrate ( $\text{kmol}/\text{s}$ ).

From the perspective of energy, it is assumed that temperature inside the tubes is only changing with convective heat transfer for getting rid of complex equations. Effects of the conduction and radiation are neglected. Resulting enthalpy balance is given in Eq. (2).

$$H(z) = H(0) + \int_0^z Q(z) \cdot \pi \cdot D \cdot dz \quad (2)$$

where  $Q$  is the heat duty ( $\text{kW/m}^2$ );  $H(0)$  enthalpy of the feed at the inlet of the furnace ( $\text{kW}$ ). Pressure drop values along the tubes are being calculated based on three different terms such as frictional, acceleration and gravity gradients. Frictional pressure gradient is calculated with Martinelli correlation with the assumption that two phases can have different properties (Thome and Cioncolini, 2015). Gradient is basically defined as functions of liquid-only or gas-only pressure multiplier and liquid-only or gas-only pressure gradients. Two-phase flow frictional pressure gradient is calculated as in Eq. (3).

$$\left(\frac{dP}{dz}\right)_{fr} = \left(\frac{dP}{dz}\right)_{lo} \phi_{lo}^2 = \left(\frac{dP}{dz}\right)_{go} \phi_{go}^2 \quad (3)$$

where  $\left(\frac{dP}{dz}\right)_{lo}$ , single phase frictional pressure gradients for the liquid-only;  $\left(\frac{dP}{dz}\right)_{go}$ , single phase frictional pressure gradients for the gas-only;  $\phi_{lo}$ , two-phase liquid-only multiplier;  $\phi_{go}$ , two-phase gas-only multiplier.

Acceleration pressure drop gradient is explained on the basis of momentum density  $\rho_m$  ( $\text{kg/m}^3$ ) gradient and mass flux  $G$  ( $\text{kg/m}^2\text{s}$ ). Momentum density term is a function of liquid density  $\rho_L$  ( $\text{kg/m}^3$ ), gas density  $\rho_G$  ( $\text{kg/m}^3$ ), quality ( $x$ ), void fraction ( $\varepsilon$ ). Acceleration pressure drop gradient is computed as follows:

$$\left(\frac{dP}{dz}\right)_{acc} = G^2 \frac{d}{dz} \left(\frac{1}{\rho_m}\right) = G^2 \frac{d}{dz} \left[ \frac{(1-x)^2}{\rho_L(1-\varepsilon)} + \frac{x^2}{\rho_G\varepsilon} \right] \quad (4)$$

where void fraction is calculated based on Lockhart and Martinelli correlation. The last term left for gradient pressure calculation is gravitational pressure drop which is expressed in terms of density and void fraction, such that (Thome and Cioncolini, 2015):

$$\frac{\Delta P_g}{\Delta z} = [\rho_L(1-\varepsilon) + \rho_G\varepsilon] g \sin\theta \quad (5)$$

where  $\frac{\Delta P_g}{\Delta z}$ , gravitational pressure drop;  $\theta$ , the angle of channel inclination from horizontal;  $g$ , acceleration gravity ( $9,81 \text{ m/s}^2$ ).

#### 4. Coker Drum Model

The VR feed enters into the coker drums as two phase composed of vapor and liquid and it exposes to the cracking reactions after a while. Cracking reactions result in vapor products and solid coke which means that there are three phases as coke, residue and distillate in the reactor. From this point of view, it can be modeled similar to the trickle bed reactor. Liquid vacuum residue phase is the primary phase and the gas distillate phase is secondary phase. The system can be modeled in the Eulerian-Eulerian approach. The coke phase is assumed as homogeneous porous medium and accumulates with time.

#### 4.1.1. Material Balance

Vacuum residue is decomposed into gas, distillate products (HCGO, LCGO, Naphtha) and coke. Coke amount changes with time but does not have any positional dependency. Therefore, vacuum residue is assumed to crack only to gas and distillate for steady-state model and coke level is associated with void fraction. Reaction kinetic expression and parameters are calculated based on the correlation proposed by Esfahani et al. (2019). General balance and component-based mass balances are given in Eq. (6a-c).

$$\frac{d(\gamma\alpha_R\rho_R v_{z,R})}{dz} = \gamma\alpha_R\rho_R\Gamma_R \quad (6-a)$$

$$\frac{d(\gamma\alpha_D\rho_D v_{z,D})}{dz} = \gamma\alpha_D\rho_D\Gamma_D \quad (6-b)$$

$$\frac{d(\gamma\alpha_R\rho_R v_{z,R} Y_{i,R})}{dz} = \gamma\alpha_R m_{i,R} \quad (6-c)$$

where  $i$  represents Gas, Distillate, Vacuum Residue lumps;  $\gamma$ , coke void fraction;  $\alpha_R$ , residue volume fraction;  $\alpha_D$ , distillate volume fraction;  $v_{z,R}$ , velocity of the residue phase (m/s);  $v_{z,D}$ , velocity of distillate phase(m/s);  $\Gamma$ , reaction velocity(1/s);  $m_{i,R}$ , mass transfer of component  $i$  from another phase (kg/m<sup>3</sup>s);  $Y_{i,R}$ , weight fraction of  $i^{\text{th}}$  lump.

#### 4.1.2. Momentum Balance

Even though the assumption of no mass transfer between phases, the phase interactions encountered in the trickle beds are involved. The momentum balance of each phase is provided in Eq. (7a-b).

$$\frac{d(\gamma\alpha_R\rho_R v_{z,R}^2)}{dz} = \gamma F_G - \gamma\alpha_R \frac{dP}{dz} + \gamma\alpha_R\rho_R g \quad (7-a)$$

$$\frac{d(\gamma\alpha_D\rho_D v_{z,D}^2)}{dz} = \gamma F_L - \gamma\alpha_D \frac{dP}{dz} + \gamma\alpha_D\rho_D g \quad (7-b)$$

where  $F_G, F_L$ , phase interaction terms (kg/m<sup>2</sup>s<sup>2</sup>);  $g$ , acceleration gravity (9,81 m/s<sup>2</sup>);  $\frac{dP}{dz}$ , pressure drop (kg/m<sup>2</sup>s<sup>2</sup>);  $\gamma$ , coke void fraction. Phase interactions are calculated by the equations provided in the Alopaus et al. (2006)'s study.

#### 4.1.3. Energy Balance

Assuming that the coke, vacuum residue and product vapors are in close contact, the temperatures of the three phases are assumed to be the same throughout the reactor. Therefore, the energy balance is given as following.

$$\frac{d(\gamma\alpha_R\rho_R v_{z,R} C_{P,R} T + \gamma\alpha_D\rho_D v_{z,D} C_{P,D} T)}{dz} = \gamma\alpha_R\rho_R\Gamma_R\Delta\dot{H}_R + U \frac{A}{V_r} (T_C - T) \quad (8)$$

where  $C_{P,R}, C_{P,D}$  are heat capacity of residue and distillate phases, respectively (J/kgK);  $\Delta\dot{H}_R$ , heat of reaction (J/kg);  $A$ , surface area(m<sup>2</sup>);  $V_r$ , volume of the reactor(m<sup>3</sup>);  $U$ , overall heat transfer coefficient(W/Km<sup>2</sup>);  $T_C$ , temperature of surrounding(K);  $T$ , temperature of the fluid(K).

## 5. Results

The models are run for vacuum residue inlet stream of three different days that differed from each other in terms of density (API) and concarbon (CCR). API and CCR values are given in Table 1. The CCR content of the VR affects the yield of the products and so the accuracy of the model predictions was evaluated against the variation of the content.

Table 1. Properties of vacuum residue stream for three different days

Date	API	CCR
1 <sup>st</sup> Day	4,35	23,55
2 <sup>nd</sup> Day	6,50	22,00
3 <sup>rd</sup> Day	4,80	18,38

Models were coded over MATLAB for only one dimension (z-direction). The balance equations of furnace model are solved sequentially until values of variables converge to a point. The coke model is computed by ode15s solver. All required properties (density, phase splits, heat capacity, enthalpy) of each lump are calculated by using Aspen HYSYS. Since the vacuum residue (VR) was first fed to the furnace, the furnace model was run first and then the coke drum model was triggered. The furnace model was run with the VR stream of the 1<sup>st</sup> day and the results in Fig. 2 were obtained. After that, the results of the heater model are used as the input of the coke drum model. The obtained coke drum model results for  $\gamma = 0,7$  are plotted as in Fig. 3.

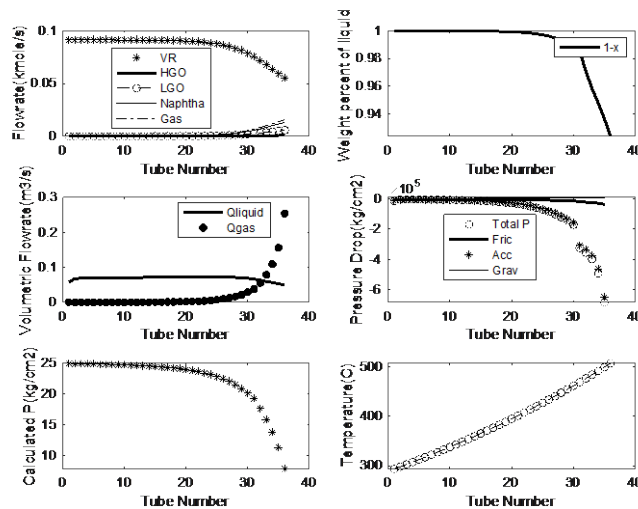

Figure 2. Results of the coker heater model for 1<sup>st</sup> Day

According to Fig. 2 and Fig. 3, it is seen that the estimated values of outlet pressures are quite close to the real outlet values. Real outlet values are represented as Actual T and Actual P in the following graph. The relative error values with respect to temperature, pressure and distillation weight fraction in Table 2 also support this. Despite varying CCR contents of VR, the maximum relative error is 15,77% with steady-state models.

Figure 3. Results of the coke drum model for 1<sup>st</sup> Day (for  $\gamma = 0.7$ )

Table 2. Relative Error with respect to Coke Drum Outlet Conditions

Date	Abs Relative Error (%) Based on Temperature	Abs Relative Error (%) Based on Pressure	Abs Relative Error (%) Based on $Y_{DIS}$
1 <sup>st</sup> Day	0,88	12	6,33
2 <sup>nd</sup> Day	0,91	11	5,79
3 <sup>rd</sup> Day	0,92	15,77	2,79

To obtain these results, correlations proposed in the literature for reaction kinetic parameters were used. On the other hand, only diameter of the coke particle was adjusted to capture the real results in the coke drum model. As shown in Fig. 4, the coke diameter increases with the coalescence of the coke particles while coke level in the drum increases.

Figure 4. Coke diameter

## 6. Conclusion

Models of both coker heater and coke drums were developed to predict the performance of DCU and verified with the real data sets from Tupras Refinery. The coker heater model is designed as two-phase plug-flow reactor based on 5 discrete lumps (VR, HCGO, LCGO, Naphtha, Gas). The coke drums are assumed as the three-phase trickle-bed reactor with 3 discrete lumps (VR, Distillate, Gas). It has been observed that models running sequentially give realistic results regardless of both density and CCR content of the VR.

## **Abstract**

In this paper, a stochastic approach is presented for optimal planning of an integrated natural gas and electricity network. The planned network can play an important role in the smart cities in order to reduce the emission pollution and operation cost. In addition, various resource and elements of a sustainable green energy system including renewable energy units and energy storage are modeled. A comprehensive investigation is carried out based on different scenarios and the extracted simulation results are discussed. In order to guarantee the global optimum results, the modeling equations of the studied problem have been linearized and the problem became to a mixed-integer linear programming (MILP). The linearized problem optimized using a mathematical based optimization algorithm.

**Keywords:** Sustainable green energy, integrated energy networks, smart cities.

## **1. Introduction**

Today's, the sustainable green energy systems play an important role in the smart cities. Reducing the emission pollution and the operation cost of energy systems is one of the main purpose of the sustainable cities' planner. Several ideas have been proposed in the literature in order to optimal management of energy systems. Optimal energy management in a micro-grid [1], optimal management of electric vehicles charging demand in terms of smart charging [2], optimal energy storage planning and operation in the energy systems [3], etc. are the most famous approaches that are presented in the literature. Although the optimal energy management in the electric network could reduce the operation cost, it can be more beneficial if the electric grid and the natural gas are integrated together [4]. Hence, the integrated energy networks are introduced to optimal operation and planning of both natural gas and electricity networks, simultaneously. In order to study the integrated network, the energy systems' elements including the power plants, gas fired units, gas storage, energy storage, renewable energy resources, etc. should be modeled mathematically. In addition, the power flow in the electricity network and the gas flow in the natural gas network should be modeled and their constraints should be considered.

In this paper, an approach is presented for optimal planning of integrated electricity and gas networks. In addition, the stochastic parameters are modeled based on the Copula method which can model the stochastic parameters more efficiently than other stochastic methods such as Monte Carlo. Furthermore, to decrease the computational burden of the scenario-based method the Kantorovich method is utilized. A comprehensive study by

modeling different resources such as renewable energy resources, and different storages are presented. Based on this method, the system operator can get the most out of these resources. The optimization problem turns into a mixed-integer linear programming (MILP) approach by using appropriate methods which can guarantee the global optimal solution.

<b>Nomenclature</b>	
<b>Indices</b>	
$c$	CHP units index
$e$	Emission type index
$n$	Index of electric and gas storages
$g$	Gas supplier index
$u$	Unit Index
$gs$	Gas storages index
$p, q$	Gas network nodes indices
$s$	Scenarios index
$t$	Time index
<b>Parameters</b>	
$a_u, b_u, c_u$	Unit's cost coefficients
$EC_e$	Externality cost of each emission type (\$/lb)
$EF_{u,e}$	Emission factor of each unit (lb/MWh)
$ES_n^{CH,MAX}, ES_n^{DIS,MAX}$	Maximum rate of charging and discharging in storages
$H_c^A, H_c^B, H_c^C, H_c^D$	Coefficients related to the amount of produced heat by CHP units (MW)
$HD_{s,t}$	Total heat demand (MW)
$P_c^A, P_c^B, P_c^C, P_c^D$	Coefficients related to the amount of produced power by CHP units (MW)
$P_u^{MIN}, P_u^{MAX}$	Minimum and maximum generated active power by units (MW)
$GP_p^{MIN}, GP_p^{MAX}$	Minimum and maximum pressure limit of nodes (Psig)
$Q_u^{MIN}, Q_u^{MAX}$	Minimum and maximum generated reactive power by units (MVar)
$SU_u, SD_u$	Startup and shutdown cost of each unit (\$)
$\eta_n^{CH}, \eta_n^{DIS}$	The efficiency of charging and discharging in storages
$\lambda_g^C$	Gas price (\$/kcf)
$\pi_s$	Probability of each scenario

Variables	
$GF_{p,q,s,t}$	Gas flow in pipelines (kcf)
$G_{g,s,t}^G$	Produced gas by gas suppliers (kcf)
$P_{u,s,t}, Q_{u,s,t}$	Generated active (MW) and reactive (MVar) power by each unit
$ES_{n,s,t}^{CH}, ES_{n,s,t}^{DIS}$	Amount of storages charge and discharge
$GP_{p,s,t}$	Pressure in nodes of the gas network (Psig)
$SOC_{n,s,t}$	Stored power (MWh) or gas (kcf) in storages
$U_{u,s,t}$	Binary variable for on/off of units
$U_{n,s,t}^{CH}, U_{n,s,t}^{DIS}$	Binary variables to control charging and discharging states

## 2. Problem Formulation

An integrated electricity and gas network as shown in Fig. 1 is considered in this paper.

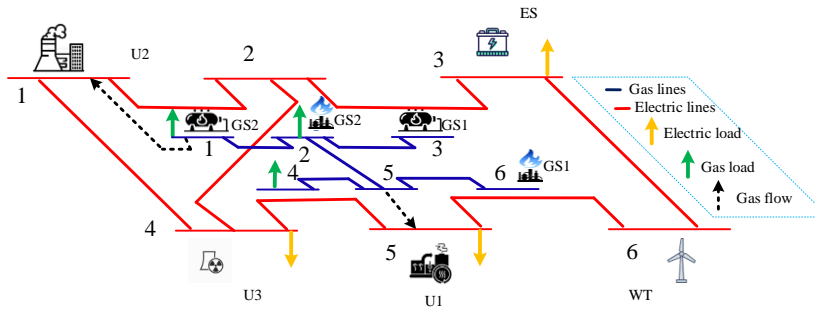

Fig. 1: overall structure of the proposed method.

This study aims to minimize the total cost of both the electricity and gas networks together as expressed in equation (1). This cost consists of three terms: the first term is the emission cost of fossil-fueled based units, the second term explains the operation cost of units to generate electricity, and the third term is related to the cost of natural gas.

$$\min \sum_s \pi_s \sum_t (\underbrace{\sum_e \sum_u EC_e EF_{u,e} P_{u,s,t}}_{\text{Emission Cost}} + \underbrace{\sum_u (a_u P_{u,s,t}^2 + b_u P_{u,s,t} + c_u + S U_u U_{u,s,t} (1 - U_{u,s,t-1}) + SD_u U_{u,s,t-1} (1 - U_{u,s,t}))}_{\text{Operation Cost of Generation units}} + \underbrace{\sum_g \lambda_g^G G_{g,s,t}^G}_{\text{Gas Cost}}) \quad (1)$$

Constraints related to the generation units are described in equations (2) and (3); these constraints limit the total active and reactive power generated by units. The minimum up and down time limits and ramp rate of units are modeled based on reference [5].

$$P_u^{MIN} U_{u,s,t} \leq P_{u,s,t} \leq P_u^{MAX} U_{u,s,t} \quad (2)$$

$$Q_u^{MIN} U_{u,s,t} \leq Q_{u,s,t} \leq Q_u^{MAX} U_{u,s,t} \quad (3)$$

For the CHP units which are responsible for satisfying heat demand besides the above constraints, constraints are investigated to control the amount of generated heat by these units [6]. Moreover, in order to model the electric and gas storages equations are used. Linear power flow equations are used to check the electric network constraints based on reference as presented in [7]. To meet the limitation of the gas network, the presented equations in [8] are utilized.

### 2.1. Equation linearization

In the equations of the system, there are some equations that make the problem a mixed-integer nonlinear programming (MINLP). Solving MINLP problems has a high computational cost. In addition, it is possible to stick to local optimal points. To overcome these issues, the appropriate linearization methods are utilized. For linearization, the multiplication of binary variables, and continuous problems the methods presented in [9] are used. For the linearization of quadratic operation cost of generation units, the piecewise linear method is utilized [10]. Finally, the Weymouth equation is linearized.

## 3. Numerical results and discussion

### 3.1. Input data

To show the effectiveness of the proposed method the electric-gas network which is shown in Fig. 1 is implemented.  $AP^{DR}$  is considered as 10%.  $\eta_n^{CH}$  and  $\eta_n^{DIS}$  are 0.8. Emission data are considered based on [7]. Generation units constraints are presented in references [4] that show the parameters of the gas network.

### 3.2. Uncertainty Modeling

In this paper, the Copula method is investigated for modeling uncertainties. The advantage of copula against other generative methods such as Monte Carlo is its ability to consider the relationship between different features.

### 3.3. Simulation Results

The results after the implementation of the proposed method are shown in figures 2-5 and Table 1. Fig. 2 shows the generated power by three units. The first unit which is responsible for heat demand too generated its maximum power during the day. However, unit 3 is not operated at all hours because the emission cost is implemented for units in this study; in this regard, unit 3 is not economical. Unit 2 produces its maximum power in the middle of the day when we have the maximum power and gas demands.

Fig. 2: Generated power by different units.

Fig. 3 demonstrates the total gas demand in the network which is the sum of gas demand and consumed gas by units. This gas demand is supplied by two gas suppliers as shown in Fig. 1, the amount of generated gas by two units are presented in Fig. 4.

Fig. 3: Total gas demand.

Fig. 4: The amount of generated gas by gas suppliers.

Fig. 5: Electric demand before and after implementation of DRP.

To better clarify the results the detail of the results is presented in Table 1 for each source.

Table 1: Different costs of integrated electricity and gas networks.

Parameters	Value of Cost (\$)
Unit 1	20483
Unit 2	21519
Unit 3	286
Gas cost	154106
Emission cost	4821
<b>Total cost</b>	<b>201215</b>

#### 4. Conclusion

In this paper, an integrated natural gas and electricity network was investigated. The elements and resources of the both networks were modeled mathematically and the power flow in the electricity network and the gas flow in the natural gas network were modeled. A mixed integer linear programming (MILP) approach is presented to optimal planning and operation of the studied integrated network. The simulation results verified the effectiveness and robustness of the proposed methodology in reducing of the emission pollution and operation cost.

## Abstract

Energy prices are nonlinear, noisy, non-stationary time-series, which are sensitive and volatile to supply and demand imbalances, changes in monetary and fiscal policies, new environmental regulations, major political and social events, as well as technological breakthroughs. Despite the fact that numerous methods have been proposed in the literature to forecast the prices of the several types and sources of energy, there is no single forecasting method that systematically performs better over the other methods for any given data set. To this respect, Energy Price Index (EPIC) extended forecasting capabilities are presented here. Statistical and machine learning forecasting methods of different nature have been incorporated into the framework, enabling the forecasting of energy prices up to 14 months in the future. The historical prices of each energy product are studied independently, so as to identify seasonality, patterns, trends and outliers. The results reveal the superiority of the deep neural networks, especially those with feedback loops, over statistical forecasting methods.

**Keywords:** forecasting framework, energy prices, machine learning, hyperparameters tuning.

## 1. Introduction

A time-series is a sequence of observations made over a period of time at equal time intervals. An inherent characteristic of time-series is that adjacent observations are often dependent. Determining the probability law that governs a time-series is a crucial task towards unraveling the underlying dynamics, and eventually forecasting future events.

Traditional methods such as autoregressive integrated moving average (ARIMA) (Box et al., 2015) and exponential smoothing (Gardner et al., 1985; Winters, 1960), focus mainly on parametric models which are approximations of the real stochastic dynamics that govern a data set. The increase in data availability and computing power over the last decades led to a new class of methods that are capable of identifying nonlinear patterns, learning by trial-and-error complex data structures, and improving their performance over time, without requiring the underlying knowledge or an analytical model (Montgomery et al., 2015). As such, various machine learning (ML) methodologies have been proposed for a variety of applications (Lim et al., 2021). However, the prevalence of the more complicated ML methodologies in fitting and learning the temporal dynamics of the available data, does not necessarily lead to more accurate forecasts (Makridakis et. al.,

2018). To this respect, hybrid models that combine both statistical and ML methodologies have illustrated superior performance against their individual components in a range of applications (Smyl, 2020).

In this work, we extend the forecasting capabilities of the Energy Price Index (EPIC) (Baratsas et al., 2021, 2022) with the incorporation of 35 statistical and machine learning forecasting methods of different natures, enabling the forecasting of the energy prices up to 14 months in the future. Since EPIC consists of 56 different energy products with 33 unique time-series data, the extended forecasting framework is applied to each one of these univariate time-series individually and the forecasting model that demonstrates the most accurate forecasting results over a testing period is then utilized for the future forecasts.

## 2. Hybrid Forecasting Framework for the Energy Sector

The large number of unique time-series that demonstrate unique patterns, trends, and cycles and need to be predicted for different forecasting horizons, introduce major challenges in the forecasting process. Figure 1 highlights these unique characteristics on a subset of the time-series.

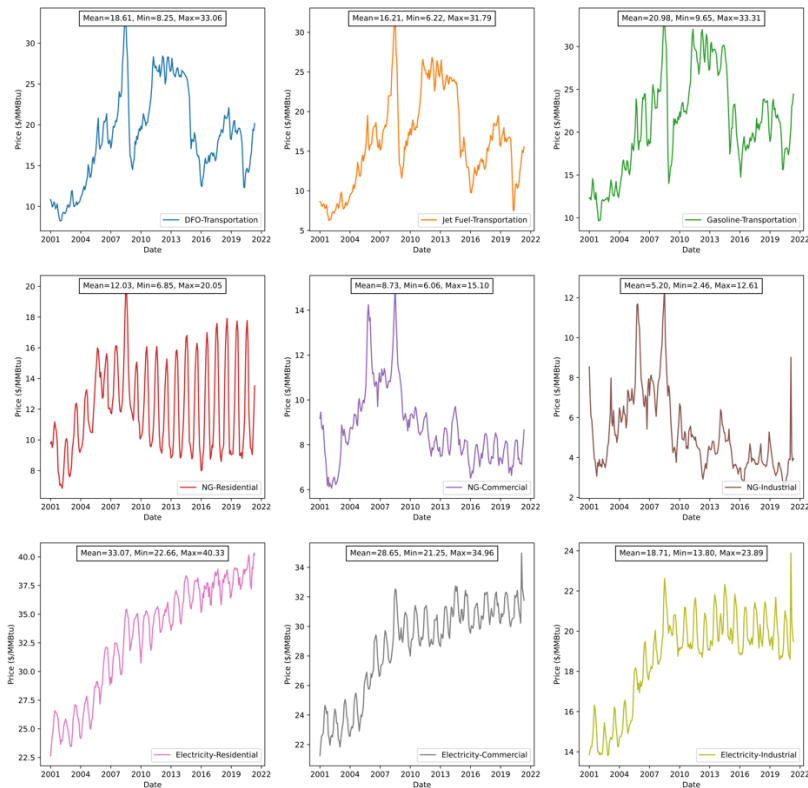

Figure 1: 20 years of monthly prices of the 9 energy products with the highest energy demand in 2017-2021

The 33 time-series are monthly indexed with data sets of 161 to 425 months. The forecasting framework incorporates 35 statistical and ML forecasting methods into 7 distinct groups, which are summarized in Table 1. The first forecasting group "Benchmark Forecasting" consists of five rather simple but quite effective methods (Hyndman, 2018). They are used to provide a benchmark on forecasting performance against the rest of the forecasting groups which are more advanced and computationally expensive. The second forecasting group "Forecasting with Decomposition" utilizes STL decomposition (Gardner et al., 1985) and then the forecasts of the STL objects are obtained by applying a non-seasonal forecasting method to the seasonally adjusted data and re-seasonalizing using the last year of the seasonal component. The third forecasting group "Exponential Smoothing" (Winters, 1960; Bergmeir et. al., 2016) consists of nine forecasting methods, where forecasts are weighted averages of past observations with the weights though decaying exponentially for the older observations. A complementary approach to exponential smoothing is the fourth forecasting group, namely "ARIMA", which combines autoregressive and moving average models, while allowing differencing of the data series. Seasonal and non-seasonal ARIMA models ( $ARIMA_{(p,d,q)(P,D,Q)m}$ ), are used. Due to the large number of hyperparameters to be determined, grid search is conducted in the last two methods (fc4d, fc4e) and the configuration with the smallest AICc and AIC value (Cleveland et. al, 1990) respectively is selected. The fifth forecasting group consists of advanced statistical forecasting methods, including dynamic regression and TBATS models (Cleveland et. al, 1990; Crone et. al., 2010), along with bootstrapped time series that use the Box-Cox and Loess-based decomposition bootstrap (De Livera et. al, 2011).

Table 1: Hybrid forecasting framework for energy prices

Group	Forecasting Method	Description of Forecasts
Benchmark Forecasting	fc1a	Average based on the historical mean
	fc1b	Random Walk (RW) – Naïve naïve w/ RW model
	fc1c	Seasonal Naïve ARIMA(0,0,0)(0,1,0) model
	fc1d	RW w/ Drift RW w/ drift
	fc1e	RW w/ Drift Transformed & Bias Adjusted fc1d adj Box-Cox transformation
Forecasting with Decomposition	fc2a	Automated STL automated STL decomposition
	fc2b	ARIMA Automated STL ARIMA seasonally adjusted data
	fc2c	Naïve Automated STL naïve seasonally adjusted data
	fc2d	RW w/ Drift Automated STL RW w/ drift seasonally adjusted data
	fc2e	ETS Automated STL STL decomposition, w/ ETS seasonally adjusted back Box-Cox transformed data
Exponential Smoothing	fc3a	Simple Exponential Smoothing
	fc3b	Holt’s Damped trend
	fc3c	Holt-Winters’ (HW) Additive
	fc3d	HW Multiplicative
	fc3e	HW Damped Additive
	fc3f	HW Damped Multiplicative
	fc3g	Error, Trend, Seasonal (ETS) exponential smoothing state space

	fc3h	ETS Transformed Bias Adjusted	fc3g w/ adj Box-Cox transform
	fc3i	Bagged ETS	ETS to all bootstrapped series
<b>ARIMA</b>	fc4a	Manual ARIMA	manually selected terms
	fc4b	Auto. Arima Non-Seasonal	automated non-seasonal ARIMA
	fc4c	Auto. Arima Seasonal	automated seasonal ARIMA
	fc4d	Grid Search Arima	grid searching of hyperparameters
	fc4e	Grid Search Arima	grid searching of hyperparameters
<b>Advanced Forecasting Methods</b>	fc5a	Dynamic Regression model	w/ Fourier terms
	fc5b	TBATS	
	fc5c	Bootstrapping ARIMA	Box-Cox & Loess-based decomposition bootstrap
<b>Neural Networks (NN)</b>	fc6a	Feed-forward NN	single hidden layer (hl), lagged inputs
	fc6b	MLP_1	MLP w/ 5 hl & 20 training reps
	fc6c	MLP_2	MLP w/ 5 hl & 50 training reps
	fc6d	MLP_3	fc6c w/ 12 autoregressive lags
<b>Grid Search NN</b>	fc7	MLP	MLP model w/ 2 hl, followed by corresponding dropout layers, and a final output layer
	fc8	RNN	RNN model w/ 2 hl layers and a final output layer
	fc9	LSTM	LSTM model w/ a single LSTM hl, followed by a dropout layer, a dense fully connected layer followed by a dropout layer, and a final output layer
	fc10	CNN-LSTM-DNN	Hybrid CNN-LSTM model w/ 2 convolutional layers for 1D inputs, followed by a pooling & a flattened layer, 2 LSTM hl, and a final output layer

The last two forecasting groups consist of ML methods. In the sixth forecasting group "NN", the hyperparameters of the models are pre-selected, while in the seventh forecasting group "Grid Search NN", a grid search is applied for tuning the hyperparameters. More details about the grid searches are given in Table 2. In the last forecasting group, each configuration is evaluated 3 times. The average of these values for each accuracy measure is considered as the final one.

Table 2: Hyperparameters tuning through grid search

#	Details	Hyperparameters
fc4d	Grid Search Arima	p=[1...5], d=1, q=[1...3], P=[1...5], D=[0...1], Q=[1...3], m=18

### 3. Data Preprocessing and Evaluation Metrics

Each time-series is preprocessed to achieve stationarity in its mean and variance, and is decomposed so as to extract time-series patterns such as trend, seasonality and cycles. This is done using Seasonal and Trend decomposition using Loess (STL), Box-Cox transformation, first order, and seasonal differencing so as to remove trend and seasonality. The residuals between the historical data and the corresponding fitted values, should be uncorrelated and have zero mean. The data sets are split into 80%-20% sets, with the first 80% of the data used for training/validating the models, and the last 20% used for testing their forecasting accuracy. Three accuracy measures are used in this paper: Root Mean Squared Error (RMSE), symmetric Mean Absolute Percentage Error (sMAPE) and Mean Absolute Error (MAE), and are defined as follows:

$$RMSE = \sqrt{\frac{1}{h} \sum_{t=1}^h (y_t - \hat{y}_t)^2} \quad sMAPE = \frac{2}{h} \sum_{t=1}^h \frac{|y_t - \hat{y}_t|}{|y_t| + |\hat{y}_t|} * 100\%$$

$$MAE = \frac{1}{h} \sum_{t=1}^h |y_t - \hat{y}_t|$$

where  $h$  is the forecasting horizon,  $y_t$  are the historical data, and  $\hat{y}_t$  are the forecasts produced by the model at point  $i$ .

### 4. Results

The forecasting framework is applied to each one of the 33 time-series. In each case, the forecasting model with the highest forecasting accuracy based on the three accuracy measures is selected for the future forecasts. If different models result from the accuracy measures, then the following process is followed: i) if the same model results from two accuracy measures, this one is selected, ii) if a different model results from each accuracy measure, then the model that has the highest overall ranking among all three accuracy measures is selected e.g. fc3a: 1<sup>st</sup> RMSE, 2<sup>nd</sup> sMAPE, 3<sup>rd</sup> MAE. In case there is still no clear winner, the model with the lowest RMSE is selected. Table 3 summarizes the forecasting results for the 33 time-series.

Table 3: Best forecasting models and accuracy measures

Energy Product	Selected Method	Average RMSE (\$/MMBtu)	Average sMAPE (%)	Average MAE (\$/MMBtu)
Distillate Fuel Oil (DFO) [R]	fc7	1.436	4.760	1.002
Kerosene [R, C, I]	fc9	3.403	8.982	1.962

Coal, [I]	fc9	0.037	0.704	0.027

*R: Residential, C: Commercial, I: Industrial, T: Transportation*

The above results clearly demonstrate the superiority of the last forecasting group "Grid Search NN" over the other forecasting groups, since 31 out of the 33 energy products are modeled more accurately using one of its four forecasting methods. In particular, LSTM is the most accurate method since it is used for 15 energy products, followed by RNN, MLP, and CNN-LSTM-DNN which are used for 9, 6, and 1 energy products respectively. Just two models are modeled using forecasting with decomposition and ARIMA groups. It is worth mentioning, that even without considering the last forecasting group, the NNs of the sixth forecasting group would only be used for 5 out of 33 energy products. Thus, NNs require special attention and proper tuning for forecasting time-series.

## 5. Conclusions

The historical prices of each energy product are analyzed independently considering seasonality, patterns, trends, cycles and outliers. Each time-series is pre-processed to establish stationarity in the mean and variance before being split into training and testing datasets. Then, the forecasting framework that consists of 35 statistical and ML forecasting methods is applied to each time-series individually, and the forecasting model that produces the best accurate results throughout a testing period is used for predictions up to 14 months in the future. The results highlight the critical importance of accurately tuning a NN's hyperparameters and demonstrate that deep NNs, especially those with feedback loops, perform better than statistical forecasting techniques.

## Abstract

Low-carbon transition of energy systems is an inevitable trend to address climate change challenges, featuring more natural gas consumption to replace coal and oil. Planning of a natural gas supply system with multiple supply sources, end-consumers, and large infrastructures are challenging tasks. Uncertainty and spatial and seasonal mismatch of natural gas supply and demand makes the natural gas supply infrastructure planning problem more complex. In this study, a chance-constrained programming approach to optimal planning of low-carbon transition of a natural gas supply system is presented. This approach considers the uncertainties of end-consumer demand, pipe aging and import fluctuation to ensure natural gas supply reliability. China is taken as a case study. Results show that with consideration of uncertainty, an additional 40.75 % of LNG ports capacity and an additional 25.59 % of gas storage capacity need to be installed per year on average, with a 38.10 % increase in the transition cost. Finally, sensitivity analysis results are provided, showing that a rapid increase of transition costs occurs when confidence level exceeds 99.9 %. The results in this study provide references for decision makers to plan the low-carbon transition of natural gas supply systems as well as weighing transition costs against natural gas supply stability.

**Keywords:** chance-constrained programming, natural gas supply system, optimization, decarbonization

## 1. Introduction

Decarbonisation is an inevitable trend to address climate change challenges. In recent years, global natural gas consumption has grown rapidly to replace coal and oil, and the share of natural gas in primary energy consumption has reached a high level of 24% (BP, 2022). Natural gas supply highly depends on specialized and high-cost infrastructure, including pipeline networks, liquid natural gas (LNG) ports, and storage facilities. Spatial mismatch between natural gas resources and natural gas demand requires a large amount of infrastructure. China surpassed Japan as the world's largest LNG importer and accounted for close to 60% of global LNG demand growth in 2021 (BP, 2022).

For the low-carbon transition in developing regions, more natural gas is needed at the current stage. Infrastructure costs are a major part of the cost of the gas supply system, and if infrastructure costs are too high, the low-carbon transition will slow, disrupt or even reverse. In addition, natural gas probably be replaced by zero-carbon energy sources in the future. Therefore, developing an appropriate planning framework to obtain the optimal planning by minimizing the overall cost would facilitate the transition and avoiding investment waste.

Modelling and optimization of a natural gas supply system has been studied in many researches. Li et al. (2019) propose a monthly-scale, multi-period and multi-regional modelling and optimization framework for planning and operation of a natural gas supply system at a transient stage. Huang et al. (2022) proposes a method based on Bayesian networks (BNs) to optimize the reliability of gas supply in natural gas pipeline networks. Dieckhoner et al. (2013) and Chaudry et al. (2014) developed a pipeline network model and obtained an expansion plan to address increasing demand of natural gas based on existing infrastructure. An interconnected natural gas and electrical transmission model was developed for the natural gas system in Illinois, considering spatiotemporal changes in energy demand (Chiang, 2016). Zhang et al. (2016) established a multi-regional natural gas distribution model of China, and optimized gas flow and infrastructure deployment by minimizing the total supply cost.

However, previous studies focus less on the impact of uncertainty in natural gas supply system optimization planning. In recent years, international turmoil led to huge fluctuations in natural gas import. There also have uncertainties about pipeline aging and natural gas demand in a natural gas supply system, which need to be considered in planning.

In this study, a chance-constrained programming approach to optimal planning of a natural gas supply system is established. It can consider the natural gas infrastructure condition of a developing region, as well as using chance-constrained programming (Charnes and Cooper, 1959) to consider the uncertainty of import volatility, aging pipelines and natural gas demand. Under the optimization goal of minimum transition cost, the optimal planning of low-carbon transition of a natural gas supply system is given. In addition, this study also quantitatively analyses the cost increase caused by considering the degree of uncertainty, so as to provide reference for policy makers.

The structure of this paper is as follows. Section 2 introduces the methodology, section 3 introduces the case study and its results, and section 4 is the conclusion.

## 2. Methodology

Regional natural gas supply system optimization model is used to quantitatively optimize the natural gas supply system transition path with the consideration of uncertainty. Input parameters include the information of existing natural gas infrastructure, monthly natural gas demand, upper limit of infrastructure construction ability, and infrastructure investment price. Decision variables of model are used to describe the capacity size and construction location of liquefied natural gas (LNG) ports, natural gas storage system and natural gas pipeline as well as how they change from year to year. The structure of the model is shown in Figure 1.

Figure 1. The structure of regional natural gas supply system optimization model

### 2.1. Mathematical formulation

In Regional natural gas supply system optimization model, the core is to meet the supply of natural gas. In each region and in each month, total supply equals total demand. Total

supply comprises of domestic production, net import, net transmission from other regions and net storage reduction, as shown in Eq. (1).

$$qua_{dem,r,t,m} = qua_{pro,r,t,m} + qua_{sto,r,t,m} + qua_{imp,r,t,m} + qua_{tra,r,t,m} \quad (1)$$

Domestic production and net import make up total natural gas supply. Natural gas import is constrained by import capacity as shown in Eq. (2). Natural gas can only be transmitted between two adjacent regions, and the transmission quantity cannot exceed the upper bound constrained by infrastructure, as shown in Eq. (3). A binary variable  $y_{r,rr}$  is introduced to represent geographic constraints, where  $y_{r,rr}$  equals to zero representing two regions are not adjacent. Natural gas storage is constrained with capacity and period, where storage quantity cannot exceed its maximum capacity as shown in Eq. (4), and ending stock of this period equals the beginning of the next period, as shown in Eq. (5).

$$qua_{imp,r,t,m} \leq capa_{imp,r,t}/12 \quad (2)$$

$$qua_{tra,r,rr,t,m} \leq capa_{tra,r,rr,t} \times y_{r,rr}/12 \quad (3)$$

$$qua_{sto0,r,t,m} \leq capa_{sto,r,t} \quad (4)$$

$$qua_{sto0,r,t,m} = qua_{sto1,r,t,m-1} \quad (5)$$

Along with the increase of the natural gas demand, more pipelines, LNG ports and storage facilities would be constructed. Expansions of natural gas storage facilities are continuous design variables, whilst expansions of pipelines and ports are discontinuous variables. The new capacity is an integer multiple of the standard capacity, as shown in Eqs. (6~7). Annual capacities of them are calculated by Eq. (8).

$$inc_{imp,r,t} = int_{imp,r,t} \times std_{imp,r,t} \leq 3 \times 41.4 \quad (6)$$

$$inc_{tra,r,t} = int_{tra,r,t} \times std_{tra,r,t} \leq 5 \times 300 \quad (7)$$

$$capa_{i,r,t} = capa_{i,r,t-1} + inc_{i,r,t} - dec_{i,r,t} \quad (8)$$

A chance-constrained programming method is established to consider the uncertainty of import fluctuation, pipeline aging and natural gas demand. At the time of natural supply, the actual values of import, pipeline capacity and natural gas demand can be seen as the sum of the predicted value and random fluctuation, as shown in Eq. (9).

$$\begin{cases} qua_{imp,t,m} = qua_{imp0,t,m} + \delta_{imp,t,m} \\ capa_{tra,t,m} = capa_{tra0,t,m} + \delta_{tra,t,m} \\ qua_{dem,t,m} = qua_{dem0,t,m} + \delta_{dem,t,m} \end{cases} \quad (9)$$

Considering chance-constraint, Eq. (1) can be expressed as a probabilistic constraint. In Eq. (10),  $\alpha$  is the confidence level, which shows the extent of considering uncertainty.

$$\Pr \{ qua_{pro,r,t,m} + qua_{imp,r,t,m} + qua_{tra,r,t,m} + qua_{sto,r,t,m} - qua_{dem,r,t,m} \geq 0 \} \geq \alpha \quad (10)$$

This study assumes these variables with uncertainty follow a normal distribution, Eq. (10) can be converted into Eq. (11).

$$qua_{pro,r,t,m} + qua_{sto,r,t,m} \geq \mu qua_{imp,r,t,m} + \mu qua_{tra,r,t,m} - \mu qua_{dem,r,t,m} + z_\alpha \times \sqrt{\sigma_{imp,r,t,m}^2 + \sigma_{tra,r,t,m}^2 + \sigma_{dem,r,t,m}^2} \quad (11)$$

The objective function of regional natural gas supply system optimization model describes the total cost of transition path, including the cost of infrastructure investment as well as import, gasification, transportation and storage of natural gas, as shown in Eq. (12).

$$cost_t = cost_{inv,t} + cost_{imp,t} + cost_{ify,t} + cost_{tra,t} + cost_{sto,t} \tag{12}$$

The mixed integer nonlinear programming optimization problem is implemented in General Algebraic Modelling System (GAMS).

### 3. Case Study

China is the largest developing country in the world. It aims to peak carbon emissions by 2030, and strive to achieve carbon neutral goal by 2060. In this study, China is taken as a case. The above approach is used to optimize the transition path of natural gas supply system of China. At the same time, the impact of consideration and non-consideration of uncertainty on planning is compared. Finally, Sensitivity of confidence level is analyzed. This model takes 2020 as base year and the transition path is optimized until 2060.

#### 3.1. Supply structure of natural gas

Figure 2 shows the changes in natural gas supply structure of China. For China, its natural gas supply will mainly rely on imports until 2050, which proportion will exceed 40% by 2050. Natural gas is mainly supplied from Central Asia import and oversea import with other import methods also account for a proportion. Multi-source imports improve energy security.

Figure 2 Natural gas supply structure of China

#### 3.2. Comparing results between considering and non-considering uncertainty

The confidence level used in the scenario of considering uncertainty is 99%. In both scenarios of considering and not considering uncertainty, the capacity of LNG ports will peak in 2040. However, after considering uncertainty, an additional 40.75% of LNG ports capacity need to be installed per year on average. Figure 3 shows the distribution of LNG ports in 2040 and 2060 with consideration of uncertainty. LNG ports will mainly be built in Shandong, Zhejiang and Guangdong. The first two will also remain the main provinces importing natural gas in 2060.

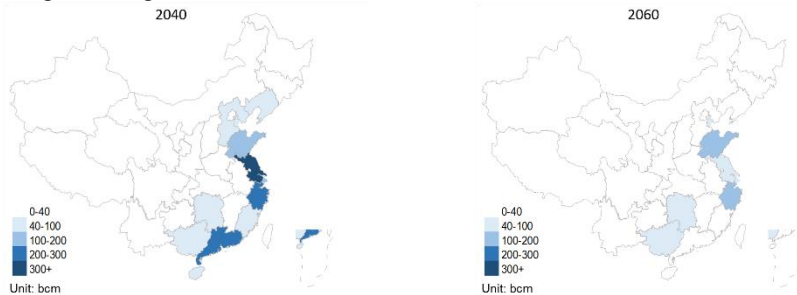

Figure 3 Distribution of LNG ports of China considering uncertainty

For nature gas storage facilities, its capacity will peak in 2040 in both scenarios. There is an additional 25.59% of storage facilities need to be installed per year on average after considering uncertainty, the distributions of which in 2040 and 2060 are shown in Figure 4. Natural gas storage is mainly built in Xinjiang, Heilongjiang and Shaanxi.

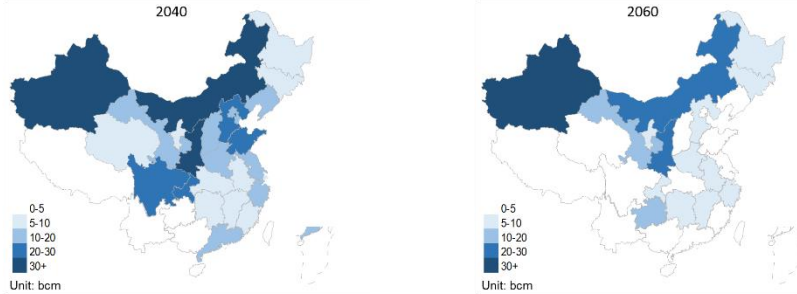

Figure 4 Distribution of storage facilities of China considering uncertainty

For natural gas networks, considering uncertainty hardly changes the total capacity of the network, but makes the capacity of each pipeline more uniform. Figure 5 shows the distribution of natural gas pipeline networks in 2040 under both scenarios. The orange lines represent the main pipelines with an annual transmission capacity of more than 100bcm, which is less than 100bcm in the grey lines. It shows that the distribution of the main pipe network is wider after considering the uncertainty.

Figure 5 Distribution of pipeline of China in 2040

### 3.3. Sensitivity Analysis

When considering uncertainty, different confidence levels may lead to different energy system optimization results. The results of sensitivity analysis are shown in Figure 6. when the confidence level is 90 % ~ 99 %, considering the uncertainty will not bring great changes to the natural gas supply system structure and transition cost. When the confidence level is higher than 99.9 %, the impact of capacity of LNG ports and the cost of transition begin to show an exponential rise. The results can provide a reference for policy makers to build what size of natural gas infrastructure in response to the uncertainty while taking the cost of transition into account.

Figure 6 Sensitivity analysis of confidence levels

#### 4. Conclusions

This study proposes a regional natural gas supply system optimization model, which can be used to quantitatively analyze the optimal transition path for a natural gas supply system with minimum transition costs. A chance-constrained programming approach is adopted to consider the impact of uncertainty of import fluctuation, pipeline aging and natural gas demand. Finally, sensitivity analysis of confidence level is carried out to show the impacts of it on the capacity planning of natural gas infrastructure as well as the transition costs.

The results show that increasing capacity of LNG ports and natural gas facilities can enhance the ability to cope with uncertainty. With consideration of uncertainty, under confidence level as 99 %, an additional 40.75 % of LNG ports capacity and an additional 25.59 % of gas storage capacity need to be installed per year on average. In addition, Sensitivity analysis of confidence level shows that rapid growth in transition cost occurs when the confidence level exceeds 99.9 %, which provides a reference for decision makers to make energy system planning while weighing transition costs against natural gas supply stability.

For future research, more uncertainties can be taken into account, such as price uncertainty. In addition, the coupling research of natural gas system and hydrogen system is meaningful. Natural gas is a transition period energy, and hydrogen will be promising in the future. Researching on the coupling of them that natural gas infrastructure can be converted into hydrogen infrastructure can reduce investment costs.

## Abstract

Hot melt extrusion (HME) involves the melting of materials and mixing and pushing of various solids under elevated temperature and pressure. It is a mature technology that has been extensively used for a broad spectrum of applications in the polymers, food, and pharmaceutical industries. HME can be a promising downstream processing method due to its high efficiency and economic value, however mathematical modelling of HME processes has always been challenging due to the limited understanding and the demanding experimental techniques. In this work, an 1D model is developed for the efficient simulation of the steady state and dynamic operation of HME processes. It is shown that the steady state operation can be described as a classical complementarity problem. The solution of the resulting complementarity problem can be performed efficiently in available software. The determination of the consistent initial conditions facilitates the solution of the system of differential and algebraic equations (DAEs).

**Keywords:** Hot melt extrusion, Pharmaceutical industry, Simulation, Complementarity problem.

## 1. Introduction

HME is a mature technology, that has been used extensively in the polymers industry, and involves the melting of materials and/or mixing and pushing of various solids under elevated temperature and pressure. There has been an active interest in extending the application of HME technology in the polymers, food, and pharmaceutical industry (Crowley et al., 2007). Mathematical modelling of HME processes has always been challenging due to the limited understanding of the material behavior, its complex geometry, the complex interactions between the material processed and the equipment, the existence of multiple zones (solids zone and melt zone) and the demanding experimental techniques necessary to validate theoretical models.

There has been extensive research in developing efficient mathematical models which can be used for process synthesis. Most of the existing modelling approaches have been reviewed recently (Grimard et al., 2016; Kohlgruber, 2020). The objective of this study is to propose a novel approach to the solution of 1D models for HME processes. The proposed methodology is based on transforming the algebraic model that describes the steady state operation using material, energy, and momentum balances as well as logical conditions, into an equivalent complementarity problem (a problem that has been extensively studied in the mathematical programming literature). The proposed novel approach is proven to be computationally efficient and is extended into the dynamic model of the HME process.

## 2. 1-D model of the HME process

### 2.1. Steady state model

Figure 1 shows the general pressure-throughput relationship for extruders that is discussed extensively by Kohlgrüber (2020). The following model is proposed for creeping flows of Newtonian fluids:

$$\dot{V}^* = \dot{V}_{max}^* - \frac{\dot{V}_{max}^*}{\Delta\dot{p}_{max}^*} \Delta p^* \quad (2.1)$$

where the dimensionless pressure drop  $\Delta p^*$  and flowrate  $\dot{V}^*$  are defined as follows:

$$\Delta p^* = \frac{D}{\eta \mathcal{N}} \cdot \frac{\Delta p}{\Delta z}, \quad \dot{V}^* = \frac{\dot{V}}{\mathcal{N} \cdot D^3} \quad (2.2)$$

where  $D$  is the diameter of the barrel,  $\eta$  is the viscosity,  $\mathcal{N}$  is the rotational frequency,  $\Delta p$  is the pressure drop observed in an element with axial length  $\Delta z$  and  $\dot{V}$  is the volumetric flowrate. After substituting Equations (2.2) into Equation (2.1) we obtain:

$$\dot{m} = m_{fb} + m_p = \dot{V}_{max}^* \cdot \rho (\mathcal{N} \cdot D^3) - \frac{\dot{V}_{max}^*}{\Delta\dot{p}_{max}^*} D^4 \frac{\rho}{\eta} \cdot \frac{\Delta p}{\Delta z} \quad (2.3)$$

where  $\rho$  is the density,  $m_{fb}$  denotes the mass flowrate for forward ( $m_f$ ) or backward ( $m_b$ ) moving elements and  $m_p$  the pressure induced mass flowrate. Equation (2.3) holds true for completely filled elements. For partially filled elements with filling ratio  $f$ :

$$\dot{m} = m_{fb} + m_p \quad (2.4)$$

$$m_{fb} = \dot{V}_{max}^* \cdot f \cdot \rho (\mathcal{N} \cdot D^3) \quad (2.5)$$

$$m_p = - \frac{\dot{V}_{max}^*}{\Delta\dot{p}_{max}^*} D^4 \frac{\rho}{\eta} \cdot \frac{dp}{dz} \quad (2.6)$$

In order to develop a mathematical description of the twin-extruder, the extruder is divided into  $i=\{1, 2, \dots, n\}$  discrete elements and material balances are applied in each element. The discrete representation of the solution space is shown in Figure 2. A material balance can be written for each discrete element as follows:

$$m_f(i-1) + m_b(i+1) + m_p(i-1) = m_f(i) + m_b(i) + m_p(i) \quad (2.7)$$

$$m_{fb}(i) = \dot{V}_{max}^*(i) \cdot (1 - \varepsilon(i)) \cdot \rho(i) \cdot (\mathcal{N} \cdot D^3) \quad (2.8)$$

$$m_p(i) = - \frac{\dot{V}_{max}^*(i)}{\Delta\dot{p}_{max}^*(i)} D^4 \frac{\rho(i)}{\eta(i)} \cdot \left( \frac{p(i+1) - p(i)}{z(i+1) - z(i)} \right) \quad (2.9)$$

where we have introduced the void fraction  $\varepsilon(i) = 1 - f(i)$ . The pressure-induced mass flowrate implied by Equation (2.9) involves a conditional statement: pressure buildup or pressure generation can only be developed in completely filled elements ( $f=1$  or  $\varepsilon=0 \Rightarrow p(i)>0$ ). For partially filled elements the pressure is equal to zero ( $f<1$  or  $\varepsilon>0 \Rightarrow p(i)=0$ , apparently the pressure is defined relative to the atmospheric pressure).

Equation (2.7), using Equations (2.8) and (2.9), can be written at steady state in the following form where the unknowns ( $\varepsilon(i)$ ,  $p(i)$ ) appear linearly:

$$\mathbf{A}(\dot{V}_{max}^*(i), \Delta\dot{p}_{max}^*(i), D, \mathcal{N}; \rho, \eta) \cdot \mathbf{x} = \mathbf{b}(\dot{V}_{max}^*(i), D, \mathcal{N}; \rho) \quad (2.10)$$

$$\mathbf{x} = \begin{bmatrix} \boldsymbol{\varepsilon} \\ \mathbf{p} \end{bmatrix} = [\varepsilon(1) \quad \varepsilon(2) \quad \dots \quad \varepsilon(n) \quad p(1) \quad p(2) \quad \dots \quad p(n)]^T \quad (2.11)$$

Figure 1. Pressure versus volumetric flowrate for a typical extruder element.

Figure 2. Building block of the 1D model for a twin-screw extruder.

For constant thermophysical properties ( $\rho, \eta$ ) and given flow characteristic and operating parameters ( $\dot{V}_{max}^*(i), \Delta p_{max}^*(i), D, \mathcal{N}$ ), Equation (2.10) is a linear underdetermined system of  $n$  equations in  $2n$  unknowns (see also Choulak et al., 2004 and Eitzlmayr et al., 2014). The system of linear equations can be solved by adding  $n$  specifications to the mathematical description. This has been done in previous studies by first establishing the state of each element (partially filled/completely filled) and then calculating the resulting pressure profile. Numerical problems have been reported in previous studies which have been attributed to inefficiencies of the commercial software used. A systematic methodology is presented in what follows that does not suffer from methodological or numerical issues and allows solution of the problem using arbitrarily fine discretization of the solution space.

The important observation towards developing an efficient methodology for the steady state simulation of extruders is that, apart from the system of  $n$  underdetermined Equations (2.10), there is for each element  $i$  an additional logical condition that needs to be satisfied. This condition can be stated as: either the element is partially filled and the pressure is zero or the element is completely filled, and the void fraction is zero. This can be expressed mathematically as follows:

$$\varepsilon(i) \cdot p(i) = 0, i = 1, 2, \dots, n \quad (2.12)$$

this is a set of  $n$  additional nonlinear equations. When Equation (2.12) is written together with Equation (2.10), then the system of  $n$  equations in  $n$  unknowns is obtained:

$$\mathbf{A} \cdot \begin{bmatrix} \boldsymbol{\varepsilon} \\ \mathbf{p} \end{bmatrix} = \mathbf{b}, \quad \boldsymbol{\varepsilon}^T \cdot \mathbf{p} = \mathbf{0}, \quad \mathbf{0} \leq \boldsymbol{\varepsilon} \leq \mathbf{1}_n, \quad \mathbf{0} \leq \mathbf{p} \leq \mathbf{1}_n P_{max} \quad (2.13)$$

Formulation (2.13) is well known in the mathematical programming literature as the linear complementarity problem (LCP), for which efficient solution methodologies are now available (Kookos, 2022, Cottle, 1992). One of the alternative methodologies can be based on the definition of binary variables  $\delta(i)$ :

$$\delta(i) = \begin{cases} 1, & \text{if } \varepsilon(i) = 0 \\ 0, & \text{if } p(i) = 0 \end{cases} \quad i = 1, 2, \dots, n \quad (2.14)$$

Using the definition (2.14) the LCP problem can be postulated as a mixed-integer, linear programming problem (MILP):

$$\begin{aligned} \min_{\boldsymbol{\varepsilon}, \mathbf{p}, \boldsymbol{\delta}} \quad & \mathbf{1}_n^T \boldsymbol{\delta} \\ \text{s. t.} \quad & \end{aligned} \quad (2.15)$$

$$\mathbf{A} \cdot \begin{bmatrix} \boldsymbol{\varepsilon} \\ \mathbf{p} \end{bmatrix} = \mathbf{b}, \quad \mathbf{0} \leq \boldsymbol{\varepsilon} \leq \mathbf{1}_n - \boldsymbol{\delta}, \quad \mathbf{0} \leq \mathbf{p} \leq \boldsymbol{\delta} \cdot P_{max}, \quad \boldsymbol{\delta} \in \{0, 1\}^n$$

## 2.2. Dynamic model of an extruder

The dynamic model of an extruder consists of the dynamic material balances:

$$\frac{dM(i)}{dt} = m_f(i-1) + m_b(i+1) + m_p(i-1) - (m_f(i) + m_b(i) + m_p(i)) \quad (2.16)$$

$$\begin{aligned} \frac{dm(i)}{dt} = & (m_f(i-1) + m_p(i-1)) \cdot \omega(i-1) - (m_f(i) + m_b(i) + m_p(i)) \cdot \omega(i) \\ & + m_b(i+1) \cdot \omega(i+1) \end{aligned} \quad (2.17)$$

where  $M(i) = \rho(i) A_{cr} \delta z f(i)$  is the total mass holdup in element  $i$ ,  $m(i) = M(i)\omega(i)$  is the mass holdup of component in element  $i$ ,  $\omega(i)$  is the mass fraction of the component of interest,  $A_{cr}$  is the cross-sectional area available for materials flow and  $\delta z$  the axial length of the discrete element. The dynamic model also includes the algebraic equations (2.8) and (2.9). There are as many differential equations as differential variables but there are  $n$  more algebraic variables than algebraic equations. To avoid using the complementarity constraint in the Differential-Algebraic Equations (DAE) model, that will give rise to a high index problem, we are assuming that the pressure dynamics is significantly faster than the flow dynamics. If the solution of the DAE model is available at time  $t$ , then the filling ratio is known, and the pressure profile can be established. With the pressure profile known the DAE model can be solved and obtain the dynamics of the material flow through the extruder. In this way the DAE model is, in effect, simplified to an ordinary differential equation (ODE) model.

## 3. Case study and discussion

We consider the twin-screw extruder studied experimentally by Puaux et al., (2000) (screw configuration B) and theoretically by Eitzlmayr et al., (2014). The experimental extruder is a twin-screw, corotating extruder with a centerline distance of  $C_L=0.021$  m, an external screw diameter of  $D=0.025$  m and a screw core diameter of  $D_C=0.016$  m. The extruder consists of seven screw type elements arranged in series with lengths (from hopper to die) 50/50/100/50/150/200/300 mm and pitches ( $T_S$ ) 16/25/33/25/16/25/33 mm. All elements are right-handed elements (forward pushing and/or pressure generating elements) apart from the fourth one which is left-handed (backward pushing or pressure

consuming element). Several combinations of operating conditions with mass flowrates in the range  $\dot{m}_0 \in [3.8 \text{ kg/h}, 10.8 \text{ kg/h}]$  and screw speeds of  $\mathcal{N} \in [200 \text{ rpm}, 500 \text{ rpm}]$  are considered in the experimental equipment and the results of residence time distribution determination experiments are presented in Puaux et al., (2000). The parameters of the pressure/volumetric flowrate characteristics ( $\dot{V}_{max}^*$ ,  $\Delta p_{max}^*$ ) of the various screw elements need to be estimated. For the maximum dimensionless volumetric flowrate Kohlgrüber (2020) proposes that  $\dot{V}_{max}^* = T_s/2D$ . Parameter  $\Delta p_{max}^*$ , which needs to be determined experimentally, was assumed to be equal to 2000, a value that appears to be reasonable for the screw diameter and pitch of the elements in the experimental extruder (according to experimental curves reported by Kohlgrüber (2020)).

The LCP formulation (2.15) is solved first for the case of  $\mathcal{N} = 400 \text{ rpm}$  and  $\dot{m}_0 = 6.5 \text{ kg/h}$  using CPLEX/GAMS with an increasing number of discretization elements. The overall length of the extruder is 900 mm and 90, 900, 9000 and 90000 discrete elements are selected corresponding to discrete element lengths of 10 mm, 1 mm, 0.1 mm, and 0.01 mm, correspondingly. In Figure 3.a the profile for the filling ratio for 90 and 90000 discrete elements, are presented and compared (the results for 900 and 9000 discrete elements coincide with that of the 90000 elements). The necessary computational time was 0.07 s for the 90 elements and 20.1 s for the 90000 elements (Intel(R) Core(TM) i5-7200U CPU @ 2.50GHz, 6GB memory computer). The computational time is found to scale with  $n^2$  for the intermediate discretizations. As the formulation as an LCP problem was proven to be extremely efficient, we were able to solve repeatedly the formulation by varying parameters such as the feed mass flowrate or the speed of rotation. In Figure 3.b the results obtained by varying systematically the mass flowrate of the feed for a constant speed of rotation is shown. Similar plots can be obtained by varying the speed of rotation for a constant mass flowrate of the feed stream.

To demonstrate the ability of the proposed formulation to predict the dynamic response of the experimental extruder, the dynamic model was solved for a unit pulse experiment in MATLAB using the ode15s DAE solver (the pressure dynamics is assumed faster than the flow dynamics). The volume of each element of the discrete formulation was determined based on the geometry, by calculating the cross-sectional area based on the work by Booy (1980). The experimental results are compared with the simulation results in Figure 4. The agreement is more than satisfactory and proves that the proposed formulation is sufficient for simulating the dynamics of complex twin-screw extruders.

#### 4. Summary and Conclusions

Preliminary results on a novel approach for solving the steady state and dynamic model for complex twin-screw extruders has been presented and validated with experimental results. The proposed formulation that is based on the linear complementarity problem has been proven to be a powerful approach for solving the steady state determination problem in twin-screw extruders. The model, at its present form, has been developed for constant thermophysical properties that are independent from pressure and temperature (density and viscosity). The model needs to be extended to incorporate the temperature dynamics that involves the energy balance for the material, barrel, and screw. It also involves the use of constitutive equations for the density and viscosity to link material flow dynamics with energy dynamics. The preliminary results are promising enough to guarantee that further investigation will improve the predictive capabilities of the model and will allow us to obtain a better and more detailed understanding of the complex and multiscale dynamics of twin-screw extruders. Finally, discrete element simulations can

be used to determine the characteristic parameters of the pressure/throughput curve so as to reduce our reliance on experimental results for developing high fidelity models.

## Abstract

Many dynamic models in process engineering rely on uncertain or even largely unknown mechanism. These parts are often modeled using best-practice knowledge or heuristics, which may result in 1) overly complex models, 2) models which do not reproduce the expected predictive outcome or 3) ill posed optimization problems. A promising approach is the use of machine learning surrogate models inside a partially known mechanistic model. In this study the impact of measurement noise and sample rate on the predictive performance of such a hybrid model is investigated. As an example, process methanol synthesis is used. Additionally, it is shown that the surrogate model can learn even unobservable states from the data.

**Keywords:** Scientific Machine Learning, Methanol Synthesis, Automated Modeling, System Identification

## 1. Introduction

Methanol is an important basic chemical. In the frame of the upcoming energy revolution, power-2-methanol processes become an interesting option for methanol production. These processes rely on green hydrogen, which is produced from regenerative electrical energy by water electrolysis and are therefore usually operated under dynamic conditions due to inevitable fluctuations in the regenerative energy supply. One approach is to generate methanol through the hydrogenation of CO and CO<sub>2</sub> (Olah et al., 2009). Although methanol synthesis is a commonly employed process, its kinetic modeling is still a field of ongoing research. The influence of the dynamic catalyst state on the reaction rates is an important part of the model, which is, however, hard to model from first principles. A promising approach to overcome this challenge is to replace this sub-model with an artificial neural network (ANN) and combine it with the remaining first principle model to obtain a hybrid model. It is not clear a priori how much data is required to successfully train the resulting model. This study investigates the influence of data quality on such a data-driven model. Artificial datasets of reactor output trajectories with

different measurement frequencies and amounts of added noise are generated from a rigorous model (Seidel et. al., 2018, 2021). A hybrid model is then derived by replacing the sub-model that describes the influence of the catalyst state on the reaction rates with an ANN. Hyperparameter optimization of different surrogate architectures, objectives, and penalty functions is conducted, and the best-performing model structure is identified. The hybrid model is trained on the different datasets and the results are evaluated by comparing the state trajectories with those of the rigorous model. Additionally, the trained ANNs are compared with the original sub-model to evaluate the ability to reconstruct the original sub-model behaviour from the different synthetic datasets. The contributions of this analysis are twofold: First, it leads to a better understanding of the necessary data quality for training hybrid models of heterogeneously catalysed methanol synthesis. Second, it generates insights into the parsimony of available rigorous models depending on the operating conditions.

## 2. Materials and Methods

The overall dynamics of the continuous stirred tank reactor (CSTR) for methanol synthesis can be described as a system of differential algebraic equations (DAE) of the form (Seidel et. al., 2018, 2021)

$$\begin{aligned} f(\dot{x}, x, p, t, u, c) &= 0 \\ h(x, p, t, u, c) &= y \end{aligned} \quad (1)$$

where  $x \in \mathbb{R}^{n_x}$  denotes the states of the system and  $\dot{x} \in \mathbb{R}^{n_x}$  its time derivative subject to the set of DAE given by  $f$ . The states of the system consist of the mole fractions of the individual species  $x_i \in (0,1)$  with the additional constraint  $\sum_i x_i = 1$ ,  $i \in (\text{CH}_3\text{OH}, \text{CO}_2, \text{CO}, \text{H}_2, \text{H}_2\text{O}, \text{N}_2)$  and the percentage of reduced centres of the catalyst  $x_\phi \in (0,1)$  (Seidel et. al., 2018).  $p \in \mathbb{R}^{n_p}$  is a vector of parameters,  $t \in \mathbb{R}$  the time,  $u \in \mathbb{R}^{n_u}$  the external inputs to the system, representing an incoming feed of species and a specific volumetric flow rate. The function  $h$  maps the states onto the observed variables  $y \in \mathbb{R}^{n_y}$ . The constant operating conditions  $c = (T, P)$  collect the information about temperature and pressure  $T \in \mathbb{R}$  and  $P \in \mathbb{R}^+$ , respectively. Three reaction pathways are used to describe the synthesis of methanol from CO, CO<sub>2</sub>, and H<sub>2</sub> over CuO/ ZnO/ Al<sub>2</sub>O<sub>3</sub> (unreduced state):

where the first two reactions describe the methanol synthesis via hydrogenation and the last reaction is the reverse water-gas shift reaction (RWGS). The dynamical system following from [Eq. \(2\)](#) is still not fully understood. Especially the influence of the catalyst

on the reaction rate is not clear. Following (Seidel et. al., 2018, 2021) a scaled reaction rate is used to take this effect into account:

$$\bar{r} = [\gamma_{CO} r_{CO} \quad \gamma_{CO_2} r_{CO_2} \quad \gamma_{RWGS} r_{RWGS}]^T \quad (2)$$

where  $\bar{r}_i \in \mathbb{R}$  represents the effective reaction rate of the reaction  $i \in$  as the product of the influence of the catalyst  $\gamma_i \in \mathbb{R}^+$  and the reaction rates based upon a Langmuir–Hinshelwood mechanism  $r_i \in \mathbb{R}$ .

The influence of the catalyst state on the effective reaction rates is of special interest, given that it is a challenging reaction over a distributed parameter space. The current implementation assumes a dependence on the catalyst state and is modeled based on practical heuristics rather known first principles

$$\gamma = \left[ 1 - x_\phi \quad x_\phi^2 \quad \frac{x_\phi}{1 - x_\phi} \right]^T \quad (4)$$

Within our study an existing model of an isochoric, isobaric, isothermal CSTR for methanol synthesis is used, which is based on the dynamics of a steady-state experiment. Its goal is to investigate the influence of data quality and sample distance on the approximative performance of an embedded ANN. While the idea of using ANNs itself is not new, see e.g., (Ljung et. al., 2020), data-driven inference of dynamical systems has gained much attention during the past decade, e.g., extracting (physical) signals (Cranmer et. al., 2020), operator learning (Kovachki et. al., 2021), and approximating solutions to PDE, ODE and DAE systems (Raissi et. al., 2021).

The rigorous model (Seidel et. al., 2018, 2021) has been implemented using Julia (Benzanson et. al., 2015). To assess the use of ANN as a tool to extract and learn unknown parts of our process model, the approach described in (Rackauckas et. al., 2021) is followed. Here, an ANN is embedded inside the known model, effectively extending the previously introduced model with a universal approximator  $\hat{\gamma} : \mathbb{R}^{n_x} \times \mathbb{R}^{n_\theta} \mapsto \mathbb{R}^3$  containing trainable parameter  $\theta \in \mathbb{R}^{n_\theta}$ . The hybrid model takes the form

$$\begin{aligned} \hat{f}(\dot{x}, x, p, t, u, c, \hat{\gamma}(x, \theta)) &= 0 \\ h(x, p, t, u, c) &= \hat{y} \end{aligned} \quad (3)$$

where  $\hat{f}$  denotes the known parts of the model in composition with the ANN  $\hat{\gamma}$  replacing  $\gamma$  within the effective reaction rates  $\tilde{r}$ .

### 3. Numerical Experiments

The fully known ground-truth model was used to generate a dataset  $\mathcal{D} = (d_1, \dots, d_{30})$  of 30 trajectories  $d_i = (X, t_X)$ . Here,  $X \in \mathbb{R}^{n_x \times n_m}$  denotes the collected state trajectory over  $m$  measurements in a matrix form and  $t_X \in \mathbb{R}^{n_m}$  the corresponding time points. The initial conditions of the different species mole fractions were sampled randomly from a uniform distribution and normalized. Additionally, the condition that  $x_{H_2} \in [0.35, 0.8]$  has been imposed by rejecting invalid samples. The initial conditions of the catalyst state  $x_\phi$  are sampled uniformly within the interval  $[0.2, 0.85]$ . The operating conditions are sampled from intervals  $[460.15, 490.15]$  K for the temperature and  $[55.0, 65.0]$  bar for the total pressure. Over all datasets, the incoming species and volumetric flow rate is kept constant. Using the forward solution of the underlying DAE system, dense solutions were created which can be subsampled. Each trajectory was simulated within the time interval  $t \in [0, 3000]$  s and a measurement sample rate  $t_M \in \mathbb{R}$  of 1 s. Synthetic noise has been added to each observable state<sup>1</sup>  $y = [x_{CH_3OH} \ x_{CO_2} \ x_{CO} \ x_{H_2} \ x_{H_2O} \ x_{N_2}]^T$  with a multiplicative error  $\tilde{y}_i = (1 + \epsilon_i)y_i$ . The error is sampled from a truncated normal distribution  $\epsilon_i \sim \mathcal{N}(0.0, \sigma_M)$ , such that  $\epsilon_i \in [-0.1, 0.1]$ . To investigate the impact of the noise, the variance  $\sigma_M \in \mathbb{R}^+$  is varied. To optimize the parameters  $\theta$  of the ANN under varying noise and sampling rates, a maximum likelihood approach is used

$$\min_{\theta, \sigma, \sigma_\theta} - \sum_{d \in \tilde{\mathcal{D}}} \ln \bar{\mathcal{L}}(d, \theta, \sigma, \sigma_\theta), \tilde{\mathcal{D}} \subseteq \mathcal{D}, s.t. \ \sigma_i \geq 0, i = 1, \dots, n_y \quad (4)$$

Here  $\bar{\mathcal{L}} : \mathbb{R}^{n_y \times n_m} \times \mathbb{R}^{n_\theta} \times \mathbb{R}^{n_y} \times \mathbb{R}^+ \mapsto \mathbb{R}^+$  denotes the likelihood function for the overall problem for a subset  $\tilde{\mathcal{D}}$  of the training data

$$\begin{aligned} \ln \bar{\mathcal{L}}(d, \theta, \sigma, \sigma_\theta) = & \overbrace{\sum_{(y_i, t_i) \in d} \ln \mathcal{L}_\Sigma(y_i, \hat{y}_i, \sigma)}^{\text{Data fitting}} + \overbrace{\sum_{\theta_i \in \theta} \ln \mathcal{L}_\theta(\theta_i, \sigma_\theta)}^{\text{Parameter penalty}} \\ & + \underbrace{\sum_{\sigma_i \in \sigma} \ln \mathcal{L}_\sigma(\sigma_i)}_{\text{Prior of the scales}} \end{aligned} \quad (7)$$

where the error distributions likelihood is given as  $\mathcal{L}_\Sigma : \mathbb{R}^{n_y} \times \mathbb{R}^{n_y} \times \mathbb{R}^{n_y} \mapsto \mathbb{R}^+$ .  $\mathcal{L}_\theta : \mathbb{R}^{n_\theta} \times \mathbb{R}^+ \mapsto [0, 1]$  represents a prior on the parameters of the ANN. The parameter  $\sigma_\theta \in \mathbb{R}^+$  represents the scaling of the prior distribution of the tuneable parameters  $\theta$ ,

<sup>1</sup> Strictly speaking  $x_{H_2O}$  is not observable. Given that  $\sum_i y_i = 1$ , we can compute it if all other mole fractions are known.

which may be interpreted as a parameter penalty to avoid overfitting<sup>2</sup>. As it is common,  $\sigma_\theta$  is introduced as a hyperparameter rather than a true optimization variable. Finally,  $\mathcal{L}_\sigma : \mathbb{R}^+ \mapsto [0,1]$  denotes a prior on the scale parameter of the error distribution  $\sigma \in \mathbb{R}^{n_y}$ , assuming  $\sigma_i \sim \text{Lognormal}(0,1)$ .

#### 4. Results

By common practice, hyperparameter optimization was performed to find a suitable architecture for the ANN, the right distribution for the prediction error, and for the prior distribution of the parameters  $\theta$  and their scale  $\sigma_\theta$ . Furthermore, it is assumed that all initial conditions are known, given that only the fitting capabilities of the ANN are investigated. The activation of the output layer has been fixed to be softplus, enforcing positive definite scaling  $\hat{y}$ . Using a Monte Carlo approach, different candidate configuration are sampled and trained using [Eq. \(6\)](#) with ADAM (Kingma and Ba, 2014). As an evaluation metric the Bayesian Information Criterion (BIC) has been chosen. Hyperparameter optimization on the generated dataset was performed using a sample distance  $t_M = 30.0$  s and noise variance  $\sigma_M = 5e^{-2}$  with a train-test-split of 0.8. In addition, the training dataset has been batched to reduce training time while keeping a relatively good performance. In total, 300 samples were evaluated. The best architecture consists of the input layer with  $n_x$  neurons followed by a single hidden layer with 2 neurons, both using a selu activation. The error and prior distribution have been chosen to be Laplacian distributed. [Figure 1](#) shows the result of the hyperparameter optimization for trajectories from both train and test set. Since the ground truth [Eq. \(4\)](#) is known, we can directly compare the learned model. A statistical evaluation of the approximation error for the data can be seen in [Table 1](#), a plot of the approximation of the missing equations can be seen in [Figure 2 \(A\)](#). The ANN learns the scaling for the hydrogenation pathways over CO<sub>2</sub> close to ideal but fails generalize on CO and RWGS. This is in good agreement with available a priori knowledge that for the conditions employed here, RWGS is close to chemical equilibrium and CO<sub>2</sub> is the dominating path for methanol synthesis.

---

<sup>2</sup> E.g., for a normal distributed variable  $x$  with mean  $\mu$  and variance  $\sigma$  we can write the loglikelihood (up to a constant) as  $-\frac{1}{2\sigma^2}(x - \mu)^2 = -\lambda(x - \mu)^2$  which can be thought of as a L<sub>2</sub> penalty with a penalty parameter  $\lambda = \frac{1}{2\sigma^2}$ .

Figure 1 Example trajectories from train and test set. The trained ANNs prediction (full line) from the noisy data (scattered) match the ground truth trajectory of the unobserved state (dashed black).

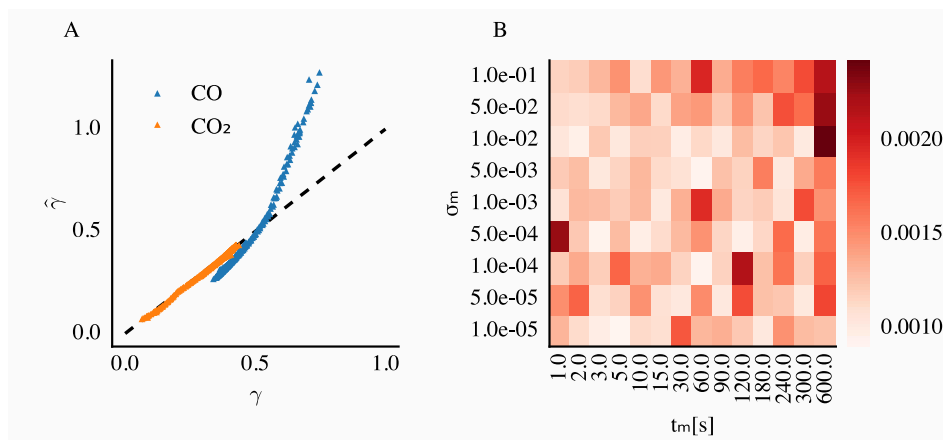

Figure 2 (A) Parity of the ground truth and approximation of the scaling of the hydrogenation pathways evaluated on the test set. RWGS is not shown. (B) Minimum  $L_1$  norm error of the unknown state over varying noise levels and sampling distances evaluated on the test set using the minimum sample distance.

Table 1 : Summary of the  $L_1$  error between the ground truth and approximation of the scaling  $\gamma$

	Train set				Test set			
	Min	Max	Mean	Std.	Min	Max	Mean	Std.
CO - Hydrogenation	1.3e-4	7.2e-1	7.9e-2	7.0e-2	6.8e-4	5.3e-1	8.0e-2	6.8e-2
CO <sub>2</sub> - Hydrogenation	8.5e-7	1.5e-1	5.0e-3	6.3e-3	5.1e-5	2.5e-1	5.5e-3	3.8e-3
RWGS	3.0e-4	2.0e0	7.9e-2	8.0e-2	4.4e-3	1.8e-1	7.4e-2	4.1e-2

For the optimal architecture, the sample distance and noise variance are varied to study the impact of the data quality on the predictive performance. For each pair  $(\sigma_M, t_M)$  the optimal structure is retrained five times and evaluated on the ground truth data with no noise and fully observable measurements. [Figure 2 \(B\)](#) shows the results of the noise

variance study. Overall, the ANN performs well with an overall median error 0.0017 on the test set. Only high noise and high measurement rates perform bad.

## 5. Conclusion

It has been shown that an embedded ANN is able to learn missing components of a physics-based model efficiently using a loglikelihood driven approach. The influence of measurement noise and rate on the predictive performance of the ANN has been

investigated and the resulting model compared to the known ground truth, showing good performance over a wide range of measurement rates and noise levels for the state trajectories. Even if some components cannot be approximated sufficiently, a suitable output is achieved. Several promising future directions open for investigation, e.g., using (optimal) design of experiments, active learning approaches, and learning with additional constraints and unknown parameters like initial conditions. In addition, further testing of our approach on real data collected via an experimental setup will be conducted.

## Abstract

As the demand for food production increases, it is crucial to reassess current water management practices to improve and optimize water use. In this study, the potential of treated sewage effluent in replacing part of the conventional water resources in the agricultural sector is assessed using a mixed integer linear programming optimization model. The proposed model is applied to a case scenario in the state of Qatar, where water from different sources is allocated to four different agricultural subsectors to minimize the carbon footprint while limiting the water stress to a safe global average level which will improve the water productivity of the agricultural sector. Results demonstrate that the proposed model emits twice as much carbon footprint as compared to the base scenario; however, the water stress level is reduced from 323% to 25%, and the water productivity of the agricultural sector increases from  $0.0027 \text{ m}^3$  to  $0.036 \text{ m}^3$ .

**Keywords:** Treated Wastewater; Agriculture; Optimization; Water Productivity; Carbon Footprint.

## 1. Introduction

The global water demand has increased by 600% in the last century and it is now estimated at  $4,600 \text{ km}^3$  (Ritchie and Roser, 2018). With the ever-increasing population and living standards, the demand is expected to increase further by at least 20% in the next 30 years (Wada et al., 2016). While there are enough freshwater resources in the world to meet the global demand, the resources are not equally distributed which leads to water scarcity in some parts of the world. Heading the list of water-scarce regions is the middle east, where countries have been relying on different solutions to reduce water stress including desalination and wastewater reuse. The state of Qatar happens to be the most water-scarce country in the world. It has an annual renewable freshwater resources rate as low as  $21 \text{ m}^3 \cdot \text{capita}^{-1} \cdot \text{year}^{-1}$ ; nevertheless, it has one of the highest water consumption rates globally with over  $182 \text{ m}^3 \cdot \text{capita}^{-1} \cdot \text{year}^{-1}$  (Planning and Statistics Authority, 2019). Whether it is groundwater (GW) abstraction, desalination or wastewater reuse, Qatar must take a holistic approach to find the most suitable solutions. Given its status as one of the most water-scarce countries globally, Qatar must continue to prioritize policies and strategies aimed at reducing its reliance on finite freshwater. The two main direct consequences of the high-water usage in Qatar are the over-abstraction of GW resources and the heavy reliance on energy-intensive desalination to

meet the population's needs. The overuse of GW has resulted in an increase in well salinity to different levels across the country, especially near the shore, such that Reverse Osmosis (RO) is required to treat GW before its safe usage. The state of Qatar also produces a large amount of treated sewage effluent (TSE) of which only a small percentage is reused. That said, TSE represents an opportunity to alleviate the water scarcity in Qatar. Currently, around 50% of the produced TSE is reused and is directed for green space irrigation and fodder production (Planning and Statistics Authority, 2019). If public perception about TSE can be overcome, the reuse of TSE represents a promising solution for Qatar as it can reduce the energy consumed in desalination, reduce water stress and increase water productivity (Lahlou et al., 2022, 2021). That said, around 95 million m<sup>3</sup> of TSE is available and can be injected into the agricultural sector which heavily relies on GW resources. Introducing TSE in the rest of the agricultural subsectors would help reduce water stress and increase the level of water productivity.

This study suggests a water planning framework that aims to optimally allocate the available water resources in Qatar which consist of GW resources, desalinated water (DW) and TSE, to four agricultural sub-sectors which currently rely 100% on wells to meet their needs. The objectives are to do so at a reduced carbon footprint and water stress, for an enhanced water productivity. The developed model is generic and can be applied to other regions.

## 2. Methodology

### 2.1. Case Study

The agricultural subsectors considered in this study are dairy, red meat, egg and poultry production. The annual GDP from these subsectors is 1,86 million Qatari Ryal (Q.R.) (Planning and Statistics Authority, 2020). The water consumption of these sectors is estimated using the annual production information provided by the local authorities and the global average water required to produce the commodities (Mekonnen and Hoekstra, 2010). The water resources considered are GW, DW, and TSE. Groundwater resources have an annual safe yield of 57 million m<sup>3</sup>.year<sup>-1</sup> and have salinity levels ranging between 1000 mg.L<sup>-1</sup> up to 12000 mg.L<sup>-1</sup> based on the well distance from the shore (Baalousha and Ouda, 2017). It is assumed that the energy required for GW pumping is 0.84 kWh.m<sup>-3</sup> and for RO to get rid of the excess Total Dissolved Solids (TDS) level is between 2.6-5.5 kWh.m<sup>-3</sup>, and that the reject water rate ranges between 30-50% (Chen et al., 2019; Enikeeva and Khadra, 2020; Philippe, 2021). The DW is produced by 13 different plants across the country. The three technologies used are Multi-Stage Flash (MSF), Multi-Effect Distillation (MED) and RO. The least energy-intensive technology is RO as it requires as little as 5kWh.m<sup>-3</sup> as opposed to MSF and MED which require 21 kWh.m<sup>-3</sup> (Darwish et al., 2016). The wastewater treatment plants considered in this study are the six plants that receive and treat at least 1% of the total wastewater produced in the country. All six plants use tertiary treatment in addition to Nitrogen & Phosphorus removal (Planning and Statistics Authority, 2019). The supply of DW is carried out using pipeline distribution. As for TSE, two types of distribution are considered, pipeline and truck tankers. Pipeline water distribution requires 0.0055 Kwh.m<sup>-3</sup>.km<sup>-1</sup> (Tow et al., 2021). As for truck tankers distribution, it required an average of 0.4 kWh.km<sup>-1</sup> for every truck tanker with a capacity of 38 m<sup>3</sup> (Lahlou et al., 2020).

### 2.2. Problem Formulation

The objective of the model is to reduce the carbon footprint associated with the supply and treatment of the three water resources considered in this study and it is described in eq (1) while limiting the water stress level of the GW resources to a safe average of 25% which would enhance the water productivity of the agricultural sector. The water stress level and water productivity are calculated using eq (2) and (3).

$$CF_t = (e^p \sum_{i=1}^{i=4} \sum_{j=1}^{j=6} W_i \cdot x_{p-i,j}^{TSE} \cdot d_{p-i,j}^{TSE} + \sum_{i=1}^{i=4} e^{TSE} \cdot W_i \cdot \sum_{j=1}^{j=6} x_{p-i,j}^{TSE} + x_{r-i,j}^{TSE} + e^p \sum_{i=1}^{i=4} \sum_{j=1}^{j=13} W_i \cdot x_{p-i,j}^{DW} \cdot d_{p-i,j}^{DW} + \sum_{i=1}^{i=4} W_i \cdot \sum_{j=1}^{j=13} e_j^{DW} \cdot x_{p-i,j}^{DW} ) \cdot CF_u + e^{GWP} \sum_{i=1}^{i=15} W_i \cdot x_i^{GW} \cdot (1 + \frac{GW_{RO-i}^{\%} \cdot R_i^{\%}}{1-R_i^{\%}}) + \sum_{i=1}^{i=15} W_i \cdot e_i^{GWT} \cdot x_i^{GW} \cdot CF_u + (\sum_{i=1}^{i=4} \sum_{j=1}^{j=6} \text{ceil}(\frac{W_i \cdot x_{r-i,j}^{TSE}}{V_c}) \cdot e^r \cdot d_{r-i,j}^{TSE}) \cdot \frac{CF_d}{E_d} \quad (1)$$

$$WS = \frac{WWD_t}{WA_t - WWI} \quad (2)$$

$$WP = \frac{GDP}{WWD_t} \quad (3)$$

$$WWD_t = \sum_{i=1}^{i=15} W_i \cdot x_i^{GW} \cdot (1 + \frac{GW_{RO-i}^{\%} \cdot R_i^{\%}}{1-R_i^{\%}}) \quad (4)$$

Such that:

- $CF_t$  is the total carbon footprint which needs to be minimized [ton-CO<sub>2</sub>-eq.month<sup>-1</sup>],
- $x_{p-i,j}^{DW}$  is the percentage of the water requirement of sinks  $i$  that is sourced from the desalination plant  $j$  [%],
- $x_{p-i,j}^{TSE}$  represents the percentage of the water requirement of sink  $i$  that is sourced from WWTP  $j$  via pipeline [%],
- $x_{r-i,j}^{TSE}$  represents the percentage of the water requirement of sink  $i$  that is sourced from WWTP  $j$  via road [%],
- $d_{p-i,j}^{DW}$  pipeline distance between the desalination plant  $j$  and the sink  $i$  [km],
- $d_{p-i,j}^{TSE}$  &  $d_{r-i,j}^{TSE}$  distances between sink  $i$  and WWTP  $j$  via pipeline and via road respectively [km],
- $x_i^{GW}$  is the percentage of the water requirement of sink  $i$  that is extracted from GW [%],
- $CF_u$  is the carbon footprint of 1 kWh depending on the country energy mix [g-CO<sub>2</sub>-eq.kWh<sup>-1</sup>],
- $E_d$  is the Energy in 1 litre of diesel [kWh.L<sup>-1</sup>],
- $CF_d$  is the Carbon footprint associated with burning 1 litre of diesel [g-CO<sub>2</sub>-eq.L<sup>-1</sup>],
- $e^p$  is the energy required to transport 1 m<sup>3</sup> of water through 1 km via pipe [kWh.m<sup>3</sup>.km<sup>-1</sup>],
- $e^p$  is the energy required for truck-tanker to travel 1 km [kWh.km<sup>-1</sup>],
- $e^{TSE}$  is the energy required to treat 1 m<sup>3</sup> of TSE [kWh.m<sup>-3</sup>],
- $e^{DW}$  is the energy required to produce 1 m<sup>3</sup> of DW [kWh.m<sup>-3</sup>],
- $e^{GWP}$  is the energy required to pump 1 m<sup>3</sup> of GW [kWh.m<sup>-3</sup>],
- $R_i^{\%}$  is the % of rejected water as brine from the RO unit for sink  $i$  [%],
- $e_i^{GWT}$  is the energy required to produce 1 m<sup>3</sup> of freshwater from GW using RO in sink  $i$  [kWh.m<sup>-3</sup>],
- $GW_{pure-i}^{\%}$  is the percentage of untreated GW required with salinity level  $TDS_{in-i}$  [%],
- $GW_{RO-i}^{\%}$  is the percentage of treated GW required with salinity level  $TDS_f$  [%],
- $R_i^{\%}$  is the percentage of GW that is rejected as brine after reverse osmosis [%],
- $GDP$  is the total gross domestic product [QAR],
- $WWD_t$  is the total water withdrawals by all economic sectors [million m<sup>3</sup>],
- $WA_t$  is the total renewable water availability [million m<sup>3</sup>],
- $WWI$  is the water withdrawal intensity [million m<sup>3</sup>],

The model is constrained by the capacities of the desalination and wastewater treatment plants, the water requirements of the subsectors, in addition to logical constraints as described by eq (5-11).

$$\sum_{i=1}^{15} W_i \cdot (x_{p,i,j}^{TSE} + x_{r,i,j}^{TSE}) \leq C_j^{TSE}, \forall j \quad (5)$$

$$\sum_{i=1}^{15} W_i \cdot x_{p,i,j}^{DW} \leq C_j^{DW}, \forall j \quad (6)$$

$$x_i^{GW} + \sum_{j=1}^{j=6} x_{p,i,j}^{TSE} + x_{r,i,j}^{TSE} + \sum_{j=1}^{j=13} x_{p,i,j}^{DW} = 1, \forall i \quad (7)$$

$$0 \leq x_i^{GW} \leq 1, \forall i \quad (8)$$

$$0 \leq x_{p,i,j}^{TSE} \leq 1, \forall i \quad (9)$$

$$0 \leq x_{p,i,j}^{TSE} \leq 1, \forall i \quad (10)$$

$$0 \leq x_{p,i,j}^{DW} \leq 1, \forall i \quad (11)$$

### 3. Results and Discussion

The total GW usage of the base scenario is estimated at over 184 million m<sup>3</sup>.year<sup>-1</sup>. Assuming that the considered agricultural subsectors are the only users of GW resources, the excessive usage puts the water stress level at over 300%, while the global water stress, which is considered to be safe, is around 18.6% (United Nations, 2022). The carbon footprint of the base scenario is found to be 121.3 thousand ton-CO<sub>2-eq</sub>. As for the water productivity it is estimated to be as little as 0.01 Q.R.m<sup>-3</sup> which is equivalent to \$0.0027 m<sup>-3</sup>.

For limited water stress that is set below or equal to 25%, and enhanced water productivity, the minimum carbon footprint that can be achieved is 253.2 thousand ton-CO<sub>2-eq</sub> which is more than twice that of the base scenario. This is due to the limited GW and TSE resources and the need to meet the rest of the demand via energy-intensive desalination. In fact, more than 70% of the calculated carbon footprint comes from the sea water desalination process (Figure 1). Although the carbon footprint of the base scenario is lower than what can be achieved using the proposed scenario, the water stress level is reduced from 323% to 25%, and the water productivity level increases from 0.010 Q.R.m<sup>-3</sup> to as much as 0.13 Q.R.m<sup>-3</sup>, equivalent to \$0.036 m<sup>-3</sup>. That said, TSE has the potential to alleviate the water stress as well as increase water productivity in the state of Qatar. The water allocation required to achieve these results is described in Figure 2.

Given that all wastewater produced in the State of Qatar has to be treated before being reused or disposed of, it can be argued that the carbon footprint associated with the process of treatment should not be borne by the agricultural sector. This would result in a 19% reduction in the carbon footprint. In addition to that, sludge produced from WWTPs can be used to offset part or all of the carbon footprint associated with the practice, if converted to power.

Figure 1: Percentage of the carbon footprint associated with the supply (SUP) and treatment (TREAT) of groundwater (GW) resources, TSE, and desalinated water (DW).

Figure 2: Water resources allocation for the four agricultural subsectors in million  $m^3 \cdot year^{-1}$ .

#### 4. Conclusion

The state of Qatar is one of the most water-scarce countries in the world but also one of the highest users of water. For this reason, there is a need for sustainable water budget planning in the country. One of the possible solutions that can alleviate the water stress in the State of Qatar is the reuse of TSE. This work investigates the optimum water planning framework for GW, DW and TSE water use in four agricultural subsectors for a reduced carbon footprint, limited water stress and improved water productivity. Results suggest that limiting the use of GW resources will increase the carbon footprint associated with the supply and treatment of the agricultural sector’s water requirements, as the needs will need to be met through desalinating seawater. However, this scenario is still considered an improved one since the water stress is reduced from 323% to 25% and the resulting water productivity level is 13 times higher than the base scenario. For future

work, it would be interesting to include the other subsectors of the agricultural sector such as outdoor and indoor farming. In addition to that, it would be interesting to look at how the use of sludge, another important byproduct of WWTPs, can further improve the environmental aspects of the agricultural sector.

## Abstract

Property models are an integral part of many chemical engineering applications and have been the subject of a lot of interest, especially with recent advancements in deep learning such as graph neural networks. Despite being of major importance, little effort has been dedicated to functional properties where the property dependency goes beyond the molecular structural information and depends on the state variables such as temperature and pressure. In this work, we demonstrate a flexible framework to extend graph neural networks to account for such use cases. A total of 13 different temperature-dependent properties were modeled covering enthalpy of vaporization, various heat capacities, densities, and thermal conductivities as well as surface tension and vapor pressure. While many were successfully modeled with some reaching an average absolute relative error below 6%, some still require further attention such as surface tension and thermal conductivity to achieve good accuracy.

**Keywords:** Graph neural networks, Thermophysical properties, Molecules, QSPR.

## 1. Introduction

In-silico evaluation of the various thermal, physical, safety, and transport properties of molecules is an integral element in many process simulation and product design software. These properties are usually the product or derived from experimental measurements and as such predictive models are necessary to perform in-silico evaluation of the properties. Quantitative structure-property relationships (QSPRs) are mathematical models that can provide such a service by leveraging the structural information of the molecule in inferring its property (Aouichaoui et al., 2023, 2022). Molecular properties of interest in the chemical engineering field can generally be divided into primary, secondary, and functional properties (Kontogeorgis and Gani, 2004). The primary properties are single-value properties that can be determined solely from the structural information, while secondary properties cannot be explicitly calculated uniquely from the structural information but rather as a function of other properties. An example of primary properties is the critical point properties as well as the normal boiling point, while the secondary properties could be the acentric factor or the solubility parameters. Both types of properties have long been the subject of various QSPR modeling through e.g. the use of group-contribution methods (Hukkerikar et al., 2012) as well as more advanced deep learning models (Aouichaoui et al., 2023, 2022). While much focus has been on taking advantage of the recent development in the field of deep learning (DL) to develop increasingly better QSPR models for primary properties and secondary properties, little

attention has been given to functional properties. Functional properties on the structural information as well as a set of intensive variables such as temperature, pressure, or composition. Such properties include saturated liquid density, vapor pressure, heat capacities, and thermal conductivity. Predictive models that can infer these properties are an integral part of any process simulation software as many unit operations are operated at varying temperatures and pressures. These properties are usually predicted through correlations that include compound-specific constants and as a function of other properties of the compounds. An example of the correlation of saturated vapor pressure ( $P^{sat}$ ) using the Antoine equation as seen in Eq.(1), where T is the temperature and A, B, and C are compound-specific constants determined through regression. A further example is a correlation for the liquid density ( $\rho^{sat}$ ) using the modified Racket equation as seen in Eq.(2), where R is the universal gas constant,  $T_c$  and  $P_c$  are the critical temperature and pressure respectively,  $T_r$  is the reduced temperature and  $Z_{RA}$  is a compound specific constant determined through regression.

$$\log_{10}P^{sat} = A - \frac{B}{T + C} \quad (1)$$

$$\frac{1}{\rho^{sat}} = \frac{R T_c}{P_c} Z_{RA}^{(1+(1-T_r)^{2/7})} \quad (2)$$

The two examples show that the property is dependent on other inputs that are either determined experimentally or through other correlations (e.g. the use of other property models to evaluate the critical properties). One major drawback of this is the fact that uncertainties become untraceable due to many input parameters. A further issue is when the property evaluation requires other QSPR models. As such, we advocate the leveraging end-to-end learning framework from the field of deep learning and extending it to build property models for functional properties that solely rely on the molecular structure and the intensive state variable such as the temperature. The developed framework is denoted state-dependent graph neural networks (S-GNN) and is elaborated on in the following.

## 2. S-GNN

Graph neural networks (GNNs) provide a unified approach that combines the feature extraction process and the regression process (Aouichaoui et al., 2022). GNNs takes as input a graph representation of the molecule where nodes correspond to atoms and edges correspond to the bonds. The node and edge are associated with feature vectors with information about the atoms and bond e.g. atom type, number of hydrogen attached, and bond type. Using a series of operations (also called convolutional layers) involving matrix multiplication, the graph representation is updated and converted into a numerical vector that is used as the molecular descriptor. This process is denoted message-passing and governs the feature extraction process and distinguishes GNN models from each other.

Figure 1: Schematic of the workflow of S-GNN

The S-GNN extends on the classical GNN models by considering the state variables as global variables that are concatenated to the learned molecular representation resulting from the GNN feature extraction step as shown in Figure 1. In this work, we demonstrate the concept using a GNN model known as *attentiveFP*, which in recent studies has demonstrated state-of-the-art performance across many properties (Aouichouai et al., 2022; Xiong et al., 2020). The model combines the attention mechanism and recurrent neural networks on two levels: node-level like any other GNN model and as part of the readout by operating on a graph where the molecule is considered a super node, while all atoms are linked to it. The node operations can be seen in Eq.(3) to Eq.(8). The initialization step aims to dimension the atom features ( $x_v^{atom}$ ) of node  $v$  to the desired hidden dimension through a learnable weight matrix  $W$  and a non-linear activation function. The edge features  $x_w^{atom}$  of neighboring atoms are combined with the node features to produce the latent representation of the neighboring atoms. The alignment aims to combine the node representation with that of its neighbors, which is used as input to a softmax to produce a weight coefficient. The coefficient is used as a weight for the importance/influence the hidden representation of the neighboring node should have when updating the hidden representation of a given node as seen in the context.

$$\text{Initialization} \quad h_v^0 = \text{ReLU}(W \cdot x_v^{atom}) \quad \text{for } t = 0 \quad (3)$$

$$n \quad h_w^0 = \text{ReLU}(W \cdot [x_w^{atom}, x_{v,w}^{bond}]) \quad \text{for } t = 0 \quad (4)$$

$$\text{Alignment} \quad \epsilon_{v,w}^{t+1} = \text{leakyReLU}(W \cdot [h_v^t, h_w^t]) \quad \text{for } t + 1 \leq T \quad (5)$$

$$\text{Weighting} \quad \alpha_{v,w}^{t+1} = \text{softmax}(\epsilon_{v,w}^{t+1}) \quad \text{for } t + 1 \leq T \quad (6)$$

$$\text{Context:} \quad C_v^{t+1} = \text{elu} \left( \sum_{w \in \text{Neighbor}(v)} \alpha_{v,w} \cdot W \cdot h_w^t \right) \quad (7)$$

$$\text{Update} \quad h_v^{t+1} = \text{GRU}(h_v^t, C_v^{t+1}) \quad \text{for } t + 1 \leq T \quad (8)$$

Similar reasoning is applied for the graph level embedding seen in Eq.(9) to Eq.(13), where  $L$  is the number of graph embedding layers and  $s$  denotes the supernode.

$$\text{Initialization} \quad h_s^0 = \sum_{v \in G} h_v^T \text{ for } l = 0 \quad (9)$$

$$\text{Alignment} \quad \epsilon_{s,v}^{l+1} = \text{leakyReLU}(W \cdot [h_s^l, h_v^T]) \text{ for } l + 1 \leq L \quad (10)$$

$$\text{Weighting} \quad \alpha_{s,v}^{l+1} = \text{softmax}(\epsilon_{s,v}^{l+1}) \text{ for } l + 1 \leq L \quad (11)$$

$$\text{Context} \quad C_s^{l+1} = \text{elu} \left( \sum_{v \in \text{Neighbor}(s)} \alpha_{s,v} \cdot W \cdot h_v^t \text{ for } l + 1 \leq L \right) \quad (12)$$

$$\text{Update} \quad h_s^l = \text{GRU}(h_s^l, C_s^{l+1}) \text{ for } l + 1 \leq L \quad (13)$$

### 3. Case study: modeling of 13 temperature-dependent properties

#### 3.1. Data

A total of 13 temperature-dependent properties were investigated: ideal gas heat capacity (ICP), liquid heat capacity (LCP), solid heat capacity (SCP), liquid and solid density (LDN, SDN), enthalpy of vaporization (HVP), surface tension (ST), liquid-solid and vapor thermal conductivity (LTC, STC, VTC), vapor pressure (VP) and liquid-vapor viscosity (LVS, VVS). All data were retrieved from the AIChE DIPPR 801 Database and only considered experimental data, smoothed or derived (Rowley et al., 2019). Chemical diversity analysis showing the different species (hydrocarbons, oxygenated, nitrogenated, chlorinated, fluorinated, brominated, iodinated, sulfonated, phosphorated, silicon-containing, or multi-functional) present can be seen in Table 1 where the number of total distinct species ( $N_{\text{spec}}$ ) and the total amount of observations ( $N_{\text{obs}}$ ) are also reported.

### 3.2. Model training

For the model training, the data were split randomly with 70% allocated for training and the remaining evenly split between validation and testing. No data scaling was performed. The model was trained over a maximum of 500 epochs using the ADAM optimizer, with mean absolute error as a loss function and the early stopping policy as a contingency against overfitting. The training-specific hyperparameters and their bounds consisted of: the batch size ([16, 1024]), the initial learning rate ( $[10^{-6}, 10^{-1}]$ ), the weight decay ([0, 0.25]), and the dropout ([0, 0.25]). The model-specific hyperparameters covered: the number of node embedding layers ([1,4]), the number of graph embedding layers ([1,4]), the length of the graph feature ([50,512]), and the number of DNN layers ([1,3]). The hyperparameter optimization was conducted using Bayesian optimization with a Gaussian process (GP) model with Matern32 kernel as covariance function, with 100 random exploration steps and 100 BO steps while the acquisition strategy chosen was as the upper confidence bound (UCB). The BO was performed using the “*Bayes\_Opt*” toolbox in python (Jiménez and Ginebra, 2017). The node and edge features used in this work are similar to those in previous studies (Aouichaoui et al., 2022; Xiong et al., 2020). The model can be accessed via: <https://github.com/gsi-lab/s-afp>. Since the data are proprietary, they are not made available, but the workings of the model are illustrated using another freely available dataset.

### 3.3. Results

The performance of the models in terms of the  $R^2$  and mean absolute percentage error and the mean absolute error and vis á vis the test set as well as the complete dataset can be seen in Table 2, an example of the parity plot for the liquid density and the saturated vapor pressure can be seen in Figure 2.

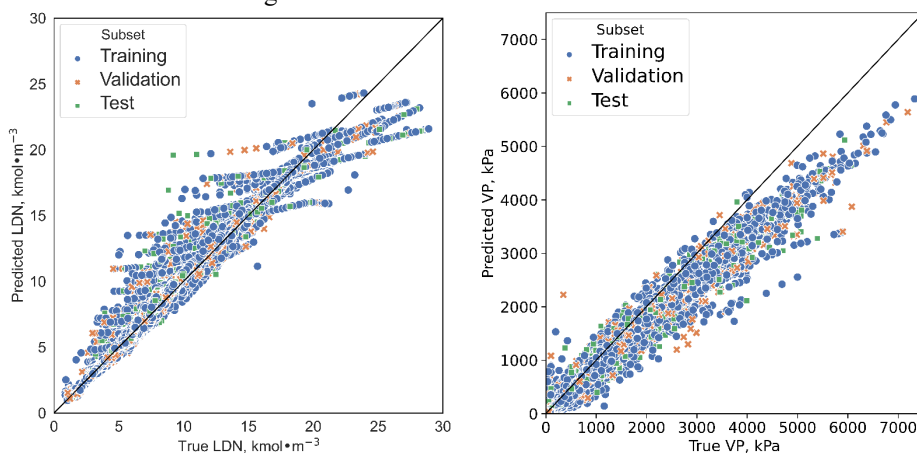

Figure 2: Parity plots for liquid density (LDN-left) and vapor pressure (VP-right)

*: Median absolute percentage error was used instead							

Many properties achieve good accuracy with 7 datasets reaching below 10% MAPE. In some cases, the use of the MAPE is not suitable as some datapoint are very small and close to zero and as such even small errors lead to a very large relative error which is misleading instead we suggest using the median absolute percentage error as it is robust to such outliers in the sample data. Especially the results obtained for the LDN, suggest the model results are similar to the state-of-the-art reported in previous studies using the modified Racket equation (Spencer and Adler, 1978). However, the absence of overall performance metrics makes it difficult to perform a comparison. However, noteworthy is also the fact that some datasets present a challenge to achieve a good accuracy performance, especially considering STC, LVS, and to some extent ST. One possible explanation for the STC dataset is the fact that the chemical diversity is very low with only 16 distinct molecules, which makes it difficult to learn any suitable representation. For the LVS, we observed some experimental data that were 7 times larger in order of magnitude, which might have been data that were tagged as derived. This highlights the requirement of addressing the data quality used during the model training as these are detrimental in allowing the model to extract knowledge it can correlate to the target property. For the ST, we observed a wide range of data with a notable bias (an intercept on the y-axis) when constructing the parity plot. This could suggest that the learning of the model has not achieved convergence enough to be able to reduce the variance observed. Another piece of evidence is the observation on the magnitude of the data points was between 0 and 0.06, which would require an even smaller learning rate than the one used during BO. One possible solution would be to perform data scaling as this will limit the spread of the data in addition to performing outlier detection to remove odd data present in the dataset.

#### 4. Conclusions

In this work, we provide an extension to graph neural networks that can generalize to any graph neural network and allow it to evaluate properties that depend on system state variables such as temperature and pressure in addition to the structural information of the molecule. Out of 13 properties evaluated, the majority of the properties were modeled with high accuracy ( $R^2 > 0.9$ ), while surface tension and thermal conductivity properties need further focus as they prove challenging to predictively model.

## Abstract

A Multi-Objective Dynamic Optimization (MODO) applied to the biomethanation process is developed. The MODO strategy was designed to find the trade-off between the maxima yield and productivity of methane and acetate modifying the inlet liquid and gas flow rates. First, a multi-objective optimization was applied to find the Pareto optimal set between productivity and yield of methane and acetate independently. Then, Pareto optimal points (POPs) were selected to develop five cases in dynamic optimization, which used a Model Predictive Control (MPC) approach. Cases 1-2 corresponded to the model simulation and the use of the POPs directly in simulation. Cases 3-4 addressed the POPs to maximize the Euclidean length for methane and acetate. Case 5 was performed to demonstrate a switch between these objectives. The ability of the MODO strategy to perform the switch was demonstrated. Additionally, the dynamic optimization allowed the reduction of the inlet gas flow rate to  $1.5m^3/d$ .

**Keywords:** Biomethanation, Multi-objective Optimization, Pareto Optimal Set, Dynamic Optimization, Process Control

## 1. Introduction

In Anaerobic Digestion (AD) organic matter is transformed by the synergistic work of different microorganisms into CH<sub>4</sub>, and CO<sub>2</sub> through four steps: hydrolysis, acidogenesis, acetogenesis, and methanogenesis. The produced biogas contains 50-75% of CH<sub>4</sub>, and 25-50 % of CO<sub>2</sub> (Iglesias et al., 2021). Biomethanation uses microorganisms to convert the CO<sub>2</sub> in the biogas from AD and syngas (a mix of H<sub>2</sub>, CO, and CO<sub>2</sub>) into CH<sub>4</sub>. This process, however, could also be used to produce value-added products such as acetate (Chaikitkaew et al., 2021). Acetate serves as a chemical platform in the textile, polymer, pharmaceutical, and food industries (Martín-Espejo et al., 2022). Nevertheless, controlling this type of process is an arduous task due to the multiple reactions and microorganisms involved. As a result, obtaining desired performances of yields or productivities at an industrial scale remains difficult, particularly when you need to optimize several of them simultaneously. The use of dynamic models plays a crucial role in the design of control strategies. For instance, Model Predictive Control (MPC) (Morales-Rodelo et al., 2020) is implemented to maintain or optimize several variables. MPC refers to control actions that optimize a criterion in a future behavior of the system, which is determined by the dynamic model (Camacho and Bordons, 2007). Multi-

Objective Optimization (MOO) implies optimizing problems where there is more than one objective to be optimized simultaneously. These objectives are usually conflictive (Vertovec et al., 2021).

This work aims at proposing a Multi-objective Dynamic Optimization (MODO) to maximize yield and productivity of the biomethanation process regarding two of the potential products: CH<sub>4</sub> and acetate. The proposed dynamic optimization approach used a MPC with two control variables corresponding to the inlets of liquid and gas flow rates. MPC uses the Pareto optimal sets, where each solution is considered as a Pareto Optimal Point (POP). The robustness of the MODO strategy is analyzed by performing a switch between the optimized values for CH<sub>4</sub> and acetate.

## 2. Multi-Objective Dynamic Optimization as Control Strategy

A MODO strategy was proposed in a previous work (Acosta-Pavas et al., 2022a) to determine the optimal values of the objectives. This strategy entails the following steps: **Step 1-Model definition.** Proposition of the dynamic model to represent the biological process.

**Step 2-Definition of the objective functions  $Y_1^*, \dots, Y_m^*$**  to be maximized/minimized in the MOO. A MOO can be formulated as a minimization problem, Eq (1).

$$\min_{x,u,p,t} \{Y_1^*(x, u, p), \dots, Y_m^*(x, u, p)\} \quad (1)$$

$$\text{Subject to } \begin{cases} dy/dt = \xi(x, u, p, t) \\ f_i(x, u, p, t) \leq 0 & i = 1, 2, \dots, n \\ g_i(x, u, p, t) = 0 & i = 1, 2, \dots, k \\ u^L \leq u \leq u^U \end{cases} \quad (2)$$

where  $Y_1^*, \dots, Y_m^*$  are the  $m$  objective functions,  $x$  the state variables,  $u$  the control variables and  $p$  the control variables. The dynamic model is represented by  $dy/dt$ ;  $f_i$  and  $g_i$  indicate inequality and equality constraints.  $u^L$  and  $u^U$  corresponds to the lower and upper bounds of the control variables.

**Step 3-Selection of the POP.** Determination of the Pareto optimal set  $Y_1^*, \dots, Y_m^*$  and selection of the POP to be used as the reference trajectory in the dynamic optimization.

**Step 4-Definition of the dynamic problem with a single weighted objective.** Formulation of an objective function considering the previously identified POP in terms of a MPC problem. The dynamic optimization determines the input variables that minimize the following objective function,

$$\min_u \left( \sum_{j=t}^{t+H_p} \left( \frac{|Y^* - y(t+j|t)|}{Y^*} \right)^2 + \sum_{j=t}^{t+H_c} W_u \Delta u(t+j|t)^2 \right) \quad (3)$$

where  $u$  is the vector of the control variables;  $H_p$  and  $H_c$  are the prediction and control horizons;  $y(t+j|t)$  is the output prediction calculated at time instant  $t+j$  using the information available at time instant  $t$ .  $Y^*$  is a reference trajectory that enables to reach the set point and is determined by the MOO. The term  $\Delta u(t+j|t)$  is the control move at time instant  $t+j$  calculated using information available at time instant  $t$ . The problem in Eq. (3) is also subject to Eq. (2).

### 3. Multi-objective Dynamic Optimization in Biomethanation Process

The main goal was to optimize yields and productivities of two value-added products, CH<sub>4</sub> and acetate, in order to demonstrate that a control strategy could attained larger values than the ones obtained from the model simulation. Two manipulated variables were proposed for the optimization: the inlet gas ( $q_{gas}^{in}$ ) and liquid ( $q_{liq}^{in}$ ) flow rates.

**Step 1.** The model used for simulation was proposed in a previous study by Acosta-Pavas et al., (2022b). This model was built upon experimental data from (Sun et al., 2021) and it considered the conversion of H<sub>2</sub> and CO to enhance CH<sub>4</sub> production. The experimental data from Sun et al. (2021) was carried out in a bubble column reactor with a working volume of  $3.75 \times 10^{-2} \text{ m}^3$  and a hydraulic retention time (*HRT*) of 20 days. The reactor operated at 37°C for 207 days. The organic loading rate (*OLR*) corresponded to  $0.53 \text{ kg}_{COD}/\text{m}^3 \text{ d}$  with  $q_{liq}^{in}$  of  $1.9 \times 10^{-3} \text{ m}^3/\text{d}$ . Gas addition was carried out in five stages (I - V) in which  $q_{gas}^{in}$  and the gas loading rate (*GLR*) were varied in time. The model (Acosta-Pavas et al., 2022b) can be rewritten as,

$$\frac{dS_{gas,i}}{dt} = \frac{q_{gas}^{in}}{V_{gas}} S_{gas,i}^{in} + N_i \left( \frac{V_{liq}}{V_{gas}} \right) - \frac{q_{gas}}{V_{gas}} S_{gas,i} \quad (4)$$

$$\frac{dS_{liq,j}}{dt} = \frac{q_{liq}^{in}}{V_{liq}} (S_{liq,j}^{in} - S_{liq,j}) + \sum_k Y_k f_{j,k} \mu_k - N_i \quad (5)$$

$$\frac{dX_k}{dt} = \frac{q_{liq}^{in}}{V_{liq}} (X_k^{in} - X_k) + Y_k \mu_k - \mu_{k,dec} \quad (6)$$

Sub-indices  $j = 1-8$  denote glucose, butyrate, propionate, acetate, H<sub>2</sub>, CH<sub>4</sub>, CO, and CO<sub>2</sub> in liquid phase; sub-indices  $i = \text{H}_2, \text{CH}_4, \text{CO}, \text{and CO}_2$  in the gas phase; while sub-indices  $k =$  biomass that degraded glucose, butyrate, propionate, acetate, H<sub>2</sub>, and CO in liquid phase.  $q_{gas}$  is the outlet gas flow rate,  $V_{liq}$  and  $V_{gas}$  are the liquid and gas volume, respectively.  $S_{liq,j}^{in}$ ,  $S_{gas,i}^{in}$ , and  $X_k^{in}$  are the inlet concentrations of components  $j$  in the liquid phase, the inlet concentration of components  $i$  in the gas phase, and the inlet concentration of biomass  $k$  in the liquid phase.  $Y_k$  is the yield of biomass  $k$ ,  $f_{j,k}$  are the stoichiometric coefficients,  $\mu_k$  and  $K_{k,dec}$  are the growth rate and the decay constant for biomass  $k$ . Finally,  $N_i$  is the mass transfer rate of component  $i$ .

**Step 2.** Two objectives were considered to optimize: the yields  $Y_{CH_4}$ ,  $Y_{ac}$  and productivities  $P_{CH_4}$ ,  $P_{ac}$ , for CH<sub>4</sub> and acetate, respectively. These are defined as,

$$Y_{CH_4} = \frac{q_{gas,CH_4}}{kgCOD_{added}}; P_{CH_4} = \frac{q_{gas,CH_4}}{V_{liq}} \quad (7)$$

$$Y_{ac} = \frac{S_{liq,ac}}{kgCOD_{added}}; P_{ac} = \frac{S_{liq,ac}}{V_{liq}} \quad (8)$$

The MOO for the maximization of  $Y_h$  and  $P_{hi}$  was proposed as,

$$\max_{\{q_{gas}^{in}, q_{liq}^{in}\}} (P_h, Y_h) \quad (9)$$

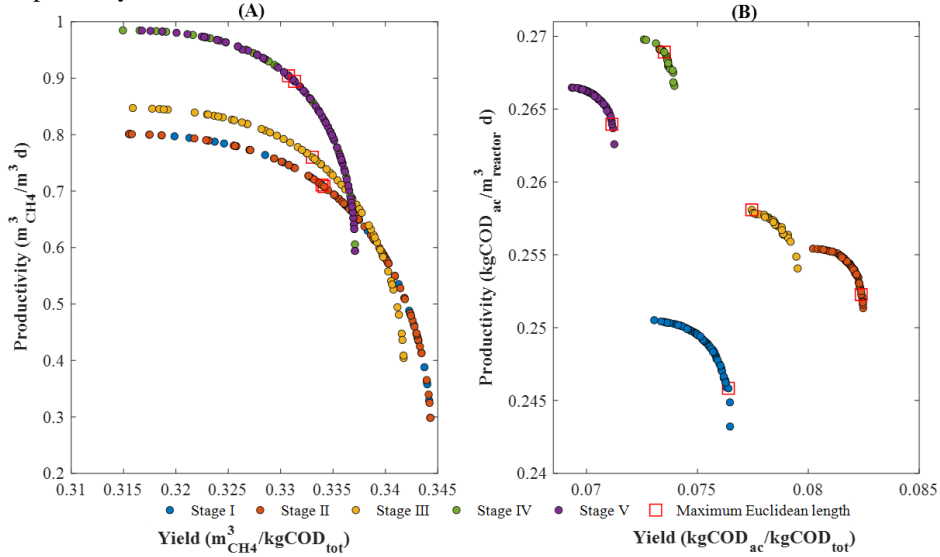

$$\text{Subject to } \begin{cases} \text{Equations 4 - 6} \\ Y_{CH_4} \leq Y_{CH_4}^{max} = 0.39 \text{ m}_{CH_4}^3/\text{kgCOD}_{added} \\ 1 \times 10^{-3} \leq q_{gas}^{in} \leq 10 \text{ m}^3/\text{d} \\ 1 \times 10^{-3} \leq q_{liq}^{in} \leq 0.1 \text{ m}^3/\text{d} \end{cases} \quad (10)$$

where  $h = \text{CH}_4, \text{acetate}$ ,  $Y_{CH_4}^{max}$  corresponds to  $0.39 \text{ m}_{CH_4}^3/\text{kgCOD}_{added}$  which represents the theoretical yield of CH<sub>4</sub> that could be obtained by kg of COD at 37°C. This

corresponds to  $0.35 m_{CH_4}^3 / kgCOD_{added}$  at standard temperature and pressure conditions (only for  $P_{CH_4}$ , and  $Y_{CH_4}$  maximization).

In this study, the simulations were run using an Intel® Core i7 8665U 2.11 GHz, 16 GB RAM computer. The *paretosearch* function from MATLAB® was used to obtain the Pareto optimal set for each stage.

**Step 3.** The Pareto fronts were computed for each stage. Concerning  $CH_4$ , 60 Pareto points were calculated for all stages. Regarding acetate, 60 Pareto points were calculated for stages I, II, and V, while 29 and 35 Pareto points were obtained for stages III and IV, respectively.

**Figure 1.** Pareto optimal sets for  $CH_4$  (A), and acetate (B) at each stage.

Figure 1 shows the Pareto optimal sets for  $CH_4$  and acetate at each stage. A progressive increase in  $P_{CH_4}$  was observed, while  $Y_{CH_4}$  decreased slightly.

$Y_{ac}$  and  $P_{ac}$  increased from stage I to II, then  $Y_{ac}$  decreased for the subsequent stages. However,  $P_{ac}$  continued to increase until stage IV to encounter a decrease in stage V.

At each stage, the POP were selected to maximize the Euclidean length ( $d_{max}$ ) for  $CH_4$  and for acetate (red squares in Fig. 1). For both cases,  $d_{max}$  was calculated as the distance from the origin, using a normalization as in Eq. (11).

$$d_{max} = \max \left( \sqrt{\left( \frac{Y_{CH_4}^* - \min(Y_{CH_4}^*)}{\max(Y_{CH_4}^*) - \min(Y_{CH_4}^*)} \right)^2} + \left( \frac{P_{CH_4}^* - \min(P_{CH_4}^*)}{\max(P_{CH_4}^*) - \min(P_{CH_4}^*)} \right)^2} \right) \quad (11)$$

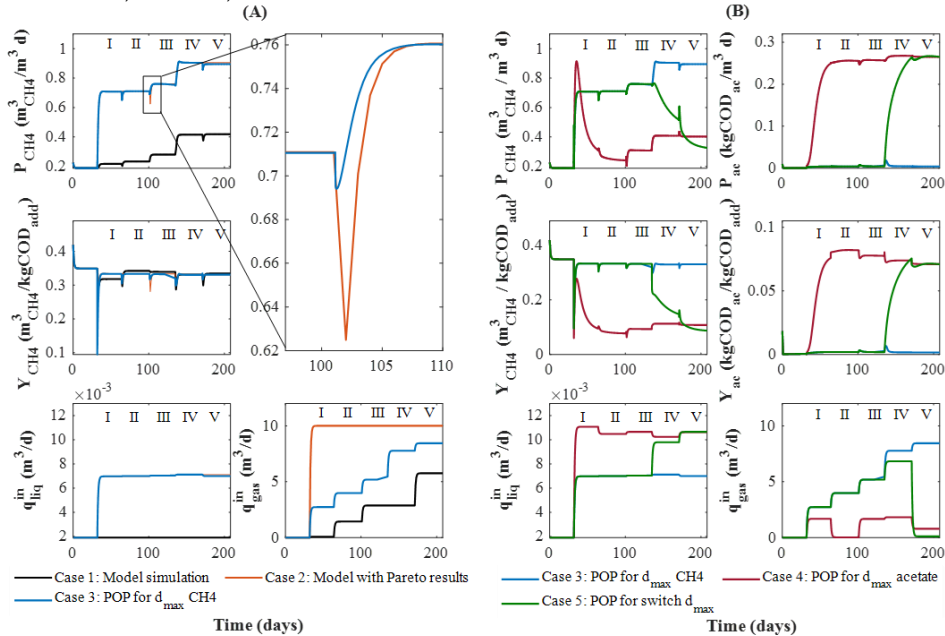

**Step 4.** The dynamic optimization for  $Y_h$  and  $P_h$  was proposed as follows ( $h = CH_4$ , acetate),

$$\min_{\{q_{gas}^in, q_{liq}^in\}} \left( \sum_{j=t}^{t+H_p} \left( \frac{|Y_h^* - Y_h(t)|}{Y_h^*} \right)^2 + \left( \frac{|P_h^* - P_h(t)|}{P_h^*} \right)^2 + \sum_{j=t}^{t+H_c} W_{u,1} \Delta q_{gas}^{in}(t)^2 + W_{u,2} \Delta q_{liq}^{in}(t)^2 \right) \quad (12)$$

Eq. (12) is subject to the constraints in Eq. (10).  $Y_i^*$  and  $P_i^*$  denote the POP values for yield and productivity computed by the MOO,  $\Delta q_{gas}^{in}(t)^2$  and  $\Delta q_{liq}^{in}(t)^2$  are the differences between the inlet gas and liquid flow rates, respectively, before and after each step of the dynamic optimization.  $W_{u,1}$  and  $W_{u,2}$  are the parameters that weight the importance of the control effort term in the optimization. In all cases, the initial values for both manipulated

variables were  $1 \times 10^{-3} \text{ m}^3/\text{d}$ .  $H_p$  and  $H_c$  were equal and equivalent to the time length of each stage. Optimization was performed with the *patternsearch* algorithm in MATLAB®.

**Step 5.** Five cases were studied to assess the dynamic optimization. Case 1 regarded model simulation (data without control). The other cases correspond to: the direct use of the POP in simulation (case 2); the inclusion of POP into a MODO for the maximization for  $d_{\max} \text{ CH}_4$  (case 3) and  $d_{\max} \text{ acetate}$  (case 4), and a switch strategy aiming at maximizing  $\text{CH}_4$  in stages I-III and then maximizing acetate in stages IV-V (case 5). The weights  $W_{u,1}$  and  $W_{u,2}$  (for cases 2-5) were manually adjusted to values of  $1 \times 10^{-6}$ .

**Figure 2.** Yields, productivities, injected and inlet gas flow rates in the MODO. Cases 1-5 (A); Case 6 (B).

Figure 2-A presents the results of cases 1 to 3. It is observed that  $Y_{\text{CH}_4}$  was maximized in the experimental part. On the other side,  $P_{\text{CH}_4}$  can be enhanced through the utilization of MODO.

The advantages to use the dynamic optimization were observed when cases 2 and 3 are compared. Both of them achieved similar results for  $P_{\text{CH}_4}$ . However, the transition between stages was smoother and faster in case 3, due to the dynamic part of the MODO (zoom in Figure 2-A). For instance, between stages II and III the time to reach 95% of the steady state decreased from 104 days in case 2 to 102 days in case 3, which could translate into less substrate consumption and thus a higher profit. Regarding  $Y_{\text{CH}_4}$ , it was similar in all cases, while  $q_{\text{liq}}^{\text{in}}$  varied from  $7.1 \times 10^{-3}$  to  $6.9 \times 10^{-3} \text{ m}^3/\text{d}$  at stage V. For  $q_{\text{gas}}^{\text{in}}$ , a value of  $10 \text{ m}^3/\text{d}$  was obtained for all stages in case 2. Nonetheless, this value was reduced in case 3 where  $q_{\text{gas}}^{\text{in}}$  ranged between 2.73 and  $8.44 \text{ m}^3/\text{d}$ .

Figure 2-B displays the cases 3 to 5. In stage V of case 3, a value of  $0.89 \text{ m}^3_{\text{CH}_4}/\text{m}^3 \text{ d}$  was obtained for  $P_{\text{CH}_4}$ , while  $0.33 \text{ m}^3_{\text{CH}_4}/\text{kgCOD}_{\text{added}}$  was obtained for  $Y_{\text{CH}_4}$ . In stage V of case 4, values of  $0.27 \text{ kgCOD}_{\text{ac}}/\text{m}^3 \text{ d}$  and  $0.07 \text{ kgCOD}_{\text{ac}}/\text{kgCOD}_{\text{added}}$  were achieved for  $P_{\text{ac}}$  and  $Y_{\text{ac}}$ , respectively.

In case 5, a switch was applied at the beginning of stage IV, where the reference values for  $P_{ac}$  and  $Y_{ac}$  were achieved at the end of the stage. Then, in stage V, values of  $0.27 \text{ kgCOD}_{ac}/\text{m}^3 \text{ d}$  and  $0.07 \text{ kgCOD}_{ac}/\text{kgCOD}_{added}$  were obtained for  $P_{ac}$  and  $Y_{ac}$ , respectively, while the control variables were calculated to maintain the values from cases 3 and 4. This case shows that the MODO strategy is robust when switching multi-objectives and attains the optima founded by the MOO. When comparing the performance of the MODO for CH<sub>4</sub> with the model simulation, (case 3 vs case 1), it is observed that  $P_{CH_4}$  increased between 3.26 to 2.13 times from stage I to V concerning case 1, while  $Y_{CH_4}$  was maintained similar.

#### 4. Conclusion

A MODO strategy was successfully applied over a biomethanation process based on the dynamic model ADM1\_ME. The feasibility of using Paretos to find the trade-off between objective functions, such as yields and productivities of CH<sub>4</sub> and acetate was demonstrated. The application of a dynamic optimization allowed an improvement in the response by reducing approximately 2 days the time in which the steady state was reached in the stage changes. Additionally, a reduction in gas flow rates of  $1.5 \text{ m}^3/\text{d}$  was achieved with the dynamic optimization. The robustness of the MODO strategy was demonstrated with a successful switch between the products of interest. These results showed that both control variables ( $q_{liq}^{in}$  and  $q_{gas}^{in}$ ) have a key role at each case and stage. Although these results show the feasibility of the proposed strategy, it is important to note that these are simulation results, and the adaptation of the microorganisms to the propose switching conditions might be different. However, this work showed the possibility to optimize in a smoother way the production of these two products and the change of objectives.

## Abstract

Roughly 30% of municipal waste is incinerated in the European Union. Because of the heterogeneity of the waste and lack of local measurements, the industry relies on traditional control strategies. However, advanced modeling strategies have been used to gain insights on the design of such facilities. In this paper, a first-principles model of the waste combustion based on the simplification of past literature works is developed. Simulations are carried out using the walking column approach, reproducing the major trends observed in other works and on site. The dynamic responses resulting from the model will serve as the centrepiece of a global model to be used for supervision assistance.

**Keywords:** Waste Incineration, First-principles Model, CFD Simulation, Supervision.

## 1. Introduction

The first municipal incinerator appeared in London in 1870 as a response to fast urbanization and sanitation issues (Bertolini, 2000). To minimize pollution and cost, and to maximize the recovery of energy, the process was improved over time.

Figure 1: Schematic view of a typical incineration process.

Nowadays, the process can be roughly separated in three main stages: the feeding stage, hot stage, and flue-gas treatment stage, each one containing several units. A typical incineration process is given in Figure 1. For municipal waste, the most common type of kiln is the reciprocating grate, as it provides good mixing and a steady movement of the solids while being robust.

Regarding chemical engineering, the difficulties inherent to the incineration process are twofold. First, the waste heterogeneity and lack of control of the feeding imply strong uncertainties right after the process inlet. Second, there are few sensors in or near the kiln due to harsh mechanical and thermal conditions. There are many more sensors towards the process outlet. Therefore, it is relevant to develop a model that considers the process from inlet to outlet. Nevertheless, as the furnace is both the heart of the process and the host of the most complicated phenomena, it deserves specific attention. This paper presents a model of the behavior of a burning bed of waste to be integrated in a complete model of a real plant. Although greatly inspired by the literature, it differs by providing significant simplifications to a family of models only dedicated to the kiln.

## 2. Literature survey

### 2.1. Experiments

Because in industrial facilities only global fluid flows and temperatures can be measured, it is useful to rapidly present the 3 main experiments conducted in the literature as they give information on the local behavior.

1. The thermogravimetric analysis gives a classification of the fractions of waste known as the immediate analysis (humidity, volatile matter, char and ash). The ultimate analysis may be obtained to get a breakdown by elements. Thermal analysis also provides data for pyrolysis kinetics. Despite a high number of experiments, it must be noted that the resulting kinetics laws are quite unreliable (White et al., 2011).
2. The so-called pipe-bowl experiments (Menard, 2003) are similar to cylindrical wood stoves. They feature an array of thermocouples and gas analyzers that allow to follow locally the combustion of medium size samples. This experiment unravels the propagation of reaction fronts through the combustible.
3. Cold grate experiments study how solid particles travel and mix along an industrial grate. In the absence of combustion, it is much easier to track objects by means of visual hints or RFID tags (Džiugys et al., 2006).

### 2.2. Modeling approaches

Few works present models geared towards the control of incinerators. Van Kessel (2003) uses a 0D CSTR model and Magnanelli et al. (2020) present a 1D horizontal model for that purpose. However, these models cannot explain the behavior observed during the 3 mentioned experiments. Therefore, other models were considered, generally developed to gain insight on the design and pollutants behavior. Lagrangian approaches offer detailed simulations at the cost of tedious mechanical descriptions and high computation time (Brosch et al., 2014). Eulerian approaches are more common, generally solved in 2D (Menard, 2003). Neglecting horizontal gradients leads to a method introduced by Goh et al. (2001) as the "walking column" approach, which is mostly retained for the present work in order to alleviate computation time.

### 3. Proposed model

#### 3.1. Model features

The waste present on the grate is subdivided in  $N$  columns which are modeled as a porous medium. It evolves dynamically while moving towards the bottom-ash pit at a constant speed. The porous medium is represented by a reduced set of 13 vertically distributed state variables: 4 solid mass fractions (humidity, volatile matter, residual carbon, inert matter), 7 gas mass fractions ( $N_2, O_2, H_2O, CH_4, CO, CO_2, H_2$ ), the solid and gas temperatures. It can be noted that in the literature, generally more state variables are necessary.

The evolution of state variables is determined by partial differential equations derived from the general transport equation, expressed as

$$\partial_t(\rho\phi) + \partial_z(\rho v\phi) = \partial_z(\Gamma\partial_z\phi) + S \quad (1)$$

where  $\rho$  is the apparent density,  $\phi$  a conservative variable corresponding to a state variable,  $\Gamma$  the diffusion coefficient,  $v$  the vertical velocity, and  $S$  the source term.

The bottom boundary condition is imposed by the primary air injection, which varies along the grate, while the top boundary condition is given by the pressure generated by the induced draft fan.

The gas phase properties are estimated by correlations (Poling et al., 2001). The properties of the solid phase are generally constant or linear with temperature, and the values are the standard estimates used in the industry.

Equation (1) written for the total mass of gas is rearranged into a pressure equation by assuming Darcy's and ideal gas laws. Its dynamics are fast and neglecting the accumulation term had no influence on the resulting pressure field. Removing the accumulation term allows to analytically solve the flow field, offering a significant simplification compared to the more general momentum equation widely used. It also makes the numerical solution more stable.

#### 3.2. Main phenomena involved

The source terms are constituted by a combination of various rates describing the main phenomena involved in the process:

- The drying rate is calculated through a classical Sherwood correlation. The driving force is the difference between the partial and saturation pressures of water.
- The pyrolysis rate is assumed to be a first order reaction. The pre-exponential factor and energy activation have been fitted with thermogravimetric experiments.
- The residual carbon burning rate is modeled by a first-order reaction and transport of oxygen through the particle boundary layer.
- The rates of light gases ( $CH_4, CO, H_2$ ) combustion are calculated with kinetic laws, which are all monomial in the gas concentrations, with mixing and channelling limitations.
- The radiative exchange rate with the flame and the kiln structure is modeled by Bouguer's law, while the radiative exchange between particles is treated using the radiative diffusion approximation.
- The convective heat exchange rate between the solid and gas phases is calculated with a classical Nusselt correlation.

The proportions of gases produced by pyrolysis are precalculated by a routine which ensures that the measured lower heating value, immediate analysis and ultimate analysis

of the waste are all respected. The atomic and energy balances used motivate the choice of exactly 7 gas mass fractions, as a smaller number would not allow the respect of the mentioned constraints.

### 3.3. Numerical solution

Simulations were carried out using MATLAB environment. Discretization is based on the finite volume method and the FVTool library (Eftekhari and Schüller, 2022). The advection term is discretized with the upwind scheme. The used grid is denser near the boundaries. The time integration is done with an adaptive implicit Euler scheme. A dynamic simulation with fixed input parameters to reach a steady state typically takes a few minutes on a personal computer, although the calculation time is highly sensitive to several parameters.

Because the vertical velocity of the solid is neglected, the volume reduction effect does not appear in transport equation (1). Instead, the volume of each cell is modified at each time step. This calculation reflects the fact that drying and devolatilization mostly leave intact pores in the particles, while char burning consumes the remaining structure and rapidly decreases the size of particles, resulting in a collapse of the solid bed.

## 4. Results and discussion

### 4.1. 1D simulation of a single column

Figure 2 presents time profiles of the gas outputs of a single column using a one-dimensional model. To make this simulation comparable with most pipe-bowl experiments found in literature, the air supply is kept constant at under-stoichiometric conditions, while the height of the waste bed is 30 cm.

Figure 2: Evolution of the gas output of a 1D column model with constant air supply.

In phase (a) (Figure 2), the radiative flux heats up and dries the top of the bed, characterized by a short temperature plateau around 373 K. In phase b, the pyrolysis starts. Light gases are emitted and quickly burned, resulting in a stiff temperature increase and a near-depletion of oxygen. Some of the heat generated is used to dry the lower layers that will in turn pyrolyze and burn. When this reaction front reaches the bottom, the remaining carbon is burned out in phase c which results in a temperature peak. In phase d, the combustion is completed, and a thermal equilibrium is reached between radiative heating and convective cooling by the primary air injection.

#### 4.2. 2D simulation of the entire bed

For a waste bed traveling on a grate, the state variables can be represented in maps such as the one given in Figure 3. The phases that were observed against time on Figure 2 can now be roughly observed with respect to position, despite large differences in primary air and bed height. After half a meter of pure drying, the pyrolysis starts early in zone 1, but not enough air is present to burn the volatile gases yet. Because the conditions are over-stoichiometric in zone 2, pyrolysis, light gas combustion and carbon combustion happen mostly simultaneously.

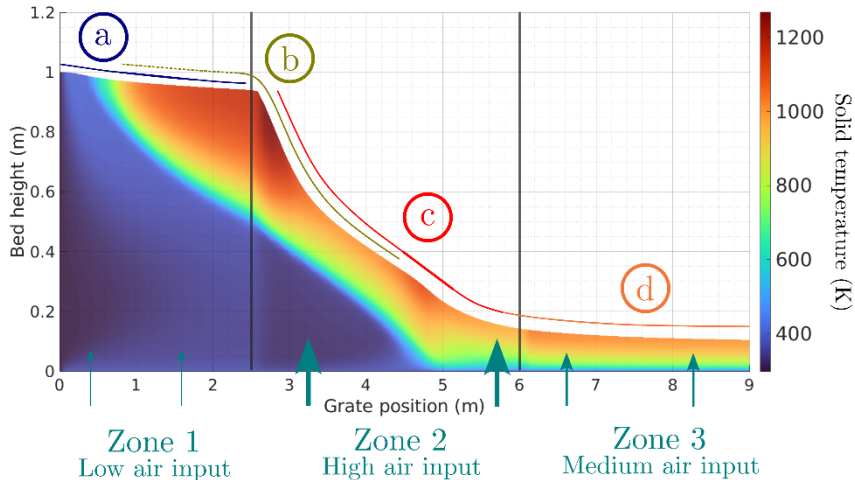

Figure 3: Solid temperature (K) distribution of a simulated waste bed. The grate and primary air injection parameters are taken from the incinerator of Schweighouse-sur-Moder (France) operated by the SUEZ company. The computation grid is 100 by 100.

#### 4.3. Waste bed response to a step change

Figure 4 displays the waste bed response to a step decrease of primary air injection.

Figure 4: Response of the kiln to a primary air step decrease of 30% at time  $t=100$ s.

The waste bed gas output temperature is computed by integrating the gas enthalpy and mass flows at the bed surface before any secondary combustion can happen. Note that because the walking columns algorithm produces nearly cyclic computation artefacts, a moving average has been applied to obtain a smoother curve (Figure 4). Since the conditions are over-stoichiometric, a decrease in primary air results in an immediate increase in temperature as less dilution occurs. Then, the temperature continues to increase closely to a 1st order response. This is mainly due to the solid thermal inertia. If the conditions were under-stoichiometric, a decrease in primary air would result in a temperature decrease due to incomplete combustion.

## 5. Conclusion and perspectives

A simplified first-principles model of the behavior of a burning bed of waste in an incinerator furnace has been developed and used to carry out simulations. Major trends observed on site and in the literature were successfully reproduced. For the first time, this type of model is used to study the dynamic responses of a burning waste bed. However, the results appear to be very sensitive to the model parameters, including the solid representation (particles, porosity), kinetic rates and heat transfer. Improvements could be made on the numerical resolution, such as an adaptive grid to follow the reaction front, the use of Total Variation Diminishing advection schemes and higher order integrators.

The next step consists in modeling the freeboard which will allow partial validation of the kiln combustion model with plant data, thanks to the secondary combustion chamber temperature and O<sub>2</sub> sensors. Then, the boiler, with its thermal inertia, will be modeled and offer steam production responses. Once the flue gas treatment stage is modeled, comparison with online gas analyzers will be possible. The final process model will be used as a basis for the prototype of a supervision tool whose exact form will depend on the characteristics of the global dynamic model, including its ability to treat uncertainty.

## Abstract

Model predictive control (MPC) and reinforcement learning (RL) are two powerful optimal control methods. However, the performance of MPC depends mainly on the accuracy of the underlying model and the prediction horizon. Classic RL needs an excessive amount of data and cannot consider constraints explicitly. This work combines both approaches and uses Q-learning to improve the closed-loop performance of a parameterized MPC structure with a surrogate model and a short prediction horizon. The parameterized MPC structure provides a suitable starting point for RL training, which keeps the required data in a reasonable amount. Moreover, constraints are considered explicitly. The solution can be obtained in real-time due to the surrogate model and the short prediction horizon. The method is applied for control of a flash separation unit and compared to a MPC structure that uses a rigorous model and a large prediction horizon.

**Keywords:** Reinforcement Learning, Model Predictive Control, Flash Separation Unit

## 1. Introduction

Model predictive control (MPC) is a powerful control concept as it can deal with process constraints and nonlinear multivariable systems. However, the control performance mainly depends on the accuracy of the system model as well as its prediction horizon. Using a rigorous first principles model and a long prediction horizon may lead to limited real-time capability due to large computational effort. One possibility to reduce the computational effort is to use surrogate models that are less complex than the original first principles ones. In addition, the prediction horizon can be kept short to reduce the number of decision variables of the optimal control problem. However, both strategies will lead to worse closed-loop performance.

Due to the digitalization of the process industry, an increasing amount of data becomes available. Data can improve process operation in different manners, for example with data-driven surrogate models or via reinforcement learning (RL). However, traditional RL approaches require very large amounts of data, and they cannot deal easily with process constraints.

In this work, we follow the success of recent approaches and utilize a parameterized MPC structure within an RL scheme to improve the closed loop performance of an MPC controller with an imperfect surrogate model and to consider process constraints

explicitly. We first show how the parameterized MPC controller can be used to approximate the action-value function of the optimal control problem and illustrate afterwards the results of the application on a flash unit.

## 2. Background on surrogate modelling for dynamic systems

Constrained dynamic systems are usually described by differential algebraic equation (DAE) systems. They consist of both ordinary differential equations and algebraic equations and can be written in semi-explicit form with state variables  $x = (y, z)$ , the control variables  $u$ , the parameters  $p$ , and time  $t$ :

$$\dot{y} = f(y, z, u, p, t) \quad (1)$$

$$0 = g(y, z, u, p, t). \quad (2)$$

High index problems frequently arise in chemical engineering, e.g., by assuming negligible vapor holdup. These systems cannot be integrated by explicit methods and are usually rather large DAE systems, which are slow and difficult to solve. This is limiting the applicability of optimization-based operation and control, such as MPC. Therefore, data-driven surrogate models are increasingly introduced.

There are many different approaches to model dynamic systems using data, e.g., Gaussian processes (Kocijan, 2016), different recurrent neural network architectures (Esche et al., 2022), and many more. In case a system is Markovian, a feedforward neural network is sufficient and can predict the state of the system at the next timestep, based on the current state and controls (Himmelblau, 2008).

## 3. Q-Learning for parameterized MPC structures

Reinforcement learning (RL) is a tool to solve Markov decision process (MDP) problems via the interaction of an agent (controller) and an environment (plant) (Sutton and Barto, 2018). The agent computes an action  $\mathbf{a}_k$  based on the current state of the environment  $\mathbf{s}_k$ . The action is applied to the system, which replies with the next state  $\mathbf{s}'_k$  and a reward  $r_k$  (stage cost). The combination gives an element of a Markov chain  $\mathcal{M} = \{(\mathbf{s}_k, \mathbf{a}_k, r_k, \mathbf{s}'_k)\}_{k=0}^N$ . The state of the environment  $\mathbf{s}_k$  does not have to be the system state  $\mathbf{x}_k$  only, for example the state of the environment can also be made up of past control actions  $\mathbf{u}_{k-1}$ . The agent's action is computed according to its policy  $\pi(\mathbf{s})$ . The policy can be learned implicitly from the optimization of the action-value function.

Q-learning focusses on finding the optimal action-value function  $Q^*(\mathbf{s}, \mathbf{a})$  of a MDP. The action-value function is a measure of how good an action  $\mathbf{a}$  in a given state  $\mathbf{s}$  is, when following a certain policy  $\pi$

$$Q(\mathbf{s}, \mathbf{a}) = r(\mathbf{s}, \mathbf{a}) + \gamma \cdot Q^\pi(\mathbf{s}', \pi(\mathbf{s}')) \quad (3)$$

where  $\gamma \in [0; 1]$  is a so-called discount factor. The optimal control policy can then be derived by optimization over the optimal action-value function. For control, the optimal policy  $\pi^*$  minimizes the expected cost. In the solution process for continuous control tasks, the action-value function is approximated using a function approximator  $Q_\theta$ .

A common choice to approximate that function is to choose deep neural networks (Mnih et al., 2015). However, they may suffer from lack of structure, therefore requiring an excessive amount of data. One way to reduce the amount of data is to use a more

structured function approximator like a parameterized MPC structure (Gros and Zanon, 2020). MPC takes an underlying system model  $f_d$  and predicts future states with it to derive an optimal control input. A parameterized MPC formulation can be written as:

$$\begin{aligned}
 Q_{\theta}(\mathbf{s}, \mathbf{a}) = \min_{\substack{\mathbf{x}_{[0:N]} \\ \mathbf{u}_{[0:N-1]} \\ \boldsymbol{\sigma}_{[0:N]}}} & \gamma^N (V_{f,\theta}(\mathbf{x}_N) + \mathbf{w}_f^T \boldsymbol{\sigma}_N) + \sum_{i=0}^{N-1} \gamma^i (\ell_{\theta}(\mathbf{x}_k, \mathbf{u}_k) + \mathbf{w}^T \boldsymbol{\sigma}_k) \\
 \text{s. t.} & \quad \mathbf{x}_{k+1} = f_{d,\theta}(\mathbf{x}_k, \mathbf{u}_k), \quad \mathbf{x}_0 = \mathbf{s}, \quad \mathbf{u}_0 = \mathbf{a}. \\
 & \quad g(\mathbf{u}_k) \leq 0, \quad \boldsymbol{\sigma}_k \geq 0 \\
 & \quad h_{\theta}(\mathbf{x}_k, \mathbf{u}_k) \leq \boldsymbol{\sigma}_k, \quad h_{f,\theta}(\mathbf{x}_N) \leq \boldsymbol{\sigma}_N.
 \end{aligned} \tag{4}$$

The parameterization is performed using the parameter vector  $\boldsymbol{\theta} \in \mathbb{R}^{n_{\theta}}$ , which can parameterize the objective function, the system model, and the constraints. For classic MPC, the discount factor is chosen as  $\gamma = 1$ . The parameterized MPC structure consists of the objective function, which is compound of the stage cost  $\ell_{\theta}$ , the terminal cost  $V_{f,\theta}$ , and penalties for the slack variables  $\boldsymbol{\sigma}$ , but also input and state constraints. The state constraints are considered as soft constraints.

Classic Q-learning updates may cause instabilities (Sutton and Barto, 2018). Mnih et al. introduce robustness via a replay buffer and target function  $Q_{\hat{\theta}}$  (Mnih et al., 2015). The replay buffer stores data from the past. In each update step, past samples are taken to perform a batchwise update. The target function is updated slower than the actual function. The target parameters are updated as  $\hat{\boldsymbol{\theta}} \leftarrow (1 - \tau)\hat{\boldsymbol{\theta}} + \tau\boldsymbol{\theta}$  with  $0 \leq \tau \leq 1$ . The Q-learning update requires the gradient of the Q-function. For the parametric MPC, the gradient of Q-function equals the gradient of the Lagrangian  $\mathcal{L}$  of the underlying optimization problem evaluated at the optimal points (Büsken and Maurer, 2001):

$$\nabla_{\boldsymbol{\theta}} Q_{\theta}(\mathbf{s}, \mathbf{a}) = \nabla_{\boldsymbol{\theta}} \mathcal{L}(\mathbf{x}_{[0:N]}^*, \mathbf{u}_{[0:N-1]}^*, \boldsymbol{\lambda}^*, \mathbf{v}^* | \mathbf{s}, \mathbf{a}). \tag{5}$$

The main idea of our work is to adapt the MPC structure (4) via the parameters  $\boldsymbol{\theta}$ , using Q-learning to counteract the imperfect surrogate model  $f_{d,\theta}$  and short prediction horizon.

## 4. MPC parameter optimization with RL on a flash simulation

### 4.1. Dynamic pressure-driven flash model

In order to build a realistic environment, a first principles model of a dynamic flash unit is created, see Figure 1. It describes the binary mixture of ethanol and water. The vapor liquid equilibrium is described assuming an ideal gas, but non-ideal liquid phase using Wilson's activity coefficient. Pressure and level are controlled via distillate and bottom stream respectively.

A surrogate model of the first principles model will be used within the parameterized MPC. For this, the rigorous model is sampled to generate data, which is used for training of a dynamic surrogate model. The control variables and their bounds for the model are the supplied heat flux  $\dot{Q}$  (0-30 kW), feed flow  $F^F$  (1-2 mol s<sup>-1</sup>), and feed composition  $x^F$  (0.01-0.99). The feed temperature is constant at 365 K.

Figure 1. Flowsheet of the flash unit with 4 inputs:  $F^F$ ,  $x^F$ ,  $T^F$ ,  $\dot{Q}$  and 7 outputs  $p$ ,  $T$ ,  $L$ ,  $F^D$ ,  $x^D$ ,  $F^B$ ,  $x^B$ .

To create training data, the former two are excited with an amplitude modulated pseudo-random binary sequence (APRBS) - which can be interpreted as a sequence of step signals with different holding times with a frequency of  $1 \text{ s}^{-1}$ . The feed composition is held constant for 50 s and then increased by 0.01. A second trajectory is created to later test the surrogate model, which uses a lower frequency for the APRBS while allowing the same number of steps.

The 50'000 samples of the first trajectory are shuffled and split into (50 %, 75 %, or 95 %) training data, while the rest is used for validation. These points are used to train three similar feed forward neural network with 10 nodes in one hidden layer for 10 epochs with the Adam optimizer (Kingma and Ba, 2014). The hyperbolic tangent was used for the activation function. The MSE on the validation data is  $5.7 \cdot 10^{-5}$ ,  $5.0 \cdot 10^{-5}$  and  $1.6 \cdot 10^{-5}$  for the three different training scenarios. The second trajectory is then used for testing and gets predicted with an MSE of  $3.1 \cdot 10^{-4}$ ,  $5.8 \cdot 10^{-5}$ , and  $1.5 \cdot 10^{-5}$ , respectively. In the following section the first model (model 1) is used to show that the presented approach works well, even for surrogate models with a rather large plant model mismatch.

#### 4.2. Design of the RL-environment based on the rigorous dynamic flash model

The RL environment consists of the rigorous first principles model. The current state of the environment  $\mathbf{s}_k$  is composite of all system states  $\mathbf{x}_k = (p, T, L, F^D, y^D, F^B, x^B)^T_k$  at time  $k$  and the previously applied control action  $\mathbf{u}_{k-1} = (F^F, Q)^T_{k-1}$  at time  $k-1$ .  $x^F$  and  $T^F$  are kept constant. Hence, it is built as  $\mathbf{s}_k = (\mathbf{x}_k^T, \mathbf{u}_{k-1}^T)^T$ . The control action applied to the environment is  $\mathbf{a}_k = \mathbf{u}_k$ . The stage cost  $\ell(\mathbf{s}_k, \mathbf{a}_k)$  of the environment is a composite of three subterms:

$$\ell(\mathbf{s}_k, \mathbf{a}_k) = L(\mathbf{x}_k, \mathbf{u}_k) + r(\mathbf{u}_k, \mathbf{u}_{k-1}) + \epsilon(\mathbf{x}_k, \mathbf{u}_k). \quad (6)$$

$L(\mathbf{x}_k, \mathbf{u}_k)$  is a quadratic cost term, which penalizes deviations of the system states to the setpoints.  $r(\mathbf{u}_k, \mathbf{u}_{k-1})$  penalizes changes in the control inputs, while  $\epsilon(\mathbf{x}_k, \mathbf{u}_k)$  penalizes constraint violations. The terms are defined as follows with the values from Table 1

$$L(\mathbf{x}_k, \mathbf{u}_k) = 10 \cdot (y_k^D - y_{SP}^D)^2 + 1 \cdot (F^D - F_{SP}^D)^2 \quad (7)$$

$$r(\mathbf{u}_k, \mathbf{u}_{k-1}) = \Delta \mathbf{u}_k^T \begin{pmatrix} 1 & 0 \\ 0 & 30 \end{pmatrix} \Delta \mathbf{u}_k \quad (8)$$

$$\epsilon(\mathbf{x}_k, \mathbf{u}_k) = \mathbf{w}_x^T \boldsymbol{\sigma}_{x,k} + \mathbf{w}_u^T \boldsymbol{\sigma}_{u,k}. \quad (9)$$

Table 1: Setpoints (SP), lower bounds (lb), upper bounds (ub) and constraint penalties ( $w_i$ ) for the states and control actions within the environment.

	$p$	$T$	$F^D$	$y^D$	$F^B$	$x^B$	$\dot{Q}$	$F^F$
	bar	°C	mol s <sup>-1</sup>	—	mol s <sup>-1</sup>	—	kW	mol s <sup>-1</sup>
SP	—	—	0.2	0.45	—	—	—	—
lb	0	20	0	0.4	0	0	0	1
ub	1	90	0.5	1	2	1	30	2
$w_i$	20	20	20	20	20	20	250	250

#### 4.3. Parameterized MPC structure for optimal control of the flash separation unit

The structure from (4) is used to learn the optimal control policy. Model 1 from section 4.1 is used to predict future states. The model is kept unchanged. The parameterization occurs solely in the terminal cost  $V_{f,\theta}$ , which is defined as

$$V_{f,\theta}(x_N) = 10^2 \cdot \theta_{11} \cdot (F_N^D - F_{SP}^D)^2 + 10^4 \cdot \theta_{22} \cdot (y_N^D - y_{SP}^D)^2 \quad (10)$$

with initial values of  $\theta_{11} = \theta_{22} = 0$ . The MPC acts subject to the constraints given in Table 1. The considered stage cost is the same as given in equation (6). The prediction horizon is chosen to be  $N = 10$ . A Q-learning update is then conducted at each time instance using a minibatch of  $m = 16$  samples taken from the replay buffer of size 4'096 with a learning rate of  $\alpha_\theta = 10^{-4}$ . The target MPC is directly updated using  $\tau = 1$ .

#### 4.4. Control performance of parameterized MPC

Figure 2 shows the control performance of a benchmark MPC (rigorous model,  $N = 20$ , solid line) compared to the parameterized MPC (section 4.3, dashed line). The figure shows the controlled states in the left half of each subplot and the control actions on the right half. The dotted lines demonstrate the respective setpoints. The left plot compares the control performance of the benchmark MPC and the parameterized MPC before any training took place. This is similar to applying just MPC with the surrogate model. It can be seen that  $y^D$  is not tracked properly by the parameterized MPC. Also, the control input trajectories differ from the benchmark especially for  $F^F$ . However, it provides a very suitable starting point for RL training in contrast to conventional RL with neural networks, for which initialization is critical for performance but very difficult to choose properly. The right plot shows the performance of the parameterized MPC controller after 100 episodes of training. One episode is a closed loop trajectory of 5 s, each consisting of 50 samples. An update is performed after each time step. The setpoints are now both tracked better. Furthermore, also the control trajectories are closer to those obtained with the benchmark controller. The benchmark achieved a closed-loop cost after 5 s of 0.21367, while the parameterized MPC reduces from initially 0.22063 (untrained) to 0.21749 (100 episodes).

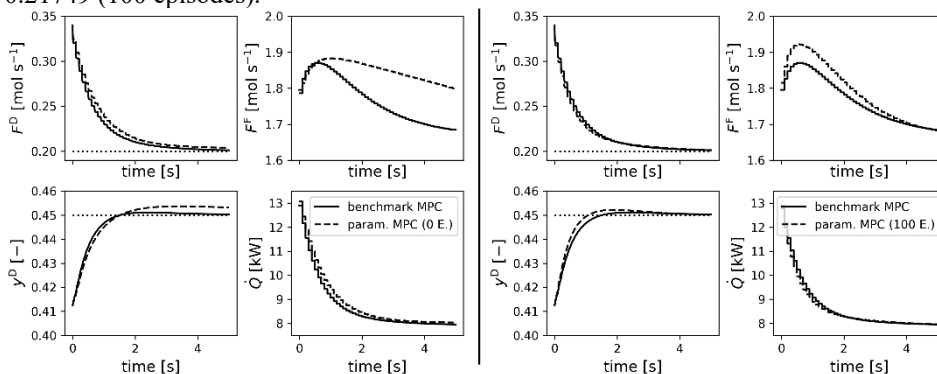

Figure 2. Left: Application of the MPC controller without RL improvements. Right: Application of the RL improved MPC controller. The dotted lines specify the setpoints. 0 E. and 100 E. specify the number of trained episodes.

Both models are also compared with respect to their computation time. The computations were conducted on an intel core i9-10900K CPU, using Python 3.9.13 and the toolbox

do-mpc with CasADi and ipopt. The computation of a single control input for the benchmark MPC took  $0.414 \pm 0.081$  s on average, which is approximately four times the sampling interval of 0.1 s. For the parameterized MPC with the surrogate model, the computation only took  $0.015 \pm 0.003$  s, which is approximately 0.15 times the sampling interval and clearly illustrates the computational advantages of the proposed approach.

## 5. Conclusion

We showed that MPC and RL can be combined to improve controllers in chemical engineering applications. Just by using a simple parameterization of the MPC structure within the terminal cost and a small amount of data, the performance of the controller could be improved to resemble the MPC with a full detailed model, while reducing the computation time by over an order of magnitude.

Future work will include the study of more detailed parametrizations, comparisons with other RL techniques and the extension to more complex control tasks.

## Abstract

Over the past 10 years AVEVA (formerly SIMSCI, Invensys) has been developing a next generation process simulator, with a clean design from the ground up. In this article we will share the experience developing and marketing this software and reflect on how early design ideas have evolved and matured into a commercially available software application. The software is based on a novel concept for setting up, parametrizing, initializing, and solving equation-based simulation models targeting the next generation of process engineers. We will discuss some of the successes and challenges in realizing this next-generation concept. We will furthermore discuss customer reaction and feedback, and how the software has been received in the marketplace.

## 1. Introduction

In recent years, two contributions were published, one from industry Broecker (2021), and one from academia Pistikopoulos (2021), which both highlight the need for process simulation software to consider advances in computing technology as well as modern algorithms and user experience expectations. Both publications highlight the need for open interfaces, enabling cross-domain applications, which combine real-world data with first principles and data-driven models. Broecker points out that future innovation will arise at the intersection and combination of tools, as complex problems demand cross-domain expertise and no tool can fill all needs. This vision of course requires open tools that allow interaction and integration into larger, more complex workflows. There seems to be a consensus that established tools have so far been lacking in this regard.

In their review article, Mitsos et. al (2018) spelled out the following conflict: “[in the petrochemical industry] many of the developed chemical processes are prototypical applications [...]. Often, there is no good business case to justify the implementation of a special solution to a very specific problem class in commercial simulation software”. Further in the article, they lament the limited interaction between software vendors and the industry and the slow adoption of novel academic techniques into commercial software. As a possible solution, they conjecture that third parties could fill the gap of capabilities lacking in commercial tools, but also admit that the limited accessibility of those tools often prohibits the implementation of new process systems engineering methods into an integrated offering acceptable for industrial use. The authors want to address this gap, by discussing a tool that is open for extension and research by academia, yet fit for every-day use by industrial practitioners.

We observe: the world of process engineering is changing fast, and next-generation tools must have an outstanding degree of flexibility and customizability to serve the needs of a future generation of process engineers, to empower them to tackle the various challenges induced by the energy transition and the need to switch to sustainable feedstocks. With this contribution we want to discuss the salient features of one commercial simulation software that was developed from the ground up with extensibility and future use-cases in mind, made possible by strong customer interaction and short development cycles.

## 2. Properties of a Next-Generation Simulator

### 2.1. Overall architecture

To address the needs discussed above AVEVA started work on developing a next-generation process simulator about 10 years ago. The main goal of this project was to create a platform (called AVEVA Process Simulation, further referred to as the software) that would be powerful enough to support all kinds of process engineering, simulation, and design workloads, while also being in line with modern standards of user experience, scalability, and responsiveness. The software is designed to drive the digital transformation in process engineering through lifecycle simulation and a holistic approach, as demonstrated in de Beer (2021).

A central pillar is our modern client/server architecture. In the software, client interactivity is separated from simulation analysis, model instantiation and solving. This design liberates the software from the requirement that both parts are being run on the same machine, enabling scalability and cloud computing.

For the end-user the simulation platform is flexible and can be adapted to changing use cases. This flexibility is mainly provided by an open-equation custom modeling environment powered by an equation-oriented solver. Instead of implementing process equations in subroutines, as sequential-modular process simulators might do, in the software, (nearly) every equation, variable, model and library can be inspected and modified by the end-user. The only exceptions to this are external equation sets, which allow external code to be connected to the platform (see sec. 2.4.). The availability of all equations and variables as first-class objects enables the dynamic restructuring and re-interpretation of the equation system depending on the problem statement. For example, a seamless transition from steady-state to dynamic simulation is supported by the platform, as only the time derivatives need to be handled differently between the solver and the dynamic integrator. Thus, it is possible to go back-and-forth between steady-state and dynamic mode for the same model, without the need to manually adjust equations or specifications.

When developing new modeling capabilities, the development team is using the same tools available to the end-user. Everything in our libraries can be reconstructed by the user as there are no hidden authoring tools, making the software an open and transparent modeling tool. A screenshot illustrating the model editor, for a model describing the heat transfer through a pipe wall, making use of steady-state and dynamic equations side-by-side is given in fig. 1. An example for this extensibility can be found in Bishop (2020), where the author developed a model for a membrane reactor using our software and performed operability studies.

In line with the platform design, thermodynamic calculations and databases are kept separate from the client/server. AVEVA Process Simulation offers a wide set of industry standard thermodynamic routines for equation of states or activity coefficient models, as well as thermodynamic codes for specialized systems (e.g., electrolytes, cryogenic hydrogen, or supercritical CO<sub>2</sub>).

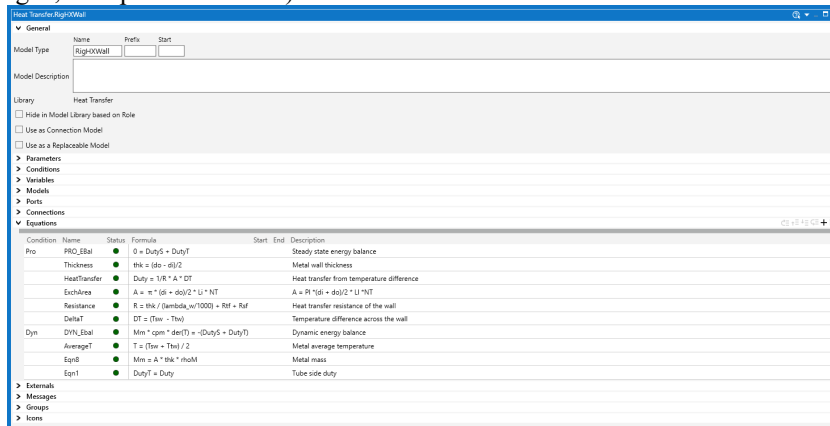

Figure 1: Model equation editor showing steady-state and dynamic equations

## 2.2. Numerics

The numerical engine powering the platform is a general-purpose equation solving system consists of an instantiation algorithm that translates a model into a flat equation system, a block decomposition algorithm that reduces a large equation system into smaller equation systems that can be solved independently, and a solver factory that applies tailored solvers to each of the equation systems. The block decomposition system is based on the graph algorithms of Tarjan (1972) and Dulmage (1958). Each well-specified block is analyzed, and if the convergence criteria are not met, a solver suitable for the block is selected to converge the residuals. If the block decomposition determined that any blocks are independent from each other, as often happens with phase equilibrium equation sets, they can be solved in parallel to reduce execution time.

## 2.3. Interactivity

Over the last years, expectations on interactivity in computer programs have shifted dramatically. Apps and smartphones have reached widespread adoption, which led to an increased demand in application ergonomics. In the past, simulators often followed a four-step procedure: define flowsheet topology, provide specifications, trigger solve and inspect output. Many times, users needed to backtrack when it became apparent that a certain topology would not allow the desired set of specifications, but that fact only became apparent during the inspection of the log files. Today users expect instant response and an exploration-driven user interface where making mistakes is cheap and easy to remedy and information is not hidden deep in nested dialogs. To address this shift in expectations for industrial software, AVEVA Process Simulation supports three paradigms that were quite uncommon in simulation tools so far: solve-as-you-go, undo/redo and a simulation repository.

Empowered by the state-of-the-art algorithms, the simulation building core of the software can identify parts of a flowsheet that have changed after a user interaction and need an update. This results in smaller equation systems to be rebuilt and solved and a very fast response and presentation of results. Likewise, the undo/redo system can undo

changes to parameter and variable values and even impactful operations like optimization runs. In addition to reverting an action, the system uses implicit snapshots of the “state before” to forego the need for an additional convergence pass after undo, resulting in an even faster response. The simulation repository is an abstraction on the file system. Once a simulation is imported from the file system into the repository, it is managed by the software. Any change to the flowsheet is persisted instantaneously (“auto-save”). Combined with undo/redo, this leads to a seamless modeling experience, without the fear of losing data (e.g., caused by a crash of the software).

Together, these three features empower a special way of approaching equation-oriented modeling and simulation that is fundamental to our software: incremental initialization. It is well-known that finding good initial guesses for an equation-oriented simulation is a non-trivial task and crucial in simulators relying on a general equation solver. In the software, the flowsheet is built up one unit operation at a time. By following a few basic rules (fully specify each unit before moving to the next, always have a square simulation with the same number of unknown variables and equations, undo as soon as the solver cannot solve a problem) it is very easy, also for inexperienced users, to bootstrap large-scale process flowsheet models, even with recycle loops. At the time when a recycle needs to be closed, the returning stream already is at a converged open-loop solution, so convergence is often quick and robust. In addition, a snapshot of the current simulation can be taken, which allows the user to re-initialize to a good solution.

#### *2.4. Extensibility*

As mentioned before the software is designed as an open platform, ready to be extended to fit the user’s need in process simulation. To support those use cases, the platform offers two main entry points for extension beyond the already flexible open-equation modeling framework.

As mentioned briefly in section 2.1 the software offers an external equation interface which is part of a software development kit (SDK). With the SDK users can provide custom calculations that cannot be expressed in algebraic form (e.g., thermodynamic algorithms, machine-learning models). Users need to provide callback methods that return equation residuals and partial derivatives to fit into our equation-oriented solver framework, but how they calculate those values is fully under their control. In this way it becomes possible to extend modeling to non-smooth equations, conditional logic, or algorithmic structures. To exemplify the power of the SDK, the default thermodynamic methods provided by the software are implemented using the external equation toolkit, keeping in line with our philosophy that any platform user should be able to use the same tools that our developers are using.

The second extension point is the scripting interface. As a side effect of the client/server architecture, any action that can be performed in the GUI client is accessible as a function call for a scripting client. The scripting interface is bundled with the product as a Python module and a .NET library. Any clients, such as Excel/VBA, Python scripts or full native desktop applications can automate our software to implement complex computing workloads such as structural optimization, training of surrogate models and uncertainty analysis.

### **3. Experiences in Developing a Next-Generation Simulator**

As part of the go-to-market strategy, the software benefitted greatly from a customer-centric approach. Instead of developing against an internally defined roadmap, customers were engaged early on and asked to provide feedback on the priority of development activities. Instead of our treating us as a regular software vendor, formal partnerships allowed both parties to synchronize migration and development activities, so that important features were made available when they were needed. We have mapped our target audience against archetypal personas, representing a wide range of users, including students, junior/senior design engineers, thermodynamicists, modelling experts and control engineers. When new features are proposed, we make sure to consult our list of personas to make sure the functionality fits with their needs.

The agile software development process underlying the development activities made it possible to release incremental improvements early and rapidly. This in turn allowed customers to give feedback quickly so that features could be fine-tuned while still in development resulting in a shorter turnover time for new features.

The users of the software are very engaged and are given ample opportunities to be heard, from user meetings over advisory boards to direct meetings with the development team in voice-of-customer sessions. The level of trust resulting from this close contact, allowed developers to get first-hand feedback from real users, a crucial requirement for our agile process. Some of that feedback was expected, some was surprising. In the following, we want to share the aspects that were most important to us.

Not surprisingly, adapting to the equation-oriented paradigm was a challenge to users accustomed to sequential-modular simulators. The benefits coming from it, e.g., near instant results and being able to select any variable to be specified or calculated were highly regarded, but especially finding the root cause of an unconverged simulation proved to be very hard for many users. Interestingly, we found out that younger users, who were not as used to the sequential-modular paradigm, found it easy and intuitive to learn our software, whereas experienced engineers struggled more often.

To address this feedback, we greatly expanded the information about the solution that was reported to the user, in the form of log files and small badges shown over flowsheet icons. Whenever possible this information was translated from the mathematical domain into the process engineering domain. For example, instead of reporting a singular solution, the software reports that for a certain variable no unique value can be determined and that a different specification set should be tried. In another example, instead of just reporting degrees of under- or overspecification, the system visually marks potential variable candidates that are part of the under- or over-specified equation sets. Our goal is to provide a list of small, actionable suggestions that could lead to a solution of the problem instead of a general “solve failed” message.

A well-liked feature is the customizability of the flowsheet canvas. The software supports variable references to be added next to unit operations, which allow variables to be displayed and changed without the need to open a new dialog. Similarly, equations can be added to the flowsheet, so that custom design specifications can be shown next to the process equipment. This feature enables customers to document their flowsheets and

simulations within the software itself and reduces the need for external explanations, improving reuse and collaboration.

#### 4. Conclusion

In this article, we have shared the fundamental architecture and design philosophy for our next-generation process simulation tool. Our conclusion is that the next generation concepts envisaged at the outset have proven viable in practice and are able to sustain an industrially relevant and capable process simulator. We base this conclusion upon customer feedback, both from industry and academia (research and teaching). Interactivity is a huge factor in attaining a better understanding of a process and is appreciated by all customers.

AVEVA Process Simulation is reaching wider adoption in the chemical industry and a feature maturity that will allow the software to expand into modern usage scenarios, such as design optimization or uncertainty quantification. We therefore think that the next generation of process engineers can look forward to new ways of working with process simulation, where the workflow is driven more by the goals of the engineer and less by the algorithms of the software.

## **Abstract**

In Multivariate Statistical Process Monitoring (MSPM), a large number of measured variables is monitored online usually in a latent variable space. To this end, various linear/nonlinear, Gaussian/non-Gaussian, and static/dynamic methods have been proposed. While implementations of deep learning methods in MSPM are frequently seen nowadays, less emphasis is given to unsupervised nonlinear manifold learning (ML) methods, such as Isomap. It is important to note that ML takes the geometry of the data into consideration while reducing dimensions, hence may have an advantage, particularly, over Kernelized methods. However, requirement of approximations for out-of-sample (test) points renders ML methods less practical. To remedy this issue, we have recently proposed independent component analysis of polynomial approximation to Isomap embeddings coupled with principal component analysis (ICA<sub>plso</sub>-PCA) method, and showed that fault detection and isolation performances are drastically improved compared to traditional methods. In the current study, we include lagged process measurements in ICA<sub>plso</sub>-PCA, i.e. dynamic ICA<sub>plso</sub>-PCA (dICA<sub>plso</sub>-PCA), and show that fault detection rate is further increased, and more robust with respect to number of selected components compared to various methods on Tennessee Eastman plant.

**Keywords:** Fault detection, dynamic PCA, ICA, Manifold Learning, Tennessee Eastman.

## **1. Introduction**

Occupational and process safety issues are nowadays more of concern than ever, hence fault detection, isolation, identification and prognosis have recently gained utmost importance. To achieve this aim, Multivariate Statistical Process Monitoring (MSPM) is one of the most frequently employed methods mainly due to i) difficulties in obtaining accurate mechanistic mathematical models for chemical industries, and ii) developments in statistical and machine learning methods making it possible to extract information from high dimensional, nonlinear and collinear process variables (Ji and Sun; 2022). Though Principal Components Analysis (PCA) and Projection to Latent Structures (PLS) are historically the benchmark methods for MSPM (Kourti and MacGregor; 1995), both methods are known to suffer from various limitations, such as extracting only static relations, and relatively poor performance under nonlinear process dynamics and non-Gaussian variable distributions. Various combinations of Kernel methods (Lee et al., 2004) and Independent Components Analysis (ICA) (Kano et al., 2003; Lee and Qin, 2007) are commonly employed to overcome these limitations. Furthermore, applications

of deep Artificial Neural Network (ANN) models are shown to increase the fault detection performance in MSPM applications (Qian et al., 2022).

With the new millennium, there has been a surge of research activity in manifold learning, such as Isomap (Tenenbaum, de Silva, and Langford, 2000), and locality preserving projections (LPP) (He and P. Niyogi, 2003), and various applications have been implemented for MSPM purposes. While manifold learning methods, unlike Kernel and ANN methods, offer the capability of determining the geometry of a low-dimensional manifold, on which the process data is deemed to lie, nonlinear manifold learning methods lack explicit mapping function to transform the future query points into embedding space. A number of solutions have been proposed to tackle this issue. One solution method is to approximate the nonlinear embedding using a linear transformation in the optimization objective function (Luo, 2014; Miao, Song, and Shen, 2015). Another method is to approximate the nonlinear transformation using various learners, such as ANN (van der Maaten, 2009). Recently, we have proposed ICA of polynomial approximation to Isomap embeddings coupled with PCA (ICA<sub>pIso</sub>-PCA) method, in which embedding approximations are performed using a high order (regularized) polynomial, rendering both high fault detection rates, and contribution plots with highly reduced smearing effect (Alakent, 2022). In the current study, we aim to investigate whether fault detection rate can further be improved including lagged process measurements; the resulting method is named dynamic ICA<sub>pIso</sub>-PCA (dICA<sub>pIso</sub>-PCA). Applications on Tennessee Eastman simulation plant show that fault detection rates of dICA<sub>pIso</sub>-PCA are generally higher compared to those of traditional and state-of-the-art MSPM methods, and ICA<sub>pIso</sub>-PCA. The most significant advantage of the suggested dICA<sub>pIso</sub>-PCA method is shown to be its high fault detection accuracy over a wide range of number of components selected, making it easier to construct a reliable monitoring model without using a very large dataset.

## 2. Dimensional Reduction Tools used in SPM

### 2.1. PCA

The aim in PCA is to determine linear projections of the original coordinates with the highest variance. Given the mean-centered (and scaled) data matrix  $\mathbf{X} \in \mathbb{R}^{N \times D}$ , where  $N$  and  $D$  correspond to number of samples and process variables, or features, respectively, eigenvalue decomposition of the covariance matrix  $\mathbf{C}$  yields the loading matrix  $\mathbf{P} \in \mathbb{R}^{p \times p}$ , on which  $\mathbf{X}$  is projected to obtain  $\mathbf{T} \in \mathbb{R}^{N \times D}$  scores matrix:

$$\mathbf{C} = \mathbf{X}^T \mathbf{X} / (N - 1) = \mathbf{P} \mathbf{\Lambda} \mathbf{P}^T \quad (1)$$

$$\mathbf{T} = \mathbf{X} \mathbf{P} \quad (2)$$

Usually, the first  $d$  ( $< D$ ) principal components (PCs) with the highest eigenvalues (variances) are used to construct a lower dimensional subspace, in which essential process variability is deemed to be captured:

$$\mathbf{T}_d = [\mathbf{t}_1 \ \mathbf{t}_2 \ \dots \ \mathbf{t}_d] = \mathbf{\Psi} \mathbf{P}_d = \mathbf{\Psi} [\mathbf{p}_1 \ \mathbf{p}_2 \ \dots \ \mathbf{p}_d] \quad (3)$$

### 2.2. ICA

The generative model of ICA is  $\mathbf{x} = \mathbf{A} \mathbf{s}$ , in which  $\mathbf{s} \in \mathbb{R}^m$ , consisting of  $m$  independent components each with unit variance, and  $\mathbf{x} \in \mathbb{R}^D$  is a zero-mean random variable vector, and  $\mathbf{A} \in \mathbb{R}^{D \times m}$  is the mixing matrix. A demixing matrix  $\mathbf{W} \in \mathbb{R}^{m \times D}$  is to be determined:

$$\mathbf{Y} = \hat{\mathbf{S}} = \mathbf{W} \mathbf{X} \quad (4)$$

The problem stated above may be solved via Fast-ICA procedure, in which each vector in  $\mathbf{W}$  and  $\mathbf{Y}$  is determined iteratively (Hyvärinen, Karhunen and Oja, 2001). Similar to PCA, a reduced  $d$  ( $< D$ ) number of ICs ( $\mathbf{W}_d$ ) may be used. However, ranking ICs is not straightforward as that in PCA, since variance of each IC is constrained to be equal to unity. In the current study, ranking ICs is based on the negentropy of  $\mathbf{y}$  values.

### 2.3. Isomap

In Isomap, sample points are assumed to lie on a smooth manifold, and approximate geodesic distances, i.e. distances measured via shortest tracks on the manifold, are used to represent pairwise sample distances. The K-Isomap method involves connecting  $K$  nearest neighbors ( $K=5$  used currently) to each sample point, and storing the squares of the geodesic distances, determined via summing the distances along the shortest paths, in a  $\mathbf{S} \in \mathbb{R}^{N \times N}$  matrix. Then, eigenvalue decomposition is employed on  $\mathbf{S}$  mean-centered via  $\mathbf{H} = \mathbf{I} - \mathbf{1}\mathbf{1}^T/N$ , in which  $\mathbf{I}$  is the identity matrix, and  $\mathbf{1} = [1 \ 1 \ \dots \ 1]^T \in \mathbb{R}^N$ :

$$-\frac{1}{2}\mathbf{H}\mathbf{S}\mathbf{H} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}^T \quad (5)$$

Similar to PCA, the eigenvalues are ranked in decreasing order, and the largest  $d$  eigenvectors of  $\mathbf{V}$  are used to construct the Isomap coordinates:

$$\mathbf{Y} = \mathbf{\Lambda}_d^{1/2}\mathbf{V}_d^T \quad (6)$$

Unlike  $\mathbf{P}_d$  and  $\mathbf{W}_d$  in PCA and ICA, respectively, Isomap does not yield an explicit transformation matrix that may be used for embedding novel samples; hence, approximations are required to determine the Isomap coordinates of future points.

### 2.4. Dynamic PCA (dPCA)

PCA is based on the assumption of time-independent samples, that is easily violated in industrial processes. In order to include the autocorrelation in process measurements in constructing the PC space, dPCA was proposed (Ku, Storer and Georgakis, 1995). The dPCA involves augmenting the features matrix  $\mathbf{\Psi}$  using the current (sample  $n$ ) and  $\tau$  time lagged (samples  $n-1, n-2, \dots n-\tau$ ) measurements as follows:

$$\mathbf{\Psi} = [\mathbf{X}(n) \ \mathbf{X}(n-1) \ \dots \ \mathbf{X}(n-\tau)] \in \mathbb{R}^{(N-\tau) \times D(\tau+1)} \quad (7)$$

The rest of dPCA involves applying eigenvalue decomposition on the covariance matrix of  $\mathbf{\Psi}$  and employ traditional PCA, as in Eqns. (1-3). The dPCA method was shown to improve fault detection performance since deterioration of the time-dependence of the variables could also be monitored. Including time lagged measurements in other dimension reduction tools, such as dynamic ICA (dICA), have been widely used.

## 3. Principal Fault Detection Indices in SPM

Based on the traditional application of PCA,  $T^2$  and  $SPE$  are the most commonly used surrogate variables (indices), which measure the proximity of the test samples to origin of normal operation in the reduced subspace, and the magnitude of the residual component of the test sample, unaccounted by the reduced space, respectively.

$$T^2 = \sum_{i=1}^d \frac{t_i^2}{\lambda_i} = \sum_{i=1}^d \frac{(\mathbf{x}^T \mathbf{p}_i)^2}{\lambda_i} \quad (8)$$

$$SPE = \|\mathbf{x} - \mathbf{P}_d^T \mathbf{t}\|_2^2 \quad (9)$$

In Eqn. 8, the coordinates of the query sample in the original (mean-centered) and projected spaces are shown with  $\mathbf{x}$  and  $\mathbf{t} = [t_1 \ t_2 \ \dots \ t_d]^T$ , respectively, while  $\lambda_i$  denotes the variance of scores of normal training data. In Eqn. 9, the squared norm of the residuals of the query point is determined. Phase I of MSPC consists of projecting historical normal operation data to a lower dimensional space, followed by determining the control limits

(CLs) of surrogate variables, i.e.  $T_{lim}^2$  and  $SPE_{lim}^2$ , at a specific Type-I error rate. Phase II consist of checking whether the surrogate indices of novel measurements ( $T^2$  and  $SPE^2$ ) fall within CLs.

#### 4. The Proposed Method: dICA<sub>pIso</sub>-PCA

We recently proposed ICA<sub>pIso</sub>-PCA, in which Isomap embeddings are approximated using ridge regression of fourth to sixth ordered polynomials, followed by ICA and PCA (Alakent, 2022), and, in the current study, we aim to improve the fault detection capability of ICA<sub>pIso</sub>-PCA via addition of lagged variables. The dICA<sub>pIso</sub>-PCA starts with employing PCA and Isomap separately on  $\Psi$ , which is the features matrix consisting of time lagged measurements (see Eqn. 7), and all the PC scores and the first  $I_p$  ( $I_p=8$  used currently) embedding coordinates are stored. Then, the following regressor matrix  $\Psi^*$  is formed:

$$\Psi^* = [\Psi \quad (\Psi)^{o2} \quad \dots \quad (\Psi)^{or}] \in \mathbb{R}^{(N-\tau) \times D\tau(\tau+1)} \quad (10)$$

Here,  $(\cdot)^{oa}$  is used to raise the power of each element in the matrix to  $a = 1, 2, \dots, r$ , and  $r$  is taken to be equal to six. Taking  $\mathbf{F} \in \mathbb{R}^{N \times I_p}$  as the matrix of Isomap embeddings, ridge regression ( $\alpha = 10^{-4}$ ) is employed to determine the approximated Isomap embeddings:

$$[\hat{f}_1 \hat{f}_2 \dots \hat{f}_{I_p}] = \Psi^* (\Psi^{*T} \Psi^* + \alpha \mathbf{I})^{-1} \Psi^{*T} \mathbf{F} \quad (11)$$

Highest linearly correlated PC scores with Isomap approximations are replaced by each of  $[\hat{f}_1 \hat{f}_2 \dots \hat{f}_{I_p}]$ , i.e. PC scores, most similar to high variance approximated Isomap embeddings, are replaced by these approximations, yielding a “nonlinear scores” matrix of reduced dimensions of the training data,  $\mathbf{T}_{nl} \in \mathbb{R}^{(N-\tau) \times D'}$ ,  $D' \geq D(\tau + 1)$ . Then, ICA and PCA are sequentially employed on  $\mathbf{T}_{nl}$ , i.e. application of ICA yields the following.

$$\hat{\mathbf{S}} = [\hat{s}_1 \hat{s}_2 \dots \hat{s}_N] = \mathbf{W} \mathbf{T}_{nl}^T \quad (12)$$

Here,  $\mathbf{W}$  is the demixing matrix in Eqn. (4), and used to transform the nonlinear (correlated) scores matrix to independent scores  $\hat{\mathbf{S}}$ . The IC scores are computed via  $I^2 = \hat{\mathbf{S}}^T \hat{\mathbf{S}}$ , and 99% CL for  $I^2$  indices ( $I_{lim}^2$ ) is computed using kernel density estimator. The  $I^2$  value of a new query point is compared with  $I_{lim}^2$ , and out-of-control alarm is given if  $I^2 > I_{lim}^2$ . The same procedure is repeated with  $T^2$  and  $SPE$  indices, which are obtained via employing PCA on the residuals of the nonlinear scores, unexplained by the ICA. For a more detailed explanation of the procedure, please refer to Alakent (2022).

#### 5. Results and Discussion

We employed dICA<sub>pIso</sub>-PCA on the simulated Tennessee Eastman plant (TEP) (Downs and Vogel, 1993). The main products in TEP are G and H with the purged byproduct F from a feed consisting of reactants A, C, D, E and inert component B. In our study, data from 33 process variables (excluding concentration measurements) sampled at 3 min intervals were used. Normal operation data is comprised of 960 samples, while test data consists of one normal operation, and 21 different faults of 960 samples (Chiang, Russell, and Braatz, 2000). The process diagram, variables and fault descriptions of TEP, omitted here for space considerations, can be found in the sources given in the References. We compared Missed Detection Rate (MDR) values, i.e. percent of faulty samples deemed to be normal, of dICA<sub>pIso</sub>-PCA with the best results obtained from dynamic and/or Kernel methods, such as KICA, dPCA, dICA, dICA<sub>PCA</sub> and dKPCA. CLs of the monitoring indices in all methods were adjusted to yield a false detection rate of 0.01 (rate of false signals for normal query points) in order to render an unbiased comparison of MDR values (Mutlu and Alakent, 2019). We used two time lags in all dynamic dimension

reduction methods. To save space, we here show only the minimum MDR obtained from all monitoring indices in Table 1. We included a state-of-the-art method, namely Global Local Preserving Projection (GLPP), which utilizes the NPP to capture both the local and global structure of data (Miao, Song and Shen, 2015).

In Table 1,  $dICA_{plso}$ -PCA gives the smallest average MDR, significantly smaller than  $ICA_{plso}$ -PCA, indicating that including time-lagged measurements improves fault detection rate of our method. Looking in more detail,  $dICA_{plso}$ -PCA yields the top and second best performances in 14 and the remaining 7 faults, respectively. On the other hand,  $dGKPP$  has the best and second best performance in 9 and 6 of the faults, respectively, while exhibiting a moderate performance in the remaining 6 faults, showing a poorer fault detection capability compared to that of  $dICA_{plso}$ -PCA.

Table 1. MDRs of various MSPC models against 21 faults in TEP.

## Abstract

In industry, the processes often consist of several subsystems with a common constraint, for example, a shared resource. This paper considers the problem of steady-state real-time optimization (RTO) for a subsea gas-lifted oil production network with multiple wells and constrained access to shared gas-lift supply. Such problems can be solved by a centralized numerical optimization, which can be computationally expensive. To avoid the use of numerical optimization, one can utilize either online primal or dual decomposition instead, where the problem is converted into a feedback-based problem. The main benefit of primal method is that it distributes local setpoints which complies with primal feasibility, however, the dual method is more general. Both the primal and dual methods allow for a distributed implementations. The dual method is more general in terms for allowing for many constraints, but as shown for the simulations with uncertainty and measurement noise, the primal method may give better dynamic constraint satisfaction.

**Keywords:** Distributed optimization, Feedback control, Production optimization.

## 1. Introduction

Industrial process often consists of several subsystems with a common constraint, for example, a shared resource. Problems like this can be decomposed and solved using distributed optimization. However, this can be computationally expensive as it solves several rounds of numerical optimization problems online at each sample time. This can be addressed by indirectly moving the optimization problem into the control layer (Morari et al. (1980)). Such problems are known as feedback-optimizing control, which can be implemented using simple tools such as Proportional-Integral-Derivative (PID) controllers.

In our previous work (Dirza et al., 2022(b)), we have experimentally validated a recently developed method of feedback-optimizing control called distributed feedback-based RTO. This method is developed based on dual decomposition and optimally handles steady-state changes in active constraints. However, the constraints are controlled in a slower time scale by updating the dual variables. This leads to the need for significant “back-off” strategy, which could lead to profit loss in the long run. To eliminate or reduce the “back-off,” Dirza et al. (2022(a)) introduces an alternative distributed feedback-optimizing control based on online primal decomposition using feedback and constraint controller(s) which distribute local setpoints without violating the common constraint to avoid or minimize use of a “back-off” strategy.

In this paper, we provide a comparative analysis of the two distributed feedback-optimizing control approaches. The model we consider represents our lab-scale experimental rig that consider uncertainty and measurement noise. The rig emulates a subsea oil production network with gas-lift rate as the manipulated variables. The experimental results will be provided as the future work.

## 2. Feedback-optimizing control

Consider the optimization problem for the entire system built by a network of  $N$  subsystems. We assume each subsystem is optimized locally and that we always have active constraint. Thus, the steady-state optimization problem can be expressed as follows,

$$\min_{u_i, \forall i \in N} J_N = \sum_{i \in N} J_{N,i} \quad (1a)$$

$$s. t. \quad \mathbf{f}_i(\mathbf{x}_i, \mathbf{u}_i, \mathbf{d}_i) = 0 \quad i \in [1, N] \quad (1b)$$

$$\sum_{i \in N} g_i(\mathbf{x}_i, \mathbf{u}_i, \mathbf{d}_i) - g^{max} = 0 \quad (1c)$$

where  $\mathbf{x}_i$ ,  $\mathbf{u}_i$  and  $\mathbf{d}_i$  denote the vector of states, inputs and disturbances respectively. Constraint (1b) is related to the entire system model, and (1c) is an equality constraint.

### 2.1. Distributed Feedback-Optimizing Control using Online Primal Decomposition

To solve problem (1) using simple feedback controller, it is possible to construct a method based on online primal decomposition (Dirza et. al (2022(a))). The main motivation for this method is that we want to achieve optimal steady-state operation in a distributed manner, with minimal dynamic constraint violation and without demand of solving numerical optimization problems online. By introducing an initial value of local constraint  $g_i^{sp}$ , (1c) can be written as

$$g_i(\mathbf{x}_i, \mathbf{u}_i, \mathbf{d}_i) - g_i^{sp} = 0 \quad i \in [1, N] \quad (1d)$$

$$\sum_{i \in N} g_i^{sp} = g^{max} \quad (1e)$$

instead. As long as (1e) is satisfied, primal feasibility is guaranteed. Each subproblem estimates local Lagrange multipliers, which is used in central constraint controllers. These controllers update the setpoints iteratively, where the goal is to provide setpoints that satisfy the primal feasibility. In this paper we assume that the constraint is always active, therefore we have two types of approaches of updating the local setpoints. To ensure that (1e) is satisfied, one of the local setpoints is updated as follows,

$$g_N^{sp,k+1} = g^{max} - (g_1^{sp,k+1} + \dots + g_{N-1}^{sp,k+1}) \quad (2)$$

This is called the compensator subsystem, and the objective is to ensure primal feasibility. For the remaining subsystems,  $i = \{1, \dots, N-1\}$ , the local setpoints is updated by

$$g_i^{sp,k+1} = g_i^{sp,k} + K_{i,i}(-\lambda_1^k + \lambda_N^k) \quad (3)$$

We may use integrating controllers with integral gain  $K_{i,i} = \frac{1}{K_i(\tau_{c,i})}$ , where  $K_i$  is the step response gain and  $\tau_{c,i}$  is the closed-loop time constant. However, a proportional integral (PI) controller can also be used. The local Lagrange multipliers,  $\lambda_i$ , can be estimated

$$\lambda_i = -\nabla_{u_i} \hat{J}_{N,i} \left( \nabla_{u_i} \hat{g}_i(\mathbf{x}_i, \mathbf{u}_i, \mathbf{d}_i) \right)^{-1} \quad (4)$$

Where  $\nabla_{u_i} \hat{J}_{N,i}$  and  $\nabla_{u_i} \hat{g}_i$  are the estimated gradient of local cost and local setpoints respectively. In figure 2.1 the online primal decomposition framework is illustrated. The central constraint controllers, which contains both normal and compensator subsystems,

provide new set points for the local constraints. As the constraints always are active, these set points are considered as inputs to the subsystems. When there is a presence of disturbance, we can use the plants current information to estimate the current state and parameters by implementing a local dynamic estimator, for instance Extended Kalman Filter (EKF). By applying the inputs, estimated states and parameters, we can estimate cost gradient as well as constraint gradient to compute the local Lagrange multipliers. The multipliers are then implemented in the central constraint controller to calculate the new set points.

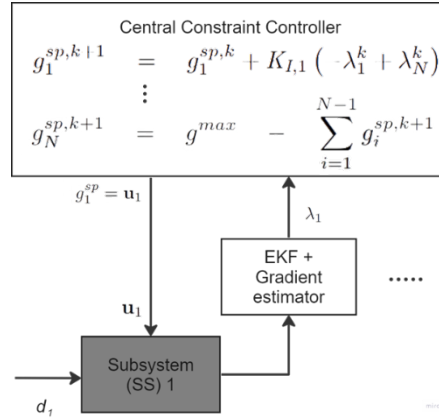

Figure 2.1 The online primal decomposition control structure.

### 3. Simulation descriptions

#### 3.1. Simulation model setup

To emulate the subsea gas-lifted oil production system, we use a model created in MATLAB R2021a based on a lab-scale experimental rig from a paper by Matias et al. (2022) and has been tested and used in earlier papers related to the lab-rig. It is implemented with noise similar to what is expected from the lab-rig. The reservoir section of the model is implemented by valve openings  $\mathbf{p} = [\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3]$  which determine the liquid flow. These valves represent the disturbances from the reservoir. In the MATLAB model the gas-lift flow controllers are given  $\mathbf{u}_i$  as setpoints. They are implemented as a 5 second delay plus input noise to simulate controller action instead of coding the actual controllers. The setpoint controllers in the central constraint controller are integral controllers tuned using SIMC tuning rules (Skogestad (2003)).

#### 3.2. Optimization problem setup

The objective of the optimization problem in this model setup is to maximize the liquid flow rate, which equals the sum of the liquid production of the three wells, with a limited amount of gas-lift injection, which is input shared constraint. Considering problem (1). the economic objective can be expressed as below,

$$J(\mathbf{u}, \mathbf{p}) = \sum_{i=1}^3 f_i(u_i, p_i) = -20Q_{l,1}(u_1, p_1) - 25Q_{l,2}(u_2, p_2) - 30Q_{l,3}(u_3, p_3) \quad (5)$$

where  $Q_{l,1}$ ,  $Q_{l,2}$  and  $Q_{l,3}$  are the produced liquid flow rates of well 1, 2 and 3 respectively. We assume different values of the hydrocarbon flows as shown in eq. 6, to illustrate how different values affect the behavior of the subsystems. The input vector is defined as  $\mathbf{u} = [Q_{gl,1}^{sp} \quad Q_{gl,2}^{sp} \quad Q_{gl,3}^{sp}]^T$  where  $Q_{gl,1}^{sp}$ ,  $Q_{gl,2}^{sp}$  and  $Q_{gl,3}^{sp}$  are the gas-lift set points from the central controller of well 1, 2 and 3 respectively. In addition, the reservoir valve  $\mathbf{p}$  is time varying.

#### 3.3. Comparative method

We consider our previous work, distributed feedback-based optimization with dual decomposition, to compare with primal decomposition. The implemented dual decomposition method is based on Dirza et al. (2022(b)) and Krishnamoorthy et al. (2021). In figure 3.1 the implemented dual decomposition framework is shown.

#### 4. Results and Discussion

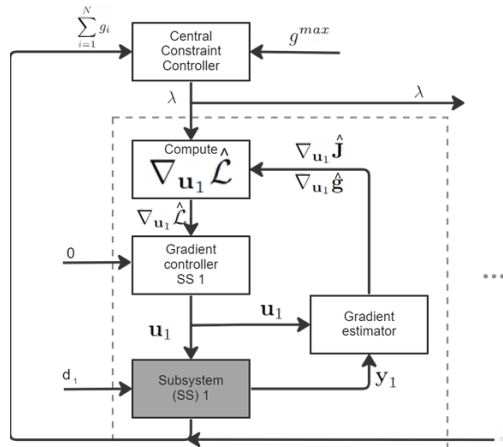

Figure 4.1 shows the disturbance in this simulation, which corresponds to the reservoir valve openings  $\mathbf{p}$  in the lab-rig model. The first disturbance occurs when  $p_1$  gradually decreases from  $t = 6$  to  $t = 12.5$  min. During this interval, we expect the gas-lift injection in well 1 to decrease, and redistribution of the gas to the other wells. The second disturbance occurs when also  $p_3$  gradually decreases from  $t = 14$  to  $t = 18$  min. As before, we expect that the gas-lift injection rate in well 3 will go down. At the same time, we expect the other wells will gain a higher gas-lift injection. The third and fourth disturbance occur from  $t = 21$  to  $t = 24.5$  and  $t = 28$  to  $t = 34.5$  respectively. During this time  $p_3$  and  $p_1$  are gradually increased back up to the initial values. This is because we want to see how the controllers behave for both decrease and increase in the disturbance.

In this paper subsystem 3 has been used as the compensator for the primal decomposition. This subsystem was chosen because it has the highest gain magnitude, which results in most profit for cases with active shared constraint.

In figures 4.2 – 4.7 we compare the simulation results from primal decomposition and dual decomposition. The calculated input setpoints are shown in figure 4.2, the actual gas-lift flow rate will deviate slightly from the setpoints due to the implemented measurement noise in the model. Another cause is how the gas flow rate controllers are implemented in the model, which is described in section 3.1.

**Figure 4.1** Disturbance profile during the simulation.

**Figure 3.1** Block diagram of dual decomposition control structure for one well. The area within the dashed gray box is duplicated  $N$  times. For a more detailed version the reader is referred to Dirza et al. (2022b).

**Figure 4.2** The gas-lift flow rate setpoint  $\mathbf{u}^{sp} = Q_{gl,i}^{sp}$  of every well due to disturbance from the simulation.

In figure 4.2 and 4.3 we see that the dual control is responding slower to the disturbances than the primal control for correcting the gas-lift setpoints. This is a consequence of the time-scale separation between the central controller and the gradient controllers needed in the dual structure (Dirza et al (2022b)).

**Figure 4.3** The constraint satisfaction of both primal and dual. There is a magnifying plot in time window 5 to 6.5 min showing only constraint satisfaction for primal.

Figure 4.3 shows the constraint satisfaction. As expected, the Primal decomposition performs much better than the dual decomposition here. This is because the compensator system, subsystem 3, "absorbs" the deviations from the constraint. The absorbing ability comes from how the compensator set point is calculated, see eq. 2, and is the reason for the primal decomposition's capability to maintain the active constraint. In terms of what this means for the operation, with the use of primal decomposition we can run the system without any significant back-off and remain feasible at all times. On the other and, for the dual decomposition we must implement back-off, especially from  $t = 21$  when the disturbances start to increase again.

**Figure 4.4** Local Lagrange multipliers for primal decomposition.

**Figure 4.5** Lagrange multiplier for dual decomposition

Figure 4.4 depicts that the local Lagrange multipliers for Primal Decomposition converge to the same value. Figure 4.5 show the Lagrange multiplier for the dual decomposition. We can observe that the multiplier converges slower and is smoother for this method. This is because the central controller for dual decomposition operates on a slower timescale. When the Lagrange multiplier converges around  $t = 3.5$  we can see that the active constraint is controlled almost as good as for the Primal case. It is also worth to notice that the Lagrange multipliers converges to the same value for both Primal and Dual.

To analyze the optimization performance of primal and dual decomposition, we compare the profit obtained by the two methods with a naive approach, where it is considered fixed inputs,  $\mathbf{u}_i = Q_{gl}^{max} / 3$ . The naive approach represents the case where no information is available, therefore, the best approach is to divide the available gas equally among the

**Figure 4.6** Total liquid flow of the system

**Figure 4.7** Instantaneous profit compared to naive approach.

wells. This additional approach is used as benchmark to show how primal and dual decomposition compares to not do any optimization at all. To display the performance, we plot the difference in percentage between the instantaneous profit of primal/dual and the naive approach. The difference is calculated as  $J_{diff} = \frac{J - J_{naive}}{J_{naive}} \cdot 100$ , where  $J$  is the profit of the method of interest and  $J_{naive}$  is the profit of the naive approach. Figure 4.7 shows that primal is more profitable than dual until  $t = 21$  min, after this dual appears to be favorable. However, in figure 4.3 we see that after  $t = 21$  dual does not achieve primal feasibility and therefore the profit here is not viable.

## 5. Conclusion

In this work, we have done simulation with uncertainty and measurement noise to compare feedback-based real-time optimization with online primal and dual decomposition. Based on the results we can conclude that primal decomposition is able to effectively ensure primal feasibility for separable systems with an active shared input constraint. It performs better than dual decomposition in this aspect, mainly because of the timescale difference of the central constraint controllers. This significantly reduces the need for any significant back off, which results in more profitable operations. While primal ensures constant feasibility, it is less general than dual. As the continuation of this work, we consider obtaining the experimental result, implementing dual with override and develop a primal structure able to switch between active constraints.

## Abstract

This paper presents a superstructure model of mid to long-term biofuel production systems in Austria and determines the optimal configurations that simultaneously satisfy the profit maximization and environmental impact minimizations. A Linear Programming (LP) mathematical model formulation is developed based on data collected from different studies on the biofuel production process. The superstructure-based model considers the availability of Austrian second-generation feedstock, conversion technologies, and final products and by-products. The economic objective function considers the total net profit. The environmental objective function considers the overall environmental impact measured through the Prospective life cycle assessment. The multi-objective model is solved in GAMS software using the  $\epsilon$ -constraint method. The results demonstrate the solution for minimum Environmental Impact is zero and profit also zero which means nothing is produced then the model solved for maximum profit which is 284 M€/Year and an overall Environmental Impact is 0.67 Mt of CO<sub>2</sub>-Eq.

**Keywords:** Biomass, Biofuels, Prospective Life Cycle Assessment (PLCA), Superstructure, Optimization.

## 1. Introduction

Renewable energy resources are emerging as an attractive option for ensuring future energy security around the world. Biomass has been demonstrated to have the potential for fulfilling energy and chemical needs as a good alternative to petroleum because of its rising prices and uncertain availability. There has been a lot of concern about the sustainability of several first-generation biofuels, which has led to discussions about the possibility of producing biofuels from non-food crops, known as second-generation biofuels (Sharma et al., 2013). Second-generation biofuels offer many potential benefits, such as converting waste oils into fuel, reclaiming abandoned land and reducing food crop competition. Also, second-generation feedstock made from locally available sources can be very beneficial to rural and emerging regions of a country's economy. A high yielding feedstock ensures a reasonable price for commercial scale biofuel production. This is a very important aspect of feedstock selection. The benefits of biomass over other renewable energy sources are that it can be stored for long periods of time until needed and that it is an excellent alternative to liquid fuels in today's transportation system. Fuels obtained can be blended to replace classic petroleum-based fuels, or used as (without blending) in existing vehicles (Kowalski et al., 2022).

Biofuels are rapidly gaining interest in society and policies for secure, sustainable, and circular economy concepts, and thus designing and optimizing the entire biorefinery value chains from various biomass feedstock types to biofuel production and end-use has become a significant research challenge (Yue et al., 2014). Superstructure-based modelling and optimization is a systematic approach when considering the commercial feasibility and perspectives of biofuel production, diverse technological options, supply chain, market scenarios, and environmental objectives. Superstructure based approach also helps to setting the boundaries for the scope of the analysis at a country level (e.g., for Austria in this study) or for a union of countries (e.g., for EU, if extending the scope) to lead the results of higher practical importance for decision makers and industrial stakeholders that can influence policies and investments, respectively. This approach is typically influence by spatial aspects with respect to feedstock supply chains and market conditions. To this end, currently the first-generation feedstock is used to produce biofuel in Austria but their overall carbon footprint, land-use change, food availability, price, and biodiversity have all been criticized (The European Parliament and the Council of the European Union, 2015).

## 2. Problem Statement

The problem addressed in this work concerns the superstructure-based model of mid to long-term second-generation biofuel production system in Austria while optimizing two objectives: the profit and the environmental impact. Figure 1 shows the superstructure-based model accounting the feedstock available in Austria according to RED II Annex IX, conversion pathways, final products, and by-products. The conversion technologies have different technology module because these are designed using a different catalyst (Morales et al., 2021). The environmental objective function considers the overall environmental impact in terms of a global warming potential including feedstock extraction, processing and final disposal of products. The economic aspects are considered in terms of total net profit. The goal of this study is to determine the optimal configuration of second-generation biofuel production system in Austria that simultaneously maximize the profit and minimize the environmental impact.

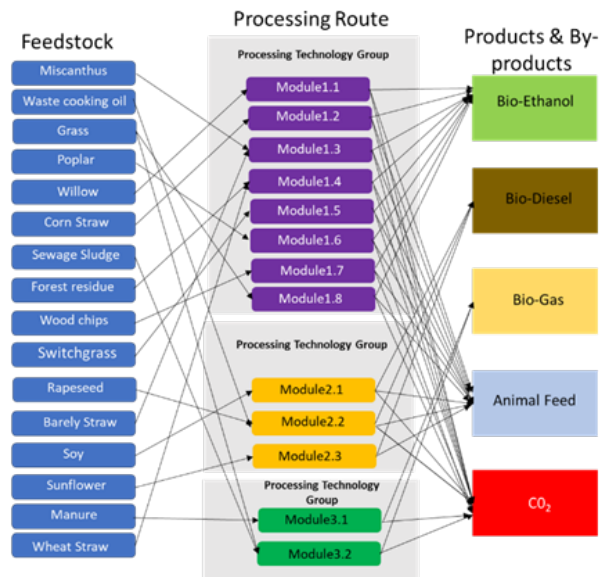

Figure 1: Superstructure for the second-generation biofuel production system

## 3. Model Formulation

The mathematical formulation is developed based on the work performed by Santibañez-Aguilar et al., 2011 to determine the optimal configuration as presented in Table 1. The mathematical model is coded in the GAMS software and solved using the solver CPLEX. The  $\epsilon$ -constraint method (Soroudi, 2017) is used to determine the set of optimal solutions that satisfy both objectives and that are used to build the Pareto front. In order to solve the multi-objective problem by  $\epsilon$ -constraint method, first the maximum and minimum values of the profit are calculated. These border values are determined by maximizing and minimizing profit separately as the objective function. Then, the profit is assumed as a constraint, and the environmental impact is calculated as the sole objective function. A Pareto optimal front is then derived for both objective functions.

### 3.1. Economic Analysis

The economic analysis considered in terms of profit is expressed in Table 1. The  $C_p^{value}$  is the selling price of products and  $C_b^{value}$  is the selling price by-products in €/Ton (IEA, 2022). The annual operating cost involve mainly the feedstock cost in Austria (Ruiz et al., 2019) and utilities consumed during the processing (including energy, catalyst, solvents, etc.). The total capital investment is calculated by process blocks build up method. This method is adopted from Tsagkari et al., 2020 and it consists of a modular approach to estimate the processing cost of different blocks inside the battery limit. The cost of each process block is calculated by the

power law equation (Tsagkari et al., 2020). The sum of the process block costs is the total capital investment. The equation, which follows the power law functions, shows a decrease in unit production costs with an increase in plant capacity. Therefore, nonlinear cost functions are linearized over different intervals between given processing limits to obtain a linear function.

Where,	
<b>Profit</b> = (Annual Sales – Annual Operating cost – Total Capital investment)	
<b>Annual Sales</b> = ( $\sum_p \sum_q \sum_r u_{pqr} C_p^{value} + \sum_p \sum_q \sum_r \sum_b \gamma_{pqr} C_b^{value}$ )	
<b>Total Capital Investment</b> = sum of the total capital investment cost of all process block	
<b>Total Capital cost of one process block</b> = $I_{rk}^{ref} \left[ \frac{\text{Output capacity of a new plant}}{\text{Output capacity of a reference plant}} \right]^{n_{r,k}}$	
<b>EI</b> = (LCA of feedstock + LCA of processing route + LCA of final product)	
<b>Constraints</b>	
$\sum_p \sum_r f_{pqr} \leq f_q^{max} \quad q \in Q$	A first set of inequality constraints are the maximum availability of the feedstock. it is restricted to use more than the existing quantity of feedstock for its processing to the corresponding final products.
$\sum_q \sum_r u_{pqr} \leq u_p^{max} \quad p \in P$	A second constraints is the product demand.This constraint helps to prevent the higher production rate than demand and also avoid to waste of sources.
$u_{pqr} \leq u_{pqr}^{max} \quad q \in Q, r \in R, p \in P$	As a final constraint, the maximum processing limit for feedstocks also considered. This is only for upper limit which are the maximum amount of feedstock for each processing route.

### 3.2. Environmental Analysis

The Environmental analysis includes the overall environmental impact measured through the prospective Life Cycle Assessment (PLCA) methodology. Prospective Life Cycle Assessment is useful tool to determine the environmental impact of current and emerging technologies in the future. The PLCA requires an inventory database that reflects the anticipated changes in technology and the environment at a particular point in time, based on a specific socio-techno-economic path. In this study PLCA contains an Ecoinvent 3.8 database along

with Integrated assessment model (IAM)(Sacchi et al., 2022). IAM describes transformation pathways of the interlinked energy-economy-land-climate system. IAM is based on Shared Socioeconomic Pathways (SSPs) which create a framework for the study of climate-related scenario outcomes. The background provides for quantification of SSP2 as a reference or 'marker' implementation (Fricko et al., 2017).

The SSP2 narrative describes a middle-of-the-road development in the mitigation and adaptation challenges space. There has been an extension of the historical experience in many dimensions of the SSP2 marker implementation, especially in terms of improving the baseline carbon and energy intensity. SSP2 can serve as a starting point to further explore integrated solutions for achieving multiple societal objectives in light of the climate adaptation and mitigation challenges that society could face over the 21st century (Fricko et al., 2017). An open source software Activity browser is used to conduct the overall environmental impact in this study. The PLCA is carried out using an attributional approach because the background scenario does not change. The goal of this LCA is to identify the environmental improvement of different technologies. The results of this analysis are used to build a superstructure optimization model. The results of Environmental impact analysis are presented in terms of GWP (kg CO<sub>2</sub> Eq) and are shown in Table 2 and 3, respectively.

Table 1: Environmental Impact Analysis for Each Feedstock using PLCA

Feedstock	GWP (Kg CO <sub>2</sub> Eq)	Feedstock	GWP (Kg CO <sub>2</sub> Eq)
Miscanthus	0.08	Switchgrass	0.08
Willow	0.051	Rapeseedoil	0.76
Poplar	0.072	Waste cooking oil	0.083
Wheatstraw	0.038	Soy	0.3
Cornstraw	0.086	Sunflower	0.55
Barleystraw	0.030	Manure	0
Forest residue	0.034	Sewage sludge	0.0099
Wood chips	0.039	Grass	0.1

Table 2: Environmental Impact Analysis for Each Processing Route PLCA

Feedstock	Processing Routes	GWP (Kg CO <sub>2</sub> Eq)	Feedstock	Processing Routes	GWP (Kg CO <sub>2</sub> Eq)
Miscanthus	Fermentation and saccharification	0.74	Switchgrass	Fermentation and saccharification	0.74
Willow	Fermentation and saccharification	0.32	Rapeseedoil	Transesterification	2.00
Poplar	Fermentation and saccharification	0.39	Waste cooking oil	Transesterification	0.38
Wheatstraw	Fermentation and saccharification	0.37	Soy	Transesterification	0.42
Cornstraw	Fermentation and saccharification	0.42	Sunflower	Transesterification	0.40
Barleystraw	Fermentation and saccharification	0.37	Manure	Biodigestion	0.67
Forest residue	Fermentation and saccharification	0.23	Sewage sludge	Biodigestion	0.40
Wood chips	Fermentation and saccharification	0.57	Grass	Biodigestion	0.16

#### 4. Results & Discussions

The proposed methodology is tested through a case study to establish a biorefinery system in Austria. This study involves the 16 types of biomass, mainly agriculture and forest residue available in Austria (Ruiz et al., 2019) used as a feedstock to obtained bioethanol, biodiesel and biogas as a product and cattle feed and carbon dioxide as by product. The conversion efficiency of processing route that converts the feedstock into products and byproducts were obtained by previous results (Morales et al., 2021). Additional required data such as selling price of products byproducts and demand of the product were taken from governmental institutions (IEA,2022; Biofuels,2022.).The solution obtained by solving this multi-objective problem is presented in Figure 2. First, the solution for the minimum profit is obtained when nothing is produced, so the profit is equal to zero which is shown at Point A in Figure 2. The solutions for point B and C in Pareto curve are shown in Figure 3 and 4 respectively. Regarding the production of bioethanol at point B 76% demand is fulfil while the biodiesel and biogas is only 20% and 2% of the total demand respectively. The

maximum profit at point B is 173.3 M€/Year and EI is 0.39 Mt of CO<sub>2</sub>-Eq. Figure 4 shows that 100% bioethanol demand is fulfilled with only 60% feedstock of woodchips available in Austria. The Production of biodiesel and biogas remains the same as point B. The overall Profit at point C is 284 M€/Year and EI is 0.67 Mt of CO<sub>2</sub>-Eq.

Figure 2: Pareto front of optimal solutions

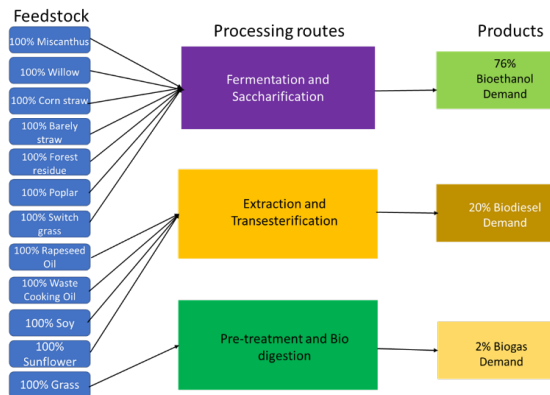

Figure 3: Solution for point B of Pareto front

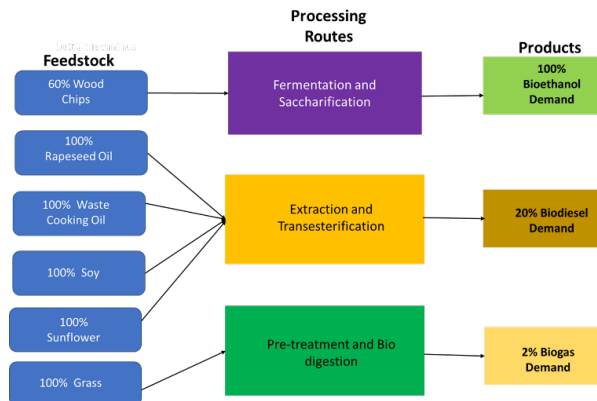

Figure 4: Solution for point C of Pareto front

## 5. Conclusions

This paper presents a systematic approach to the design of superstructure for optimal configuration of biofuel considering simultaneously maximum profit and minimum environmental impact. An Austrian second-generation feedstock mainly agriculture residue and forest residue considered. In this study we considered different constraints the maximum feedstock available, maximum demand of biofuel in Austria prospective. The multi-objective optimization is solved using the  $\epsilon$ -constraints method to establish the tradeoff among the economic and environmental objectives. Results shows that model can help to solve the problem of biofuel production from agriculture residue or forest residue.

## Abstract

This study presents the dynamic optimization of an industrial low-pressure gas carburizing (LPC) furnace. The objective is to determine the optimal operating conditions that minimize the production of harmful substances, i.e., polycyclic aromatic hydrocarbons (PAH) and soot, while meeting the industrial and mechanical requirements of the treated steel parts. A dynamic optimization problem is proposed and solved by means of a control vector parametrization approach and a gradient-based method using the software MATLAB. Optimized operating conditions are proposed and they are experimentally tested on an industrial LPC furnace. The results confirm that the proper treatment of steels parts is ensured and show that the PAH generated are reduced.

**Keywords:** Low-pressure gas carburizing, polycyclic aromatic hydrocarbons, dynamic hybrid optimization, control vector parameterization.

## 1. Introduction

Low-pressure gas carburizing (LPC) is a process that aims to improve the mechanical properties of steels by increasing the carbon content on their superficial layers. Since its introduction in the 20th century, LPC has become quite widespread in the heat treatment industry as it is an environmentally friendly process that reduces carburizing time and causes no intergranular oxidation of steel (Zajusz et al., 2014). This is achieved by carrying out the process at high temperatures and low pressures while supplying a cyclic feed of carbon-bearing gases like acetylene. Like other carburizing processes however, LPC has proven to be a significant source of occupational exposure to toxic substances like soot and polycyclic aromatic hydrocarbons (PAH) (Champmartin et al., 2017). The challenge is therefore to determine the best sequence of acetylene feed that minimizes the production of toxic compounds without compromising the carbon content constraints on the steel parts. The present paper addresses this challenge by formulating a hybrid dynamic optimization problem involving two modes (acetylene feed on and off), where each mode is characterized by model equations, a transition condition and transition functions. A control vector parametrization (CVP) approach is used to transform the problem into a nonlinear programming (NLP) problem that is solved by means of a gradient-based method. The results of the optimization and the experimental studies carried out to verify the validity of the findings are presented.

## 2. Materials and methods

The experimental installation used for the carburizing of gear box pinions (shown in

Figure 1) is presented in Figure 2. It consists of an industrial furnace made up of two independent chambers, i.e., a quenching chamber and a carburizing chamber, an acetylene and nitrogen feeding system, pressure and temperature control and regulation systems and a gas collection system consisting of a sampling rod and a cold trap connected to a pump. Nitrogen is used to inert the gas collection system to keep oxygen out of the setup.

Figure 1: gear box pinion  
(23MnCrMo5 steel)

Figure 2 : experimental setup

The experiments consist in programming the operating conditions (the “recipe”) used for carburizing, i.e., temperature, pressure, gases inlet flowrates and feeding durations, then in loading the steel parts into the furnace. The gas collection system is used to collect the gases generated all throughout the process. At the end of carburizing, the metal parts undergo a 15-minute nitrogen quench under 15 bars of pressure. The contents of the cold trap are analyzed offline by gas chromatography coupled to a mass spectrometer (GC-MS). The results of the Vickers hardness tests conducted on the carburized steel parts to determine their micro hardness profiles are presented in this paper. Two recipes are used for the carburizing of the steel parts: an industrial recipe and a recipe obtained by solution of the optimization problem presented in the following section.

### 3. Formulation of the optimization problem

#### 3.1. Process model

The process model considers the formation of gaseous and solid species due to the thermal decomposition of acetylene, as well as the interactions between the fluid and solid phases. The pyrolysis of acetylene is modeled by means of a 140 species and 444 reactions kinetic mechanism obtained by reduction of the detailed mechanism proposed by Bensabath (2017). It is completed by the modeling of soot by means of the method of moments (Frenklach, 2002) and the modeling of pyrocarbon by assuming pseudo-homogenous deposition kinetics (Ziegler, 2004). The external transfer of acetylene to the surface of the steel and the diffusion of carbon in the steel are modeled by means of Fick’s second law. The interaction between the fluid and the steel is described by a Langmuir-Hinshelwood Hougen Watson model. Temperature and pressure are assumed to be constant throughout the reaction zone. The gas mixture is assumed to obey the ideal gas law and the reactor is assumed to be a perfectly mixed stirred tank reactor (PSTR). Under these assumptions, the mass balances on gas species and the differential equations for the moments of soot particles are given by equations (1) and (2) respectively:

$$\rho_g V \frac{dY_k}{dt} = \dot{m}_{in}(Y_{k,in} - Y_k) + \dot{m}_{prod,k} - Y_k(\dot{m}_{surf} - \dot{m}_{soot}) \quad (1)$$

$$\frac{dM_r}{dt} = R_r + G_r + W_r - \frac{M_r Q_{out}}{V} \quad (2)$$

where  $\rho_g$  is the mass density of the gas mixture,  $V$  is the volume of the reactor,  $Y_{kin}$  and  $Y_k$  are respectively the inlet mass fraction and the mass fraction of gaseous species  $k$  in

the reactor,  $\dot{m}_{in}$  is the inlet mass flowrate,  $\dot{m}_{prod,k}$  is the mass production rate of species  $k$  by all reactions,  $\dot{m}_{surf}$  is the total mass production rate of gaseous species by the reaction at the surface of the steel,  $\dot{m}_{soot}$  is the mass production rate of soot,  $M_r$  is the moment  $r$ ,  $R_r$ ,  $G_r$  and  $W_r$  are soot source terms due to the phenomena of nucleation, coagulation and surface growth respectively, and  $Q_{out}$  is the outlet volumetric flowrate. The mass balances in the fluid/solid boundary layer and in the steel lead to set of equations (3) and (4) respectively:

$$\begin{aligned} \frac{\partial [C_2H_2]}{\partial t} &= D_{C_2H_2} \frac{\partial^2 [C_2H_2]}{\partial z^2} \\ [C_2H_2](z, t_0) &= 0 \\ [C_2H_2](z = 0, t) &= [C_2H_2(PSTR)] \\ -D_{C_2H_2} \frac{\partial [C_2H_2]}{\partial z} \Big|_{z=z_L} &= \frac{V_p}{A_p} r_{surf} \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{\partial \omega_C}{\partial t} &= D_C \frac{\partial^2 \omega_C}{\partial y^2} \\ \omega_C(y, t_0) &= \omega_{C,0} \\ -D_C \frac{\partial \omega_C}{\partial y} \Big|_{y=0} &= r_{surf} \frac{V_p}{A_p} \frac{100W_C}{\rho_p} \\ D_C \frac{\partial \omega_C}{\partial y} \Big|_{y=y_L} &= 0 \end{aligned} \quad (4)$$

where  $[C_2H_2]$  is the concentration of acetylene in the boundary layer,  $[C_2H_{2PSTR}]$  is the concentration of acetylene in the PSTR,  $\omega_C$  is carbon weight percentage in the steel,  $D_{C_2H_2}$  and  $D_C$  are the diffusion coefficients of acetylene in the gas phase and of carbon in the steel respectively,  $z$  and  $y$  are acetylene and carbon diffusion directions,  $W_C$  is carbon molar weight,  $V_p$ ,  $A_p$  and  $\rho_p$  are the volume, surface and density of the steel respectively, and  $r_{surf}$  is the volumetric rate of the reaction at the surface of the steel given by:

$$r_{surf} = k_{app} K_1 \frac{[C_2H_{2(surf)}]}{(1 + K_1 [C_2H_{2(surf)}] + K_2 [C_{(fe)}])^2} \quad (5)$$

where  $[C_2H_{2(surf)}]$  is the concentration of acetylene in the gas phase at the surface of the steel and  $[C_{(fe)}]$  is the concentration of carbon at the surface of the steel. Parameters  $K_1$  and  $K_2$  are Langmuir equilibrium constants of the adsorption of acetylene and carbon respectively, and  $k_{app}$  is an apparent kinetic constant. A hybrid model is proposed to take into account the phases where acetylene feeding is on (boost stages, designed by mode 1) and off (diffusion stages, designed by mode 2). The model equations on state variables  $x$  are given by:

$$\dot{x} = f^{(1)}(x) \quad (6)$$

$$\dot{x} = f^{(2)}(x) \quad (7)$$

where  $f$  are the relations described above. The transition conditions  $L$  and transition times  $t_{boost}$  and  $t_{diff}$  are given by:

$$L^{(2k)} = t_{boost}^{(k+1)} - t = 0, \quad \text{where } t_{boost}^{(k)} = \sum_{i=1}^{k-1} (a_i + b_i), \quad k = 1, \dots, N_C - 1, \quad (8)$$

$$L^{(2k-1)} = t_{\text{diff}}^{(k)} - t = 0, \quad \text{where } t_{\text{diff}}^{(k)} = a_k + \sum_{i=1}^{k-1} (a_i + b_i), \quad k = 1, \dots, N_C \quad (9)$$

where  $a_k$  and  $b_k$  are the lengths of boost and diffusion stage  $i$  respectively and  $N_C$  is the number of cycles, where each cycle corresponds to one boost stage followed by a diffusion stage. The transition functions are given by:

$$x_{\text{boost}}^{(k+1)}(t_0^{(k+1)}) - x_{\text{diff}}^{(k)}(t_f^{(k)}) = 0, \quad k = 1, \dots, N_C - 1 \quad (10)$$

$$x_{\text{diff}}^{(k)}(t_0^{(k)}) - x_{\text{boost}}^{(k)}(t_f^{(k)}) = 0, \quad k = 1, \dots, N_C \quad (11)$$

### 3.2. Performance index

The performance index corresponds to the total mass of PAH and soot generated:

$$J = \int_{t_0}^{t_f} (\dot{m}_{\text{HAP}} + \dot{m}_{\text{soot}}) dt = \int_{t_0}^{t_f} \dot{x}_{\text{obj}} dt = x_{\text{obj}}(t_f), \quad \text{where } x_{\text{obj}}(t_0) = 0$$

### 3.3. Decision variables and constraints

The decision variables considered are the operating conditions, i.e., the number of cycles  $N_C$ , the lengths of the boost and diffusion stages  $a_1 \dots a_{N_C}$  and  $b_1 \dots b_{N_C}$ , and the inlet flowrate of acetylene  $Q$ . The lengths of boost and diffusion stages vary in the [1-60] min range and acetylene flowrate in the [800-3500] NL/h range.

### 3.4. Constraints on the state variables

Constraints on the state variables related to the industrial requirements on the steel parts are considered and are given by the following relations:

$$\omega_c^{\text{surf}}(t_f) = 0.6 \% \quad (12)$$

$$\omega_c^{0.4 \text{ mm}}(t_f) = 0.34 \% \quad (13)$$

$$\omega_c^{\text{surf}}(t) \leq 1.2 \%, \quad t_0 \leq t \leq t_f \quad (14)$$

where  $\omega_c^{\text{surf}}$  and  $\omega_c^{0.4 \text{ mm}}$  are the carbon weight percentage at the surface of the steel and a depth of 0.4 mm respectively,  $t_f$  is the duration of the process and the value of 1.2 % corresponds to the saturation of carbon in the steel at the current operating conditions.

### 3.5. Optimization algorithm

To solve the optimization problem, it is necessary to deal with some difficulties that arise due to the nature of the decision variables. Firstly, the number of cycles  $N_C$  is an integer variable, making the optimization problem a mixed integer dynamic optimization problem. To overcome the ensuing difficulty in trying to solve such a problem, a decomposition of the original problem is proposed. Various sub-problems are thus established and for each one, the number of cycles is fixed and is thus not considered as a decision variable. Several sub-problems are then solved, each with a different number of cycles. The optimal number of cycles is then determined by selecting the sub-problem that leads to the minimum of the optimization criterion. Another difficulty that arises is the fact that the inlet flowrate of acetylene  $Q$  is a time-dependent variable of infinite dimension. A CVP approach is adopted to transform the problem into a finite dimension problem. The time interval is therefore divided into  $2N_C$  segments and  $Q$  is approximated by a piecewise constant function.

$$Q(t) = Q_k, \quad t \in [t_{\text{boost}}^{(k)}, t_{\text{diff}}^{(k)}], \quad k = 1, 2, \dots, N_C \quad (15)$$

$$= 0 \quad \text{otherwise}$$

The resulting NLP problem is solved by means of *fmincon* optimizer in the MATLAB environment. The hybrid model is integrated by means of *odes15s* solver.

## 4. Results and discussion

### 4.1. Optimization results

Figure 3 shows the results of the optimization : Figure 3(a) shows the performance index (PI), the quantity of acetylene consumed and the carbon integrated into the steel parts; Figure 3(b) shows the total durations of boost and diffusion stages. Six different sub-problems were considered and  $N_c$  varies between 5 and 10. For each  $N_c$ , the results are normalized by the results obtained with the industrial recipe R0.

Figure 3 : Results of the optimization of the different sub-problems and predictions with the industrial recipe R0

The results show that the optimization of the different sub-problems leads to a considerable reduction of the optimization criterion when compared to the industrial recipe (Figure 3 (a)). This can be directly related to the reduction of the quantity of acetylene that is fed to the reactor, as the toxic substances are generated from its thermal decomposition. However, even if less acetylene is used, the carbon added to the steel parts is of the same order of magnitude for all sub-problems and for R0. This suggests that acetylene is in excess with R0 and thus decomposes to produce PAH and soot. Figure 3(b) shows that all sub-problems lead to an increase in the total duration of the diffusion stages and a decrease in the total duration of boost stages when compared to R0. Recipes with shorter boost times and longer diffusion times thus lead to a decrease of toxic compounds.

### 4.2. Experimental results

Among the different sub-problems, the operating conditions of sub-problem  $N_c = 7$  were chosen as the optimal conditions. Compared to the industrial recipe, the total process duration is 33% longer but leads to a 44% decrease in acetylene consumption. The results of the hardness tests conducted on a pinion carburized with the industrial recipe and one carburized with the optimized recipe are shown in Figure 4(a) and Figure 4(b) respectively. The tests were performed according to different directions along the teeth of the pinions to study the homogeneity of carburizing in space. The results show that both recipes lead to homogeneous carburizing and to very similar hardness profiles. The results obtained for PAH production with both recipes are shown in Figure 4(c). They show a clear decrease in the production of PAH with the optimized recipe as compared to the industrial one. The experimental results obtained thus show that it is possible to significantly reduce toxic compounds without compromising the industrial quality of steel parts.

## 5. Conclusions

In this study, a first-principles modeling and optimization methodology was proposed to optimize an industrial low-pressure gas carburizing furnace. Experiments were performed on an industrial scale to quantify PAH formation and to evaluate the quality of the steel parts carburized with an optimized recipe. The results show that it is possible to ensure

industrial quality while reducing toxic compounds by carefully selecting the acetylene feed profile. In future works, although the objective will remain the minimization of the process toxicity, the methodology adopted here will be used to consider other aspects to ensure the feasibility of the approach from an industrial viewpoint. Multi-objective optimization will thus be applied to deal with different case studies, e.g., problems that consider the total process duration or even the deposition of pyrocarbon on the furnace walls. Indeed, the former entails higher energy demands, and the latter leads to an increased number of maintenance operations, which not only expose the operators to toxic compounds, but also represent higher operating expenses.

## Abstract

Starting with a candidate set of kinetic models for a reaction, model-based design of experiment (MBDoE) techniques can be used to determine experimental conditions for fast model identification of reaction kinetics using the minimum number of experimental runs to specify both model structure and corresponding parameters. However, practically, determining optimal settings, including criteria and selection methods for model discrimination for efficient model identification under consideration of parametric uncertainty in the whole identification procedure is still an open and challenging task.

In this work, a holistic Python package is presented which comprises MBDoE for model discrimination and, subsequently, MBDoE for parameter precision. The new package is tested on in-silico experiments for the identification of a Baker's Yeast model to evaluate and compare: *i*) the total number of experiments required for kinetic model identification considering different experimental design criteria; *ii*) the rate of correct model selections using different model selection methods.

**Keywords:** model-based design of experiments, model discrimination, experimental design criteria

## 1. Introduction

In chemical engineering, kinetic models are used to mathematically describe and predict the time-dependent behavior of reaction systems whereby mechanistic models, in contrast to data-driven models, can provide easy interpretability and reliable extrapolations. Starting with several candidate model formulations and assuming insufficient information to statistically determine the best formulation among the proposed ones, model-based design of experiment (MBDoE) can be a promising strategy to select further experimental conditions to facilitate model identification (Asprey and Macchietto, 2000). In sequential MBDoE strategies, the optimal experimental design problem is formulated as an iterative optimization problem through the maximization of a design criterion related to model identification based on the current state of knowledge from collected data. The MBDoE strategy reflects the motivation of pursuing model identification with the minimum number of experiments to avoid experimental costs, resources and time.

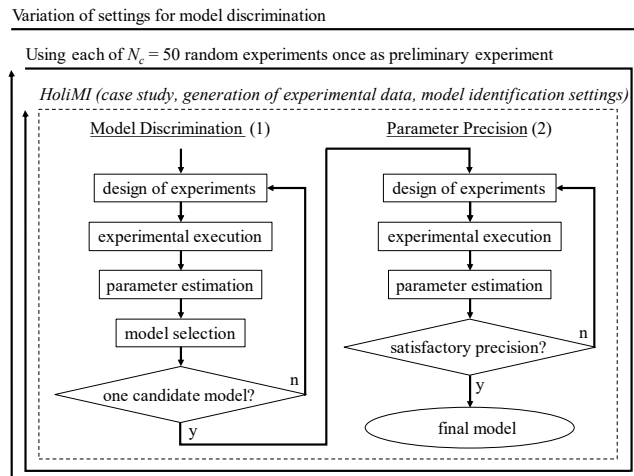

The classical procedure for model identification using MBDoE according to Asprey and Macchietto (2000) comprises three stages: *i*) a theoretical preliminary identifiability analysis of the set of proposed model candidates, *ii*) MBDoE for model discrimination

and *iii*) parameter precision for the selected model determined in *ii*). Several MBDoE design criteria for model discrimination, used in stage *ii*) as design objective function, have been proposed in literature in terms of statistical approaches of discrimination and complexity of the formulation (Michalik et al., 2010, Olofsson et al., 2019). Multiple MBDoE design criteria also exist for improving parameter precision, but the practical differences have been discussed in literature (Franceschini and Macchietto, 2008). So far, comparative studies of different design criteria for model discrimination (Burke et al., 1997, Olofsson et al., 2019) are limited to the stage of model discrimination only, so that the impact of parametric uncertainty on the whole identification procedure, and thus the effect on the number of experiments required in stage *iii*), is neglected. Practically, selection of settings for model identification is necessary, including experimental design criteria and probabilistic model selection settings. However, it is generally complex to determine which settings for the stage of model discrimination would provide the best prerequisites for model identification with the minimum number of experiments.

In order to address the question of optimal settings for model discrimination, a Python package is presented in this paper where different MBDoE criteria for model discrimination and for parameter precision are implemented as well as different model selection strategies from literature (cf. Olofsson et al., 2019). Applying this tool to the case study of yeast fermentation demonstrates a new holistic approach for comparing MBDoE design criteria and model selection settings to achieve fast model identification with the minimum number of experimental runs.

## 2. Model Identification using Model-Based Design of Experiments

The proposed framework of comparative study using the holistic model identification function (*HoliMI*) implemented in the Python package *HoliMI* is illustrated in Figure 1. For each combination of settings, the model identification function (*HoliMI*) is called repeatedly considering different scenarios for preliminary experiments.

**Figure 1** Proposed framework of comparative study and model identification function (*HoliMI*) implemented in the Python package including variants of settings for model discrimination.

The sequence of operations implemented as main function (*HoliMI*) in the Python package follows the MBDoE procedure for holistic model identification presented in Asprey and Macchietto (2000). Function inputs are: *i*) specifications of the case study, *ii*) configurations defining in-silico experiments and *iii*) settings of the implemented

sequence of operations for model identification. In the comparative study, settings for *iii*) related to model discrimination (criteria, model selection settings) are investigated.

### 2.1. Bioprocess Case Study

The fermentation of Baker's Yeast is considered as in-silico system for the comparative study (Chen and Asprey, 2003). The best approximating model structure, which describe the biomass ( $X$ ) and substrate ( $S$ ) concentration in a fed-batch reactor, i.e.  $\hat{\mathbf{y}} = [\hat{S}, \hat{X}]$ , should be selected among four proposed candidates. An experimental budget of  $N_{\text{exp max}} = 10$  experiments limits the model identification task. Each experiment is defined by a design vector  $\boldsymbol{\varphi} = [D, S_f, X_0]$  including dilution rate  $D$  [ $\text{h}^{-1}$ ], substrate concentration in the feed  $S_f$  [g/L] and initial concentration of biomass  $X_0$  [g/L] while samples are taken at fixed time points  $\mathbf{t}_{\text{sp}} := [10 \text{ h}, 20 \text{ h}, 30 \text{ h}, 40 \text{ h}]$ . Candidate model formulations, initial conditions of the system, initial parameter guesses and experimental design space are chosen in accordance with Chen and Asprey (2003).

### 2.2. In-Silico Experiments

For the generation of in-silico experiments, Monod kinetics including a term for biomass mortality are assumed as true model of the system. In addition to the mathematical solution of the model, a gaussian-distributed measurement error affects the true model predictions, i.e. the in-silico generated experimental data is defined by  $\mathbf{y} = N(\hat{\mathbf{y}}(\boldsymbol{\varphi}), \boldsymbol{\Sigma})$ , where  $\boldsymbol{\Sigma} := \begin{pmatrix} 0.12 & 0 \\ 0 & 0.12 \end{pmatrix}$  is the time-constant variance-covariance matrix used.

### 2.3. Sequence of Operations for Model Identification

The holistic model identification function (*HoliMI*), see Figure 1, comprises the iterative procedure for model discrimination (step 1) and the subsequent iterative procedure for parameter precision of the selected model (step 2) which approximates the experimental data best among the proposed candidates. Using MBD<sub>oE</sub>, experiments are designed such that the design criterion  $\Psi$  for model discrimination is maximized in each iteration and the specific formulation of the design criterion for model discrimination is defined by the settings as function input. Based on the set of experimental data, the parameters of each model are then estimated so that the weighted sum of squared residuals  $\chi^2$  as measure for the lack of fit is minimized (Chen and Asprey, 2003). The lack of fit  $\chi^2$  is then used to assign the models a probability  $p$  of being the best approximating model structure. These relative probabilities are used by Schwaab et al. (2006) to reject model candidates with low probabilities. If one of the model probabilities reaches 99.9%, model discrimination is terminated and parameter precision for the selected model is pursued until the confidence interval of all parameter estimates fall below 0.05. D-optimality is used as design criterion for the subsequent MBD<sub>oE</sub> for parameter precision.

## 3. Comparative Study

Besides following a holistic approach for comparing the number of experiments required for correct model identification including a precise parameter estimation, the comparative study is characterized by taking different parametric initializations for the first MBD<sub>oE</sub> iteration into account. Results are averaged over multiple runs considering accurate and inaccurate parameter estimates scenarios based on preliminary system knowledge.

### 3.1. Characterization of Preliminary Knowledge on Model Parameters

In order to provide the most general comparison of settings for model identification, numerous scenarios to describe the preliminary knowledge on model parameters are considered. A set of 50 randomly selected experimental conditions and corresponding measurements from in-silico experiments is generated. For each combination of settings,

the model identification function (*HoliMI*) is called  $N_c = 50$  times to consider a different preliminary experiment from the generated set in each realization so that different scenarios of parametric uncertainty in the subsequent MBDoE steps are considered.

### 3.1.1. Settings Used in the Comparative Study

Investigated settings in the comparative study are *i*) the MBDoE design criterion used for model discrimination as objective function of optimization problem; *ii*) the probability calculation method for model selection; *iii*) the probability-based model rejection method. The design criterion of Hunter and Reiner (1965), Eq. (1), is a summation of differences between model predictions over all pairs of  $M$  candidate models. In contrast to this basic formulation, the criterion of Box and Hill (1967), Eq. (2), takes model probabilities  $p$  and the variance of model predictions  $\hat{\mathbf{V}}$  into account. A statistically different approach has been proposed by Buzzi-Ferraris and Forzatti (1990), Eq. (3). Michalik et al. (2010) have derived the Akaike's weights design criterion, Eq. (4), from the Akaike Information Criterion of the candidate models with  $N_\theta$  as number of estimated model parameters. Recently, Olofsson et al. (2019) presented the Jensen-Rény divergence as design criterion, Eq. (5), for  $N_y$  measurement variables. Furthermore, the comparison of different MBDoE design criteria is set in relation to a random design of experimental conditions.

$$\Psi_{\text{HR}} = \sum_{i=1}^{M-1} \sum_{j=i+1}^M (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j)^T (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j) \quad (1)$$

$$\Psi_{\text{BH}} = \sum_{i=1}^{M-1} \sum_{j=i+1}^M p_i p_j \left( \text{tr} \left\{ \frac{\hat{\mathbf{V}}_i}{\hat{v}_j} + \frac{\hat{\mathbf{V}}_j}{\hat{v}_i} - 2\mathbf{I} + (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j)^T \left( \frac{1}{\hat{v}_i} + \frac{1}{\hat{v}_j} \right) (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j) \right\} \right) \quad (2)$$

$$\Psi_{\text{BF}} = \sum_{i=1}^{M-1} \sum_{j=i+1}^M \frac{(\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j)^T (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j)}{\hat{v}_i + \hat{v}_j} \text{tr} \left\{ \frac{2\boldsymbol{\Sigma}}{\hat{\mathbf{V}}_i + \hat{\mathbf{V}}_j} \right\} \quad (3)$$

$$\Psi_{\text{AWDC}} = \sum_{i=1}^M \frac{1}{\sum_{j=i}^M \exp \left\{ -\frac{1}{2} (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j)^T \hat{\mathbf{V}}_i^{-1} (\hat{\mathbf{y}}_i - \hat{\mathbf{y}}_j) + N_{\theta_i} - N_{\theta_j} \right\}} \quad (4)$$

$$\Psi_{\text{JRD}} = H_2(\sum_{i=1}^M p_i g_i) - \sum_{i=1}^M p_i H_2(g_i) \text{ with} \quad (5)$$

$$H_2(\sum_{i=1}^M p_i g_i) = \frac{N_y}{2} \log\{2\pi\} - \log \left\{ \sum_{i=1}^M \frac{p_i^2}{2^{\frac{N_y}{2}} |\hat{\mathbf{V}}_i|^{\frac{1}{2}}} + 2 \sum_{j=1}^{i-1} p_i p_j \exp \left\{ -\frac{1}{2} \phi_{ij} \right\} \right\},$$

$$\phi_{ij} = \frac{\hat{\mathbf{y}}_i^T \hat{\mathbf{y}}_i}{\hat{v}_i} + \frac{\hat{\mathbf{y}}_j^T \hat{\mathbf{y}}_j}{\hat{v}_j} - \frac{(\hat{\mathbf{y}}_i + \hat{\mathbf{y}}_j)^T (\hat{\mathbf{y}}_i + \hat{\mathbf{y}}_j)}{\frac{1}{\hat{v}_i} + \frac{1}{\hat{v}_j}} + \log|\hat{\mathbf{V}}_i| + \log|\hat{\mathbf{V}}_j| + \log \left| \frac{1}{\hat{v}_i} + \frac{1}{\hat{v}_j} \right| \text{ and}$$

$$H_2(g_i) = \frac{N_y}{2} \log\{4\pi\} + \frac{1}{2} \log|\hat{\mathbf{V}}_i|$$

Four different calculation methods of probability weights  $w$  with  $p_i = w_i / \sum_{k=1}^M w_k$  are compared: M1 as inverse of lack of fit; M2 resulting from comparing the lack of fit with the  $\chi^2$  distribution including the degrees of freedom of the model; M3 being based on the Akaike Information Criterion and M4 being similarly based on the likelihood function  $L_i = \prod_{q=1}^{N_{\text{exp}}} \prod_{r=1}^{N_{\text{sp}}} \prod_{s=1}^{N_y} (1/2\pi \boldsymbol{\Sigma}_{s,s})^{1/2} \exp \left\{ - (y_{q,r,s} - \hat{y}_{i,q,r,s})^2 / 2\boldsymbol{\Sigma}_{s,s} \right\}$  (Michalik et al., 2010) as M3 but without penalty term to include the degrees of freedom of the model.

$$\text{M1: } w_i = \frac{1}{\chi_i^2} \quad (6) \quad \text{M2: } w_i = 1 - F_{\text{DoFi}}(\chi_i^2) \quad (7)$$

$$\text{M3: } w_i = \frac{1}{\sum_{k=1}^M \exp\{AIC_i - AIC_k\}} \quad (8) \quad \text{M4: } w_i = \frac{1}{\sum_{k=1}^M \exp\{\pi_i - \pi_k\}} \quad (9)$$

with  $AIC_i = -2\log\{L_i\} + 2\text{DoFi}$  with  $\pi_i = -2\log\{L_i\}$

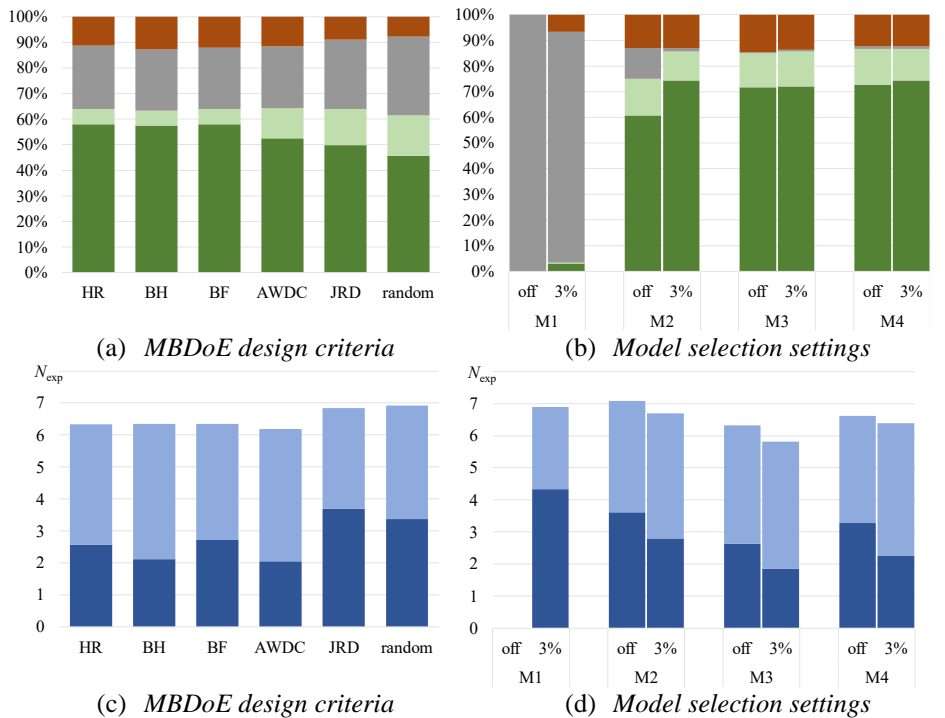

The probability calculation method and preferences for model rejection define the settings used for model selection: either probability-based model rejection is deactivated (“off”) or candidate models with  $p \leq 3\%$  are rejected as indicated by Schwaab et al. (2006).

3.2. Evaluation Metrics

The model identification function (*HoliMI*) is not deterministic since the measurement error generated for the in-silico experiments is randomly distributed. Possible return values are: *i*) correctly selected model with precise parameter estimation; *ii*) correctly selected model with interruption (i.e. maximum number of experiments reached) of parameter precision; *iii*) interruption of model discrimination and *iv*) false model selection. Thus, the different setting variants are compared by means of effectiveness  $EFN \propto \frac{\text{number of correct model selections}}{\text{number of model identifications}}$  and efficiency  $EFC \propto \frac{1}{\text{total number of experiments}}$  of cases with identification of correct model structure and precise parameters, return *i*).

3.3. Results and Discussion

Figure 2 shows the distribution of returns from the model identification function (*HoliMI*) averaged over all realizations with respective design criterion (2.a) and model selection settings (2.b). The average number of experiments required for correctly selected models and precise parameter estimation with respective settings is also presented (2.c, 2.d). The required number of experiments is split in number of experiments required for model discrimination and those required for parameter precision.

**Figure 2** Performance of MBDoe design criteria and a random design strategy (a, b). Distribution of experiments required for model identification (c, d).

(a, b) wrong (orange), undecided (grey), correct: imprecise parameters (light green), correct: precise parameters (dark green)  
 (c, d) experiments for parameter precision (light blue), experiments for model discrimination (dark blue)

In general, MBD<sub>oE</sub> in contrast to a random design is the more efficient strategy to design experiments for the identification of both model structure and parameters. However, MBD<sub>oE</sub> effectiveness is affected by parametric uncertainty as can be seen by the small improvement compared to a random design (2.a, 2.c) when averaging over multiple parametric scenarios. In contrast, the probability calculation method M1 is significantly less effective than the other methods (2.b), with M3 performing most efficiently (2.d). Furthermore, rejecting models at a probability of 3% resulted in faster model identification than in probability-free model rejection methods and in lower rates of false model selections due to the risk of rejecting the true model.

#### 4. Conclusion

The proposed [Python package HoliMI](#) allows a holistic comparison of settings for model identification using MBD<sub>oE</sub> techniques for both model discrimination and improvement of parameter precision. Results on the application of the package to a benchmark case study related to the identification of kinetics in a bioreactor system showed that the selection of model selection settings can affect the model identification performance substantially. Depending on the number of candidate model, a threshold for probability-based model rejections should be considered to enhance model identification with minimum number of experiments. Furthermore, it is recommended to use probability weights based on the probability likelihood function (M3 or M4) for efficient correct model selections. General guidelines on optimal MBD<sub>oE</sub> design criteria for model discrimination can be derived from the application to further study cases and the implementation of the proposed package in autonomous reactor platforms.

## Abstract

In the present study, a dynamic polymer degradation-drug diffusion model is developed to calculate the drug release rate from a population of size-distributed drug-loaded biodegradable polymer particles and analyze the effects of particle size distribution (PSD), drug loading distribution (DLD), and polymer molecular properties on degradation kinetics and drug release rate. The derived model, comprising a system of partial differential and algebraic equations, is numerically solved using the method of lines and validated against published experimental data on the drug release rate from drug-loaded PLGA microspheres. By controlling the PSD, DLD, molecular and morphological properties of the polymeric carriers, a desirable drug release profile can be realized. Toward this objective, a model-based dynamic optimization approach is developed to determine the optimal PSD and DLD of the biodegradable polymer carriers to achieve a drug release rate of zero-order over an administration period of three weeks.

**Keywords:** Controlled drug delivery; polymer degradation kinetics; drug diffusion; model-based optimal design of DDS.

## 1. Introduction

Neurological diseases encompass a broad spectrum of brain pathological conditions, i.e. Parkinson's and Alzheimer's diseases, multiple sclerosis, meningitis, etc., which can cause alterations to neural functions and progressive loss of neural tissue. Despite the recent advances in both drug delivery research and improved understanding of the pathogenesis of neurological diseases, effective treatment options are still missing due to the complexity of the central nervous system (CNS) and the alleged multifactorial pathogenic mechanisms. Thus, currently available therapeutic formulations have been generally proven ineffective because they are unable to reverse or/and completely restore normal neural functions. Moreover, the delivery of therapeutics to the brain by conventional systemic approaches is hindered by several barriers, including the Blood brain barrier (BBB) and the Blood-Cerebrospinal Fluid Barrier (BCSFB). In all cases, the delivery of active pharmaceutical ingredients (APIs) to the brain in sufficient quantities and in a highly controlled and sustainable way (e.g., over a time period of three weeks) is required in order to achieve a desired therapeutic effect.

In a recent EU Horizon collaborative research program, [www.n2b-patch.eu](http://www.n2b-patch.eu), a novel formulation was developed for nose-to-brain controlled delivery of biopharmaceuticals for the chronic treatment of CNS disorders. The novel drug formulation consisted of

biodegradable PLGA particles loaded with a cognition enhancing drug, embedded into a biodegradable hydrogel matrix. The hydrogel patch was deposited, via a nasal endoscopic applicator as a thin liquid-gelling film, onto the olfactory region (Kiparissides et al., 2019). The research goal was to obtain a desirable drug release profile over a long period of time (e.g., 3-4 weeks) by controlling the PSD, drug loading, molecular and morphological properties of the embedded PLGA drug carriers into a hydrogel patch. By controlling the molecular and morphological properties of the biodegradable hydrogel and embedded PLGA carriers, a desirable drug release profile from the embedded particles into the hydrogel matrix to the mucus layer and then to the olfactory bulb can be established.

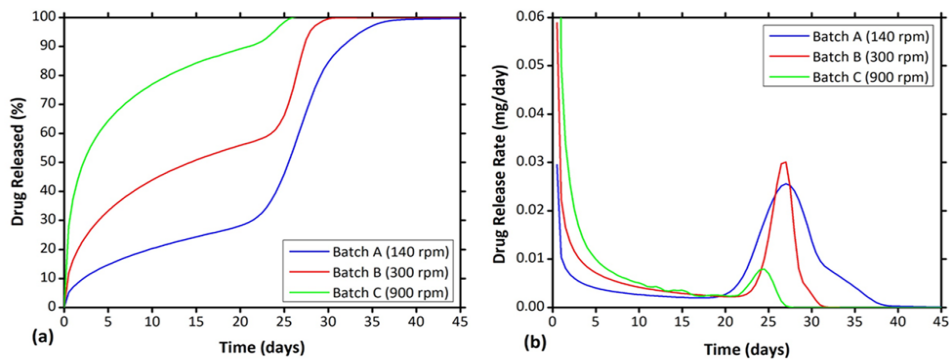

**Figure 1.** The basic concept of the proposed nose-to brain drug delivery system. Illustration of local hydrogel formation at the olfactory cleft via the aid of an endoscopic applicator. Drug-loaded nanoparticles are embedded into the deposited hydrogel patch. Blue arrows show the potential intracellular and extracellular pathways through which the API is transferred to the brain ([www.n2b-patch.eu](http://www.n2b-patch.eu)).

In the present contribution, a process systems computational approach, comprising models at different time and length scales, is developed to elucidate the fundamental physical, transport and biological processes in relation to the nose-to-brain delivery of selected APIs from drug-loaded biodegradable PLGA carriers, embedded into a hydrogel film deposited at the olfactory mucosa, to the epithelium and then to the olfactory bulb (Kiparissides et al. 2020). A polymer degradation-drug diffusion model is derived to calculate the drug release rate from a population of size-distributed drug-loaded particles and analyze the effects of particle size distribution (PSD), drug loading distribution (DLD), polymer molecular and morphological properties on polymer degradation kinetics on drug release profile. The model takes into account the spatial-temporal variation of the drug and water diffusion coefficients due to polymer degradation that results in a decrease of the molecular weight of the polymer. The unknown model parameters are estimated by fitting model predictions to the experimental data of Berchane et al. (2007). Finally, a multi-parametric optimization problem is formulated to calculate the optimal PSD and DLD of drug-loaded polymer carriers to obtain a desired drug release profile over a drug administration period of several weeks.

## 2. Model-based optimal design of drug-loaded polymeric carriers

Frequently, a zero-order release profile is required for sustainable, controlled delivery of a specific drug dose to a patient in order to achieve a maximum therapeutic outcome. As shown in Figure 2a, the experimentally prepared drug delivery formulations of Berchane et al. (2007) exhibit a tri-phasic drug release profile (see blue, red and green lines). The corresponding drug release rates of the three formulations are depicted in Figure 2b. As can be seen the respective drug release rate exhibits an initial burst followed by an almost zero drug release rate and at approximately 20-30 days, the release rate shows a second drug release burst. This means that the prepared formulations cannot maintain a sustainable drug release rate of zero-order over a long period and thus cannot yield an optimal therapeutic effect. In the present study, a model-based dynamic optimization approach was developed to determine the optimal particle size and drug-loading distributions to obtain a sustainable drug release rate profile of zero-order over a specified period of time.

**Figure 1.** (a) Experimental profiles of cumulative drug amount released from three size-distributed populations of piroxicam-loaded PLGA particles. (b) Respective drug release rates for the three experimental formulations (Berchane et al. 2007).

### *Selection of the optimal particle size distribution*

In this study, it was assumed that the optimal drug-loaded PLGA particles followed a log-normal volume probability distribution,  $N_V(d)$ , given by

$$N_V(d) = \frac{1}{d\sigma\sqrt{2\pi}} \exp\left(-\frac{1}{2}\left(\frac{\ln d - \mu}{\sigma}\right)^2\right); \quad 0 < d < \infty \quad (1)$$

Where  $\mu$  is the mean value and  $\sigma$  is the standard deviation of the log-normal distribution. Thus, the values of  $\mu$  and  $\sigma$  were selected as control variables in the optimization problem.

### *Selection of the optimal drug loading distribution*

Regarding the drug loading distribution (i.e., drug mass per unit of polymer mass), it was assumed to follow a size-dependent logarithmic function with respect to particle size. Moreover, the initial particle concentration at  $t=0$  was assumed to be independent of particle radius.

$$f_{DL}(d) = -\alpha \cdot \ln(d) + \beta \quad (2)$$

Thus, the two drug loading parameters  $\alpha$  and  $\beta$  were treated as two additional control variables in the optimization problem.

*Drug release from a size distributed population of drug-loaded particles*

To calculate the drug release rate from a monodisperse population of biodegradable drug-loaded PLGA microspheres, two partial differential equations were formulated and numerically solved to calculate the spatial-temporal variation of drug and water concentrations in the PLGA microspheres. Accordingly, the following partial differential equation and associated initial and boundary conditions were derived to describe the drug diffusion and release from the PLGA microspheres.

$$\begin{aligned}\frac{\partial C_d(r, t)}{\partial t} &= \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 D_{d,eff}(t, r) \frac{\partial C_d(r, t)}{\partial r} \right) \\ &= D_{d,eff} \left( \frac{\partial^2 C_d}{\partial r^2} + \frac{2}{r} \frac{\partial C_d}{\partial r} \right) + \frac{\partial C_d}{\partial r} \frac{\partial D_{d,eff}}{\partial r},\end{aligned}\quad (3)$$

$$\left. \frac{\partial C_d(r, t)}{\partial r} \right|_{r=0} = 0 \quad (4)$$

$$D_{d,eff}(t, r) \left. \frac{\partial C_d(r, t)}{\partial r} \right|_{r=R} = -k_{c,d}(C_d(R, t) - C_{out}(t)) \quad (5)$$

$$C_d(r, 0) = C_{in} \quad (6)$$

$$V_{out} \frac{dC_{out}(t)}{dt} = N_p k_{c,d} A_p (C_d(R, t) - C_{out}(t)) \quad (7)$$

The symbols  $C_d(r, t)$  and  $C_{out}(t)$  denote the drug concentration in the particles and release medium, respectively.  $C_{in}$  is the initial drug concentration in the particles at  $t=0$ , independent of particle radius.  $D_{d,eff}(r, t)$  and  $k_{c,d}$  are the effective intra-particle drug diffusion coefficient and drug mass transfer coefficient from the particle's external surface ( $A_p$ ) to the continuous release medium, respectively.  $R$  is the particle radius,  $V_{out}$  is the volume of the release medium,  $N_p$ , is the total number of drug-loaded particles. Note Eq. (7) is a dynamic mass balance on the drug concentration in the continuous release medium (sink).

Similarly, one can derive a partial differential equation describing the temporal-spatial variation of water in the PLGA particles

$$\begin{aligned}\frac{\partial C_w(r, t)}{\partial t} &= \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 D_{w,eff}(t, r) \frac{\partial C_w(r, t)}{\partial r} \right) - k_{a,1} C_w(r, t) \mu_0(r, t) \\ &\quad + k_{\alpha,2} C_{H^+}(r, t) \lambda_0(r, t) \\ &\quad - k_d C_{H^+}(r, t) C_w(r, t) (\mu_1(r, t) - \mu_0(r, t)) \\ &= D_{w,eff} \left( \frac{\partial^2 C_w}{\partial r^2} + \frac{2}{r} \frac{\partial C_w}{\partial r} \right) + \frac{\partial C_w}{\partial r} \frac{\partial D_{w,eff}}{\partial r} - k_{a,1} C_w \mu_0 \\ &\quad + k_{\alpha,2} C_{H^+} \lambda_0 - k_d C_{H^+} C_w (\mu_1 - \mu_0)\end{aligned}\quad (8)$$

$$\left. \frac{\partial C_w(r, t)}{\partial r} \right|_{r=0} = 0 \quad (9)$$

$$D_{w,eff}(t, r) \left. \frac{\partial C_w(r, t)}{\partial r} \right|_{r=R} = -k_{c,w}(C_w(R, t) - C_{w,eq}) \quad (10)$$

$$C_w(r, 0) = 0 \quad (11)$$

Where  $C_w(r, t)$  and  $C_{w,eq}$  are the water concentration in the particles and at equilibrium, respectively.  $D_{w,eff}(r, t)$  is the effective intra-particle water diffusion coefficient and  $k_{c,w}$  is the mass transfer coefficient of water from the release medium to the particle's external surface.

Note that in order to reduce the computational effort (i.e., the number of differential equations to be integrated), the particle size distribution was discretized into four particle classes,  $N_c$ . The final model comprised a system of 2549 non-linear ordinary differential equations (i.e., 9 variables for each discrete particle class times 71 or 70 discretization points in the radial coordinate plus the  $C_{out}$  variable) and 28 algebraic equations.

*Definition of the objective function and numerical solution*

Based on the above stated optimization objective (i.e., of zero-order drug release rate), the following dynamic optimization problem was formulated.

$$\min J_{obj,2} = \|\mathbf{R}_p - \mathbf{R}_d\|_2, \quad w. r. t. (\sigma, \mu, \alpha, \text{ and } \beta) \quad (12)$$

Where the vectors  $\mathbf{R}_d = (R_{d,1}, R_{d,1}, \dots, R_{d,max})$  and  $\mathbf{R}_p = (R_{p,1}, R_{p,1}, \dots, R_{p,max})$  denote the desired and model-based optimal values of the drug release rate, respectively. The maximum number of discrete drug release rate values was set equal to 50 over a drug release horizon of 25 days, which corresponds to one drug release rate value per 1/2 day.

It is important to note that the above optimization problem was solved together with the following equality constrain regarding the conservation of the total drug mass in the system.

$$\left( \sum_{j=1}^{N_c} m_{d,j}(t = 0) \right) = m_{d,total} \quad (13)$$

where  $m_{d,total}$  is the total drug dose (i.e., 0.4 mg ) and  $m_{dj}$  is the drug mass in the “j<sup>th</sup>” particle class at t=0.

Thus, our optimization objective was to deliver a total therapeutic drug dose of 0.4 mg over a time period of 25 days by maintaining an almost zero-order drug release rate, 0.0128 mg/day. The above stated optimization problem was numerically solved in MATLAB®, employing the ode15s solver for the integration of the differential-algebraic equations and the “MultiStart” global optimizer (a MATLAB® built-in function) for the estimation of the four control variables. From the numerical solution of the optimization problem the parameters  $\mu$  and  $\sigma$  of the log-normal PSD (Eq. (1)) and the parameters  $\alpha$  and  $\beta$  of the drug loading function (Eq. (2)) were estimated so that a desired zero-order drug release rate profile could be realized. The optimal estimates of the four control variables are reported in Table 1 as well as the optimal dug loading per discrete class of particles.

**Table 1.** Estimated optimal values of the four control variables.

Control Variables				Drug Loading Per Particle Class			
$\mu_x$ ( $\mu\text{m}$ )	$\sigma_x$ ( $\mu\text{m}$ )	$\alpha$	$\beta$	Class 1	Class 2	Class 3	Class 4
80.15	16.60	0.0139	0.1475	9.30%	8.59%	8.12%	7.77%

In Figure 3a, the calculated optimal PSD and optimal drug loading distribution are depicted. As can be seen the calculated particle size distribution varies from 40  $\mu\text{m}$  to 140  $\mu\text{m}$  while the drug loading per particle class (i.e., % of drug mass per polymer mass of a class) decreases as the particle size increases. In Figure 3b, the optimal and desired percentage of cumulative drug released and respective drug release rate are plotted with respect to the drug release time. As can be seen the optimal formulation of the drug-loaded PLGA carriers (see optimal values of  $\sigma$ ,  $\mu$ ,  $\alpha$ , and  $\beta$  in Table 1) closely follows the desired drug release rate of zero-order from the second to the twenty third day of the total release period. Note that the observed deviations in the calculated drug release rate from the desired zero-order profile are primarily due to the inherent initial burst in drug release rate while the observed deviation after the 23<sup>rd</sup> day is due to the depletion of drug concentration in the PLGA carriers. The results of the present investigation do show that the proposed model-based optimal design of drug-loaded polymer carriers can aid the development of new drug delivery systems exhibiting a desired drug release profile that can largely enhance the *in vivo* drug bioavailability and efficacy.

**Figure 3.** (a) Calculated optimal drug loading values per particle class. In the inset graph, the calculated optimal particle volume fraction distribution is depicted. (b) Total drug released and drug release rate from a size-distributed population of particles.

## Abstract

In this work, a novel approach for the development of surrogate models is presented. It aims to combine traditional model-based design of experiments and global estimability analysis. The approach is based on the Fisher Information Matrix to set two objective functions to be maximized. The first is given by D-optimal design of experiments criterion that maximizes the determinant of FIM, thus minimizing the volume of the confidence region and resulting in more precise parameter estimate. The second is given by the sum of Euclidian norms of FIM's columns to improve the estimability of all the unknown parameters. The resulting multi-objective optimization problem is solved to determine the Pareto front of the optimal solutions. The Multi-Attribute Utility Theory is used as a decision making aid method to select the best solution, needed for the development of the surrogate model. For demonstration purposes, a polynomial Response Surface Model (RSM) based surrogate is developed. It mimics a computationally expensive first-principles model that predicts the conversion rate of a phosphate ore digestion by phosphoric acid. The results are very promising, showing how the approach allows to select the most estimable model parameters from intelligently designed data points. High performance of the developed surrogate is demonstrated by comparing its predictions and computation time to those obtained by first-principles model.

**Keywords:** Surrogate modeling, Model-based design of experiments, Sensitivity and Estimability analysis, Multi-objective optimization, Decision making aid.

## 1. Introduction

The development of reliable first-principles models is of utmost importance in process engineering. Recently, there is an increasing demand for high fidelity, large and multi-scale mathematical models. However, in most cases, the process models usually involve sets of ODEs, PDEs etc., that take time to integrate making the developed models very slow/expensive to converge. To overcome these problems, high-fidelity and accurate surrogate models that allow to quickly compute the required model outputs from the inputs are needed. Indeed, surrogate models have been increasingly investigated recently (Rabhi et al., 2018; Elmisaoui et al., 2022). They are developed to mimic the behavior of a given simulation model or an outcome of interest that cannot be easily measured or computed, as closely as possible, while being computationally cheap to evaluate.

Surrogate modeling is usually based on a limited number of intelligently chosen data points (black-box modeling), and on choosing an appropriate mathematical expression of the surrogate, which involves in most cases many unknown parameters to be identified.

For the development of accurate surrogates, it is very important to design the most optimal data points that maximize the estimability of the surrogate model parameters in order to determine the most estimable parameters to be identified.

These two objectives are generally overlooked in most of the current published papers. The main purpose of the present work is to develop a novel approach that enables to (i) firstly, select intelligently the dataset of points to mimic by the surrogate model, and (ii) secondly to determine with accuracy, the unknown surrogate model parameters to be identified from the selected dataset of points.

This approach is based on a constrained multi-objective optimization problem that accounts for two objectives, one from Model-based design of experiments and one from parameter estimability, while the constraints are mainly given by the range of variation of the operating conditions. The solution of the formulated problem will be a set of optimal profiles, i.e., a Pareto front, from which, the best solution can be chosen using a decision making aid method. For demonstration purposes, the approach is applied to the case of polynomial Response Surface Model (RSM)-based surrogate, to mimic the behavior of a computationally expensive first-principals model that predicts the conversion rate of the digestion reaction of phosphate ore by phosphoric acid.

## 2. Models and methods

### 2.1. First-principals model of phosphate ore digestion

The case study in this work deals with a phosphate ore digestion model previously developed by Elmisaoui et al. (2021). It describes the dissolution behavior of a pure tri-calcium phosphate (TCP) in phosphoric acid to produce mono-calcium phosphate (MCP). The dissolution reaction is given by:

The conversion rate of this reaction depends on several operating conditions such as, the reaction temperature, the initial phosphoric acid concentration, the tri-calcium phosphate particle size distribution and porosity, the hydrodynamic conditions, the solid/liquid ratio, the residence time etc. In this work, four sensitive parameters are considered. They include the initial TCP particle size ( $R_0$ ), the initial phosphoric acid concentration ( $C_0$ ), the tank stirring speed through a hydrodynamic parameter ( $\alpha$ ), and the residence time ( $\tau$ ) inside the reactor. Moreover, to predict the dissolution rate, the shrinking core model is used considering three main phases: (i) the liquid bulk, (ii) the liquid film that surrounds the solid particles, (iii) and the solid phase. Some assumptions are made for the development of the first-principals model and can be found in Elmisaoui et al. (2021).

The resulting model is given by the following system of mass balance equations:

$$\frac{dX}{dt} = \frac{3M_{TCP}D_{MCP}}{x_{TCP}R_0\delta\rho_S} (1 - X)^{\frac{2}{3}} (C_{MCP}|_{r=R} - C'_{MCP}) \quad (2)$$

$$\frac{\partial C_i}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left( D_i r^2 \frac{\partial C_i}{\partial r} \right) \quad i = H_3PO_4, Ca(H_2PO_4)_2 \quad (3)$$

$$r = R: -D_i \frac{\partial C_i}{\partial r} \Big|_{r=R} = v_i k_r C_{H_3PO_4} \Big|_{r=R} \quad (4)$$

$$r = R + \delta: C_i|_{r=R+\delta} = C'_i \quad (5)$$

$$\delta = R \left[ 1 + \alpha \left( \frac{R}{R_0} \right)^{8/9} D_{MCP}^{-1/3} \right]^{-1} \quad (6)$$

$$C'_{MCP} = \frac{3n_{TCP}^0}{V_L} \text{ and } C'_{\Pi_3PO_4} = C_{H_3O_4}^0 - \frac{4n_{TCP}^0}{V_L} \quad (7)$$

In the system of equations above, (2) describes the solid phase, (3) describes the liquid film surrounding the solid particles, (4 and 5) are the two main boundary conditions, (6) is used to predict the film thickness  $\delta$ , and (7) describes the liquid bulk.  $m_s$  and  $R$  are respectively the mass and radius of the solid phosphate ore particles,  $x_{TCP}$  and  $M_{TCP}$  are the mass fraction of TCP and its molecular weight.  $C_{MCP}|_{r=R}$  and  $C'_{MCP}$  are the concentrations of MCP at the solid surface and in the liquid bulk.  $k_r$  is a rate constant,  $D_i$  and  $v_i$  are the diffusion coefficient and stoichiometric coefficient of component  $i$ , respectively.  $n_{TCP}^0$  is the initial number of moles of TCP in the solid,  $V_L$  is the liquid volume in the tank,  $\alpha$  is a hydrodynamic parameter calculated from the stirring speed of the tank. The solution of (2-6) allows to predict the conversion rate  $X(\tau, C_0, R_0, \alpha)$  to be mimicked by the surrogate model.

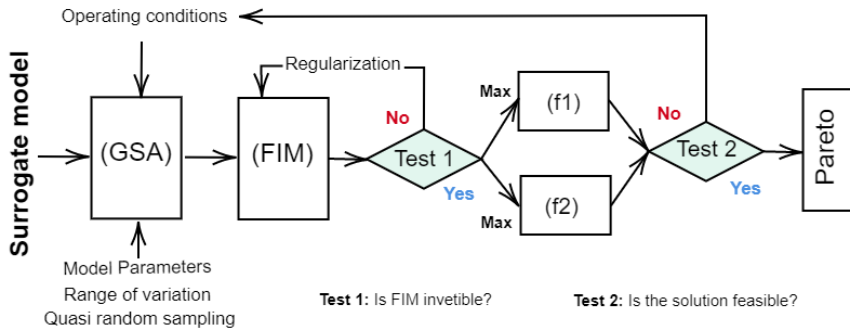

### 2.2. Polynomial Response Surface Model-based surrogate

Surface Response model-based surrogates have been extensively used recently. They proved to be accurate, flexible, and available in many commercial data analysis software. The third degree polynomial RSM-based surrogate model used in this work writes as:

$$\hat{Y} = y_0 + \sum_i a_i X_i + \sum_i b_i X_i X_i + \sum_{i \neq j} d_{i,j} X_i X_j + \sum_i c_i X_i X_i X_i + \sum_{i \neq j \neq k} e_{i,j,k} X_i X_j X_k \quad (7)$$

*Cst*      *Linear terms*      *Binary interaction terms*      *Ternary interaction terms*

Considering four main sensitive operating parameters, i.e.,  $u = \{\tau, C_0, R_0, \alpha\}$ , the surrogate model above involves 23 unknown parameters (table 1). The main challenges that the proposed approach addresses are (i) which data points (from the first-principals model) to mimic, and (ii) which unknown model parameters to estimate.

**Figure 1:** Framework of the multi-objective model-based design of experiments. (GSA): Global Sensitivity Analysis. (FIM): Fisher Information Matrix.

### 2.3. Multi-objective model-based design of experiments

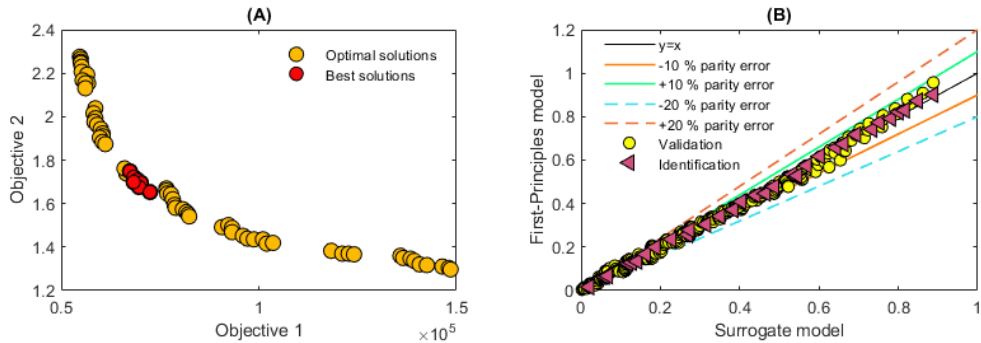

Figure 1 shows the proposed approach for the development of the surrogate models. It is based on the Fisher Information Matrix (FIM), which is computed from the global sensitivity indices of the model's unknown parameters as:

$$Z = \begin{pmatrix} S_{1,1|m_1} & \cdots & S_{1,d|m_1} \\ \vdots & \ddots & \vdots \\ S_{n,1|m_n} & \cdots & S_{n,d|m_n} \end{pmatrix}, \quad \mathbf{FIM} = Z.Z^T \quad (8)$$

where  $m_i$  is the  $i^{th}$  sampling point,  $d$  is the number of model parameters and  $n$  is the number of measurements.  $S_{i,j}$  are the individual sensitivity indices of the  $i^{th}$  output with respect to the  $j^{th}$  parameter. They are calculated by means of the method developed by Saltelli (2012). FIM is then used to compute the two objective functions  $f_1$  and  $f_2$ . They represent the D-optimal model-based design of optimal experiments (MBDoe) criterion and the Euclidian norm of FIM's columns, respectively (Bouchkira et al., 2021; 2022; 2023). A regularization test is performed to ensure that the FIM is invertible (Test 1). Then, multi-objective optimization is performed to maximize the two objective functions and to determine the Pareto front of the optimal solutions (Test 2). The multi-objective optimization problem is formulated as:

$$\begin{aligned} \max_{\varphi} \mathbf{F} &= [f_1, f_2]^T \\ f_1 &= \det(\mathbf{FIM}) \\ f_2 &= \sum_{i,j} \|S_{i,j}\| \\ \mathbf{FIM} &= Z(X, \theta).Z(X, \theta)^T \\ \varphi &= [C_{0,1}, \dots, C_{0,n}, R_{0,1}, \dots, R_{0,m}, \alpha_1, \dots, \alpha_k, t_1, \dots, t_w] \\ \text{s.t.} \quad &0 < C_{0,j-1} \leq C_{0,j}, j \in [1; n]; \quad 0 < R_{0,r-1} \leq R_{0,r}, r \in [1; m]; \\ &0 < \alpha_{s-1} \leq \alpha_s, s \in [1; k]; \quad 0 < t_{p-1} \leq t_p, p \in [1; w] \\ &C_{0,j-1} - C_{0,j} \leq \omega_C; \quad R_{0,r-1} - R_{0,r} \leq \omega_R \\ &\alpha_{s-1} - \alpha_s \leq \omega_\alpha; \quad t_{p-1} - t_p \leq \omega_t \\ &Cond(\mathbf{FIM}) \leq \theta \end{aligned} \quad (\text{S.1})$$

where  $\omega_C$ ,  $\omega_R$ ,  $\omega_\alpha$  and  $\omega_t$  are used to avoid duplicated experiments.  $\theta$  is a cut-off criterion to guarantee that FIM is revertible,  $\theta = 10$  is considered as in (Cenci et al., 2022).

**Figure 2:** Optimization and identification results. (A): Pareto front. (B): Parity diagram.

### 3. Results and discussion

Global sensitivity analysis is first performed based on the method of Saltelli (2002), and a Quasi-Monte Carlo sampling of size 10.000 was sufficient to achieve sensitivity indices convergence. The sensitivity indices were then used to build the FIM which is used in the multi-objective optimization problem. The latter is then implemented and solved under MATLAB, and a Genetic Algorithms solver was used to achieve global optimality.

Resolution of the multi-objective optimization problem allowed to generate the Pareto front (Figure 2A) of the optimal compromises to be mimicked by the surrogate model. It is worth mentioning that all the points on the Pareto front are optimal. However, for further development of the surrogate model, the best compromises of the Pareto front should be selected to be implemented. To this end, the Multi-attribute Utility Theory method was used as a decision making aid method as in our previous works (Bouchkira et al. 2022). It allowed to classify the solutions and to select the best one. Five best solutions are highlighted in red color in figure 2A. The best solution was selected to be implemented and suggests to mimic 32 outputs of the first-principles model predictions, based on the combination of two initial phosphoric acid concentrations i.e.,  $C_0 = 115$  and  $C_0 = 453$ ; two initial particle radius, i.e.,  $R_0 = 6.9 10^{-4}$  and  $R_0 = 5.1 10^{-4}$ ; two hydrodynamic parameters, i.e.,  $\alpha = 2.73$  and  $\alpha = 3.18$ ; and four residence times, i.e.,  $\tau = 155$ ,  $\tau = 215$ ,  $\tau = 403$ , and  $\tau = 600$ .

Table 1 summarizes the results obtained in the development of the polynomial RSM-based surrogate model using the best solution. It shows first the ranking of the surrogate unknown parameters according to their estimability from the selected best solution. Moreover, the results show that only 12 unknown parameters out from 23 are estimable, and this is deduced from the estimability magnitudes of the parameters that were computed within the optimization approach, and their comparison to an estimability cut-off criterion proposed in (Yao et al. 2011). The values of the estimable parameters are provided along with their confidence intervals.

It should be noted here that the proposed approach has the advantage of identifying only the estimable model parameters, which avoids the model overfitting and improves the model precision by ignoring uncertain parameters.

Figure 2B shows a comparison between the predictions of the developed surrogate model and those of the expensive first-principals model. The results show the accuracy and good performance of the developed surrogate model, and this can be shown in the parity errors that do not exceed -10% and +10% for all the data points used for the identification of the model parameters (red triangle), while the errors on other data points that were not used during the identification process (validation: yellow circles) lie between -20% and +20%. It is finally worth mentioning that the developed surrogate model proved to be more than three times faster than the first-principals model, and this was deduced by running both models several times on an ASUS workstation with 12th Gen Intel(R) Core (TM) i9-12900K 3.20 GHz 128GB Ram processor.

#### 4. Conclusion

A novel multi-objective optimization-based approach for the development of accurate surrogate models is presented. It has the advantage of designing intelligently the data points from the computationally expensive model to be mimicked by the surrogate model, while selecting only its estimable unknown parameters. To demonstrate the effectiveness of the proposed approach, it is used in this work for the development of a surrogate model to mimic the predictions of a computationally expensive first-principals model that predicts the conversion rate of a phosphate ore digestion using phosphoric acid. High performance of the developed surrogate model was finally demonstrated by comparing its predictions and computation time to those obtained by the first-principals model.

## Abstract

Using numerical optimization for the hierarchical integration of decision-making units is crucial to provide feasibility and optimality of all levels. However, realistically modelling hierarchical decision-making calls for multilevel formulations, which are numerically intractable and mathematically difficult. In this work, we show how to leverage two data-driven techniques – derivative-free optimization and optimality surrogates – to decrease the computational burden of multilevel problems. We reformulate a tri-level planning-scheduling-control problem into a single-level black-box problem wherein each evaluation calls a scheduling instance with embedded optimal control surrogates. We show that solving this integrated problem instead of the single-level instance leads to changes in the optimal production planning and scheduling sequence, and discuss trade-offs associated with both techniques.

**Keywords:** Derivative-free optimization; Optimization with embedded surrogates; Enterprise-wide optimization; Hierarchical decision-making

## 1. Introduction

Chemical enterprises can capture significant value by using mathematical optimization for the integration of hierarchical levels of operations from supply chain and process design down to control. Traditionally, in *sequential* decision-making, upper-level decisions are taken while disregarding lower-level considerations, and then fed as setpoints to the lower levels. In the *monolithic* approach, lower-level feasibility considerations are included into upper-level optimization problems accompanied by a significant drop in computational tractability. In the *hierarchical* approach, upper-level decision-makers consider lower-level optimality, accounting for how lower-level optimization problems affect upper-level objectives. This results in multi-level formulations, which are often numerically intractable and mathematically difficult (Chu and You, 2015). In this work, we show how we can leverage derivative-free optimization (DFO) (van de Berg et al., 2022) and surrogate modelling techniques to efficiently approach the tri-level optimum of an integrated planning-scheduling-control optimization problem.

To solve hierarchically integrated optimization problems, we reformulate multiple nested levels of decision-making into a single-level formulation. To this end, we can leverage data-driven techniques in a bottom-up or top-down approach. In the bottom-up approach, we first construct ‘optimality surrogates’ that map the optimal response variables of the lower level appearing in the upper levels as a function of the upper-level variables

appearing in lower levels. Similar techniques are known under various names across different fields, such as multi-parametric model predictive control, approximate explicit optimal control laws, amortized learning in Machine Learning, or policy-based methods in Reinforcement Learning (Avraamidou and Pistikopoulos, 2019; Sacchio et al., 2021). The top-down approach relies on derivative-free optimization (DFO), which is closely related to black-box and simulation-based optimization. The reader is referred to van de Berg et al. (2022) for a review on DFO for process systems engineering applications and to Beykal et al. (2022) for an exposition of how DFO could be used to solve multilevel problems.

Figure 1 shows our approach to the planning-scheduling-control problem: The bottom-up technique constructs optimality surrogates for the lower-level control problem. This surrogate is created offline and included as a constraint in the middle scheduling problem. As such, we collapse the two lower levels of scheduling and control into a single level. We then use DFO to find the optimal upper-level planning variables: DFO iteratively proposes a set of planning-level variables which are fixed and fed as setpoints to the lower-level integrated scheduling-control problem. The lower-level is then solved via traditional optimization software (Pyomo) which returns the complicating quantities that inform the upper-level objective to be optimized via DFO. As such, we manage to find a tractable solution to an otherwise intractable trilevel integrated planning-scheduling-control problem. It is worth noting that there will always be an approximation error when using surrogates, therefore, these must be trained and cross-validated appropriately.

## 2. Methodology

### 2.1. Problem Statement

We consider canonical planning, scheduling, and planning problems as described in Chu and You (2015). Using the hierarchical approach to integrate these decision levels yields the following tri-level optimization problem:

$$\begin{aligned}
 & \min_{\substack{\mathbf{x}_p, \mathbf{x}_{\text{prod}}, \mathbf{x}_s^*, \mathbf{c}_s^*, \\ \mathbf{x}_b^*, \mathbf{c}_c^*, t^*, \mathbf{x}_c^*}} f_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) + \mathbf{c}_s^* + \mathbf{c}_c^* & (1) \\
 & \text{s. t.} \quad \mathbf{h}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\
 & \quad \mathbf{g}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \\
 & \quad \substack{\mathbf{x}_s^*, \mathbf{c}_s^*, \mathbf{c}_c^* \\ \mathbf{x}_b^*, t^*, \mathbf{x}_c^*} \in \arg \min_{\substack{\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{c}_s, \\ \mathbf{x}_{\text{ctrl}}^*, t_{\text{ctrl}}^*, \mathbf{c}_{\text{ctrl}}^*}} f_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, t_{\text{ctrl}}^*; \mathbf{x}_{\text{prod}}) \\
 & \quad \text{s. t.} \quad \mathbf{h}_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{c}_s, t_{\text{ctrl}}^*; \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\
 & \quad \mathbf{g}_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, t_{\text{ctrl}}^*; \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \\
 & \quad \mathbf{x}_{\text{ctrl}}^*, t_{\text{ctrl}}^*, \mathbf{c}_{\text{ctrl}}^* \in \arg \min_{\substack{\mathbf{x}_c, t_{\text{ctrl}}, \mathbf{c}_{\text{ctrl}}} f_c(\mathbf{x}_c, t_{\text{ctrl}}, \mathbf{x}_{\text{batch}}) \\ \text{s. t.} \quad \mathbf{h}_c(\mathbf{x}_c, t_{\text{ctrl}}, \mathbf{c}_{\text{ctrl}}; \mathbf{x}_{\text{batch}}) = \mathbf{0} \\
 & \quad \mathbf{g}_c(\mathbf{x}_c, t_{\text{ctrl}}, \mathbf{x}_{\text{batch}}) \leq \mathbf{0}
 \end{aligned}$$

Eq. (1) denotes a tri-level optimization problem where  $f_p(\cdot), f_s(\cdot), f_c(\cdot)$  denote the objective functions,  $\mathbf{h}_p(\cdot), \mathbf{h}_s(\cdot), \mathbf{h}_c(\cdot)$  denote the equality constraints, and  $\mathbf{g}_p(\cdot), \mathbf{g}_s(\cdot), \mathbf{g}_c(\cdot)$  denote the inequality constraints of the planning, scheduling, and control problems respectively.  $\mathbf{x}_p, \mathbf{x}_{\text{prod}}$  denote the planning-specific and the production targets. The highest-level objective consists not only of  $f_p(\cdot)$  but also the optimal scheduling and operating costs appearing as  $\mathbf{c}_s^*, \mathbf{c}_c^*$  in the planning,  $\mathbf{c}_s, \mathbf{c}_{\text{ctrl}}^*$  in the scheduling, and  $\mathbf{c}_c^*$  in the

control (no scheduling cost in the control problem) that are obtained as the result of the scheduling optimization and its nested control optimization in the constraints. The mid-level scheduling problem takes the planning variables as setpoints  $\mathbf{x}_{\text{prod}}$  and optimizes the scheduling and batch variables  $\mathbf{x}_s, \mathbf{x}_{\text{batch}}$  which appear as optimal response variables in the planning level as  $\mathbf{x}_s^*, \mathbf{x}_b^*$ . The scheduling problem is also influenced by the optimal batch processing time as defined in the lower-level control problem. The control problem takes as setpoint the batch variables from the scheduling  $\mathbf{x}_{\text{batch}}$  and determines the optimal control variables, batch processing times, and operating cost  $\mathbf{x}_c, \mathbf{t}_f, c_{\text{ctrl}}$  (planning),  $\mathbf{x}_{\text{ctrl}}, \mathbf{t}_f^*, c_{\text{ctrl}}^*$  (scheduling), and  $\mathbf{x}_c, \mathbf{t}_f, c_{\text{ctrl}}$  (control) for said batch. It is worth noting that our considered planning, scheduling, and control problems would, in isolation, represent linear, mixed-integer linear, and optimal control problems, respectively.

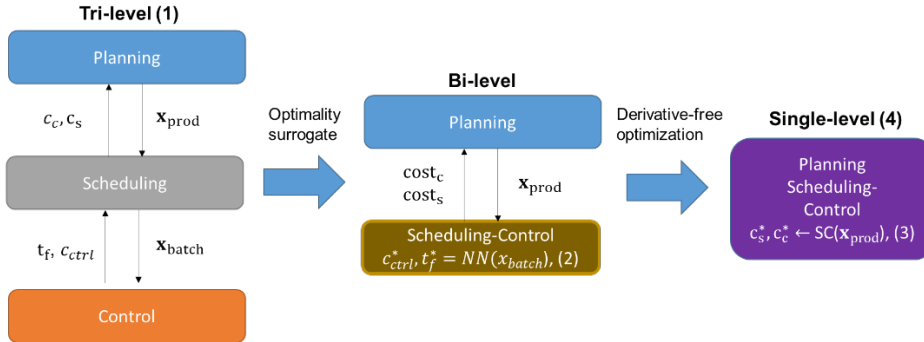

Figure 1. We reformulate tri-level planning-scheduling-control problem (1) by collapsing the control problem as an optimality surrogate into the scheduling problem (2), and then using derivative-free optimization to solve the remaining bi-level problem as a single-level black-box optimization problem (4), where each evaluation calls the scheduling model with the embedded optimal control surrogate (3).

As illustrated in Figure 1, we will start by reformulating the bi-level scheduling and control problems into a single-level formulation using the bottom-up approach, before collapsing the integrated scheduling-control level into the planning level.

## 2.2. Collapsing scheduling and control levels using optimality surrogates

By inspection of Problem (1), we notice that the optimal operating cost and batch processing time  $c_{\text{ctrl}}^*$  and  $\mathbf{t}_f^*$  are the only control-level variables appearing in upper levels. Consequently, we can formulate surrogates that map the optimal control response variables  $c_{\text{ctrl}}^*$  and  $\mathbf{t}_f^*$  as a function of the batch production targets  $\mathbf{x}_{\text{batch}}$  as the only setpoints feeding into the control level.

$$c_{\text{ctrl}}^*, \mathbf{t}_f^* = NN(\mathbf{x}_{\text{batch}}) \quad (2)$$

While there are many potential surrogates we could use (Dias and Ierapetritou, 2020), we use neural networks for their general approximation qualities, their potential for MILP reformulation and their ease of incorporation into optimization pipelines (Cecon et al., 2022). We uniformly sample batch sizes and solve the corresponding optimal control problem, logging the optimal response variables. Then, we train a small neural network of two hidden layers with five nodes each using Pytorch to predict the optimal response variables given the setpoints. We can then reformulate the neural network surrogate into mixed-integer linear constraints that can be incorporated as a Pyomo block into the planning Pyomo model using OMLT (Cecon et al., 2022). Since we are using rectified linear unit (ReLU) activation functions, we can use the full-space formulation to ensure

that the bi-level scheduling-control model can be reformulated into a single-level mixed-integer linear program (3), which is crucial for computational tractability. This allows us to use specialized solvers (Gurobi). Following the monolithic approach or using other formulations would require less efficient mixed-integer *nonlinear* solvers.

$$\begin{aligned} \mathbf{x}_s^*, \mathbf{c}_s^*, \mathbf{c}_c^*, \mathbf{x}_b^*, \mathbf{t}^*, \mathbf{x}_c^* \in \text{SC}(\mathbf{x}_{\text{prod}}) = \arg \min_{\substack{\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{c}_s, \\ \mathbf{t}_f, \mathbf{c}_{\text{ctrl}}}} f_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{t}_f^*; \mathbf{x}_{\text{prod}}) \\ \text{s. t.} \quad \mathbf{h}_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{c}_s, \mathbf{t}_f^*; \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\ \mathbf{g}_s(\mathbf{x}_s, \mathbf{x}_{\text{batch}}, \mathbf{t}_f^*; \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \\ \mathbf{c}_{\text{ctrl}}^*, \mathbf{t}_f^* = \text{NN}(\mathbf{x}_{\text{batch}}) \end{aligned} \quad (3)$$

### 2.2.1. Single-level black-box optimization given optimal scheduling-control

After collapsing the bi-level scheduling-control problem into an integrated single-level formulation, we need to incorporate the integrated model with the higher-level planning, resulting in bi-level Formulation (4):

$$\begin{aligned} \min_{\substack{\mathbf{x}_p, \mathbf{x}_{\text{prod}}, \mathbf{x}_s^*, \mathbf{c}_s^*, \\ \mathbf{x}_b^*, \mathbf{c}_c^*, \mathbf{t}^*, \mathbf{x}_c^*}} f_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) + \mathbf{c}_s^* + \mathbf{c}_c^* \\ \text{s. t.} \quad \mathbf{h}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\ \mathbf{g}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \\ \mathbf{x}_s^*, \mathbf{c}_s^*, \mathbf{c}_c^* \in \text{SC}(\mathbf{x}_{\text{prod}}) \\ \mathbf{x}_b^*, \mathbf{t}^*, \mathbf{x}_c^* \end{aligned} \quad (4)$$

Inspired by Beykal et al. (2022), we intend to use derivative-free optimization (DFO) to find the planning variables that optimize the planning-level objective. DFO is closely related to black-box and simulation-based optimization. Its aim is to find input variables that optimize a system whose gradient expressions cannot be cheaply obtained. DFO solvers can be loosely categorized into direct methods, which handle function evaluations directly, and model-based methods, which rely on the intermediate construction and optimization of surrogates. As opposed to traditional numerical optimization where all variables are considered ‘decision variables’, in DFO, we only optimize the degrees of freedom, a subset of the variables that when fixed allow for the remaining quantities to be determined using the remaining equality constraints. To this end, we first decompose the planning-specific variables  $\mathbf{x}_p$  into  $\mathbf{x}_{\text{store}}$ ,  $\mathbf{x}_{\text{transp}}$ ,  $\mathbf{x}_{\text{sales}}$ , the storage, transportation, and sales variables respectively. We notice that when fixing  $\mathbf{x}_{\text{prod}}$ ,  $\mathbf{x}_{\text{transp}}$ ,  $\mathbf{x}_{\text{sales}}$ , we can obtain the storage variables  $\mathbf{x}_{\text{store}}$  by leveraging  $\mathbf{h}_p(\mathbf{x}_{\text{store}}, \mathbf{x}_{\text{transp}}, \mathbf{x}_{\text{sales}}, \mathbf{x}_{\text{prod}}) = \mathbf{0}$ . We can then obtain all quantities of the planning-level objective:  $\mathbf{c}_s^*, \mathbf{c}_c^* \in \text{SC}(\cdot)$  and  $f_p(\cdot)$ . In the DFO, we augment the planning-level objective with a penalty term on the inequalities

$$\begin{aligned} g_{\text{viol}} = \max(\mathbf{0}, \mathbf{g}_p(\cdot))^2 \\ \min_{\mathbf{x}_{\text{prod}}, \mathbf{x}_{\text{transp}}, \mathbf{x}_{\text{sales}}} f_p(\mathbf{x}_{\text{store}}, \mathbf{x}_{\text{transp}}, \mathbf{x}_{\text{sales}}, \mathbf{x}_{\text{prod}}) + \mathbf{c}_s^* + \mathbf{c}_c^* + g_{\text{viol}} \\ \text{where} \quad \mathbf{x}_{\text{store}} \leftarrow \mathbf{h}_p(\mathbf{x}_{\text{store}}, \mathbf{x}_{\text{transp}}, \mathbf{x}_{\text{sales}}, \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\ g_{\text{viol}} \leftarrow \mathbf{g}_p(\mathbf{x}_{\text{store}}, \mathbf{x}_{\text{transp}}, \mathbf{x}_{\text{sales}}, \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \\ \mathbf{c}_s^*, \mathbf{c}_c^* \leftarrow \text{SC}(\mathbf{x}_{\text{prod}}) \end{aligned} \quad (4)$$

As such, we have reformulated the tri-level Problem (1) into a single-level black-box optimization problem (4), where in each evaluation of the DFO input we evaluate the remaining planning-level variables necessary to compute the planning-specific objective

and inequality penalty term. We obtain the lower-level optimal costs by calling the integrated planning-scheduling optimization instance.

2.3. Notes on the derivative-free optimization

Since the black-box evaluations are expensive, we only have a restricted budget of 400 evaluations to optimize the 178-dimensional problem. This makes the DFO problem very challenging to be solved without *a priori* insights. As such, we hot-start the solution to the problem by extracting the relevant DFO variables from the solution of the following planning-only problem:

$$\begin{aligned} \min_{\mathbf{x}_p, \mathbf{x}_{\text{prod}}} \quad & f_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) \\ \text{s. t.} \quad & \mathbf{h}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) = \mathbf{0}, \\ & \mathbf{g}_p(\mathbf{x}_p, \mathbf{x}_{\text{prod}}) \leq \mathbf{0}, \end{aligned} \tag{5}$$

Given the expensive nature of the evaluations, we only have enough budget to perform a ‘local search’ around the optimum obtained from (5) rather than perform extensive exploration of the solution space. Informed by van de Berg et al. (2022), we use the trust-region method Py-BOBYQA given its highly exploitative nature.

3. Results

The alternative to solving the tri-level optimization problem is solving the planning-only problem in (5) and sending its optimal planning target as a setpoint to the scheduling problem which is optimized and finally fed to control (sequential approach). We use the solution of the planning problem of the sequential approach as an initial guess for the DFO and decrease the tri-level objective from a cost of 4.762 to -0.132 million, turning the tri-level objective profitable. The tri-level solution also translates into tangible production and scheduling changes: Figures 2A and 2B demonstrate that going from the initial guess to the DFO solution finetunes the production targets of some products (in red case) given more accurate accounting of storages costs from the scheduling level. Figures 2C and 2D illustrate that the production assignment of products P1 and P2 changes (in red case) due to a more accurate estimate of the processing time from the control problem.

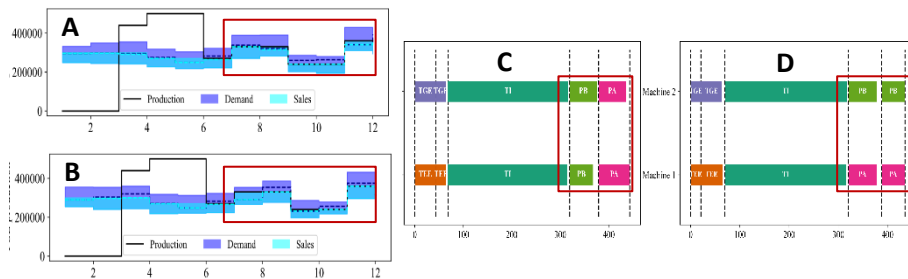

Figure 2. Figures A and B represent the production target of one product in kg over 12 weeks for the planning-only initial guess (A) and the tri-level solution (B) respectively. Figures C and D show the scheduling job assignments for all products in a particular week for the planning-only initial guess (C) and the tri-level solution (D) respectively. Changes highlighted in red.

4. Discussion

Our proposed methodology lends itself well to the decision-making frameworks of the process industries. Given the expensive nature of monolithic or hierarchical decision-making, planning, scheduling, and control problems are usually solved sequentially. Our proposed integrated approach leverages an initial guess to the DFO problem using the

single-level planning problem. As such, we can always fall back on the sequential approach if the DFO fails to make significant progress. This way, when applying exploitative DFO solvers, our proposed methodology can be interpreted as ‘fine-tuning’ the single-level planning optimum towards a tri-level objective in the available evaluation budget available to decision-makers. Our methodology begs the question if the two techniques (DFO and optimality surrogates) can be used interchangeably. There are clear trade-offs associated with both techniques. DFO for bi-level optimization has the advantage that it does not have to sacrifice solution accuracy through approximation errors. However, DFO performs best in lower dimensions. To use DFO for bi-level optimization requires all degrees of freedom in the upper-level optimization problem to be determined, which scales rapidly with the problem size, especially given our tight evaluation budget due to the expensive scheduling-control solution at each iteration. On the other hand, while optimality surrogates present the more tractable alternative, they inevitably introduce approximation error. As such, the choice of optimality surrogates should be followed by strategies that mitigate approximation error, such as cross-validation of the surrogate’s performance. Future work will apply this methodology to different case studies, investigate the potential of the surrogate approach to the planning-scheduling integration and of decision trees to be used as optimality surrogates.

## 5. Conclusion

We leverage DFO and optimality surrogates to reformulate a tri-level optimization problem into a single-level black-box optimization problem that we solve using the derivative-free optimizer Py-BOBYQA where each evaluation calls a scheduling instance with an embedded optimal control surrogate. We suggest hot-starting the solution to our problem using the solution to the planning-only optimization problem. As such, we use the remaining computational budget to approach the tri-level optimum from the hierarchical approach, which most accurately reflects decision-making. Nonetheless, we can always fall back on the ‘status quo’, i.e. the solution of the planning-only optimization problem from the sequential method. Our approach leads to tangible changes in the optimal production planning and scheduling sequence from the ‘status quo’.

## Abstract

Decomposition-based optimization algorithms are widely used for the solution of optimization problems. However, the choice of whether a decomposition-based solution approach should be selected over a monolithic one is not apparent in general. In this work, we propose a graph classification approach for determining a-priori when to use a decomposition-based solution approach for the solution of convex mixed integer nonlinear optimization problems. We apply the proposed approach to benchmark optimization problems and analyze the predictive performance of the classifier.

**Keywords:** Graph Classification, Decomposition-based solution algorithms, convex MINLP

## 1. Introduction

Decomposition-based solution algorithms have been widely used to solve optimization problems by exploiting the underlying structure of the problem. Although these algorithms are usually employed for the solution of large-scale problems (Conejo, 2006) for some cases, such as convex Mixed Integer Nonlinear Programs (MINLPs), they are more efficient than monolithic solution approaches even for problems with few variables and constraints (Duran and Grossmann, 1986). However, the effectiveness of a decomposition-based solution approach can only be determined after an optimization problem is solved with both approaches. Although this is a reasonable task for a simple problem, it is computationally expensive for large-scale problems. Hence, a method to determine a-priori when to apply a decomposition-based solution algorithm is necessary. In this work, we will pose this as an algorithm selection problem (Rice, 1976) in which given an optimization problem  $\mathcal{P}$  and a set of algorithms  $\mathcal{A} = \{\alpha_1, \alpha_2, \dots, \alpha_n\}$ , one must find the algorithm  $\alpha^*$  that solves problem  $\mathcal{P}$  in the minimum computational time. Mathematically this problem can be stated as follows:

$$\alpha^* \in \arg \min_{a \in \mathcal{A}} m(\mathcal{P}, a), \quad (1)$$

where  $m : \mathcal{P} \times \mathcal{A} \rightarrow R$  is the solution time of problem  $\mathcal{P}$  using algorithm  $\alpha$ . This is a black box optimization problem since the function  $m$  is not known explicitly. Machine learning techniques have been used to approximate either the solution time or the solution of the problem itself with a surrogate model based on some features of the problem (Kerschke et al. (2019), Xu et al. (2011), Bonami et al. (2022), Kruger et al. (2017)). These approaches considered the selection of monolithic solution algorithms for Mixed

Integer Linear (MILPs) and Mixed Integer Quadratic Programs (MIQPs) and determined if a MILP should be solved using the Dantzig-Wolfe (DW) reformulation or Branch and Cut. In all these cases, the regression or classification is performed based on problem features obtained from the problem formulation and the preprocessing step. However, the features aggregate information about the problem and do not explicitly consider the structural coupling between the variables, which is the basis for the application of decomposition-based solution algorithms (Conejo (2006), Allman et al. (2019), Mitrai and Daoutidis (2021), Mitrai et al. (2022)).

In this paper, we propose a graph classification approach to determine if a convex MINLP should be solved using a monolithic or a decomposition-based solution approach. Specifically, we use graph convolutional neural networks (Kipf and Welling, 2016) to capture the structural and functional interactions among the variables of the problem. Given this representation, a graph classifier is trained to determine if a convex MINLP should be solved using Branch and Bound (B&B) (Gupta and Ravindram, 1985), a monolithic solution approach, or the Outer Approximation (OA) algorithm (Duran and Grossmann, 1986) a commonly used decomposition-based solution approach. The rest of the paper is organized as follows: In Section 2 we present the combined structural and functional graph representation of an optimization problem. In Section 3 we present the graph classification-based algorithm selection solution approach and in Section 4 we analyze the classifier's performance on benchmark convex MINLPs.

## 2. Graph representation of an optimization problem

We assume that the following convex MINLP must be solved:

$$\begin{aligned} \mathcal{P} : \min_{x,y} f(x,y) \\ \text{s. t. } g(x,y) \leq 0 \\ x \in \mathbb{Z}^{n_x}, y \in \mathbb{R}^{n_y} \end{aligned} \quad (2)$$

where  $n_x + n_y = n$ , and  $g, f$  are convex in the variables  $y$  and in the relaxed integer variables  $x$ . Based on our previous work (Mitrai et al. (2022), Allman et al. (2019)), we will represent problem  $\mathcal{P}$  as a graph.

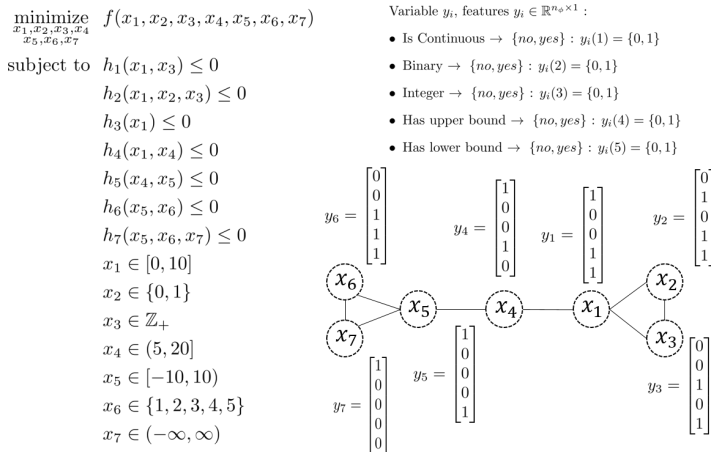

Figure 1: Graph and feature representation of an optimization problem

Three graphs can be generated to capture the structural coupling among the variables and constraints, the bipartite variable-constraint graph, the constraint graph, and the variable graph. For the rest of the paper, we will use the variable graph  $\mathcal{G}_n(V_n, E_n)$  ( $|V_n| = n$ ), where every node represents a variable and the edges represent constraints that couple two variables. In this work, we extend the aforementioned representation to a combined structural and functional graph representation of an optimization problem. Specifically, for every node in a graph, we add a set of features that capture different characteristics of the node, such as the domain of the variable and the upper and lower bounds (see Fig. 1). These features form the feature matrix  $F$ . Given this representation, a graph is represented by the adjacency matrix  $A$  and the feature matrix  $F$ , i.e.,  $\mathcal{G}_n(A, F, E)$ .

### 3. Algorithm selection via graph classification

#### 3.1. Graph classification approach

Given an optimization problem  $\mathcal{P}$  and the variable graph  $\mathcal{G}_n(A, F, E)$  the goal is to develop a classifier  $\mathcal{C}: F(\mathcal{P}) \times A(\mathcal{P}) \mapsto p \in \mathbb{R}^{N_a}$  to determine if problem  $\mathcal{P}$  should be solved using Branch and Bound (B&B) or the Outer Approximation (OA) algorithm ( $\mathcal{A} = \{B\&B, OA\}, |\mathcal{A}| = N_a = 2$ ). The inputs in the classifier are the adjacency  $A(\mathcal{P})$  and feature  $F(\mathcal{P})$  matrix (which depend on the problem  $\mathcal{P}$ ), and the output is a vector  $p \in \mathbb{R}^{N_a}$ , where  $p_i$  is equal to the probability that algorithm  $\alpha_i$  solves the problem in the minimum computational time. Under this setting, the algorithm selection problem is transformed into a graph classification problem, where a given problem  $\mathcal{P}$  is solved using the algorithm with the maximum probability  $a^* = \arg \max p$  with  $p = \mathcal{C}(F(\mathcal{P}), A(\mathcal{P}))$ . The overall framework is presented in Fig. 2.

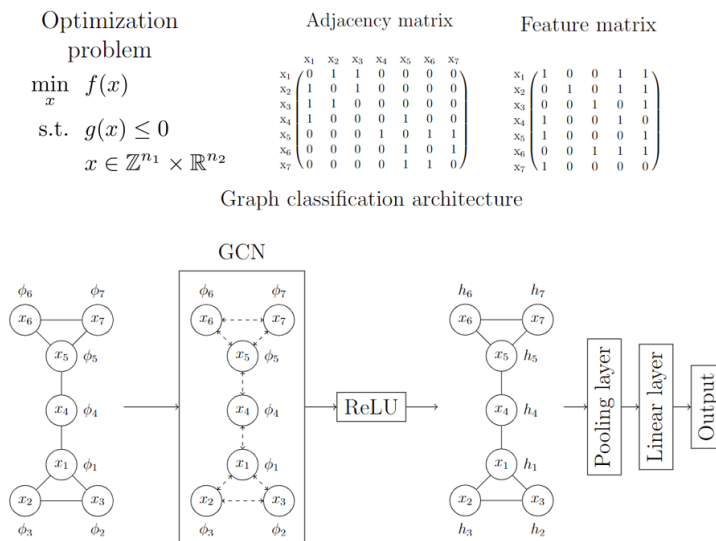

Figure 2: Learning when to decompose framework

#### 3.2. Graph classifier architecture

The graph classification task is performed using graph convolutional neural (GCN) networks (Kipf and Welling, 2016). Given an optimization problem  $\mathcal{P}_i$  (see Eq. 2) with  $N_v$  variables and  $N_m$  constraints, we can generate the variable graph  $\mathcal{G}_v(V_v, E_v)$  ( $|V_v| = N_v$ ) and obtain the adjacency  $A \in \mathbb{R}^{N_v \times N_v}$  and feature  $F \in \mathbb{R}^{N_v \times N_\phi}$  matrices where  $N_\phi$

is the number of features per node. We define as  $\phi_i$  the features of node  $i$  ( $\phi_i$  is the  $i^{th}$  row of matrix  $F$ ). We will assume that  $L$  GCN layers are stacked sequentially and the features of the nodes are updated using a GCN layer as follows:

$$H^{(1)} = \sigma \left( \widehat{D}^{-\frac{1}{2}} \widehat{A} \widehat{D}^{-\frac{1}{2}} F W^{(1)} \right)$$

$$H^{(l)} = \sigma \left( \widehat{D}^{-\frac{1}{2}} \widehat{A} \widehat{D}^{-\frac{1}{2}} H^{(l-1)} W^{(l)} \right) \forall l \in \{2, L\},$$

where  $l \in \{1, L\}$  denotes the layer number,  $\sigma$  is the activation function,  $\widehat{A} = A + I$  ( $I$  is the identity matrix of appropriate dimension),  $\widehat{D}_{ii} = \sum_{j=0}^{N_v} \widehat{A}_{ij}$  is the degree of node  $i$  and  $\widehat{D} = \text{diag}(\{\widehat{D}_{ii}\}_{i=1}^{N_v})$ .  $W^{(1)} \in \mathbb{R}^{N_\phi \times N_h}$  are the weights for the first layer,  $W^{(l)} \in \mathbb{R}^{N_h \times N_h}$  are the weights for layer  $l$ , and  $N_h$  is equal to the number of hidden features for each node. The output of the last layer  $L$  is passed through a pooling layer which creates a graph-level feature  $r \in \mathbb{R}^{N_h \times 1}$  which is equal to

$$r_i = \frac{1}{N_v} \sum_{j=1}^{N_v} H_{ij}^L \quad \forall i = 1, \dots, N_h.$$

Finally, the graph level feature is an input to a linear transformation layer, where the output is  $y \in \mathbb{R}^{N_A \times 1}$  ( $y_i$  is the probability that algorithm  $i$  solves the problem in the minimum computational time) and is equal to  $y = \Theta r + b$ , where  $\Theta \in \mathbb{R}^{N_A \times N_h}$ ,  $b \in \mathbb{R}^{N_A \times 1}$  are parameters.

This classifier can classify problems with different number of variables and constraints since the pooling layer after the last convolution layer creates the vector  $r$  which has  $N_h \times 1$  dimension. Therefore, for the final classification step, every problem is represented in the hidden features dimension space  $N_h$ .

### 3.3. Training of the graph classifier

We assume that a set of optimization problems  $\{\mathcal{P}_i\}_{i=1}^{N_{data}}$  is available and for these problems we can obtain the variable graphs  $\{\mathcal{G}_i\}_{i=1}^{N_{data}}$ , the adjacency and feature matrix  $\{A_i, F_i\}_{i=1}^{N_{data}}$ , and labels  $\{z_i\}_{i=1}^{N_{data}}$  where  $z_i$  is the algorithm that solves problem  $\mathcal{P}_i$  in the minimum computational time. Given these data, the task is to learn the classifier's parameters that will maximize its accuracy by optimizing some loss function, such as the cross entropy.

## 4. Deciding when to decompose convex MINLPs

In this section, we apply the proposed approach to benchmark convex MINLPs from the MINLPLib (2022) to determine if a given convex MINLP should be solved using Branch and Bound (Gupta and Ravindram, 1985) or the Outer Approximation algorithm (Duran and Grossmann, 1986) as implemented in the BONMIN solver (Bonami et al., 2008).

### 4.1. Feature representation of the problem and data generation for classification

We will consider the following features for every node in the variable graph: variable domain (continuous, binary, integer) and bound (upper, lower). We use one-hot encoding for the representation of these features as follows:

$$\phi(1) \in \{0,1\}: 1 \text{ if the variable is continuous and } 0 \text{ otherwise}$$

$$\phi(2) \in \{0,1\}: 1 \text{ if the variable is binary and } 0 \text{ otherwise}$$

- $\phi(3) \in \{0,1\}$ : 1 if the variable is integer and 0 otherwise
- $\phi(4) \in \{0,1\}$ : 1 if the variable has an upper bound and 0 otherwise
- $\phi(5) \in \{0,1\}$ : 1 if the variable has a lower bound and 0 otherwise

Under this representation, every node has five features ( $N_\phi = 5$ ).

#### 4.2. Data generation for classification

The MINLPlib library contains 295 convex optimization problems which are solved with both algorithms (B&B and OA) using BONMIN 1.8.8 with a maximum computational time of 3000 seconds. From the 295 problems, 227 are solved with at least one solver (151 problems are solved faster with OA and 57 with B&B), and for each problem we obtain the adjacency and feature matrix  $(A_i, F_i)$ . Overall, we obtain the dataset  $\mathcal{D} = \{(A_i, F_i), y_i\}_{i=1}^{N_{data}}$ , where 66% of the data points have label OA and 34% B&B.

#### 4.3. Graph classification architecture and implementation

We split the dataset  $\mathcal{D}$  at random into a training set and a testing set. The training set has 197 data points and the testing set has 30 data points picked at random (15 random data points have label OA and 15 have label B&B). The graph classifier has four convolution layers ( $L = 4$ ), a global mean pooling layer, a linear layer (with dropout probability equal to 0.5), the number of hidden features is 12 ( $N_h = 12$ ), and ReLU is used as the activation function. For the training, we use the Adam algorithm (Kingma and Ba, 2014) for 50 iterations with random initialization, the learning rate equal to 0.005, and batch size equal to 10. The loss function is the cross entropy and different weights are assigned to the two classes to account for the imbalance in the training dataset. The weights are computed as follows:  $\omega_i = N_{data} N_\alpha^{-1} \left( \sum_{j=1}^{N_{data}} 1_i(y_j) \right)^{-1}$ , where  $1_i$  is the indicator function, i.e.,  $1_i(y_j) = 1$  if  $y_j = i$  and 0 otherwise. The weight for class B&B is 1.6148 and for class OA is 0.7243. The GCN is implemented in PyTorch Geometric (Fey and Lenssen, 2019) and the training is done using PyTorch (Paszke et al., 2015).

#### 4.4. Classification results

The performance metrics of the classifier on the testing data set are presented in Table 1.

Table 1: Performance metrics for the graph classifier on the testing data set

Accuracy	0.9	F1 score	0.9	Confusion matrix		
				Predicted label		
Label	Precision	Recall	F1 score	True label	OA	B&B
OA	0.83	1.00	0.91	OA	15	0
BB	1.00	0.80	0.89	B&B	3	12

From the results, we observe that the classifier has 90% accuracy and the F1 score is 0.9. A few data points with label B&B are misclassified as OA. This misclassification could be caused by the small size and the imbalance in the training set. Finally, we observe that the classifier can accurately predict all the problems that are solved faster with the OA algorithm.

## 5. Conclusions

The selection of the appropriate solution method for a general optimization problem can be a challenging and time-consuming step. In this work, we propose a graph classification approach to determine whether a convex MINLP should be solved using a decomposition-based or a monolithic-based solution approach by considering simultaneously the

structural and functional coupling between the variables and the constraints of a problem. Application of this approach to benchmark problems shows that the graph classifier can achieve 90% accuracy. However, more data are necessary to reduce the imbalance in the dataset and improve the performance of the classifier.

## Abstract

In this work, we developed new models using an enhanced group-interaction contribution method for the prediction of freezing point and enthalpy of fusion of pure organic compounds. These enhancements proved their efficiency by results presented on an earlier published paper, (Mansour and Korichi (2016)), which includes the extension of the training dataset by new experimental data, add 85 new structural groups and additional correction groups to distinct between isomers including Cis or Trans as well as Ortho, Meta or Para structures. 1124 and 501 experimental data points used for the new ( $T_{fp}$ ) and ( $\Delta H_f$ ) models development and testing respectively.

**Keywords:** Thermophysical Properties Prediction, Group-Interaction Contribution, Freezing point, Enthalpy of Fusion, Pure Organic Compounds.

## 1. Introduction

Freezing point is of high importance property for pure organic compounds characterization; it is influenced by the presence of other substances (impurity) made it an important criterion for purity.

The enthalpy of fusion also known as the latent heat of fusion ( $\Delta H_f$ ) is an important physical property of the solid state, and can be useful in correcting thermo-chemical data to a standard state when combined with other thermodynamic properties, Wang et al., (2010).

The knowledge of these two properties for pure organic compounds is a great challenge for any new process and/or products design, especially when taking in consideration the enormous number of molecules, and not forgetting time and costs. An alternative solution available to solve the lack of experimental data and the request for these properties, prediction methods. Numerous based group-contribution methods and models developed for the prediction of freezing point and enthalpy of fusion in order to fill the gap between new available molecules and the properties values, Boethling et al., (2000); Poling et al., (2004).

Group contribution methods divide the molecules in to groups (fragments; atoms, bonds or group of atoms, etc) each group has a partial value contribute in the total value of the calculated property. These contributions calculated from known experimental data. Property of a compound obtained by a summing up the values of all contributions presented in the molecule via the developed mathematical model. Kolská, et al., (2012).

Marrero and Pardillo (1999) proposed, the group-interaction contribution (GIC) which defined a fragment as the interaction between two simple groups e.g the interaction between  $-\text{CH}_3$  and  $>\text{CH}_2$  make a group, this approach was not applied for the development of models allowing the prediction of freezing point and enthalpy of fusion.

The appearance of new experimental data helps the development of new models, an enhanced group interaction contribution method published, Mansour and Korichi (2016) presenting new models using the (GIC) approach. In this paper, the enhanced approach applied for the development of new models for the prediction of freezing point and enthalpy of fusion at the freezing point.

## 2. Models development

### 2.1. Approach

The mean benefits of the new developed models are accuracy and isomers distinction (due to new available data, which conduct to new added groups). In this work, the (GIC) approach adopted for the prediction of these properties with some modifications in order to enhance the models prediction efficiency:

- Initially, after studying the utility of the groups, some of them were eliminated because they are useless, e.g. ( $=\text{CH}_2$  and  $=\text{CH}_2$ ), which appears only in ethene, this group has no use because it will not be used in the prediction of new compounds properties, and we have the properties of the mentioned compound.
- Secondly, modify some structural groups, such as ( $-\text{CH}_3$  and  $-\text{CN}$ ) and ( $-\text{CH}_2$  and  $-\text{CN}$ ), which they will be replaced by only one group ( $-\text{C}\equiv$  and  $\equiv\text{N}$ ) to reduce the groups number in order to simplify the method.
- Then, add new groups according to the new available data in our database taking in consideration the approach philosophy in generating groups, for example ( $>\text{CH}-$  and  $-\text{Br}$ ), ( $>\text{CH}-$  and  $-\text{C}\equiv$ ) are new added groups.
- Also, add some groups based on the functional chemical groups e.g.  $-\text{OH}$  and  $-\text{OR}$  for the distinction between alcohols and ethers,  $\text{O}=\text{C}-\text{OH}$  and  $\text{O}=\text{C}-\text{O}-\text{R}$  for the distinction between acids carboxylic and esters...etc, to enhance the method isomers distinction ability.
- Finally, introduce the differentiation between the aromatic and double bonds, which was not the case for the method of Marrero and Pardillo (1999).

### 2.2. Groups selection

Selection of contributions is based mainly on the interaction between two groups and the type of this interaction (bonds type; simple, double, triple or aromatic), these groups are similar to the groups used by Marrero and Pardillo (1999) with new added groups according to the modifications mentioned above, Fig. (1) shows the group's selection methodology. The groups used for the generation of contributions illustrated in table (1).

**Fig. 1:** Groups selection methodology.

**Table 1:** Groups used for the generation of group-interaction ((a), aromatic; (s), single; (d), double; (r), rig. For the correction groups, we have proposed cis, trans, ortho, meta and para.)

<b>Groups with single bond</b>					
-CH <sub>3</sub>	>CH <sub>2</sub>	>CH-	>C<		
<b>Groups with double bond</b>

	=N- (s)			-N= (d)	

### 2.3. Database

Special care was taking while the collection of the experimental data by choosing the right sources, the book of Yaws and Narasimhan (2008) was the main sources of our data base, beside, other sources were also used as verification for the database; table (2) resumes the available data points for each property, for every class.

**Table 2:** Properties and their experimental data points in the database

Class*	CH	O	N	S	H	multi	Total
T <sub>fp</sub>	422	299	123	60	192	29	1124
ΔH <sub>f</sub>	265	95	37	33	62	9	501

\*CH, hydrocarbons; O, oxygenated; N, nitrogenated; S, sulfur containing; H, halogenated; multi, multifunctional compounds.

### 2.4. Proposed models

Two types of regression used for the obtaining of the models. The first is a nonlinear regression using 100% of the data points, which allows as getting the adjusted parameters a<sub>1</sub> and b<sub>1</sub>. The second one is a linear regression, the data points was divided in two parts, 90% was used as training set for the obtaining of the contributions values and the adjusted parameters c<sub>1</sub> and c<sub>2</sub>, and 10% reserved for the testing of models performances.

Several models with different types of functions passed through the processes of models development and testing as mentioned above, and the adopted models for the prediction of ( $T_{fp}$ ) and ( $\Delta H_f$ ) are respectively equations (1) and (2):

$$\frac{T_{fp}}{(K)} = a_1 * \left( \sum_i N_i C_i + c_1 \right)^{b_1} \quad (1) \quad \text{Where } a_1=10.944, b_1= 1.522 \text{ and } c_1=3.6155$$

$$\frac{\Delta H_f}{(kJ/mol)} = T_{fp} * \left( \sum_i N_i C_i + c_2 \right)^2 \quad (2) \quad \text{Where } c_2=0.14327$$

### 3. Results and discussion

The mean tools for the validation of our models are: MAPE; Mean Absolute Percentage Error, MAE; Mean Absolute Error and SD; Standard Deviation Qiang *et al.* (2009) which also will be used for the judgment of the proposed models performances, beside the two determination coefficients  $R^2$  and adjusted  $R^2$ . The values of these parameters calculated for the total data points and for each class, as illustrated in table (3).

**Table 3:** Performances of the proposed models for the prediction of  $T_{fp}$  and  $\Delta H_f$

Class	$T_{fp}$				$\Delta H_f$			
	Data points	MAPE (%)	MAE (K)	SD (K)	Data points	MAPE (%)	MAE (kJ/mol)	SD (kJ/mol)
CH	421	8.19	14.76	18.48	265	17.32	1.24	1.63
O	299	6.44	14.79	18.77	95	10.25	1.07	1.56
N	123	6.12	14.55	18.74	37	10.11	1.15	1.6
S	60	6.93	11.82	15.90	33	10.7	0.84	1.3
H	192	8.27	16.76	20.30	62	17.76	1.01	1.43
Multi	29	4.60	11.69	15.68	9	11.06	1.31	2.03
Testing set	112	8.35	16.78	20.36	50	16.52	1.55	1.98
Total	1124	7.35	14.85	18.72	501	14.95	1.15	1.58
		$R^2 = 0.901$	$Adj. R^2 = 0.879$			$R^2 = 0.905$	$Adj. R^2 = 0.868$	

The new proposed models present accurate results for all the classes according to the validation parameters presented in the table (3), the hydrocarbon classes for both models offer the most accurate results among all the classes.

The value of the two determination coefficients  $R^2$  and adjusted  $R^2$  for the two models are very high and close to one unit, which represent another indication for the accuracy and reliability of the suggested models.

Beside validation parameters, distributions between experimental values and estimated values for both properties presented in Fig. (2) as validation tool for the chosen models. As illustrated, we can observe the accuracy obtained using the proposed models, these figures testify to an excellent reliability presented by the new models.

**Fig. 2:** Distributions of experimental and estimated values for (a)  $T_{fp}$ ; (b)  $\Delta H_f$  for training set (○) and testing set (+).

**Table 4:** Comparison between our model and earlier published models for the prediction of  $T_{fp}$

Methods	Data Points	Groups number	MAPE (%)	MAE (K)	SD (K)
Constantinou and Gani (1994)	312	66 1 <sup>st</sup> order	8.90	17.39	22.51
		41 2 <sup>sd</sup> order	7.23	14.03	18.28
Marrero and Gani (2001)	1547	166 1 <sup>st</sup> order	9.30	24.90	33.87
		117 2 <sup>sd</sup> order	7.90	21.41	29.52
		62 3 <sup>rd</sup> order	7.60	20.22	27.67

<b>This work</b>	<b>1124</b>	<b>203</b>	<b>7.35</b>	<b>14.85</b>	<b>18.71</b>

**Table 5:** Comparison between our model and earlier published models for the prediction of  $\Delta H_f$

Methods	Data points	Groups number	MAPE (%)	MAE (kJ/mol)	SD (kJ/mol)
Marrero and Gani (2001)	711	131 1 <sup>st</sup> order	18.30	2.58	4.16
		68 2 <sup>sd</sup> order	16.40	2.32	3.88
		40 3 <sup>rd</sup> order	15.70	2.17	3.65
<b>This work</b>	<b>501</b>	<b>143</b>	<b>14.95</b>	<b>1.15</b>	<b>1.58</b>

Tables 4 and 5 presents the comparison between the proposed models and the models available in the literature, using the validation parameters MAPE, MAE and SD. Although, the difference between the accuracy of new models and old ones is not great, but the extension of the application range and isomers distinction gives more power to the new models, beside the simplicity of the method.

#### 4. Conclusion

We presented new models allowing the estimation of ( $T_{fp}$ ) and ( $\Delta H_f$ ); these models developed via an enhanced group-interaction contribution method. Comparing with other methods available in literature, the proposed models showed excellent results concerning reliability; accuracy and application range.

Although, the (GIC) method has no theoretical background on how the groups are selected, but it bases on the bound type as criteria for the groups selection, which enhance its performance concerning the distinction between structural isomers Cis, Trans and Ortho, Meta and Para, which offers more accuracy for the prediction of the mentioned properties.

# Single and Multi-Objective Superstructure Optimization of an Integrated Continuous Multistage Reaction-Crystallization-Filtration Process with Recycles

Jiaxu Liu, Brahim Benyahia\*

*Department of Chemical Engineering, Loughborough University, Loughborough, LE11 3TU, United Kingdom*

*B.Benyahia@lboro.ac.uk*

## Abstract

A superstructure optimization methodology is developed to identify optimal design and operation strategies of a combined continuous multistage reaction and crystallization process. The production of aspirin is used as a case study. The main objective is to maximize yield and minimize wastes while meeting tight critical quality constraints. The synthetic pathway involves a two-step reaction, which runs continuously, followed by a multistage seeded continuous cooling antisolvent crystallization process, and finally a wash filtration stage. To reduce the environmental footprint of the process and enhance its circularity, the filtrate (mother liquor) is purified using a multistage purification process then made available as recycle streams to the reaction and crystallization steps. The superstructure also considers that part of the filtered crystals can be recycled to the crystallization stages. A purge is used to control the level of impurities present in the system. Based on the proposed approach, several optimization scenarios were developed with a large set of decision variables, including jacket temperatures, antisolvent flow rates, recycle flow rates, residence times, and recycled crystal mass flow rate. The objective functions include maximizing the mean crystal size, and yield and minimizing the coefficient of variation (CV). It was shown that a maximum mean crystal size of 628  $\mu\text{m}$ , a maximum yield of 87.91% and a minimum CV of 0.3596 can be achieved using the single objective optimization options. In addition, a multi-objective mixed integer nonlinear optimization problem was proposed to identify the best design and operation compromises captured by the Pareto front. Finally, a multicriteria decision-aiding approach based on the multi-attribute utility theory was used to rank the optimal Pareto trade-offs and help identify the most suitable solution.

**Keywords:** Multistage Reaction and Crystallization, Superstructure Optimization, MINLP, Multi-Objective Optimization, Multicriteria Decision Aiding.

## 1. Introduction

Over the last decade, continuous processing and flow chemistry have gained increasing interest in pharma as the most cost-effective, flexible, and environmentally friendly operation option. Despite the increased adoption of continuous processing, the development of fast and systematic approaches to synthesize integrated continuous processes and the identification of robust operating strategies is still an open topic in the pharmaceutical industry. Despite the high costs of pharma grade raw materials, which includes high purity reagent, intermediates and solvents, the implementation of recycles to rationalize resources consumption and minimize wastes is still not a common practice in pharma, and only a few investigations have been published to date (Benyahia 2018).

However, the presence of impurities and the inherent stringent regulatory requirements make the design and implementation of recycling even more challenging in pharma. As such, the development of more rigorous and systematic design and operation strategies is critical to demonstrate the benefits of the recycles and reduce inherent risks.

Pharmaceutical upstream processing, also referred to as drug substance manufacturing, commonly involves several reaction and purification steps which often involve a crystallization step followed by a wash-filtration. Often, the filtrate (mother liquor), which in the current practice is considered as waste, contains significant amounts of residual API, reagents, and solvents. However, the filtrate may also contain substantial amounts of impurities. Consequently, the design of an effective and environmental process with recycles requires effective purification technologies of the filtrates, and most importantly, optimal and robust design and operating strategies.

To address the optimal design problems from a more general perspective while embedding circularity principles, several operating and design options were introduced to the system along with systematic recycling strategies, which include recycling both solid products (crystals) and purified filtrate (mother liquor). In addition, optimal seeding policies were also considered as a possible option in all crystallization stages. These generic design options provide a solid basis for a systematic and effective process synthesis of multistage reaction and crystallization processes based on a superstructure optimization framework. The objective is to maximize flexibility and enhance the targeted key performance indicators such as the mean crystal size, yield, and coefficient of variation (CV). The generic optimal design problem, which captures all possible design scenarios, will be introduced in the following part. The resulting optimization problem is a mixed integer nonlinear programming problem (MINLP) which will deliver the optimal design options and the most effective recycling strategies. In addition to the single objective MINLP problem, a multi-objective MINLP is developed to identify the best design and operation compromises. Furthermore, the resulting set of optimal Pareto solutions is analyzed and ranked based on a multicriteria decision-aiding method to help determine the best design and operation option.

## **2. Method**

The synthesis and purification of aspirin is used as a case study. This involves two continuous reaction steps (Joiner, Billeter et al. 2014), a multistage continuous crystallization (Liu and Benyahia 2022), and a filtration stage. The mathematical models and experimental data were obtained from the literature and the proposed superstructure is shown in figure 1. The fresh feed and antisolvent are added to each stage separately at a fixed total mass flowrate, used as a constraint in the optimization problems. Crystal seeds and recycles (both liquid and crystals) can be introduced at any crystallization stage. Before recycling, the filtrate or mother liquor, obtained at the filtration stage, goes through a multistage membrane purification process to increase the concentration of API (Espinoza-Gomez, Saucedo-Castillo et al. 2018) but must be delivered at undersaturated level to avoid crystallization in the recycle stream. A purge stream is also used to control the level of impurities in the process.

Combining the reaction and crystallization allows us to investigate the impact of recycling unreacted reagents and even API and solvents on the overall process performance. Here the recycle is connected to the second reactor due to the fact that reaction 1 is a water-free reaction and the addition of water will significantly reduce reaction yield. The potential advantage is to reduce the antisolvent (water) in the recycled mother liquor and

recycle the API in the mother liquor, which will increase the overall yield and decrease the SA waste (all added water will end up in the SA waste stream).

Based on these generic settings, a series of optimization scenarios were developed by manipulating a large set of decision variables, namely: the jacket temperatures, antisolvent flow rates, feed flow rates, seeding policies, liquid recycles, crystals recycles, and a set of binary (integer) variables which determine whether a stream is required or not (0/1). The objective of the superstructure optimization problem is to maximize the mean crystal size, yield or minimize the CV. These criteria are optimized individually using single objective optimization strategies, and then a combination of these criteria is addressed using a multi-objective optimization approach to deliver the best design and operation compromises. Finally, the Pareto optimal solution are classified using the Multi-Attribute Utility Theory (MAUT) (Benyahia et al. 2011).

### 2.1. Formulation of the optimization problems

Firstly, a MINLP is proposed based on the generic flow diagram depicted in figure 1. Each of the recycles, fresh feeds and seeding streams is allocated a real variable, to determine the required flow rate, and an integer variable, to determine whether the stream is needed. The mathematical formulation of the optimization problem is shown in equation 1. The objective function can be the mean crystal size, CV, Yield (for single objective optimization) or a combination of the above (multi-objective optimization).

In the mathematical formulation below (equation 1),  $T_{j,i}$  is the temperature of jacket temperature ( $^{\circ}\text{C}$ ),  $F_{AS,i}$  is the antisolvent flow rate (g/min),  $F_{feed,i}$  is the feed flow rate (g/min), and  $F_{seed,i}$  is the suspended seed flow rate (g/min).  $\mu_{0,seed}$ ,  $d_{seed}$  are the number density of the suspended seed solution and crystal size ( $\mu\text{m}$ ) respectively.  $R_{l,i}$ ,  $R_{p,i}$  are the recycles flow rate of mother liquor (g/min) and crystals (g/min).  $I_i$  is the binary (integer) variable associated with the  $i$ th stage.

The constraints C1 to C9 represent the upper bound and lower bounds of the decision variables. C10 is used to allow cooling only, and C11-C13 defined the final constraints of the jacket temperature and antisolvent ratio. The supersaturation should be maintained above 1 during the process as no dissolution is allowed.

### 3. Results and discussion

#### 3.1. Single objective optimization

The MINLP problem described above was solved using a genetic algorithm (GA) in MATLAB. The maximum mean crystal size of 628  $\mu\text{m}$ , 87.91% yield, and 0.36 CV were obtained based on the three single objective optimization scenarios. Here, for the sake of brevity, only the first scenario which maximizes the mean crystal size, is discussed in detail. The corresponding optimal process design shows that the optimal solution, shown in Table 1, indicates that all fresh feed must be delivered to the first crystallization stage along with the entire liquid recycle stream (purified mother liquor) to promote growth. Compared to the feed, the purified mother liquor has a lower API concentration. Therefore, its introduction into the second and third stage may dilute the crystallization medium and significantly reduce supersaturation, which in turn leads to reduced crystal growth. The optimal design scenario, in the case maximization of the mean crystal size, recommends that larger residence times are required in the second and third crystallization stages to promote growth, while the first crystallization is used as a nucleator. Furthermore, the crystals recycle streams are implemented at all crystallization stages at their maximum allowed flow rates (upper bound) to prioritize the production of very large crystals. However, the implementation of the crystal recycles strongly depend on the targeted CV value and may be removed under different CV considerations.

#### 3.2. Multi-objective optimization

A multi-objective optimization problem is developed to optimize three critical objectives to help identify the best design and operation compromises. Here, the mean crystal size and yield are maximized while the CV is minimized. The optimization problem is subject to the same set of constraints as those in the problem formulated above. The corresponding Pareto solutions are shown in the 2D bubble map, where the grey scale and

	size ( $\mu m$ )					24.40						
	Mean crystal size ( $\mu m$ )					628						

bubble size represents the mean crystal size (third objective function). To help the decision maker identify few alternative optimal designs and operation options for the experimental verification, the multi attribute utility theory (MAUT) is used to rank all Pareto optimal solutions. The 210 Pareto solutions were ranked according to the utility function scores. The size of the circle represents the mean crystal size. It can be found in the 2D Pareto solutions distribution shape (figure 2 (largest)) that the mean crystal size and CV performance go in opposite directions. The crystals lie at the right side of the shape, where CV is the worst. However, the yield doesn't vary significantly but overall stays within acceptable range.

### 3.3. Combined multistage reaction and crystallization process

Here the reactions stages are also optimized. By adding the ratio of SA and AA, represented by  $r$ , as one of the decision variables, the conversion of SA can be manipulated. With the optimal operation profile, a mean crystal size of 307  $\mu m$  can be obtained based on the proposed superstructure optimization.

Compared to scenario 1 (maximize mean crystal size), the optimal solution requires higher seeding flowrates, but the required seed concentration/density is lower compared to the previous case. It is because the seed is suspended in a saturated solution, which has a higher solubility than the outlet flow from the reactor. It means that the dissolved API is a priority to generate more growth. Besides, the optimal solution also indicates that recycling the purified mother liquor is not advised to maximize the mean crystal size

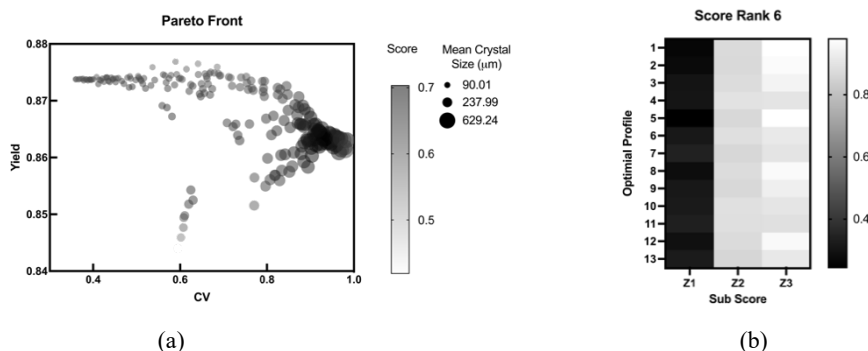

Figure 2 Ranking of the Pareto solutions based on MAUT (a) and sub-scores (b)

when the optimization is based on the combined reaction and crystallization. Because of the conflicting effect between a better reaction conversion and better crystallization yield, the recycle stream may dilute the crystallization system more significantly far beyond what was observed in scenario 1, when the concentration of API is higher than the nominal/initial concentration in the outlet flowrate (fresh feed) from the reactor.

#### 4. Conclusion

A superstructure optimization approach was proposed to design an integrated reaction-crystallization-filtration process with recycles. All possible options for the recycle streams, crystal seeding, and fresh feed additions were considered and allocated binary and real decision variables. Other critical decision variables were also considered which include the design and operating options such as cooling temperatures and crystallizer capacity (residence time). Firstly, single objective optimization problems were solved separately to (1) maximize mean crystal size, (2) minimize the CV, (3) maximize yield. This was followed by a combination of three objectives to address a mixed integer multi-objective optimization problem. The resulting Pareto solutions were analyzed and ranked using MAUT. The exploration of the combination of the reaction and crystallization also indicate that recycling the purified mother liquor to the second and third stage in crystallization are not recommended. And with the recycles to the reactor, the mean crystal size was maximized to 307  $\mu\text{m}$  with less water added in the second reactor. The proposed systematic approach shows that wastes can be significantly reduced, and resources consumption may be rationalized without compromising on product quality.

# Prediction of product distribution using machine learning techniques

Praveen Kumar Bommineni,<sup>a</sup> Manohar Kakunuri,<sup>a</sup> Sarat Babu Anne,<sup>a</sup>

<sup>a</sup>*Department of Chemical Engineering, National Institute of Technology Warangal, Warangal – 506004, India*

## Abstract

The product distribution of multi-product processes involving series-parallel reactions depends on several variables. Hence, traditional experimental and computational approaches are laborious, time consuming and the results may not be satisfactory. Data driven approaches serve as an alternative to the traditional approaches in predicting and optimizing the product distribution. Machine learning (ML) provides reliable and accurate predictions. In this work, application of ML techniques to predict product distribution of one such complex process is demonstrated. Chlorination of methane has been chosen as case study for this purpose. Data required for the ML models is generated by simulating the process flow sheet in aspenONE. Of the several ML models used, k-nearest neighbors (kNN) method provides most accurate product distribution with high R-square value and low mean absolute error (MAE).

**Keywords:** Series-parallel reactions, product distribution, aspenONE, Machine Learning.

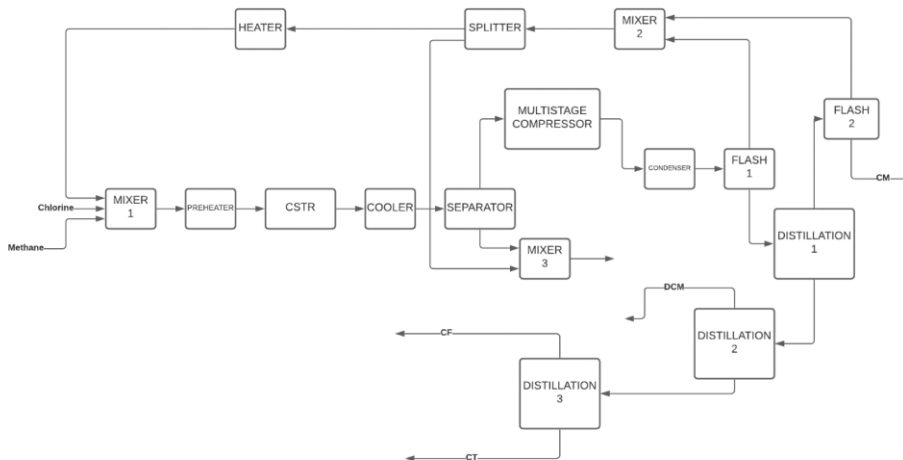

## 1. Introduction

Reactions and processes are typically desired to operate at optimum conditions of process variables such as temperature, pressure, flow rates, compositions etc. (Tabor 2018, Gupta 2021). Therefore, the chief goal is to find the optimal conditions so as to maximize performance in terms of yields, purity etc. However, it is not a trivial task to find optimum conditions even at lab scale as many variables/parameters effect the performance and it requires iterative costly procedures. Data-driven approaches serve as an alternative and reliable way to achieve the same (Shields 2021, Marcus 2021, Hein 2021, Joung 2021).

Machine learning is proving to be useful tool for applications in various fields including materials discovery from failed experiments, optimizing reaction conditions, reaction classification, synthesis of small molecules (Park 2022, Raccuglia 2016, Zunyun 2020, Schwaller 2021, Probst 2022, Segler 2018). In this article we demonstrate prediction of product distribution using ML techniques. First we present the process simulation followed by application of machine learning techniques to predict product flow rates and compositions.

## 2. Methane chlorination process simulation

### 2.1. Steady state process simulation

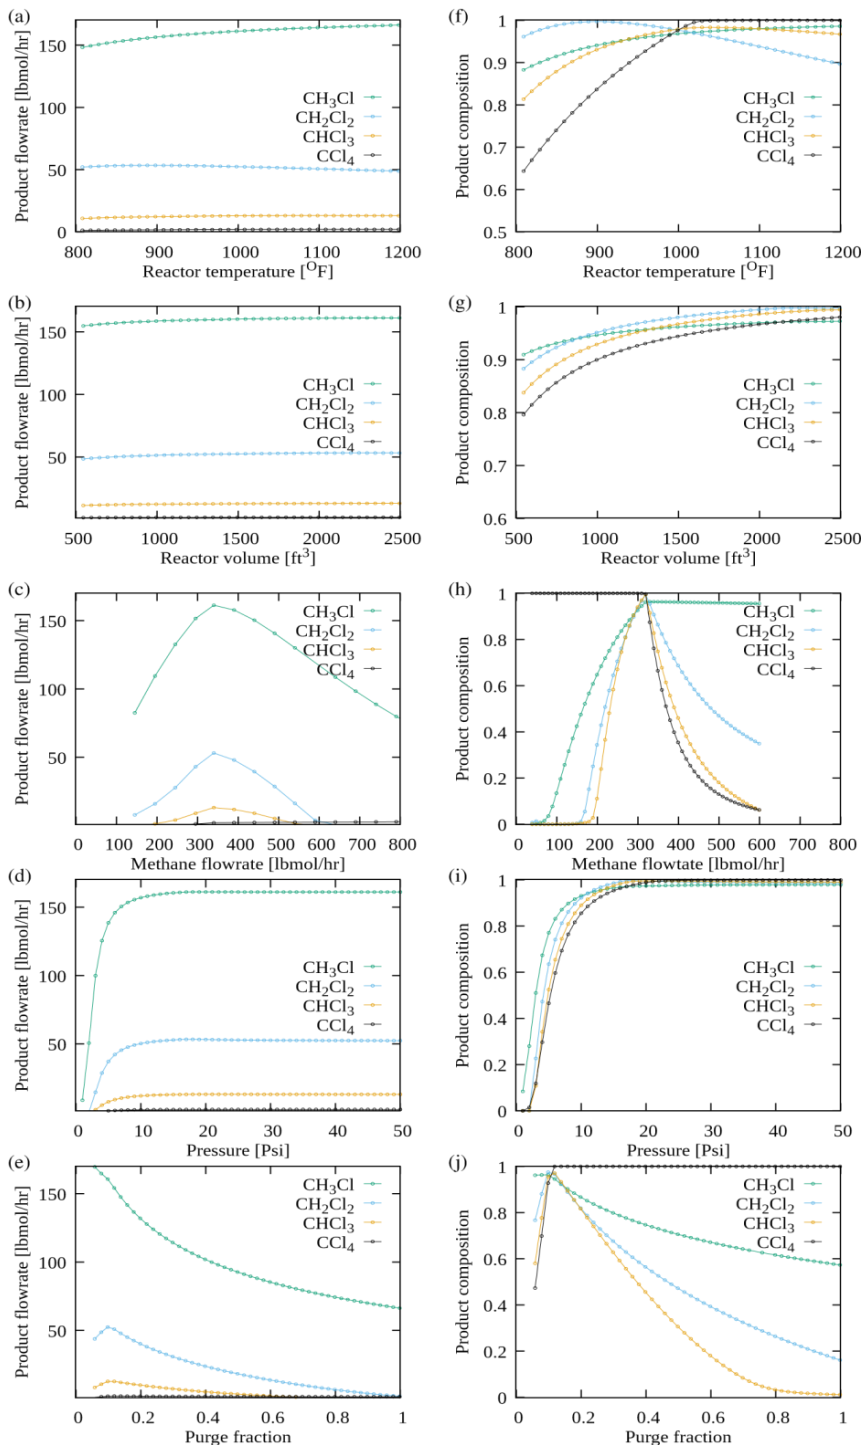

**Figure 1.** Methane chlorination process block diagram

Methane chloride can be produced by hydrochlorination of methanol (Thyagarajan 1966, Habata 1976) and chlorination of methane (Dantus 1996, Dantus 1999) processes. In this work, chlorination of methane which is one of the widely studied systems since 1930's (Robert 1931, Dantus 1996, Dantus 1999, Rozanov 2010) has been simulated. For industrial application, thermal chlorination is generally employed which is highly exothermic in nature. Methane undergoes following chlorination reactions to produce chloromethane ( $\text{CH}_3\text{Cl}$ ), dichloromethane ( $\text{CH}_2\text{Cl}_2$ ), trichloromethane ( $\text{CHCl}_3$ ) and tetrachloromethane ( $\text{CCl}_4$ ).

Of these four reactions, the main reaction that takes place is methane and chlorine reacting to form methyl chloride. Based on the operating conditions, the product distribution varies by a wide margin. The data required for ML techniques is generated by simulating the process flow sheet in aspenONE (Dantus 1996, Dantus 1999). Methane chlorination process block diagram is shown in Figure 1.

**Figure 2.** Effect of all five variables on (a-e) Product flow rates, (f-j) Product compositions.

## 2.2 Sensitivity analysis

Once the basic flow sheet is simulated, sensitivity analysis has been carried out in order to identify the parameters on which product flow rates and compositions are highly dependent. From the sensitivity studies, it is found out that the 5 parameters, i.e., reactor temperature, reactor volume, methane feed flow rate, reactor pressure, and purge fraction are the key parameters. Varying the above key parameters within the effective range for each of these variables, simulations are carried out to obtain product flow rates and compositions. The parameter ranges for which data generated is listed in Table 1. All the four product flow rates and compositions as a function of the five variables are shown in Figure 2(a-e) & (f-j) respectively.

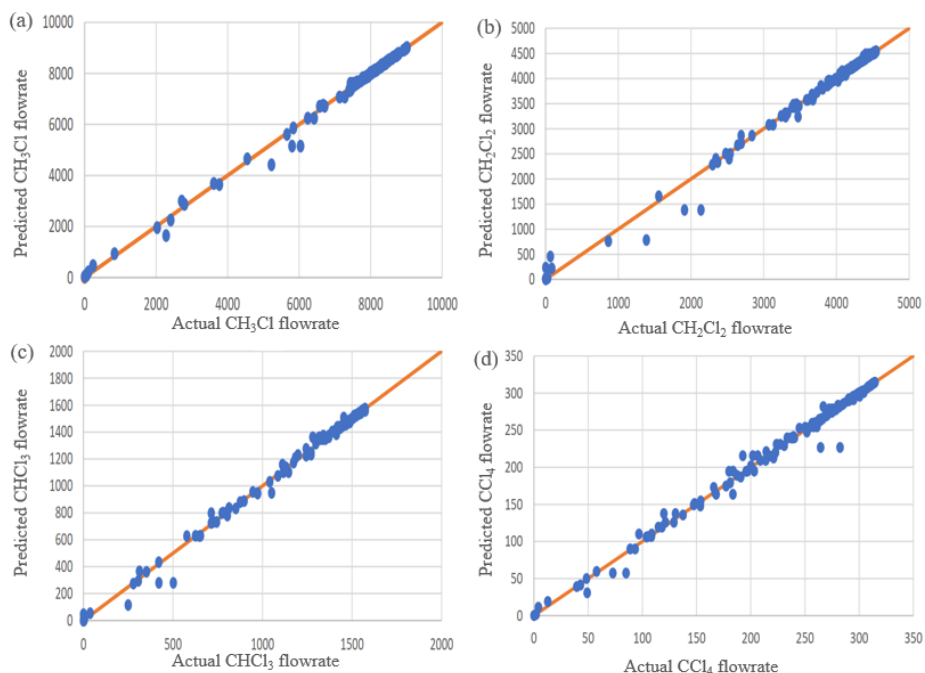

**Table 1.** Effective parameter ranges (in fps units) in which sensitivity analysis is carried out.

Variable	Range
1. Reactor temperature	800 – 1200 °F
2. Reactor volume	500 – 2500 ft <sup>3</sup>
3. Methane feed flow rate	30 – 600 lbmol/hr
4. Reactor pressure	0.1 – 25 psia
5. Purge fraction	0.04 – 0.8

## 3. Machine learning models

The data generated using sensitivity analysis is used to train five different ML models. These models include multi-output linear regression (MLR), support vector regression (SVR), decision trees, kNN and artificial neural networks (ANN). Data set from sensitivity analysis generated consisting of 2500 data points for each variable is divided in the ratio of 80:20 for training and testing ML models respectively. These models train by mapping the function relating input variables to the output variables in the given training data set. The trained model is then evaluated by predicting the output for the inputs given in the test set and comparing the predicted output to actual output. The predicted flow rates and compositions from five ML models are compared against actual values. However, for one ML model i.e., kNN, product flow rates obtained from simulations and values predicted by the model are shown in Figure 3 for four products. Two metrics i.e., R-square and mean absolute error (MAE) are used to measure the goodness of fit and accuracy of the models. These values are given in Table 2. The results indicate that the kNN model is found to be more accurate compared to the other models with high R-square value of 0.995 and low MAE of 23.38 for the process chosen to study. The next best model to kNN is decision trees. MLR has a low R-square and SVR has high MAE compared to other

models. However, it is observed that increasing number of data points to train SVR and ANN results in low MAE.

**Figure 3.** Parity charts of flowrates obtained from simulation and kNN model for all four products (a)  $\text{CH}_3\text{Cl}$  (b)  $\text{CH}_2\text{Cl}_2$  (c)  $\text{CHCl}_3$  and (d)  $\text{CCl}_4$

**Table2:** Comparison of R-square and MAE for different ML models.

ML Model	R-Square	MAE
1. Multi output linear regression	0.57	396.58
2. SVR	-	2777.61
3. Decision trees	0.98	39.27
4. kNN	0.995	23.38
5. ANN	-	345.40

#### 4. Conclusions

In conclusion, we have shown the application of ML techniques to predict the product distribution for multi-product series-parallel reactions. Data generated from simulations is used to train and test different models. R-square and MAE are used as model performance metrics. For the methyl chloride process considered in this study, kNN model performs better than other techniques considered. Better performance of the kNN model may be attributed to the large data set used to train the model. Our work demonstrates that ML models can be successfully used to predict the product distribution our multi product series-parallel reactions with good accuracy and without the involvement of cumbersome experiments or simulations.

## Abstract

A mixed integer nonlinear programming (MINLP) formulation is developed for the automatized design of chemical and biological pathways. The proposed formulation is solved using rigorous algorithms and enables the selection of reactions whose rate constants have the highest sensitivity. Unlike the traditional parameter estimation approach, the training performance is introduced as constraint which is pre-defined to balance the architectural simplicity and fitting performance. Adjoint sensitivity expressions are additionally solved simultaneously in the formulation and the resulting parameter sensitivities are included in the objective. Binary variables are introduced in the linking constraints for the selection of a reaction subset from a more complex pathway, also tightening the search space for the optimization algorithm. The approach is implemented on a complex chemical/biological pathway which processes glucose as a primary feedstock to produce hydroxymethylfurfural (HMF). The reduced pathway prediction bounds are narrower ensuring a similar mean predictions, despite 25% reduction in the superstructure.

**Keywords:** Parameter identifiability; Mixed integer programming; Sensitivity; Uncertainty.

## 1. Introduction

Chemical and biological pathway models include a high number of rate expressions with tunable parameters to be estimated from the experimental data. The lack of spatial and temporal measurements might result in statistically ill-defined inverse problems with multiple solutions in parameter estimation (McClean and McAuley, 2012). Furthermore, the computational load and identifiability problems increase once the disturbances and measurement noises appear especially when the model architecture is large.

Usually, trial and error procedures or sequential methods are applied for the architectural synthesis and parameter identifiability tasks, which require significant manual effort in addition to decentralized computations on theoretical level. The most sensitive parameter selection based on fisher information matrix is compared to LASSO, which is least absolute shrinkage and selection operator, and applied to a biomechanical system in (Ramadan et al., 2018). Shapiro et al. developed a heuristic algorithm to eliminate some

parameters and re-calculate the sensitivities until desired condition value is obtained (Shapiro et al., 2014).

A simultaneous approach using rigorous formulations to obtain the pathway architecture and corresponding parameters based on the parameter sensitivity values and their contribution to uncertainty is scarce and would have the potential to exploit available statistical knowledge from experimental data for a better model development. This study focuses on the development of a mixed-integer formulation to perform architectural synthesis and parameter estimation tasks based on sensitivities in addition to the model training performance.

## 2. Methodology

A typical reaction pathway is represented by ODEs and given by:

$$\frac{dy}{dt} = f(t, y, p) \quad (1)$$

where  $y$  is the vector of outputs which are typically concentrations;  $p$  is the vector of time-invariant parameters;  $t$  is the time;  $f$  is the vector of mathematical rate expressions.

The derivative of the terms in Eq. 1 results in forward sensitivity ODE for a particular parameter and output:

$$\frac{ds_{ij}}{dt} = \frac{df_j}{dy_j} s_{ij} + \frac{df_j}{dp_i} \quad (2)$$

where  $s_{ij}$  is the sensitivity of  $j^{\text{th}}$  output,  $y_j$ , to  $i^{\text{th}}$  parameter,  $p_i$ . A simultaneous solution of Eq. 1 and Eq. 2 is required to address the specific considerations on parameter selection process to account for the model performance, additionally.

A modified mixed integer formulation is developed for the architectural design and estimation of its parameters who have the highest sensitivity, eliminating the parameters with relatively smaller impact on the outputs. The formulation after the ODEs are discretized based on orthogonal collocation enables the simultaneous solution based on rigorous optimization algorithms and is given by:

$$\begin{aligned} & \text{Min}_{p,b} \quad - \sum s_{ij,k}^2 \\ & \text{s.t.} \\ & \frac{dy}{dt} = f(t, y, p) \\ & \frac{ds_{ij}}{dt} = \frac{df_j}{dy_j} s_{ij} + \frac{df_j}{dp_i} \quad i = 1, 2, \dots, M \quad j = 1, 2, \dots, P \\ & s_{ij}(0) = 0 \quad i = 1, 2, \dots, M \quad j = 1, 2, \dots, P \\ & y_j(0) = (0.25, 0, 0, 0, 0, 0) \quad j = 1, 2, \dots, 6 \\ & \sum \|y_k - y_{m,k}\| \leq \varepsilon \\ & b_i p_{i,\min} \leq p_i \leq b_i p_{i,\max} \quad i = 1, 2, \dots, P \\ & b_{\min} \leq \sum b_i \leq b_{\max} \quad b_i \in \{0, 1\} \quad i = 1, 2, \dots, P \end{aligned} \quad (3)$$

where  $s_{ij,k}$  is the sensitivity at sample time  $k$ ;  $y_k$  is the model prediction at  $k$ ;  $y_{m,k}$  is the measurement at  $k$ ;  $\varepsilon$  is the desired maximum training error;  $p_{i,min}$  and  $p_{i,max}$  are lower and upper bounds of  $i^{th}$  parameter,  $p_i$ , respectively;  $b_i$  is the binary variable to account for the existence of  $p_i$ ;  $b_{min}$  and  $b_{max}$  are lower and upper bounds of number of parameters desired in the ultimate architecture.

Solution of Eq. 3 requires an explicit formulation for sensitivity ODEs for the rigorous approach, which calls for an automatic or symbolic differentiation. There are various solver packages which deliver such expressions (Andersson et al., 2019), to avoid numerical approximation errors. On the other hand, sensitivity equations are mostly nonlinear and further mathematical reformulations and decompositions, in addition to dense discretization, might be essential for pathways with high complexity. In contrast to nonlinear optimization which applies to parameter estimation with fixed architectures, the proposed mixed integer formulation includes binary variables to account for the existence of particular parameter values which represent the reaction rate constant once they have a nonzero value. Linking constraints are also introduced to tighten the search space by fixing the parameter values while eliminating the corresponding reaction path from the network. The formulation is flexible and can address measurements and sensitivity considerations at desired sample times. Current formulation includes the selection of the parameters which deliver the maximum squared sensitivity at measurement points.

The parameter covariance matrix for a particular architecture ( $c_p$ ) is subsequently calculated using bootstrapping method (Godo-Pla et al., 2019) for further analysis on the identifiability issues. The uncertainty in the outputs due to parameter variations is calculated using (Tellinghuisen, 2001):

$$c_y = S_k c_p S_k^T \quad (4)$$

where  $c_y$  is an under estimator of actual output covariance matrix;  $S_k$  is the sensitivity matrix at  $k$ .

The approach is implemented on a complex chemical/biological pathway and solved using BONMIN solver in PYOMO computation environment (Hart et al., 2011).

### 3. Results

The proposed approach is implemented on 5-Hydroxymethylfurfural (HMF) synthesis from glucose (Tang et al., 2017) which can be obtained through biological processes, providing a promising opportunity for sustainability considerations. The full network superstructure is shown in Fig. 1a, where several different reaction paths enable the production of a particular compound, which in turn contributes to identifiability of these paths. With a coupled and dependent set of ODEs, the unique estimation of the parameters becomes a challenging task and the proposed formulation is implemented to demonstrate the impact, unlike (Erturk et al., 2021) where sensitivity considerations are not included. Thus, in addition to six differential equations to represent the compounds, 72 additional sensitivity ODEs are introduced to account for 12 parameters in the full network. Once the simultaneous architectural synthesis and the parameter estimation are performed based on the selection of the most sensitive parameters, the resulting reduced network is presented in Fig. 1b.

Figure 1. Reaction pathway  
(a) Full network (b) Reduced network

The eliminated reaction paths from Fig. 1a are shown in Fig. 1b using red arrows. Next, the performance of the full network and the reduced network is compared in terms of prediction similarity and uncertainty. The uncertainty for the solutions is evaluated from the diagonal elements of  $c_y$ , which is calculated from Eq. 4 after bootstrapping procedures are performed.

Fig. 2a and Fig. 2b include solutions of pathway ODEs for the full network and the reduced network, respectively, for Fructose and Formic Acid (FA) + Humins. With relatively smaller mean values, Levulinic Acid (LA) is excluded from figures. The mean predictions, which exclude the parameter covariance matrix and related propagation equations, show similar profile due to constraint in Eq. 3 to deliver a satisfactory training performance characterized by  $\varepsilon$  and shown in full lines. The uncertainty ranges are represented by dashed lines. In turn, a similar profile is obtained despite elimination of four reaction paths as shown in Fig. 1b.

Figure 2. Mean solution and uncertainty interval for Fructose, FA+Humins  
(a) Full network (b) Reduced network

As a result of numerical scale differences among pathway variables, the solution profiles for  $\text{HMF}_{aq}$  and  $\text{HMF}_{org}$ , are presented in Fig. 3b, from which the latter is for the reduced network. Compared to the other components, the impact on  $\text{HMF}_{org}$  uncertainty is less significant as the corresponding component related reactions have not changed (see Fig. 1a and Fig. 1b). However, some decrease in the uncertainty range is still observed due to a more robust parameter estimation which accounts for the identifiability.

Figure 3. Mean solution and uncertainty interval for  $HMF_{aq}$ ,  $HMF_{org}$   
 (a) Full network (b) Reduced network

Table 1 includes a comparison on the maximum and minimum dependent variable values based on uncertainty at final time. The prediction bounds for the reduced model is significantly more tightened compared to the full network. However, a more drastic reduction in uncertainty is favored by the elimination of the reaction paths associated with a particular component.

Table 1. Impact on output uncertainty

	Full Network [ $\times 100$ ]		Reduced Network [ $\times 100$ ]		Difference [%]
	Min	Max	Min	Max	
Glucose	19.15	21.16	19.96	20.32	82.09
Fructose	1.41	3.35	2.28	2.56	85.57
$HMF_{aq}$	0.05	0.15	0.09	0.11	80.58
$HMF_{org}$	0.12	0.23	0.13	0.23	5.45
FA+Humins	1.89	2.29	1.99	2.14	62.50
FA+LA	0.00	0.10	0.00	0.09	10.00

#### 4. Discussion

Traditional parameter estimation problems for complex pathways usually process a fixed architecture and include the training error in the objective function under physically constrained rate expression parameters. In contrast to traditional approach, the proposed mixed-integer formulation performs simultaneous architectural design and parameter estimation by adding binary variables which consider the existence of a particular path and tighten the search space during the optimization through linking constraints. The model training performance is introduced as a constraint to balance the structural reduction and fitting performance, since elimination of some reaction paths from the superstructure hinders the fitting capability, in theory. Moreover, the simultaneous evaluation and consideration of sensitivity expressions enable the calculations to be performed by rigorous optimization algorithms, which can include advanced mathematical reformulations, decompositions, and approximations to account for various

sensitivity requirements. Such a centralized processing of the complex problem delivers the best configuration and high identifiable parameters, especially when global or sophisticated solvers are utilized.

As a downside, the approach calls for more computational load compared to traditional methods, due to binary variables to represent the existence of parameters, evaluation of higher number of equations during optimization, additional nonlinearity terms, the rigorous solution algorithm delivers a more robust model architecture. Thus, subsequent tasks related to model update or control tasks become computationally more feasible.

A biochemical pathway is considered to demonstrate the impact of the approach. However, the problem formulation is flexible and can be further tailored to various applications. Current focus includes the development of sophisticated mathematical reformulations to address the computational problems when larger networks with more parameters are needed.

## Abstract

Unwanted materials in fluids deposit on heat transfer surfaces in time, which is called fouling, and it negatively affects heat exchangers regarding operation and maintenance costs. Therefore, fouling rate should be monitored to prevent unexpected costs and possible failures due to deposition limit of heat transfer area. Monitoring also allows process engineers to improve operating conditions to keep fouling under control for longer cleaning cycles and schedule cleanings effectively. In this work, to monitor fouling rate in the shell and tube crude oil preheat exchanger in the real refinery, the data-driven heat transfer rate prediction model is developed from processed and to-be-processed crude oil planning, on-line sensor and laboratory sample data. Results of various machine learning and deep learning techniques are compared, and as Multiple Linear Regression is found to be the best performing predictive model. Developed fouling rate model predictions are actively used for scheduling of crude oil preheat exchanger cleaning and improving operating conditions to reduce costs in the refinery.

**Keywords:** crude oil, pre-heat train exchangers, fouling, machine learning, multiple linear regression

## 1. Introduction

Petrochemical industries, especially oil refinery, include one of the most energy-required processes among other industries. Maintaining sustainability and reducing gas emissions while keeping the process profitable is a significant problem for refinery processes. This challenging problem can be solved with energy saving solutions (Mrayed et al., 2021). Since the crude distillation unit (CDU) is the front-end operation of the refinery, any intervention in CDU can reduce the energy consumption of the entire refinery by 24% (Yang et al., 2020). Crude oil preheat train (PHT) exchangers recover energy, which is necessary for CDU, by up to 70%. However, recovered energy via PHT exchangers decreases over time because of the deposition of unwanted materials on the heat transfer surface area, which is called fouling (Coletti et al., 2011). Therefore, the fouling rate should be monitored to prevent unexpected energy and maintenance costs, gas emissions and possible failures due to the deposition limit of the heat transfer area (Santamaria & Macchietto, 2019). Monitoring also allows process engineers to improve operating conditions to keep fouling under control for longer cleaning cycles and schedule cleanings effectively. Thus, monitoring of fouling in crude oil PHT exchangers has been studied by many researchers.

Fouling modeling and as a further step fouling prediction enable monitoring fouling in heat exchangers effectively. In literature, fouling is modeled in the first place as empirical and theoretical (Wang et al., 2019). Since, crude oil fouling contains many simultaneous

and different mechanisms, empirical or theoretical models are not generalized and not enough to reflect the nonlinear nature of fouling properly (Sundar et al., 2020). Therefore, data-driven approach for fouling in heat exchanger is introduced to the literature in recent years. Neural network based methods for fouling monitoring and prediction of heat exchanger are preferred methods thanks to their natural capacity to exhibit nonlinear relationships easily (Davoudi & Vaferi, 2018). Also, Sundar et al. (Sundar et al., 2020) proposed a robust deep learning fouling prediction approach which learns heat exchanger flow and heat transfer physics. Furthermore, Hosseini et al. (Hosseini et al., 2022) estimated the fouling factor in a comprehensive study using five different algorithms namely Gaussian Process Regression, Decision Trees, Bagged Trees, Support Vector Regression and Linear Regression. Data-driven approaches are appropriate methods in Industry 4.0 where lots of data is generated and they have proved their success in heat exchangers to determine fouling in complex processes.

In this work, to monitor the fouling rate in the shell and tube crude oil preheat exchanger, the data-driven overall heat transfer rate prediction model is developed. Daily overall heat transfer rate predictions for the next 15 days are predicted from some of the processed and to-be-processed crude oil planning data, on-line sensor and laboratory sample data to calculate heat transfer rate based on the theoretical model. To the best of authors' knowledge, there are limited PHT exchanger fouling prediction models for long time horizon, that consider all processed and to-be-processed crude oil planning data, on-line sensor and laboratory sample data. In order to choose the best prediction model in real crude oil PHT exchangers, a comparison of different machine learning and deep learning techniques, which are XGBoost, Multiple Linear Regression, Random Forest, Extra Trees, Gradient Boosting, Decision Tree, LightGBM and Multilayer Perceptron are studied. The aim of this study is efficient scheduling of crude oil PHT exchanger cleaning and improving operating conditions by reducing energy loss to reduce costs in the refinery, while considering safety by preventing unexpected failures in normal operation. Moreover, proposed data-driven modeling approach can be generalized for other heat exchangers just by revising crude oil properties related inputs.

## 2. Materials and Methods

### 2.1. Crude Oil Preheat Train

PHT exchangers have a simple design, but they have an important role in terms of the economical aspect of refinery operations. Before crude oil is heated in the furnaces, crude oil passed through these PHT exchangers, which increases energy efficiency. In this work, the multi-pass shell and tube eight identical parallel heat exchangers in PHT, undergoing fouling deposition in both shell and tube side are modeled (see Figure 1). While crude oil flows from the shell-side, the overhead fluid of the atmospheric distillation column flows from the tube-side in this heat exchanger network. Crude oil is heated with overhead fluid while overhead fluid is cooled. If there is fouling in the heat exchanger, temperature and pressure differences are highly affected and energy efficiency decreases over time. To keep the process efficient and safe, the fouling level in the heat exchanger network in refinery should be conducted properly.

### 2.2. Fouling Model

Fouling can be defined as the deposition of unwanted materials on the heat transfer area, and it negatively affects heat transfer efficiency in operations. Cross section of one of heat exchanger from network and detailed fouling scheme of shell and tube heat exchanger can be seen in Figure 1. Fouling formation can be happen both inside and outside of tubes. Foulants in crude oil cause fouling inside tubes and crude oil flows at

low temperature ( $T_c$ ) which increases formation of fouling. Hot overhead fluid flows at shell side and  $T_h$  temperature, which causes fouling outside of tubes. Since one of the fouling indicators is the heat transfer rate, which can be calculated easily via a theoretical model, with the help of on-line sensors and laboratory data also known real PHT exchanger-specific coefficients. Therefore, in this work, the overall heat transfer rate is modeled to monitor fouling in the PHT exchanger network of real-time crude oil distillation unit operations. Energy efficiency of heat exchangers will be increased, and unexpected failures can be prevented by the help of this model. Also, maintenance of heat exchangers can be scheduled efficiently. Furthermore, data-driven modeling approaches can be generalized for other heat exchangers by revising crude oil related inputs.

Figure 1. Crude oil PHT exchanger network and detailed fouling scheme of heat exchanger

### 2.3. Industrial Data Set Preparation For Modeling

30 different features related to PHT exchanger network and crude oil assays were used in this study. 16 of them belong to the online sensor data and the rest are laboratory sample data. In addition to online sensor and laboratory sensor data, unique crude oil properties are added to the dataset which is collected from crude oil assays. The planning department decides which crude oil will be used in the future and shares this information with the process units. In this study, to-be processed crude oil blend properties (viscosity, asphaltenes, naphthenes, total acid number, and API) are calculated as weighted averages of unique crude oil properties from crude oil assays according to the planning department's decision. Since different crude oil blend properties can aggregate effects on the process, the cumulative sums of these properties are also added to the dataset. Whole online sensor data, laboratory sample data and crude oil blend properties features have been fetched on a daily basis, and they are aggregated as one dataset. In addition, some new features to calculate the overall heat transfer rate were created by inputs that are already in the dataset. For instance, the shell-side delta temperature was calculated by the subtraction between the shell inlet temperature and the shell outlet temperature. Similarly, tube-side delta temperature was calculated by the subtraction between tube inlet temperature and tube outlet temperature. The delta pressure data for both shell and tube sides were calculated in this way, and they are added to the dataset because of possible indicators of fouling. Since the model predicts the overall heat transfer rate 15 days in advance, 15 days lagged data and the data which represents 1, 3, 7 and 15 days rolling means to see the trends of all inputs in the dataset, except laboratory sample data. Consequently, the final dataset has 947 sample points from real-time crude oil operations and 97 features with one target, which is the overall heat transfer rate.

## 2.4. Machine Learning and Deep Learning Algorithms

### 2.4.1. Multiple Linear Regression

Multiple Linear Regression (MLR) tries to find the linear relationship between a dependent variable (target) and one or more independent variables (predictors). The relationship between the target and predictors is represented as an equation that has an intercept and a coefficient for each predictor. The goal is to find the coefficients that minimize the difference between the predicted and actual values of the target. The obtained model can be used to predict the target value for a new set of predictor values. Linear Regression is a simple but powerful tool for modeling linear relationships and is widely used in various applications (Hosseini et al., 2022). The coefficients are estimated from the training data using normal equation as optimization algorithm in this work.

### 2.4.2. Decision Tree

Decision Tree is a non-parametric supervised learning algorithm. Decision Tree has the capability of predicting the target variable by learning simple decision rules inferred from the data features (Hosseini et al., 2022).

### 2.4.3. Ensemble Methods

Ensemble methods contain set of models, which are integrated to obtain final prediction. Many randomized decision trees on various sub-samples of dataset are used in Random Forest and Extra Trees to improve prediction accuracy. Also, techniques such as Gradient Boosting, XGBoost and LightGBM, that fit boosted decision trees by minimizing an error gradient (Hosseini et al., 2022), are used in this work.

### 2.4.4. Multilayer Perceptron

Multilayer Perceptron (MLP) is widely accepted technique as a promising tool for solving complex engineering problems in real industrial processes. The MLP can include any number of the layer with specified number of neurons in each layer, which transfers information between first and last layers (Davoudi & Vaferi, 2018). Since 1 hidden layer and 30 neurons give the best result, these parameters are used for MLP in this work.

## 3. Results and Discussion

Correlation of features in the final dataset with the target -overall heat transfer rate- is observed, and the most correlated 8 features have been selected as inputs for modeling. Selected inputs are 15 days lagged data of shell-side delta temperature, 15 days lagged data of overall heat transfer rate, 15 days lagged data of viscosity, 1 day rolling mean of viscosity, 3 days rolling mean of viscosity, 7 days rolling mean of viscosity, 15 days rolling mean of viscosity and cumulative sum of asphaltene.

Different machine learning and deep learning techniques are compared their performances to find the best fouling prediction model in real-time operations. While MLR, Decision Tree, Random Forest, Extra Trees, Gradient Boosting, XGBoost and LightGBM were used as machine learning techniques, MLP was used as a deep learning technique. All algorithms are implemented in Python 3.8.

In this study, three different test periods were selected, and each test period contains 15 sample points. The reason why preferred 3 test periods is the business unit wanted to see the results of these periods whether models can catch the expected fouling results. Also, Mean Absolute Error (MAE) was preferred as the model evaluation metric for this work. After the results were tested in 3 different test periods, the best fouling prediction model for real-time operations is the MLR model. Figure 2 shows the comparison of the different model techniques' performances in terms of MAE for a test period.

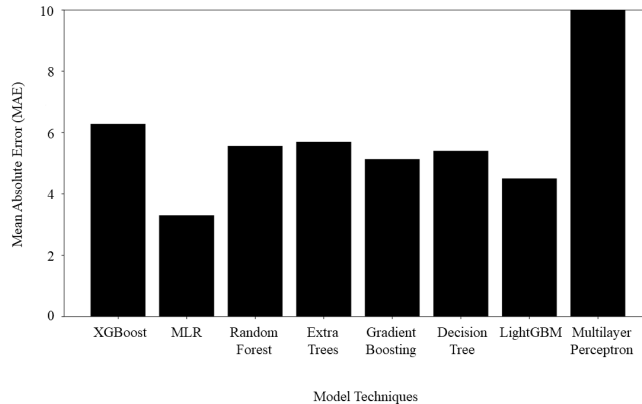

Figure 2. Different machine learning and deep learning techniques comparison

As it can be easily seen from Figure 2, the MLR model has the best performance with 3.29 MAE score. Multilayer Perceptron as a deep learning technique gives the highest MAE score. The reason why Multilayer Perceptron technique fails is deep learning techniques perform well on more sample point dataset than this study dataset. Besides, boosting techniques also failed because of the scarcity of data. MLR technique, which has the best results, is used for real-time PHT fouling modeling within 15 days horizon. One of the test set results for comparison of MLR fouling model predictions and actual overall heat transfer rate real-time operation of PHT exchanger values within 15 days horizon are shown in Figure 3. The results were deemed successful by the business unit. With the help of the fouling prediction model, the business unit can monitor fouling before reaching the critical limit, and can intervene in the process parameters by taking an action to slow down the fouling effect. Also, the business unit can schedule crude oil PHT exchanger cleaning efficiently and can improve operating conditions to reduce costs in the refinery. Furthermore, this modeling approaches can be generalized for other heat exchangers by revising crude oil related inputs.

Figure 3. Fouling model predictions and actual values comparison of the test set

#### 4. Conclusions

Oil refineries have the most energy-required processes, thus any energy saving solutions has a great impact on sustainability, gas emissions and operating costs. One of the energy saving solution is that energy efficiency increases while crude oil passed through PHT exchangers before crude oil is heated in the furnaces in CDU. However, fouling causes the deposition of a layer from unwanted materials in these heat exchangers, which

decreases the heat transfer rate. If the fouling rate in PHT exchangers can be known before reaching the critical limit, the business unit can take action that slows down the fouling effect. Therefore, data-driven fouling rate prediction in the shell and tube crude oil PHT exchangers model is developed to real-time monitor fouling rate for a long time horizon. Since one of the fouling indicators is the heat transfer rate, which can be calculated easily via a theoretical model, the overall heat transfer rate is modeled to monitor fouling. Daily overall heat transfer rate predictions for the next 15 days are predicted from some of the processed and to-be-processed crude oil planning data, on-line sensor and laboratory sample data. Combining of all processed and to-be-processed crude oil planning data, on-line sensor and laboratory sample data are increased prediction accuracy and provides predicting capability to fouling modeling for long time horizon. In order to choose the best prediction model in real crude oil PHT exchangers, a comparison of different machine learning and deep learning techniques, which are XGBoost, Multiple Linear Regression, Random Forest, Extra Trees, Gradient Boosting, Decision Tree, LightGBM and Multilayer Perceptron are studied. Proposed data-driven modeling approach can be implemented on other heat exchangers easily just by revising crude oil related parameters. With the help of the fouling prediction model, the business unit can monitor fouling before reaching the critical limit, and can intervene in the process parameters by taking an action to slow down the fouling effect. Also, the business unit can schedule crude oil PHT exchanger cleaning efficiently and can improve operating conditions to reduce costs in the refinery.

## Abstract

In recent studies, machine learning (ML) applications in the heterogeneous catalysis field for material properties prediction accelerate the catalyst discovery with desired properties. However, due to its high complexity, most ML models suffer from the black-box problem, which cannot provide a basis for prediction. Thus, reliable application and physical insight generation are challenging with conventional black-box models. Here, we developed an ML model that predicts formation energy ( $E_f$ ) from the density of states (DOS). More importantly, by interpreting the model, we also confirmed the possibility of uncovering the relationship between the electronic structure of materials and their stability. Our model achieves successful performance demonstrating its superior capability of DOS featurization.

**Keywords:** Heterogeneous Catalyst, Stability, Artificial Intelligence, Convolutional Neural Network, Explainable AI (XAI)

## 1. Introduction

In the heterogeneous catalysis field, the discovery of new materials with desired properties is challenging because of its large parameter space (Esterhuizen J.A., 2022). In this context, computational material discovery has grown continuously over the past decade thanks to the development of various crystal structure prediction algorithms. Previously, density functional theory (DFT) calculation was a major tool to search chemical space, however, due to its high computational cost, the demand for an efficient tool has been increasing. Recently, machine learning (ML) models, which generate predictions within sub-seconds, have emerged as a powerful approach to bypassing the formidable computational cost and navigating the large chemical space more efficiently (Fung V., 2021). However, to maximize the prediction performance, ML models have become more complex with tremendous trainable parameters, which makes it nearly impossible to interpret the internal logic underlying the prediction (Doosun Hong Jaehoon 2022). Beyond mere prediction tools, in order for an ML model to play a conducive role in scientific advancement in the heterogeneous catalysis field, the model should be interpretable and able to provide meaningful knowledge and testable hypotheses. As an alternative, theory-infused models integrating physical interaction into the algorithm and thus, inherently interpretable were studied (Wang S.H., 2021). However, due to their

restricted architecture and enforced simplicity, it is difficult to achieve high performance. Furthermore, since most of these models are system-specific, there is a limitation in extension to general application for various system. In order to satisfy both predictive performance and interpretability simultaneously, the implementation of the explainable AI (XAI) technique on the fully trained predictive model is in the spotlight. These studies are mainly conducted by utilizing descriptors related to material properties and obtaining the importance of each descriptor in prediction, for ease of interpretation and visualization (OmidvarNoushin 2021). Especially, since it is well-known that the electronic structure is closely related to physical properties of materials, there have been many efforts to utilize electronic features, such as *d*-band center, extracted from the density of state (DOS) (LinicHongliang 2012). Yet, the problem remains that it does not extend well to a wide range of data with only a few existing features identified by human experts. In addition, only constrictive interpretation is possible, which describes intricate physical interaction within the previously defined features. In this perspective, an approach for direct interpretation from the DOS signal itself, without human intervention in feature extraction, is required.

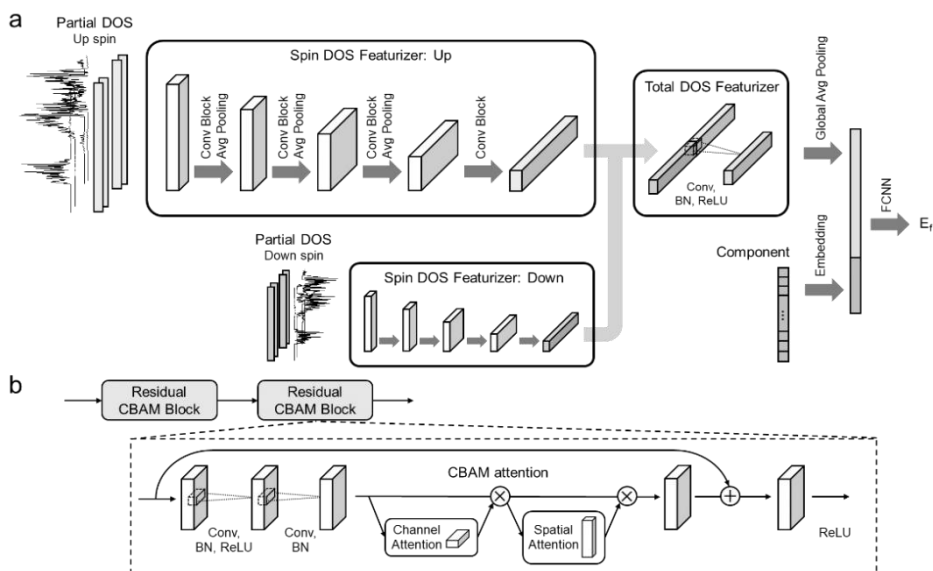

In this work, we developed a convolutional neural network (CNN) based ML model taking DOS directly as input for accurate formation energy prediction. Further, the possibility of translating the relationship between the electronic structure of materials and the crystal's thermodynamic stability via linking the XAI technique to the model is presented. Thanks to the convolution operation, which has strength in recognizing patterns of signal data, electronic features of DOS are self-explored inside the model with high flexibility. Particularly, our model, whose architecture is motivated by chemical background, is specialized to featurize DOS. After training, the SHapley Additive exPlanation (SHAP) (LundbergS.M., 2020) value of features discovered by the model was calculated to determine what factors on each input affected the prediction in which way. By visualizing how SHAP values show the pattern toward formation energy, common characteristics of stable materials can be confirmed.

## 2. Results

### 2.1. ML approach for accurate formation energy prediction

We developed a ML model with a chemically motivated architecture optimized to featurize partially projected DOS for accurate formation energy prediction. The model is built based on a convolutional neural network (CNN), which is well-established for learning high-level features from signal data with multiple channels (KiranyazSerkan 2019). Given that CNN takes input made up of separate channels and featurizes input preserving its spatial information, which indicates spin state according to energy here, it is advantageous to manage DOS input consisting of various projected states. Additionally, the convolution operation gathers input features  $h_k^{n-1}$  multiplying weight matrices  $w_{kj}^n$ , then aggregates them by sum to generate featurized output features represented as  $h_j^n$  (KimYoon 2014). Since each partial DOS represents a relative contribution of a particular state at total DOS, total DOS features can be obtained via aggregating features from partial DOS, which resembles convolution operation. Based on the similarity, the CNN-based featurizer generates abundant features of the total DOS from the input partial DOS.

Meanwhile, the sign of DOS is determined depending on its spin state, that is, positive and negative for up spin and down spin, respectively. Thus, total DOS is generally considered according to its spin state (YeoByung 2019). Inspired by the background, we introduced the CNN-based featurizer for each spin state, named spin

**Figure 1.** (a) Schematic representation of model architecture. Partial DOS in each spin state and component vector are fed into the model as different inputs. Three featurizers are used to generate total DOS feature maps. (b) Convolutional block architecture employing CBAM self-attention and residual connection. Each convolutional block is connected through average pooling.

DOS featurizer. As shown in Figure 1a, there are two spin DOS featurizers for each spin state respectively. Each featurizer takes orbital projected DOS as input according to the spin state and extracts features based on the convolution operation mentioned above. Note that, the featurizers are independent of each other, using separate weight matrices. The spin DOS featurizer is constructed with four convolutional blocks with two residual convolutional block attention module (CBAM) blocks (WooSanghyun 2018) for automatic and adaptive feature learning. Each block is designed with the aim of producing well-learned feature maps which abundantly contain meaningful features, and the detailed structure is represented in Figure 1b. The CBAM self-attention module performs dynamic feature selection that learns the importance of the features differently for each input, rather than imposing the same weight on all extracted features as general CNN does. In addition, the residual connection prevents the loss of these weighted features due to the depth of the network (DuXue 2020). After further learning through the subsequent convolutional blocks, total DOS feature maps of each spin state are obtained at the end of the featurizers.
